Monaxonida, Mr. RIDLEY and I suggested that *Rhizochalina* and *Oceanapia* should be united in one genus, and in a subsequent paper (**10**) I have carried out this suggestion. Our reason for this proposal was that at one of the "Challenger" stations (188, off New Guinea) specimens with and without sigmata appear to occur together, and are so closely similar in external appearance that they cannot be distinguished otherwise than microscopically. It seems equally reasonable, however, to suppose that the two genera actually occur together in this locality, or that there has been some confusion in the sorting out of the specimens. We can hardly suppose that the same species sometimes occurs with, and sometimes without, sigmata. I therefore propose to return to the arrangement originally adopted in the "Challenger" Report, substituting, for the reason above given, the name "*Phlœodictyon*" for "*Rhizochalina*."

Neither Mr. CARTER nor I have been able to find sigmata in the Ceylon specimens, though I have myself examined about half-a-dozen microscopically.

One of Professor HERDMAN's specimens has the body, which varies much in shape and is often very irregular, up to 48 millims. in maximum diameter. As pointed out by Mr. CARTER, the fistular processes are long and may be ramified. They sometimes appear to be naturally closed at the extremity (except, perhaps, for small pores), and sometimes open. In nearly all cases they have been broken off short.

R.N. 81, 90, 237 (all from deep water off Galle and onwards up West Coast of Ceylon); 260; 363 (fistulæ only, Stat. I., hauls 1–4, January 31, 1902, Colombo to Negombo, 12 to 20 fathoms). Also other unnumbered specimens and loose fistulæ.

Histoderma, CARTER.

Phlœodictyinæ with usually diactinal megascleres and microscleres in the form of isochelæ, to which others may be added.

An examination of Mr. CARTER's own preparations of his *Phlœodictyon singaporense* (**54**) has revealed the presence of small palmate isochelæ. I therefore propose to place this species, together with a closely related Ceylonese form, in the genus *Histoderma*.

The presence of isochelæ in this genus is of great interest and necessitates the inclusion of the Phlœodictyinæ amongst the Desmacidonidæ, the two species referred to forming an important connecting link between *Phlœodictyon* and *Oceanapia* on the one hand and *Desmacidon* on the other.

Histoderma vesiculatum, n. sp.—Plate XI., figs. 8, 9.

This remarkable sponge is represented in the collection by two fragments of about equal size and closely similar appearance. Each consists of an elongated cylindrical body inflated at irregular intervals to form oval vesicles. In one specimen there are two distinct vesicles connected by a short cylindrical piece, and from the larger of the two, which is broken across at the end, another short cylindrical piece is given off as a branch. The slender cylindrical portions, and the vesicles too, are now more or less hollow, but they contain the remains of the coarse skeleton network and a certain amount of decomposed soft tissue. Thus, in the present condition of the specimens, the outer wall of the sponge forms a thin but firm shell enclosing a wide cavity in which lie the remains of the choanosome. How far the sponge was hollow in life cannot now be ascertained. The colour (in spirit) is dark brown throughout, with a slight purplish tinge on the surface. The surface is smooth, but has a very characteristic tessellated appearance, caused by the very stout sub-dermal reticulation of spicular fibre showing through the thin dermal layer. Each specimen has a total length of about 27 millims. The largest vesicle measures about 11 millims. by 9 millims., and the slender cylindrical portions are about 4 millims. in diameter (sometimes rather less).

The main skeleton forms a very wide-meshed reticulation of very stout spicular fibre, occupying the interior of the sponge; the meshes being very irregular in shape and size. The diameter of the fibre, which appears to be composed entirely of very closely packed megascleres, is about 0·165 millim. There is a sub-dermal reticulation of similar fibre with roundedly polygonal meshes, the meshes being about 1 millim. in diameter. This supports the dermal skeleton (Plate XI., fig. 8), which is very well developed and extremely beautiful, consisting of a single layer of strongyla of various lengths lying tangentially side by side as closely packed together as possible, with a few much larger oxea, or sometimes styli, intermingled with them.

Spicules.—(1.) Oxea (Plate XI., fig. 8, *o*, *o*, *o*); rather long and only moderately stout; slightly curved, usually sharply but sometimes rather abruptly pointed at each end; size about 0·3 millim. by 0·009 millim., but variable. Abundant in the fibres of the skeleton and scattered in the soft tissues between, where numerous very slender, hair-like forms, possibly young, also occur.

(2.) Strongyla (Plate XI., fig. 8, *s*, *s*); cylindrical, more or less curved, and evenly rounded off at each end; size extremely variable, from 0·04 millim. by 0·005 millim. to 0·1 millim. by 0·007 millim., or perhaps more. Characteristic of the dermal skeleton, but also found in the spicular fibres and soft tissues of the choanosome.

(3.) Palmate isochelæ (Plate XI., fig. 9), about 0·016 millim. long; very similar to those of *Desmacidon conulosa*, as figured in the Report on the "Challenger" Monaxonida; numerous.

(4.) I have also seen one "birotulate" of about the same length as the ordinary isochelæ; with very slender and apparently straight shaft and short umbrella-like ends with minutely dentate margins. Whether or not this forms a constant element in the spiculation I am not prepared to say, but its presence is very interesting in view of the normal occurrence of such spicules in the genus *Amphiastrella*.

This species differs from *Histoderma singaporense* (Carter) chiefly in external form, but also in the more slender character of the oxea.

Lindgren, however, has described (86), under the name *Rhizochalina singaporensis*

(CARTER), a sponge from the China Sea, in which he also discovered isochelæ. This specimen seems to resemble the Ceylon form very closely, and it is possible that future investigations may show them all to be specifically identical.

R.N. 212 (deep water outside pearl banks, Gulf of Manaar).

SUB-FAMILY: ECTYONINÆ.

Desmacidonidæ in which some of the megascleres take the form of spined styli, originally developed as echinating spicules of the skeleton fibre or projecting at right angles from the substratum.

The members of this sub-family are usually easily recognised by their spined styli, but, as in the case of perhaps every type of spicule, the spined styli may be lost again by degeneration. Such degeneration has obviously taken place in the genus *Raspailia*, which, until recently, has been confounded with the Axinellidæ. As a rule, microscleres are present in the form of isochelæ (to which toxa are frequently added), but these also may be lost.

Myxilla, SCHMIDT.

Ectyoninæ, usually of massive, irregular form, in which the megascleres are spined styli, which may or may not be echinating, and variously ended diactinal forms which typically belong to the dermal skeleton. The typical microscleres are tridentate isochelæ, to which other forms may be added.

This genus in a certain sense occupies, as pointed out by Mr. RIDLEY and myself in the Report on the "Challenger" Monaxonida, a position intermediate between the sub-families Esperellinæ and Ectyoninæ, including both species with definite echinating spicules and species in which such spicules cannot be distinguished from those of the ordinary skeleton reticulation. It appears probable, from their form, that the spined styli originated in the first instance as echinating spicules, *i.e.*, spicules in which the growth of one end (the base) became arrested by pressure against a firm substratum, while the apex projected freely into the surrounding soft tissues and thus formed an internal defence against the attacks of parasites. In some species these echinating spicules appear to have passed into the main skeleton and form a reticulation with one another.* It appears desirable, therefore, to regard the presence of spined styli (or tylostyli) as constituting the leading feature of the Ectyoninæ, without insisting too strongly upon their actual arrangement.

In the genus *Myxilla* itself it is sometimes impossible, owing to the irregular character of the skeleton reticulation, to distinguish sharply between echinating and non-echinating styli, and, as I have pointed out before (**10**), I cannot, therefore, agree with TOPSENT (**62**, &c.) and HANITSCH (**46**) in retaining GRAY'S genus *Dendoryx* for species in which no special echinating spicules are recognisable.

* Compare *Rhabderemia indica* and its relationship to the thin encrusting forms of the same genus. See also below, under *Myxilla tenuissima*.

This important genus is represented in the present collection by only two species, but both of these are of exceptional interest owing to their unusual habit, the one being a typical sand-sponge and the other a very thinly encrusting form.

Myxilla arenaria, n. sp.

Sponge massive, irregular; intensely and coarsely sandy, with a distinct translucent dermal membrane visible in places. Pores and vents (?). Greatest diameter of type (R.N. 263) 30 millims. Colour (in spirit) light brown (the colour of the sand) or grey; texture very friable.

Main skeleton composed almost entirely of sand, with slender strongyla scattered between the sand-grains and also collected in loose, wispy fibres; and with small spined tylostyli or styli very sparsely echinating the sand-grains. Dermal skeleton composed of slender strongyla scattered irregularly in the dermal membrane.

Spicules.—(1.) Strongyla, perhaps sometimes faintly tylote; straight, slender, smooth; measuring about 0·146 millim. by 0·002 millim.

(2.) Spined tylostyli or styli; straight; gradually and very sharply pointed at the apex; rather sparsely and irregularly spined, chiefly at and near the base, which is generally distinctly tylote. Size variable, say about 0·056 millim. by 0·004 millim. (near the head, including spines).

(3.) Tridentate isochelæ, with small teeth and fairly stout, strongly curved shaft; length about 0·014 millim.; not very abundant.

(4.) Slender sigmata; C-shaped and contort; measuring about 0·032 millim. from bend to bend, but rather variable in size.

As usual in sand-sponges, the proper skeleton is reduced in accordance with the arenaceous habit. In external appearance the sponge closely resembles *Paresperella bidentata*, and might easily be mistaken for that species.

R.N. 263 (Gulf of Manaar); 266 (pearl banks off Aripu).

Myxilla tenuissima, n. sp.—Plate XI., fig. 5.

Sponge extremely thin, encrusting. The single specimen forms a small crust of a pale yellowish colour growing on a mass of calcareous worm-tubes in association with *Discodermia emarginata.* Vents and pores not seen.

The skeleton consists partly of slender tylota, scattered irregularly and in loose wisps, and partly of spined tylostyles projecting vertically from the substratum, upon which their bases rest while their apices point outwards.

Spicules:—(1.) Tylota (Plate XI., fig. 5, *a*); smooth, slender, straight or nearly so, with rather feebly developed oval heads and commonly with the shaft slightly inflated (tylote) in many places at irregular intervals. Size about 0·148 millim. by 0·002 millim.

(2.) Spined tylostyli (Plate XI., fig. 5, *b*); quite straight and abundantly spined all over; with spherical head not much wider than the shaft, which tapers gradually from the head to a fine, sharp apex. Spines rather small, conical and sharp pointed; on the head rather longer than elsewhere and arranged in a radiating manner, so that the head, when viewed end on, resembles a spheraster. Size variable, up to about 0·08 millim. in length by 0·008 millim. in thickness where the shaft joins the head (exclusive of spines). These spicules are very numerous and, though quite separate from one another, are placed pretty close together.

(3.) Stout tridentate isochelæ (Plate XI., fig. 5, *c*, *d*) of the usual *Myxilla* type, with rather strongly curved shaft; length about 0·032 millim.; very numerous.

This is a *Myxilla* with the encrusting habit of a *Hymedesmia*, and with correspondingly arranged skeleton. In spiculation it closely resembles TOPSENT'S *Dendoryx certa* (**48**), but differs in skeleton arrangement, the spined styli forming a network in the latter species. In fact, *Myxilla tenuissima* bears much the same relationship to *Myxilla* (*Dendoryx*) *certa* that *Rhabderemia pusilla* does to *Rhabderemia indica.*

R.N. 234A (on same mass as R.N. 234, "deep water off Galle and onwards").

Clathria, SCHMIDT.

Ectyoninæ of various habit, frequently clathrous; skeleton a reticulation of fibre, usually with much spongin, containing smooth styli and echinated by spined styli. Typical microscleres small palmate isochelæ, to which toxa are frequently added.

I have already (**10**) indicated the necessity for abandoning the genus *Rhaphidophlus* of EHLERS, which differs from *Clathria* only in the possession of a dermal crust of radially disposed styli. The degree of development of this crust varies to such an extent, however, that it is quite impossible to base a generic distinction on this character alone.

Clathria frondifera (BOWERBANK).

1875, **Halichondria frondifera,** BOWERBANK (**49**); 1884, **Clathria frondifera,** RIDLEY (**16**); 1889, **Clathria corallitincta,** DENDY (**3**).

I do not think it is possible to keep the Ceylonese form, described by me under the name *Clathria corallitincta*, separate from the common Australian and Indian Ocean species, originally described by BOWERBANK from the Straits of Malacca and Gaspar Straits under the name *Halichondria frondifera* and subsequently re-investigated by RIDLEY.

The external form of the sponge is very characteristic, and one of Professor HERDMAN'S specimens (R.N. 44) bears a remarkably close resemblance to a specimen from the Mascarene group figured by RIDLEY (*loc. cit.*, Plate liii., fig. j). The spiculation, however, seems to be somewhat variable, and I must add to the description which I gave of Mr. THURSTON'S specimens the following particulars concerning those in the present collection.

The palmate isochelæ may be abundant. Smooth, slender toxa of very various length are also met with. These are best developed in R.N. 85 and 281, where they attain a length of about 0·184 millim., being almost straight from end to end except for a small bow in the middle. The stout styli of the main skeleton vary greatly in thickness. The slender styli or tylostyli may form a fairly distinct dermal skeleton, in which they are either irregularly scattered or arranged in more or less definite radiating brushes. The bases of these spicules are sometimes minutely spined (R.N. 169).

One of the specimens (R.N. 97) is attached to a pearl oyster (*Margaritifera vulgaris*).

R.N. 44, 97, 268 (all Gulf of Manaar); 85, 169, 281 (all deep water off Galle and onwards up West Coast of Ceylon).

Clathria indica, DENDY.

This common species (DENDY, **3**) is represented in the collection by four specimens.

R.N. 27, 106 (both from Gulf of Manaar, Stat. IX., &c.); 166; 291 (Ceylon seas).

Clathria spiculosa (DENDY).

1889, **Rhaphidophlus spiculosus**, DENDY (**3**).

There is one small specimen of this sponge which makes a close approach to the original types both in external form and spiculation.

R.N. 335 (Ceylon seas).

Clathria spiculosa, var. **ramosa**, nov.

This variety agrees closely with the types of the species in skeleton arrangement and spiculation, but differs conspicuously in its elongated, slender, sub-cylindrical, irregularly branching external form. It thus makes a very close approach to RIDLEY'S *Echinonema gracilis* from the Mascarene Islands (**16**), but the megascleres in the Mascarene species are much stouter.

R.N. 168; 308; 310; 333; 368 (deep water outside pearl banks, Gulf of Manaar).

Clathria spiculosa, var. **tessellata**, nov.—Plate VIII., fig. 2.

This variety again differs from the types of the species only in external features, which are, however, very characteristic. The sponge consists of more or less erect, thick, irregular lamellæ, with the margin rising up here and there into short, digitiform processes. The vents are minute and few, marginal or on the ends of the processes. The most striking character of the variety, however, is the tessellated appearance of the surface, due to the presence of a close, polygonal-meshed reticulation of (presumably) pore-bearing grooves; the meshes of the reticulation are about 1 millim. to 1·5 millims. in diameter. The general appearance of the sponge is well shown in the figure. One specimen (R.N. 92A) measures about 70 millims. in greatest breadth and the same in height. The colour (in spirit) is dark grey, and the texture characteristically firm and fleshy, and very tough.

R.N. 92; 92A (Gulf of Manaar).

Raspailia, Nardo.

Ectyoninæ of elongated, slender, branching habit. Skeleton composed of a dense central axis of spicular fibre containing much spongin, from which bundles or tufts of spicules radiate to the surface. Smooth monactinal (sometimes diactinal) megascleres are present, and also (normally) spined echinating styli. No microscleres.

As already indicated, the members of this genus bear a strong superficial resemblance to Axinellidæ, but it is evident from the presence of the spined echinating styli (though these may be vestigial) that they are really highly modified Ectyoninæ.

Raspailia thurstoni, Dendy.

There is one specimen of this sponge (Dendy, **2**, 1887) in the collection.

R.N. 39 (Stat. LX., outside Muttuvaratu Paar, 30 fathoms)

Raspailia fruticosa, Dendy, var. **tenuiramosa,** nov.—Plate VIII., fig. 5.

1887, **Raspailia fruticosa,** Dendy (**2**).

There are in the collection two specimens, one dry and one in spirit, which differ from the type of the species only in the much more slender and much shorter branches, and in the greater density of the skeleton, which is less distinctly reticulate. The branches are usually only from 2 millims. to 3 millims. in diameter, and very numerous, so that the whole sponge is even more fruticose than the type. The largest specimen (dry) is about 55 millims. in total height and 78 millims. in greatest breadth; it is represented in Plate VIII., fig. 5.

R.N. 100 (dry, Gulf of Manaar); 173.

Raspailia hornelli, n. sp.—Plate XI., fig. 7.

The single specimen is erect, arborescent, branching in one plane. The branching at first sight appears to be dichotomous, but in reality the two branches present are both given off from the same side of a main axis which in no way differs from them in appearance, except that the part below the first branch, which we may consider as representing the stalk, is more rounded in transverse section and slightly expanded below at the attachment, while the branches themselves are slightly flattened. Each branch is very much narrowed at the end to form a slender, elongated apex. The surface is rather coarsely granular, with numerous minute apertures between the granules; slightly hispid in places. Colour (in spirit) dark brown. Texture tough, compressible, resilient. Total height about 99 millims. Length of stem below the first branch 33 millims., diameter about 5 millims. Length of longest (lowest) branch about 64 millims.; greater transverse diameter of branches when fully developed about 6 millims.

The skeleton consists of a network of stout horny fibre, irregularly cored by smooth megascleres and fairly abundantly echinated by spined styli. There is a well marked axial condensation of the reticulation, in which most of the larger spicules are to be found densely packed together lengthwise in the stout horny fibre. From this axial portion more slender fibres run obliquely outwards to the surface, where each one ends (typically) in a projecting brush composed of a very few long, stout styli, surrounded at the base by numerous much shorter and very slender styli (these often appear to be absent). The outwardly-directed horny fibres are irregularly cored by usually slender megascleres and abundantly echinated towards their outer ends by spined styli. They are connected together to form a network by short secondary fibres of similar structure, but more slender. There are also many of the smooth megascleres scattered through the soft tissues apparently without any relation to the fibres at all

Spicules.—(1.) Smooth styli (Plate XI., fig. 7, *a*); long and comparatively stout, evenly rounded off at the base, gradually and sharply pointed at the apex; usually slightly curved towards the base; size about 0·65 millim. by 0·018 millim.; found chiefly in the axial condensation (but also scattered in the soft tissues outside it) and in the surface brushes.

(2.) Smooth styli (Plate XI., fig. 7, *b*, *c*); very slender, straight or nearly so, evenly rounded off at the base and very finely and gradually pointed at the apex; size, say about 0·24 millim. by 0·0027 millim., but sometimes longer; characteristic of the surface brushes, but also occurring frequently between the axis and the surface; perhaps sometimes oxeote.

(3.) Smooth oxea (Plate XI., fig. 7, *d*, *e*, *f*, *g*); rather short and fairly stout, fusiform, more or less curved or angulated in the middle, gradually sharp pointed at each end; size very variable, commonly about 0·2 millim. by 0·012 millim., but may be as much as 0·46 millim. by 0·014 millim.; abundant, scattered irregularly outside the horny fibres, and within them.

(4.) Strongyla (Plate XI., fig. 7, *h*, *h*); very short and comparatively stout, straight, equal-ended and broadly rounded off at each end; size very variable, say about 0·2 millim. by 0·024 millim.; sometimes pretty numerous in the axial condensation and occasionally met with outside it, but very erratic in occurrence.

(5.) Spined styli or sub-tylostyli (Plate XI., fig. 7, *k*, *l*, *m*); rather short, straight, tapering gradually from base to apex, which, though narrow, is bluntly pointed; covered all over with very minute, sharp spines, which are most abundant at the base and apex; size about 0·08 millim. by 0·008 millim. (at the base, including spines).

Numerous small, spherical, granular, brown pigment cells, about 0·01 millim. in diameter, are scattered through the outer part of the soft tissues.

This species, though evidently closely related to the European *Raspailia* (*Dictyo-*

cylindrus) *hispida*, is readily distinguished by the details of its spiculation. I have much pleasure in naming it after Mr. HORNELL, to whose energy this collection owes, I am told, so much of its value.

R.N. 59 (Stat. IV., off Karkopani, Gulf of Manaar).

Agelas, DUCHASSAING and MICHELOTTI.

Ectyoninæ in which the skeleton is composed of horny fibre echinated by verticillately spined styli; with no other spicules.

For synonymy and references I must refer to the Report on the "Challenger" Monaxonida (p. 163).

Agelas mauritiana (CARTER).

1883, **Ectyon mauritianus**, CARTER (**54**); 1887, **Agelas mauritianus**, RIDLEY and DENDY (**1**); 1903, **Agelas cavernosa**, THIELE (**87**).

This species is represented by a tubular fragment 31 millims. long and up to about 16 millims. in diameter; widely open at both ends and with the wall of the tube only about 3·5 millims. thick. It is of rather dark brown colour and firm, resilient consistence.

The skeleton is a close, irregular network of stout, amber-coloured horny fibre echinated very abundantly by the characteristic verticillately spined styli, which measure about 0·176 millim. by 0·016 millim. (including spines).

This beautiful species has hitherto been recorded from Mauritius (CARTER), off Tristan da Cunha (?) ("Challenger"), and from Ternate (THIELE).

R.N. 358 (Ceylon seas).

Agelas ceylonica, n. sp.—Plate XII., fig. 9.

The type specimen* consists of a few slender, anastomosing, sub-cylindrical branches, arising from an irregular, proliferous basal crust attached to a calcareous nodule. The branches are only about 2 millims. in diameter, and their surface is irregular and sometimes minutely hispid. Texture (in spirit) compressible, resilient, fibrous and fairly tough. Colour brown. Vents minute and scattered on the branches.

The skeleton is an irregular network of pale-coloured horny fibre about 0·03 millim. in diameter, abundantly echinated by the spined styli, which are occasionally also found embedded lengthwise in the fibre, two or three side by side.

Spicules.—Verticillately spined styli (Plate XII., fig. 9), straight or slightly curved; the spines mostly small and conical, especially about the middle of the spicule; those at the base irregularly arranged, larger, and often hook-shaped, with the sharp points curved towards the apex of the spicule; apex sharp-pointed and free from spines for a short distance. Size variable, but characteristically long, say about 0·24 millim. by

* A second specimen closely resembles the type.

0·02 millim. at the base (including spines). Although they are verticillately spined, the annulation of these spicules is not nearly so distinct as in *Agelas mauritiana.*

R.N. 304; 312 (type). (Both from Ceylon seas.)

Echinodictyum, Ridley.

Ectyoninæ with reticulate main skeleton composed of spicular fibre containing smooth oxea and echinated by spined styli. Smooth styli may also be present. Microscleres usually absent.

Echinodictyum clathratum, n. sp.—Plate XI., fig. 4.

The single specimen forms a sub-spherical, clathrous mass of rather thin, short, flattened trabeculæ, echinated on the outer surface by slender conuli. Vents and pores not seen. Colour (in spirit) pale greyish-yellow; texture soft and resilient, fairly tough. Total diameter about 20 millims.

The main skeleton is a very irregular network of fairly stout spicular fibre; the size and shape of the meshes and the thickness of the fibres varying greatly. The fibres contain a very large number of oxeote megascleres closely packed together side by side, while the spongin cement which unites them is inconspicuous on account of its very pale colour. The fibres are echinated more or less abundantly by spined styli which project from them almost or quite at right angles. Numerous loose megascleres (oxea and styli) are scattered between the fibres. There is a dermal skeleton of well developed brushes of very slender styli; the brushes are well separated from one another, and each exhibits a beautiful radiate arrangement of its component spicules. These brushes appear to be confined to the outer surface of the sponge as a whole, and are absent from the surfaces of the inner trabeculæ.

Spicules.—(1.) Oxea (Plate XI., fig. 4, *c*, *d*); smooth, slender, usually more or less sharply bent at or near the middle, gradually and sharply pointed at each end; size very variable, commonly about 0·25 millim. by 0·006 millim. In the fibres and scattered between them, forming the greater part of the skeleton.

(2.) Smooth styli (Plate XI., fig. 4, *a*, *a*); very long and fairly stout, tapering gradually from the evenly rounded base (which may be very faintly tylote) to the sharply pointed apex; nearly straight but generally slightly curved towards the base; size variable, say about 1·26 millims. by 0·012 millim. These spicules lie parallel to the surface in the thickness of the sponge-lamella, without any definite arrangement.

(3.) Smooth styli (Plate XI., fig. 4, *b*); very slender, almost hair-like; straight or gently curved; evenly rounded at the base, very gradually and finely pointed at the apex; size about 0·34 millim. by 0·002 millim. In the dermal brushes.

(4.) Spined tylostyli (Plate XI., fig. 4, *e*, *f*); rather long and slender, straight, tapering gradually from the slightly developed head to the narrow, fairly sharp-pointed apex. Spines small but abundant all over, especially on the head. Size about 0·1 millim. by 0·006 millim. where the shaft joins the head.

I have also seen three small isochelæ about 0·018 millim. long, and two or three sigmata, one of which measured about 0·05 millim. from bend to bend; but these spicules are so scarce that I am doubtful whether they are proper to the sponge.

This is an interesting species, having (if we leave out of account the doubtful microscleres) the spiculation of an *Echinodictyum* combined with the habit of an *Echinoclathria*. It is evidently nearly related to THIELE'S *Echinodictyum cavernosum* from Celebes (**39**), but differs in its pale colour and in the presence of the large styli.

R.N. 325 (Ceylon seas).

Aulospongus, NORMAN.

Massive Ectyoninæ with plumose columnar skeleton, comprising both smooth and spined styli in the spiculation. Without microscleres.

In my 'Report on a Second Collection of Sponges from the Gulf of Manaar' (**3**) I expressed the opinion that NORMAN'S genus *Aulospongus* (**55**) was unnecessary, and that the species for which it was established might be included in the genus *Axinella*. Further consideration has, however, induced me to alter my views on this question, and to consider the presence of the spined styli as constituting a sufficient generic distinction from *Axinella*, and, indeed, necessitating the removal of the genus to the Ectyoninæ.

This genus is evidently closely related to *Raspailia*, and constitutes one of the apparent connecting links between the Ectyoninæ and Axinellidæ. THIELE (**39**) has referred to the genus *Raspailia* two or three Japanese species, one, at least, of which (*Raspailia* (?) *villosa*) should perhaps be included in *Aulospongus*. The Australian *Raspailia cacticutis* (*vide* DENDY, **10**) may also possibly belong here, and likewise Mr. CARTER'S *Dictyocylindrus sessilis* from the Gulf of Manaar (**4**).

Aulospongus tubulatus (BOWERBANK).

1873, **Haliphysema tubulatum**, BOWERBANK (**8**); 1878, **Aulospongus tubulatus**, NORMAN (**55**); 1889, **Axinella tubulata**, DENDY (**3**).

Fig. 3. *Aulospongus tubulatus* (BOWERB.); from Gulf of Manaar; nat. size.

There are a number of specimens of this sponge in Professor HERDMAN'S collection. The species (fig. 3) forms one of the most characteristic elements in the Sponge-Fauna of Ceylon, and is of especial biological interest as affording an example of symbiosis, or perhaps commensalism, between a Sponge and an Annelid. I have nothing to add to the account which I gave in my 'Report on a Second Collection of Sponges from the Gulf of Manaar' (**3**).

R.N. 1, 2, 3 (and others not numbered; all from Gulf of Manaar (Stats. V., IX., XV., LV., LXI., LXVIII.).

Acarnus, Gray.

Ectyoninæ in which the megascleres may be stylote, oxeote, tylote and cladotylote, the latter forming the characteristic "grapnel-spicules" which typically echinate the skeleton fibre. Microscleres may be present in the form of palmate isochelæ and toxa.

Acarnus ternatus, Ridley.—Plate VIII., fig. 4.

There is in the collection a remarkably fine dry specimen of this species (R.N. 105, Plate VIII., fig. 4), of proliferous and thickly flabellate habit, with rather large vents (about 8 millims. in diameter) on the summits of the lobes. The specimen measures 270 millims. in greatest breadth by 150 millims. in height, and its colour is brown. There are also a couple of small specimens in spirit, the best of which is sub-cylindrical in form and irregularly branched.

The spongin of the skeleton fibres is very strongly developed but very pale-coloured.

Spicules.—(1.) Styli, measuring about 0·3 millim. by 0·0164 millim.

(2.) Cladotylota (grapnels), with usually three large, strongly recurved, sharp teeth; shaft about 0·21 millim. by 0·012 millim.

(3.) Slender tylota with slightly spined heads; about 0·22 millim. by 0·0035 millim. in the middle.

(4.) Oxea; long and very slender, gradually sharp-pointed at each end, may be angulated at or near the middle; say about 0·74 millim. by 0·004 millim.

(5.) Toxa; say about 0·152 millim. by 0·008 millim., but often more slender.

(6.) Palmate isochelæ, about 0·02 millim. long.

The slender oxea occur irregularly distributed outside the horny fibres. Ridley (**16**) makes no mention of them in his description, but they might be overlooked or regarded as accidental. Keller, on the other hand, describes and figures similar spicules in his *Acarnus wolffgangi* from the Red Sea (**61**). The latter species may possibly prove to be a mere synonym of *A. ternatus*.

The species has hitherto been recorded from Torres Straits (Ridley), Bombay (?) (Ridley), Amirante Islands (Ridley), and Tahiti ("Challenger").

R.N. 105 (dry, Gulf of Manaar); 313; 329 (Ceylon seas).

Cyamon, Gray (*emend.*).

Ectyoninæ in which the principal megascleres are smooth styli and tylostyli; the echinating spicules have a radiate form, and there are no microscleres.

In 1867, Gray (**31**) proposed this genus for Bowerbank's *Dictyocylindrus vickersii*, of which a single spicule was figured and described in the 'Monograph of British Spongiadæ.'* It was not until 1879 that this species was first really described by

* Vol. i., p. 267, fig. 234.

CARTER (**56**), who, however, did not adopt GRAY's genus, but adhered to BOWERBANK's original name.

In 1880, CARTER (**4**) also described two species from the Gulf of Manaar, which he named *Microciona quadriradiata* and *M. quinqueradiata* respectively, and called attention to the resemblance of the echinating spicules in these species to those of "*Dictyocylindrus vickersii*." It appears to me that all these three species must be included in one genus, distinguished as in the diagnosis given above, for which we may retain GRAY's name *Cyamon*.

This genus appears to be nearly related to *Trikentrion*, but is distinguished from it by the absence of oxeote megascleres (compare CARTER, **56**).

The peculiar radiate echinating spicule is probably derived from a spined echinating stylus by great enlargement of three or four of the basal spines. In this way it may come to resemble a tetractinellid spicule or an aster. It is extremely interesting to compare with these forms the equally peculiar echinating "grapnel" spicule of *Acarnus*, in which a tetractinellid form may also be arrived at secondarily, but by enlargement of spines at the apex instead of at the base of the spicule.

Cyamon quinqueradiatum (CARTER).

1880, Microciona quinqueradiata, CARTER (**4**).

The single specimen in the collection forms a sub-circular crust, about 11 millims. in diameter and 3 millims. thick in the middle, attached to a mass of nullipore.* The surface is uneven and irregularly conulose, and there is in parts a distinct, thin dermal membrane. In parts also the surface is sparsely hispid from the projection of some of the large spicules. The texture is soft and compressible, internally somewhat cavernous, and the colour (in spirit) is pale yellowish-brown.

The skeleton consists chiefly of tylostyles and styles of various sizes, the latter (at any rate usually) longer than the former. These spicules sometimes have their bases resting on the substratum and sometimes they are arranged in short plumose columns; some have their apices projecting for a considerable distance beyond the surface. The echinating spicules are rather scarce and local in their distribution, mostly to be found amongst the bases of the other spicules; though plentiful here and there, they might easily be overlooked except in fortunate preparations.

The spiculation agrees fairly closely with CARTER's description, but I think he has laid too much stress upon the distinction of the various forms of styli and tylostyli. In our specimen these pass gradually into one another; the slender "acuate" is not recognisable as a distinct type (it may be simply a young form), while the tylostyli have larger heads than appears from CARTER's description and figure. There may be either three or four smooth rays in the echinating spicule (in addition to the spined ray), but it agrees very closely with CARTER's description and figure.

R.N. 270 (deep water off Galle and onwards up West Coast).

* In association with a small specimen of *Petromica massalis*, R.N. 269.

Plocamia, Schmidt.*

Ectyoninæ of varying form; may be encrusting or erect and branched. The characteristic spicules are dumb-bell-shaped or sausage-shaped megascleres, in addition to which styli or tylostyli of various forms (some of which are typically echinating) may be present. The microscleres are isochelæ and (at any rate usually) toxa.

Plocamia manaarensis (Carter)—Plate VIII., fig. 1.

1880, **Dictyocylindrus manaarensis**, Carter (**4**); 1881, **Dirrhopalum manaarense**, Ridley (**60**).

There are several specimens of this curious sponge in the collection. Mr. Carter figured and described both external form and spiculation, and Mr. Ridley added valuable information on the latter point and on the question of systematic position. It is therefore unnecessary for me to do much more than refer to Plate VIII., fig. 1, which represents a much finer specimen than any hitherto obtained. The colour of the sponge (in spirit) varies from pale yellowish-grey to almost black,† and the branching is extremely irregular. One specimen (R.N. 367) shows very clearly how the main stem may be attached to the substratum by an expanded base.

Lambe (**85**) has recorded this species from California, but I think that his identification is probably erroneous.

R.N. 41 (Gulf of Manaar); 76 (Stat. XXXIII., 18 fathoms); 107 (off Galle, February 13, 1902); 278 (deep water off Galle and onwards up West Coast of Ceylon); 367 (deep water outside pearl banks); 374 (Stat. LX., 20–30 fathoms, Gulf of Manaar).

Bubaris, Gray.

Ectyoninæ of usually encrusting habit. Skeleton consisting of an inner mass of diactinal (vermicular) spicules, from which large styli or tylostyli project vertically outwards. Without microscleres.

This genus was founded by Gray (**31**) for Bowerbank's *Hymeraphia vermiculata*, the type of the genus *Hymeraphia* (*H. stellifera*) being a totally different sponge. Topsent (**59**, **62**) has already adopted the genus.

It is probable that there are a large number of encrusting sponges, with skeleton arrangement very similar to that of *Bubaris*, which are in reality not closely related to one another, but derived from several groups by adaptation to an encrusting habit (compare *Hymedesmia* amongst Astromonaxonellida). In such cases we must judge of their systematic position rather by the form of the spicules than by the mere arrangement of the skeleton.

The possible relationship of the genus *Bubaris* to the Axinellidæ is indicated in the Report of the "Challenger" Monaxonida (p. 182).

* For literature, &c., *vide* Ridley and Dendy (**1**).

† See footnote under *Iotrochota purpurea*.

Bubaris eruca (Carter).

1880, **Hymerhaphia eruca,** Carter (4); 1894, **Rhabderemia eruca,** Topsent (59).

There are three specimens of this very curious encrusting sponge in the collection; it has been well described and figured by Carter (*loc. cit.*), who himself pointed out its close resemblance to Bowerbank's *Hymeraphia vermiculata*, which is the type species of the genus *Bubaris*.

Topsent (62) has recently proposed to include this species in his genus *Monocrepidium*, distinguished from *Bubaris* by the tuberculation of the diactinal megascleres. In *Bubaris eruca* the spicules in question are annulated rather than tuberculated.

R.N. 183 (Stat. XLIII., off Kaltura, February 19, 1902, depth 22 fathoms); 239a, 240a (both from deep water off Galle and onwards up West Coast).

Rhabderemia, Topsent.

Encrusting or massive Ectyoninæ in which the principal megascleres are styli with strongly curved base, shaped like a hockey stick, and the principal microscleres are contorted sigmata. There are no chelæ and the echinating spicules appear to be greatly reduced or absent.

Topsent (48) established this genus in 1892, originally for the reception of Carter's *Microciona pusilla* and *M. intexta* (57), and a new species described by himself under the name *Rhabderemia guernei*. *R. pusilla*, being mentioned first, may be taken as the type of the genus. *R. guernei* and the new species which I am about to describe under the name *Rhabderemia indica*, agree so closely with *R. pusilla* that there can be no reasonable doubt of their generic identity. *R. intexta* differs more from the typical species, but may still, I think, be included in the genus. It is distinguished from the others by the possession of spined megascleres and the absence of small slender styli. There is in Mr. Carter's cabinet, however, a preparation labelled by him "*Microciona minutula*," which is intermediate in spiculation, having large bent styli minutely spined at the apex and also very slender styli slightly roughened at the base. It is further characterized by having toxa amongst the microscleres, and is evidently quite distinct from *Rhabderemia* (*Microciona*) *pusilla*, with which Mr. Carter has apparently confounded it.*

It is probable that some other species hitherto referred to the genus *Microciona* will also have to be included under *Rhabderemia*; on the other hand, as I have shown in dealing with *Bubaris eruca*, this species has been erroneously included in the genus *Rhabderemia* by Topsent.

Rhabderemia indica, n. sp.—Plate XII., fig. 10.

The specimen encrusts and almost completely envelopes some large fragments of shell, and attains on one side of the shell a thickness of 7 or 8 millims. The shape of the entire specimen with its enclosed shell-fragments is massive and irregular.

* The name *pusilla* was intended by Carter to be *minutula*, *vide* Carter (57 and 4).

The surface is uneven but fairly smooth; granular; with a distinct, translucent dermal membrane in places. Vents probably small and scattered. Texture rather soft, spongy and friable. Colour (in spirit) dull grey. Greatest diameter of the entire mass about 48 millims.

The skeleton is a close-meshed, very irregular reticulation of megascleres, many of which are collected together into loose multi-spicular bands running perpendicularly to the surface. These primary fibres, if we may so call them, are connected together by still looser and more irregular secondary bands, and the whole is confused by immense numbers of irregularly scattered megascleres. There is no special dermal skeleton and I have detected no spongin.

Spicules.—(1.) Styli, "rhabdostyles" of Topsent (Plate XII., fig. 10, *a*, *b*, *c*); base evenly rounded off, not tylote; basal part of shaft sharply bent at an angle to the remainder, like the end of a hockey stick, occasionally somewhat spirally curved; remainder of shaft straight or nearly so; gradually or somewhat hastately pointed at the apex; size fairly uniform, about 0·24 millim. by 0·006 millim., the bent basal portion being about 0·018 millim. long. These make up the main skeleton.

(2.) Very small, slender styli (Plate XII., fig. 10, *d*); straight or nearly so; tapering gradually from rounded base to finely pointed apex; with very slightly roughened surface; size about 0·044 millim. by 0·002 millim. at the base. Scattered very abundantly through the soft tissues as microscleres, and very uniform in size. I am inclined to think that these spicules are vestigial echinating styli.

(3.) Sigmata (Plate XII., fig. 10, *e*); very much contort, slender, often twisted into a kind of half-knot in the middle, sharply pointed at each end (when one end appears bluntly rounded, or even knobbed, it is probably due either to its having been broken short or to fore-shortening in perspective). The greatest length, measured in a straight line from bend to bend, is only about 0·012 millim., but if the spicule were straightened out it would measure at least twice as much. Very abundant.

This species is distinguished from *Rhabderemia pusilla* by the greater length of the bent styli and the much smaller size and roughened surface of the minute styli; from *R. guernei* by the absence of the peculiar microscleres which Topsent terms "thraustoxes," and by the smaller size of the megascleres and the roughening of the minute styli; from *R. intexta* by the presence of the minute styli, the smoothness of the large megascleres and the form of the sigmata. It differs from all in its much more robust growth, which constitutes perhaps its most noteworthy feature.

R.N. 341 (Ceylon seas).

Family: AXINELLIDÆ.

Sigmatomonaxonellida in which the microscleres have usually been entirely lost by degeneration; the megascleres are usually, in part or entirely, stylote; the skeleton arrangement is usually, but not always, plumose; and there are no spined echinating styli.

Owing to their loss of microscleres and want of other well-marked characters, this family is one of the most unsatisfactory with which we have to deal. The plumose arrangement of the megascleres in the main skeleton cannot be regarded as exclusively diagnostic, for it is met with also in Ectyoninæ and even in Chalininæ, and too great reliance upon this character has led to the inclusion of forms amongst the Axinellidæ which certainly should not be included in that family. I have already indicated that those so-called Axinellids in which true asters have been observed (*e.g.*, *Vibulinus*) should be placed amongst the Astromonaxonellida. The genus *Raspailia*, similarly, has been removed from the Axinellidæ to the Ectyoninæ, but we are still left with a somewhat heterogeneous collection of sponges which it is extremely difficult to define, and which will probably be subjected to considerable re-arrangement in the future. A curiously constant feature in this group is the irregularity exhibited by the ends of the megascleres and the manner in which the stylote and oxeote forms tend to pass into one another.

It is highly probable that the group, even as here restricted, is of polyphyletic origin.

Spongosorites, Topsent (*emend.*).

Axinellidæ with the main skeleton composed of an irregular but dense reticulation of large oxea or styli, and dermal skeleton composed of a thin layer of very much smaller oxea lying tangentially, and in close contact with the main skeleton; oxea typically biangulate.

Topsent (**14**, &c.) places the genus *Spongosorites* in his family Coppatiidæ, assuming that it has lost the characteristic microscleres, and calling attention to the apparent tetractinellid affinity indicated by the biangulate oxea. It appears to me, on the other hand, to come more naturally amongst the Axinellids, being not distantly removed from *Leucophlœus* and *Ciocalypta*, as indicated by the new species described below, in one of which we perhaps find a clue to the evolution of the curious finger-shaped "processes" of the latter genus. In *Ciocalypta tyleri*, var. *aberrans*, we also sometimes find biangulate oxea.

The genus *Spongosorites* may also be nearly related to Thiele's *Dactylella* (**39**).

Spongosorites topsenti, n. sp.—Plate XII., fig. 1.

There are six specimens of this curious sponge in the collection, differing so much amongst themselves in external form that it seems desirable to give a short account of each.

R.N. 152 is a depressed cake-shaped sponge of nearly circular outline, with convex upper and almost flat lower surface, the latter having been evidently attached to the substratum all over. Greatest diameter 36 millims., thickness in the middle 13 millims. The upper surface is somewhat corrugated, with shallow grooves (indicating underlying canals) radiating in a stellate manner from low, mound-like projections, one at least of which bears at its summit a small group of vents through which the radiating canals open, while another bears no visible apertures at all. The upper surface also bears one very small digitiform process, about 5 millims. long and 2 millims. in diameter, with no visible opening, and there may have been more of these processes, now broken off. The texture is hard and compact, almost stony, and the colour (in spirit) is dull brownish-grey.

R.N. 68 is similar in general features, but the upper surface is much more strongly convex; the broad, mound-like projections are rather better developed, but still few in number (about three, grouped in the middle of the upper surface), and one bears a conspicuous vent. The slender digitiform processes without visible openings are more numerous than in R.N. 152. Greatest diameter of specimen 34 millims.

R.N. 182 is a small hemispherical specimen only about 15 millims. in diameter, with the convex upper surface produced in the middle into a single stout digitiform process, about 11 millims. long by 6 millims. thick, but of irregular shape. This process contains wide canals which enter it from the body of the sponge. There are apparently none of the slender digitiform processes. I have seen no vents, but the specimen is somewhat damaged.

R.N. 202 is closely similar to the last, but rather larger, with a single stout digitiform process in the middle, containing longitudinal canals, but now broken short.

R.N. 134 is a small specimen about 26 millims. in diameter, with slightly conulose surface and two very short but stout finger-like processes.

R.N. 77 is much larger than any of the preceding, and the base, instead of being flat below, has grown partially round several loose calcareous nodules. It is strongly convex and more or less conulose and corrugated above, and the upper surface also bears two or three well-developed, stout, erect digitiform processes, very irregularly distributed. These processes contain more or less well-developed longitudinal canals, but there are no visible vents. On the general surface of the sponge the usually low conuli are in places elongated to form slender projections about 4 millims. long, and with strongly hispid surface. The base of this specimen is about 78 millims. long by 35 millims. in greatest breadth. One of the larger processes is about 26 millims. high by 15 millims. broad at the base, tapering upwards almost to a point.

From the above descriptions it would appear that the sponge is normally cushion- or cake-shaped, with the upper surface conulose or rugose, and sometimes bearing processes of two kinds, viz., (1) large processes which appear to contain the exhalant canals and to be produced by elongation of low, mammiform, vent-bearing projections, with the conspicuous vents probably replaced by a cribriform dermal membrane; and (2) small slender processes produced by elongation of the surface conuli, and apparently bearing no special relation to the canal system.

The main skeleton in the body of the sponge consists of a very dense and confused reticulation of scattered spicules lying in all directions and varying greatly in form and size, stout and slender mixed up together. At the surface, lying immediately on the main skeleton, there is a thin dermal layer of short and rather slender oxea, through which the apices of the large underlying spicules frequently project. In the processes of both kinds, large and small, the spicules of the main skeleton for the most part run lengthwise, and there is the same irregular dermal reticulation of small oxea. There are none of those characteristic radiating pillars of spicules, supporting the dermal membrane over large sub-dermal cavities, which we find in a typical *Ciocalypta*.

Spicules.—(1.) Large and very stout (Plate XII., fig. 1, *a–k*), typically fusiform oxea, but variously ended, sometimes stylote or strongylote, always more or less curved, sometimes biangulate, sometimes very crooked and irregular; size about 1·1 millims. by 0·065 millim., but variable.

(2.) Short, slender oxea (Plate XII., fig. 1, *l*); usually biangulate, gradually and sharply pointed at each end, symmetrical; measuring about 0·18 millim. by 0·008 millim., but variable. These forms occur chiefly, but not entirely, in the dermal skeleton; while between these and the largest spicules numerous intermediate forms (Plate XII., fig. 1, *m*) may be observed.

The above account of the spiculation is taken from R.N. 152, but the spiculation of the other specimens does not differ in any important respect.

The species may be distinguished from its European congener, *S. placenta* (the type of the genus), by the development of the finger-like outgrowths (which, however, may be not always present) and by details of spiculation, such as the absence of the central inflation of the oxea.

R.N. 68 (Gulf of Manaar); 77 (Stat. XLV., off Pantura, 25 fathoms); 134, 202 (deep water off Galle and onwards up West Coast); 152; 182 (Stat. XLIII., off Kaltura, February 19, 1902).

Spongosorites (?) lamellata, n. sp.—Plate XII., fig. 2.

Sponge irregular, compressed, lamello-digitate; only 3 millims. or 4 millims. in average thickness, with a maximum length of about 45 millims. ? Erect. Surface granular in appearance and minutely hispid, fairly smooth but uneven; margins rounded. Colour (in spirit) pale greyish-yellow.

The main skeleton consists of a dense and very irregular reticulation of styli, mostly scattered singly, but occasionally collected in loose strands. The dermal skeleton is formed of a thin layer of small slender oxea, lying tangentially to the surface and very irregularly scattered.

Spicules.—(1.) Styli (Plate XII., fig. 2, *a*, *b*, *c*); usually fairly stout and slightly curved or crooked (especially towards the base), narrowing slightly to the base, which is evenly rounded, and tapering gradually to the apex, which is sharply pointed; size, when fully grown, about 0·95 millim. by 0·02 millim., but numerous smaller and more slender forms occur which are apparently young.

(2.) Oxea (Plate XII., fig. 2, *d*, *e*); slender, sub-fusiform, slightly curved or angulated once or twice, sharply pointed at each end; size very variable, averaging, say, about 0·2 millim. by 0·0055 millim. These spicules occur chiefly at the surface of the sponge, but are also found in the interior.

This species differs widely from *Spongosorites topsenti*, not only in external form but also in the (? invariably) stylote character of the larger spicules.

R.N. 236 (deep water off Galle and onwards up West Coast of Ceylon).

Spongosorites (?) **lapidiformis**, n. sp.—Plate XII., fig. 3.

The three specimens by which this species is represented in the collection are quite irregular in shape; massive, and everywhere evenly rounded off, like water-worn pebbles, with no recognisable points of attachment or differentiation of surfaces. The surface is granular and very shortly hispid; harsh to the touch; occasionally veined by underlying ramifying canals. Vents few, small, sometimes hardly recognisable. Texture hard and compact, without separable dermal membrane. Colour (in spirit) pale wax-yellow. The largest specimen measures about 29 millims. in maximum diameter.

The skeleton is a very dense, irregular reticulation of megascleres, partly collected together in ill-defined bands. This reticulation extends right up to the surface of the sponge, and there is no special dermal skeleton, and apparently no spongin.

Spicules.—(1.) Very stout, fusiform oxea (Plate XII., fig. 3, *a*, *b*); slightly curved and gradually and sharply pointed at each end; measuring, say, about 0·87 millim. by 0·0495 millim.; pretty frequently becoming stylote (Plate XII., fig. 3, *c*) by rounding off of one end, and rarely even strongylote. These oxea are connected by intermediate forms (Plate XII., fig. 3, *d*) with

(2.) Slender oxea (Plate XII., fig. 3, *e*); slightly curved, gradually sharp-pointed at each end; measuring, say, about 0·54 millim. by 0·012 millim.; irregularly intermingled with the large oxea, and perhaps only young forms thereof.

This species is of very doubtful systematic position. Had it not been for the presence of so many stylote spicules, I should probably have referred it to *Halichondria*. It differs from typical species of *Spongosorites* in the absence of a special dermal layer of small oxea.

R.N. 143, 144, 145 (all from deep water off Galle and onwards up West Coast).

Hymeniacidon, Bowerbank (*emend.*).

Axinellidæ of massive habit. Skeleton reticulate, composed of spicular fibre usually containing a good deal of spongin; with no special dermal skeleton. Megascleres styli or sub-tylostyli; no microscleres.

I have pointed out on a previous occasion (10) that Lendenfeld's genus *Stylotella* (with which Topsent's *Stylinos* is admittedly synonymous) is not distinguishable from *Hymeniacidon.* The position of the genus amongst the Axinellidæ is, of course, open to question, but it seems to come at least as naturally here as anywhere else.

Hymeniacidon petrosioides, n. sp.—Plate XII., fig. 4.

The type specimen (R.N. 151) is massive, cushion-shaped, strongly convex above and irregularly concave below, having evidently been attached to the substratum at a few points only. Upper surface fairly even but coarsely granular. Vents (probably) few, small and scattered. Texture very hard and compact; surface harsh to the touch. Colour (in spirit) dull grey, with a purplish tinge here and there. Greatest breadth about 47 millims.; maximum thickness about 19 millims. There is another much smaller specimen of irregularly massive form.

The skeleton is a dense, close-meshed reticulation of short, stout styli, in which one can readily distinguish stout, multispiculous main fibres running at right angles to the surface at distances of about one spicule's length from one another, and connected crosswise by isolated spicules and bundles of spicules, with other similar spicules irregularly scattered in the soft tissues.

Spicules.—Short, stout, more or less curved or bent styli (Plate XII., fig. 4), broadly rounded off at the base (occasionally slightly tylote) and gradually sharp pointed at the apex; fairly uniform in size, measuring about 0·39 millim. by 0·022 millim. (There are apparently no oxea.)

This species appears to be nearly related to TOPSENT'S *Stylinos jullieni* from the Atlantic (**48**), but the spicules are much larger. In external appearance it bears a very close resemblance to *Thrinacophora durissima*, with which it may easily be confounded until microscopically examined, and, indeed, I am inclined to think that these species of *Hymeniacidon* are really closely related to the massive species of *Thrinacophora.* We may also have here, so to speak, a point of contact between the Axinellidæ and Desmacidonidæ, indicated both by the form and arrangement of the megascleres and the presence of trichodragmata in the last-named genus. The spicular fibre in *Hymeniacidon* is not plumose, or, at most, very feebly so, but it is impossible to draw a hard and fast line between the plumose type of fibre characteristic of the Axinellidæ and the non-plumose type characteristic of the Desmacidonidæ, &c.

R.N. 151; 316 (Ceylon seas).

Thrinacophora, RIDLEY and DENDY.

Axinellidæ with typically plumose skeleton and with microscleres in the form of trichodragmata.

Thrinacophora agariciformis, n. sp.—Plate XII., fig. 6.

Sponge consisting (usually, at any rate) of a short, thick stalk (which has evidently been attached below), supporting a thick, rounded, cushion-shaped body which is irregularly depressed above so as to form a more or less shallow, very thick-walled cup; or the top of the sponge-body may be flattened, with several irregular, shallow depressions. Surface minutely and uniformly conulose; the conuli barely 0·5 millim. in diameter and separated from one another by deep but narrow, meandering grooves. In the depression at the top the conuli may be covered over by a thin translucent membrane containing small circular vents. Consistence compressible, resilient. Colour (in spirit) pale yellowish-grey. A typical specimen (R.N. 163, not quite the largest) gave the following measurements: total height 25 millims.; length of stalk 8 millims.; diameter of stalk 13 millims.; longer diameter of body 31 millims.; shorter diameter 21 millims.

The skeleton is arranged in a typical axinellid manner, consisting chiefly of plumose columns of spicules running at right angles to the surface and ending in the conuli. These columns lie pretty close together and are connected with one another crosswise by occasional groups of spicules, or by single spicules, running across at right angles from one to the other; there are also numerous irregularly scattered spicules in the interspaces. The spicules are cemented together in the columns, and sometimes also in the cross connections, by a large amount of very pale-coloured spongin. There is no special dermal skeleton, but the surface may be rendered slightly hispid by the projection of the terminal spicules of the columns.

Spicules.—(1.) Short styli (Plate XII., fig. 6, *b*, *c*); fairly stout and more or less curved, especially towards the base, which is broadly rounded off; with gradually and finely pointed apex; size about 0·268 millim. by 0·01 millim., but variable.

(2.) Oxea (Plate XII., fig. 6, *d*, *e*); usually gently and evenly curved and sharply pointed, but often irregularly ended; of about the same size as the short styli, and very numerous.

(3.) Very long and slender, setaceous styli (Plate XII., fig. 6, *a*) (sometimes oxea), measuring, say, about 0·75 millim. by 0·008 millim., but variable. These spicules are found lying lengthwise in the interspaces between the plumose columns.

(4.) Trichodragmata (Plate XII., fig. 6, *f*); bundles of short and very slender, hair-like microscleres, slightly curved, the whole bundle measuring, say, about 0·032 millim. by 0·005 millim., but variable. These occur scattered quite irregularly between the spicular columns.

This beautiful and well-characterised little sponge is represented in the collection by seven specimens. It differs widely from any of its known congeners in external form, and spirit specimens are easily mistaken, at first sight, for young examples of *Phakellia donnani*, though readily distinguished on closer inspection by their paler colour, more finely conulose surface, &c. It is apparently common and may be looked upon as one of the most characteristic species of the Ceylon Sponge-Fauna.

R.N. 160A; 160B; 163; 163A; 314; 332; 356 (all from Ceylon seas).

Thrinacophora durissima, n. sp.—Plate XII., fig. 5.

Sponge sessile, cushion-shaped, very strongly convex above and somewhat contracted below, but attached by a broad base. Surface even, but granular or minutely conulose, the conuli being in part covered over by a translucent dermal membrane; very minutely hispid. Vents small, few, scattered; surrounded by feebly developed grooves arranged in a somewhat stellate fashion. Colour (in spirit) pale yellowish-grey. Texture compact, very hard; surface harsh to the touch; internal structure radially columnar. Greatest diameter about 23 millims.

The skeleton is composed chiefly of close-set, rather irregular, plumose columns of megascleres, running at right angles to the surface and ending in the small conuli or granules. These columns are connected by numerous spicules, isolated or in loose bands, which run across at right angles from one to another, while numerous megascleres are also scattered irregularly in the soft tissues.

Spicules.—(1.) Oxea (Plate XII., fig. 5, *b*); short, fairly stout, fusiform, gently and symmetrically curved, gradually sharp-pointed at each end; size up to about 0·39 millim. by 0·024 millim., but usually somewhat less, especially in diameter.

(2.) Styli (Plate XII., fig. 5, *a*); with broadly rounded base and gradually sharp-pointed apex; usually more or less curved towards the base; dimensions about the same as those of the oxea. Perhaps not quite so abundant as the oxea.

(3.) Trichodragmata (Plate XII., fig. 5, *c*, *d*); short, stout bundles of very slender, hair-like spicules, the whole bundle having, as usual, a faint brownish colour; dimensions of the entire bundle about 0·02 millim. by 0·008 millim.; abundant towards the surface of the sponge.

This curious little sponge is evidently closely related to TOPSENT'S *Thrinacophora spissa* (**48**) from the North Atlantic, and forms an interesting connecting link between that species (which has only oxeote megascleres, apparently arranged in a halichondrioid rather than an axinellid fashion) and the more typical species of the genus.

R.N. 355 (Ceylon seas).

Axinella, SCHMIDT.

Axinellidæ of varying habit, but not flabellate. With plumose skeleton composed of smooth styli or oxea and no microscleres.

Axinella labyrinthica, DENDY.

There are three specimens of this sponge in the collection. The species is easily recognisable by its external appearance, and I have nothing to add to my former description, DENDY (**3**), 1889.

R.N. 33, 103 (both from Gulf of Manaar); 357 (Ceylon seas).

Axinella manus, n. sp.—Plate XII., fig. 8.

Sponge erect, stipitate, branched in a somewhat palmate manner, but with the branches coming off at different levels and curving slightly towards one another (so as to suggest a hand holding a ball). Stem cylindrical, slightly expanded below, about 25 millims. long and 9 millims. in diameter. Branches about as thick as the stem, slightly flattened, short (usually about 30 millims. long), rather few in number, terminating in abrupt, conical apices. The vents are small openings in the floors of stellately arranged or longitudinal grooves, which give a characteristic appearance to the sponge, and are chiefly placed on the inner surface of the branches, but also occasionally on the outer surface and on the stem. Surface between the vent-bearing grooves granular or minutely conulose. Texture compressible, resilient but tough, with the stem a good deal harder than the branches. Colour (in spirit) rather light grey. Total height of specimen 84 millims.

The skeleton is rather loose and irregular, consisting (in the branches) of plumose columns radiating outwards to the surface and with many spicules irregularly scattered between; the whole becoming quite confused towards the middle of the branch, but without any special axial condensation.

Spicules.—(1.) Rather short and fairly stout styli (Plate XII., fig. 8); more or less curved towards the base, which is broadly rounded off; gradually and sharply pointed at the apex; size about 0·295 millim. by 0·016 millim., but often more slender.

(2.) Oxea; almost symmetrically curved and gradually sharp pointed at each end; of about the same dimensions as the styli; abundant.

This species, in the arrangement of the vents and in the skeletal characters, makes a close approach to *Phakellia donnani* and *P. symmetrica*, and demonstrates very clearly the impossibility of distinguishing sharply between the genera *Phakellia* and *Axinella*.

R.N. 53 (Gulf of Manaar).

Axinella tenuidigitata, n. sp.—Plate XIII., fig. 4.

The single specimen is a small massive sponge of short, thick, irregularly cylindrical form, attached by a broad base below and strongly convex on the upper surface, from which a number of slender, elongated, finger-like processes are given off. Surface uneven and irregularly hispid, especially on the digitiform processes; in part minutely and irregularly conulose and in part covered by a distinct, sub-glabrous, translucent dermal membrane. The digitiform processes are solid and they may unite with one another. Vents apparently small and scattered between the processes. Colour (in spirit) pale wax-yellow; texture hard and compact. Height of body about 20 millims., diameter about 15 millims.; length of processes, of which there are about half a dozen, about 11 millims., with a diameter of not much more than 1 millim.

The skeleton in the body of the sponge consists of an irregular reticulation of long styli, which, as they approach the surface, arrange themselves in loose, irregular, plumose columns. The digitiform processes are composed each almost entirely of a dense axis of similar spicules closely crowded together and placed longitudinally, with a few spicules projecting outwards beyond the surface, so as to give rise to its hispid character.

Spicules.—Apparently all stylote and all long (Plate XIII., fig. 4), but varying much in thickness; usually only very slightly curved (towards the base), but sometimes crooked; broadly rounded off at the base, which may be somewhat narrower than the middle part of the spicule, and gradually and sharply pointed at the apex. The stouter forms measure about 1·18 millim. by 0·0328 millim. In the digitiform processes they are a good deal more slender, and slender forms also occur intermingled with the stout ones in the body of the sponge.

R.N. 202A (deep water off Galle and onwards up West Coast of Ceylon).

Axinella halichondrioides, n. sp.—Plate XII., fig. 7.

Sponge encrusting, extended horizontally. Upper surface somewhat convex and rather uneven, with small monticular elevations, each bearing a single vent, scattered at fairly regular intervals; granular (minutely conulose) between the elevations, the conuli being normally covered over by a thin, transparent dermal membrane. Colour (in spirit) light brown; texture firm and compact, columnar in vertical section. Greatest breadth of specimen about 64 millims.; thickness in the middle about 16 millims. Height of vent-bearing projections up to about 2 millims. Diameter of vents about 1 millim. Distance between vents about 9 millims.

The skeleton consists chiefly of very stout but rather loose and irregular and only slightly plumose columns of spicules running vertically to the surface and ending in loose brushes in the small surface conuli. These columns contain a very large number of spicules and are connected together by short, loose bands of spicules running across the interspaces at right angles. There are also a large number of spicules irregularly and loosely scattered through the soft tissues.

Spicules.—Mostly oxeote (Plate XII., fig. 7, *a*); gently and uniformly curved, gradually and sharply pointed at each end; size about 0·31 millim. by 0·01 millim. A few styli of about the same size also occur (Plate XII., fig. 7, *b*, *c*).

This species resembles pretty closely THIELE'S *Axinella incrustans* (**39**) from Japan, but its spiculation shows it to be distinct.

R.N. 75 (outside pearl banks, Gulf of Manaar).

Phakellia, BOWERBANK.

Axinellidæ of compressed, flabellate (or cup-like) form, usually with vents on one of the flat surfaces and inhalant pores on the other. Without microscleres.

Phakellia donnani (BOWERBANK).

1873, **Isodictya donnani**, BOWERBANK (**8**); 1887, **Axinella donnani**, DENDY (**2**).

There are a dozen specimens of this characteristic species in the collection, in various stages of growth. The spiculation, as usual in the Axinellidæ, is somewhat variable, and oxeote as well as stylote spicules occur. In view of the cup-shaped (or sometimes flabellate) form (see fig. 4) it seems desirable to remove the species from the genus

Axinella and put it in *Phakellia*, if indeed the distinction between these two genera is to be maintained.

Fig. 4. *Phakellia donnani* (Bowerb.), from Gulf of Manaar, nat. size. A, flabellate; B, cup-shaped form.

R.N. 10, 15, 20, 21, 22, 23 (all from Gulf of Manaar); 160; 160a; 160b; 160c; 181, 181a (the last two from Stat. XLIII., off Kaltura, depth 22 fathoms, February 19, 1902).

Phakellia symmetrica, n. sp.—Plate XIII., fig. 3.

The single specimen is a short-stalked, flabellate sponge, the somewhat compressed stalk widening out not very suddenly into a single vertical expansion with evenly rounded margin and without any proliferation. The two surfaces are exactly alike; minutely conulose with small circular openings (? inhalant pores) everywhere between the conuli, and with numerous stellate vents scattered at moderately wide intervals. Towards the margin the surface becomes longitudinally grooved rather than conulose, and there are also a few marginal vents. Colour (in spirit) dull yellowish-grey; texture compressible, resilient, tough. Total height of specimen about 55 millims.; length of stalk about 16 millims.; greatest breadth of frond about 41 millims.; thickness of frond in the middle about 8 millims.

The skeleton is composed of moderately stout, slightly plumose fibres curving upwards and outwards to the surface (where they terminate in the small conuli) and connected together by short, irregular cross fibres, so as to form an ill-defined reticulation with many spicules scattered irregularly in the interspaces. The skeleton fibres contain much spongin, not very conspicuous, however, on account of its pale colour.

Spicules.—Styli (occasionally oxeote) of two principal varieties: (*a.*) Comparatively short and stout (Plate XIII., fig. 3, *a*, *b*); more or less curved towards the base, which is evenly rounded off, and gradually and sharply pointed at the apex; size about 0·23 millim. by 0·009 millim. (*b.*) Comparatively long and slender (Plate XIII., fig. 3, *d*), slightly curved towards the base, which is evenly rounded off, and gradually and finely pointed at the apex; size about 0·5 millim. by 0·008 millim.

This pretty little sponge may prove to be merely a variety of *Phakellia donnani*, connected with the typical form by the flabellate variety figured in my paper on the Sponge-Fauna of Madras (**2**). For the present, however, it is perhaps better to keep the two distinct.

R.N. 159 (Muttuvaratu Paar, 8 fathoms).

Phakellia ceylonensis, n. sp.—Plate VIII., fig. 3; Plate XIII., fig. 5.

The single specimen (Plate VIII., fig. 3) is shortly stipitate, erect, thinly flabellate and very proliferous. The branching and anastomosing vertical lamellæ of which it is composed all terminate at about the same level in thin, sinuous margins. The lamellæ are scarcely 3 millims. in thickness and have a tendency to become perforated by larger and smaller apertures. The two surfaces of the lamella are not distinguishable; each is finely conulose (granular) and minutely and slightly hispid. Vents not recognisable. Texture tough and resilient; colour (in spirit) greyish-brown. Total height only about 41 millims., but with a maximum breadth of about 90 millims.

The skeleton is dense, composed of plumose columns radiating upwards and outwards into the small surface conuli, and merging internally into an irregular but fairly dense reticulation of spicules. There is a large development of very pale-coloured spongin.

Spicules.—(1.) Styli; slightly curved or bent, evenly rounded off at the base, usually very gradually and finely pointed at the apex; of two principal sizes, but very variable: (*a.*) Comparatively short and stout (Plate XIII., fig. 5, *a*), say about 0·2 millim. by 0·008 millim. (*b.*) Long and slender (Plate XIII., fig. 5, *b*), say about 0·44 millim. by 0·005 millim.

(2.) Oxea (Plate XIII., fig. 5, *c*, *d*, *e*); subject to much the same variations in size as the styli, and variously ended.

This species is nearly related to CARTER'S *Phakellia flabellata* from Australia (*vide* DENDY, **10**), but for the present at any rate it may be regarded as specifically distinct.

R.N. 34 (Gulf of Manaar).

Phakellia crassistylifera, n. sp.—Plate XIII., fig. 6.

The single specimen is a small, irregular, proliferously lamellar and slightly clathrous sponge, without recognisable point of attachment. The surface is granular and minutely hispid, and there are no visible vents. Texture hard, tough, resilient. Colour (in spirit) pale wax-yellow. Height (?) 31 millims.; greatest breadth about 19 millims.; thickness of lamellæ variable, say about 2 millims.

The skeleton is a very dense, close and irregular reticulation of very stout fibre, composed of a large quantity of almost colourless spongin, in which numerous usually stout styli are more or less completely embedded. The primary fibres are stouter than the secondaries, and may have a somewhat plumose character; but the whole reticulation is so confused, and the spongin, though very abundant, so pale in colour, that at first sight the entire skeleton looks like a dense, irregular network of thickly scattered styli.

Spicules.—Styli (Plate XIII., fig. 6); usually stout and comparatively short and more or less curved; broadly rounded off at the base, which is not narrowed, and usually sharply and gradually pointed at the apex; but the apex is occasionally bluntly rounded off, so that the spicule becomes strongylote with unequal ends. Size commonly about 0·46 millim. by 0·0285 millim., but very variable in diameter; often much more slender than the measurement given, and occasionally a good deal stouter; sometimes rather longer.

R.N. 256 (Ceylon seas).

Acanthella, Schmidt.

Axinellidæ of usually flabellate form and more or less cartilaginous consistence. With more or less strongly aculeate or conulose surface. With no microscleres.

Acanthella carteri, Dendy.—Plate VIII., fig. 6.

There are several specimens of this sponge in the collection, and as the external form has not yet been figured, Professor Herdman has kindly had one of them photographed for this report (Plate VIII., fig. 6). There is a strong development of very pale-coloured spongin fibre associated with the spicules, which I omitted to mention in my original description, Dendy, **3** (1889).

Keller's *Acanthella aurantiaca* (**61**), from the Red Sea, comes very near to this species, if it be not identical with it.

R.N. 11, 36, 49 (all from Gulf of Manaar, Stats. II., IV., V.); ? 301 (perhaps young); ? 336 (perhaps young).

Acanthella flabelliformis, Keller.

The single specimen is thinly flabellate; ? stipitate (the stalk may have been broken off, the specimen being somewhat damaged and worn); both surfaces beset with rather sharp longitudinal ridges, showing a tendency to break up into conuli; with deep, semi-cylindrical, longitudinal grooves between the ridges. The floor of the grooves is formed by a rather thick, translucent dermal membrane, containing no spicules and easily stripping off; in this membrane are scattered numerous small vents. Colour (in spirit) dark greyish-brown. Texture tough, compressible, resilient. Height of the single lamella of which the specimen consists 37 millims.; breadth 51 millims.; thickness (including ridges) about 5 millims.

The skeleton is a reticulation of stout spicular fibre, containing much spongin and comparatively few, though still very numerous, spicules. The main fibres curve upwards and outwards to the surface, and are united by irregular cross-fibres. The arrangement of the spicules, both in the fibres and between them, is very irregular and confused. The main fibres are often somewhat plumose.

Spicules.—Oxea; straight or curved, slender, gradually and sharply pointed at each end; size fairly uniform, up to about 0·3 millim. by 0·0065 millim.; occasionally stylote.

The soft tissues are densely charged with small, round, granular brown cells, probably pigment cells.

This species is chiefly characterised by its oxeote spicules and by the distinctly reticulate skeleton with its strong development of spongin. It appears to form a connecting link between the genera *Acanthella* and *Phakellia.*

I have little doubt of the specific identity of the Ceylon form with that from the Red Sea, where it is, according to KELLER, one of the most abundant and characteristic forms on the reefs. Such slight differences as I have observed will be sufficiently evident by comparison of the description given above with that given by KELLER (**61**), in 1889. KELLER tells us that the colour in life is blue.

R.N. 31 (Gulf of Manaar).

Auletta, SCHMIDT.

Axinellidæ of tubular form; without microscleres.

Auletta lyrata (ESPER).

1798–1806, **Spongia lyrata**, ESPER (**6**); 1870, **Raspaigella lyrata**, EHLERS (**58**); 1889, **Auletta aurantiaca**, DENDY (**3**).

There are a number of specimens of this species in the collection, which show it to be an extremely variable one, both as regards external form and spiculation. The re-discovery of the typical flabellate form, agreeing closely with ESPER'S figs. 1 and 2 (Plate 67), enables me to identify my *Auletta aurantiaca* with ESPER'S *Spongia lyrata*, which was also obtained from Ceylon.

Typical examples may be described as follows:—

Sponge erect, flabellate, shortly stalked. Lamella thick, slightly proliferous, with broadly rounded margin bearing a row of small, sometimes sphinctrate vents, which are the outlets of vertical oscular tubes. Surfaces of lamella rather minutely conulose or rugose, and slightly hispid. Texture (in spirit) compressible and resilient, but tough; colour yellowish-grey. One specimen (R.N. 345) has a total height of about 31 millims., the lamella is about 42 millims. in breadth, and 7 millims. in thickness. The vents are rather less than 1 millim. in diameter.

The main skeleton consists of wispy bands of long, slender spicules united together by abundant very pale-coloured spongin, running upwards and outwards to the surface conuli (from which their terminal spicules project more or less) and connected with one another by occasional short cross-fibres of one spicule's length, forming an ill-defined, rectangular-meshed network of spicular fibre. In these fibres the spicules lie approximately parallel to one another, there being none of the typical axinellid arrangement except in the surface brushes. Between the fibres, which have a very loose, irregular appearance, numerous isolated spicules are scattered.

Spicules.—(1.) Styli; long and very slender, nearly straight; evenly rounded off at the base and fairly sharply pointed at the apex; size about 0·41 millim. by 0·005 millim., but variable.

(2.) Slender oxea; variously ended; mostly a good deal shorter than the styli.

A second specimen (R.N. 174) differs in having the margin of the sponge thinner, the vents fewer and somewhat larger (with a tendency to occupy separate prominences of the margin), and the spicules somewhat stouter.

In the arrangement of the vents, this typical form of the species resembles *Phakellia tumida*, from Australia (**10**), but the genus *Phakellia*, if retained, should probably be restricted to species with the vents arranged on one or both of the flat surfaces of the lamella. It differs from my "*Auletta aurantiaca*" in the more slender form of the spicules, as well as in the distinctly flabellate character of the sponge, which may be regarded as formed from a number of *Auletta* tubes fused together side by side.

R.N. 174; 345 (Stat. LXVIII., Gulf of Manaar, 10 fathoms).

Auletta lyrata, var. **glomerata**, nov.

In this variety the sponge consists of an irregular agglomeration of short, finger-like processes, more or less united together laterally, and each containing a longitudinal oscular tube terminating at the apex of the process in a sphinctrate vent. In other respects, including spiculation, this variety resembles the preceding, and the whole mass is attached to the substratum by a short stalk.

This variety makes a near approach to THIELE'S *Auletta halichondrioides*, from Japan (**39**), while in external form it closely resembles fig. 3 of ESPER'S Plate 67.

R.N. 170 (pearl banks off Aripu); 194 (south of Dutch Modragam Paar); 303.

Auletta lyrata, var. **crassispiculata**, nov.

I propose this name for three irregularly branched, loosely bushy specimens, characterised mainly by the large size of the spicules, which, however, vary so much that it is almost impossible to express the difference by measurements. The tubular branches of which the sponge is composed are short and rather slender.

R.N. 43, 60 (both from Gulf of Manaar); 161 (deep water off Galle and onwards up West Coast).

Auletta lyrata, var. **brevispiculata**, nov.

This variety is represented in the collection by one very fine specimen of much larger size than usual and consisting of a great mass of branching and anastomosing tubes, each ending in a sphinctrate vent now more or less completely closed by the membranous sphincter. The whole mass is attached to a very short, stout stem, and the shape and size of the individual branches do not differ from those of the specimens of "*Auletta aurantiaca*" originally described by me. The total height of the specimen, however, is 122 millims., and the greatest breadth about 73 millims. The branching is very irregular.

The spicules commonly measure about 0·35 millim. by 0·0164 millim.

R.N. 45 (Gulf of Manaar).

Auletta elongata, n. sp.—Plate XIII., fig. 7.

The type specimen (R.N. 73) consists of a bunch of seven elongated, sub-cylindrical tubes, branching out from each other and from the short, thick stem by which they are attached to the substratum. All the tubes grow vertically upwards, close together and parallel with one another, and they do not vary greatly in length. Each terminates in a wide vent, which may be more or less closed by a membranous sphincter. Colour in spirit, dull yellowish-grey. Texture of tubes compressible, resilient, stiff; stem hard and tough. Total height of specimen 90 millims.; length of stem about 18 millims.; diameter of stem about 10 millims.; length of longest unbranched tube about 52 millims.; diameter of tube about 8 millims. The thickness of the wall of the tube is about 2 millims., and the inner surface of the wall bears the numerous small apertures of the exhalant canals, while the outer surface is granular and porous in appearance and minutely hispid.

The skeleton consists chiefly of very stout bands of spicular fibre, which run longitudinally through the inner half of the tube-wall, branching and anastomosing with one another in a quite irregular manner. From these stout fibres very short, irregular, loose, somewhat plumose columns of long, slender spicules run almost vertically outwards to the surface of the sponge, beyond which the apices of some of them project; the distance between the longitudinal fibres and the outer surface being only about one spicule's length. No spongin is recognisable in ordinary unstained sections.

Spicules.—Very variable in form and thickness, the stoutest being found for the most part in the coarse longitudinal fibres, while more slender ones radiate thence to the surface. The following may be regarded as the chief varieties :—

(1.) Styli (Plate XIII., fig. 7, *a*, *b*); fairly stout or slender, slightly curved, evenly rounded off at the base, bluntly or sharply pointed at the apex; size about 0·83 millim. by 0·022 millim.; passing into

(2.) Oxea (Plate XIII., fig. 7, *c*), of about the same dimensions, but more or less sharply pointed at each end.

(3.) Strongyla (Plate XIII., fig. 7, *d*, *e*); more or less crooked, often very much so; size, say, about 1·2 millims. by 0·022 millim.

More slender forms of all occur, and the slenderer styli may be nearly as long as the strongyla or much shorter than the stout styli whose measurement is above given.

This species is evidently nearly related to *Auletta lyrata*, differing chiefly in the arrangement of the skeleton and the length of the tubes.

R.N. 73 (outside pearl banks, Gulf of Manaar); 148, 283 (fragment, both from deep water off Galle and onwards up West Coast of Ceylon).

Leucophlœus, Carter.*

Axinellidæ of massive habit, often clathrous. Skeleton reticulate, composed of stout multispicular fibres with little if any spongin; with a well-developed dermal skeleton composed of a reticulation of spicule-bundles or a crust of tangentially placed spicules. Megascleres typically stylote, sometimes oxeote. No microscleres.

* *Vide* Carter (**54**), p. 323.

This genus, which was never diagnosed by its author, is an extremely difficult one to deal with. In our Report on the "Challenger" Monaxonida, Mr. RIDLEY and I decided to suppress it as a synonym of *Hymeniacidon*, but it has lately been revived by THIELE (39) as a distinct genus, and I am prepared to follow him in this respect. I cannot quite see, however, why THIELE should, in the same work, have established another genus (*Amorphilla*) for the reception of closely similar forms (especially as he gives no definite generic diagnoses), unless it be on account of the comparatively small size of the spicules.

If we decide to separate *Leucophlœus* from *Hymeniacidon*, as I think we must, it must be mainly on the ground of the presence in the former of a strongly developed dermal skeleton (composed, mostly at any rate, of tangentially placed spicules) which often forms a white crust in dry specimens.

Our knowledge of these sponges, however, is still very deficient, and their systematic position very doubtful. I retain the genus amongst the Axinellidæ on account of the presence of stylote megascleres and the apparent relationship to *Ciocalypta* as pointed out by Mr. CARTER. *Leucophlœus fœtidus*, with its long oxeote megascleres, perhaps comes nearer to *Halichondria* than any other species, and may indicate a close relationship with the Renierinæ.

Leucophlœus fœtidus (DENDY).

1889, **Hymeniacidon** (?) **fœtida**, DENDY (3); 1897, **Amorphinopsis fœtida**, TOPSENT (83); 1898, **Ciocalypta fœtida**, LINDGREN (86).

There is one good specimen of this sponge in the collection, differing from the type as originally described in its partially trabecular and clathrous external form, and in the pale yellowish (not blackish) grey colour of the surface (in spirit).

I have already pointed out the resemblance which this species bears to RIDLEY and DENDY'S *Hymeniacidon* (?) *subacerata*, and it is not impossible that the presence of the small projecting styli in the dermal membrane of both these species may ultimately prove to be of generic import.

R.N. 63 (Gulf of Manaar).

Ciocalypta, BOWERBANK.

Axinellidæ provided with elongated, digitiform processes springing from a massive body. In the processes the skeleton is arranged in a plumose manner with a dense central axis. There is a thin dermal membrane supported on spicular columns and usually strengthened by a reticulation of tangentially placed spicules, overlying extensive sub-dermal cavities. There are no microscleres.

Ciocalypta tyleri, BOWERBANK.

There is in the collection one specimen which I must refer to the typical form of this species (22). This specimen (R.N. 29), which I examined hastily in Liverpool, has unfortunately not been sent out to me, as it appeared to be identical with another which was sent instead (R.N. 29A), and the only preparation which I have of it (made in Liverpool) shows none of the very large spicules characteristic of the variety *manaarensis* previously described by me (**3**), though it is not impossible that such may occur in other parts of the sponge.

R.N. 29 (Gulf of Manaar).

Ciocalypta tyleri, var. **aberrans,** nov.

The single specimen consists of a flattened, cushion-shaped body of oval outline, with a number (now four, but apparently one at least has been broken off) of slender, upright, digitiform processes springing from the upper surface. These processes are long and conical, tapering gradually almost to a point, and with no visible vents; their walls, however, are pierced by numerous small dermal pores. The surface of the sponge between the roots of the processes is rather uneven and somewhat rugose, with branching canals radiating from the roots of the processes beneath the surface, through which they are plainly visible; these canals are continuous with the large canals which run lengthwise through the digitiform processes, about four in each. The general surface of the sponge is very minutely hispid; the walls of the processes have a minutely reticulate appearance and may also be very slightly hispid. The texture of the basal part of the sponge (which has been cut off below) is fairly compact, except for the numerous cylindrical canals, some of which run almost vertically downwards from the bases of the digitiform processes. The colour of the sponge (in spirit) is dull brownish-grey. The longer diameter of the base measures about 45 millims., the shorter diameter about 24 millims.; the thickness in the middle of the base (now) is about 13 millims. The digitiform processes are about 29 millims. long and 6 millims. in diameter at the base, from which they taper gradually to the narrow, blunt apex.

The skeleton in the body of the sponge is a dense, irregular reticulation of loosely scattered spicules, chiefly oxeote, of various sizes. There is no special dermal skeleton and no extensive sub-dermal cavities, and the spicules at the surface do not differ in size, form, or arrangement, from those below. In the digitiform processes there is a central axis surrounded by about four longitudinal canals, separated from one another by rather thin longitudinal septa radiating from the central axis. Both axis and septa are crowded with spicules similar to those in the body of the sponge, but mostly arranged lengthwise. From the more peripheral portions of the septa radiate loose brushes of, for the most part, more slender and shorter oxea, which spread out beneath the dermal membrane and support it on their apices, which may project slightly beyond the surface. Although the more peripherally placed spicules of each brush are inclined very obliquely to the surface, there is no true dermal reticulation, but the dermal membrane may contain irregularly scattered spicules of various sizes.

Spicules.—Oxea of various dimensions; usually gently curved, symmetrical, gradually and fairly sharply pointed at each end; sometimes biangulate instead of simply curved; occasionally stylote with broadly rounded base. Size varying up to about 0·69 millim. by 0·025 millim.; sizes indiscriminately mixed in the body of the sponge, partially sorted out as described above in the digitiform processes, measuring in the surface brushes usually only about 0·377 millim. by 0·0082 millim.

This variety differs from the typical form of the species in the absence of the special dermal skeleton of slender oxea placed tangentially.

R.N. 29A (Stat. XLIII., off Kaltura, 22 fathoms).

Collocalypta, n. gen.

Axinellidæ consisting of a basal crust, from which isolated digitiform processes spring vertically upwards. With a thick, collenchymatous ectosome which, in the digitiform processes, is penetrated by wide longitudinal canals communicating with the exterior by groups of small canals ending in dermal pores. Skeleton consisting in the basal portion of erect plumose columns of megascleres; in the digitiform processes of an axial core of spicular fibre from which loose bands of spicules radiate outwards between the longitudinal canals to surface conuli. Spicules more or less cemented together by spongin. Without microscleres.

This remarkable genus bears a very striking superficial resemblance to *Ciocalypta*, from which, however, it differs widely in the presence of the thick, collenchymatous ectosome and the typically axinellid (plumose) character of the main skeleton, as well as in the total absence of dermal skeleton (compare, however, *Ciocalypta tyleri*, var. *aberrans*), and the presence of abundant spongin cement.

Collocalypta digitata, n. sp.—Plate VII., fig. 6; Plate XIII., figs. 1, 2.

Sponge (Plate VII., fig. 6) consisting of a flat, wide-spreading, encrusting base, about 8 millims. thick, from which arise erect digitiform processes widely separated from one another by irregular intervals. These processes vary much in size, the largest in my possession is about 53 millims. high by 8 millims. in diameter in the middle. They usually taper to a sharp apex and are, as a rule at any rate, unbranched. The surface of the basal crust, between the processes, is smooth or nearly so, but it may be slightly hispid, and it is covered by a good deal of foreign matter in places. The digitiform processes have a distinctly conulose and, at the same time, longitudinally corrugated surface. They bear no visible vents, but numerous minute pores (now all closed). The colour of the sponge (in spirit) is pale grey; the consistence tough and fleshy.

The skeleton in the basal crust consists of stout, erect, plumose columns of spicular fibre, closely crowded together. The spicules are arranged in the typical axinellid manner, with their outer ends projecting obliquely upwards and outwards, while their inner portions are cemented together by a considerable amount of spongin. Each column is continued through the ectosome as a loose tuft of more slender and longer spicules than those which compose its deeper portion, and the apices of these spicules commonly project beyond the surface. There is no dermal skeleton. In the digitiform processes we find a very dense, stout axial core of spicules more or less cemented together by spongin, from which numerous loose bundles of spicules radiate obliquely outwards and upwards into the surface conuli, beyond which their apices may project. Here, again, there is no dermal skeleton.

Spicules.—Oxea (Plate XIII., fig. 1), of various shapes and sizes according to situation; (*a.*) in the columns of the basal skeleton, stout, sub-fusiform, slightly curved, irregularly ended, variable in size, say about 0·56 millim. by 0·03 millim.; (*b.*) in the ectosome of the base, comparatively long and slender, slightly curved, irregularly ended, measuring, say, about 0·88 millim. by 0·02 millim.; (*c.*) in the digitiform processes the spicules are mostly of the long and slender type just described, but occasionally stout and comparatively short forms occur.

One of the most characteristic features of this sponge is the thick gelatinous ectosome (Plate XIII., fig. 2, *ect.*), composed of collenchyma, with a hyaline, or sometimes finely granular, matrix containing an immense number of large, stellate, connective-tissue cells. In the basal crust this ectosome is about 0·65 millim. thick. In the digitiform processes it forms an even thicker layer around the dense central axis of spicular fibre (Plate XIII., fig. 2), but it is penetrated by large longitudinal canals (*l.c.*), about half a dozen in number, and varying in diameter up to about 2·25 millims. These canals are separated from one another by radially arranged longitudinal septa (*sept.*), in which the bundles of spicules run out from the central axis to the surface conuli. The ectosome on the outer sides of the longitudinal canals is reduced to a membrane of varying thickness, containing no spicules and penetrated by short, narrow canals which place the great longitudinal canals in communication with the exterior. These short canals are arranged in groups at wide intervals, and those of each group unite together into a single larger canal before opening into the longitudinal canal. The dermal pores are doubtless arranged in corresponding groups, probably with one pore at the end of each of the smaller canals, but they are now all closed (their position is shown in Plate XIII., fig. 2, *d.p.*). The fact that the smaller canals unite together as they pass inwards to the great longitudinal canals seems to indicate that this is an inhalant system. The arrangement of the exhalant system I have not succeeded in making out, and the choanosome is not sufficiently well preserved to enable me to give any details with regard to the flagellate chambers.

The digitiform processes may contain a good deal of sand outside the spicular axis.

R.N. 74, 74A (outside pearl banks, Gulf of Manaar).

Order 4: EUCERATOSA.

Non-calcareous sponges without siliceous spicules, but with a skeleton consisting of horny fibres developed independently, *i.e.*, not in relation to any pre-existing spicular skeleton. (The skeleton is sometimes replaced or supplemented to a greater or less extent by foreign bodies.)

The study of the very interesting series of twenty-two species, by which the horny sponges are represented in the present collection, has caused me greatly to modify my views as to the phylogeny of this group. Hitherto I have, in common with certain other writers on the subject, been in the habit of regarding it as a group of polyphyletic origin, derived probably from several distinct groups of monaxonellid sponges by substitution of spongin for spicules. This view I now believe to be true only for a very limited number of horny sponges, which might be distinguished from the true Ceratosa (or "Euceratosa," as I propose to term them) under the name "Pseudoceratosa," until such time as our increased knowledge shall enable us to assign them to their proper systematic positions. This is already possible in some cases, as, for example, in certain species of the Chalinine genus *Siphonochalina* (*Spinosella*), concerning which I observed as far back as 1887, in my memoir on the West Indian Chalinine Sponges (**75**):—

"Here we can trace in different species of the same genus the gradual degeneration and disappearance of the spicules until we come down to forms like *Spinosella maxima*, mihi (Plate LXI.), and *Spinosella plicifera*, D. and M. (Plate LVIII., fig. 5; Plate LX., fig. 1), which sometimes still contain traces of the spicules imbedded in the horny fibre, and apparently on the verge of disappearance, while at other times they contain no spicules whatever; and yet the specimens with spicules and those without are specifically indistinguishable."

As regards the great majority of the horny sponges, however, I feel convinced that they form a natural and compact group, in which it is almost impossible to separate even the genera from one another by hard and fast lines. Thus I am in close agreement with Poléjaeff, who summarizes (**74**) his own observations on the classification of the group as follows:—"*With the exception of the genera Darwinella, Ianthella, and Psammopemma, all genera are devoid of any properties separating them absolutely from one another.*"

Lendenfeld (**66**) has endeavoured to show that the Ceratosa are divisible into two great groups of very different phylogenetic origin, viz., "Monoceratina" and "Hexaceratina." It would not be difficult to expend a very large amount of criticism upon his system, but, without going into detail, I must remark that this main sub-division appears to me to be wholly erroneous, and that the connection between these two groups is so close that it is quite impossible to separate them from one another; while, instead of the "Hexaceratina" being derived from the Hexactinellida and the "Monoceratina" from the Monaxonellida, as Lendenfeld would have us believe, it appears to me tolerably certain that the majority of the "Monoceratina"* are descended from ancestral "Hexaceratina," and the latter in turn from Myxospongida.

Some justification of my views concerning the phylogeny of the Euceratosa will,

* It must be remembered that Lendenfeld's "Monoceratina" include both Pseudoceratosa and Euceratosa; the latter alone are here referred to.

I hope, appear in the course of the subsequent pages; in the meantime I may give the following summary of the conclusions at which I have arrived:—

In the first place it is pretty obvious that the Aplysillidæ (constituting a large part of the so-called "Hexaceratina") form the starting point of the evolutionary series within the order. The primitive character of such genera as *Aplysilla* and *Darwinella* is clearly indicated by the simple canal-system, the large sac-shaped flagellate chambers, and the very simple skeleton of branched spongin-fibres, supplemented in *Darwinella* by detached spicules of spongin. The presence of these so-called spicules at first sight seems to lend colour to LENDENFELD'S views as to the relationship between the Aplysillidæ and Hexactinellida. It is very difficult to see, however, how the horny spicules in question can have anything to do with the siliceous spicules of the Hexactinellida; their shape is extremely variable and they are probably best regarded simply as isolated portions of the general spongin skeleton, secreted by groups of spongoblasts which, for some unknown reason, have become isolated from their fellows.

Altogether the Aplysillidæ agree very closely in structure with the Myxospongida, especially with the genera *Halisarca* and *Hexadella*, and it is not impossible that the curious fibres of *Halisarca* may represent a rudiment of a horny skeleton. That the spongin skeleton in the Aplysillidæ has been developed quite independently of that of the Monaxonellida, and with no relation to a pre-existing siliceous skeleton, admits, I think, of little doubt. The character of the skeleton, consisting in the simplest cases of a thin basal lamina of spongin, from which slightly branched fibres spring vertically upwards and end in surface conuli, without anastomosing with one another to form a network, is quite different from what we find in typical horny Monaxonellida, in which the spongin is originally deposited as a cement which binds together the spicules of a reticulate skeleton, and in which, consequently, when the spicules disappear, the spongin is left in the form of a network of horny fibres. A very similar network of horny fibres appears, however, to have been independently evolved in the higher Euceratosa.

This difference in the arrangement of the horny skeleton—in the one case in the form of a network and in the other case in the form of separate tree-like fibres—has given occasion to MINCHIN (12) to divide his "Grade" Keratosa into two orders, viz., "Dictyoceratina (= Monoceratina, LDF.)" and "Dendroceratina (= Hexaceratina, LDF., *pars*)," the latter group including only the family Aplysillidæ. MINCHIN'S distinction cannot, however, be maintained as a basis of classification, for, as LENDENFELD himself recognised, there are undoubted Aplysillids (*e.g.*, *Dendrilla elegans*, LENDENFELD) which possess a reticulate skeleton, and in the present report I propose the new genus *Megalopastas* for such forms, of which two species occur in Ceylon waters.

The importance of the genus *Megalopastas* lies in the fact that it forms a connecting link between the Aplysillidæ and Spongeliidæ, and thus completely breaks down the distinction between "Monoceratina" and "Hexaceratina," or "Dictyoceratina" and "Dendroceratina." The Spongeliidæ, like the Aplysillidæ, have large sac-shaped flagellate chambers, simple canal-system, and clear transparent ground-substance. In fact, they differ from the Aplysillidæ only in their reticulate skeleton and in their habit of taking foreign bodies into the fibre. The so-called "pith" in the fibre is also less obvious, but this is an extremely variable character, and one upon which we cannot place very much reliance for purposes of classification. In *Megalopastas pulvillus*, for example, one and the same section may show great differences in this respect, some fibres showing a strongly marked pith, differentiated by its darker colour, and others apparently having no pith at all (Plate XV., fig. 3), the difference apparently depending upon differences in local conditions at the time when the fibre is growing, which give rise to a more or less distinct lamination analogous to the annual rings in a tree trunk.

Moreover, when we remember that SCHULZE has described (**71**), under the name *Spongelia spinifera*, a species in which the arenaceous fibres do not form a network at all, but are arranged in a tree-like manner, as in the genus *Aplysilla*, we see at once that the distinction between the Spongeliidæ and Aplysillidæ is purely arbitrary, though, as a matter of convenience, it may, perhaps, still be maintained. From the Spongeliidæ the transition to the Spongiidæ, by complication of the canal-system, reduction in the size of the flagellate chambers and granulation of the ground substance between them, is very simple.

I therefore conclude that the Euceratosa are a natural group descended from the Myxospongidæ, that their evolution starts with the Aplysillidæ and ends with the Spongiidæ, between which the Spongeliidæ occupy an intermediate position, and that the reticulate skeleton of the higher types has been independently evolved from a more primitive dendritic skeleton.

FAMILY: APLYSILLIDÆ.

Euceratosa with a dendritic or reticulate skeleton composed of spongin-fibres containing a more or less distinct pith, but usually without foreign inclusions; sometimes also with isolated spicules of spongin; with a lacunar canal-system and large sac-shaped flagellate chambers opening by wide mouths direct into wide exhalant lacunæ.

Darwinella, MÜLLER.

Aplysillidæ with a dendritic skeleton and with isolated spicules of spongin.

Four species of this remarkable genus have been described, viz., *D. aurea*, MÜLLER (**67**); *D. australiensis*, CARTER (**18**); *D. joyeuxi*, TOPSENT (**89**); and *D. simplex*, TOPSENT (**84**); but it appears to me somewhat doubtful whether they should all be regarded as specifically distinct from one another.

Darwinella simplex, Topsent, 1892 (**84**, *vide* also **62**)--Plate XV., figs. 1, 2.

The single specimen forms a thin crust extending over a considerable area on the surface of a branching tube which has apparently belonged to some annelid worm. The surface of the sponge is glabrous and covered with sharp-pointed conuli, about 1 to 1·5 millims. in height and some 2 to 3 millims. distant from one another. The maximum thickness of the crust is only about 2 millims. The dermal membrane is minutely reticulate and lifted up in a tent-like manner on the ends of the vertical skeleton fibres to form the surface conuli. The colour (in spirit) is dark purple,* and the texture very soft and tender. The vents are inconspicuous, only one small one having been detected. The inhalant pores are abundantly grouped in pore-sieves, which occupy the oval or rounded meshes of the dermal reticulation.

The skeleton consists, in the first place, of sparingly and irregularly branched, pithed horny fibres (Plate XV., figs. 1, 2) of the usual *Darwinella* type, which rise more or less vertically from the base of the sponge and terminate in rounded apices in the surface conuli. These fibres have a diameter of about 0·165 millim. near the base, diminishing to about half as much in the conuli. The base of the fibre is expanded into a thin plate of spongin, doubtless attached to the substratum; the fibres themselves do not appear to form any anastomoses. The wall of the fibre is only about 0·01 millim. thick, and the interior is generally occupied by a much-branched filamentous fungus (?), composed of rows of short cells, which more or less completely replaces the pith in the older parts of the fibre (Plate XV., fig 2). In the younger parts of the fibre (Plate XV., fig. 1) the pith exhibits the characteristic thimble-shaped layers described and figured by Lendenfeld in *D. aurea*.

In the second place we have horny spicules of the usual *Darwinella* type, but rather sparingly developed and, so far as I have been able to ascertain, all of the triradiate form. They are irregularly scattered through the soft tissues, and I have seen no union between them. The rays are long, slender and tapering; say about 0·5 millim. long by about 0·025 millim. thick near the base.

The canal-system and general anatomy agree very closely with the description and figures given by Lendenfeld (**66**) for *D. aurea*.

The Ceylon specimen agrees very well with Topsent's descriptions of the species, but the horny spicules (in the single specimen available) do not appear to attain so large a size. The species has hitherto been recorded only from the Mediterranean and the Azores.

R.N. 302 (Ceylon seas).

Megalopastas, n. gen.

Aplysillidæ with an entirely reticulate skeleton and without spongin spicules.

As I have already pointed out, Lendenfeld (**66**) includes in his genus *Dendrilla* both species (*e.g.*, *D. rosea*) without and species (*e.g.*, *D. elegans*) with a reticulate

* *Vide* footnote under *Iotrochota purpurea*.

skeleton. It is very doubtful, however, whether the genus, as constituted by LENDENFELD, is separable from the older *Aplysilla*. The type species of *Dendrilla* appears to be a form with a dendritic skeleton, viz., *D. rosea*, and if we are to separate the species with reticulate skeleton, we can, for etymological reasons, hardly employ the name *Dendrilla* for them.

In my report on Mr. THURSTON'S Second Collection of Sponges from the Gulf of Manaar (3) I attempted to avoid the necessity for erecting a new genus by employing BOWERBANK'S old name *Spongionella* for what must now be regarded as the type of the genus *Megalopastas*, viz., *Megalopastas nigra*. I must admit, however, that BOWERBANK'S type of the genus *Spongionella*, viz., *S. pulchella*, is probably not an Aplysillid at all (according to LENDENFELD it is a "*Leiosella*"), while, on the other hand, BOWERBANK (8) also applied the name *Spongionella* to another totally different sponge, viz., *Phyllospongia* (*Spongionella*) *holdsworthi*, and *Spongionella* is retained by LENDENFELD (66) as a sub-genus of *Phyllospongia*. I therefore now revert to what was my original intention in 1889, and propose the new genus *Megalopastas*, the name being chosen in allusion to the large size of the flagellate chambers.

The anatomical characters of the genus are shown in Plate XV., fig. 4, which represents, somewhat diagrammatically, a vertical section of an Australian species, *M. elegans* (LENDENFELD'S *Dendrilla elegans*), of which I happen to have much better preserved material than of the Ceylon species. Excepting that in *M. elegans* the ectosome is thicker and the outermost secondary fibres of the skeleton do not lie so near the surface, so that there is no "dermal skeleton," the figure would serve almost equally well for either of the Ceylon species. My preparations of *M. elegans* contain numerous embryos, enclosed in spherical endothelial capsules, and mostly in the stage represented in the figure, consisting of a solid inner mass of cells surrounded by an outer layer modified near one end to form a pigment ring. This embryo agrees pretty closely with those described by SCHULZE in *Spongelia* (71) and *Euspongia* (72), and its occurrence perhaps tends to show the correctness of my views as to the close relationship of the so-called "Hexaceratina" to the other Euceratosa.

Megalopastas nigra (DENDY).—Plate XIV., fig. 7; Plate XV., figs. 5–8.

1889, **Spongionella nigra**, DENDY (3).

This very remarkable species was originally discovered by Mr. THURSTON and is represented in Professor HERDMAN'S collection by two specimens. The sponge (Plate XIV., fig. 7) is sessile, and consists of a number of vertical lamellæ, branching and anastomosing with one another, often in a very complex manner. The largest specimen I have seen was about 250 millims. high and the same in breadth, with lamellæ about 5 millims. thick. The colour of the living sponge is black (THURSTON), when dry, dull black, and in spirit rather lighter, blackish-grey. Texture (in spirit) very compressible and resilient; moderately tough. Surface granulated, the granules being really minute, close-set conuli. Vents abundantly scattered, but almost or quite confined to one surface of each lamella. The vents are compound, each consisting of an aggregation of several smaller ones, the entire group only from 1 millim. to 2 millims. in diameter.

The main skeleton (Plate XV., fig. 5) is a rectangularly meshed network of very distinct primary and secondary fibres, the primaries running vertically to the surface and the secondaries crossing them more or less at right angles. The primary fibres average about 0·049 millim. in diameter, and the secondaries about half as much. The outermost secondary fibres form a well-developed dermal or sub-dermal skeleton (Plate XV., fig. 5, *d.s.*; fig. 6), in the form of an irregular network with fairly wide polygonal meshes, the fibres averaging about 0·02 millim. in diameter.

There are many more minute conuli on the surface than there are of the stout primary fibres, and those which do not contain the apices of such fibres are supported by short fibres which spring vertically from the tangential fibres of the dermal skeleton (Plate XV., figs. 5, 8).

All the fibres of the skeleton are composed of pale-coloured spongin without any foreign enclosures. They are not distinctly "pithed" except at the growing apices (Plate XV., fig. 7), where the usual thimble-shaped layers of spongin are added one on top of the other, as in other Aplysillidæ, but even here the "pith" is not distinctly differentiated.

The ectosome forms a thin dermal membrane containing the inhalant pores, and the choanosome is very delicate and gelatinous. The canal-system agrees closely with that of *Aplysilla*, as described and figured by SCHULZE (70). It is lacunar, and the flagellate chambers are sac-shaped and large, averaging when full-grown about 0·07 millim. in diameter. They are not placed very close together and they open directly into the excurrent lacunæ, without special exhalant canaliculi.

R.N. 71, 161A (Pearl banks, Gulf of Manaar—not uncommon).

Megalopastas pulvillus, n. sp.—Plate XV., fig. 3.

The single specimen has the form of a small flattened cushion, slightly convex above and (has been) attached by a broad flat base below. The outline of the specimen is irregularly rounded. The upper surface bears several small, compound vents, each about 2 millims. in total diameter; it also appears granular from the presence of numerous minute, slender, sharp-pointed conuli containing the ends of the primary fibres. The inhalant pores are conspicuous under the microscope in small groups in the thin, translucent dermal membrane. Texture (in spirit) firm, but compressible and resilient; colour, pale yellowish-grey. Diameter of specimen about 18 millims.; thickness in the middle about 5 millims.

The skeleton (Plate XV., fig. 3) is a partly rectangular- and partly polygonal-meshed network of pale amber-coloured horny fibre, in which the primary fibres are very clearly differentiated, radiating towards the surface and terminating in long, slender apices in the surface conuli. The primary fibres not infrequently branch, while at the base of the sponge they are seen to originate in a thin horizontal spongin-lamella, which evidently forms the means of attachment to the substratum. The primary fibres are about 0·096 millim. in diameter, the secondaries are usually a good deal more slender, say about 0·04 millim. in diameter, but variable. Both primary and secondary fibres frequently exhibit a very distinct pith of variable thickness, which evidently simply represents the older part of the fibre surrounded by fresh accretions of spongin. Even in old parts of the primary fibres the old slender apices may frequently be observed thus imbedded in the new growth (Plate XV., fig. 3, *ap.*). The principal secondary fibres run across at right angles between the primaries, but numerous others run in various directions. The outermost secondary fibres form a pretty definite dermal skeleton with polygonal meshes of very variable size. Here and there short, vertical, gradually tapering branches arise from this network and enter some of the surface conuli. These branches evidently form the commencements of new primary fibres, as in *M. nigra.*

The ectosome is feebly developed, forming a thin dermal membrane containing the inhalant pores and overlying the sub-dermal cavities. The canal-system is lacunar. The flagellate chambers are large and sac-shaped, about 0·088 millim. in longer diameter; they open by wide mouths direct into wide exhalant lacunæ. The ground substance between them is very feebly developed, gelatinous-looking and broken up into trabeculæ by the smaller inhalant lacunæ in the characteristic aplysillid fashion. The larger exhalant canals converge towards the compound vents, where they open to the exterior.

It will be seen from the above description that this species agrees closely in skeletal characters and canal-system with *M. nigra*, but it differs widely in external form and colour (in spirit). The fact that the specimen contains large ova and embryos in endothelial capsules likewise seems to indicate that it is not merely a young form of *M. nigra.* Owing to the much greater distinctness of the pith in the horny fibres the species is a more typical aplysillid than its congener.

R.N. 191 (Muttuvaratu Paar, Gulf of Manaar).

Family: SPONGELIIDÆ.

Euceratosa with a (usually) reticulate skeleton of horny fibres without distinct pith, but containing foreign bodies; or with a skeleton composed of foreign bodies united together by little if any spongin. With lacunar canal-system and large, sac-shaped flagellate chambers opening directly by wide mouths into wide exhalant lacunæ.

This family may be retained as a matter of convenience, but it is, as I have already indicated, logically impossible to separate it sharply from the Aplysillidæ, for the genus *Megalopastas*, on the one hand, and Schulze's *Spongelia spinifera*, on the other, are strictly intermediate between the two groups.

Spongelia, NARDO.

Spongeliidæ with a skeleton composed of distinct, but more or less areniferous, horny fibres.

Spongelia fragilis, MONTAGU, var. **ramosa**, SCHULZE.

1879, **Spongelia pallescens**, sub-species **fragilis**, var. **ramosa**, SCHULZE (**71**); 1889, **Spongelia fragilis**, var. **irregularis**, LENDENFELD (**66**), *pars*.

There is a single, partly macerated specimen of this variety in the collection. The external form appears to have been loboso-digitate. The skeleton network is very coarse, with rectangular meshes, and densely charged throughout with sand. The soft tissues are very densely charged with chains of algæ, probably *Oscillaria spongeliæ*. The large sac-shaped flagellate chambers measure up to about 0·1 millim. in longer diameter.

Under the name *Spongelia fragilis*, var. *irregularis*, LENDENFELD has already (**66**) recorded a sponge from Ceylon which probably belongs to this variety, as he himself admits that his var. *irregularis* partly corresponds with SCHULZE'S var. *ramosa*. The species, at any rate, appears to be cosmopolitan, if not the variety also.

R.N. 307 (Ceylon seas).

Spongelia elastica, var. **lobosa**, SCHULZE.

1879, **Spongelia pallescens**, sub-species **elastica**, var. **lobosa**, SCHULZE (**71**); 1889, **Spongelia elastica**, var. **lobosa**, LENDENFELD (**66**).

There is one specimen of this variety in the collection, consisting of a massive, columnar and slightly clathrous basal portion, giving off numerous short, irregular, digitiform processes above. The surface is covered with acute conuli, larger and further apart on the lower than on the upper portions of the sponge, varying from about 0·5 millim. to 2·5 millims. in height. Between the conuli is stretched the usual reticulate dermal membrane, and the lines of the dermal reticulation are areniferous. The texture (in spirit) is soft and elastic and the colour pale greyish-yellow. The specimen measures about 58 millims. in height by 40 millims. in maximum diameter. The apices of the branches are commonly occupied by parasitic barnacles, each enclosed in a cavity which opens to the exterior by a small terminal aperture resembling a vent.

The primary fibres of the skeleton, ending in the conuli, are abundantly charged with foreign matter, chiefly sponge-spicules, while the connecting fibres are almost free from foreign matter, and form a moderately close network. The canal-system and histology agree closely with SCHULZE'S classical description. The large, sac-shaped flagellate chambers, about 0·08 millim. in maximum diameter, are imbedded in a sparsely developed gelatinous ground substance. They have numerous prosopyles and open directly by wide mouths into the exhalant canals.

This variety is well known in the Mediterranean and, according to Lendenfeld, occurs also in the North Atlantic and in Australian seas.

R.N. 165 (deep water off Galle and onwards up West Coast of Ceylon).

Spongelia elastica, var. **crassa,** nov.—Plate XIV., fig. 4.

This variety differs from var. *lobosa* in the much coarser main fibres, filled with much larger foreign particles (sand grains), and in the more areniferous character of the connecting fibres, which, however, are still occasionally quite free from sand. In external appearance (Plate XIV., fig. 4) the single specimen closely resembles the specimen of var. *lobosa* described above, but it may readily be distinguished by its much more rigid and coarsely arenaceous character. The very stout main fibres contain sand grains of extremely various size. The network of connecting fibres is very irregularly developed and sometimes is absent over wide areas. The sponge is infested by numerous small chætopod worms imbedded in the soft tissues.

R.N. 35 (Gulf of Manaar).

Spongelia incrustata, n. sp.

Sponge compressed, irregularly lobose, proliferous. Surface with small acute conuli irregularly scattered over it at varying intervals, and only about 1 millim. in height; minutely reticulate over large areas, while over areas quite as large the dermal reticulation is completely obliterated by the sand cortex. Vents rather small and mostly on the margins of the lobes. Texture (in spirit) rather soft, compressible, flaccid, cavernous internally. Colour yellowish-grey throughout. The largest specimen is about 100 millims. in maximum diameter, and the lobes are generally not more than 5 millims. or 6 millims. thick, though variable.

The skeleton consists in the first place of the dense arenaceous cortex, which is well developed everywhere, except in the thin dermal membrane of the pore-areas which lie between the meshes of the dermal reticulation (where present). This cortex is about 0·5 millim. thick. Internally the skeleton also consists chiefly of sand-grains, arranged in irregular tracts rather than in well-defined fibres, but often held together by spongin cement. Between these tracts are wide areas free from sand.

The canal system is that of a typical *Spongelia*. The sub-dermal cavities, underlying the pore-sieves, are large, and the whole canal-system is lacunar in a high degree. The flagellate chambers are sac-shaped and up to about 0·08 millim. in longer diameter, opening by wide mouths into the exhalant canals and provided with numerous prosopyles. The mesoglœa between them is very scantily developed, clear and gelatinous, but with numerous stellate connective-tissue cells. The walls of the larger exhalant canals contain numerous elongated muscle-cells.

This species appears to be nearly related to Lendenfeld's *Spongelia laxa* from the South Coast of Australia (**66**), but the surface conuli are more or less acute instead of rounded, the skeleton fibres are apparently much less well-defined, and the sand cortex is apparently much thicker.

R.N. 72 (outside pearl banks, Gulf of Manaar); 279 (deep water off Galle and onwards up West Coast of Ceylon).

Psammopemma, Marshall.

Spongeliidæ in which the skeleton is composed of densely aggregated sand-grains which are more or less connected together by spongin.

Psammopemma crassum (Carter), var. **clathrata**, nov.

1885, **Holopsamma crassa**, Carter (18): 1889, **Psammopemma crassum**, Lendenfeld (66).

The specimens differ from the types as described by Mr. Carter in their clathrous form and in the absence of large conspicuous vents. They are extremely irregular and friable, and densely charged with coarse sand, over which a distinct pellucid dermal membrane, free from sand, is frequently stretched. The surface is very uneven, sometimes ribbed and sometimes conulose; the texture incompressible but fragile, and the colour (in spirit) pale brown.

The sand grains are not arranged in distinct fibres, but in ill-defined bands forming an irregular reticulation. They are connected at the points of contact by a very small quantity of spongin cement.

The flagellate chambers are large (about 0·08 millim. in longer diameter) and sac-shaped, and open direct into the exhalant canals by wide mouths. The ground substance between them is clear and transparent and very sparsely developed, except in the neighbourhood of the larger canals, which are surrounded by an abundant gelatinous collenchyma, with numerous stellate or fibrous connective-tissue cells.

The types of the species came from Australia, and Lendenfeld also records it from New Zealand.

R.N. 64 (type of variety, Gulf of Manaar); 330 (Ceylon seas).

Family: SPONGIIDÆ.

Euceratosa with a reticulate horny skeleton and with small, more or less spherical flagellate chambers, commonly provided with special narrow exhalant canaliculi. The ground-substance between the chambers is compact and densely charged with fine granules.

Cacospongia, Schmidt.

Spongiidæ with a very wide-meshed skeleton network, and with distinctly lamellated horny fibres which are usually of a brown colour and of very variable diameter.

Cacospongia scalaris, Schmidt.

1862, **Cacospongia scalaris**, Schmidt (47); 1879, **Cacospongia scalaris**, Schulze (72); 1889, **Stelospongia scalaris**, Lendenfeld (66).

There are several rather small specimens in the collection which agree closely with the Mediterranean form as described and figured by SCHULZE. The connecting fibres are often very irregular in arrangement and very variable in diameter. The histological features are not very well preserved, but the flagellate chambers probably have elongated exhalant canaliculi, as described by SCHULZE.

The main fibres may contain many foreign bodies. What can LENDENFELD mean by saying that the fibres are all of uniform diameter and never contain foreign bodies, in direct opposition to the observations of SCHMIDT and SCHULZE?

R.N. 18 (Gulf of Manaar); 162 (three specimens); 347 (all Ceylon seas).

Euspongia, BRONN.

Spongiidæ of compact structure and with a very fine-meshed skeletal network of slender and fairly uniform horny fibre. Primary fibres, usually containing foreign bodies, radiate towards the surface and are connected together by a close but very irregular-meshed network of more slender connecting fibres free from foreign bodies.

LENDENFELD (66) has already recorded several species of *Euspongia* from Ceylon, viz.:—

E. trincomaliensis, which he identifies with one of HYATT'S American varieties of "*Spongia officinalis*";

E. irregularis, var. *pertusa*, which is also recorded from North America, Australia, and the tropical Pacific; and

E. irregularis, var. *dura*, also recorded from Madagascar and Australia.

There are two forms in Professor HERDMAN'S collection which appear to be quite distinct from all these.

Euspongia officinalis, AUCTORUM, var. **ceylonensis**, nov.—Plate XIV., fig. 3; Plate XVI., fig. 5.

There are in the collection several nice specimens of a bath sponge which obviously belong to a variety of *Euspongia officinalis*, closely resembling *E. officinalis*, var. *rotunda*, of HYATT (69) and LENDENFELD (66). The latter is one of the American varieties, and there is probably sufficient difference in the Ceylon sponge to merit recognition under a new varietal name.

The sponge is massive and compact, without vestibules Of the two specimens which I now have before me, the one (in spirit) is slightly elongated vertically and at the same time slightly compressed laterally and slightly flattened on the top, while the base is somewhat constricted and charged with pebbles and other foreign matter. The vents are rather large and conspicuous, scattered on the top and sides of the sponge, from 2·5 millims. to 5 millims. in diameter, sometimes more or less prominent. Each vent forms the termination of a long vertical oscular tube, of the same diameter as itself. The surface is thickly and uniformly covered with minute, low conuli (about 0·8 millim. apart, from apex to apex), from the summits of which fine ridges radiate into the intervening valleys, where they branch and anastomose with one another, so as to give rise to a delicate reticulation which is scarcely visible to the naked eye, and in the meshes of which the dermal pores are situate in small groups.

The colour of the surface in spirit is black, paling to grey below and internally, and the texture compact, but compressible and very elastic. The specimen thus described measures about 90 millims. in height by 73 millims. in greatest breadth. Another somewhat similar spirit specimen has been photographed for me by Professor HERDMAN, and is represented, about two-thirds natural size, in Plate XIV., fig. 3.

Professor HERDMAN has also sent me part of the macerated skeleton of a much larger specimen. The piece sent is a segment of what appears to have been a massive, hemispherical sponge, with very strongly convex upper surface and broad flattened base. Numerous large vents, up to 8 millims. in diameter, are scattered singly over the upper surface, each at the end of a long, vertical oscular tube. Between these vents the surface is rather uneven (but not channelled or grooved) and honeycombed by close-set narrow vertical canals (inhalant) about 0·5 millim. in diameter, which reduce the skeleton reticulation to a mesh-work of thin trabeculæ which terminate at the surface in small, slightly projecting villi. The texture, after soaking in water, is very soft and elastic and not very tough, and the colour is pale greyish-yellow. The specimen from which this piece was taken must have been about 200 millims. in diameter by 100 millims. in height.

The primary fibres of the skeleton (Plate XVI., fig. 5) run parallel with one another (at distances of about 0·8 millim.) towards the surface, where they end singly in the conuli. They rarely branch, and apparently never anastomose. They are about 0·04 millim. in diameter and composed chiefly of broken sponge spicules, with comparatively little spongin cementing them together. They are connected with one another by a polygonal-meshed network of secondary fibres, in which the meshes vary greatly in size and shape, while the fibres are of fairly uniform diameter and only rarely contain foreign matter. Average diameter of meshes, say, about 0·17 millim. ; diameter of the secondary fibres themselves, when fully developed, about 0·02 millim., but often less.

Owing to the quantity of broken spicules which they contain, the primary fibres are distinctly visible to the naked eye in the macerated sponge, appearing as very fine threads of a paler colour than the rest of the skeleton, and thus constituting what is perhaps the most obvious distinctive feature of the variety.

The dermal membrane contains numerous broken sponge-spicules scattered through it.

In internal anatomy this variety agrees minutely with SCHULZE's classical account of the bath sponge (72), so that it is unnecessary to describe the canal-system and histology in this place. One point perhaps deserves mention, and that is the very strong development of long bands or cords of granular fibrous cells, running through the sponge in various directions (but mostly more or less at right angles to the surface), and not by any means confined to the neighbourhood of the larger canals. These bands are, as already suggested by SCHULZE for closely similar structures in the Adriatic bath sponge, probably muscular, and their function appears to me to be to effect the contraction of the sponge as a whole and thus squeeze the water out very thoroughly when necessary.

This Ceylon bath sponge appears to differ from most of the varieties of *Euspongia officinalis* in the greater slenderness of the very pale-coloured secondary or connecting fibres of the skeleton. SCHULZE gives the average thickness of these fibres in *Euspongia officinalis* as 0·03 millim. to 0·035 millim., while in our variety they attain only a thickness of about 0·02 millim., and are often less.

Owing to this character the sponge acquires a remarkable softness, but at the same time loses somewhat in durability. This want of durability may impair its value as an article of commerce, but in view of its softness and elasticity and its great absorbent power, combined with its good shape and size, I am inclined to think that it would be worth while to experiment in the way of placing it upon the market if it can be obtained in sufficient quantity.

R.N. 37 (several specimens in spirit); 101 (dry). All from Trincomalee.

Euspongia tenuiramosa, n. sp.

Sponge consisting of irregular, slender branches, usually only about 5 millims. or 6 millims. in diameter and apparently repent. The branches are more or less angular or nodose, and usually very crooked. The surface is more or less concealed by coarse, calcareous débris, such as the shells of large Foraminifera, &c. Where free from foreign matter, it is covered with small, sharp conuli, scattered at very various intervals. Vents small and few; pores not observed. Colour (in spirit) purplish-brown or nearly black. Texture, where free from foreign matter, which occurs internally as well as at the surface of the sponge, compressible and resilient. The longest branch is about 60 millims. in length by 5 millims. in diameter, but the diameter varies much.

The skeleton is an irregular but fairly close, polygonal- or sometimes quadrangular-meshed network of rather dark-coloured fibre varying much in diameter. Here and there primary fibres can be recognised running into the surface conuli, and these may contain a rather slender core of broken sponge-spicules. The primary fibres have a diameter of about 0·05 millim. The connecting fibres vary from about the same diameter downwards to about 0·008 millim. The diameter of the meshes varies so much that it is useless to give measurements.

The material is not very well preserved for histological investigation, but, so far as I have been able to make out, the internal anatomy offers no features of special interest and agrees closely with that of other species of the genus. The flagellate chambers are small, about 0·024 millim. in diameter, and nearly spherical, and the ground-substance between them is finely granular. I have not been able to make out the nature of their openings. The usual cylindrical cords of elongated fibre-cells are present, and there is a collenchymatous ectosome. There appears also to be a thin cuticle similar to that of various species of *Hippospongia.*

As regards skeletal characters this species agrees closely with LENDENFELD's very comprehensive *Euspongia irregularis*, but the external appearance is so characteristic that it seems to deserve a distinct specific name.

R.N. 311; 339 (Yard Cove, Trincomalee, shallow water).

Hippospongia, SCHULZE.

Spongiidæ of clathrous structure, but otherwise resembling *Euspongia*, except that the skeleton fibre may be much coarser and the whole sponge harder.

Except in its harder and more incompressible character, I cannot see that LENDENFELD's genus *Hyatella* differs from SCHULZE's *Hippospongia*, yet LENDENFELD himself describes a *Hippospongia dura* which is, perhaps, as hard as any *Hyatella.*

Hippospongia intestinalis (LAMARCK).

1813, **Spongia intestinalis**, LAMARCK **(73)**; 1877, **Spongelia velata**, HYATT **(69)**; 1884, **Hippospongia intestinalis**, RIDLEY **(16)**; 1889, **Hyatella intestinalis**, LENDENFELD **(66)**.

This species is represented in the collection by several specimens of elongated tubular form, very intestinal in appearance and of a light brown colour, with their walls perforated here and there at irregular intervals, and the surface slightly conulose. The tubes may branch and anastomose, but are for the most part well separated from one another and usually about 10 millims. in diameter, but variable. The characteristic surface reticulation of slender horny fibre is very well developed, and the surface appears to be covered by a remarkable continuous but separable cuticle, which possibly has some connection with the dermal skeleton, but I have not been able to elucidate its true nature. The main skeleton is very irregular and composed of mostly stout amber-coloured horny fibre. Primary fibres cored with foreign bodies are visible here and there.

The flagellate chambers are small (about 0·03 millim. in diameter) and approximately spherical, and the ground-substance between them is finely granular. The special exhalant canaliculi, if present, are short. Stout bands of elongated fibres, presumably muscular and mostly longitudinal in direction, are developed as in other Spongidæ, and there may be a good deal of collenchyma around some of the larger canals.

The species has been recorded from the Mediterranean, Zanzibar, the Mascarene Islands, and the Amirante Group **(66)**, and from Porto Rico **(29)**.

R.N. 65 (Gulf of Manaar); 83 (deep water off Galle and onwards up West Coast); 337 (Ceylon seas).

Hippospongia clathrata (Carter)—Plate XIV., fig. 2.

1881, **Hircinia clathrata**, Carter (5); 1887, **Hircinia clathrata**, Dendy (2); 1889, **Hircinia clathrata**, Dendy (3); 1889, **Hyatella clathrata**, Lendenfeld (66).

There is a single specimen of this well-characterised sponge in the collection. Lendenfeld (66) has added particulars as to the canal-system to our previous knowledge. The sponge contains no filaments, but the bands or cords of fibrous tissue in the choanosome, so characteristic of many other Spongidæ, are very well developed. The species was recorded by Carter from the Gulf of Manaar and the Red Sea, and it also occurs in Australia (Dendy, Lendenfeld) and on the American coast of the North Atlantic (Lendenfeld).

The figure represents the characteristic appearance of a spirit specimen, no good illustration of the external form having yet been published.

R.N. 24 (Gulf of Manaar).

Hippospongia anomala, Poléjaeff.

1884, **Hippospongia anomala**, Poléjaeff (74); 1889, **Hippospongia anomala**, Lendenfeld (66).

There is one specimen in the collection which, although of smaller size, agrees very well in nearly all respects with Poléjaeff's description and figure of the type specimen from Torres Straits. Our specimen consists of an erect, sub-cylindrical cavernous body, expanding gradually below and giving off two short digitiform processes on one side. The interior, especially in the lower portion, is sub-divided by trabeculæ, and the surface is covered over by a thin, parchment-like dermal membrane pierced by numerous larger and smaller circular apertures, especially abundant towards the extremity. These apertures lead into the large vestibular spaces in the interior of the sponge. The end of the main body and those of the two processes taper suddenly to rather sharp apices, and are covered with fairly numerous small conuli, elsewhere the surface is nearly smooth and glabrous and provided with a delicate cuticle, like that of *Hippospongia intestinalis*. Poléjaeff's expression "shagreen-like" may refer to the same character. The colour (in spirit) is pale grey, the texture compressible and very resilient. The height of the specimen is about 120 millims. and the maximum diameter at the base about 50 millims.

The skeleton is a pretty close but irregular polygonal-meshed network of fibres of very uniform diameter, about 0·02 millim. to 0·03 millim. thick, and free from foreign bodies. Occasionally only one observes much stouter primary fibres, composed principally of broken sponge spicules, running towards the surface and sometimes branching. Occasionally also one sees very slender connecting fibres amongst the ordinary ones; these are probably young. There is no specially differentiated dermal skeleton, but the main skeleton reticulation comes close to the surface. A good many broken spicules are scattered in the dermal membrane.

The canal system is remarkable for the unusual length of the exhalant canaliculi of the flagellate chambers, reminding one of the similar condition described by

SCHULZE (72) in *Cacospongia scalaris.* POLÉJAEFF (74) has already called attention to variability in the development of the cameral canaliculi in this species, so that we can hardly consider the presence of long exhalant canaliculi as a character of specific value.

R.N. 56 (Gulf of Manaar).

Hippospongia dura, LENDENFELD (66).

The single specimen consists of an irregular massive body tapering gradually upwards (?) or on one side (?) into a sub-cylindrical fistular process, the conical extremity of which is perforated by numerous small, round apertures leading into the internal vestibular space. Similar apertures are scattered more sparsely on other parts of the sponge. Internally the sponge is cavernous, with wide, sub-cylindrical, vestibular spaces, more or less sub-divided by trabeculæ of smaller diameter than the vestibules. The vestibular spaces are covered in at the surface partly by a somewhat parchment-like dermal membrane and partly by superficial extensions of the trabeculæ themselves. The surface is rather uneven, but not distinctly conulose ; a considerable amount of calcareous and other foreign matter is attached to it. The texture, in spirit, is hard and only slightly compressible, and the colour rather dark brown throughout. The specimen measures about 110 millims. in greatest length (height ?) and 60 millims. in greatest breadth at right angles to the length.

The skeleton is an unusually close and fairly uniform network of rather stout, amber-coloured horny fibre. There is no distinction between primary and secondary fibres, except at wide intervals, where the network becomes somewhat closer and forms stout columns radiating towards the surface. In these columns many primary fibres run side by side and nearly parallel with one another, connected at frequent intervals by short, transverse secondaries to form a very stout, but ill-defined, compound, trellis-like fibre. Elsewhere the stouter fibres frequently run parallel with the surface of the sponge and are connected together by more slender fibres which run transverse to the stouter ones. In other places again the network is quite irregular. The stouter fibres, forming the bulk of the skeleton, are about 0·04 millim. or 0·05 millim. in diameter; the more slender ones are very variable. Usually the fibres are quite free from foreign bodies, but broken spicules may be found occasionally in fibres of the trellis-like groups. There is no special dermal skeleton, but the ordinary reticulation of fibres comes close to the surface, which is covered by a thin cuticle like that of *Hippospongia intestinalis* and *H. anomala.* A remarkable feature of the skeleton fibre is the brilliant yellow colour which it assumes in sections stained with picro-carmine. The superficial cuticle stains in the same way, and sometimes appears to be continuous with the more superficial skeleton fibres, but this is a point which requires further investigation.

The flagellate chambers are nearly spherical, only about 0·024 millim. in diameter, and the ground-substance between them is finely granular. There is a rather thin, collenchymatous ectosome, containing a good many brown pigment cells. Cylindrical bands or cords of elongated fibrous cells are developed as usual.

Lendenfeld describes the species, apparently from a dry specimen, from the American coast of the North Atlantic. Under these circumstances the identification may seem somewhat hazardous, but the species is so well characterised by its general form, its colour and texture, and its peculiar skeleton arrangement, that I do not think there can be much doubt about it. Of course, it is possible that there has been a mistake about the locality of the type specimen, which is in the British Museum Collection.

R.N. 57 (Gulf of Manaar).

Phyllospongia, Ehlers.

Spongiidæ of thin, lamellar form, often cup-shaped. With a close-meshed skeleton network of slender horny fibre.

Phyllospongia papyracea (Esper), var.—Plate XIV., fig. 6.

1798-1806, **Spongia papyracea**, Esper (6); 1870, **Phyllospongia papyracea**, Ehlers (58); 1877, **Phyllospongia papyracea**, Hyatt (69); 1884, **Phyllospongia papyracea**, Ridley (16); 1889, **Phyllospongia papyracea**, *pars*, Lendenfeld (66).

This variety is represented in the collection by a fine dry specimen, of which a photograph is reproduced in Plate XIV., fig. 6. The specimen is frondose, proliferous and decumbent, and has apparently been attached to the substratum at many points. The thickness of the fronds is about 1·25 millims. The consistence (when perfectly dry) is stiff and rather fragile, the colour light brownish-yellow. The upper surfaces of the fronds are marked with feebly developed concentric and radiating ridges, and also by numerous narrow grooves, frequently arranged in a branching or stellate manner and probably containing minute exhalant apertures. The lower surface is entirely free from such grooves. Both surfaces appear minutely reticulate under a lens, and neither possesses a continuous sand-cortex, though there is a good deal of sand scattered on the upper surface.

The skeleton is a close network of very pale-coloured horny fibres usually about 0·02 millim. in diameter. The fibres are mostly free from foreign matter, but the primary lines, radiating to the surface, contain many comparatively large sand-grains.

Except for the presence of the stellate or branching grooves on the upper surface and the sand-grains in the primary fibres, this species agrees very closely with the figures and description of the type given by Esper and Ehlers. As the type came from Southern India (Tranquebar), it is not likely that the Ceylon form is more than varietally distinct.

The species has been previously recorded from Tranquebar (Esper); Cape of Good Hope (Hyatt); and Mozambique (Ridley). Lendenfeld also records it from

Australia and New Zealand, but his identifications are not always trustworthy, and he appears to me to have got a wrong conception of the species. Thus he states that "in every case the sponge is attached by a short peduncle." He also includes (perhaps rightly) the cup-shaped *Phyllospongia holdsworthi* in the species.

R.N. 104A (Gulf of Manaar).

Phyllospongia holdsworthi (BOWERBANK).

1873, **Spongionella holdsworthii**, BOWERBANK (8); 1889, **Phyllospongia papyracea**, *pars*, LENDENFELD (66).

There are several exquisitely cup-shaped specimens of this sponge in the collection. BOWERBANK's figures and descriptions do not appear to me to be very typical, and it seems not impossible that he had also before him, when writing, specimens of *Phyllospongia papyracea*. The specimens which I have examined are regularly cup-

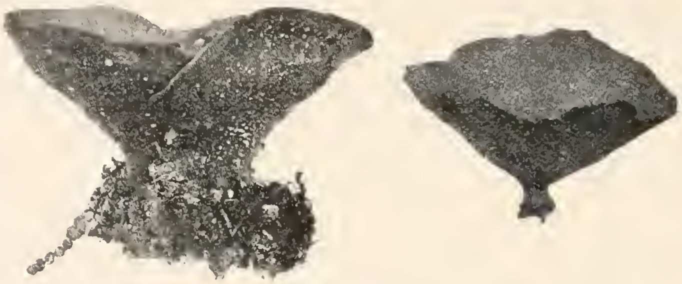

Fig. 5. *Phyllospongia holdsworthi*, half nat. size.

shaped (see text-fig. 5), with an entire margin and a very well developed peduncle branching out into root-like processes below. The wall of the cup is only about 1·5 millims. thick, stiff and tough and slightly flexible in the perfectly dry state. Both surfaces are smooth or nearly so, but show feebly developed concentric and sometimes radiating ridges. The vents are minute, usually circular in outline, and abundantly scattered over the inner surface only of the cup, which is covered by a thin sand-cortex not sufficiently developed to conceal the minutely reticulate character of the dermal skeleton. There is no sand-cortex on the outer surface, which is also minutely reticulate. Professor HERDMAN informs me that the colour of the sponge in life is purplish-brown, and my dry specimens still retain a distinctly purple tinge in places.

The skeleton is a close-meshed but very irregular network of horny fibre, mostly about 0·02 millim. in diameter and free from sand, but with stouter primary lines radiating to the surface and containing numerous comparatively large sand-grains, especially towards the inner surface of the sponge.

Bowerbank's figures certainly represent a form which is intermediate in external appearance between what I regard as the typical cup-shaped *P. holdsworthi* and the foliaceous *P. papyracea*, and it is quite possible that the two are not more than varietally distinct.

Bowerbank quotes from a letter of Mr. Holdsworth the following interesting particulars:—"Spongionella is only found on the 9-fathom line of the large pearl-bank. It is attached to pieces of dead coral or stones. When alive it is of a dark brown; and when taken out of the water it looks exactly like dirty wet leather. If you soak a bit of one of the dark specimens* you will see it with as nearly as possible the original appearance. This sponge is so strictly confined to the locality above mentioned, that its discovery by the divers is considered the strongest evidence that the outer part of the bank has been reached."

Professor Herdman adds, as the result of his much more extended examination of the Gulf of Manaar, that "although very characteristic of the Periya Paar and other deeper grounds west of the Cheval Paar, still it is not absolutely confined to these, but may be found elsewhere, as on the Muttuvaratu Paar."

R.N. 30; and other specimens (dry). (Periya Paar, Muttuvaratu Paar, &c., Gulf of Manaar.)

Hircinia, Nardo.

Spongiidæ with a coarse-meshed skeleton network usually containing much foreign matter. Denser aggregations of the network along the primary lines frequently form trellis-like compound fibres. Filaments are usually present in the ground-substance.

Hircinia fusca, Carter—Plate XIV., fig. 1.

1880, **Hircinia fusca**, Carter **(4)**, not **Hircinia fusca**, Ridley **(16)** and Lendenfeld **(66)**.

This is a very remarkable and well-characterised species. It was originally described by Carter in less than four lines, and the species was styled "provisional." It is, therefore, little wonder that Ridley and Lendenfeld have erred in identifying certain slender branching sponges from other localities with the Ceylon species. Carter's description of the external form should, however, have been sufficient to prevent any such misconception, for a slender, branched, cylindrical sponge, narrower at the base, and with conuli only 1 millim. high, can hardly be identical with one which is described as "massive, digitate, branched lobate, cactiform on the surface." In addition to these characters, the dark brown colour and the resemblance to *Aplysina fusca*, noted by Mr. Carter, leave no doubt in my mind that Professor Herdman's specimens really belong to the species in question, an opinion which is rendered almost

* Professor Herdman's dry specimens are very pale in colour.

certainly correct by the fact of their coming from the same locality. Under the circumstances it seems desirable to give some details with regard to the species.

There are two good specimens in the collection, one in spirit (R.N. 48) and one dry (R.N. 99). The former (figured) is massive, irregular, attached by a broad spreading base, from which compressed digitate or flabellate processes rise vertically upwards, bearing small vents at their apices (vents about 1·5 millims. in diameter). The surface is cactiform, with usually sharp-pointed but broad conuli, up to about 3 millims. in height, but usually less. The distance between the conuli varies greatly, but they are usually widely separated from one another by intervals of about 8 millims. The surface between the conuli is smooth or wrinkled, finely granular, under a lens very minutely reticulate and porous. The colour on the surface (in spirit) is warm brown, internally it is much paler, yellowish. The texture is compressible and resilient, but extraordinarily tough and leathery, so that it is very difficult to cut sections. This leathery character is obviously due to the enormous quantity of "filaments" which the sponge contains. Internally it is somewhat cavernous, owing to the presence of numerous cylindrical canals running vertically upwards towards the vents. This specimen measures about 190 millims. in greatest breadth of base and 56 millims. in greatest height.

The dry specimen is strongly compressed, flabellate, and only very slightly proliferous, with a narrow margin bearing a row of vents. It contains much more sand than the spirit specimen, but in other respects agrees closely. It measures about 135 millims. in height by 120 millims. in greatest breadth.

The skeleton is composed principally of large sand-grains, with a comparatively small quantity of spongin; arranged as follows:—(1) Very stout columns or tracts of sand-grains run vertically through the sponge and end in the surface conuli. These columns are compound structures, in which the sand-grains are held together by numerous short, slender spongin threads running from one to the other, in much the same way as LENDENFELD (**66**) has figured for *Psammopemma marshalli*. They apparently represent an exaggerated condition of the trellis-like main fibres of certain other Hirciniæ. (2) A very irregular network of more slender secondary fibres, composed of sand-grains held together by spongin threads as in the main columns, but the large sand-grains often only in single series. (3) In the dermal membrane there is a thin layer of broken sponge-spicules and large sand-grains, the former lying somewhat more superficially than the latter. Numerous broken spicules also occur along with the sand in the deeper parts of the sponge.

The canal-system appears to be that of a typical *Hircinia*, but, owing to the large quantity of sand and "filaments," it is impossible to get satisfactory sections. The flagellate chambers are not well preserved, but they appear to be about 0·04 millim. in diameter and approximately spherical, and the ground-substance between them is finely granular. The soft tissues are very densely charged with filaments. These have a maximum thickness of about 0·004 millim. between the heads. The heads, which stain deeply with picro-carmine, are about 0·008 millim. in diameter and somewhat variable in shape, sometimes nearly spherical and sometimes more or less pointed at the end.

Ridley's *Dysidea fusca*, which that author (**16**) supposed might be identical with Carter's *Hircinia fusca*, appears to be quite a different sponge.

R.N. 48, 99 (pearl banks, Gulf of Manaar); 271 (small specimen with fewer filaments. "Deep water off Galle and onwards up West Coast of Ceylon").

Hircinia tuberosa, n. sp.—Plate XVI., fig. 2.

The sponge consists of a very irregular, somewhat tuber-like body, from which irregular, finger-like processes are given off in various directions, the whole much mixed up and partially coated with calcareous débris. In the largest specimen the central portion of the sponge measures about 60 millims. in diameter, and the two larger processes each about 44 millims. in length by 18 millims. in diameter. The surface is very uneven, but sub-glabrous (not reticulate) between the foreign adhesions, and only slightly conulose, the conuli being low, irregular, and widely separated from one another. Internally the sponge is cavernous, being permeated by wide, cylindrical, meandering vestibules, which are covered in at the surface of the sponge by a thin, parchment-like dermal membrane, pierced here and there by rounded apertures. These apertures are evidently vents. They vary from about 0·5 millim. to 4 millims. in diameter, and are frequently arranged in groups. They are found sometimes on the central portion of the sponge, but more frequently on the more or less fistular, finger-like processes. Texture extremely coarse and gritty throughout, but tough. Colour (in spirit) pale yellowish-grey throughout. There is a distinct but thin sand-cortex in the parchment-like dermal membrane.

The skeleton (Plate XVI., fig. 2) is an extremely irregular network of more or less trellis-like horny fibre, partly enclosing and partly connecting together the very numerous sand-grains and other foreign bodies with which the sponge is filled. Main fibres are recognisable, but not very well defined, and the whole is so irregular that it is useless to give measurements.

The flagellate chambers are about 0·03 millim. in diameter and approximately spherical, and the ground-substance between them is finely granular.

Filaments are present in enormous numbers and usually collected together in more or less dense bundles. They measure about 0·006 millim. in maximum diameter between the heads, and their heads are approximately spherical and about 0·008 millim. in diameter.

R.N. 86, 88, 88a (all from deep water off Galle and onwards up West Coast).

Hircinia schulzei, n. sp.—Plate XVI., fig. 3.

Sponge slender, cylindrical, irregularly branched, and attached at many points to fragments of calcareous débris, amongst which it appears to creep. A few rather short and somewhat club-shaped branches, about 25 millims. in length and 3 millims. in maximum diameter, probably rose vertically upwards from repent stems of about the same diameter. The surface is pretty uniformly covered with low conuli, between which narrow longitudinal canals may be seen running beneath a thin membrane, which is occasionally broken through by a single small vent or by a sieve-like group of very small vents. The colour (in spirit) is very pale yellow and the texture pretty stiff, but compressible and resilient.

The skeleton (Plate XVI., fig. 3) consists of widely distant, longitudinal main fibres curving outwards towards the surface and connected at irregular intervals by a round-meshed lattice work of secondaries. The main fibres are pretty regularly cylindrical and about 0·12 millim. in diameter, not fascicled, and containing a good many fragments of sponge-spicules. The connecting fibres are entirely free from foreign matter; they vary much in diameter, but are usually pretty stout.

The canal-system is of the type usually met with amongst the Spongiidæ. The small flagellate chambers are approximately spherical and up to about 0·04 millim. in diameter, with short, wide, exhalant canaliculi. The ground-substance between them is finely granular. A very conspicuous histological feature is the presence of numerous long, cylindrical cords of fibrous tissue running longitudinally through the sponge. These cords are composed each of a compact mass of elongated, finely granular cells, each with a very distinct, darkly staining nucleus. They closely resemble the similar fibrous bands found in *Euspongia*, &c., and are probably contractile. The characteristic *Hircinia* filaments are abundantly scattered through the soft tissues. They are, however, very slender, and I have not succeeded in making out the nature of their terminations.

This appears to be a very distinct and well-characterised species, differing from *Hircinia dendroides*, Schmidt, which is, perhaps, its nearest ally, in its much more slender branches and much more regular main fibres. I have much pleasure in dedicating it to the zoologist to whom we chiefly owe our accurate knowledge of the Spongiidæ.

R.N. 277 (deep water off Galle and onwards up West Coast of Ceylon).

Hircinia anomala, n. sp.—Plate XIV., fig. 5; Plate XVI., fig. 1.

Sponge massive, irregular, with a tendency to become lobose or digitate. Surface uniformly covered with small, sharp conuli, about 1 millim. in height and 2 millims. apart; with a minute reticulation of fine ridges chiefly radiating from the apices of the conuli. Sometimes the surface reticulation is suppressed, and it may be present or absent in different parts of the same specimen. The surface is not sandy, except sometimes at the apices of the conuli. Vents inconspicuous, the sponge being, perhaps, sometimes lipostomous. Pores scattered abundantly in the meshes of the dermal reticulation. Colour (in spirit) varying from pale brown to black on the surface; pale brown internally. Consistence firm, but compressible and elastic. The largest specimen is about 75 millims. in length by 42 millims. in greatest breadth; another is about 140 millims. long, with a maximum diameter of 25 millims.

The skeleton (Plate XVI., fig. 1) is an extremely irregular network of highly arenaceous fibres. There is no distinct differentiation into main and secondary fibres, but the reticulation is much closer along tracts which run vertically to the surface and end in the surface conuli. These denser parts of the reticulation are evidently homologous with the trellis-like main fibres of other Hirciniæ. Between them large tracts may remain entirely devoid of skeleton. The fibres themselves vary a good deal in thickness and in the amount of foreign matter which they contain. Usually there is a very large proportion of sand or sponge spicules, and comparatively little spongin; occasionally, however, I have seen fibres without foreign inclusions. The spongin of the fibres is very distinctly lamellated.

The flagellate chambers are approximately spherical, up to about 0·04 millim. in diameter (but often smaller), and either eurypylous or with short exhalant canals. The ground-substance between them is finely granular, though perhaps somewhat less markedly so than in typical Spongiidæ. The larger canals are surrounded by a very large quantity of gelatinous, vesicular-looking collenchyma, and commonly more or less sub-divided by septa. Bands of fibrous tissue penetrate the soft tissues as in other Spongiidæ, but I have not found any of the "filaments" so common in the genus *Hircinia*. R.N. 13 contains an immense number of unicellular bodies of a pale yellow colour (staining brown with picro-carmine); these are oval or nearly spherical, and about 0·02 millim. in diameter; each with a small nucleus. Occasionally they appear to be broken up into fragments. Probably they are unicellular Algæ, comparable to those which I have described in *Hexadella*. R.N. 82 and 171 contain numerous groups of smaller cells which are, perhaps, the same Alga in process of division.

This species exhibits characters intermediate between those of the Spongeliidæ and those of the Spongiidæ. The skeleton, in its highly arenaceous character, agrees with that of *Spongelia*, but the small size of the flagellate chambers and the granular character of the ground-substance prevent us from including it in that genus. The absence of filaments, on the other hand, militates against our regarding the species as a typical *Hircinia*, but the nature of these filaments and their taxonomic value are still so obscure that I am not inclined to exclude the sponge from the genus solely on account of their absence.

In external appearance the species somewhat resembles *Cacospongia scalaris*.

R.N. 13 and 91 (Gulf of Manaar); 82 and 171 (deep water off Galle and onwards).

Aplysina, Nardo.

Spongiidæ with distinctly pithed horny fibres forming a coarse-meshed skeleton network. Of very compact texture, with narrow canals and very small flagellate chambers.

Aplysina purpurea, CARTER.

1880, **Aplysina purpurea**, CARTER (**4**); 1881, **Aplysina purpurea**, CARTER (**65**); 1889, **Aplysina purpurea**, DENDY (**3**); 1889, **Psammopemma fuliginosum**, LENDENFELD, *pars* (**66**).

There is only a single dry specimen of this sponge in the collection, so that I am not in a position to add anything to the descriptions of the species given by CARTER and myself, except by referring back to some preparations of spirit material collected by Mr. THURSTON, which show the sponge to be a true *Aplysina* and not, as LENDENFELD has supposed, a *Psammopemma*.

The skeleton is composed of dense local aggregations of very irregular, branching and anastomosing horny fibres, accumulated along certain tracts to form the so-called "compound fibres," while large intervening areas remain free from fibre altogether. The fibres themselves have a very curious structure, consisting of a very thin outer layer (if any) and a very thick "pith," the latter exhibiting a granular or often minutely reticulate appearance. They are free from foreign bodies. The inhalant pores are abundantly scattered over certain parts of the surface. The structure of the soft tissues is very compact and the flagellate chambers are small and probably aphodal or diplodal. In short, the canal-system probably agrees closely with that described and figured by SCHULZE in *Aplysina aërophoba*, although the condition of my material is not good enough to render a detailed comparison possible.

LENDENFELD has, as already indicated, made the curious mistake of confounding this species with "*Psammopemma fuliginosum*," a totally different sponge. CARTER'S specimens of *Aplysina purpurea* were from the Gulf of Manaar and Trincomalee, but he subsequently (**65**) identified an Australian sponge with the same species. Still later, however, when describing his *Pseudoceratina durissima* (**18**), he showed that the *Australian* specimen previously identified by him as *Aplysina purpurea* should really be considered as a specimen of *Pseudoceratina durissima*. LENDENFELD, accordingly (**66**), in a manner very characteristic of that writer, observes that "CARTER himself has shown that his *Aplysina purpurea* and his *Pseudoceratina durissima* are identical," which, of course, is by no means the case. At the same time he omits the locality from which the types of *Aplysina purpurea* were obtained from the geographical distribution of *Psammopemma fuliginosum*, under which name (while admitting that it is not the oldest) he also includes (rightly or wrongly) CARTER'S *Pseudoceratina durissima*.

Mr. CARTER has given a characteristic sketch of the external form of the sponge, together with figures of the skeletal structure (**65**, Plate IX., fig. 1), which are sufficient for the identification of the species.

There can be no doubt that KELLER'S *Psammaplysilla arabica* from the Red Sea (**61**) is very closely related to, if not identical with, this species. The compound skeleton fibres, consisting entirely (according to KELLER) of reticulate "Marksubstanz," the cactiform surface, and black-violet colour in alcohol, all point to generic if not specific identity. In the Ceylon specimens, however, there appears to be (usually at any rate) no sand in the skeleton fibres. KELLER makes his species the type not only of a new genus, but even of a new family. He considers it to be closely related to *Aplysilla*, but, unfortunately, his material did not enable him to investigate the form and arrangement of the flagellate chambers, or he would probably have seen that the affinity was rather with *Aplysina*, as the firm, almost leathery texture of the living sponge and its stony hardness when dry might alone have indicated. I follow Mr. CARTER in retaining the Ceylon species, at any rate (with which KELLER does not appear to have been acquainted), in the latter genus, from which it differs in no important respect. In any case the name *Psammaplysilla* appears to have been very unfortunately chosen, as the sandy character of the fibre is hardly of generic value, and the relationship with *Aplysilla* is not nearly so close as that with *Aplysina*, a very distinct genus.

R.N. 95 (Stat. IV., off Karkopani, 6–9 fathoms, Gulf of Manaar).

Aplysina herdmani, n. sp.—Plate XVI., fig. 4.

The single specimen consists of a rather thin, irregular, flattened crust, from which short, slender, cylindrical, digitiform processes rise vertically upwards at wide and irregular intervals. The ends of these processes are truncated, and each has a single small vent in the middle.* The surface, both of the basal crust and of the digitiform processes, is glabrous, but beset with numerous minute conuli, from the apices of which the ends of the primary fibres sometimes project. The colour, in spirit, is dull purple throughout ; the texture compact and rather fleshy, but compressible and resilient. The maximum diameter of the basal crust is about 55 millims. and its thickness about 4 millims. The digitiform processes are about 11 millims. high by only 2 millims. or 3 millims. in diameter.

The skeleton, in the basal crust, consists of a reticulation of thin-walled, pithed fibres of a rather dark brown colour, amongst which distinct primary fibres, running vertically into the surface conuli, are clearly differentiated (Plate XVI., fig. 4). These primary fibres are about 0·08 millim. in diameter, and the very thick, granular "pith" contains abundant broken sponge spicules as foreign inclusions. The primary fibres sometimes branch, and they are connected together by a network of secondaries which vary greatly in diameter, being sometimes as stout as the primaries and sometimes very slender, only about 0·016 millim. in diameter. The secondary fibres are free from foreign matter and the stouter ones commonly run across between the primaries and thus form rectangular meshes, but the meshes are usually irregularly polygonal and very variable in diameter.

In the digitiform processes the main fibres—containing broken spicules—run longi-

* One of the processes forks into two close to its extremity, and each of the very short branches thus produced bears a small vent on its truncated end.

tudinally and give off short branches—also containing broken spicules—into the surface conuli. The secondaries are arranged as in the basal crust.

The flagellate chambers are very small, only about 0·024 millim. in diameter, and approximately spherical, but the arrangement of the collared cells, on the inhalant side of the chamber only, gives them a curious crescentic appearance; moreover, they frequently appear in sections to be arranged in single curved rows; surrounding the narrow exhalant canals at about equal distances, and doubtless communicating with them by very long and narrow canaliculi, but the condition of the specimen is not good enough to enable me to make out minute histological details. The ectosome is chondrenchymatous rather than collenchymatous, but a large quantity of gelatinous tissue is developed around the larger canals in the choanosome. In the neighbourhood of the flagellate chambers the choanosome is abundantly granular, and both ectosome and choanosome contain numerous pigment cells.

It affords me much pleasure to name this well-characterised species after Professor W. A. Herdman.

R.N. 340 (Ceylon seas).

Class: CALCAREA.

Porifera with a skeleton composed of calcareous spicules.

The number of calcareous sponges in the collection is remarkably small, only four species being represented, two of which, however, are new. I have discussed the classification of the group in considerable detail in my earlier writings (**76, 78, 80**) and adhere to the opinions therein expressed.

Order 1: HOMOCŒLA.

Calcareous sponges in which the endoderm consists throughout of collared cells.

Leucosolenia, Bowerbank.

With the characters of the order.

Leucosolenia (Clathrina) coriacea (Montagu), var. **ceylonensis**, nov.—Plate XIII., fig. 8.

[For literature and synonyms *vide* Haeckel (**7**)].

This well-known European species is represented in the collection by a slight variety belonging to the reticulate section of the genus *Leucosolenia* as defined by the present writer (**76**). The sponge forms massive, closely reticulate colonies of slender ascon-tubes, each colony with a constricted base of attachment; with fairly numerous, small but prominent true oscula formed each by the coalescence of several tubes in a projection from the general surface. The ascon-tubes are only about 0·16 millim. in diameter and there is no pseudoderm. The entire colony attains a diameter of some 10 millims. or 20 millims. The colour in alcohol is pale grey.

The spicules are nearly all regular triradiates (Plate XIII., fig. 8, *a.*, *b.*, *c.*); with slender, not very sharply pointed rays of pretty uniform diameter and measuring about 0·088 millim. in length by 0·008 millim. in diameter at the base. The apex is rather abruptly and rather irregularly pointed. There are apparently no quadriradiates at all, but two (R.N. 377, 378) of the three specimens in the collection show a few very slender oxea (Plate XIII., fig. 8, *d*) projecting from the surface of some of the tubes. I have not been able to obtain these spicules in an unbroken condition, but they apparently closely resemble those found in the next species; whether or not they should be regarded as constant features of this variety, I am unable to say with certainty.

R.N. 377, 378, 379 (all from Cheval Paar).

Leucosolenia (Clathrina) tenuipilosa, n. sp.—Plate XIII., fig. 9.

Sponge forming massive, reticulate colonies of ascon-tubes, closely resembling the preceding variety but somewhat coarser. Here and there on the surface of the colony the tubes converge to unite in small, prominent, true vents. The tubes themselves are about 0·5 millim. in diameter, and they form a close reticulation without any pseudoderm. The colour in alcohol is pale grey. The largest specimen (R.N. 158, which may be regarded as the type of the species) is cake-shaped and flattened, measuring about 47 millims. in length, 37 millims. in breadth, and 16 millims. in thickness.

The skeleton is arranged as usual in the genus, and the spicules are of three kinds :—

(1.) Regular triradiates (Plate XIII., fig. 9, *a*), with rather stout, slightly fusiform rays, bluntly and rather abruptly pointed at the apex, which is often somewhat irregular. Rays measuring about 0·1 millim. in length by 0·012 millim. in diameter at the thickest part.

(2.) Quadriradiates (Plate XIII., fig. 9, *b*, *c*) abundant; resembling the triradiates, but with an apical ray projecting at right angles into the gastral cavity. This ray is somewhat variable in form and size; typically it is long and slender, gradually and sharply pointed, and slightly undulated towards the extremity; in the type specimen it attains a length of about 0·14 millim.

(3.) Very slender, hair-like oxea (Plate XIII., fig. 9, *d*), sparsely hispidating the surface of the tubes. These may attain a length of more than 0·4 millim., with an average diameter of only about 0·002 millim. They taper very gradually from the proximal extremity, which is somewhat hastately sharp-pointed and may be as much as 0·004 millim. thick, to the distal, which is hair-like and apparently nearly always broken off.

This species is evidently closely related to *Leucosolenia coriacea*, var. *ceylonensis*, but differs in the presence of the quadriradiates, and also in the greater stoutness and the frequently fusiform shape of the rays of the triradiates.

R.N. 158 (Stat. LXIV., 5 fathoms, south-east of Modragam, March 17, 1902); 158A (south of Cheval); 380 and 381 (both from Cheval Paar, March 4, 1902).

ORDER 2: HETEROCŒLA.

Calcareous sponges in which the collared cells are confined to more or less well-defined flagellate chambers.

FAMILY: GRANTIIDÆ.

Heterocœla with a distinct and continuous dermal cortex, completely covering over the chamber-layer and pierced by inhalant pores. There are no sub-dermal sagittal triradiates, nor conspicuous sub-dermal quadriradiates. The flagellate chambers vary from elongated and radially arranged to spherical and irregularly scattered; while the skeleton of the chamber layer varies from regularly articulate to irregularly scattered

Leucandra (HAECKEL).

Grantiidæ in which the flagellate chambers are spherical or sac-shaped, never arranged radially around the central gastral cavity, with which (or with the main exhalant canals derived therefrom) they communicate by a more or less complicated exhalant canal-system. The skeleton of the chamber layer is composed of irregularly scattered radiate spicules, but it may still present traces of its derivation from a radially symmetrical type in the presence of a few sub-gastral sagittal triradiates.

Leucandra donnani, n. sp.—Plate XIII., fig. 10.

The only specimen in the collection consists of a single Leucon person of sac-like form; elongated, sub-cylindrical, but slightly compressed; rather strongly curved; tapering gradually from broadly rounded base to narrower apex, where the terminal osculum is situated. The outer surface is nearly smooth, but slightly granulated in appearance. The osculum has no spicular fringe, but a slightly developed membranous margin. The total length of the specimen is 23 millims.; the maximum diameter at the base is about 9·5 millims., and the diameter of the vent is 2 millims. The thickness of the sponge-wall in the middle is about 2 millims. The colour (in spirit) is light brown and the texture firm but brittle.

The dermal cortex, of sagittal triradiates, is only about 0·05 millim. thick; beneath it lie large, irregular sub-dermal cavities, without, however, any special supporting skeleton of their own. The gastral cortex, of sagittal quadriradiates, is about as thick as the dermal cortex and pierced by the numerous apertures of the exhalant canals. The skeleton of the chamber layer consists for the most part of very large sagittal triradiates, generally arranged with the basal ray pointing outwards.

The canal-system is typically leuconoid; the flagellate chambers, abundantly scattered in the ground-substance between the gastral and dermal cortex, being spherical or sac-shaped, and having a maximum diameter of about 0·08 millim. The epithelial cells lining the larger canals contain numerous brown pigment granules.

Spicules.—(1.) Dermal triradiates (Plate XIII., fig. 10, *c*, *d*); sagittal, with slender rays of not very unequal length, measuring, say, about 0·276 millim. in length by 0·016 millim. in thickness at the base, and tapering pretty gradually from base to apex, which is sharp-pointed. The rays are all straight, and the angle between the two paired rays is only slightly greater than the other two angles.

(2.) Triradiates of the chamber-layer (Plate XIII., fig. 10, *a*, *b*); stout, sagittal, with the basal ray somewhat shorter than the paired rays. Rays usually straight; somewhat fusiform and gradually and very sharply pointed. Angle between paired rays only slightly greater than the other two angles. The paired rays in a typical example measured about 0·7 millim. in length by 0·066 millim. in maximum diameter, with a basal ray about 0·57 millim. long and of about the same thickness as the others.

(3.) Gastral quadriradiates (Plate XIII., fig. 10, *e*, *f*); strongly sagittal, with the paired rays extended nearly, or quite, at right angles to the conspicuously shorter basal ray, and with the still shorter apical ray directed forwards almost in a line with the basal. The rays are all straight, or nearly so, and only moderately stout, and taper gradually from the base to the sharp-pointed apex. Length of paired rays about 0·188 millim., with a diameter at the base of 0·012 millim.; with basal ray about 0·072 millim. long and apical ray about 0·048 millim. long; the basal ray of about the same diameter as the paired rays; the apical ray rather more slender.

(4.) Fusiform oxea (Plate XIII., fig. 10, *g*); very slightly curved; gradually and finely pointed at the inner end, but with the outer end nearly always broken off; moderately stout, measuring, say, about 0·74 millim. in length by 0·02 millim. in maximum diameter. Arranged in sparse bundles at right angles to the surface, with the outer ends projecting but slightly.

This species is perhaps most nearly related to Lendenfeld's *Leucandra typica* (79) [= *Leuconia typica*, var. *tuba*, of Poléjaeff (77)], from the East Coast of Australia (and Bermudas ?), but differs considerably in details of spiculation. I have much pleasure in naming it after Captain Donnan, the veteran Inspector and explorer of the Ceylon pearl banks.

R.N. 186 (Donnan's Muttuvaratu Paar, Gulf of Manaar).

Family: AMPHORISCIDÆ.

Heterocœla with a distinct and continuous dermal cortex. With conspicuous subdermal quadriradiate spicules with inwardly directed apical rays. Flagellate chambers varying from elongated and radially arranged to spherical and irregularly scattered.

Heteropegma, Poléjaeff.

Amphoriscidæ with elongated flagellate chambers arranged radially around the central gastral cavity. With a vestigial tubar skeleton of minute radiates. With a very thick dermal cortex, composed principally of triradiate spicules.

Heteropegma nodus-gordii, Poléjaeff (77).

This remarkable and well-characterised species is represented in the collection by a single good-sized specimen, which agrees very closely with the types described by Poléjaeff in 1883 from Australia (Cape York) and the Bermudas. The only other species known is the very closely related *H. latitubulata* from near Port Phillip Heads (80), so that the genus is apparently a characteristic Australian one, and the discovery of *H. nodus-gordii* (the Northern Australian form) at Ceylon affords another good example of the close relationship between the Ceylonese and Australian Sponge-Fauna. The anatomy of this species has been figured both by Poléjaeff (77) and by myself (78).

R.N. 155 (Ceylon seas).

LIST OF THE CEYLON SPONGE-FAUNA

so far as at present known; showing the classification adopted and the geographical distribution of those species which have been recorded from localities beyond the Ceylon area. The species marked H occur in Professor Herdman's collection; those marked D are doubtful* :—

Class: NON-CALCAREA.

Order: Myxospongida.

H 1. *Hexadella indica*, n. sp.
D 2. *Halisarca* (?) *rubitingens*, Carter (5).

Order: Tetraxonida.

Grade: Tetractinellida.

Sub-order: Homosclerophora.

Family: Plakinidæ.

H 3. *Dercitopsis ceylonica*, n. gen. et sp.

Sub-order: Astrophora.

Family: Pachastrellidæ.

* According to LENDENFELD (66), this species is identical with HYATT'S *Dendrospongia crassa*. If so, the geographical range must be extended to Nassau.

† CARTER (5) adopts HAECKEL'S varietal name *indica* for the Ceylon form.

It appears from the above list that no less than 215 species of sponges (including about seven doubtful ones) have now been recorded from Ceylon waters, which evidently form an extremely rich centre of sponge distribution. Of these 215 species, 146 occur in Professor HERDMAN'S collection, of which 77 (or 52·7 *per cent.*) are here described as new. I consider it very satisfactory to have been able to identify as many as 69 previously known species in the collection, especially as I always prefer giving a new specific name to making a doubtful identification; mistakes of the latter kind being often far more difficult to correct than those of the former. Seventy-five out of the total number of species have been recorded from localities beyond the Ceylon area.

As regards the general character of the Ceylon Sponge-Fauna, the most striking feature, next to its richness, is its close relationship with the Sponge-Fauna of Australia and the adjacent islands. In the Report on the "Challenger" Monaxonida we defined an area of distribution (No. IV. on the chart) including Australia and the islands north of Australia as far as the Philippines (inclusive). This we called the Indo-Australian area. No less than 47 out of the 75 species whose range is known to extend beyond the Ceylon region are common to the latter and our Indo-Australian region—the majority of them occurring actually along the Australian Coast.

Of these 47 species, the following are not known to occur except in the Indo-Australian area (in the "Challenger" sense) and westwards as far as Southern India:—*Stœba simplex*, *Myriastra clavosa*, *Pilochrota haeckeli*, *Geodia globostellifera*, *Xenospongia patelliformis*, *Chondrilla australiensis*, *Toxochalina robusta*, *Reniera madrepora*, *Petrosia testudinaria*, *Chalina sub-armigera*, *Siphonochalina communis*, *Esperella parishii*, (?) *Iotrochota purpurea*, *Histoderma fistulatum*, *Leucophlœus fœtidus*, *Hippospongia anomala*, *Hircinia vallata*, *Leucilla cucumis*. The following extend (so far as known) westwards not further than the East Coast of Africa or eastwards not further than New Zealand:—*Spirastrella vagabunda* (Aden), *Ceraochalina multiformis* (New Zealand), *Iotrochota baculifera* (Western Indian Ocean), *Clathria frondifera* (Western Indian Ocean, Red Sea), *Acarnus ternatus* (Western Indian Ocean, Tahiti), *Ciocalypta tyleri* (Port Elizabeth), *Psammopemma crassum* (New Zealand), *Phyllospongia papyracea* (Mozambique, Australia ?, New Zealand ?), *Aplysina fusca* (Seychelles), *Leucosolenia darwini* (Red Sea), *Leucandra pulvinar* (Red Sea). Another characteristic Indo-Australian species is *Agelas mauritiana*, hitherto recorded only from Mauritius, Ceylon, Ternate (under the synonym *A. cavernosa*, THIELE), and doubtfully from Tristan da Cunha.

If, on the other hand, we compare the Ceylon Sponge-Fauna with that of the Red Sea, as elaborated chiefly by KELLER (**61**), we notice a considerable difference. KELLER records a total of 88 species from the Red Sea, to which TOPSENT (**91**, **92**) has added 13. Of these, only 14 are known to occur in Ceylon, viz.:—*Spongelia fragilis*, *Euspongia officinalis*, *Cacospongia cavernosa*, *Hippospongia clathrata*, *Clathria frondifera*, *Acanthella flabelliformis*, *Spirastrella vagabunda*, *Placospongia* *melobesioides*, *Chondrilla nucula*, *Chondrosia reniformis*, *Leucosolenia darwini*, *Sycon raphanus*, *Leucandra primigenia*, *Leucandra pulvinar*, of which all but five (*Clathria frondifera*, *Acanthella flabelliformis*, *Spirastrella vagabunda*, *Leucosolenia darwini*, and *Leucandra pulvinar*) are so widely distributed that their occurrence is of little significance. A few other Red Sea species, however, are very closely related to Ceylon forms, and it is not improbable that two or three which have been described by KELLER under new names may be identical with Ceylon species, as will appear from the descriptive part of this report. Amongst the Australian Sponge-Fauna also a number of species occur which are very nearly related to Ceylon species, and which have not been taken account of in the above comparison.

A considerable number of sponges have also been described from South and East African waters outside the Red Sea. The "Challenger" made collections in the neighbourhood of the Cape of Good Hope, and KIRKPATRICK (**17**) has lately described 45 species collected by Dr. GILCHRIST. KELLER (**61**) also gives a considerable list of species from the East African area, in which, however, while excluding South Africa, he includes the islands of the Western Indian Ocean visited by the "Alert." In spite of these researches only four Ceylon species appear to have been met with along the African Coast itself (outside of the Red Sea), viz. :—*Phyllospongia papyracea* (Mozambique), *Ciocalypta tyleri* (Port Elizabeth), *Tedania digitata* (Mozambique), and *Spongelia fragilis* (Zanzibar), the last two being cosmopolitan. On the other hand, a number of Ceylon species extend, as we have seen, to the islands of the Western Indian Ocean, viz. :—*Hippospongia intestinalis*, *Euspongia irregularis*, *Cacospongia cavernosa*, *Spongelia* (?) *conica*, *Aplysina fusca*, *Tedania digitata*, *Iotrochota baculifera*, *Iotrochota purpurea*, *Clathria frondifera*, *Acarnus ternatus*, *Agelas mauritiana*, *Chondrilla nucula*, *Samus anonymus*, *Leucandra primigenia*. These species have very possibly spread south-westwards from Ceylon along the chain of small islands formed by the Maldives, Seychelles, Chagos, Amirantes, &c.

Even if we make allowance for errors and omissions in identification and doubtful species, and also for the important fact that many more species are known from Australasian waters than from the Red Sea and East African Coast, it appears probable from the above data that the Sponge-Fauna of Ceylon is more closely related to that of the eastern side of the Indian Ocean than it is to that of the western side, and the Ceylon region may be safely included zoo-geographically in our Indo-Australian area. The similarity of the Sponge-Fauna of Ceylon to that of Australia is doubtless to be accounted for by the facilities of distribution and suitable habitats afforded by the broken coast line which extends between the two, for it is probable that, owing to the brief duration of their free-swimming larval condition, shallow-water sponges are rarely able to traverse wide areas of deep ocean.

A few other points concerning the geographical relationship of the Ceylon Sponge-Fauna are, perhaps, worth noticing in this place. The Sponge-Fauna of the Azores has lately been worked out in great detail by TOPSENT (48, 62), who records eight species from that area which are also met with in Ceylon, while two of these, *Dotona pulchella* and *Rhabdoploca unispiculifera*, have not yet been met with elsewhere. The genus *Petromica*, also, is only known as yet from the Azores and from Ceylon, the two species being almost identical. Hence, in spite of the great difference in point of distance, the Sponge-Fauna of the Azores appears to resemble that of Ceylon nearly as much as does that of the Red Sea!

There also appears to be a certain amount of affinity between the Sponge-Fauna of Ceylon and that of the American coast of the North Atlantic, especially amongst the horny sponges (*e.g.*, *Hippospongia dura*), though, perhaps, some of the identifications in this group are a little doubtful. The Lithistid genus *Aciculites*, however, has, so far as I am aware, only been recorded from Ceylon and Havannah, and the two species in these two remote localities are closely similar.

Very nearly two-thirds of the total number of species are, however, so far as is known at present, peculiar to the Ceylon area, and, although the number of such species (at present 140) will certainly be largely decreased by future identifications and discoveries in other localities, it will, on the other hand, also be augmented by fresh additions to the list of the Ceylon Sponge-Fauna. My investigations of the Sponge-Fauna of other parts of the world also lead me to believe that while a considerable number of species enjoy a very wide geographical range, the majority have comparatively small areas of distribution. I strongly suspect, however, that a large number of our so-called "species" will ultimately be found to be so closely connected by intermediate forms that it will no longer be possible to separate them sharply from one another. In the meantime they must be distinguished by separate names, and, if the different forms are fully and properly described, it should be easy for future workers to trace out their true relationships.

DESCRIPTION OF PLATES.

PLATE I.

Fig. 1. *Hexadella indica*; vertical section of R.N. 46, combined drawing.

Ch., inhalant chones; *Ch.L.*, choanosomal lamella; *Cr.*, sub-cortical crypts; *Ect.*, ectosome; *F.C.*, flagellate chambers; *L.E.C.*, larger exhalant canal; *Mem.*, roofing membrane of inhalant chones; *P.E.C.*, primary exhalant canals; *P.I.C.*, primary inhalant canals; *Sy.A.*, symbiotic algæ.

,, 2. *Hexadella indica*; small portion of vertical section through choanosomal lamella, more highly magnified (Zeiss F., Oc. 2).

C.T.C., connective-tissue cells; *Ep.*, epithelium lining primary inhalant and exhalant canals; *I.Ca.*, inhalant canaliculi. (Other lettering as before.)

,, 3. *Hexadella indica*; tangential section of the ectosome, seen from below, showing the inhalant chones, &c. × 52. (Lettering as before.)

,, 4. *Plakinastrella intermedia*; R.N. 224. × 2.—*o.*, vent.

,, 5. *Ecionema carteri*; R.N. 175. × 2.—*o.*, vents; *p.s.*, pore-sieves.

,, 6. *Tetilla poculifera*; R.N. 230. × 3. Upper part in section.

Cl., cloaca; *L.E.C.*, larger exhalant canals.

,, 7. *Tetilla limicola*; R.N. 70. Nat. size.

o., vents; *r.t.*, root tuft of spicules matted together with mud.

,, 8. *Taprobane herdmani*; R.N. 40. Slightly reduced; from a photograph.

PLATE II.

Fig. 1. *Dercitopsis ceylonica*; R.N. 139. Spicules. All × 230.

a.–h., calthrops and triods; *i.–o.*, oxea.

,, 2. *Plakinastrella intermedia*; R.N. 224. Spicules.

a.–d., dichotriænes, × 52; *e.–n.*, oxea, × 52; *o.–p.*, microxea, × 230; *q.–v.*, oxyasters, × 230.

,, 3. *Plakinastrella schulzei*; R.N. 149. Spicules.

a.–d., triænes, × 52; *e.–q.*, oxea, × 52; *r.–t.*, microxea, × 230; *u.–x.*, oxyasters, × 230.

,, 4. *Pilochrota haeckeli*?; R.N. 127. Spicules. All × 52.

a., orthotriæne; *b.*, monstrous form of orthotriæne; *c.*, anatriæne; *d.*, *e.*, monstrous forms of anatriæne.

,, 5. *Pilochrota hornelli*; R.N. 176. Spicules.

a., *b.*, orthotriænes, × 52; *c.*, *d.*, cladomes of orthotriænes seen from above, × 52; *e.*, anatriæne, × 52; *f.*, oxeote, × 52; *g.–i.*, chiasters, × 230.

,, 6. *Stelletta herdmani*; R.N. 137. Spicules.

a.–c., triænes, × 52; *d.*, oxeote, × 52; *e.–h.*, chiasters, × 230; *i.–k.*, oxyasters, × 230.

,, 7. *Stelletta vestigium*; R.N. 200A. Spicules. All × 230.

a.–d., reduced triænes; *e.*, oxeote; *f.*, *g.*, spherasters; *h.*, *i.*, oxyasters.

PLATE III.

Fig. 1. *Erionema carteri*; R.N. 175. Spicules.

a., *b.*, plagiotriænes, ×52; *c.*, plagiotriæne (protriæne ?), ×52; *c'.*, cladome of *c.*, ×230; *d.*, anatriæne, ×52; *d'.*, cladome of *d.*, ×230; *e.*, oxeote, ×52; *f.*, microstrongyla, ×230; *g.*, chiasters, ×230.

„ 2. *Ecionema laviniensis*; R.N. 265. Spicules.

a., dichotriæne, ×52; *b.*, cladome of dichotriæne, seen from above., ×52; *c.*, anatriæne, ×52; *c'.*, cladome of *c.*, ×230; *d.*, oxeote, ×52; *e.*, chiasters, ×230; *f.*, oxyasters (?), ×230; *g.*, microstrongyla, ×230; *h.*, microxeote (?), ×230.

„ 3. *Geodia perunicinata*; R.N. 223. Arrangement of the skeleton as seen in vertical section, ×52.

a., *a'.*, dichotriænes; *b.*, somal anatriæne; *c.*, reduced cortical anatriænes; *d.*, oxea; *e.*, sterrasters in cortical layer; *e'.*, young sterrasters in choanosome; *f.*, large spherasters.

„ 3A. *Geodia perunicinata*: R.N. 223. Reduced anatriæne, ×230.

„ 3B. *Geodia perunicinata*; R.N. 223. Microscleres. All ×230.

a., small spheraster (chiaster ?); *b.*, large spheraster; *c.*, outline of sterraster, to show relative size.

„ 4. *Tetilla poculifera*; R.N. 230. Spicules.

a., *b.*, plagiotriænes, ×52; *c.*, anatriæne, ×52; *c'.*, cladome of *c.*, ×230; *d.*, protriæne, ×52; *d'.*, cladome of *d.*, ×230; *e.*, oxeote, ×52; *f.*, *g.*, microxea, ×230; *h.*, sigmata, ×230.

„ 5. *Tetilla anomala*; R.N. 153. Spicules.

a., part of protriæne, ×230; *b.*, anatriæne, ×52; *b'.*, cladome of *b.*, ×230; *c.*, oxeote, ×52; *d.*, sigmata, ×230.

„ 6. *Tetilla limicola*; R.N. 70. Spicules from body. All ×230.

a., anatriæne, cladome and part of shaft; *b.*, protriæne, cladome and part of shaft; *c.*, oxeote; *d.*, sigmata.

„ 7. *Paratetilla cineriformis*; R.N. 214. Spicules.

a.–d., modified triænes, ×230. (The central canal of these spicules is indicated by the dark shading.) *e.*, protriæne, ×52; *e'.*, cladome of *e.*, ×230; *f.*, anatriæne, ×52; *f'.*, cladome of *f.*, ×230; *g.*, oxeote, ×52; *g'*, *g''*, ends of *g.*, ×230, showing their irregularity in shape and the central canal; *h.*, sigmata, ×230.

PLATE IV.

Fig. 1. *Craniella elegans*; R.N. 193. Vertical section, ×28.

a., anatriænes; *b.*, protriænes; *c.o.*, cortical oxea; *d.m.*, dermal membrane; *emb.*, embryo; *f.c.*, fibrous layer of cortex; *i.c.c.*, intracortical (sub-dermal) cavities; *r.b.*, radiating spicule-bundles of main skeleton.

„ 2. *Taprobane herdmani*; R.N. 40. Desmas. All ×230.

a., *b.*, young monocrepid desmas; *c.*, adult desma.

„ 3. *Aciculites orientalis*; R.N, 150. Spicules. All ×230.

a., *b.*, *c.*, young monocrepid desmas; *d.*, adult desma; *e.*, *f.*, strongyla.

„ 4. *Discodermia emarginata*; R.N. 234. Spicules. All ×230.

a.–d., stages in the development of the tetracrepid desma; *e.*, end of branch of an adult desma; *f.*, very young discotriæne, side view, *s*, shaft; *g.*, adult discotriæne, surface view *s*, shaft; *h.*, microrhabds.

„ 5. *Petromica massalis*; R.N. 257. Spicules. All ×52.

a., monocrepid desma; *b.–d.*, monaxonid megascleres, showing variation in form.

PLATE V.

Fig. 1. *Staba extensa* : R.N. 167. Spicules.
a.–d., dichotriænes (*sh.* = shaft), × 230 ; *e.*, *e.*, microxea, × 530.

,, 2. *Coppatias reptans* : R.N. 242. Spicules.
a.–c., oxea, × 52 ; *d.*, chiasters, × 530.

,, 3. *Asteropus haeckeli* ; R.N. 219. Spicules.
a., oxeote, × 52 ; *b.*, oxyaster, × 530 ; *c.*, *d.*, sanidasters, × 530.

,, 4. *Cryptotethya agglutinans* ; R.N. 62. Half the specimen, after division in the median plane. Natural size.
ch., choanosome ; *ect.*, ectosome ; *f.b.*, foreign bodies adhering to the surface ; *f.l.*, inner fibrous layer of ectosome ; *f.p.*, finger-shaped process of ectosome ; *x.*, process of ectosome flattened at the end and containing longitudinal canals.

,, 5. *Cryptotethya agglutinans* ; R.N. 62. Spicules.
a., *b.*, oxea, × 52 ; *c.*, chiasters from ectosome, × 230.

,, 6. *Hymedesmia curvistellifera* ; R.N. 320. Spicules.
a., tylostyle, × 230 ; *b.*, *c.*, *d.*, asters, × 530.

,, 7. *Spirastrella tentorioides* ; R.N. 239. Spicules.
a., *b.*, tylostyli, × 230 ; *c.–g.*, spirasters, × 530.

,, 8. *Negombo tenuistellata* ; R.N. 362. Spicules.
a.–c., styli, × 230 ; *d.*, sanidasters, × 530.

,, 9. *Cliona margaritiferæ* ; R.N. 261. Spicules.
a., tylostyle, × 230 ; *b.–d.*, spirasters, × 530 ; *e.*, *g.*, intermediate microscleres, × 530 ; *h.*, *k.*, spined microxea, × 530.

,, 10. *Suberites cruciatus* ; R.N. 315. Spicules.
a., *b.*, tylostyles, × 230 ; *c.–g.*, heads of tylostyles, showing variations, × 530.

PLATE VI.

Xenospongia patelliformis, R.N. 375.

Fig. 1. Entire specimen (young), upper surface, slightly diagrammatic, × 2.
a., projection caused by foreign body ; *m.f.*, marginal fringe of spicules ; *m.p.g.*, marginal pore-grooves ; *o.*, vents ; *r.p.g.*, radiating pore-grooves, feebly developed.

,, 2. Radial vertical section, showing the ectosome (cortex), the sand-free portion of the choanosome, and part only of the sandy layer of the choanosome ; slightly diagrammatic.
cort., cortex ; *d.b.*, dermal brushes of styli ; *ex.c.*, exhalant canal ; *f.b.*, bands of fibrous tissue running inwards from the cortex to the sandy layer ; *m.f.*, marginal fringe of styli ; *m.p.g.*, marginal pore-grooves, showing inhalant pores and canals ; *o.*, vent. ; *s.g.*, sand grains.

,, 3. Small portion of similar section, including the entire thickness of the cortex and a small portion of the choanosome, × 230.
cort., cortex ; *f.b.*, band of fibrous tissue running inwards from the cortex ; *fl.c.*, flagellate chambers ; *scl.*, scleroblasts, containing small asters.

,, 4. Megascleres.
a., *b.*, styli, × 52 ; *b′.*, *b″.*, basal and apical portions of *b*, × 230.

,, 5. Larger microscleres, × 230.
a.–c., various forms of aster ; *d.*, a much-branched aster from the interior of the sponge.

,, 6. Smaller microscleres, × 530.
a.–m., various forms of aster.

PLATE VII. (All the figures from photographs.)

Fig. 1. *Siphonochalina communis*, var. *tenuispiculata* ; R.N. 117, reduced to nearly $\frac{1}{2}$.
,, 2. *Ceraochalina multiformis*, var. *manaarensis* ; R.N. 98, $\times$ about $\frac{4}{7}$.
,, 3. ,, *ceylonica* ; R.N. 5, $\times$ about $\frac{1}{2}$.
,, 4. *Pachychalina spinilamella* ; R.N. 94, $\times$ about $\frac{4}{7}$.
,, 5. *Gelliodes carnosa* ; R.N. 69, $\times$ about $\frac{1}{2}$.
,, 6. *Collocalypta digitata* ; R.N. 74A, nearly natural size.

PLATE VIII. (All the figures from photographs.)

Fig. 1. *Plocamia manaarensis* ; R.N. 107, $\times$ about $\frac{2}{3}$.
,, 2. *Clathria spiculosa*, var. *tessellata* ; R.N. 92, $\times$ about $\frac{2}{3}$.
,, 3. *Phakellia ceylonensis* ; R.N. 34, $\times 1\frac{3}{8}$.
,, 4. *Acarnus ternatus* ; R.N. 105, $\times$ about $\frac{1}{2}$.
,, 5. *Raspailia fruticosa*, var. *tenuiramosa* ; R.N. 100, $\times$ about $\frac{5}{7}$.
,, 6. *Acanthella carteri* ; R.N. 36, $\times$ about $\frac{2}{3}$.

PLATE IX.

Fig. 1. *Strongylophora durissima* ; R.N. 244. Part of dermal skeleton, $\times$ 230.
m., microxea ; *s.*, strongyla.
,, 2. *Toxochalina robusta*, var. *ridleyi* ; R.N. 109. Part of main skeleton in vertical section, $\times$ 230.
o., oxea ; *t.*, toxa.
,, 3. *Gelliodes petrosioides* ; R.N. 146. Spicules, $\times$ 230.—*a.*, *b.*, *c.*, megascleres ; *d.*, sigmata.
,, 4. *Desmacella tubulata* ; R.N. 324. Spicules, $\times$ 230.
a., *b.*, styli ; *c.*, sigmata ; *d.*, trichodragmata ; *e.*, isolated microxeote.
,, 5. *Acanthoxifer ceylonensis* ; R.N. 247. Spicules, $\times$ 230.
a., smooth oxeote ; *b.*, stylus ; *c.*, spined oxeote ; *d.*, trichodragmata.
,, 6. *Gelliodes incrustans* ; R.N. 112. Part of dermal skeleton, $\times$ 230.—*o.*, oxea ; *s.*, sigmata.
,, 7. *Gellius angulatus*, var. *canaliculata* ; R.N. 140. Spicules, $\times$ 230.
a., oxeote ; *b.*, sigmata ; *c.*, toxiform.
,, 8. *Reniera zoologica* ; R.N. 262. Oxea, $\times$ 360.
,, 9. *Petrosia densissima* ; R.N. 138A. Oxea, $\times$ 360.
,, 10. *Reniera pigmentifera* ; R.N. 290. Spicules, $\times$ 360.—*a.*, oxeote ; *b.*, strongylote ; *c.*, *d.*, stylote.

PLATE X.

Fig. 1. *Pachychalina subcylindrica* ; R.N. 292. Part of dermal skeleton, $\times$ 52.
,, 2. ,, R.N. 292. Oxea, $\times$ 360.
,, 3. *Chalina clathrata* ; R.N. 102. Part of skeleton in tangential section near the surface, $\times$ 360.
,, 4. *Ceraochalina retiarmata* ; R.N. 342. Oxea, $\times$ 360.
,, 5. *Chalina subarmigera* ; R.N. 116, about half natural size (dry specimen, from photograph).
,, 6. *Ceraochalina ceylonica* ; R.N. 50. Oxea, $\times$ 360.
,, 7. *Pachychalina brevispiculifera* ; R.N. 110. Oxea, $\times$ 360.
,, 8. *Ceraochalina reticutis* ; R.N. 58. Part of dermal skeleton, $\times$ 360.
o., well developed oxea, lying for the most part outside the horny fibre ; *r.s.*, vestigial oxea, lying in the horny fibre.
9. *Chalina obtusispiculifera* ; R.N. 370. Part of surface skeleton, $\times$ 360.
10. *Trachyopsis halichondrioides* ; R.N. 147. Oxea, $\times$ 230.

PLATE XI.

Fig. 1. *Paresperella bidentata*: R.N. 263A. Spicules, ×530.
a., tylostyle with bidentate apex; *b.*, *b.*, serrated sigmata; *c.*, anisochela, side view; *d.*, anisochela, front view.

„ 2. *Paresperella serratohamata*: R.N. 220C. Spicules, ×530.
a., tylostyle with mucronate apex; *b.*, *b.*, serrated sigmata.

„ 3. *Paresperella*, sp. Gigantic serrated sigma, ×230.

„ 4. *Echinodictyum clathratum*: R.N. 325. Spicules, ×230.
a., large stylus; *b.*, slender stylus; *c.*, *d.*, oxea; *e.*, *f.*, spined tylostyli.

„ 5. *Myxilla tenuissima*: R.N. 234A. Spicules, ×530.
a., polytylote; *b.*, spined tylostyle; *c.*, isochela, front view; *d.*, isochela, side view.

„ 6. *Esperella crassissima*; R.N. 240. Spicules, ×230.
a., tylostyle; *b.*, anisochela, side view; *c.*, anisochela, front view; *d.*, sigmata; *e.*, trichodragmata.

„ 7. *Raspailia hornelli*; R.N. 59. Spicules, ×230.—*a.*, large stylus; *b.*, *c.*, small surface styli; *d.*, *e.*, *f.*, *g.*, oxea; *h.*, *h.*, strongyla; *k.*, *l.*, *m.*, spined subtylostyli.

„ 8. *Histoderma vesiculatum*: R.N. 212A. Part of dermal skeleton, ×230.
o., *o.*, *o.*, oxea; *s.*, *s.*, strongyla.

„ 9. *Histoderma vesiculatum*; R.N., 212A. Isochelæ, ×460.—*a.*, side view; *b.*, front view.

PLATE XII.

Fig. 1. *Spongosorites topsenti*; R.N. 152. Spicules, ×52.
a.–*k.*, various forms of large megascleres; *l.*, two small oxea; *m.*, intermediate form.

„ 2. *Spongosorites* (?) *lamellata*; R.N. 236.
a. b. c., styli, ×52; *d.*, two small oxea, ×52; *e.*, small oxeote, ×230.

„ 3. *Spongosorites* (?) *lapidiformis*; R.N. 145. Spicules, ×79.

„ 4. *Hymeniacidon petrosioides*; R.N. 151. Spicules, ×230.

„ 5. *Thrinacophora durissima*; R.N. 355. Spicules, ×230.
a., stylote; *b.*, oxeote; *c.*, *d.*, trichodragmata.

„ 6. *Thrinacophora agariciformis*; R.N. 160A. Spicules, ×230.
a., *b.*, *c.*, styli; *d.*, *e.*, oxea; *f.*, trichodragmata.

„ 7. *Axinella halichondrioides*; R.N. 75. Spicules, ×230.—*a.*, oxeote; *b.*, *c.*, stylote.

„ 8. *Axinella manus*; R.N. 53. Spicules, ×230.

„ 9. *Agelas ceylonica*; R.N. 312. Spicules, ×230.

„ 10. *Rhabderemia indica*; R.N. 341.
a., *b.*, *c.*, rhabdostyli, ×230; *d.*, minute spined styli, ×530; *e.*, contort sigmata, ×530.

PLATE XIII.

Fig. 1. *Collocalypta digitata*: R.N. 74. Oxeote spicule from body, ×230.

„ 2. „ R.N. 74. Part of transverse section of a digitiform process, ×52.
ax., axial skeleton of spicules and spongin; *d.p.*, position of dermal pores; *ect.*, collenchymatous ectosomal tissue; *l.c.*, longitudinal canals; *sept.*, septum between two longitudinal canals.

„ 3. *Phakellia symmetrica*; R.N. 159. Spicules, ×230.—*a*, *b*, short styli; *c*, oxeote; *d*, long stylus.

„ 4. *Axinella tenuidigitata*; R.N. 202A. Styli, ×79.

„ 5. *Phakellia ceylonensis*; R.N. 34. Spicules, ×230.—*a*, *b*, styli; *c*, *d*, *e*, oxea.

„ 6. *Phakellia crassistylifera*; R.N. 256. Three spicules, ×230.

Fig. 7. *Auletta elongata*: R.N. 73. Spicules, × 79.—*a*, *b*, styli; *c*, oxeote; *d*, *e*, *f*, strongyla.

„ 8. *Leucosolenia coriacea*, var. *ceylonensis*; R.N. 377. Spicules, × 360. *a*, *b*, *c*, triradiates; *d*, portion of oxeote.

„ 9. *Leucosolenia tenuipilosa*; R.N. 158. Spicules, × 360.—*a*, triradiate; *b*, quadriradiate, facial view; *c*, quadriradiate, side view, showing apical ray; *d*, part of oxeote.

„ 10. *Leucandra donnani*: R.N. 186. Spicules, × 79. *a*, *b*, parenchymal triradiates; *c*, *d*, dermal triradiates; *e*, *f*, gastral quadriradiates; *g*, oxeote.

PLATE XIV. (All the figures from photographs.)

Fig. 1. *Hircinia fusca*; part of R.N. 48, × $\frac{2}{3}$.

„ 2. *Hippospongia clathrata*; R.N. 24, × $\frac{11}{16}$.

„ 3. *Euspongia officinalis*, var. *ceylonensis*; R.N. 37A, × about $\frac{2}{3}$.

„ 4. *Spongelia elastica*, var. *crassa*; R.N. 35, × about $\frac{3}{4}$.

„ 5. *Hircinia anomala*; R.N. 13, × about $\frac{2}{3}$.

„ 6. *Phyllospongia papyracea*, var.; R.N. 104A, × $\frac{14}{25}$.

„ 7. *Megalopastas nigra*: R.N. 71, × $\frac{5}{8}$.

PLATE XV.

Fig. 1. *Darwinella simplex*: R.N. 302.—End of primary fibre, enclosed in conulus, × 230.

„ 2. *Darwinella simplex*: R.N. 302.—Portion of primary fibre, in which the pith (*p.*) is partially replaced by fungal (?) filaments (*f.*), × 230.

„ 3. *Megalopastas pulvillus*; R.N. 191.—Portion of skeleton as seen in vertical section, showing the old apices of primary fibres (*ap.*) enclosed in younger portions of the fibres, × 79.

„ 4. Diagrammatic sketch of the general anatomy of the genus *Megalopastas*, based upon vertical sections of a specimen of *M. elegans* (= *Dendrilla elegans*, Lendenfeld) from Port Phillip Heads, Australia, × 52.—*c.*, surface conuli; *e.c.*, embryo capsules; *em.*, embryo; *ex.c.*, exhalant canals; *f.c.*, flagellate chambers; *i.c.*, inhalant canal; *p.f.*, primary skeleton fibres; *p.s.*, pore-sieves; *s.c.*, subdermal cavities; *s.f.*, secondary skeleton fibres.

REPORT

ON SOME

ALCYONIIDÆ

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902,

BY

EDITH M. PRATT, D.Sc.

[WITH THREE PLATES.]

THIS collection of Ceylon Alcyoniidæ* is remarkably similar to one made by Mr. STANLEY GARDINER some three or four years ago in the Maldive Islands (PRATT, 1903).† The resemblance in many cases is so pronounced as to indicate a very intimate relationship between the Alcyoniid fauna of these islands. The genera *Sarcophytum*, *Lobophytum*, *Sclerophytum*, and *Alcyonium* are common to both localities. These genera are represented in the present collection by 17 species, and of these 9 occur also in the Maldive collection, 5 are new, and 3 have only been recorded hitherto from the Pacific.

The Ceylon collection includes :—

I. Five species of *Sarcophytum:* of these, three are new; one, *S. ehrenbergi*, has been recorded from the Maldives and Red Sea, and one, *S. plicatum*, has been recorded only from the Pacific (Ternate and North Celebes).

II. Two species of *Lobophytum:* one, *L. pauciflorum*, appears to be widely distributed in the tropical and southern sub-tropical waters of the Pacific and Indian Oceans, having been recorded from Tonga, Moluccas, Funafuti, New Britain

* See also the Report on the other Alcyonaria by Professor J. ARTHUR THOMSON, which follows in this volume.—W. A. H.

† See List of Literature on p. 265.

and New Zealand in the Pacific, from the Red Sea, and from the Maldive Islands and Gulf of Manaar in the Indian Ocean. The second species, *L. hedleyi*, has only been previously recorded from the Pacific (Funafuti). Its record from the Gulf of Manaar indicates a wide distribution of this hitherto little-known species.

III. Eight species of *Sclerophytum*: of these three, *S. marenzelleri*, *S. polydactylum*, and *S. densum*, are comparatively well-known species. *S. marenzelleri*, however, has only been before recorded from the Pacific (New Britain and New Hebrides); *S. polydactylum* from the Pacific (British New Guinea, China Seas), the Red Sea, Indian Ocean (Maldives), and now the Gulf of Manaar. *S. densum* is the most common species of the genus, and has a wide geographical range—it is now known from the Pacific (Funafuti, China Seas, British New Guinea), the Indian Ocean (Maldive Islands), and now the Gulf of Manaar.

Four species: *S. gardineri*, *S. palmatum*, *S. querciforme*, and *S. durum*, have been recorded only from the Maldives. One species is new.

IV. Two species of *Alcyonium*, one of which is new, and the other, *A. pachyclados*, is apparently generally distributed in the warm southern and tropical waters of the Pacific and Indian Oceans.

Several specimens of species common to Ceylon and the Maldive Islands vary considerably in size, external form, colour, consistency, size of spicules, &c., so that it was sometimes impossible to determine the identity of a species from a study of superficial characters. When examining a specimen of this family in the preserved condition, it is necessary to note that (1) the size of a specimen may vary according to age or environment; (2) external form is, to a certain extent, dependent on the state of expansion or otherwise of the colony at the time of fixing, and also upon the nature of the fixing re-agent; (3) the colouring matter in Alcyonaria, apart from that of the spicules, is usually acted upon, and in many cases dissolved, by alcohol; (4) the consistency of a colony, and to a certain extent the size of the spicules, may be affected by the use of an acid preservative. When these more or less artificial causes of difference are eliminated, the identification of most species, when based upon general anatomical principles, can usually be determined with considerable ease and accuracy.

List of Species occurring in Professor Herdman's Collection.

Sarcophytum bicolor, n. sp.
,, *oligotrema*, n. sp.
,, *contortum*, n. sp.
,, *plicatum*, Schenk.
,, *ehrenbergi*, Marenzeller.
Lobophytum hedleyi, Whitelegge.
,, *pauciflorum*, Ehrenberg.
Sclerophytum herdmani, n. sp.
,, *marenzelleri*, Wright and St.
Sclerophytum polydactylum, Dana.
,, *gardineri*, Pratt.
,, *palmatum*, Pratt.
,, *densum*, Whitelegge.
,, *querciforme*, Pratt.
,, *durum*, Pratt.
Alcyonium ceylonicum, n. sp.
,, *pachyclados*, Klunzinger.

Sarcophytum bicolor, n. sp.—Plate I., figs. 1 and 2.

Four complete and several fragmentary specimens were taken from the Gulf of Manaar and from the coral-reef at Galle. The largest specimen is incomplete, but is 250 millims. high and 190 millims. broad, and is provided with huge marginal lobes.

One complete specimen is irregularly mushroom-shaped, with four lobes, and is attached basally to hard coral. It is 120 millims. high and the capitulum measures 150 millims. by 85 millims. across its surface. The stalk is 65 millims. high and has a transverse diameter of 96 millims. by 60 millims. The capitulum has a thick marginal seam.

The second complete specimen is very much smaller. It is only 50 millims. high, and the capitulum measures 47 millims. by 29 millims. across its surface (Plate I., fig. 1).

The stalk varies in length in individual specimens; its surface is usually smooth, but here and there are occasional longitudinal wrinkles. In many cases the autozooids may be seen through the transparent body-wall.

The colour (in spirit) varies from a dark slaty grey to a pale brownish-grey. In all specimens the autozooids and siphonozooids are of a beautiful creamy white colour.

Some of the specimens are moderately hard and tough, others are soft and fleshy, while a few are quite brittle. The texture of the species seems to vary with the age of the colony, locality, and state of preservation.

The small complete specimen differs from the larger specimen in the feeble development of the marginal seam, which is very thick in the older colony.

The *Autozooids* are extremely numerous and are usually uniformly distributed over the upper surface of the capitulum. In the largest colony they are most numerous on the upper surface of the marginal seam, where they average 12 to the centimetre, and are few in number or entirely absent on the extreme edge of the seam, where siphonozooids are very abundant. None of the specimens are completely expanded, but anthocodia of partially expanded zöoids are fully 2 millims. in length and 0·5 millim. in diameter.

The tentacles are all contracted, and, although very small, are similar to those of other species. The stomodæum, mesenteries and mesenterial filaments do not apparently differ in any important respect from those of other species, but the specimens are not sufficiently well preserved to permit of histological examination.

The *Siphonozooids* (in spirit), of a beautiful cream colour, are outlined by a network of brown pigment, which also defines the outlines of the canals.

The average superficial diameter of a siphonozooid is 0·3 millim. The stomodæum is well marked and has an average length of 0·28 millim. The mesenteries are similar to those occurring in other species.

The *Canal System* is well marked, but exhibits no specially interesting features, with the exception of the presence in the canals of an orange-brown coloured pigment which may owe its existence to the disintegration of algæ cells, so abundant in many tropical corals (see below).

The *Spicules* are long and slender, and in form are characteristic of the genus (fig. 2). They are smaller in the actively growing superficial tissues than elsewhere. When an autozooid is in a state of contraction, the external aperture is effectually closed by a small conical cap of minute tentacular spicules.

This species exhibits considerable variation in form and consistency, but is characterised externally by the distinctive creamy white autozooids and siphonozooids and the greyness of the remaining portions of the colony.

Sarcophytum oligotrema, n. sp.—Plate I., figs. 3 to 5.

A complete cup-shaped colony attached basally to stony coral was taken in the Gulf of Manaar (fig. 3).

The specimen is almost stalkless and is 42 millims. high. The capitular cup, irregular in outline, is 32 millims. in depth and is 62 millims. by 50 millims. in breadth. The base of the cup is 10 millims. in thickness, the sides are about 5 millims. in diameter near the base, but thin out towards the edge, so that they are wedge-shaped in vertical section. Zooids are only present on the inner surface of the cup. The colour in spirit is of a dirty brownish-grey, with autozooids of a more pronounced brownish hue. The outer surface of the cup is moderately smooth, with few wrinkles. The specimen is moderately hard and tough.

Autozooids are very small, and are relatively very numerous on the sides and edges of the cup, but are somewhat scanty in the middle. As the colony is in a state of extreme contraction, it is impossible to determine the actual size of the autozooids; the young autozooids near the edge of the cup are smaller than elsewhere. The average diameter of a mature autozooid at the surface is about 0·3 millim.

The tentacles, stomodæum, mesenteries and mesenterial filaments do not differ in any essential respect from those of other species. Reproductive organs were not observed.

Siphonozooids are remarkably few in number (fig. 4). Usually only one or two of these zooids occur between two autozooids, but in the middle of the capitulum the number is slightly increased. The average superficial diameter of a siphonozooid is 0·35 millim., the mouth is sunk in a slight depression, and the stomodæum has an average length of 0·25 millim.

The canal system presents no specially interesting features. Transverse ciliated vessels connecting the cœlentera of neighbouring zooids (Pratt, 1903, p. 507, fig. 3) are very numerous.

The spicules, in the form of irregular warted spindles, are extremely small, but are characteristic of the genus. They are from 0·09 millim. to 0·3 millim. in length and from 0·09 millim. to 0·1 millim. in diameter (fig. 5).

This species has a superficial resemblance to *S. roseum*, from which however it differs chiefly in colour, form of spicules, in its abundance of autozooids and paucity of siphonozooids.

Sarcophytum contortum, n. sp.—Plate I., figs. 6 and 7.

Two complete specimens and one fragment were taken from the reef at Galle.

The largest specimen is 47 millims. high. The capitulum has a curiously lobed appearance, somewhat resembling a *Lobophytum*. This is due to the growth inwards of 8 more or less digitate marginal lobes (fig. 6, *c.m.l.*). All the lobes arise from the capitular margin and not from the upper surface of the capitulum as in *Lobophytum*. The convoluted character is not so strongly marked in the two other specimens of the species. The capitulum measures 47 millims. by 35 millims. across its surface. The lobes are somewhat flattened and rise slightly above the level of the true capitular margin. They are from 18 millims. to 30 millims. long and are from 9 millims. to 15 millims. broad at the base. The edges of the lobes curl upwards and slightly inwards (fig. 6, *c.m.l.*). The stalk is 40 millims. high, tapers towards the base and is drawn into furrows by the inward growth of the marginal lobes. Its surface is minutely granular and is marked by few longitudinal wrinkles.

The colony is in a state of extreme contraction, which may, to a certain extent, account for the complication of the marginal folds. All the specimens (in spirit) are of a pale fawn colour. They are hard to the touch, minutely granular, compact, and are readily cut with a knife.

The *Autozooids* are very small, and as they are withdrawn some distance below the surface, it is almost impossible to perceive their external apertures without the aid of a lens. The average surface diameter of an autozooid cavity is 0·25 millim. Autozooids are apparently more numerous in the margin of the capitulum and capitular lobes than elsewhere.

The tentacles, stomodæum and mesenteries with mesoglœal thickenings are similar to those of other species. Ova in several stages of development are present on many of the mesenteries, development proceeding from below upwards, as is usual in these forms. In one instance two series, one a little distance below the other, of developing ova were observed on one mesentary.

The *Siphonozooids* cannot be seen without the aid of a lens. They are fairly numerous, two or three may usually be counted between two autozooids. The average surface diameter of a siphonozooid is 0·3 millim. The stomodæum has an average length of 0·18 millim.

The canal system does not exhibit any specially noteworthy features.

The *Spicules* are of the usual *Sarcophytum* type, and are extremely numerous. They are from 0·3 millim. to 0·4 millim. in length, and from 0·1 millim. to 0·15 millim. in breadth. Occasionally a club with a pointed handle may be seen (fig. 7B).

This species is characterised by the curiously convoluted marginal lobes, the small size of the zoids, the hardness and compact character of the colony.

Sarcophytum plicatum, SCHENK (1896).

Two moderately large colonies of a pinkish-brown colour were taken from Station XXII., 13 fathoms, in Dutch Bay, near Trincomalee.

This species has previously only been recorded from Ternate, but in the zoological laboratories of the Victoria University are two specimens, one taken by Professor HICKSON in North Celebes and the other taken by Mr. J. STANLEY GARDINER at Funafuti (Ellice Islands). The latter has been identified by Miss HILES. This species therefore appears to have a very wide distribution within the tropical belt.

Sarcophytum ehrenbergi, MARENZELLER (1886).

One large and complete specimen was taken on the reef at Galle.

The colony is 50 millims. high, and the capitulum measures 245 millims. by 215 millims. across its surface. The capitular margin is thrown into deep folds.

The specimen is of a dark grey colour, but towards the middle of the capitulum it assumes a lighter shade.

The species has previously been recorded from the Red Sea and from the Maldive Islands (see PRATT, 1903).

Lobophytum hedleyi, WHITELEGGE (1897).

A single complete specimen and a fragment were taken from the reef at Galle; these agree with specimens from Funafuti in all essential respects, and only differ slightly in external form. The complete specimen is short and squat, and is 75 millims. high. The capitulum measures 136 millims. by 115 millims. across its surface. It has a fairly broad marginal seam, and is deeply concave in the middle; the lobes are arranged in fairly regular radiating lines from the middle of the capitulum, and vary in height from 36 millims. to 53 millims. The colony is hard and smooth, the stalk is here and there marked by wrinkles. The specimens in spirit are of a dirty greenish-grey colour with brownish patches. The autozooids are contracted, but in sections are seen to be of a paler shade of grey than the prevailing tint. They are relatively few in number, but are more abundant on the summits of the lobes, where they are from 1 millim. to 2 millims. apart, than in the furrows between the lobes, where they are separated from each other by wide intervals.

The average diameter of a contracted crown of tentacles is about 1 millim. Owing to their extreme contraction it is impossible to distinguish their pinnules. The stomodæum appears to be longer than in the species *L. pauciflorum* or *L. crassum*, but the walls are folded in such a manner that it is impossible to measure the actual length. The mesenteries and mesenterial filaments do not apparently differ from those of other species. Ova, exhibiting several stages of development, are present on the mesenteries of the autozooids. They are from 0·08 millim. to 0·2 millim. in diameter, and each is enveloped in a follicle which, in the largest ova, is 0·03 millim. in thickness.

The *Siphonozooids* are arranged with great regularity in the spaces between the autozooids, and are consequently most numerous where autozooids are fewest. Whitelegge describes the siphonozooids as being numerous and distinct, and states that there may be as many as 12 siphonozooids between two autozooids. On the side of one of the lobes 43 siphonozooids were counted in a straight line between two autozooids, but the distance between the autozooids is not so great on the summits of the lobes, where they are seldom more than 3 siphonozooids apart.

The siphonozooids are extremely well marked in this species, their average surface diameter of 0·27 millim. is slightly less than in the species *L. pauciflorum* and *L. crassum*, but their length is greater than in those species. The average length of the stomodæum is 0·23 millim.

The canal system does not differ in any essential respect from that of other species; transverse ciliated vessels are very numerous, especially near the surface.

Spicules.—The spicules of this species have been described and figured by Whitelegge (1897, p. 217). Those of the cortex are tiny spindles or clubs from 0·12 millim. to 0·15 millim. in length, and from 0·02 millim. to 0·05 millim. in breadth. The more deeply seated spicules are tuberculate spindles, and short, stout, sub-cylindrical spicules. These are from 0·15 millim. to 0·3 millim. in length, and from 0·03 millim. to 0·19 millim. in breadth.

Lobophytum pauciflorum, Ehrenberg (1834).

One fairly large fragment and two young mushroom-shaped colonies were taken from the Gulf of Manaar.

One of the latter was 10 millims. high, with a capitulum 12 millims. by 10 millims. in diameter, and the other was 12 millims. high, with a capitulum 12 millims. by 10·5 millims. in diameter.

This species (see Marenzeller, 1886, and Pratt, 1903) appears to be very widely distributed and has been taken from the Red Sea, New Zealand, Andaman Islands, Tonga, Moluccas, Funafuti, New Britain and the Maldive Islands.

Sclerophytum herdmani, n. sp.—Plate II., figs. 8 and 9.

One complete and several fragmentary specimens were taken from the reef at Galle, and two specimens from the Pearl Banks off Aripu.

The complete specimen from Galle has a much lobed capitulum, the lobes are similar in size, and are regularly arranged on the capitular surface (fig. 8). The colony is 85 millims. high and the capitulum measures 135 millims. by 140 millims. across its surface. The stalk is 70 millims. high and 120 millims. broad. The capitulum has no marginal seam, but passes almost imperceptibly into the stalk. On the wrinkled stalk, some little distance below the capitulum, are three small tubercles which bear zooids on their upper surface (fig. 8, *tu*). This appears to be the only recorded instance of the occurrence of zooid apertures on the stalk. The colour in spirit is pale drab, the summits of the branches have a yellowish tinge. When living, the zooids were of a pale brown colour, which, however, has been dissolved by the spirit preservative.

A specimen from Aripu is smaller. It is 50 millims. high and measures 45 millims. by 35 millims. across the surface of the capitulum, which is seamed at the margin. In spirit the stalk is light brown and the capitulum yellowish-drab. When living, the capitulum was a pale yellowish-green colour.

The fragmentary specimens are of a uniform drab colour. All the specimens are moderately hard, yield slightly to the touch, and are somewhat brittle.

The species is monomorphic. The autozooids appear to be rudimentary. They are extremely small, numerous, and are arranged with great regularity on the capitular surface. The average surface diameter of a contracted autozooid is 0·04 millim. Frequently as many as 20 zooids may be counted in a linear centimetre. It is unfortunate that the preservation of the specimens will not permit of a more complete investigation of the anatomy of this interesting species.

The ventral mesenterial filaments are extremely small, but the dorsal filaments are as well developed as in other species. The superficial and internal canal systems do not differ in any essential respect from those of other species. The endodermal tissues and canals are crowded with zoochlorellæ. The minuteness of the ventral mesenterial filaments and the smallness of the autozooids is doubtless correlated with the extreme abundance of zoochlorellæ, and is discussed in a paper now in the press (PRATT, 1905).

The *Spicules* (fig. 9) are similar in character to those of other species. Tuberculate spicules usually in the form of spindles, but sometimes forked, are comparatively numerous, and average 3 millims. in length and 0·5 millim. in breadth. Clubs sometimes with spiny handles, and spindles set with minute spines, are closely packed near the surface, so as to form an outer crust. The average size of the clubs is 0·09 millim. by 0·04 millim., of the spindles 0·25 millim. by 0·03 millim. A few spiny crosses also occur.

Sclerophytum marenzelleri, WRIGHT and STUDER (1889).

A single specimen of this species was taken in the Gulf of Manaar.

The colony forms an extremely hard cake-like mass, with lobes of varying size arising vertically from the upper surface of the capitulum. The basal attachment consists of hard coral encrusted with Polyzoa and shells. The colony is 93 millims. high; the capitulum has a transverse diameter of 337 millims. by 257 millims; the stalk is 55 millims. in height and is irregular in outline. The capitulum has a well-marked marginal seam and bears numerous conical lobes—many being fully 20 millims. high. A few of the lobes are branched.

The specimen in spirit is of a pale pinkish-brown colour, which originally was doubtless of a more intense hue, as the spirit is of a golden-brown colour. The capitulum is tough in consistency and slightly yielding to pressure; that of the stalk hard, granular and more brittle. Towards the base the stalk is extremely hard owing to the great abundance of spicules in this region.

The spicules are relatively small compared with other species. They are adequately described by WRIGHT and STUDER (1889, p. 251).

The species is monomorphic. The autozooids are all contracted, but appear to be extremely small. They are much more numerous in the lobes than in the furrows between, where they are often from 2 millims. to 4 millims. apart. They are also very scantily distributed on the capitular margin. Owing to the extreme contraction of the autozooids, the pinnate character of the tentacles cannot be distinguished. The stomodæum is comparatively long and has a well-marked siphonoglyph. As in other species, the dorsal mesenteries are of considerable size. There are of course no siphonozooids.

This species has been previously recorded from Api Island, New Hebrides (60 fathoms to 70 fathoms) and Cape Gazelle, New Britain.

Sclerophytum polydactylum (DANA).

One complete specimen and several fragments were obtained from the Gulf of Manaar.

The complete colony is 35 millims. high, the capitulum measures 37 millims. by 22 millims. across its surface. It is smaller, slightly harder and more brittle than the Maldive specimen, but does not appear to differ from it in any essential respect. This species (see PRATT, 1903) has been recorded from the Red Sea, China Strait, British New Guinea, the Maldive Islands and now the Gulf of Manaar.

Sclerophytum gardineri, PRATT (1903).

Three complete specimens were obtained from the Gulf of Manaar.

Two of the specimens (in spirit) are of a beautiful cream colour, while the third is of a pale drab colour. These specimens agree with the type specimen from the Maldive Islands in all essential respects. Two are slightly larger, while the third is of similar size.

This species has been hitherto recorded only from the Maldive Islands.

Sclerophytum palmatum, PRATT (1903).

Two complete and several fragmentary specimens were taken from the reef at Galle and from the Gulf of Manaar.

The complete specimens are small, and from their manner of growth do not appear to be so robust as the type specimen from the Maldive Islands. The fragmentary specimens are from shorter and stouter colonies, and have broader and larger lobes. The zooids are very similar in all the specimens, the tentacles having the double row of pinnules characteristic of the species (PRATT, 1903, p. 526). None of the Ceylon specimens in spirit show the vivid green colour of the type specimen when living, but several of the specimens have a greenish tinge.*

This species has hitherto only been recorded from the Maldive Islands.

Sclerophytum densum, WHITELEGGE (1897).

One very young mushroom-shaped colony (PRATT, 1903, fig. 18) was taken from Gulf of Manaar; two specimens, brown in colour, were taken from the reef at Galle; one reddish-brown specimen from a coral bank in the Gulf of Manaar, and a light brown and a fawn specimen were taken from the reef at Galle.

The light brown specimen is complete, and is comparatively young, having not yet outgrown its early mushroom shape. It is 22 millims. high, and the capitulum measures 46 millims. by 27 millims. across its surface.

The capitulum is concave, with a central depression of 12 millims. Small lobes from 2 to 4 millims. high arise from the middle of the cup, while larger ones from 5 to 6 millims. high occur near the edge.

The fawn-coloured specimen was taken on the reef at Galle. It is 70 millims. high, and the capitulum measures 240 millims. by 200 millims. across its surface. The colony forms a large, hard, cake-like mass, with a more or less vertical short and thick stalk, having almost the same breadth as the capitulum, which has no marginal seam. Lobes are very numerous near the edge of the capitulum, but are few and small in the middle. Zooids are numerous on the lobes, but are scantily distributed over the centre of the capitulum.

This species appears to be the most common as well as the most widely distributed species of the genus. It is known from Funafuti, China Seas, British New Guinea, Maldive Islands, and now from the Gulf of Manaar and Galle.

Sclerophytum querciforme, PRATT (1903).

Two specimens similar in form, size, texture, and apparently in all essential respects, to the specimens from the Maldive Islands, were taken from the Gulf of Manaar.

This species has hitherto only been recorded from the Maldive Islands.

Sclerophytum durum, PRATT (1903).

Four specimens were taken. Three from the Reef at Galle and one from the pearl banks in the Gulf of Manaar.

Three specimens, one complete and two fragmentary, are of a beautiful orange colour (in spirit)—of a deeper shade towards the middle and paling towards the margin. The fourth, a cup-shaped colony, is of a deep cream colour.

As already pointed out (PRATT, 1903, p. 528), specimens of this species from the limited area of the Maldive Islands exhibit great diversity in form and colour. Further modifications in these respects occur in the Ceylon specimens. The cup-shaped colony is similar in form, size, and texture to the cup-shaped Maldive

* Some of these colonies from Ceylon were certainly green when alive.—W. A. H.

specimens. The remaining three specimens, which appear to be very much older, are extremely hard, irregular, mushroom-shaped masses, with convex capitula thinning out towards the edges, set with short frequently laterally compressed lobes, usually arranged in radiating ridges.

The lobed specimen from the Maldive Islands appears to be intermediate in form and age between the cup-shaped specimens and the hard, irregular, mushroom-shaped specimens from Ceylon.

The complete specimen is 47 millims. high and the capitulum measures 92 millims. by 80 millims. across its surface. The stalk is short, broad, laterally compressed and constricted in the middle. It is 25 millims. high and has a diameter at the base of 80 millims by 40 millims. A few of the lobes are branched. Their average height near the middle is 10 millims. All the specimens give off a peculiar pungent odour even in spirit.

Only autozooids are present in this species. They are fairly numerous on the margin of the colony and on the lobes, but are few in number in the furrows between the lobes. All the specimens are hard and granular, owing to the enormous spicules which are very thickly set and extremely abundant.

This species has hitherto only been recorded from the Maldive Islands.

Alcyonium ceylonicum, n. sp.—Plate II., figs. 10 to 12.

A single complete colony was taken from the reef at Galle.

The specimen has an irregularly ridged capitulum and is creamy white in colour. The colony is 60 millims. high and the capitulum measures 75 millims. by 55 millims. across its surface.

It is tough and fleshy in consistency, slightly softer and more fleshy in the middle than near the surface, where the spicules are much more abundant.

The *Zooids* are extremely small and are very numerous (13 or 14 to the centimetre), they are uniformly distributed over the entire upper surface of the capitulum. Measurements across the partially expanded crown of tentacles average 0·6 millim. None of the zooids are completely expanded. The apertures of contracted zooids are so minute as to be almost imperceptible without the aid of a lens. As the tentacles are only partially expanded, it is difficult to distinguish their pinnate character. They are extremely short, the longest measuring only 0·16 millim. in length. The stomodæum averages 0·5 millim. in length and has a moderately large siphonoglyph.

The mesenteries are small, and the musculature only feebly developed. As in many other tropical forms, the dorsal mesenteries have extremely long and well developed filaments, but the ventral mesenteries have no filaments (Plate II., fig. 11, *v.m.*). As in several other instances (PRATT, 1904, in the press), this reduction of the digestive surface is accompanied by an abundance of zoochlorellæ in the superficial endodermal tissues.

The *Spicules* are similar in form (fig. 12) to those of *A. pachyclados*, but are slightly larger than in that species and are much less numerous. They have the form of tuberculate dumb-bells. They are fairly abundant in the superficial tissues, but are scantily distributed in the more deeply seated portions of the colony.

The average size of the spicules is 0·14 millim. by 0·1 millim.

As in other species of *Alcyonium*, there is only one system of canals. This, the internal system, is extremely well developed in the interior of the colony, but becomes less well marked towards the surface of the capitulum. This system consists chiefly of short transverse vessels which connect the cœlentera of the zooids (PRATT, 1903). Owing to the great number of zooids, which in this species penetrate deeply into the interior, the longitudinal canals are comparatively few in number.

This species is characterised by its soft fleshy consistency, its numerous but very minute zooids, the entire absence of ventral mesenterial filaments, accompanied by an abundance of zoochlorellæ in superficial tissues, and the small spicules.

It approaches *A. pachyclados* in the absence of ventral mesenterial filaments and in the form of the spicules. It differs however from that species in the texture of the colony, the minuteness of the zooids and in its less numerous but larger spicules.

Alcyonium pachyclados, KLUNZINGER (1877).

Three complete specimens of this widely distributed species were taken from the Gulf of Manaar.

They are all similar in external form, consistency and colour, but specimens in the Victoria University of Manchester from different localities exhibit considerable variation in these respects. The Ceylon colonies form low, more or less lobate, sessile, encrusting masses, from 10 millims. to 20 millims. high and from 28 millims by 18 millims. and 42 millims. by 23 millims. broad. The capitulum has a more or less convex surface, on which are studded, with varying frequency, the short and broad, rounded or conical lobes; the largest lobe is 7 millims. high and has a basal diameter of 8 millims. by 7 millims. These colonies are very similar in external form and character to specimens from the Maldive Islands (PRATT, 1903), China Strait and New Britain, but differ considerably in colour and manner of growth from the arborescent specimens which have been attributed to this species from the Cape of Good Hope (HICKSON, 1900). The Ceylon specimens are harder and more brittle than the forms I have examined from other localities, this being no doubt attributable to the great abundance of spicules.

The Ceylon specimens (in spirit) are of a creamy-white colour with autozooids of a darker shade, and are similar in this respect to the specimens from China Strait. The Maldive specimen (in spirit) is a pale brownish-grey colour, of a darker shade between the lobes. The specimen from New Britain is a uniform grey colour, while some of the Cape specimens are white, some yellow and others red in colour.

In distribution this species is known from the Red Sea, Maldive Islands, China Strait, New Britain, Cape of Good Hope and now the Gulf of Manaar.

ANATOMICAL NOTES.*

NEMATOCYSTS (figs. 13 and 14).

MOSELEY was unable to find nematocysts in specimens of *Sarcophytum*, and therefore states (1881, p. 119) that they do not occur in this genus. In his description of the occurrence of nematocysts in several members of the Alcyonaria, ASHWORTH (1899, p. 193) records them for *Sarcophytum pauciflorum*. This species, however, is now placed in the genus *Lobophytum*, for which the record of the presence of nematocysts is new. Hitherto they have not been observed in any species of *Sarcophytum*.

On examining several preparations of a single species stained with iron brazilin, some specimens seemed to contain no nematocysts, many contained few nematocysts, and in only a very few instances were they at all numerous. The apparent absence or scarcity of nematocysts in individual members of a species may be attributed to the use of a fixing preservative which permeates the tissues so slowly that the stinging cells are discharged before the colony is fixed. If a rapidly fixing preservative such as an 8 per cent. aqueous solution of hot formalin be employed, the tissues apparently suffer no contraction and the tentacles are found to contain innumerable batteries of nematocysts.

Nematocysts in *Alcyonium digitatum* were first described by HICKSON (1895).

I have been successful in observing nematocysts in all the species of *Alcyonium*, *Sarcophytum*, *Lobophytum*, and *Sclerophytum* which I have examined. They are, however, apparently more numerous in the British species than in the tropical representatives of the family. They always occur in batteries, and are never uniformly distributed in the ectoderm. The most common type is the well-known form occurring in *Alcyonium*. Modifications of this with regard to size, and length and thickness of thread are not infrequent, and may be found in *Sarcophytum roseum* (fig. 13*a*) and *S. glaucum* (fig. 13*c*), and in *Sclerophytum gardineri*. The accompanying table shows that they vary considerably in size in specific members of the family, and are apparently more uniform in this respect in *Alcyonium* and *Lobophytum* than in *Sarcophytum*, where they are from 6μ to 22μ long, and from 2μ to 14μ broad, and in *Sclerophytum*, in which they are from 5μ to 12μ long, and from 2μ to 4μ broad.

Nematocysts attain their greatest size in *Sarcophytum glaucum* (fig. 13*c*), in which species they are comparatively few in number. The thread is extremely short and broad, being usually fully 2μ in breadth. In sections, the internal portion exposed at the cut surface stains more deeply than the external portion of the thread. Within the cell the thread lies loosely and irregularly coiled, there being usually only from 3 to 4 turns of the spiral. The smallest nematocysts occur in *Sclerophytum*

* I have given an account of the physiology and comparative anatomy of the digestive organs of the Alcyonaria in a paper which is in the Press at the time of writing (PRATT, 1905).

durum. In this species they are extremely difficult to see, and are only about 5μ long and 2μ broad.

Throughout the family the thread is apparently unbarbed; nematocysts of *Alcyonium* with discharged threads are figured by HICKSON (1895). The nucleus of the cnidoblast is usually long and curved (fig. 13), and stains very readily. Nematocysts, similar to those occurring in batteries in the tentacles, are frequently to be found in the ectoderm of the mouth disc, in the stomodæum, imbedded in the peripheral portions of the mesenterial filaments, in the endoderm of the canals, and in some cases in the mesoglœa some little distance below the surface. They are extremely rare in the ectoderm covering the general surface of the colony between the zooids.

Genus. Species.	Size of nematocysts.	Author.

TENTACLES.

When the tentacles of *Alcyonium* are expanded, their ectoderm is extremely thin, and is composed almost entirely of batteries of cnidoblasts, columnar interstitial cells, scleroblasts, and a few mucous cells. I have observed no granular gland cells such as occur on the mouth disc. In the ectoderm of the body wall, nematocysts are comparatively few in number, and are rarely seen in the ectoderm covering the colony.

ZOOCHLORELLÆ.

Zoochlorellæ are more or less fully described in a publication now in the Press (PRATT, 1905). In a specimen of *Sclerophytum densum* some of the zoochlorellæ are seen to have lost their cellulose cell walls (fig. 16). In such a case the nucleus, chromatophore, and protoplasm of a cell exhibit unmistakable signs of division. This probably represents an early stage of sporogenesis. Very minute zoochlorellæ (fig. 16, *c.*) are also seen in the canals, but I have been unable to determine the intermediate stages of spore formation.

Yellow Cells.

The more or less rounded cells of a yellow colour which occur in the ectodermal as well as endodermal tissues are to be found in many tropical forms, but are more numerous in the specimens of *Sarcophytum* (Pratt, 1903, fig. 4) than in those of *Lobophytum* and *Sclerophytum*. They appear to be very abundant in certain Madreporaria, and have been described and figured by Duerden (1903, p. 439).

As small portions of yellow granular matter, similar in all respects to the contents of the yellow cells, may be frequently observed in the zoochlorellæ, it is suggested that the yellow cells represent an early stage of sporogenesis. The presence of yellow granular matter may be due to the breaking up of the chromatophores, but this point can only be satisfactorily settled by a systematic study of the life-history of the zoochlorellæ in living corals.

Generative Organs.

Comparatively few specimens in the collection contain generative organs, and in such instances they are entirely of a female character. Hickson (1895, pp. 376–380) has already described the oogenesis, and to a certain extent the spermatogenesis, of *Alcyonium*, and Ashworth (1898, pp. 207–209) has described the spermatogenesis of *Xenia*. In the British *Alcyonium digitatum* the development of the sexual cells occupies a very considerable period, as the ova begin to appear about April or May, and are usually not sexually ripe until December or even later. I have observed the discharge of ripe ova at Port Erin during the early part of April. In the British species the period of the sexually mature condition is extremely short. Apparently the colonies inhabiting a particular district discharge all their ripe ova and spermatozoa almost simultaneously. In tropical members of the family, however, such is not the case.

In his description of the spermatogenesis of *Xenia*, Ashworth (1898, p. 207) states that the spermatozoa closely resemble those of *Alcyonium* in development and structure, but spermatozoa occur in a single specimen in all stages of development, so that the discharge of ripe spermatozoa extends over a considerable period ; this he attributes to the fact that as the coral lives on reefs in the shallow waters of tropical seas, it is not subjected to any great variation in temperature and food supply.

The development of the ovum in *Sarcophytum*, *Lobophytum*, and *Sclerophytum* closely resembles that of *Alcyonium*, and is typically Alcyonarian in character (figs. 17 and 18). Frequently (in specimens of *Sarcophytum latum*, *Sclerophytum durum*, and *Sclerophytum gardineri*), however, ova in several stages of development may be observed on a single mesentery, the development proceeding from above downwards, so that the youngest ova usually occur nearest the lower end of the stomodæum. In a specimen of *Sarcophytum latum*, ova on a single mesentery vary in size from 0·03 millim. to 0·5 millim. in diameter. Two series of developing ova, one a little distance below the other, were observed on a single mesentery in *Sarcophytum contortum*.

On comparing the oogenesis of *Sarcophytum*, *Lobophytum*, and *Sclerophytum* with Ashworth's description of the spermatogenesis of *Xenia*, it would appear that the sexually mature condition, in these tropical genera, extends over a considerably longer period than in the case of corals inhabiting temperate waters. The complete absence of male colonies, and of generative organs in many specimens, in the collection, is very noteworthy. I can offer no explanation, for many of the colonies are of considerable size, and the zooids appear to be mature in every other respect.

In the Alcyonaria generative organs usually occur on the ventral and lateral mesenteries only (fig. 17). In a specimen of *Sclerophytum gardineri*, however, ova occur also on the dorsal mesenteries (fig. 18). They are not connected with the ectoderm of the mesentery, but are borne and supported by lateral outgrowths of the mesenterial endoderm. Ashworth (1898, p. 207) records the presence of spermaria on the dorsal mesenteries of *Xenia*, but these are apparently the only records of their occurrence on these mesenteries in the Alcyonaria. As both forms in which they occur present modifications in other respects, this must be regarded also as a secondary feature, and of no special morphological interest.

Siphonozooids.

I have slight additions to make to the description of the siphonozooids of *Sarcophytum*, *Lobophytum* and *Sclerophytum* already given in a previous publication (Pratt, 1903).

In *Sarcophytum* and *Lobophytum* the siphonozooids are small in comparison with the size of the autozooids, but in *Sclerophytum* they are either very minute (fig. 20) or absent. In all well marked cases of dimorphism the stomodæum is large, usually ciliated throughout, and has a well marked siphonoglyph furnished with long flagella (fig. 19). The dorsal mesenteries are long and have large, grooved and ciliated filaments. Even when of considerable size siphonozooids are usually only slightly contractile, and have only small ventral mesenteries. The specialisation of these zooids to fulfil a circulatory function has been accompanied by a reduction and atrophy of those organs which are concerned in the capture and digestion of food. Throughout the Alcyonaria siphonozooids apparently have no tentacles and their ventral mesenteries no filaments. The increase of the flagellate surface of the stomodæum has been at the expense of the digestive surface. The increased current of sea water within the zooids would carry away the food particles so rapidly, that they would be unable to receive the secretion of the gland cells, which, however, would be rendered so dilute as to be quite useless for digestive purposes. These zooids therefore have become incapable of capturing and digesting food. The increased circulation brought about by their specialisation would relieve the autozooids to a certain extent of that function, hence the feebly marked siphonoglyph in the autozooids of *Sarcophytum* and *Lobophytum*.

The stomodæal ectoderm of the siphonozooids in *Sarcophytum* and *Lobophytum* is composed of the same elements as in the autozooids, but owing to the physiological division of labour they occur in very different proportions.

In the stomodæum of the siphonozooid there is a pronounced increase in the number of flagellate cells, so that the siphonoglyph is proportionately larger than in the autozooid—this is accompanied by a very pronounced reduction in the number of granular gland cells, which are extremely rare in these two genera, but are entirely absent in *Sclerophytum*. The stomodæum of the siphonozooid in *Sarcophytum* and *Lobophytum* consists chiefly of flagellate cells, which constitute the well marked siphonoglyph and the ciliated columnar epithelial cells which line the remaining portion of the stomodæum. Among the latter are interspersed a few interstitial cells, nematocysts, scleroblasts, and a very few gland cells.

Siphonozooids and autozooids frequently communicate with each other by means of short ciliated canals, which differ from the vessels of the canal system in the presence of long columnar endoderm cells provided with fairly long cilia (fig. 22).

In *Sclerophytum* modification of the stomodæal ectoderm has proceeded still further. In this genus the siphonozooids are very much reduced. The stomodæum has neither flagellate cells nor gland cells, but consists in the species *S. densum* and *S. hirtum* (fig. 20) of a short simple tube opening to the exterior and lined apparently by undifferentiated ectoderm cells. In the species *S. palmatum* and *S. capitale* there is no aperture to the exterior ; in *S. durum* and *S. polydactylum*, an aggregation of a very few ectoderm cells is the degenerate representative of the stomodæum in other forms. The stomodæum is entirely unrepresented in *S. gardineri* and *S. querciforme*. Mesenteries are only present in very few cases and are extremely small and very feebly developed (fig. 20 *m*).

Development by Budding.

The siphonozooid buds differ from those which are destined to become autozooids in that their development is arrested at a very early stage, which appears to be constant for the species, and also to a certain extent in development, although the very early stages of both forms of zooids are identical.

In *Sclerophytum* the siphonozooids are extremely small and retain throughout life their intimate connection with the transverse vessels of the canal system from which they originated. In the development of the siphonozooids of *S. densum* a cæcum is formed by an outgrowth from an endodermal canal near the surface of the colony. This is accompanied by a multiplication and aggregation of the ectoderm cells at the surface, immediately opposite the cæcum (fig. 20). These cells arrange themselves so as to form a tube, usually one cell in thickness, which is at first blocked by a plug of mesoglœal-like substance (*pl.*). Rudiments of mesenteries frequently appear (*m.*), and by the removal of the plug an aperture is formed to the exterior. If a bud is destined to become an autozooid, mesenteries appear at a very early stage and usually attain a considerable size before the completion of the stomodæum or formation of the tentacles. My study of the development of the buds is yet incomplete, but there can be no doubt of the ectodermal origin of the stomodæum and the endodermal origin of the mesenteries. I have not yet worked out the origin of the ventral mesenterial filaments.

Canal Systems.

The canal systems of the Alcyonaria have been described by Hickson (1895) for *Alcyonium*, Moseley (1881) for *Sarcophytum*, Ashworth (1898) for *Xenia*, and Pratt (1903) for *Lobophytum* and *Sclerophytum*.

The canals in *Alcyonium* are very similar to each other in form and structure, but very irregular in their course; there appear to be no large vessels which maintain a course parallel to the periphery or to the longitudinal direction of the zooids, so that it is impossible to divide the canals into superficial and internal systems as in *Sclerophytum*. The vessels of the canal system are most numerous near the surface—in the deeper portions of the colony they are very sparingly distributed and are confined to the basal portions of the secondary polyps and the adjacent portions of their neighbours (Hickson, 1895, p. 362, Plate 37, fig. 8).

In *Sclerophytum* the superficial and internal canal systems are extremely well marked throughout the colony; near the base the internal system is very complex, owing to the branching and anastomosing of numerous vessels. In the presence of two systems of canals, and in their manner of distribution, *Sclerophytum* resembles *Xenia*.

The canal system of *Sarcophytum* is very similar to that of *Lobophytum*, and differs from *Sclerophytum* and *Xenia* in the absence of a superficial system, and in the fact that the principal longitudinal vessels are direct prolongations of the cœlentera of the siphonozooids.

New canals frequently arise as outgrowths from pre-existing vessels in the following manner :—One or more endoderm cells wander from a canal into the mesoglœa and divide and multiply to form a strand of cells; the individual cells of the strand multiply and form a fairly solid cord of endoderm, which usually remains attached to the canal from which it grew. Eventually a longitudinal splitting occurs and the lumen of the canal is formed (fig. 23).

This investigation of the Ceylon Alcyoniidæ has been carried out in the Zoological Laboratories of the Victoria University of Manchester. I am greatly indebted to Professor Hickson for much valuable advice and kind assistance in my work.

EXPLANATION OF PLATES.

List of Reference Letters.

amb.c., amœboid cell in mesoglœa.
ap.c., aperture of canal.
au., contracted autozooid.
b.cn., battery of nematocysts.
c.m.l., capitular marginal lobe.
e.au., expanded autozooid.
c.c., cœlenteric cavity.
cap., capitulum.
cap.mar., capitular margin.
cl., clubs.
col.end., columnar endoderm.
c.v., ciliated vessel.
d.m.f., dorsal mesenterial filament.
ect., ectoderm.
end., endoderm.
end.b.w., endoderm body-wall.
end.can., endodermal canals.
g.v., germinal vesicle.
in.m.sp., inter-mesenterial space.
l.m.f., lateral mesenterial filament.
l. lobe.
m., mesentery.
m.ap., mouth aperture.
mar.lob., marginal lobe of capitulum.
mg., mesoglœa.
mg.b.w., mesoglœa body-wall.
mg.c., mesoglœal cells.
mg.d., dense layer of mesoglœa surrounding siphonozooids.
nuc., nucleus.
ov., ovum.
s., stomodæum.
si., siphonozooid.
sp., spicule.
sp.h., hole left by spicule after decalcification.
st., stalk.
tent., tentacle.
tr.s.c., transverse superficial canal.
tu., tubercle-like zooid on the stalk.
v.m., ventral mesentery.
v.m.f., ventral mesenterial filament.
y.au., young autozooid.
yk., yolk of ovum.
zo., *zx.*, zoochlorellæ.

PLATE I.

Fig. 1. *Sarcophytum bicolor*, n. sp.—Drawing of the smaller specimen, which has no capitular marginal seam. Autozooids and siphonozooids are of a beautiful creamy white colour, the remaining portion of the colony being dark grey. × 2.

Fig. 2. *Sarcophytum bicolor*, n. sp.—Different forms of spicules. × 60.

Fig. 3. *Sarcophytum oligotrema*, n. sp.—Drawing to show cup-like form of colony. × $1\frac{1}{3}$. The autozooids on the margin are smaller and relatively more numerous than in the middle of the capitulum. Siphonozooids are very few in number in this species.

Fig. 4. *Sarcophytum oligotrema*, n. sp.—Surface view of a decalcified fragment of the capitulum, about an inch from the margin, to show the relative abundance of autozooids and of siphonozooids. × 27.

Fig. 5. *Sarcophytum oligotrema*, n. sp.—Three warted spicules. × 60.

Fig. 6. *Sarcophytum contortum*, n. sp.—Drawing to show the complicated folding inwards of the capitular marginal lobes (*c.m.l.*). All these lobes arise as marginal ingrowths and not, as in *Lobophytum* and *Sclerophytum*, from the general surface of the capitulum. Autozooids and siphonozooids in this specimen can only be seen with the aid of a lens and are, therefore, not indicated in the drawing. × $1\frac{1}{3}$.

Fig. 7. *Sarcophytum contortum*, n. sp.—Three warted spicules. × 60.

PLATE II.

Fig. 8. *Sclerophytum herdmani*, n. sp.—From a photograph, showing the zooids on the stalk. About $\frac{1}{2}$ nat. size.

Fig. 9. *Sclerophytum herdmani*, n. sp.—Drawings of the different forms of spicules found in this species. *a.b.c.* × 7. *d.e.f.* × 60.

Fig. 10. *Alcyonium ceylonicum*, n. sp.—From a photograph. About $\frac{1}{2}$ nat. size.

Fig. 11. *Alcyonium ceylonicum*.—A contracted autozooid showing 2 large dorsal mesenterial filaments and a ventral mesentery which has no filament. × 60.

Fig. 12. *Alcyonium ceylonicum*.—Three spicules characteristic of the species. × 140.

Fig. 13. Nematocysts of *a*. *Sarcophytum roseum*.—Actual size $8 \cdot 5\mu$ by $4 \cdot 5\mu$.
b. *Sclerophytum densum*.—Actual size 6μ by $4 \cdot 5\mu$.
c. *Sarcophytum glaucum*.—Actual size 20μ by 12μ.
d. *Lobophytum pauciflorum*.—Actual size 7μ by $2 \cdot 5\mu$.

The nematocysts of *Sarcophytum glaucum* are enormous. The thread is loosely coiled within the cell. The internal portion of the thread stains more deeply than the external.

Fig. 14. *Alcyonium digitatum* (British).—Drawing of an extended living tentacle, showing the batteries of nematocysts and the single bi-lateral row of pinnules (*b.cn.*). Cam. luc. × 26.

Fig. 15. *Lobophytum pauciflorum*.—An autozooid tentacle, showing the asymmetrical arrangement of pinnules. × 60. Cam. luc. The tentacles of the tropical species are usually much smaller than those of the British species (fig. 14).

Fig. 16. *Sclerophytum densum*.—Zoochlorellæ: *a* and *b* show early stages of sporogenesis. The cellulose cell walls have disappeared, and the protoplasm and nuclei of the cells show unmistakable signs of division. In *b* the division is more complete than in *a*. *c* represents two very young zoochlorellæ. I have been unable to observe the intermediate stages between *b* and *c*. *a* × 1300, *b* × 1600, *c* × 1200. Cam. luc.

PLATE III.

Fig. 17. *Sclerophytum gardineri.*—Transverse section through a ventral mesentery bearing a typical Alcyonarian ovum. × 930. Cam. luc.

Fig. 18. *Sclerophytum gardineri.*—Transverse section showing the unusual occurrence of two young ova on a dorsal mesentery. × 930. Cam. luc.

Fig. 19. *Lobophytum pauciflorum.*—Transverse section through a siphonozooid just below the surface. All the columnar cells lining the stomodæum are ciliated, but those of the siphonoglyph are more closely packed and have very long flagella. The endoderm is greatly distorted owing to the presence of zoochlorellæ. × 80.

Fig. 20. *Sclerophytum densum.*—Longitudinal section showing stages in development of siphonozooids, Si_1, Si_2, Si_3, by budding. Si_1 is the youngest and is formed as a bud from the endodermal canal leading from Si_3, and by an aggregation of ectodermal cells to form the stomodæum, which in the section consists at this stage of only two cells. A plug of mesoglœa at this stage closes the mouth aperture. Si_2 is an older bud. The development of the stomodæum has advanced, but the mouth aperture is still closed. Si_3 is a siphonozooid which has attained its normal development in this species. The mouth aperture is present and a very rudimentary mesentery (*m.*) is seen on the right. × 600.

Fig. 21. *Sclerophytum densum.*—Longitudinal section through a developing autozooid. The mesenteries are fairly well developed before the mouth aperture and tentacles are formed. Only one mesentery is indicated in the drawing. × 360.

Fig. 22. *Lobophytum pauciflorum.*—Transverse section showing the ciliated communication between two siphonozooids. The endoderm cells differ from those lining the cœlenteron in that they are long, columnar, and are provided with fairly long cilia. × 600.

Fig. 23. *Sclerophytum densum.*—Drawing showing the formation of an endodermal canal by the splitting of a solid cord of cells. × 700.

REPORT

ON THE

ALCYONARIA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

PROFESSOR J. ARTHUR THOMSON, M.A., UNIVERSITY OF ABERDEEN,

AND

W. D. HENDERSON, M.A., B.Sc., CARNEGIE SCHOLAR,* UNIVERSITY OF ABERDEEN.

[WITH SIX PLATES.]

THE rich collection of Ceylonese Alcyonarians† here reported on was made in 1902 from the Pearl Oyster Banks in the Gulf of Manaar, by dredging within the 100-fathom line off Trincomalee and off Galle, and in adjacent littoral areas. The localities are more precisely referred to in Professor HERDMAN'S "Narrative" in Part I. of the general Report (1903).

As only a few Alcyonarians from Ceylon have been previously recorded, *e.g.*, by THURSTON‡ (1890) and RIDLEY§ (1883), Professor HERDMAN found an almost fresh field, which his faunistic genius recognised as extraordinarily rich. We have not been able to exhaust the material which his skilful collecting has garnered. His collection

* It is more than a formal duty to make grateful acknowledgment of the assistance of the Carnegie Trust: Mr. HENDERSON did part of his share in this Report as a Carnegie Scholar, and I received from the Trust £30 towards the expenses of preparations and drawings.—J. A. T.

† The "fleshy" Alcyoniidæ, *e.g.*, *Alcyonium*, *Lobophytum*, *Sarcophytum*, *Sclerophytum*, are reported on separately by Miss EDITH M. PRATT, D.Sc. (see this volume, p. 247).

‡ THURSTON'S list is as follows:—*Echinogorgia pseudosasappo*, *E. sasappo*, *E. cerea*, *E. furfuracea*, *Plexaura flabellum*, *Juncella juncea*, *Gorgonia (Leptogorgia) miniacea*, *Gorgonella umbella*, *Suberogorgia suberosa*, *Pteroeides javanicum*, *Pt. esperi*, *Virgularia juncea* and *Lituaria* sp.

§ RIDLEY'S list is as follows:—*Alcyonium polydactylum*, *A. submurale*, *Sarcophytum pauciflorum Spongodes* sp., *Rhizoxenia* sp., *Menacella reticularis*, *Echinogorgia pseudosasappo*, *Plexaura flabellum*, *Juncell juncea*, *Suberogorgia verriculata*, *S. suberosa*, and (?) *Corallium nobile*.

is "*littoral*" in the wide sense, but it may be noted that the explorations of the "Investigator" show that the *deep water* off Ceylon is also very rich in Alcyonarians. In reporting on Professor HERDMAN'S collection, we have had to deal with at least 75 species, representing at least 40 genera. About 32 of the species seem to us to be new, and the number might have been considerably increased if we had exercised less restraint. Our restraint in multiplying species has been mainly due to the ignorance that obtains in regard to the internal structure of many Alcyonarian types—an ignorance that cannot be removed without specimens specially preserved for histological purposes. Wonderfully diagnostic as spicules often are, they have been used too confidently and liberally in the establishment not only of species, but of genera, and a secure natural classification of Alcyonarians is still far to seek. Moreover, in some of the forms which we have studied, *e.g.*, *Spongodes*, there is great specific variability both as regards spiculation and branching. As an astounding illustration of diversity of spiculation in a single species, we may refer to our description of the form which we have called *Echinogorgia multispinosa*, n. sp.

Before proceeding to the systematic report, we may call attention to a few facts of general interest :—

(*a*) Very striking is the frequent illustration of "convergence," *i.e.*, the occurrence of superficially similar forms which are not in reality nearly related. Thus, on one occasion, three similar bright red forms were collected in one haul and loosely bound together with thread. An examination of this small parcel disclosed three species belonging to separate genera—*Keroeides gracilis*, *Verrucella rubra*, n. sp., and *Telesto rubra*. Equally marked is the resemblance between *Echinomuricea indo-malaccensis*, RIDLEY, and *Echinogorgia pseudosasappo*, KÖLLIKER, to which RIDLEY calls attention (1883, p. 235), and many other examples might be given.

(*b*) We have compared the Ceylon collection with two others entrusted to us, one made in the Indian Ocean by Major A. ALCOCK, F.R.S., the other made at Zanzibar by Mr. CYRIL CROSSLAND, M.A., and we find that the three collections have extremely little in common. This is mainly because ALCOCK'S collection was from deep water, and CROSSLAND'S chiefly from close in-shore, but it may also indicate that many Alcyonarians have a restricted local distribution. There is also a great difference between the collection here discussed and those made off the Maldives by Mr. GARDINER, and off New Britain, New Guinea, &c., by Dr. WILLEY. It may be of interest to note that three Alcyonarians brought from Patani (Siam) by Mr. NELSON ANNANDALE and Mr. H. C. ROBINSON are unrepresented in HERDMAN'S collection (though included in this report), viz., *Telesto trichostemma*, *Astromuricea ramosa*, n. sp., and *Juncella trilineata*, n. sp.

(*c*) Some of the distributional facts, on the other hand, point in a different direction, showing that species occur in Ceylonese waters which enjoy a wide range elsewhere. Thus the exceedingly beautiful *Primnoa ellisii* is known from the

Mediterranean and from off the Andaman Islands, and *Gorgonia capensis* is known from the Cape and further south. In many respects the Ceylonese Alcyonarian fauna is, *as regards genera*, remarkably cosmopolitan. Few naturalists, however, have contrived to collect so exhaustively as Professor HERDMAN did in his Ceylon expedition.

(*d*) There is in some species great variability in colour, in mode of branching, in dimensions of spicules, and in the proportionate numbers of different forms of spicules. In illustration we may refer to *Spongodes pulchra*, n. sp., *Spongodes bicolor*, WRIGHT and STUDER, *Chironephthya variabilis*, HICKSON, *Bebryce hicksoni*, n. sp., *Verrucella flexuosa*, RIDLEY. In many cases we have given details in regard to these variations, partly as a contribution to the data of variability in general, and partly to facilitate a future revision of species. It can hardly be doubted that many of the Alcyonarian species, *e.g.*, of *Xenia*, *Spongodes*, *Scirpearella*, *Juncella*, and *Verrucella*, are in a state of evolutionary flux, and yet it is at present difficult to reduce the number of species. As we have had numerous specimens of many of the apparently most variable forms, we have not felt justified in regarding these as instances of merely individual variation.

(*e*) As a simple illustration of the way in which even these Alcyonarians may interact with the life of such animals as pearl oysters, we may refer to *Clavularia margaritiferæ*, n. sp., which spreads on the pearl oyster shell, and to the occurrence of young pearl oysters attached to Alcyonarians, *e.g.*, to the branches of *Heterogorgia* sp. Not a few specimens, *e.g.*, *Nephthya lobulifera*, were found attached to dead pearl oyster shells.

(*f*) We have had the pleasure of confirming in *Gorgonia capensis* Professor S. J. HICKSON'S interesting discovery of viviparity.

It may be convenient to place here a classified list of the species reported on :—

ALCYONARIA (EXCLUDING MOST OF THE ALCYONIIDÆ).

ORDER I.: STOLONIFERA.

FAMILY: Clavulariidæ.

FAMILY: Veretillidæ.

Cavernularia obesa, VALENCIENNES.
**Stylobelemnoides herdmani*, n. gen. et sp.

* The forms with an asterisk are reported as new.

DESCRIPTION OF THE SPECIES.

ORDER I.: STOLONIFERA.

FAMILY: CORNULARIIDÆ.

Clavularia margaritiferæ, n. sp.—Plate III., fig. 8.

The stolon consists of a number of thin and narrow branching threads, forming a network on the surface of a pearl-oyster shell. The strands of the stolon vary in breadth from 0·4 millim. to 0·6 millim. They do not form any membranous expansion. The polyps arise vertically from the branches of the stolon at intervals of 2 millims. to 2·5 millims.; there does not seem to be any interpolation of new polyps among the older.

The polyps measure 3 millims. in height, with a distal diameter of 0·9 millim., and a proximal of 0·5 millim. to 0·65 millim. They are thus broader than the stolon branches, *cf. Clavularia reptans*, HICKSON (1895). They have, in all cases, their crowns retracted; there is no indication of longitudinal grooves or lines.

The walls of the polyps and of the stolons show thickly crowded spicules of minute size (0·06 millim. to 0·07 millim. × 0·03 millim. to 0·04 millim.) interlocked by their wart-like projections, *cf. Clavularia flava*, HICKSON (1895). Most of the spicules are substantial rods bearing blunt wart-like projections often in a whorl of four towards each end. The short and simple tentacles, bearing a few blunt pinnules (not sufficiently fixed to allow of precise examination) are supported by numerous longitudinally disposed elongated and curved rods, which may measure 0·1 millim. in length. They are smooth and only occasionally bear projections. All the spicules are colourless, and the whole colony is white in its preserved condition.

Locality:—Pearl banks, Gulf of Manaar.

FAMILY: XENIIDÆ.

Xenia ternatana, SCHENCK.

A single specimen attached to a sandy worm-tube, with polyps in three groups, agrees on the whole with *Xenia ternatana*, SCHENCK, notably in having only two rows of pinnules on each side of the tentacles, and about 18 slender pinnules in each row, as also in the measurements of the polyp-body and of the tentacles.

Xenia umbellata, SAV.

Attached to the substratum of another specimen, which we unfortunately omitted to note in the business of assortment, there was a species of *Xenia* which appears to be referable to *X. umbellata*. The locality was low water at Pamban. We assume that the presence of only two species of *Xenia* in the collection simply means that Professor HERDMAN'S work was outside the *Xenia*-zone. There must be many species of *Xenia* in Ceylon.

ORDER II.: ALCYONACEA.*

FAMILY: ALCYONIIDÆ.

The genera *Sarcophytum*, *Sclerophytum*, *Lobophytum*, and *Alcyonium* are discussed in Miss PRATT'S Report, this volume, p. 247. There has been left to us to describe what seems to be a new species of the little-known genus *Bellonella*.

Bellonella indica, n. sp.—Plate VI., fig. 5.

A small cylindrical specimen of a crimson-vermilion colour with yellow calyces and white polyps. It is attached to a fragment of rock and stands 24 millims. in height, with a basal diameter of 10 millims. and an apical diameter of 6 millims. The lower half is a sterile trunk, the upper half bears crowded polyps, whose white colour contrasts well with the red of the general cœnenchyma and the rich yellow of the calyces. Many of the calyces measure 1 millim. in diameter, and the interval between them is often the same. Smaller forms occur among the larger, but there is no evidence of dimorphism of zooids. The margin of the calyx is neatly 8-lobed, and here and there the white polyps are expanded. The tentacles, which seem to run somewhat markedly to a triangular point, bear on each side about 18 finger-like pinnules. A longitudinal cut shows the large longitudinal canals traversing the bright red cœnenchyma, and the eight longitudinal strands in each canal stand out sharply as bright white lines.

The spicules of the cœnenchyma are of an orange-red to yellowish colour, mostly like knobbed capstans, or double clubs with large warty heads, or double wheels with a very slight constriction between them. They form a granular pavement over the surface and densely fill the cœnenchyma. In the sterile trunk there seem to be no double clubs in the strict sense; the form is more like a knobbed dumb-bell with an exceedingly slight and short constriction in the middle. In all cases the warts are few, large, and blunt. The spicules are thus unlike the fusiform echinate forms reported as characteristic of *Bellonella*, but the genus has not been well defined, and it may be noted that two isolated polyps showed a few colourless or faintly yellowish fusiform spicules with a few thorns. It is not certain, however, that these belonged to the polyp; they may have been artificial inclusions.

The following measurements of the typical spicules were taken, length and breadth, in millimetres:—

0·08 × 0·06 (0·04 at middle); 0·06 × 0·06 (0·04 at middle); 0·06 × 0·045; 0·06 × 0·04; 0·05 × 0·04 (0·03 at the middle); 0·045 × 0·0375 (0·025 at the middle).

The specimen is very different from *Bellonella* (*Cereopsis*) *bocagei*, SAV. KENT, and *B. variabilis*, STUDER, but neither of these agrees conspicuously well with GRAY'S

* Exclusive of the Alcyoniidæ described by Miss PRATT (this vol., p. 247).

original definition. GRAY's description of *Bellonella granulatum* ('Proc. Zool. Soc.,' 1862, p. 35) is unfortunately short and vague. He speaks of the "angular tips" of the calyces; he figures longitudinal furrows on the stem, and these features are here absent. It seems better, therefore, to start afresh with a new species.

Locality :—Deep water south of Galle.

FAMILY: NEPHTHYIDÆ.

SUB-FAMILY: SPONGODINÆ.

Nephthya chabrolii, AUD., var. **ceylonensis**, n.

To this species, known to include several varieties (KÜKENTHAL, 1903, p. 157), we refer a specimen which differs from ordinary forms of *N. chabrolii* in being dull greyish-white, and in having a "Stützbündel" spicule projecting beyond the polyp for 0·5 millim. The following comparison with KÜKENTHAL's description of *N. chabrolii* may serve to illustrate dimensional variability.

	Polyp.		Polyp spicules.		Stem spicules.	
	Length.	Breadth.	Length.	Breadth.	Length.	Breadth.
	millims.	millims.	millims.	millims.	millims.	millims.
KÜKENTHAL's measurements.	0·5 to 0·7	0·5 to 0·7	0·08 to 0·45	0·015 to 0·06	1·1 to 1·9	0·12 to 0·26
HERDMAN's specimen . . .	0·6 ,, 0·7	0·6 ,, 0·65	0·15 ,, 0·35	0·02 ,, 0·06	0·65,, 2	0·16 ,, 0·26

For description, see HOLM (1895).

Locality :—Pearl banks, Gulf of Manaar, March, 1902, and DONNAN's Paar.

Nephthya lobulifera, HOLM.

From an elongated base attached to an oyster shell there rise 7 main branches apparently flaccid in character, bearing numerous lobes of unequal size and variable arrangement. On these the polyps occur in groups often united by a few individuals scattered in the intervening spaces. The polyps are light yellow and stand out prominently against the general white colour of the colony. They measure 0·7 millim. to 1·3 millims. in length. The "Stützbündel" spicules are strong, slightly curved, warty spindles up to 1·9 millims. in length; the three longest project beyond the polyp. The polyp spicules measure 0·06 millim. to 0·25 millim., and the stem spicules 1·1 millims. to 1·95 millims. in length. For description, see HOLM (1895).

Locality :—1½ miles off Old Dutch Modragam Paar, Gulf of Manaar.

Nephthya ceylonensis, n. sp.—Plate I., fig. 4.

A small rigid colony fixed to a stone rises to a height of 38 millims., giving off three lobes crowded with polyps. The general colour of the lower part of the stem is greyish-white, but in the region of the polyps the colour is light violet, and the polyps themselves are canary-yellow. The lower part of the stem has a stiff leathery character and a granular appearance; the upper part is entirely covered with large spicules which are for the most part disposed longitudinally.

The polyps occur in small almost contiguous groups or singly. Each is an elongated cylinder, standing at right angles to the "Stützbündel," measuring 1·2 millims. in length by 0·8 millim. in breadth.

The spicules of the lower part of the stem consist of short thick spindles (1·1 millims. to 1·4 millims. in length by 0·1 millim. to 0·2 millim. in breadth), sometimes bifurcate or trifurcate at one end, and also of triradiate and quadriradiate forms. All exhibit numerous blunt warts.

In the upper part the spicules are spindle-shaped, covered with numerous spines, and tinged with violet. Some of them are forked at one end, and a few give off a short branch about the middle of their length. They vary in length from 1·1 millims. to 2·4 millims., and in breadth from 0·1 millim. to 0·18 millim. Those of the "Stützbündel" measure 1·55 millims. to 1·8 millims. There is only a slight projection beyond the polyp.

The polyp spicules are very small, deeply tinged with yellow, measuring 0·4 millim. by 0·08 millim.

Eunephthya purpurea, n. sp.—Plate I., fig. 3; Plate V., fig. 5.

This species is represented by several specimens which present a striking appearance owing to the contrast between the yellow polyps and the purple-red of the stem and branches. The stem is large and flaccid, and gives off numerous small branches and twigs. The superficial cœnenchyma is rough, and has a granular appearance due to the arrangement of the numerous small spicules. The twigs, however, have a different appearance, for there the spicules are longer and are mainly disposed transversely. Two good specimens measured in centimetres,—11 × 7 and 12 × 3.

The spicules of the lower part of the stem are very short, irregularly branched rods with prominent spines. They measure 0·1 millim. in length by 0·08 millim. in width. The spicules of the twigs and the tip of the stem are slender spindles, varying in length from 0·23 millim. to 0·25 millim. and in breadth from 0·02 millim. to 0·023 millim.

The polyps are scattered over the stem and branches, occurring either singly or in small groups. They are yellow in colour, and they contrast well with the red colour of the twigs and branches. The length of the polyps is 0·9 millim. to 1 millim. and the width varies from 0·5 millim. to 0·6 millim. The polyp spicules are very small yellow spindles with prominent warts and spines. Their measurements are 0·14 millim. to 0·3 millim. in length and 0·015 millim. to 0·03 millim. in breadth. Below the anthocodial part of the polyp there is a collar formed of several rings of spicules, red in colour, which measure from 0·5 millim. to 0·7 millim. in length by 0·04 millim. to 0·06 millim. in breadth.

Localities :—Pearl banks off Aripu, Gulf of Manaar; and deep water off Galle.

Paraspongodes striata, n. sp.—Plate II., figs. 2 and 7.

A specimen without "Stützbündel," with no spicules in the canal walls, and polyps disposed in well-defined bundles must be referred to the genus *Paraspongodes* (see Kükenthal, 1896).

The colony studied stands 67 millims. high by 49 millims. in maximum breadth; the general colour is whitish. A short substantial stem gives off three main branches which divide and re-divide, so that the appearance of an irregular corymb of umbels results. The average length of a terminal branch is 4 millims. The polyps occur in bundles of 6 to 7, and these bundles are grouped to form an umbel. A much finer specimen, which was left at Liverpool, measured 22 centims. in height, 11 centims. before the first branching, and 4 centims. across at the base.

The superficial cœnenchyma of the branches is deeply striated transversely, we may almost say ringed, and is tough in character; on the main stem the surface is irregularly wrinkled and rough in texture.

The polyps vary in length from 1·1 millims. to 2·3 millims., and in breadth from 0·65 millim. to 0·9 millim. They are supported by spindle-shaped spicules uniformly disposed in contiguous longitudinal rows, and measuring 0·18 millim. to 0·6 millim. in length by 0·04 millim. to 0·06 millim. in breadth. The tentacles measure 0·6 millim. in length, and two or three pairs of plump pinnules are visible.

In the cœnenchyma the spicules are minute but very numerous. They occur as rough spindles or rods irregularly branched, and also as what may be called irregular stars. They vary in length from 0·09 millim. to 0·16 millim., and in breadth from 0·03 millim. to 0·06 millim.

Locality :—Deep water outside pearl banks, Gulf of Manaar.

Another larger specimen, 169 millims. in length by 69 millims. in maximum breadth, from the same locality seemed at first different.

It had a relatively much longer stalk with basal rhizoid branches; it showed greater transparency of texture, less abundant superficial spicules, less marked transverse wrinkling, and a larger number (7 to 11) of polyps in each bundle. Closer examination showed essential agreement as to spicules, polyps, tentacles, &c. The measurements for this specimen show considerable variation, as the following table indicates :—

Polyps.		Polyp spicules.	
Length.	Breadth.	Length.	Breadth.
millims.	millims.	millims.	millims.
1·2	0·8	0·6 0·63	0·05 0·05
1·3	0·85	0·7	0·05
0·9	0·7	1·0 0·9	0·10 0·08
1·0	0·8	0·25 0·18	0·016 0·03

Capnella manaarensis, n. sp.—Plate II., fig. 4 ; Plate V., fig. 14.

A specimen without "Stützbündel," with numerous spicules in the canal walls, and with the polyps arranged not in bundles but in conical lobes or catkins, we refer to the genus *Capnella*, as reconstructed by KÜKENTHAL (1902).

The colony is fairly rigid and stands 79 millims. high by 75 millims. in maximum breadth. The general colour is a greyish-white or a dirty white. A short stem gives off several main branches, which in their ultimate divisions give rise to polyp-bearing lobes or catkins.

The superficial cœnenchyma of the branches and the main stem is rough in texture and has a stringy appearance owing to the arrangement of the spicules.

The polyps have an average length of 0·95 millim. by an average breadth ot 0·65 millim. They are supported by spindle-shaped spicules which are arranged longitudinally, and vary in length from 0·29 millim. to 0·55 millim. and in breadth from 0·04 millim. to 0·08 millim.

In the cœnenchyma the spicules are spiny spindles. They are usually straight or curved, but several show a bifurcation at one end, or give off a short branch near their middle point. They show considerable variation in size, measuring from 0·5 millim. to 1·35 millims. in length and 0·10 millim. to 0·16 millim. in breadth.

Locality :—Pearl banks off Aripu, Gulf of Manaar.

Spongodes pulchra, n. sp.*—Plate I., fig. 5 ; Plate V., fig. 10.

This species is represented by many specimens, 3 of which give the following measurements :—

* The third instalment of Professor W. KÜKENTHAL'S "Versuch einer Revision der Alcyonarien" ('Zool. Jahrb.,' xxxi., 1905, pp. 503–726, 7 pls., and 61 figs.) appeared while this report was being passed for press, and it could not be utilised. He splits the old genus *Spongodes*, with which one is loth to part, into the two new genera *Dendronephthya* and *Stereonephthya*, with 90 species to the former and 8 species to the latter. Everyone will welcome KÜKENTHAL'S important contribution to the study of a difficult and polymorphic genus, but what is gained by trying to do away with the old title *Spongodes*, which is practically equivalent to *Dendronephthya*, just as *Spongodia* is to *Stereonephthya?* KÜKENTHAL has studied

	(A.)	(B.)	(C).
Total height	66 millims.	66 millims.	36 millims.
Length of trunk	14 ,,	13 ,,	9 ,,
,, ,, head	52 ,,	53 ,,	27 ,,
Maximum width of same .	39 ,,	43 ,,	21 ,,

The trunk or bare part of the stem is granular in appearance and leathery in texture. In (B.) and (C.) it is greatly wrinkled, owing to the large canals and the weak partition walls between.

The branching is very profuse, the stem giving off a large number of primary branches which break up into secondaries, and these in their turn into the twigs bearing the polyps. The twigs or tertiary branches bear the polyps in corymb-fashion, so that they all reach the same level, and owing to the large number of the polyps the stem and branches are completely hidden.

The polyps are arranged in groups of 4 to 6, and they in their turn are aggregated into larger bundles. They are red, with markedly white tentacles. Although some of the spicules close to the polyps become a little stronger, none of them project, so that the colony has not the slightest appearance of being spiny.

The surface of the stem is rough to the touch and has a granular appearance. In the primary and secondary branches, however, the spicules appear more prominently and give the surface an irregular stringy appearance, and finally they take an almost longitudinal arrangement in the twigs.

In (A.) the stem, primary and secondary branches are almost white, while in (B.) and (C.) they are yellow. In (A.) the twigs are white, but become pinkish below the polyps, while in (B.) and (C.) they are yellowish, but also become pink below the polyps. Thus there is considerable colour-variation.

The spicules of the trunk are very short and furnished with long spines. They are very varied in shape—short rod-like bodies, 3-rayed stars, and irregular crosses. In all, however, the spines are well developed. They measure, length by breadth, in millimetres, as follows :—$0{\cdot}15 \times 0{\cdot}1$; $0{\cdot}2 \times 0{\cdot}05$; $0{\cdot}20 \times 0{\cdot}1$; $0{\cdot}5 \times 0{\cdot}15$. All these measurements include the spines, which often measure $0{\cdot}04 \times 0{\cdot}02$; $0{\cdot}03 \times 0{\cdot}02$; and $0{\cdot}045 \times 0{\cdot}01$.

The spicules of the stem and branches are long slender spindles, usually curved or bent and covered by fairly prominent spines. They measure, length by breadth, in

213 specimens in all, but in many cases he only studied one (32) or two (21). He makes 30 new species, some of which may correspond to those here described as new, though we have not been able as yet to satisfy ourselves as to any identity. We venture to predict, however, that further study of this prolific genus, whether it be called *Spongodes* or *Dendronephthya*, with say ten specimens of each species, will *increase* the number of quite distinct species, and will *lessen* the number of closely adjacent species, reducing them to varietal forms. Even on a single colony there is often great diversity, and the impression of great lability is increased when we compare different specimens of the same species collected on the same date from the same locality.—J. A. T.

millimetres, as follows:—1·05 × 0·56; 0·55 × 0·06; 0·73 × 0·04; and 0·47 × 0·05. The longest reach a length of 1·7 millims., 1·6 millims., and 1·5 millims.

The specimens differ markedly from all the previously described species of this large and difficult genus.

Locality:—Station LXVI., off Mutwal Island, 10 to 35 fathoms; Cheval Paar, Gulf of Manaar.

Spongodes bicolor, WRIGHT and STUDER.

This species is represented by a fairly large complete colony, which consists of a short trunk and a long head, formed by a large number of branches given off on all sides. The base is formed of numerous rhizoid-like offshoots, which are attached to grains of sand, to sponge spicules, and to particles of shells.

The stem is soft and flaccid, and gives off flabby branches on all sides. The majority of the lower branches are flattened, the flattening taking place not from above downwards but from side to side.

The stem and branches have thin semi-transparent walls with numerous fine spicules scattered all over, some of them projecting so as to give the surface a pubescent appearance. The measurements of the polyps and of the spicules agree with those given by WRIGHT and STUDER (1889).

Locality:—Deep water off Galle.

Spongodes bicolor, WRIGHT and STUDER, var. **ceylonensis,** n.

The trunk of this specimen is very short, and does not seem to be distinctly marked off from the stem except in the spiculation.

Small branches are found coming off to within a few millimetres of the lower end of the trunk. The spicules are more distinct in the stem and give a net-like appearance to its surface, while the surface of the trunk is granular.

Two of the lower branches are flattened from above downwards and nearly surround the stem, but just below the two spaces left between them there are two ordinary branches.

The polyps are red, with white tentacles, and a "Stützbündel" spicule projects behind each polyp.

The colour of the trunk, stem, and branches is a yellowish-white, that of the polyps and twigs being red; the lower part of the twig may be yellowish.

This form differs from *Spongodes bicolor* in several respects, but yet comes very near it.

Spongodes bicolor, WRIGHT and STUDER, var. **dubia,** n.—Plate V., fig. 13.

Another variety is represented by a specimen measuring 71 millims. in height and 61 millims. in maximum breadth. It may be a portion of a larger colony or an entire colony in which the base is wanting.

The stem is flaccid and gives off branches almost to the base, the lower branches are flattened and give off ordinary branches from their upper surfaces.

The polyps are arranged in umbels of 10 to 13 polyps. The polyps are white, but have a red appearance, owing to the spicules; the tentacles have white or colourless spicules.

The spicules of the stem are long, slender, colourless spindles covered with spines, and varying in length from 1·55 millims. to 0·6 millim., and in width from 0·12 millim. to 0·08 millim. The spicules of the terminal twigs and polyps are slender spindles, yellowish-red in colour and thickly beset with spines. They vary in length from 0·1 millim. to 1·65 millims., and in breadth from 0·02 millim. to 0·09 millim.

As this form agrees in many respects with *Spongodes bicolor*, we have ranked it provisionally as a variety.

Spongodes aurantiaca, n. sp.—Plate I., fig. 9; Plate V., fig. 6.

In this species the trunk is long, stiff, leathery in character, and granular in appearance, but the individual spicules become evident at the upper end.

The stem is divided into two main branches, from which the primary and secondary branches arise. The four lowest branches are flattened from above downwards, and so form a complete collar to the trunk. They are also recurved, so that they hide the upper part of the trunk. Their edges are very much divided, and they carry the polyps singly on the edges. From their upper surface spring ordinary branches. The other branches stand at right angles to the stem, but the upper ones are directed obliquely upwards.

The polyps are borne singly at the ends of the twigs, and also in bundles of 6 to 7, all reaching the same level. They are white in colour and backed by strong "Stützbündel" spicules.

The colony presents a striking appearance, due to the marked contrast between the orange-coloured stem and branches and the white polyps. The trunk is orange-coloured at the upper end, but it gradually becomes a whitish-grey as the lower end is reached.

The "Stützbündel" spicules vary in length from 2·7 millims. to 3·3 millims., while the stem and branch spicules vary from 0·5 millim. to 2·1 millims. in length.

Spongodes rosea, Kükenthal—Plate V., fig. 1.

What we regard as a variety of this species is represented by a stiff colony, with a bare stalk very much shrunken, owing to the large canals and the thin partitions between them. Height of colony, 70 millims.; length of stalk, 22 millims.; diameter of same, 11 millims.

The lower branches, 6 in number, are flattened from above downwards, breaking up at their edges into single polyps and groups of polyps, and giving off cylindrical branches from their upper surfaces. Immediately above these the stem gives off a large branch which repeats the structure of the stem. Over the whole surface of stem and branches smaller branches are given off which also branch.

The colour of the stem is greyish-white below, white above, while the smaller branches are orange-coloured. The polyp-cups are a dark purple-red, the tentacles white.

The surface texture of the specimen presents two quite different aspects. On the bare stalk the surface has a granular appearance caused by the large number of very small closely packed spicules which grow larger as the upper part of the stalk is reached. On the branch-bearing part, and also on the branches, a stringy appearance is produced by the larger spicules.

The polyps occur in bundles of 4 to 8. The projecting spicules are usually red throughout, but sometimes the lower part is yellow. The spicules are as follows:—

(*a.*) *Of polyps and terminal twigs.*—Yellow, or red, or partly yellow, partly red, covered by numerous small spines; Stützbündel, 2·6 millims. × 0·17 millim.; polyp spicules, 0·03 millim. × 0·04 millim.; others, 1·5 millims. × 0·1 millim., 1·7 millims. × 0·12 millim.

(*b.*) Of the stem, upper part.—Similar to those of (*a.*), but the majority are colourless, or very faintly tinged with yellow. Spines more prominent and appear rougher.

(*c.*) Of the bare lower part of stem.—Shorter, thicker, and with more prominent spines than (*a.*) and (*b.*). Spines more numerous and of greater diameter than the above. The spicules of (*c.*) measure 0·76 millim. to 0·69 millim. × 0·16 millim., 0·42 millim. × 0·18 millim., 0·26 millim. × 0·10 millim. Many of the spicules in (*c.*) are in the form of crosses. In several an X-shaped marking is seen as if the 4 arms of the cross were dovetailed into one another.

Another specimen similar in appearance to the above has its branching *restricted to one plane.*

In its texture and flattened branches, &c., it agrees with the above. The tentacles are white, but owing to their state of retraction they do not show so much. The base of attachment shows the rhizoid outgrowths frequent in *Spongodes* and allied genera.

While these specimens do not rigidly correspond to the description given of *Spongodes rosea*, the resemblance is too close to warrant separation.

Localities:—Deep water outside pearl banks, Gulf of Manaar; and Trincomalee.

Spongodes armata, HOLM, var. **ceylonensis,** n.—Plate I., fig. 6.

This foliate divaricate colony consists of a cylindrical barren trunk, attached at its base by means of rhizoid outgrowths to sand and fragments of Mussel shells, and a much branched upper portion which forms an irregularly oval-shaped head. Everywhere spicules project, thus giving a spiny appearance to the head portion. The little violet coloured polyp heads contrast well with the orange coloured twigs.

	Specimen A.	Specimen B.
Length of trunk (bare part of stem) .	21 millims.	32 millims.
Diameter of same	10 ,,	13 ,,
Length of head	52 ,,	55 ,,
Maximum width of same	32 ,,	41 ,,

The trunk (or bare part of the stem) has a leathery rigid character and a rough granular appearance. It is slightly thicker at the top, and at its lower end gives off thin rhizoid-like outgrowths. In specimen B these are also given off for a short distance up the trunk.

The stem gives off larger and smaller branches, and divides at the tip into 2 or 3 branches. It appears longitudinally streaked, owing to the disposition of the large spicules. The lower branches are flattened (6 in one, 4 in the other). The others rise at right angles to the stem, the upper ones being directed obliquely upwards. Some of the lower ordinary branches are slightly flattened. The 4 to 6 flat branches are recurved and directed downwards.

Locality :—Deep water off Galle.

Spongodes dendrophyta, Wright and Studer.

This species is represented by several specimens, one of which is evidently a young form. The base of attachment consists of rhizoid-like outgrowths. The lowest branches are flattened from above downwards, and bear the polyps on the edge of the flattened portion. The appearance of the stem in the older specimens is quite granular, but this gives place in the younger form to a slightly stringy appearance, due to the spicules being larger. In the older specimens the polyps are more markedly arranged in bundles, while they have a tendency to stand singly in the younger. Several of the lower branches are colourless, and there is a great variability in the colour of the spicules.

The geographical range of this species is worthy of note, as its previous record is from the Philippines.

Locality :—Gulf of Manaar.

Spongodes splendens, Kükenthal—Plate I., fig. 2.

This species is represented by numerous stiff and rigid colonies. The following measurements are taken from two of them :—

	A.	B.
Length of trunk	29·5 millims.	17 millims.
Diameter of same	13·5 ,,	12 ,,
Length of head	69 ,,	30 ,,
Maximum width of same	61 ,,	40 ,,

The stem in its lower portion is tough and rigid in character and granular in appearance, which in the upper portion gives place to a streaked appearance due to the larger spicules being disposed for the most part longitudinally.

The lowest branches, two in number, are flattened from above downwards, and are bent downwards so as to hide the upper portion of the trunk. The other branches are more or less cylindrical and rise at right angles to the stem, the uppermost being directed obliquely upwards. The secondary branches give rise to the twigs which bear umbels of 6 to 8 divergent stipitate polyps.

The lower portion of the stem has a yellowish-white colour, the upper portion of the stem and the branches are yellow, while part of the twigs and the polyp spicules are brick red to dull red in colour. Several of the spicules consist of a colourless sheath surrounding a central core of a deep yellow to orange-yellow which extends for about half the length of the spicule.

The spicules vary very much in the specimens. The "Stützbündel" spicules vary in length from 2·9 millims. in some to 2·2 millims. in others, and even to 1·5 millims. The stem spicules vary from 0·75 millim. to 2·3 millims. in length, but in one specimen they reach 4·5 millims. in length. The polyp spicules also show considerable variation, but it does not cover such a range as in the others.

Some other specimens correspond more closely than the above do to previous descriptions of this species. It appears to us that many of the species of *Spongodes* are exceedingly variable, and we have therefore refrained from accentuating minor differences.

Locality :—Cheval Paar ; pearl banks, Gulf of Manaar.

SUB-FAMILY : SIPHONOGORGINÆ.

Paranephthya pratti, n. sp.—Plate II., fig. 6 ; Plate V., fig. 18.

A peculiar specimen with only the basal attachment missing was included in the collection. We are indebted to Miss PRATT for a figure and the following notes.

The colony, which is apparently young, is small and measures as follows :—

Height 21 millims. ; stalk 15 millims.

Breadth of stalk, 13 millims. to 11 millims., of capitulum, 24 millims. to 20 millims.

The capitulum is lobate, with deep grooves between the digitate lobes.

The lobes (7 in number) are digitate and are comparatively large. The largest is 13 millims. in height by 7 millims. to 5 millims. in diameter. The smallest is 3 millims. in height by 5 millims. to 4 millims. in breadth. Some of the lobes are beginning to branch dichotomously.

The capitula are dotted with minute tubercles, and when observed under the microscope have a curious polyzoon-like appearance. These tubercles indicate the presence of the zooids which are small, degenerate in character, and are so overgrown with minute spicules as to be only slightly contractile. They have apparently only rudiments of tentacles. The mesenteries are crowded with brown cells which are probably zoochlorellæ. In many cases there appears to be no aperture to the exterior.

The colony is extremely hard, the surface being rough and granular to the touch. The colour of the spirit specimen is medium brownish-grey, which becomes deeper towards the base of the stalk.

There is no doubt that this interesting form is near *Paranephthya capitulifera*, WRIGHT and STUDER; but it is a quite distinct species.

Chironephthya variabilis, HICKSON.

This species is represented by a magnificent specimen, measuring 21 centims. by 20 centims. The base measures 3·5 centims. by 4 centims. There is a very marked "weeping willow" appearance, as almost all the twigs are pointing downwards. This is probably the finest specimen of its kind that has been hitherto obtained. There are also numerous fragments, and one or two specimens which may be complete young forms.

The colour is very variable in the different specimens and even in the different parts of the same specimen. In several fragments the general cœnenchyma is white with red spots here and there on the surface; in others it is yellowish-white with red spots. When the general cœnenchyma is white in colour, a pinkish tinge becomes gradually more marked in the branches until it finally predominates, thus giving the tips of the branches and twigs a deep pinkish-red colour. In the specimens with a yellowish-white general cœnenchyma the pinkish tinge increases as before, but in this case the tips of the branches have an orange colour. In other cases the tips of the branches may be pinkish-red with the projecting edges of the calyces an orange-yellow.

There is also great variation in the colour of the polyp spicules; in some the spicules of the crown and points are red, in others they are yellow, while in others the crown spicules are red and the point spicules orange-yellow. Considerable variation is also found in the measurements of the crown and the point spicules; so great is the range of variation, in fact, that they do not appear to be of any value as a specific distinction. The crown spicules vary in one specimen from 0·24 millim. to 0·5 millim. in length, and the point spicules from 0·3 millim. to 0·55 millim. in length, while in the same specimen the breadth of the crown spicules varies from 0·026 millim. to 0·06 millim.

Locality:—Deep water off Galle; Pearl banks, Gulf of Manaar.

Siphonogorgia pustulosa, WRIGHT and STUDER.

Locality:—Ceylon seas.

Siphonogorgia miniacea, KÜKENTHAL.

Locality:—Ceylon seas.

Siphonogorgia köllikeri, Wright and Studer—Plate I., fig. 7.

Locality :—Deep water off Galle.

In the examination of the specimens in the collection belonging to the genera *Chironephthya* and *Siphonogorgia* the following distinction suggested by Hickson (" Fauna of Maldives, 1900 ") has been adopted : "That the name *Chironephthya* be retained for the species or facies with a form and mode of branching resembling that of the genus *Nephthya*, with anthocodiæ rarely completely retracted in preserved specimens and with four principal spicules arranged *en chevron* in the points of the anthocodiæ ; and that the name *Siphonogorgia* be retained for species or facies of more massive *Gorgonia*-like form of growth, with anthocodiæ capable of complete retraction within the general cœnenchym and with spicules irregularly placed or arranged in a *fan-like* manner in the points of the anthocodiæ." While adopting this suggestion we have been impressed by the great similarity of the two genera. There are many reasons for thinking that they ought to be merged in one.

Order III. : PSEUDAXONIA.

Family : BRIAREIDÆ.

Solenocaulon tortuosum, Gray.

The collection includes magnificent specimens of a brilliant red *Solenocaulon*, probably a variety of *S. tortuosum*. We have studied a representative piece about 8 inches in length.

The substantial axis, measuring 5 millims. in diameter at the base of the specimen, is composed of closely packed colourless spinose needles, all of the same type, varying from 0·4 millim. to 1 millim. in length by 0·016 millim. to 0·018 millim. in breadth, and thus much longer than those measured by Hickson. When boiled with caustic potash the axis remains coherent, but crumbles readily. In a section 20 nutritive canals are seen between the cœnenchyma and the axis across the base of the specimen. Towards the top of the stem the axis gradually decreases in size and finally disappears. The rest of the stem forms a continuous tube with large lateral openings, the margins of which are prolonged into the slender polyp-bearing branches. These are mainly directed away from the side bearing the axis ; they often measure 17 millims. in length by 2 millims. in breadth.

The cœnenchyma of the tubular stem contains (*a.*) colourless needles from 0·4 millim. to 0·7 millim. in length by 0·018 millim. in width, with few and short spines ; (*b.*) shorter and broader rods (0·28 millim. to 0·4 millim. in length by 0·06 millim. to 0·07 millim. in width), both coloured and colourless, thickly beset with rough wart-like projections ; and (*c.*) coloured somewhat irregular ovals (0·1 millim. to 0·12 millim. by 0·06 millim. to 0·07 millim.), covered with blunt tubercles. The coloured spicules are pale yellowish-red ; and an orange variety occurs among the other brilliant red specimens.

The polyps are white, and are for the most part restricted to the twigs. A few occur on the stem on the side away from the axis. The polyp-spicules are arranged in a crown with slightly projecting triangular points. Each point consists of about 7 spicules, the longest median one being supported by three on each side. Below these running transversely are the rows of crown spicules. All the spicules are colourless warty spindles, varying in length from 0·2 millim. to 0·6 millim., and in breadth from 0·02 millim. to 0·08 millim. The verrucæ are truncated cones, with a height of 1 millim. to 2 millims., and a basal diameter of 2 millims. A small crab was found in the lumen of the tubular stem.

Localities :—Station LIX., 6 to 9 fathoms ; deep water outside banks, Gulf of Manaar ; Periya Paar, 9 fathoms ; deep water off Galle.

Keröeides gracilis, WHITELEGGE.

This species is represented by a complete colony and several fragments. The complete specimen stands 85 millims. in height, with a maximum width of 56 millims. The verrucæ alternate on the sides of the stem and branches. They are low and conical in shape, 1 millim. in height and in basal diameter. The cœnenchyma is thin, smooth, and filled with large closely packed compound-tuberculated spicules.

The irregularity of the spicules is fairly well marked and agrees with WHITELEGGE'S description. By transmitted light they are of a bright red brick colour.

The spicules are on the whole slightly larger than those of WHITELEGGE'S specimen. The measurements obtained were :—(1) For the spindles, 1·4 millims. to 2·2 millims. in length by 0·2 millim. to 0·5 millim. in width ; (2) Irregularly shaped spicules of verrucæ up to 1·6 millims. in length by 0·5 millim. in width ; (3) Spicules of the axis from 0·3 millim. to 0·6 millim. in length.

With the exception of the slightly larger measurements of the spicules, the specimen approximates very closely to that described by WHITELEGGE (1897), and also to that described by Miss HILES (1899).

Locality :—Deep water off Galle, Ceylon.

Previously recorded from :—Milne Bay, British New Guinea, depth 20 fathoms, and Funafuti, Ellice Islands.

FAMILY : SCLEROGORGIDÆ.

Suberogorgia verriculata, ESPER.

Several incomplete specimens, mostly about 7 centims. by 5 centims., forming networks in one plane. One colony with its base complete has a height of 9 centims. In a portion measuring 5·5 centims. by 3·5 centims., there were 22 complete meshes and 11 incomplete meshes. The meshes differ widely in size, but 7 millims. by 5 millims. is a size which occurs very frequently. The average thickness of branch is 1·5 millims. The colour is brown or drab, and the general texture of the cœnenchyma is granular.

The verrucæ are thickly crowded and occur all round the branches. They project very slightly and have a diameter of 1 millim. They are often separated about 1 millim. from one another. The verruca is a truncated cone, in some cases like a widely open crater, in other cases with eight spiculated lobes projecting inwards like small sepals in an almost open bud. A low-power view shows that there are eight opercular coverings formed from spindle-shaped spicules.

Careful dissection of the included polyp, under low power, shows a cylindrical body with eight vertical external muscle-strands and with a low conical apex. Around the base of this apex there seems to be a ring of horizontally disposed spindles in two or three rows, and from this there arise the eight triangular converging opercular coverings, with spicules more or less at right angles to those of the basal ring. But the specimens were extremely brittle, and the gentlest touch of the dissecting needle almost invariably shivered the microscopic architecture.

The extremely calcareous sclerogorgic axis is densely packed with more or less spindle-like spicules embedded in the matrix of horny fibres. It varies from 1 millim. to 2 millims. in diameter.

The cœnenchyma spicules are mostly minute spindles with numerous regularly arranged blunt tubercles; a common measurement is 0·1 millim. to 0·125 millim. in length by about 0·025 millim. in maximum thickness. There are also minute warty double clubs or capstans, with a very short middle zone and broad disc-like ends; they measure about 0·025 millim. by 0·02 millim. Some of the spindles have very few tubercles.

We have given these details to supplement the previous descriptions of *Suberogorgia verriculata*, to which, we believe, these specimens must be referred.

Locality :—Deep water off Galle.

Another specimen is 281 millims. in height and 134 millims. in maximum breadth, but this does not represent the full size of the specimen, as a part has been broken off the main stem. The branching is confined to one plane, and there is a very complete anastomosis of the branches, thus giving rise to a fine reticulate fan-shaped colony. The chief branches rise at an acute angle and are directed upwards, and assume a position roughly parallel to the main stem. The tips of the branches are clavate.

The polyps come off from all sides of the stem and branches and appear to be spirally arranged in some parts. They are completely retractile, and in the specimen they are all withdrawn within the small verrucæ.

The spicules are small spindles with prominent rough warts, larger spindles and minute double wheels or capstans. The measurements length by breadth in millimetres are as follows :—

Capstans, 0·037 × 0·02 ; 0·035 × 0·02 ; 0·03 × 0·02.

Slender spindles with few warts, 0·09 × 0·018 ; 0·15 × 0·02 ; 0·10 × 0·03.

Other spindles, 0·10 × 0·03 ; 0·12 × 0·037 ; 0·16 × 0·045.

The axis measures 6·4 millims. in diameter at the base.

We were at first inclined to record this specimen as a new species of *Suberogorgia*, but further study has convinced us that it is only a variety of *S. verriculata*.

[*Note.*—FAMILY: CORALLIIDÆ. RIDLEY reported with some hesitation the alleged occurrence of a specimen of *Corallium rubrum* on the Ceylon shore. It is interesting, therefore, to record that Professor HERDMAN found in deep water (34 fathoms) off Galle a specimen which he named *Corallium* (?). It was scarlet in colour, with yellow polyps, and measured about an inch in length. The sketch in his note-book suggests a young specimen of the noble coral, but the unsatisfactory point is that the specimen has not been found in the collection.]

ORDER IV.: AXIFERA.

FAMILY: PRIMNOIDÆ.

Primnoa ellisii, VON KOCH.

This beautiful species is represented by two specimens, the larger of which measures 68 millims. in height by 39 millims. in maximum width. The specimens agree with the description given by VON KOCH (1890), and the measurements obtained are in *absolute* accord with those given by him.

The geographical distribution of the species is interesting, ranging as it does from the Mediterranean to the Andaman Isles. The exact localities from which it has been recorded are: The Gulf of Naples and the coast of Sardinia in the Mediterranean; deep water off Galle, Ceylon; and the Andaman Sea, 275 to 45 fathoms (ALCOCK'S "Investigator" Collection).

Acanthogorgia media, n. sp.—Plate II., fig. 8; Plate III., fig. 7.

The specimens are similar to *A. ridleyi* in mode of branching and in the arrangement of the polyps but they are like *A. muricata*, HILES, in the disposition of the spicules on the calyces. But they do not seem referable to either species, or to any other whose description is known to us. In the figure on Plate III. the gracefulness of the colony has been inadequately represented.

The dimensions of the polyps are as follows:—

Height	1·3 millims.	1·1 millims.	0·8 millim.
Diameter at base . .	0·95 millim.	0·95 millim.	0·7 ,,
,, ,, apex . .	0·8 ,,	0·8 ,,	0·6 ,,

The polyps and the cœnenchyma of the stem and its branches have many projecting spicules. Round the apex of the polyp a number of spicules project. The polyps are arranged in some parts opposite one another, in other parts spirally. The arrangement is complicated by the interpolation of smaller polyps between the older ones. The branching is irregular and not confined to one plane. On the whole, the branching is alternate. The distances between branches varies from 8 millims. to 2 millims., and even to 1 millim. The axis measures 0·35 millim. in its thickest part, is brownish-yellow in older, yellow in younger portions, and is chambered. The spicules are long slender spindles, with few warts, and tri- and quadri-radiate stars. Among the spicules a considerable number are seen with an abrupt bend and one arm long in comparison to the other (golf-club-like). In these there is a poor development of the warts, the long shaft being free from the warty protuberances for a considerable portion of its length, while the short head has a good number of rough warts.

The spicules measure, length by breadth, in millimetres :—

Projecting opercular spicules, 0·4 × 0·05 ; 0·45 × 0·04 ; 0·4 × 0·045.

Ordinary spindles, 0·5 × 0·036 ; 0·3 × 0·04 ; 0·6 × 0·045.

Quadri-radiate forms, 0·25 × 0·15 ; 0·25 × 0·02 ; arms about 0·1 millim. in length.

Tri-radiate forms, 0·3 × 0·25 ; the arms being about 0·12 millim. in length. Some apparently sex-radiate and quinque-radiate forms occur.

Locality :—Trincomalee.

Acanthogorgia muricata, Verrill, var. **indica**, n.—Plate IV., fig. 11.

As a variety under this species we rank a beautiful complete colony, which has a height of 78 millims. and a maximum width of 105 millims.

The basal attachment is a flat spreading portion from which the main stem rises.

The axis is dark brown in colour, fading to a light yellow in the younger part. It is covered with close set furrows at the base, and at that point has a diameter of 3 millims., but it becomes extremely thin at the ends of the branches. The branching is very profuse and is confined to one plane, but the type of branching gives the main stem a slightly zig-zag arrangement.

The calyces are densely crowded all round the stem and branches. They measure from 2·5 millims. to 3 millims. in height and have a basal diameter of 0·9 millim. and a width of 1·1 millims. to 1·2 millims. at the crown. At the free end of the calyces there are 8 projecting spicules. The cœnenchyma on the stem and branches is very thin.

The specimen comes near *Acanthogorgia spinosa*, but differs from it in having only 8 single projecting spicules, while *A. spinosa* has 8 groups of 2 or 3. The spicules also differ slightly. It agrees closely with *A. muricata* except for slight differences in the polyps and spicules. The species *A. muricata* illustrates wide distribution ; it has been previously recorded from Barbados and Funafuti. See Hiles (1899), p. 48.

Locality :—Trincomalee.

Acanthogorgia ceylonensis, n. sp.—Plate IV., fig. 6 ; Plate V., fig. 12.

This species is represented by one specimen which measures 55 millims. in maximum height and 30 millims. in maximum width. The branching is both alternate and opposite and is confined to one plane. The polyps are arranged in threes or in twos or in loose spirals. The verrucæ vary in height from 0·6 millim. to 0·7 millim. and are placed at intervals of about 1 millim. The spicules are arranged on the verrucæ in 8 rows *en chevron*. The figure (Plate IV., fig. 6) is unfortunate in exaggerating the thickness of the stem and branches.

The spicules are of two types: (1) spindles which vary in length from 0·5 millim. to 0·6 millim. and have an average diameter of 0·04 millim.; and (2) quadri-radiate forms which measure length by breadth in millimetres as follows: 0·08 × 0·06, 0·13 × 0·12, 0·14 × 0·12. We have been unable to refer this specimen to any of the described species.

Locality:—Trincomalee.

Astromuricea ramosa, n. sp.—Plate I., fig. 8; Plate V., fig. 17.

A beautiful deep crimson colony, 8 centims. in height by 4 centims. in maximum breadth, but lacking its basal portion. Most of the numerous branches spread out laterally, but a few project forwards and a few backwards. Most of the branches arise at an acute angle and rapidly attain a vertical direction, giving off short secondary branches, almost always to the outside. The almost uniform thickness is 2 millims.; there is a slight swelling at the tips.

The surface of the cœnenchyma is rough with stellate spicules; the slightly prominent verrucæ (about 1 millim. in diameter) occur all round the axis; from their summits the yellowish polyps are projecting (about 0·5 millim. in diameter). The horny axis is bright yellow, with apparent longitudinal striation; it has a basal diameter of 1 millim.

The crimson spicules are mostly irregular, warty stars, with 4, 5, 6, or more rays. Some of the measurements taken are 0·2 millim. by 0·15 millim.; 0·2 millim. by 0·2 millim.; 0·3 millim. by 0·3 millim.; 0·3 millim. by 0·2 millim.

There are some irregular triangles, numerous discs, too irregular to be called stellate, and some small double wheels.

A few straight or curved spindles of diverse dimensions occur, 0·3 millim. by 0·03 millim.; 0·4 millim. by 0·05 millim.; 0·25 millim. by 0·1 millim.; 0·2 millim. by 0·025 millim.

The species is nearly related to *Astromuricea theophilasi*, Germanos, but is quite distinct. There is superficial resemblance to *Echinogorgia pseudosasappo*.

Locality:—Off Patani (Annandale and Robinson).

Echinomuricea indo-malaccensis, Ridley.

This species is represented by a single specimen, from the upper part of which the cœnenchyma has been rubbed off. The specimen measures 57 millims. in total height.

The basal attachment consists of a flat, spreading portion, from which the stem arises. The axis is dark in colour in the older parts, but becomes lighter in the younger branches. Branches arise from all sides of the larger branches, but the primary branches arise from the stem in one plane. The arrangement of the branches gives the colony a bushy appearance.

The specimen agrees closely with the description of *Echinomuricea indomalaccensis* given by RIDLEY (1884). There are several differences, however, thus (1) the verrucæ in this specimen are fully twice as long as in RIDLEY'S, they measure 0·8 millim. instead of 0·3 millim. in height; (2) the verrucæ spicules with ramifying basal portion vary in this case from 0·7 millim. to 0·9 millim. in length instead of a maximum length of 0·65, as given by RIDLEY. For discussion of four known species, see HEDLUND (1890), pp. 14 and 15.

Locality :—Pearl banks, Gulf of Manaar.

Previously recorded from Port Curtis, 5 fathoms to 11 fathoms; Port Molle, 12 fathoms to 20 fathoms; Warrior Reef, Torres Straits, Australia.

Echinomuricea ceylonensis, n. sp.—Plate VI., fig. 6.

Colony much branched in one plane, 11 centims. in height by the same in breadth at its broadest part. The colour is reddish-chocolate to crimson. The polyps may occur all round the branches, but in one specimen they are absent from the concave side of the plane of ramification. There is no regularity in the manner in which the branches arise from the stem. The verrucæ, which project almost at right angles, are about 1 millim. in height. The whole surface of the verrucæ and of the branches is rough with the sharp projecting points of crimson spicules, which are sometimes imbricating. Within the verruca cup there is a distinct special cone of tapering spicules forming an opercular covering. The polyps are entirely retracted. The horny axis is almost black at the base, about 1 millim. in breadth; it tapers to a breadth of 0·35 millim. near the tips of the twigs, where it shows a horny yellow colour. The cœnenchyma is relatively thin. The following types of spicule occur :—

(*a*) Numerous roughly triradiate forms, with a usually tuberculate main spine and with irregular foliaceous and ramifying expansions connecting the two other rays; 0·3 millim. to 0·5 millim. in length by 0·275 millim. to 0·3 millim. in breadth at base are common measurements; (*b*) irregular approximately stellate forms; and (*c*) curved spindles and boomerangs bearing a few tubercles and spines and sometimes forked or irregularly trifid at one end.

Locality :—West of Periya Paar.

Echinogorgia pseudosassapo, KÖLLIKER.

A single specimen of a crimson-red colour. It rises from a spreading base, about 15 millims. by 5 millims., and consists of two branches, about 50 millims. and 20 millims. in height. The longer branch gives off a branch at its base and another a third of the way up; the shorter branch gives off a branch near its end. The diameter varies from 2 millims. to 3 millims. It is probably a young specimen.

The surface is very rough owing to the sharp projecting points of the large spicules.

There are practically no verrucæ. The polyps appear yellowish, and the mouth is seen in most cases as a very precise oval aperture.

The red spicules are very variable :—

(1.) Fusiform, pointed at both ends, with distant tubercles; common lengths are 0·2 millim., 0·3 millim., 0·4 millim.

(2.) Larger fusiform, with tubercles and a few teeth, up to 0·7 millim.

(3.) Large and variable "Blattkeulen," often roughly triangular, with a shaft often divided into tubercled branches and a foliar expansion with 2 to 5 teeth; some measure 0·6 millim. in length.

(4.) Irregular stellate forms, with transitions to irregular discs; 0·2 millim. by 0·3 millim. is a common size.

(5.) Triradiate to hexradiate forms, with transitions to the stellate type.

The spiculation is not quite in agreement with the description and figures given by WRIGHT and STUDER, but the differences do not seem important.

Echinogorgia multispinosa, n. sp.—Plate VI., fig. 1.

An imperfect colony, branching irregularly in one plane without anastomosis, 11 centims. in height by 6 centims. in breadth. The horny axis measures 3·5 millims. in diameter at the base. Some of the twigs bear galls. The surface of the cœnenchyma is finely granular and of a cream-white colour. Verrucæ occur mostly on the sides of the branches, and are almost quite absent from the convex surface of the plane of ramification. In some regions they are crowded, almost touching one another, in other parts they are separated by intervals varying from 2 millims. to 4 millims. A few spines project slightly round the margin of the verruca opening, and there is an opercular covering with small spicules arranged in eight rays. Under low power the surface is seen to be uniformly covered with what seem to be tuberculate spindles irregularly arranged. When these spindles are examined an extraordinary diversity of form is disclosed.

(1.) Large tuberculate or spiny spindles, straight or curved, 0·4 millim. in length by 0·1 millim. in maximum breadth; some show a prominent spine on one side.

(2.) Small tuberculate spindles, 0·2 millim. by 0·05 millim.

(3.) Small almost smooth spindles, 0·2 millim. in length by 0·05 millim.; 0·3 millim. by 0·05 millim.; 0·275 millim. by 0·04 millim.

(4.) Slender boomerangs, 0·35 millim. by 0·05 millim.

(5.) Irregular tuberculate and denticulate clubs, 0·4 millim. by 0·2 millim.; 0·45 millim. by 0·15 millim.

(6.) Foliate clubs, 0·4 millim. in length by 0·2 millim. at broadest part; 0·3 millim. by 0·2 millim.; 0·275 millim. by 0·2 millim.

(7.) Irregularly-shaped warty scales with denticulate margins, *e.g.*, 0·3 millim. by

0·2 millim.; 0·25 millim. by 0·2 millim.; 0·2 millim. by 0·2 millim.; 0·25 millim. by 0·15 millim.

(8.) Almost stellate scales, 0·25 millim. by 0·25 millim.; 0·15 millim. by 0·15 millim.

(9.) Warty triradiate forms, 0·25 millim. by 0·2 millim.; 0·2 millim. by 0·13 millim.; 0·2 millim. by 0·2 millim.

(10.) Tetraradiate forms, 0·23 millim. by 0·1 millim.; 0·25 millim. by 0·15 millim.

The variety of spicules is greater than we have seen in any other Alcyonarian.

Heterogorgia verrilli, n. sp.—Plate VI., fig. 2.

A handsome branched colony, greyish-black in colour, 20 centims. in height by 8 centims. in maximum breadth. The short common stem, from which two main branches arise, is 5 millims. in diameter. The branches are generally alternate, and there is a tendency to swelling at the tips of the twigs. The surface of the cœnenchyma appears granular and bears many sponge spicules. The verrucæ are usually, but not constantly, disposed on the sides of the branches; they are conical warts under 1 millim. in height. In some cases the upper part of the anthocodia protrudes from the cone, and is seen to bear spindle-shaped spicules. In the retracted state a whorl of spindles is seen projecting vertically outwards within the margin of the crater-like verruca. The characteristic spicules of the cœnenchyma are more or less regular, bluntly tuberculate crosses of varying dimensions, *e.g.*, 0·1 millim. by 0·1 millim.; 0·2 millim. by 0·2 millim. There are also tuberculate double clubs and rough discs of various sizes, like crosses with the arms scarcely discernible.

The specimen, apparently a Muriceid, is very difficult to locate; we have referred it to Verrill's genus *Heterogorgia* ('Am. Journ. Sci.,' xlv. (1868), p. 413).

Bebryce hicksoni, n. sp.—Plate III., fig. 1; Plate VI., fig. 9.

An imperfect specimen, irregularly branched in one plane, about 6·5 centims. in height by 6·5 centims. in breadth. There are four branches, measuring about 2 millims. to 2·5 millims. in diameter, which is thicker than the main stem at its base (1·5 millims.). There is distinct flattening of the branches and twigs. The cortex has a smoothly granular punctate appearance and a greyish-white colour. The verrucæ, which are disposed mainly on the sides of the branches and twigs, usually with intervals of 2 millims. to 2·5 millims. separating an adjacent pair on the same side, are truncate rounded cones, crater-like when the polyps are dislodged. In many cases the anthocodiæ of the polyp project at the apex of the cone, and are supported by triangular strands of small spicules longitudinally and transversely disposed. Under low power the superficial spicules appear like rounded grains of sand or like fish-roe, each grain appearing as if it had a clear nucleus surrounded by a whitish rim. Higher magnification shows that there are multi-lobate warty spheroidal discs, some of which show a short central boss projecting inwards; the diameter of the disc varies considerably, 0·1 millim., 0·15 millim., 0·2 millim., and 0·25 millim.

In some cases the boss is borne on a distinct stalk, and this type measures 0·25 millim. in height by 0·2 millim. in the diameter of the disc Some small spicules are capstan-like, double clubs in fact, and various transitional forms show a gradual reduction of one-half of the capstan till only a boss is left, or not even that.

In the polyps there are curved tuberculate spindles, 0·25 millim. in length.

The spicules are so characteristic that we have no hesitation in referring this specimen to the genus *Bebryce*, and it cannot be identified with *B. mollis*, von Koch (1887), or *B. studeri*, Whitelegge (1897), or *B. philippii*, Studer. Hickson has reported *Bebryce*, sp. (?) from the Maldives; *B. mollis* is Mediterranean; *B. studeri* was obtained at Funafuti; *B. philippii* from the Arafura Sea—a remarkable distribution.

This seems to be a somewhat variable species, and the five specimens obtained differ considerably in general appearance, in the degree of prominence assumed by the verrucæ, in their distance apart, and in the shapes and sizes of the spicules. In all cases, however, the characteristic *Bebryce* spicules are unmistakable.

In a fragment of a greyish colour, 23 millims. in length, with two short branches, the verrucæ are usually about 1 millim. apart, along one line, and seem to occur equally all round the branches. Their diameter is 1 millim., and that of the light brown non-calcareous axis is the same.

We made a study of two other specimens. The more complete of the two represents a young colony, the other is a fragment of a large colony. In both the branching is confined to one plane, the branches and twigs being given off at an angle which varies little from a right angle. The branches grow out for a short distance in this direction and then bend upwards.

The tips of the twigs and the branches are clavate, but in one or two cases they are flattened. The two specimens present a greenish appearance, due to the presence of a siliceous sponge on the branches. The sponge has covered each branch with a thick coating, through which the tips of the verrucæ are seen. The spicules of the sponge are monaxonial and are oxytylotes.

The general cœnenchyma is thin and granular in appearance, and is composed of small spherical or irregularly oval bodies covered with numerous rough warts. There are also some more definite spindles, but they are very few in number.

The axis is horny and black in the lower parts, becoming lighter in colour in the twigs and younger portions of the branches. The axis is marked by irregular ridges and has a core of lighter coloured material. This core diminishes in size with the age of the portion of the axis. It is crossed by a number of bands, thus appearing to be chambered, and a longitudinal section shows a number of curved lamellæ crossing the core at about equal distances.

The verrucæ occur in the younger portions on all sides of the twigs and branches, but in the older portions they are confined more or less to the lateral faces. They are small and seem to be conical in shape. After carefully cutting away the sponge, we found that the verrucæ were conical and truncated.

There is no differentiation between the spicules of the general cœnenchyma and those forming the verrucæ; in both cases they are mostly oval or spherical discs covered with rough warts and sometimes with an internal boss. There are also some rough warty spindles. The spicules measure, length by breadth in millimetres, as follows :—

(1.) Globular discs, 0·1 × 0·1 ; 0·14 × 0·14 ; 0·14 × 0·08 ; 0·11 × 0·105.
(2.) Spindles, 0·26 × 0·038 ; 0·12 × 0·025 ; 0·16 × 0·03.

The colour of the colony when devoid of the sponge is a greyish-white.

Acamptogorgia atra, n. sp.

This species is represented by a complete colony, measuring 211 millims. in height and 98 millims. in maximum width.

The axis is horny, almost black at the base, but light brown in the younger branches. The stem is almost of the same diameter throughout its whole length. It measures 4 millims. in diameter at the base and 3·9 millims. at the tip of the main branch. The branching is confined to one plane. The branches arise at a right angle, but soon turn upwards and run roughly parallel with the main stem.

The polyps are restricted to the lateral edges of the stem and branches, but here and there they appear either on the back or on the front. They stand out almost perpendicularly to the stem and branches at intervals of about 2 millims. Each branch bears close to its tip 3 or 4 polyps, none of which can be said to occupy the end of the branch.

The colony is black in colour, though it presents a greyish appearance owing to its being closely coated with a sponge.

Locality :—Ceylon seas.

Acamptogorgia spinosa, Hiles.

This species is represented by several colonies, two of which give the following measurements :—

	(A.)	(B.)
Height of colony	76 millims.	74 millims.
Maximum width of same . .	39 ,,	42 ,,

A finer, but much weathered specimen afterwards found in the collection measured 15 centims. by 15 centims.; it was branched in one plane and showed much anastomosis.

The polyps on the branches vary from 0·6 millim. to 0·7 millim. in length and from 0·5 millim. to 0·6 millim. in diameter. In a few of the polyps a height of 0·9 millim. may be reached. The spicules in the present specimens are slightly larger than in

Acamptogorgia spinosa, but even then the relation of length to breadth is almost the same. The specimens agree with *Acamptogorgia spinosa* in axis, colour, and thickness, and in the chambered central core. For description, see HILES (1899).

Locality :—Deep water off Galle.

Acamptogorgia spinosa, var. **ceylonensis**, n.—Plate I., fig. 1.

This variety is represented by one complete colony and a colony in which the base is wanting. The complete colony has the following measurements:—Maximum height 114 millims. and maximum breadth 176 millims., while the incomplete one measures 154 millims. in maximum height and 142 millims. in maximum width. The colony is fan-shaped, caused by the profuse branching which is strictly confined to one plane. Anastomosis of the branches is, however, common.

The stem is dark in colour near the base, but gradually becomes lighter in the younger parts of the stem and branches. The axis in the stem and principal branches is oval in shape, the longest diameter being perpendicular to the plane of branching, but it gradually becomes more cylindrical in shape in the younger branches and in the younger part of the stem.

The cœnenchyma is thin and allows the axis to shine through; it presents a very rough appearance under the lens.

The verrucæ are arranged on three sides of the axis, they have a series of spines projecting round the mouth, and have a maximum height of 0·8 millim. and a maximum diameter of 0·6 millim.

A few expanded polyps were found at the end of a branch, but almost all were withdrawn within the verrucæ and showed a tentacular operculum, conical in shape, formed by the spindle-shaped spicules which lie on the aboral surface of the tentacles.

The spicules are (1) triradiate, with large irregular processes in the angles which often fuse, thus leaving plate-like portions with perforations; (2) a modified form of the triradiate with a long arm, which gradually thickens and then gives off two smaller arms from the thicker end; and (3) spindles and club-shaped half-spindles, curved or straight, either with very rough projections or fairly smooth.

Locality :—Deep water off Galle.

Acis indica, n. sp.—Plate II., fig. 3; Plate V., fig. 7.

The colony is large and fan-shaped, rising to a height of 149 millims. and having a maximum width of 167 millims. From a conical base, which has a flat spreading margin and is attached to a mass of worm-tubes, the short main stem arises. At a distance of 14 millims. from its origin, where it has a diameter of 3·5 millims., it divides into two principal branches. The branching is for the most part confined to one plane, but several of the smaller branches and twigs arise at right angles to the principal plane of branching. The branching is very profuse and at several points shows anastomosis of the branches, but this is by no means common. The branches are cylindrical, but there are traces of slight flattening in the plane of branching. The twigs arise usually at right angles to the branches, and their tips as well as those of the branches are slightly clavate.

The polyps are small and are scattered over the whole surface of the stem and branches. In no place can it be said that they are confined to three surfaces, nor can any attempt at lateral arrangement be seen. The verrucæ are very small and the polyps can be completely retracted within them. The edges of the verrucæ show a variable number of spines which project above the slightly conical operculum formed by the tentacular spicules when the polyps are withdrawn.

The superficial cœnenchyma of the stem and the branches presents a striking appearance, due to the arrangement of the large flat whitish spicules and to their being outlined against the darker ground-colour of the stem and branches.

The spicules of the general cœnenchyma are flat and multituberculate, varying very much in size and shape. The tubercles are low and rough and very numerous. Many of the larger spicules extend the whole distance between two adjacent polyps, and sometimes even exceed this length. They fall into three groups, fairly distinct in shape: (*a*) large modified fusiform spicules, which taper more or less towards the ends and measure from 0·9 millim. to 3 millims. in length by 0·25 millim. to 0·45 millim. in breadth; (*b*) squamous or scale-like spicules, often with slightly lobed margins, which measure from 0·8 millim. to 1·1 millims. in length by 0·4 millim. to 0·6 millim. in breadth; and (*c*) large modified squamous spicules, consisting of a flattened tuberculate basal portion and of a projecting part which forms the projecting spine of the verrucæ. They measure, in length by breadth in millimetres, as follows:—0·7 × 0·5; 0·6 × 0·4; 0·5 × 0·3.

In the polyps there are slender spindle-shaped and club-shaped spicules. They are often slightly curved and either taper to both ends or are blunt and rounded at one end and pointed at the other. Many of these exhibit fairly prominent spines towards the thicker end. They vary considerably in size, being from 0·3 millim. to 0·5 millim. in length and from 0·02 millim. to 0·06 millim. in breadth. They are found chiefly in the tentacles, where they form an operculum to the retracted polyp; but an incomplete and irregular crown or collar is formed by them at the base of the tentacles.

In colour the spicules vary from white to semitransparent, while the whole colony has a whitish-brown appearance.

This species differs from *Acis pustulata* in not having violet-coloured opercular spicules and in the branches not being compressed in the plane of branching. It also differs from *Acis orientalis* in having the polyps on all sides of the stem and branches and in the branching not being confined to one plane.

Locality:—Deep water off Galle.

Acis alba, n. sp.—Plate III., fig. 9; Plate V., fig. 4.

This species is represented by a complete colony which gives the following measurements:—Height of colony, 127 millims.; maximum width of same, 115 millims.; diameter of axis at base, 2·5 millims.

The basal attachment consists of a flat plate-like expansion from which the main stem rises. The stem reaches a height of 26 millims. and then divides into two principal branches, but branching is represented between this point and the base by a stump. The branches are given off at an angle which closely approaches a right angle; they soon turn upwards, however, and run roughly parallel to the main branches. The tips of the branches and the twigs are sometimes slightly clavate. The colony presents a fan-shaped appearance, due to the branching being strictly confined to one plane.

The axis is horny, greyish-black in colour in the older parts, and amber-yellow in the twigs and younger portions of the colony. It is cylindrical and marked by a number of irregular ridges in the lower part.

The polyps occur on all the faces of the stem and branches, and are arranged so that they give the appearance of three or four irregular lines. The verrucæ are small, slightly conical in shape, with a blunt tip and fairly wide base. They are covered by spicules similar to those of the cœnenchyma. In several cases a verruca seems to occupy the tip of a branch or twig.

The general cœnenchyma is thin and granular in appearance, the surface appearing scaly owing to the arrangement of the large flat spicules.

The spicules appear to be in two layers, the outer consisting of thick irregularly shaped flattish spicules, closely covered with rough warts, while the inner layer consists of spindles often with blunt ends and more irregularly formed spicules. The measurements, length by breadth in millimetres, are as follows:—

(1.) The outer layer, $0·48 \times 0·23$; $0·5 \times 0·4$; $0·43 \times 0·29$; $0·45 \times 0·2$; $0·2 \times 0·1$.

(2.) The inner layer, $0·25 \times 0·07$; $0·18 \times 0·05$; $0·22 \times 0·08$; $0·14 \times 0·04$; $0·12 \times 0·04$.

The appearance of two layers may be due to the fact that the flattish spicules are thicker and so stand up above the level of the other spicules. If this be so, then the spicules are in one layer only.

Towards the base of the tentacle on the aboral surface two slender converging spicules are present and at their base one or more transversely placed, thus giving a triangular arrangement of spicules at the base of each tentacle.

Galls are present on several of the branches, mostly caused by cirripedes.

The colour of the colony is greyish-white.

Localities:—Trincomalee; deep water off Galle.

Acis ceylonensis, n. sp.—Plate VI., fig. 3.

A small specimen, 4 centims. in height, with five branches, three of which are broken. The stem measures 2 millims. in diameter at the base and is scarcely reduced in thickness higher up. Verrucæ occur all round and have the form of truncated cones, about 0·5 millim. in height and about 1 millim. in diameter at the base. The intervals between them vary greatly, from 2 millims. to almost nil. The surface is covered with pebble-like spicules predominantly oval in shape and neatly fitted together like a mosaic of rounded fragments, which show almost no trace of overlapping or imbrication. Smaller oval scales occur outside the verrucæ and spindles project very slightly from within.

The large cœnenchyma spicules are mostly warty irregular ovals, but some are almost rectangular and others are like flint axe-heads.

They give the following measurements in length and breadth in millimetres:— 0·55 × 0·35; 0·5 × 0·32; 0·4 × 0·3.

Various kinds of spindles occur: (*a*) large thick forms, very warty, measuring 0·3 millim. by 0·15 millim., 0·45 millim. by 0·175 millim.; (*b*) long thin curved or straight forms, with smaller tubercles or almost smooth, measuring 0·5 millim. by 0·03 millim., 0·45 millim. by 0·03 millim.; and (*c*) minute warty spindles, 0·06 millim. by 0·02 millim.; 0·08 millim. by 0·02 millim.

Besides these forms there are others which approach the club-type, and are probably modifications of the large spindles.

Locality:—Deep water off Galle.

Acis ceylonensis, n. sp., var. **imbricata,** n.

Another specimen, measuring 4 centims. in height, with only hints of branches, showed a general superficial resemblance to *Acis ceylonensis*, n. sp., except that the large cœnenchyma spicules were much less regular in form and were much imbricated. An examination of the spicules showed the following forms:—

(1.) Large, modified fusiform, elaborately tuberculate, of very various dimensions, *e.g.*, 0·5 millim. by 0·25 millim.; 0·65 millim. by 0·4 millim.; 1 millim. by 0·5 millim.; without the monticular prominences characteristic of *Acis orientalis*.

(2.) Large rounded or almost oblong tuberculate scales, of various dimensions, *e.g.*, 0·35 millim. by 0·4 millim.; 0·5 millim. by 0·45 millim.

(3.) Tuberculate clubs, with the ends often much swollen, often 0·45 millim. in length by 0·2 millim. in maximum width; 0·35 millim. in length by 0·2 millim. in maximum width.

(4.) Tuberculate spindles, about 0·35 millim. to 0·4 millim. in length by 0·1 millim. in breadth, some 0·25 millim. in length by 0·05 millim. in breadth.

This specimen obviously differs markedly in the details of its spiculation from that which we have named *Acis ceylonensis*, but it may be sufficient to erect a variety within the species. Until more data accumulate it seems quite impossible to tell how far marked differences in spiculation can be relied on as specific.

Locality:—Trincomalee.

Acis orientalis, Ridley.

This species is represented by three complete specimens, of which the largest measures 136 millims. in height by 86 millims. in maximum breadth. The specimens agree with the description given by Ridley [1882 (II.), pp. 126–128].

The terminal branches reach a length of 45 millims. to 50 millims., and the tips of the branches and twigs are clavate, measuring 3·5 millims. to 4 millims. in diameter, and are occupied by three polyps.

The axis measures 3 millims. at the base, but in branches which have a diameter of 2·6 millims. it measures only 0·5 millim. or 0·45 millim. in diameter.

The spicular measurements agree very closely with those given by Ridley (1882), the differences being so slight as not to be of any importance. We may perhaps, having found other Ceylonese species of *Acis*, quote Ridley's note :—" The occurrence of this otherwise West-Indian genus in the Indian Ocean, and in its western portion in particular, has a peculiar significance for the student of geology, as showing that a communication probably existed between these two areas at a period later than that at which the genus was differentiated from the main stem of the family."

Locality :—Deep water off Galle.

Previously recorded from Mauritius, 80 fathoms.

Muricella ramosa, n. sp.—Plate III., figs. 2 and 3.

The colony is branched in one plane, and forms a beautiful network with abundant anastomoses. The branches and twigs are given off, sometimes opposite, sometimes alternate, at an angle which varies little from a right angle. One of the specimens, though not complete, measures 170 millims. in height and 273 millims. in maximum width.

The axis is black in colour in the lower part, but becomes brownish-yellow in the tips of the branches and in the twigs. It is rather irregular in shape, being somewhat oval shaped, the longer diameter being at one place in the plane of branching, at another place at right angles thereto. The general cœnenchyma is thin and practically composed of warty spindles which may be either straight, curved, or slightly **S**-shaped.

The verrucæ are small and vary greatly in appearance. A number of spicules horizontally arranged form the lower part of the verruca, and a number of longitudinally disposed spicules form the upper part. The appearance of the upper set of spicules varies according to the stage of retraction of the anthocodial part of the polyp. The spicules composing the verrucæ do not differ from those of the general cœnenchyma except in size. They are smaller, but are as closely covered with warts as the other spicules.

The polyps are arranged on the stem and branches in what appear to be short spirals, but on some of the twigs they assume a more or less bilateral disposition.

The spicules are thick spindles, either straight or curved, or slightly **S**-shaped, covered with numerous rough warts. Their measurements, length by breadth in millimetres, are as follows:—1·6 × 0·2; 0·8 × 0·14; 1·3 × 0·2; 0·9 × 0·16; 0·25 × 0·06; 0·1 × 0·02; 2·1 × 0·26.

In the complete colony the outer spicules *often stretch the whole distance between the polyps*. In certain conditions of the polyps there appear to be 8 projecting spicules on each calyx.

Localities:—Deep water outside pearl banks, Gulf of Manaar; and deep water off Galle and onwards up West Coast of Ceylon.

Muricella ceylonensis, n. sp.—Plate VI., fig. 4.

The colony is branched in one plane, with a strong tendency to anastomosis even between twigs of different main branches. It measures 12 centims. in height by 8 centims. in breadth. Most of the twigs arise at right angles from the main branches and almost all the short ones remain perpendicular. Many arise in opposite pairs, others are alternate, and in other regions the twigs may be restricted for an inch or more to one side of the branch. A common interval between the origin of two adjacent branches on the same side is 4 millims. The verrucæ stand out prominently at right angles to a height of about 0·5 millim., and the interval between two on the same side is on the average 1 millim. The surface of the colony is covered with huge white spicules readily visible to the naked eye. Spicules slightly curved at the base run up the sides of the verruca, and their tips project at the mouth. The black horny axis measures 2 millims. in diameter at the base, it tapers to a diameter of 0·1 millim. at the tips of the twigs, and in these delicate parts it shows a brownish tint. The general colour of the colony is grey. In another specimen measuring 8 centims. by 6 centims. the colour was whiter owing to the more densely packed large spicules; there was *no hint of anastomosis*, and the perpendicular mode of branching was not so pronounced.

The spicules, which are longitudinally disposed, are straight or curved, densely tuberculate spindles, the largest of which seem here and there to be disposed in definite strands or lines. They vary in size from 3·5 millims. to 0·35 millim.

Compared with *M. ramosa* this species is much less thickly branched; it shows much less anastomosis, it bears polyps at wider intervals, and has larger spicules.

Muricella nitida, Verrill.

This species is represented by a colony with a maximum height of 105 millims. and a maximum width of 80 millims. The base consists of a broad flattened portion from which the fan-shaped colony rises. The axis is dark brown, almost black in colour in the lower parts, but it becomes yellowish in the upper portions of the branches and in the twigs. It has a basal diameter of 2 millims.

The branches, which are confined to one plane, come off at an angle which approaches a right angle and then bend upwards, so that they appear to be parallel to one another. The younger branches and twigs often present a pinnate appearance, which is sometimes disguised by a larger development of one of the branches. The stem and branches are flattened in the plane of branching, and the tips of the twigs form blunt broad expansions due to the two divergent terminal polyps.

The polyps are more or less confined to the lateral edges of the branches; they are all withdrawn, but their tentacular portions are yellowish in colour.

The spicules vary in length from 0·9 millim. to 1·65 millims., and in breadth from 0·1 millim. to 0·2 millim.

The colour of the colony is a deep coral-red; and the spicules of the cœnenchyma are visible to the naked eye.

The specimen presents close resemblances both to *Muricella perramosa* and *M. nitida*, but because of the greater resemblance in the arrangement of the polyps and the more marked coral-red colour, it was thought best to place it under *M. nitida*.

Locality :—Ceylon seas.

Muricella complanata, WRIGHT and STUDER.

This species is represented by a fragment of a colony, consisting of the lower part of the stem with basal attachment, and a branch bearing secondary branches or twigs. The basal attachment consists of a slightly conical spreading portion, from the summit of which the stem arises. The stem measures 2·2 millims. near the base, and at a distance of 11 millims. from the base the first branch, which is represented by a fragment, was given off. The secondary branches or twigs are given off at right angles, and may reach a length of 25 millims. to 37 millims.

The polyps are arranged on the lateral edges of the stem and branches, and are directed some to the front and some to the back. On the whole they are arranged alternately, but this is not quite constant. The polyps measure 0·95 millim. in height by 0·74 millim. in width, and are contained within verrucæ which measure 0·35 millim. in height by 0·8 millim. to 1 millim. in width at the base.

The stem is of a violet tint with yellow polyps and verrucæ, but this tint gives place gradually on the twigs to an orange-yellow. The tips of the twigs end in two divergent polyps, and this expansion measures 3 millims. in width.

The spicules of the cœnenchyma vary in length from 0·7 millim. to 1·3 millims., and in breadth from 0·1 millim. to 0·16 millim. They are straight spicules covered with warts.

This specimen, though not agreeing with *Muricella complanata* in every detail, may be included in this species, which is variable in the colour and the size of its spicules.

We studied a second specimen of a more pronounced violet colour and with much larger spicules. It was a complete colony which is attached to a piece of coral, and measures 68 millims. in height and 53 millims. in maximum width. The basal attachment consists of a flattened portion spreading over the surface of the coral. The stem measures 2 millims. at the base, and at a height of 17 millims. the first branch is given off. The branching is confined to one plane, the primary branches being given off almost at a right angle. They in turn give off secondary branches or twigs at an angle which approximates even more closely to a right angle.

The verrucæ are placed on the lateral edges of the stem and branches, and are arranged more or less alternately. They are conical and abruptly truncated, with usually a few of the spicules projecting at the opening. The spicules in the calyces are much smaller than those of the general cœnenchyma.

The colour of the whole colony is a beautiful violet tint, with the tentacles of the polyps yellowish in colour.

The spicules of the cœnenchyma are spindle-shaped, either straight or curved and sometimes broad and flat in comparison to their length, or bluntly rounded at the two ends. They can be divided into two fairly distinct types:—

(1.) The larger spicules with rough warts, which vary from 0·7 millim. to 2·7 millims. in length and from 0·075 millim. to 0·32 millim. in width; and

(2.) The smaller spicules with warts more pointed than rough, which vary in length from 0·11 millim. to 0·55 millim., and in width from 0·03 millim. to 0·05 millim.

Another very beautiful form with large violet and colourless spicules seems at first sight very different from the foregoing species and variety. This is mainly due, however, to the fact that there is a prominent opercular covering of small but very conspicuous rose-red spicules sometimes disposed in eight rays.

Localities:—West of Periya Paar, Gulf of Manaar; deep water off Galle and onwards up West Coast of Ceylon.

Family: PLEXAURIDÆ.

Plexaura prælonga, var. **typica** (Ridley).

Plexauroides prælonga (Wright and Studer).

This species is represented by one specimen, which reaches a height of 425 millims. The branching is confined to one plane and forms an irregular dichotomy. The main stem is 4 millims. in diameter at its base, tapering to 3 millims. at its termination, thus agreeing with the measurements given by Wright and Studer.

The verrucæ are numerous and irregularly scattered and the polyps are completely retractile. The cœnenchyma is comparatively thin and very friable. The spicular measurements are the same as those given by Wright and Studer. The colour is a deep brownish-red in spirits.

Locality:—Outside pearl banks, Gulf of Manaar.

Previously recorded from Port Curtis, 5 fathoms to 11 fathoms; Port Denison, 4 fathoms; and Station 186, Cape York, 8 fathoms. (See Wright and Studer (1889), '"Challenger" Reports,' vol. xxxi.: Ridley (1884), '"Alert" Expedition,' p. 339, Plate xxxvi., fig. F, and Plate xxxviii., fig. *g*, *g'*.)

Plexaura prælonga, Ridley, var. **elongata**, n.

Several incomplete specimens, dull crimson in colour, with two or three elongated cylindrical branches, 3 millims. to 4 millims. in diameter and up to 30 centims. in length. The axis, blackish-brown, 1 millim. to 2 millims. in diameter, is entirely horny. The surface of the colony is covered with the pore-like apertures of the polyps; around each aperture the spicules are disposed in a ring 0·3 millim. to 0·5 millim. in diameter.

The most characteristic spicules are very variable discs, "Blattkeulen," 0·4 millim. to 0·5 millim. in length, with a rounded foliaceous expansion (0·3 millim. in breadth) at one end and an irregular ramification at the other. The surface of the disc bears a few large blunt tubercles. When the thin foliaceous expansions are broken off, the rest of the spicule may be described as irregularly stellate. Actually stellate forms also occur, and 3- to 6-rayed forms are represented. A few tuberculate spindles occur here and there.

As regards types of spicules, this form resembles *Plexaura prælonga*, but the details of the "Blattkeulen," the rough cortex and the crimson colour, and some other features, mark it as quite distinct from Ridley's varieties *typica* and *cinerea*.

Plexaura antipathes, Klunzinger, var. **flexuosa**, n.

To a variety of this species we refer two specimens, the larger of which measures 120 millims. in height and the same in width. The colonies are bush-shaped and very profusely branched, with the branching not confined to one plane. The branches are sometimes thickened during a part of their length, while all are swollen at the tip into a knob or club-shaped portion, which measures from 2 millims. to 3 millims. in diameter.

The polyps are scattered over the whole surface of the stem and branches. No projecting calyces are present, but the position of the polyp is marked by an oval or circular opening, round which the cœnenchyma is slightly raised.

The axis is thick at the base, measuring 3·5 millims. in diameter, but it becomes slender and thread-like at the tips of the branches. The colour is a dark brown, very little difference being seen throughout the whole ramifications of stem and branches. The base consists of a broad, flat, spreading portion, from which in one specimen several stems rise in addition to the main stem.

The spicules are short, many branched, rod-like needles or small spherical bodies, which bear many protuberances. They measure, length by breadth in millimetres, as follows:—$0{\cdot}12 \times 0{\cdot}08$; $0{\cdot}12 \times 0{\cdot}10$; $0{\cdot}14 \times 0{\cdot}08$; $0{\cdot}15 \times 0{\cdot}10$; $0{\cdot}20 \times 0{\cdot}08$.

The colour of the colony is a dirty greyish-white, with a light brownish tinge in many places.

Though differing slightly from *Plexaura antipathes*, yet the differences are not sufficient to warrant the formation of a new species. See Hiles (1899), pp. 51–2; Whitelegge (1897), pp. 317–8.

Locality: Gulf of Manaar.

Lophogorgia lutkeni, Wright and Studer.—Plate III., fig. 6.

This species is represented by many pieces of colonies; the largest piece measures 33 centims. in height by 38 centims. in breadth, and has three main branches. It measures 18 millims. across at the base, narrows to 12 millims., and expands again to 28 millims. where the branches arise. The axis is dark brown in colour with a lighter coloured central core. It is very calcareous as well as horny and measures fully 2 millims. at the lower end of the branch which we studied. It has two shallow grooves which correspond to the two grooves on the stem and the branches. The branching is usually confined to one plane and is fairly profuse. In the largest specimen one of the branches comes off from the main stem almost at right angles to the plane ot branching, but it bends over almost directly and comes to lie in that plane. In this specimen, also, several of the secondary branches rise in a similar manner to the above. In the other specimens, however, the branching is strictly confined to one plane. The stem and the branches are flattened in the plane of branching and are marked on the flat sides by a narrow winding groove or furrow which is continued along the flattened surfaces of the secondary branches. The tips of the branches and twigs are almost cylindrical. In the twigs the nutrient canals occur all round, but in the larger branches and in the stem they correspond to the grooves on the flattened surfaces.

The polyp-bearing surface is divided into two lateral bands by means of the two grooves. On both of the bands the polyps occur in irregular rows. Verrucæ can scarcely be said to be present, as the general cœnenchyma seems only to be slightly raised at the point where the polyp issues. On the polyp being retracted, the edge of the pore-like opening curves in and forms a star-shaped figure in which the rays are slightly variable. The slight thickening at the point of issue of the polyp seems more marked in some of the specimens than in others.

The polyps are either completely or partially withdrawn into the general cœnenchyma; the expanded part in the case of those partially withdrawn is white in colour. On the body of the polyp there are eight bands of spicules running up towards the base of the retracted tentacles. In each band the spicules, which are numerous, are arranged *en chevron*.

The spicules are spindle-shaped, but slightly flat in appearance, and sometimes curved and with fairly large prominent projections. They measure (*in situ*) from 0·18 millim. to 0·2 millim. in length. They are colourless.

The general cœnenchyma of the stem and the branches is thick, measuring about 1 millim. in depth, and friable in texture. In colour it is yellowish, with darker brownish patches scattered over the whole surface. It is composed of short spindle-shaped spicules with rough wart-like projections arranged in whorls, the whorls varying in number with the size of the spicules.

They measure, length by breadth in millimetres, as follows:—$0·1 \times 0·04$; $0·12 \times 0·04$; $0·14 \times 0·05$; $0·14 \times 0·02$; $0·13 \times 0·035$; $0·14 \times 0·06$.

The specimens agree with the description of *Lophogorgia lutkeni* in most respects, *e.g.*, the branching, the flattening, the absence of verrucæ, the disposition of the polyps and nutrient canals. On the other hand, there are some peculiarities: (1) there is a distinct groove and not a wavy line; (2) the spicules of the general cœnenchyma are smaller in the Ceylon specimens; and (3) the pore-like openings left by the retracted polyps form star-like figures, not slits.

These differences do not seem important enough to warrant us in separating it from *L. lutkeni*.

To this species two other fragments belong. The larger measures 168 millims. in height and has a diameter of 5 millims. at the lower end of the main stalk. These two specimens differ from those described above in having no projections of the cœnenchyma at the point of issue of the polyps. The openings left by the polyps when withdrawn are more like slits than in the former specimens. The specimens are also more brick-red in colour. In every other respect they agree with the specimens above described. As the two sets of specimens come from the same locality we are furnished with a good example of individual variation.

Locality :—Cheval Paar, Gulf of Manaar.

Lophogorgia rubrotincta, n. sp.—Plate IV., fig. 12.

The base of the colony is expanded for 25 millims. on a shell; the branching is approximately in one plane; the measurements are about 100 millims. in height by a maximum of 30 millims. in breadth; the longest branches are about 30 millims. in length; the primary branches arise irregularly on the two sides of the main stem and some give off secondary branches. As regards spicules and polyps, it seems to be a *Lophogorgia*. Most of the cœnenchyma spicules are rough spindles; 0·1 millim. by 0·04 millim. is a common measurement, but many are much smaller. On the median line of each flattened surface of the stem and its branches there is a line of red spicules making a characteristic feature in contrast to the general orange-yellow. If it be not worthy of recognition as a new species, it is a very distinctive variety.

Lophogorgia irregularis, n. sp.—Plate VI., fig. 7.

An irregularly branching specimen of a dirty white colour, about 3 centims. in maximum breadth by 1·5 centims. in height. The extraordinarily quaint mode of branching may be described as somewhat antler-like, but the tips of the branches are mostly bent downwards. The branches expand, constrict, and re-expand in a peculiar way, and there is considerable flattening in the general plane of branching. The polyps occur all over, completely retracted within slightly prominent rounded verrucæ, which are closest together and best defined towards the ends of the branches. Many of the verrucæ measure about 1 millim. in diameter, but the aperture of the polyp on the apex of the gently rounded elevation is usually very much less (about 0·25 millim.).

The axis is black in colour and seems to be non-calcareous. It measures 2 millims. in breadth at the base, soon expands to 4 millims., and then narrows again. It is markedly flattened. Towards the ends of the branches, which measure about 3 millims. in greatest breadth, the axis is thread-like, brown in colour, and very flexible. The cœnenchyma is thick, its texture recalls that of *Iciligorgia;* several sections through a branch showed three large longitudinal canals symmetrically disposed close round the axis.

The spicules are broad spindles, 0·2 millim. by 0·1 millim.; narrow spindles; clubs; and double clubs.

Locality:—Pearl banks, Gulf of Manaar.

Leptogorgia australiensis, Ridley, var. **flavotincta**.—Plate IV., fig. 10.

This species is represented by numerous complete specimens, which differ considerably in size, the largest being 154 millims. in height and 130 millims. in maximum breadth. In all the specimens the cœnenchyma is rubbed off near the base, thus exposing the axis to view. The axis rises from a flat spreading basal portion, it is black in colour and slightly oval in shape, measuring 2·2 millims. in diameter at the base, but becoming lighter in colour and thread-like in form in the tips of the branches and in the pinnæ. It is horny in texture and very tough. The branching is confined to one plane, and each of the branches has a pinnate appearance. On the main stem and branches there is a distinct groove running up both the surfaces, thus dividing the polyp-bearing part into two lateral bands. In some parts it seems as if the groove had disappeared and left a ridge in its place. Some of the specimens show galls.

The verrucæ are arranged on the two lateral faces of the branches and the pinnæ in two alternating rows. They are scarcely elevated above the level of the general cœnenchyma, and their openings are slit-like in shape, the slit running parallel to the long axis of the branch.

In every respect the specimens agree with the description given by Ridley (1884). The spicules in the present specimens seem on the whole to be smaller than those measured by Ridley either for the species itself or for any of the varieties, varying, as they do, from 0·09 millim. to 0·16 millim. in length, and from 0·04 millim. to 0·05 millim. in breadth. Few of the spicules, however, attain the latter dimension in breadth.

The colour of the specimen, not agreeing exactly with any of the colours given for the species, may be best described as deep crimson. The yellow verrucæ stand out conspicuously in the younger branches, and also in two young colonies (Station I.) 30 millims. in height.

Localities:—Cheval Paar, Gulf of Manaar; Station I., off Negombo, 12 to 20 fathoms; deep water off Galle and onwards to Colombo.

Previously recorded from Torres Straits (see Ridley, 1884, p. 342, Plate 36).

Leptogorgia australiensis, Ridley, var. **perflava**—Plate IV., fig. 10.

This variety is represented by a complete colony which has a maximum height of 80 millims. and a maximum width of 88 millims. The type of branching agrees very closely with that described, even to the pinnate arrangement of some of the pinnæ themselves. The groove or furrow is more tortuous than in Ridley's description, and in several places it shows the transition between a groove and a ridge. The size and the arrangement of the verrucæ, and their manner of opening by longitudinal slits, are all in close agreement with Ridley's descriptions. The axis just above the flat spreading basal portion has a diameter of 1·35 millims.

The spicules are spindle-shaped, with whorls of warts, distinct free spaces being visible between the whorls near the middle portion of the spicule. Their measurements, length by breadth in millimetres, are as follows:—0·12 × 0·04; 0·15 × 0·05; 0·11 × 0·04; 0·16 × 0·04; 0·17 × 0·03; 0·08 × 0·04.

In this specimen the spicules show a greater range in size than is found in the specimen described by Ridley.

Neither in this variety nor in the variety described above can any trace be found of the double-headed spicules which Verrill has described. They are almost certainly, as Ridley has suggested, pieces of broken fusiform spicules.

A point of some interest in regard to the varieties described above is, that the spicules of the crimson variety are wholly crimson and the spicules of the yellow variety are wholly yellow. In no case can any trace of both red and yellow spicules be found in one specimen. Ridley, however, found that red spicules occurred in the cortex of the yellow varieties, and that in the cortex of the main branches of the red form there were almost, if not quite, as many yellow as red spicules. We have examined our specimens very carefully, and it may be that we have here the initiation of a more definite splitting up of the species into distinct colour-varieties.

Leptogorgia (?) sp.

We have been unable to come to a definite decision in regard to an interesting form which we rank provisionally with the genus *Leptogorgia*. It is represented by an incomplete specimen showing two branches arising from a common basal portion. The longest branch is 84 centims. in length, 2 millims. to 2·5 millims. in breadth, and gives off two short branches at an acute angle. The branches are flattened, the edges show a crenate row of gentle elevations and depressions indicating the position of the verrucæ and the minute intervals between them. The colour is greyish with a tint of vandyck brown; the texture of the cœnenchyma appears smooth to the naked eye, finely granular under the hand lens. The axis measures 0·85 millim. across at its base, and a surprising feature is its markedly calcareous composition.

The spicules are:—(*a*) Small warty double spindles, measuring in length by maximum breadth in millimetres, 0·08 × 0·025; 0·1 × 0·025; 0·15 × 0·03; 0·16 × 0·04; and (*b*) minute warty double clubs, 0·03 × 0·02; 0·05 × 0·03; 0·075 × 0·03; 0·08 × 0·03.

Stenogorgia ceylonensis, n. sp.—Plate II., figs. 1 and 1A; Plate V., fig. 9.

This new species is represented by two complete colonies, which measure as follows:—

	(A.)	(B.)
Height of colony	125 millims.	73 millims.
Maximum width of same . . .	117 ,,	76 ,,

The colonies are fan-shaped and, on the whole, branched in one plane. The basal attachment consists of a broad, flat, plate-like portion which spreads over the surface of the object to which it is attached. From the basal portion the short main stem arises and soon divides into a number of principal branches. These give off secondary branches, which in their turn give rise to twigs of similar structure. The branches are, on the whole, given off in one plane, but several of the smaller branches and twigs come off in a different plane. The tips of the branches and twigs consist of flat expansions formed by two divergent terminal polyps; the expansion in many cases measures as much as 4 millims. from side to side.

The axis is horny, rigid in the lower part, but flexible and light brown in colour in the younger branches and twigs.

The verrucæ are very abundant on the branches and twigs, a little less numerous on the principal branches. They are cylindrical in shape, and measure, length by breadth in millimetres, as follows:—1·9 × 1·2; 1·5 × 1·1. They occur on all sides of the branches and twigs, and may be said to occur in short spirals which are closely crowded on the branch or twig. When the polyps are withdrawn the verrucæ present all the phases between a mere pore with a lobed margin and a minute 8-rayed star, in proportion to the extent of the retraction.

The cœnenchyma is thin and is easily rubbed off. It is mainly composed of short rough spindles closely covered with warts and spines. They are light yellow to deep yellow in colour, and measure, length by breadth in millimetres, as follows:— 0·4 × 0·08; 0·5 × 0·10; 0·41 × 0·079; 0·5 × 0·08.

The colour of the colony is a chocolate-brown.

Locality:—Trincomalee.

Gorgonia capensis, Hickson.

Several complete specimens and many fragments belong to this species. Two of the complete specimens measure 428 millims. and 439 millims. respectively in length. The basal attachment is in the form of a flat, plate-like expansion, from which the thread-like axis arises.

The axis is dark brown to black in colour, very tough and flexible, never measuring more than 0·5 millim. in diameter. In the larger complete specimen it has a basal diameter of only 0·15 millim. The branching is not profuse, the one specimen having two branches, the other only one, though in some of the broken fragments several branches are present.

The cœnenchyma is moderately thick, both on the main stem and on the branches, the terminations of which are knob-like. The colour is practically white, not yellow as in HICKSON's specimens.

Verrucæ are absent, the position of the polyps being marked by oval-shaped openings.

The spicules agree in measuring not more than 0·2 millim.

From these specimens it has been possible to corroborate HICKSON's discovery of viviparity in this species, but the disc-like embryos only measured 0·4 millim. by 0·39 millim. in size. Here we may be allowed to note our discovery of embryos in *Juncoptilum* sp., from ALCOCK's Indian Ocean collection.

Localities:—Station I., off Negombo, 12 fathoms to 20 fathoms; deep water off Galle and onwards to Colombo, hauls off Kaltura and off Mount Lavinia.

Previously recorded from 10 miles south of Cape St. Blaize (HICKSON, 1902).

Rhipidogorgia (?) sp.

A large fan-shaped reticulate colony was found, but so much weathered that secure identification was impossible.

FAMILY: GORGONELLIDÆ.

Scirpearella aurantiaca, n. sp.—Plate IV., fig. 7; Plate V., fig. 15.

The collection included several portions of what seems a new species of this genus. We have studied a fork-shaped fragment which has a total length of 366 millims. The lower part of the colony is wanting, but the axis at the point where it divides measures 2 millims. in diameter. It is cylindrical in shape, very calcareous and smooth in the one branch, but marked by two or three slight winding grooves in the lower part of the other. The general colour of the branches is yellowish-white. A larger specimen, 470 millims. in length, bore a small comatulid on one of its branches.

The verrucæ occur on all sides of the branches. They are conical in shape, truncated at the tip, and measuring 2 millims. in maximum height and 1·5 millims. in basal diameter. In colour they resemble the stem in the lower part, but the tip is orange-yellow, thus standing out against the general colour of the branches. The edges of the oral end curve inwards, and all stages from an opening with an 8-lobed margin to a simple pore-like opening and finally to a completely closed tip may be seen.

The polyps are all completely withdrawn into the cœnenchyma. The general cœnenchyma is yellowish-white in colour, granular in texture, and only of medium thickness. It is practically composed of spindles and double clubs.

The spicules are small in size, and measure, length by breadth in millimetres, as follows:—

(1.) Spindles, 0·06 × 0·02; 0·08 × 0·02; 0·085 × 0·03.

(2.) Double clubs, 0·055 × 0·03; 0·07 × 0·04; 0·06 × 0·04.

This specimen does not agree with any described species of *Scirpearella*, but comes nearest to *Scirpearella rubra*, with which, however, we cannot identify it.

Locality :—Deep water outside pearl banks, Gulf of Manaar.

Scirpearella divisa, n. sp.—Plate VI., fig. 8.

A fragment of a reddish-orange colony with four branches, 7 centims. in height, about 2 millims. in diameter. The verrucæ are very low and gently rounded; towards the end of the highest branch, where they are closely crowded and very distinct, the arrangement appears to be in four rows with a suggestion of a spiral; in the older parts the verrucæ are very inconspicuous, not close together, and somewhat irregularly disposed. There are two enormous cirriped galls, the broadest almost 1 centim. across. The cœnenchyma is finely granular, almost smooth to the naked eye. The axis is very calcareous, light yellow in colour, with ten shallow grooves on the part examined. It measured there about 1·4 millims. in diameter out of the total branch diameter of 2 millims. Thus the thickness of the cœnenchyma is very moderate.

The spicules are chiefly minute, warty, double clubs, measuring 0·04 millim to 0·06 millim. in length, but usually 0·05 millim.; most are yellowish, a minority colourless. The bare middle part of the double club is very short. There are also yellowish and uncoloured warty spindles, measuring 0·1 millim. in length by 0·02 millim. in maximum breadth.

Scirpearella sp. *α*.

One specimen with a length of 307 millims. The stem is divided at a distance ot 39 millims. from the flat base, and is flexible. Prominent verrucæ occur all round the stem in rows. The axis is deeply grooved in the lower part, but the grooving is hardly noticeable higher up.

The fragment approaches *Scirpearella moniliforme*, but differs in colour and in predominance of warty clubs over spindles, and in not having shallow verrucæ.

Scirpearella sp. *β*.

Another fragment, measuring 205 millims. in length. Verrucæ scarcely prominent, polyps white, a longitudinal white line is seen on one side. The axis is horny and very calcareous, faintly and irregularly marked by grooves.

The spicules, length by breadth in millimetres, are as follows :—

Stellate forms, $0·06 \times 0·05$; $0·07 \times 0·06$.

Double clubs, $0·06 \times 0·03$.

Spindles, $0·06 \times 0·02$; $0·08 \times 0·025$.

This does not agree with any of the formerly described species.

Scirpearella sp. *γ*.

Another fragment which measures 258 millims. in length is included in the collection.

The stem has a groove on one side, and on the side directly opposite there is a bare strip. The polyps are in three rows on each side of the groove. The verrucæ are very small.

The following measurements were taken :—

Diameter of stem at lower end, 3·2 millims.

,, axis ,, ,, 2 ,,

,, stem at upper ,, 2 ,,

The spicules measure, length by breadth in millimetres, as follows :—

Spindles, 0·06 × 0·03 ; 0·07 × 0·03.

Double clubs, 0·05 × 0·04 ; 0·06 × 0·04.

Double spindles, 0·06 × 0·04 ; 0·05 × 0·035.

Scirpearia, sp. (?)—Plate IV., fig. 1 ; Plate V., fig. 16.

This specimen is a fragment without the base. It measures 410 millims. in length and divides at a distance of 38 millims. from its basal end into two long whip-like branches.

The axis is deeply grooved. There is a median bare space on each side. The polyps are darker in colour than the stem.

The spicules measure, length by breadth in millimetres, as follows :—

Double clubs, 0·06 × 0·04 ; 0·063 × 0·04. Darker coloured, 0·08 × 0·025 ; 0·07 × 0·02. In its spicules it is quite distinct from any *Juncella*.

It may seem of little service to suggest problematical species based on a study of fragments, but as we have given some description of each, our procedure is probably preferable to that of some other students of Alcyonacea, who have given names nude of any description.

Our impression is that the elongated forms of *Scirpearella*, *Juncella*, and the like, so monotonous in general appearance, so perplexingly diverse when one gets beneath the surface, are subject to great variability. The same remark applies to *Spongodes*, *Acis*, *Muricella*, *Verrucella*, and many other Alcyonarians.

Juncella gemmacea (Valenciennes)—Plate IV., figs. 4 and 5.

There are several specimens of this species in the collection. The finest one was 3 feet 7 inches in length, with a yellow basal expansion 3 centims. across, and with a stem measuring 9 millims. in diameter at the base. The stem increased to 12 millims. in diameter, and 10 millims. was a fair average. The lateral lines were spirally twisted. Another specimen measures 193 millims. in length and tapers from 7 millims. in diameter at the base to 4·5 millims. at the tip ; another measures 292 millims. in length with a basal diameter of 4 millims. The thickest piece measured 9 millims. in basal diameter, the axis alone amounting to 5 millims., and had an apical diameter of 3 millims. The side-line on either side of the stem is distinct. The axis is longitudinally grooved.

The spicules agree with those described and figured in the '"Challenger" Report, and are (*a*) unsymmetrical double clubs, and (*b*) double stars. The measurements, length by breadth in millimetres, are of (*a*), $0·12 \times 0·04$; $0·11 \times 0·04$; $0·10 \times 0·04$; and of (*b*), $0·10 \times 0·06$. A few single clubs and rough needles were seen.

The colour of the specimens in spirit is bright red with tints of orange when closely examined; the polyps appear white.

Locality :—Gulf of Manaar; Vankali Paar; Muttuvaratu.

Previously recorded from Red Sea; Torres Straits; Queensland and Mermaid's Straits, N.W. Australia.

Juncella juncea, Pallas.

The collection includes numerous fragments of various species of *Juncella*, more numerous than we could examine; some of these belong to *Juncella juncea* which Ridley reported from Ceylon (1883).

Juncella fragilis, Ridley.

This species is represented by several fragments, in which the axis is marked by longitudinal grooves or striæ. In some of the fragments the verrucæ measure nearly 2 millims. in height and the axis has a diameter of 1 millim., while in the other fragments the verrucæ are much smaller and the axis measures 2 millims. in diameter. The spicular measurements in the one set of fragments are almost identical with those previously given for *Juncella fragilis*, but in the other set they measure as follows, length by breadth in millimetres :—

Unsymmetrical clubs, $0·08 \times 0·03$; $0·065 \times 0·03$.

Double clubs, $0·08 \times 0·04$; $0·075 \times 0·03$.

Juncella fragilis (Ridley), var. *rubra*, n.

This species is also represented by one complete specimen on which this new variety has been founded. The specimen shows no trace of branching, and measures 508 millims. in length. It is long and flexible, and tapers very gradually throughout its entire length to the pointed apex. The cortex is thick and red coloured, with numerous reddish-brown verrucæ. There is no trace of a lateral line or groove throughout the entire length of the stem, but the cortex has been rubbed off the lower part.

The verrucæ are numerous and closely appressed, measuring about 1 millim. in height. The axis is grooved and very flexible, measuring 3 millims. in diameter at the base and becoming hair-like near the tip where the stem measures 2 millims. in diameter. The base consists of a broad flat plate which has a diameter of 14 millims.

The spicules are double clubs and double stars, which measure, length by breadth in millimetres, as follows :—

Double clubs, $0·08 \times 0·03$; $0·087 \times 0·04$.

Stars, $0·05 \times 0·03$; $0·06 \times 0·03$.

The specimen approximates closely to the description of *Juncella fragilis* given by Ridley (1884). The only marked differences are in the colour and in the diameter of the axis at the base. The larger diameter can be easily accounted for by the large size of the specimen, 508 millims. But it seems useful to record a new colour variety.

Locality:—Gulf of Manaar.

Previously recorded from Port Denison, Queensland; 4 fathoms.

Juncella trilineata, n. sp.

Height of specimen 238 millims. It is sparingly branched in one plane, the first branching occurring at a height of 67 millims. There is a distance of 16·5 millims. between this and the next branching. The colony is exceedingly flexible and very graceful. The base is wanting, but the stem at its lower end measures 3·5 millims. in diameter.

Polyps arise in three different bands, leaving three narrow bare strips, each of which has in its centre a slight rib or keel. Under each bare strip lies a large longitudinal canal. The axis shows longitudinal grooves.

The polyps, which measure from 1·1 millims. to 1·5 millims. in height, are arranged in transverse rows of 3 or 4, but many smaller polyps occur which break this regularity.

The spicules resemble those of *Juncella gemmacea* in several of their forms. Unsymmetrical clubs, length by breadth, 0·08 millim. by 0·03 millim.; 0·065 millim. by 0 03 millim.; 0·07 millim. by 0·04 millim.; 0·07 millim. by 0·03 millim.

Double stellate forms, 0·08 millim. by 0·04 millim.; diameter of spindle, 0·02 millim.
,, ,, ,, 0·09 ,, ,, 0·035 ,, ,, ,, 0·02 ,,

Locality:—Patani, Siam.*

Verrucella rubra, n. sp.—Plate IV., fig. 13; Plate V., fig. 8.

A fragment of a colony, which has a total height of 98 millims. and a maximum width of 69 millims., appears to require the establishment of a new species. The base and the lower part of the colony is wanting, and many of the branches seem to be without the upper portion.

The axis, which measures 2·25 millims. in diameter at the lower end, is greyish-brown in colour, with a white central core, very calcareous, rigid, and brittle.

The branching of the colony is very profuse and is confined to one plane. The branches and twigs are given off at a right angle or at a close approximation thereto. There does not appear to be any fixed arrangement in the branching.

* This specimen, along with two others (*Astromuricea ramosa*, n. sp., and *Telesto trichostemma*), was given to me on a visit to Professor Herdman's laboratory by Mr. Nelson Annandale, who asked that it might be incorporated in this Report.—J. A. T.

The verrucæ are small, low, conical, wart-like bodies. They are confined on the whole to the lateral faces, but on the older branches, and on some parts of the stem and of the twigs, they seem to be scattered over three surfaces.

The general cœnenchyma is thin and easily rubbed off (in several places the axis is laid bare); it is mainly composed of double clubs, spindles, and double spindles. The spicules are covered with large rough warts, which are arranged in whorls. The spicules measure, length by breadth in millimetres, as follows:—

Double clubs, 0·10 × 0·047; 0·09 × 0·05; 0·09 × 0·06.

Spindles, 0·10 × 0·035; 0·08 × 0·03; 0·09 × 0·035.

Double spindles, 0·07 × 0·04; 0·08 × 0·04; 0·06 × 0·035.

The colour of the specimen is a bright crimson.

Locality:—Gulf of Manaar.

Verrucella flexuosa, Klunzinger, var. **aurantiaca**, n.—Plate III., fig. 4; Plate IV., fig. 8.

This form is represented by several complete specimens and many fragments. One complete colony has a height of 210 millims. and a maximum width of 180 millims.; another is 74 millims. by 80 millims. The colonies rise from a flat portion which spreads over the surface of a stone. In the largest specimen branching begins at the base, in a smaller the stalk rises to a height of 30 millims. before it gives off the first branch. In the lower portion of the stalk, which has a diameter of 2 millims., there are no polyps present. The verrucæ begin to appear at a height of 14 millims. from the base, but they are not abundant in the older basal region. There are numerous galls.

The branching is profuse and confined to one plane. The branches are given off at various angles—acute for some of the main branches, and almost always a right angle for the minor branches or twigs.

The tips of the branches and the twigs are sometimes slightly flattened in the plane of branching. The branches and the twigs come off very irregularly.

The verrucæ on the younger portions of the branches and on the twigs are somewhat more numerous towards the lateral edges, but on the stem and the older portions they occur all round. The verrucæ are conical in shape and truncated, measuring about 0·75 millim. in height and having a basal diameter of 1 millim.

The general cœnenchyma is granular in appearance, not of great thickness, and composed of spicules in the form of spindles and double clubs. They measure, length by breadth, in millimetres, as follows:—

Spindles, 0·08 × 0·03; 0·07 × 0·02; 0·10 × 0·04; 0·08 × 0·02.

Double clubs, 0·065 × 0·04; 0·08 × 0·04; 0·08 × 0·045.

The specimens described here approach very closely to *Verrucella flexuosa*, Klunzinger, but as this species appears to be very variable, it may be useful to class them as an orange variety.

In another specimen the branching was not at all in one plane; in another there was abundant anastomosis.

Locality:—West of Periya Paar.

Verrucella flexuosa, var. **gallensis**, n.—Plate III., fig. 9; Plate V., fig. 11.

This variety is represented by a slightly damaged colony and several large and small pieces of colonies. The complete specimen has a height of 47 millims. and a maximum diameter of 53 millims. The basal attachment consists of a flat plate-like spreading portion from which the main stem rises. The stem is rigid and brittle, very calcareous in nature, and rises to a height of 13 millims. before it gives off the first branch. The branches are given off at right angles and they in their turn give off branches in a similar manner. The tips of the twigs and branches are occupied by two divergent polyps which gives them a slightly flattened appearance. The branches are given off in an irregularly alternate manner from the main stem and from the larger branches. The branching is confined to one plane. The colour varied from rose-red to vermilion.

The verrucæ are blunt and conical shaped, measuring 0·7 millim. in height and having a basal diameter of 0·8 millim. to 1 millim. They are confined to the lateral surfaces of the stem and branches, but are directed a little more to one surface than to the other. They are arranged in such a way that the verrucæ on the one lateral face alternate with the verrucæ on the other face.

The general cœnenchyma is very thin and is composed of spindles, double clubs and double spindles.

This variety is represented by a large number of fragments, mostly small. The branching in some of the fragments is confined to one plane, but in others the branches are given off on all sides. The axis is cylindrical, white in colour and very calcareous. In the several fragments it shows considerable differences in diameter.

The verrucæ are small, conical shaped, with a wide base. They measure 0·5 millim. in height and have a basal diameter of fully 1 millim. They occur all round the main stem or branch and also on the other branches, but on portions of the older branches and on the younger branches they are more or less confined to the lateral surfaces.

The general cœnenchyma is thin and is chiefly composed of spindles and double clubs. They are covered by whorls of rough warts. In the double clubs there is a very short bare shaft in the middle. Their measurements, length by breadth in millimetres, are as follows:—

Spindles, $0·10 \times 0·04$; $0·08 \times 0·03$; $0·10 \times 0·03$; $0·12 \times 0·03$.

Double clubs, $0·08 \times 0·06$; $0·10 \times 0·04$; $0·07 \times 0·04$; $0·085 \times 0·04$.

Localities:—Deep water off Galle; Gulf of Manaar.

Verrucella sp. (?).

A small fragment, from which several branches are given off in one plane, measures 63 millims. in height.

The axis is very calcareous and brittle.

The polyps on the main stem or branch are more or less restricted to the lateral edges, but on the younger branches they occur on the four surfaces in such a way that they all alternate and appear as if arranged in a spiral manner. They are contained in verrucæ which are small, slightly conical and truncated at the top. The polyps themselves are all withdrawn into the verrucæ, but they present yellowish-white apices at the opening of the verrucæ. Towards the base of the tentacles on the aboral surface two or three pairs of spicules are arranged *en chevron*, and at their bases a few are arranged transversely so as to form a collar. These spicules are short warty spindles, either straight or slightly curved.

The cœnenchyma is thin and is composed of two layers of spicules, the outer layer being coloured and giving the characteristic colour to the colony, while the inner layer is colourless.

In the coloured layer the spicules show a considerable range in shades, varying from a light to a deep amber tint.

The spicules are spindle-shaped, thick in comparison to length, or slender, and covered with rough warts. The coloured, or outer layer, contains the bigger spicules. Their measurements, length by breadth in millimetres, are as follows:—

(*a.*) Coloured, 0·3 × 0·075; 0·4 × 0·08; 0·22 × 0·05; 0·11 × 0·05; 0·10 × 0·03; 0·08 × 0·02.

(*b.*) Colourless, 0·14 × 0·04; 0·175 × 0·04; 0·10 × 0·035; 0·28 × 0·025.

Order V.—STELECHOTOKEA.

Section I.—ASIPHONACEA.

Family: TELESTIDÆ.

Telesto rubra, Hickson.

This species is represented by two fragments, one of which (A) measures only 30 millims. in height.

Specimen A agrees closely with the description given by Hickson. Thus, in the basal portion of the youngest calyces, the spicules are fused to form tubes, the axis has eight longitudinal ribs, and prolonged boiling in caustic potash does not disintegrate it.

Specimen B seemed at first sight to have a black axis, but this was found to be due to *débris* which had collected in the hollow tube.

The whole surface of specimen (A) is covered by an encrusting sponge, which has completely destroyed the cœnenchyma. The spicules of the sponge are monaxonial and triaxonial.

Locality:—Trincomalee.

Telesto (Carijoa) trichostemma, Wright and Studer.

This species is represented by one specimen, which agrees with the description given by Wright and Studer.

The spicules are of two distinctly marked types :—

(1.) Long slender spicules with few lateral processes, often bifurcated at the end;

(2.) Strong, relatively broader spicules, with prominent lateral processes which interlock and form a felted covering.

They measure, length by breadth in millimetres, as follows :—

(1.) 0·3 × 0·02 ; 0·28 × 0·019 ; 0·15 × 0·012 ; 0·26 × 0·014.

(2.) 0·2 × 0·03 ; 0·25 × 0·02 ; 0·23 × 0·03.

The distance between the bifurcations at the ends of the spicules of type (1) often measured 0·02 millim.

Locality : Patani (Siam). This was one of Mr. Nelson Annandale's three specimens already referred to.

Section II. : PENNATULACEA.

Family : UMBELLULIDÆ.

Umbellula, sp.

The collection included* a small specimen, doubtless a young colony, of a species of *Umbellula*. As the specimen is a poor one, we have not studied it in any detail. We may refer to our forthcoming report on Professor Alcock's "Investigator" collection of deep-sea Alcyonacea from the Indian Ocean, which includes numerous Umbellulids of large size.

Family : VIRGULARIIDÆ.

Virgularia multiflora, Kner.

The specimen representing this species is fragmentary. It consists of a piece of the rachis, which seems to come from the lower portion of the colony. It measures 51 millims. in length and has 20 pairs of pinnules. The pinnules are crescent-shaped, 3 millims. in breadth and 2 millims. in height, with 11 polyps on each. The axis is white, almost perfectly cylindrical, with a pitted appearance on the surface and with a diameter of 1·2 millims. The specimen agrees very well with the description given by Kölliker. The following comparison will show the close similarity between the specimens :—

	Kölliker's.	Herdman's.
Breadth of pinnule	3·3 millims. to 4 millims.	3 millims.
Height ,, ,, ...	2 millims.	2 ,,
Number of polyps in a pinnule .	11 to 15	11.
Diameter of axis	1·29 millims.	1·2 millims.

Locality :—Trincomalee.

* From Station LX., Gulf of Manaar, 20 to 30 fathoms. See Professor Herdman's "Narrative," this Report, Part I. (1903), p. 75.

Virgularia loveni, Kölliker.

This species is represented by three fragments, the largest of which measures 106 millims. in length, and appears to consist of nearly the whole rachis, while the other two fragments represent the upper portions of two specimens.

The axis shows slight differences in form; in one it is cylindrical, in another quadrangular, with two of the sides rounded, while in the third it returns to the cylindrical shape, but with one surface slightly flattened. It is covered by transverse ridges or by tubercles, which gives it a pitted appearance. On the prorachidial face of the rachis there is a well-defined narrow groove. The diameter of the axis is 1·5 millims.; the rachis measures 106 millims. in length by 5·3 millims. in width.

The pinnules are folded so as to form a double S-shaped figure. They are almost touching one another near the tip, but lower down they stand considerably apart (3·5 millims.). They vary from 3·5 millims. to 4·8 millims. in breadth, and from 2 millims. to 2·5 millims. in height. The polyps are well defined, arranged in one row on the pinnule, and vary in number from 19 to 24.

The specimens agree with the description of *Virgularia loveni* given by Kölliker (1872), although there are a few slight differences.

Locality:—Trincomalee.

Virgularia, sp.—Plate IV., fig. 2.

The collection includes two fragments which approach *Virgularia loveni*. As they may be young forms, in regard to which little is known, and as they are only fragments, we have been content to give a brief description. The measurements are stated in the following table:—

	Rachis.		Pinnules.		Number of polyps on pinnule.	Number of rows.	Axis diameter.	Stalk diameter.
	Length.	Width.	Breadth.	Height.				
	millims.	millims.	millims.	millims.			millims.	millims.
(A.) . . .	53	4·5 to 5·5	4·8	2·5	23	1	1·5	2
(B.) . . .	56	4·5 ,, 5·5	4·7	2·4	24	1	1·5 (white in colour).	2

The pinnules are folded so as to form a double S-shaped figure. The polyps are well defined. There is a distinct groove on the prorachidial surface which measures 0·4 millim. from edge to edge.

At the tip the pinnules are almost touching, but lower down the distance between them is 3·4 millims.

The axis is almost rectangular in one specimen, with two shorter sides slightly rounded. In the other it is almost circular, but one surface is slightly flattened. In both cases it is covered by tubercles, which gives it a characteristic appearance. The tip of the axis is blunt.

A third specimen gave the following measurements :—

Total length.	Stalk.		Rachis.		Number of polyps.	Number of rows.	Zooids.
	Length.	Width.	Length.	Width.			
millims. 57	millims. 22·7	millims. 1·5	millims. 34·3	millims. At base 2, half-way up 3, near top 5.	26	1	Occurring over the whole surface of rachis. Brownish colour.

Specimen is club-shaped and tapers gradually from base till it reaches maximum width at a point near the tip of rachis.

Abundant spicules both in the stalk and in the rachis.

Calyx ridged.

A distinct groove runs the whole length of the rachis.

Locality :—Trincomalee.

Virgularia tuberculata, n. sp.—Plate II., figs. 5 and 9.

This species is founded to include six fragments which it was found impossible to place under any of the known species. The fragments are very incomplete and are not in good preservation. The two largest specimens are 110 millims. and 81 millims. in length.

The axis is cylindrical and presents a characteristic pitted appearance, due to the tuberculated structure of the surfaces. The tubercles appear at some parts to be irregularly arranged, at other parts to be arranged in whorls. The colour of the axis is a deep coral red shading into a yellowish-red. The diameter is 0·6 millim.

One of the fragments represents the lower part of the rachis, while other two represent the upper extremity. In the lower part the pinnules are small and appear as ridges, which run across the lateral surfaces of the rachis. The polyps are borne in one row on the edge of the pinnule and number six on each pinnule. Higher up the pinnules become more mature, larger, and separated by a longer interval. They present a quite different appearance, becoming slightly crescent-shaped. The polyps are somewhat barrel-shaped and are quite distinct, except for a small portion at their bases, which are fused together to form the pinnule.

The cœnenchyma is very thin, but on the pararachidial surface it is produced into two ridges, on which the siphonozooids are found. Their arrangement cannot be exactly ascertained, but they seem to form an interrupted line on each of the ridges, and also occur either singly or in small groups below each pinnule.

The polyps on the separated parts vary from barrel- to flask-shape in the retracted condition, and measure in this state from 0·5 millim. by 0·4 millim. to 0·65 millim. by 0·4 millim. In their expanded condition they are more cylindrical in shape and measure 0·9 millim. by 0·4 millim. They still present a slightly swollen appearance about the middle of their length.

The six fragments represent parts of the rachides of at least three different specimens. In no case is there any part of the stalk left, so that it is impossible to give any idea of its shape and size.

Locality :—Trincomalee.

FAMILY : PENNATULIDÆ.

Halisceptrum periyense, n. sp.

The collection included a couple of specimens of what appears to be a new species of *Halisceptrum*. Both specimens were complete and the natural colour is recorded by Professor HERDMAN as pink and white.

The lower portion of the stalk is curved and stands at right angles to the axis of the rachis, with its lower extremity marked by a ball-shaped swelling. The stalk passes almost imperceptibly into the lower portion of the rachis, which forms a long spindle-shaped swelling marked by two narrow **V**-shaped lines of pores, one on each lateral surface. The upper part of the rachis bears the pinnules, which show a marked difference in appearance. On the upper portion they are fairly large and show well-marked polyps on a wavy outline, while on the lower part they are reduced to straight ridges across the lateral faces of the rachis. The proportion of the mature to the immature pinnules is rather striking, there being in one specimen 14 mature to 53 immature, and in another 10 mature to 36 immature.

The pinnules in the immature state have the polyps arranged in one row, but soon the pinnule begins to get folded and the polyps begin to alternate, thus giving the appearance of multiple rows of polyps. The distance between the origins of the pinnules is 2·5 millims. in the case of the mature, but the immature lie almost touching one another. The pinnules are translucent, and they show a stringy appearance when held between the eye and the light.

The prorachidial surface of the rachis is free from pinnules and is marked by a distinct narrow groove. This groove fades away and disappears entirely between the immature polyps.

We add a table of measurements of the two specimens. There is in each a single row of polyps on the pinnules, but they alternate in arrangement so as to appear like two or more rows.

	Stalk.		Rachis.		Pinnules.		Number of polyps on each lower pinnule.	Distance between origins of pinnules.
	Length.	Width.	Length.	Width.	Breadth.	Height.		
	millims.	millims.	millims.	millims.	millims.	millims.		millims.
(A)	41	3	78	6·5	3·3	3·1	29 to 31	2·5
(B)	36	2·2	49	6	3	2·8	28 ,, 30	2·5

Locality :—Periya Paar, Gulf of Manaar, $9\frac{3}{4}$ fathoms.

Halisceptrum gustavianum (Herklots).

This species is represented by one complete specimen. Of the 23 millims. forming the stalk the lower 11 millims. consist of nothing but the axis which tapers to a point. At the upper end of the 11 millims. the axis has a diameter of 1·3 millims. and is cylindrical in shape.

In the rachis the stalk becomes grooved and approximates to a quadrangular shape. A groove is distinctly seen in the prorachidial face of the rachis, but this fades away and disappears in the lower part of the rachis.

The pinnules show a large number of polyps which appear to be arranged in a number of rows. In the immature pinnules the polyps are in a single row, but they soon begin to alternate, and in the mature pinnules they seem to be in six rows. The number of mature pinnules is very small compared with that of the immature, the numbers being 16 pairs to 40 pairs.

Pinnules : Breadth, 2·5 millims. ; height, 2·5 millims.

Distance between origins of pinnules, 4 millims.

Length of whole colony, 86 millims.

Locality : Station LII., Gulf of Manaar, 3 to 6 fathoms.

Pteroeides lacazei, var. **spinosum**, Kölliker.

This species is represented by a fragment only of the upper portion of the rachis, measuring about 36 millims. in length, with 15 pinnules on one side, 16 on the other.

The principal measurements are as follows :—Width of rachis, 48 millims. ; breadth of pinnule, 20 millims. ; height of pinnule, 12 millims. ; number of main rays, 12.

There is a single row of zooids running down the centre of the meta-rachidial surface.

The wart-like termination of the rachis is almost completely hidden between the two uppermost pinnules. The rachis seems to have been swollen towards the tip and the fragment seems to be a part of the swelling.

The zooid plate is basal. The pinnules are marked by a number of V-shaped black markings on their margins. The polyps are situated both on the upper and on the lower surface of the pinnule, but they are more abundant on the upper surface.

This specimen resembles *Pteroeides lacazei*, var. *spinosum*, in having one row of zooids, in the termination of the axis, in the number and composition of the main rays and in the texture of the pinnules.

Locality:—Station XXI., Back Bay, Trincomalee, 8 to 12 fathoms; Station LXIII., West of Periya Paar, 40 fathoms.

Family: VERETILLIDÆ.

Cavernularia obesa, Valenciennes.

This species is represented by a number of specimens obtained from shallow water in the northern part of the Gulf of Manaar. The largest specimen is evidently only the upper portion of a large colony. The part measures 61 millims. in height, and has a diameter which varies from 10 millims. near the tip to 17 millims. near the lower end. In shape it is irregularly elliptical.

The autozooids are scattered over the surface, and the parts not occupied by the autozooids are thickly beset with siphonozooids. The position of the autozooids, which are all retracted, is marked by bluish- to brownish-black spots.

A cross-section in the lower part shows four large central canals which run parallel to the long axis of the specimen and are apparently continuous. Radiating from the central part thus formed numerous canals can be seen, some of which run down to the central canals, others end blindly, and others join with one another. Some of the larger canals seem to open into one or other of the four central canals.

The spicules are perfectly smooth rods, with blunt ends, some cut abruptly across, others slightly tapered and rounded.

Another specimen, which is quite complete, probably belongs to the same species. It has a total length of 53 millims. and a rachidial diameter of 7 millims. near the tip. The rachis is slightly elliptical in cross-section, but becomes almost cylindrical near the tip. The whole surface not occupied by the autozooids is covered by numerous minute wart-like bodies which represent the upper parts of the siphonozooids.

The autozoöids occur scattered over the whole surface, and all are almost completely withdrawn. The incurved tentacles are just visible on the surface as brownish- to bluish-black circles. There is a marked difference between the autozooids in size, but this is probably due to a difference in the state of retraction.

The stalk is marked off from the rachis by an abrupt diminution in size, and it, with the lower part of the rachis, is marked by a number of grooves which run parallel to the length of the specimen.

Localities:—Station LII., near Vankali Reef, Gulf of Manaar, 3 to 6 fathoms; and Cheval Paar.

Stylobelemnoides, n. gen.

Veretillid with polyps over the whole surface; spicules long, rod-like spindles; axis cylindrical; calyces with 8 double rows of spicules.

Stylobelemnoides herdmani, n. sp.—Plate III., fig. 5; Plate IV., fig. 3.

The specimen is a broken club, 32·5 millims. in length, 2·8 millims. in breadth at thickest upper part, 2 millims. at lower end. The axis is straw coloured, square, with somewhat prominent angles, 0·85 millim. in thickness. The whole surface of the club is covered with small rod-like spicules, which form tubular calyces with 8-lobed apertures. The polyps are arranged all round the club, in two intersecting (but not exact) spirals. They form nine irregular rings. The siphonozooids fill up the interstices, and no bare streak is left.

The radial disposition of the polyps indicates a Veretillid; that they cover the whole surface indicates a Veretillean. As the limy bodies are long rod-like spindles, the specimen must be near *Stylobelemnon.*

But it differs from *Stylobelemnon* in many ways: *e.g.*, the axis is round not square; the calyces show 8 double rows of spicules; and the spicules are much larger, 2·25 millims. in length.

Under a magnification of 32 diameters the surface is seen to be closely covered with small straight spicules, among which the siphonozooids can be seen.

The polyp calyces are built up of similar spicules very closely packed together, and lying with their long axes parallel to the length of the calyx, thus forming a stiff protective case.

The spicules are present both in the cutis and in the deeper tissue.

Locality:—Trincomalee.

REPORT

ON THE

OPISTHOBRANCHIATE MOLLUSCA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

GEORGE P. FARRAN, B.A.,
ASSISTANT NATURALIST (FISHERIES BRANCH) DEPARTMENT OF AGRICULTURE AND TECHNICAL INSTRUCTION FOR IRELAND.

[WITH SIX PLATES.]

THERE are about 50 species of Opisthobranchs in the collection, and of these 16 are now described as new to science.

The Report is divided into two sections, I. NUDIBRANCHIATA and II. TECTIBRANCHIATA, with an Appendix containing (1) *Onchidium* and (2) *Marsenia*.

I. NUDIBRANCHIATA.

The collection of Nudibranchs made by Professor HERDMAN in Ceylon and handed over to me for identification amounts to 30 species. Of these 9 must be described as new, 12 are fairly well known tropical species, 4 are now identified with species previously described by ABRAHAM or by QUOY and GAIMARD, but of which little was known, and 5 are too small to identify satisfactorily.

The list of species is as follows :—

Hervia ceylonica, n. sp.
Galvina producta, n. sp.
Eolis sp. ?
,, sp. ?
Doto sp. ?
Melibe fimbriata, A. and H.
Scyllæa pelagica, L.
Pleurophyllidia formosa, KEL.

Linguella cinerea, n. sp.
Hexabranchus marginatus (Q. and G.).
Discodoris labifera (ABR.).
Platydoris inframaculata (ABR.).
,, *speciosa* (ABR.).
,, *herdmani*, n. sp.
,, (?) *spinulosa*, n. sp.
Halgerda punctata, n. sp.
Thordisa (?) *caudata*, n. sp.
Chromodoris reticulatus, PSE.
,, *tenuilinearis*, n. sp.
Casella cincta, BGH.
Ceratosoma cornigerum, GRAY.
,, *ornatum*, BGH.
Doris sp. ?
,, sp. ?
Doriopsis aurea, Q. and G.
Phyllidia varicosa, LEUCK.
,, *nobilis*, BGH.
Ægires villosus, n. sp.
Trevelyana bicolor, A. and H.
Kalinga ornata, A. and H.

It is, perhaps, premature to institute comparisons between the Nudibranch fauna of Ceylon and those of other localities, as so little is known comparatively of the distribution of the group in the warmer seas, and as the identification of spirit specimens from written descriptions is attended with great uncertainty.

The capture of four species of Eolids and a *Doto* on the hanging oyster cages is of interest, as it seems to show that absence or rarity of these families in tropical seas is, perhaps, due more to the difficulty of finding them than to their actual scarcity, the larger and more showy Dorids attracting the attention of collectors to the exclusion of more insignificant forms.

There has been but little work done in the past on Ceylonese or Indian Nudibranchs. Dr. KELAART, in 1859 (**3**) (**4**), described 33 species of *Doris* from specimens collected in Ceylon, but his descriptions are based mainly on the colour and texture of the living animal. ALDER and HANCOCK (**5**), in examining a collection of Nudibranchs from Madras, re-discovered six of KELAART'S species with the aid of his original drawings, and added 32 more, besides recording three others previously described.

Of more recent works should be mentioned a paper by COLLINGWOOD on Nudibranchs from the Eastern seas (**8**) and a list of the Dorididæ in the British Museum Collections by ABRAHAM (**7**), who there describes the external characteristics of a number of spirit specimens. Reference should also be made to the work of Sir CHARLES ELIOT, who has published papers on the Nudibranchs and Tectibranchs of Samoa, the Maldives and Laccadives, and East Africa (**11**) (**12**) (**13**).

Most, however, of the adequate descriptions of Oriental Nudibranchs are due to the long-continued work of Dr. RUDOLPH BERGH, culminating in the magnificent series of papers in SEMPER'S 'Reisen im Archipel der Philippinen.'

In working out the collection no attempt has been made to investigate the anatomy of the specimens beyond what seemed to be necessary for their identification.

In conclusion, I should like to express my thanks to Professor HERDMAN for his kindness in allowing me to work out this collection and use his notes, and for the facilities which he afforded me, and also to Mr. E. A. SMITH for kindly allowing me to examine the Nudibranchs preserved in the British Museum Collections.

NUDIBRANCHIATA CLADOHEPATICA

FAMILY: ÆOLIDIIDÆ.

SUB-FAMILY: CRATENIINÆ.

Hervia ceylonica, n. sp.—Plate I., figs. 1 to 5.

Amongst the Nudibranchs obtained from oysters hung over the ship's side, in the Gulf of Manaar, were 12 specimens of a small Eolid, length 8 millims., which seems to belong to the genus *Hervia.* This genus is closely allied to *Cratena,* and is distinguishable externally by the large tentacles, smooth rhinophores, grouped papillæ, and produced anterior angles of the foot; and internally by the single series of arched teeth strongly denticulate on either margin.

The specimens here described have the body pale and semi-translucent, the papillæ with fawn-coloured hepatic contents, probably faded, long and slender, with distinct white cnidogenous sacs. They are arranged in 5–6 irregular transverse rows, the first row widely separated from the rest. The tentacles are long, very thick at the base, and tapering evenly to a point. The rhinophores are short, slender, and smooth, the eyes being visible at their base. The anterior angles of foot are moderately produced, the tail slender and moderately long (Plate I., fig. 1).

The jaws are of the usual shape in the Cratenidæ, with rather short cutting edge, irregularly denticulate. The radula has a single row of arched teeth, with an acute apex and 5 strong lateral denticulations on either side (Plate I., fig. 2).

The genital organs did not show any sign of armature.

BERGH refers three species to this genus, two from the Mediterranean, and one, *H. rosea,* BGH., from Amboyna; and in addition to these ALDER and HANCOCK (**5**) have described another species from Ceylon, under the name of *Eolis militaris,* which appears to be undoubtedly a *Hervia,* though BERGH (**9**), probably by an oversight, refers it to *Coryphella.* It is distinguishable from the present species by its much larger size and the possession of 7 lateral denticulations on the radula teeth.

KELAART has given names to 8 species of *Eolis* from Ceylon, but his descriptions are so vague as to be practically worthless.

SUB-FAMILY: TERGIPEDINÆ.

Galvina producta, n. sp.—Plate I., figs. 6 to 9.

In company with the last-mentioned species was one specimen whose characters, with one exception, agree with those of the genus *Galvina.*

Length, 9·5 millims., papillæ inflated, tapering, constricted below the tips, which are somewhat opaque, hepatic contents vesicular-looking, rhinophores moderately long, tentacles short, anterior angles of foot produced.

Colour, faded, a light transparent brown without markings; hepatic contents whitish-yellow; jaws and teeth as in the genus *Galvina*. The median teeth of the radula robust, with short point, and 5, sometimes 6, lateral denticles. This species differs from the other members of the genus in having the anterior angles of the foot produced, but otherwise it is a typical *Galvina*. All hitherto recorded Galvinæ are either Atlantic or Mediterranean, with the exception of *G. exigua*, which BERGH (**15**) has recorded from the Pacific. This adds the Gulf of Manaar.

Eolis, spp. ?

There are two other small Eolids, representing two different species, in the collection, both from the oyster cages hung over the ship's side in the Gulf of Manaar, which are too small to identify. One of these, length 4 millims., is, perhaps, a *Hervia*. It has the anterior angles of the foot produced, the tentacles long and slender, the rhinophores small; the papillæ are crowded, long and slender, with acute white cnidogenous tips and dark greenish-black contents. The body colour is a transparent reddish-yellow.

The other specimen, length 4 millims., has the papillæ in 5 distant transverse rows; the larger papillæ are ringed in a manner that recalls the genus *Zatteria*, described by Sir C. ELIOT (**11**, p. 62) from Zanzibar specimens. The rhinophores are moderately large and rugose, the tentacles small and the anterior angles of the foot produced.

FAMILY: DOTONIDÆ.

Doto, sp. ?

One specimen of a *Doto*, length 2·5 millims., too small to identify, was obtained from the above-mentioned oyster cages in the Gulf of Manaar. Externally it bears a close resemblance to *D. pinnatifida*, MONT., the form, coloration, and black spots on the papillar tubercles being in agreement with that species.

BERGH (**9**, p. 795) has recorded a species of *Doto* (*D. indica*) from Mauritius, to which it is possible that the specimen should be referred.

FAMILY: TETHYMELIBIDÆ.

Melibe fimbriata, ALD. and HANC.

There are three specimens of this species from separate localities on the West Coast of Ceylon. One from off Negombo, one from Periya Paar, 9 fathoms, and one from Chilaw Paar, 11 fathoms. As usual, they are in a very imperfect state, having lost several of their dorsal papillæ.

Professor HERDMAN notes in his diary the colour of the living animal as follows: "Pale amber brown, in front, with brownish papillæ and white spots—clear, gelatinous." This species, as was first pointed out by ALDER and HANCOCK (**5**), and subsequently confirmed by Sir CHARLES ELIOT (**11**), differs from the rest of the genus in having no trace of labial or buccal armature.

M. fimbriata is found throughout the Indian Ocean.

FAMILY: SCYLLÆIDÆ.

Scyllæa pelagica, LINN.

Amongst the nudibranchs found on the oyster cages which were kept hung over the ship's side from February 15 to March 15, 1903, in the Gulf of Manaar, were two specimens of *Scyllæa* which agree fairly closely, both in general appearance and also in form of radula and jaws, with *S. pelagica*. Externally they also rather closely resemble *S. marmorata*, ALD. and HANC., from Madras, agreeing with it in the rounded dorsal wings and slight development of the caudal ridge, but it seems to me that there are hardly sufficient grounds for regarding the latter as a distinct species.

The colouring of the Ceylon specimens, the largest of which measures 3·0 centims., is mainly due to large irregular areas of light-brown stellate chromatophores, amongst which are vacant pale blotches. There are scattered dark spots formed by aggregations of stellate chromatophores which seem to correspond to sub-dermal patches of pigment and also a few small ocellated spots, the centre formed of contracted brown chromatophores, possibly of a different colour during life, and the surrounding paler area of very finely-branched chromatophores. These ocelli occur on the sides and in a row down the centre of the back.

The body bears a few small colourless tubercles. The buccal mass and, more noticeably, the œsophagus are pigmented with brown stellate chromatophores.

FAMILY: PLEUROPHYLLIDIIDÆ.

Pleurophyllidia formosa, KEL.—Plate I., figs. 14 to 16; Plate II., fig. 1.

One specimen from northern part of the Gulf of Manaar.

Length of preserved specimen 5·2 centims., width 4 centims., width of foot 2·3 centims. Colour an opaque greyish-brown, paler on the sides of the foot, with remains of black pigment between the dorsal ridges and on the dorsal surfaces of the tentacle shield.

The form of the animal corresponds closely to the figure given by BERGH (**10**, plate i., fig. 1). The tentacle shield is broad, with thin projecting upper margin. The back is marked with about 36 slightly raised longitudinal lines, larger and smaller ones irregularly alternating.

The gill lamellæ are about 5 millims. in length, and lie in a crowded transverse band, which runs at about right angles to the direction of the anterior lateral lamellæ. The lateral lamellæ are numerous, about 50, and run transversely from the body almost to the margin of the mantle, the direction of the anterior ones being somewhat diagonal.

The jaws (Plate I., fig. 14) are powerful, of a dark horn colour, and of the usual form. The radula (Plate I., figs. 15 and 16) consists of 70 rows of 140–1–140 teeth. The median tooth is very broad (0·3 millim. × 0·12 millim.), with four lateral denticles and a strong, rather blunt median point with toothed margins, the basal pair of denticulations being very large. The 1st lateral tooth is strong, with a broad somewhat rectangular base and an irregularly serrulate or smooth outer margin. In the 2nd tooth the margins are smooth and the point entire. The 3rd tooth has a small sub-apical denticle on the outer margin. This denticle is found on all the teeth outwards till the outermost one is reached; it increases in size outwards, so that the lateral teeth are for the most part bifid or, in a few cases, trifid. The outermost tooth is simple. This specimen differs slightly as to its radula from that examined by BERGH, in which the apical denticulation begins on the 5th tooth and is absent from the 3–6 outermost. It agrees, however, in other respects. The other Ceylon species, *P. ceylanica*, has, like *P. formosa*, the lateral teeth bidentate, but differs in having a much smaller number of lateral teeth and in having the outermost teeth finely serrulate.

Linguella cinerea, n. sp.—Plate I., figs. 10 to 13.

A single specimen of this species was dredged 10 miles north of Cheval Paar.

Length about 1·5 centims., width 1·4 centims., width of foot 0·9 centim.

Mantle moderately smooth, of a greenish-grey colour, which is denser on the head and front of cloak. The margin of the cloak studded with distant tubercles marked with a ring of grey, becoming larger towards the centre of the back and merging into irregular raised areas separated by deeply pigmented grey furrows.

Lateral margin of underside of mantle with a band of opaque yellow cnidopores, 2 to 3 deep. Lateral lamellæ about 32, slightly oblique.

Radula of 35 rows, formula 46–1–46. The central tooth (Plate I., fig. 10) has a median spine with 3 lateral serrulations, and 3 lateral denticulations. The 1st lateral tooth with about 9 denticulations on the outer edge. The teeth increase in length outwards, the number of denticulations decreasing (Plate I., fig. 12), and the two outermost teeth being smooth (Plate I., fig. 13).

The jaw plates (Plate I., fig. 11) of the usual form, strongly curved (in the figure they are flattened out), of a dark horn colour.

This species seems outwardly to come rather near to *L. sarasinica*, BGH., from Ceylon, but differs in not having the tubercles densely crowded on the mantle edge. The radula also is very different both in form and number of teeth.

NUDIBRANCHIATA HOLOHEPATICA.

DO RIDIADÆ CRYPTOBRANCHIATÆ.)

SUB-FAMILY: HEXABRANCHIDÆ.

Hexabranchus marginatus, Q. and G.

There are in the collection two specimens of *Hexabranchus*, both from Periya Paar, which I think it is probable belong to this species. One specimen is very small, length only 1·1 centims., the other is somewhat larger, length 3·5 centims., but both fall far short of the size usually attained by members of the genus, and are probably immature.

Professor HERDMAN'S notes, referring to the larger specimen, are "scarlet and white, swimming species," and "red blotched with white, especially at sides of mantle." The spirit specimen is somewhat depressed, of a dirty semi-translucent white colour. The mantle wide and thin and frilled at the margins, total width 2·4 centims., free margin 0·55 centim. The free edge of the mantle in front of the head is 2·5 millims. wide and has a smooth entire margin.

Rhinophores far apart, of the usual shape, with about 28 lamellæ. Tentacles large, flattened, with crenated margins. Branchiæ in 6 groups surrounding the short tubular anus.

The jaws are powerful, with about 8 transverse ridges.

The radula has about 32 rows of teeth, the formula being 46–0–46. The innermost 2–3 teeth on each side are imperfect.

The identification of species of *Hexabranchus* from preserved specimens is, as both BERGH and ELIOT (**12**) have remarked, a matter of difficulty, but in this instance there seems little doubt that the specimen is *Hexabranchus marginatus*, as the white marginal blotches, crenate margin to tentacles, and distinct anal tube, as well as the agreement of the radula, seem to indicate.

COLLINGWOOD'S *Albania formosa* (**8**, p. 132), from Formosa, seems to be undoubtedly the same species, as also, perhaps, ALDER and HANCOCK'S "Undescribed species of a new genus apparently related to *Goniodoris*," from Madras (**5**, Plate XXXIII., fig. 20).

SUB-FAMILY: DISCODORIDIDÆ.

Discodoris labifera (ABR.).—Plate I., figs. 17 and 18.

There are three small specimens of *Discodoris*, one from the pearl banks off Aripu and two from Cheval Paar, which I doubtfully refer to the above species. The animal is quite unrecognisable from ABRAHAM'S original description (**7**); but on examination of what appeared to be the type specimen in the British Museum, I found that, making allowance for difference of size, it agreed fairly well in external features with the Ceylon specimens. The British Museum specimen is undoubtedly a *Discodoris*, as the partially protruded buccal armature is distinctly visible, though there is no mention of this in ABRAHAM'S description. There are also in the British Museum collection some unnamed specimens from South Africa which apparently belong to the same species.

The Ceylon specimens measure about 1·6 centims. in length, and the width of the most symmetrical is 0·95 centim. The colour of the Aripu and one of the Cheval Paar specimens is a dirty greyish-brown. The other Cheval Paar specimen, though much distorted, has preserved its colour and texture better than the rest. It is of a slaty blue-grey colour above and below. The mantle has a number of moderate brownish spots, absent from the centre and extreme margin. The underside of the mantle and foot are finely dotted with brown. The mantle is covered with fine tubercles, somewhat pointed, giving it a slightly pilose appearance ; this is not so marked in the other specimens. The branchiæ are 6 in number, compoundly pinnate. The branchial opening is placed far back and has the form of a transverse slit. The jaws are of the usual form, made up of blunt rods ; colour, a pale brownish-straw. Radula with 18 rows, the last two immature, formula 26–0–26, the teeth increasing in size gradually outwards (Plate I., fig. 18), the outermost four teeth again rapidly decreasing (Plate I., fig. 17).

ABRAHAM's original specimen of *D. labifera* came from the Seychelles Islands.

SUB-FAMILY: PLATYDORIDIDÆ.

Platydoris inframaculata (ABR.).—Plate II., figs. 2 to 7 ; Plate III., figs. 8, 9.

Amongst the Nudibranchs obtained at Galle is one well-preserved specimen of *Platydoris*, which is, I think, referable to the above. The general appearance, markings, and tuberculation of the mantle of the type specimen from Amboyna preserved in the British Museum agree fairly well, but it is impossible to decide with certainty upon the identity of closely allied species of *Platydoris* without an examination of the radula and the usually very characteristic armature of both penis and vagina.

The ground colour of the Ceylon spirit specimen is pale reddish-brown, the mantle having a few irregular dark rusty markings formed by minute reticulations round the tubercles ; the lower surface of the mantle bears large circular purplish-black blotches, rather larger and fewer than in the type specimen. The mantle is much depressed and covered with minute, close-set, spiculose tubercles. The rhinophore pores are slightly raised. The branchiæ are 6 in number, large, 3-pinnate surrounding the long, tubular anus, partially retracted into a wide, deep collar (Plate II., fig. 3). The total length of the animal is 4·7 centims., width 3 centims., width of foot 1 centim.

The radula consists of 44 rows ; there are 70 lateral teeth on each side and no median tooth. The teeth are simply hooked, increasing in size outwards (Plate II., fig. 4 ; Plate III., figs. 8 and 9).

The retracted penis (Plate II., figs. 5 and 7) is armed internally with numerous hook-bearing discs, crowded and rather large below, becoming smaller and more distant as it passes upwards, and taking the form of small prickles on the glans. The vaginal wall bears 6 stout, chitinous discs (Plate II., fig. 6) arranged in opposing pairs. These discs are peltate, the boss being formed of 5–6 rounded nodules, and the whole surface being finely granulated. They measure 0·65 millim. in diameter. The size of the largest penial discs is about 0·19 millim. by 0·155 millim.

Platydoris speciosa (ABR.).—Plate II., figs. 8 to 12, and Plate III., fig. 10.

The type of this species from Amboyna is, like the preceding, preserved in the British Museum, and has been described by ABRAHAM (7), but nothing is known of the form of its radula or genital organs. A specimen of *Platydoris* from the Gulf of Manaar appears to belong to this species. Its length is 5·7 centims., width 4·5 centims., width of foot, much contracted, 0·9 centim. The mantle is very wide, covered above with closely-set, minute tubercles with radial spicules. The ground colour of the specimen is an opaque muddy brownish-grey. The mantle is marked above with collections of small, purplish-brown spots, irregularly placed over the whole surface.

The lower sides of the mantle are marked with large, purple-brown, circular blotches, with smaller ones on the side of the body. The rhinophore pores have their margin slightly raised. The branchial pore is 6-lobed, stellate, tightly closed over the retracted branchiæ. The walls of the pore are moderately high. The branchiæ are 6 in number, compoundly pinnate surrounding the long tubular anus, the margin of which is crenulated.

The radula (Plate II., figs. 8 to 10; Plate III., fig. 10) contains 46 rows, with about 58 teeth on either side of the naked rachis. The teeth are simple, hooked, decreasing in size slightly towards the centre of the radula. Compared with those of the previous species, they are somewhat smaller and much more slender.

The penis (Plate II., figs. 11 and 12) is armed as usual with hooked discs, rather large and closely set below, much smaller surrounding the glans, which bears a few still smaller spines. The armature of the vagina, owing to an accident during examination, could not be noted.

This, or the preceding species, may perhaps prove to be identical with the *Doris formosa* or *Doris elliotti* described by ALDER and HANCOCK from Madras, but this cannot be determined without an examination of specimens in their natural colours.

Platydoris herdmani, n. sp.—Plate II., figs. 13 to 17.

A single specimen of this species was taken at Galle, and three others, without recorded locality, are in the collection. Length 3 centims., width 1·4 centims., width of foot, edges approximated, 0·4 centim., height 0·5 centim., length of foot 2·1 centims.

The mantle is large, minutely tuberculate, with its edges thin and very much frilled. Its centre is marked by a large, irregular, pale reddish-brown blotch, spotted with darker, and breaking up into smaller spots towards the margins of the mantle.

The extreme margin of the mantle is marked by a series of black sub-dermal spots, equally visible from above and below. The under side is very faintly dotted with pale brown, the margins of the foot being marked with darker brown.

The ground colour is a waxy flesh colour. The texture of the body is stiff and brittle, the spicules are numerous, small, slightly roughened, and arranged in dense, closely-packed, stellate clusters. The branchial and rhinophoral pores are raised and closed, not distinctly stellate. The tentacles are comparatively large and conical. The foot is very narrow, with its margins approximated in all the specimens.

The radula consists of 44 rows with no median tooth and about 70 lateral teeth on each side increasing gradually outwards from the centre. The outermost tooth is rudimentary, without a lamina, the 2nd is fringed, the 3rd broad and flattened with a slightly denticulate edge, the 4th normal.

The penis is armed with comparatively few small, distant, hooked plates which are not found on the glans. The vagina bears four large chitinous hooks arranged in pairs one above the other on opposite sides of the lumen. This species belongs to quite a different group of the genus from that of the two preceding. It appears to be distinct from any described species, though approaching somewhat to *P. angustipes*, Bgh., from the Antilles.

Platydoris (?) spinulosa, n. sp.—Plate II., figs. 20 to 23; Plate III., figs. 1 to 3.

There is one specimen of an apparently undescribed Dorid from 10 miles north-east of Cheval Paar, which I have provisionally referred to the genus *Platydoris*, though it differs from it in some particulars.

Its length is 2·8 centims., width 1·9 centims., height 0·8 centim. The mantle is wide with straight entire margin, covered above with moderate unequal tubercles placed fairly widely apart on the centre of the back and more closely near the margin, but not crowded anywhere. The largest tubercles lie in an irregular ring, 3 to 4 deep, parallel to and some distance from the edge of the mantle, the centre and margin being occupied by smaller tubercles. The tubercles are rounded or slightly conical, spiculose, the ends of the spicules protruding distinctly. There are also larger spicules arranged in reticulating bundles between the tubercles.

The foot is contracted and rather narrow, the front margin bilaminate and divided. The tentacles are very small, pointed and recognisable with difficulty.

As to colour, Professor Herdman has made a note in his diary on a specimen from this locality which I think there is little doubt refers to the species in question. "Flat red Doris, 1 inch, spotted with dark purple on under-side, wide mantle." There is little trace of colour remaining, the ground colour is white above and below, and the larger tubercles surrounding the centre of the mantle have each a faint light brown ring, the under-side is rather thickly spotted with darker brown, the spots having a deep nucleus and a fainter halo; their diameter varies from 0·5 millim. to 1·5 millims. The rhinophores are white, the branchiæ yellowish, shaded with brown internally at their base, rachides white. The branchiæ are 6 in number, tri-pinnate, the branches small, the rachides long and thick, joined at the base and each with a median groove exteriorly. The branchial pore is raised, circular but not produced into a tube. The rhinophoral pores are slightly raised.

The radula (Plate III., figs. 1 to 3) differs somewhat from that usually found in *Platydoris* on account of the rapid decrease in size inwards of the innermost 14 teeth.

The number of lateral teeth on each side is 48, the 6 or 7 outermost being fringed instead of simply hooked. The penis seems to have been armed as in *Platydoris* with hooked plates, but the preparation was unfortunately mislaid before examination. The vagina (Plate II., figs. 22 and 23) is very strongly armed with two longitudinal rows of peltate discs, very convex, the boss formed of a single powerful spine; there are about 16 discs on each side opposite each other, but not arranged in pairs. They are largest in the centre of the rows and become much smaller towards each end.

The stomach (Plate II., fig. 21) is of an unusual structure, the intestine leaving it medio-dorsally instead of anteriorly, as is usual. The radula sac is long and curved upwards on the left side of the œsophagus (Plate II., fig. 20).

This species differs from the usual type of *Platydoris* in the long radula sac, form of the radula, structure of stomach and larger size of dorsal tubercles. It agrees with it in its general flattened form and genital armature. It is probable that an examination of further specimens will make it clear that a generic distinction exists.

Sub-family: DIAULULINÆ.

Halgerda punctata, n. sp.—Plate III., figs. 4 to 7.

There are in the collection (Gulf of Manaar) two specimens of a moderately large glabrous Dorid with the mantle raised into tubercles, more or less connected by ridges, for which I propose the above name. I have placed it in the genus *Halgerda*, as it agrees in most points with the single known species *Halgerda formosa*. Professor Herdman's notes describe what must be this species as follows:—"Dorid, W. of Donnan's Paar, 29 faths., March 11th, 1902; pale whitish-grey, rather translucent, with yellow papillæ on mantle, and purple spots on foot and a few also on mantle."

The ground colour of both the preserved specimens is white on both sides of the mantle, and on the foot. The mantle is flecked with a few black spots, which measure from 0·5 millim. to 1·5 millims. in diameter, appearing to be of tougher consistency than the rest of the body, and to extend to a slight depth. In one specimen there are only four such spots, very small, near the posterior end, but in the other they are more numerous, about twenty, arranged more or less symmetrically. There is a pinkish tinge on the apices of some of the tubercles. The under-side of the body of both specimens is marked with black spots similar to those found on the notæum, but more numerous, especially on the specimen which is more spotted above. The size is about the same in both specimens: length about 3 centims., width 2·8 centims., height 1·5 centims. The mantle is glabrous, moderately tough, and bears numerous large blunt tubercles arranged in more or less diagonal lines connected by ridges which form an irregular triangular network. This arrangement is much more distinct in one specimen (figured on Plate III., fig. 4) than in the other, which has much fewer tubercles, and in which the ridges are almost obsolete. The branchial opening is circular and measures about 0·6 millim. in diameter, its edges are thin and raised into a collar with smooth even margin. The rhinophoral pores are oval, placed longitudinally with even edges somewhat raised. The pseudo-peritoneum is of a blackish-brown colour. The foot is moderately wide: in the preserved specimen it is much contracted and measures 0·45 centim. across. It is bi-lipped in front, the anterior lip bifid. The head is small, the tentacles very small and apparently tubercular.

The branchiæ (Plate III., fig. 6) are 4 in number and tri-pinnate, the anterior pair larger, the posterior pair shorter and divided deeply into two main branches. The rachides are rather thick, white on the outer side and black interiorly. The lamellæ are black. The anus is rather long and tubular, white with a black crenulate margin. The rhinophores are stout, with black lamellated tips and thick white base.

The radula sac is unusually long and curved towards the left side. The radula consists of 50 rows of hooked teeth; the lateral teeth on each side number about 50, a median tooth being absent. The 20 innermost teeth (Plate III., fig. 5) are very small, increasing outwards; the 3 outermost teeth (Plate III., fig. 7) are small and thin, but not fringed or denticulate. There is no buccal armature, but the buccal tube has a stiff chitinous lining in which were embedded several grapnel-shaped sponge spicules.

The penis and vagina are as far as could be made out unarmed. The stomach and gut were both crowded with tapering rod-shaped spicules roughened at the apex and slightly bent at the base.

This species agrees with Bergh's diagnosis of the genus *Halgerda* in the following particulars: The smooth leathery mantle raised into tubercular ridges, the bi-lipped foot, small tentacles, small number of branchiæ, absence of jaws, long curved radula sac, radula without median tooth and with the innermost teeth markedly smaller, unarmed penis and vagina. The genus *Dictyodoris*, though placed by Bergh in a different sub-family, also approaches it in some respects.

Halgerda formosa from Mauritius differs from the species now described in having more numerous and apparently narrow dorsal ridges, and in having two outermost teeth of the radula on either side denticulate. It is marked with crimson spots and yellow lines, and Professor Herdman states that the black spots found on *H. punctata* are purple during life.

Thordisa (?) caudata, n. sp.—Plate II., figs. 18 and 19.

I have provisionally placed this species in the genus *Thordisa*, though one of the most noticeable features of the genus, the villose mantle, is absent.

A single specimen was taken to the south-east of Cheval Paar in February, 1902. The length of the animal is 2·9 centims., width 1·1 centims., height 1·6 centims.; the contracted foot is 0·8 centim. wide. The colour is a creamy white without markings, the rhinophores grey, the branchiæ white.

The body is elevated, evenly rounded; the mantle well developed posteriorly, slightly longer than the foot, the postero-lateral margins bent inwards towards the foot; the distance from the branchial opening to the end of the mantle 0·8 centim. The branchial opening is oval, transversely placed, measuring 5 millims. by 3 millims., its edges raised into a low smooth collar. The edges of the rhinophore pores are slightly raised. The texture of the mantle is firm and spiculose, it is covered with rather small but not very crowded low truncated or flattened tubercles with the ends of the spicules showing through their surface. The front margin of the foot is bilobed, the head is small, the tentacles very small and flattened.

The radula (Plate II., figs. 18 and 19) consists of about 38 rows. The lateral teeth on each side number 39. The 10 innermost teeth are rather small, hooked, and have a minute denticulation on the outer side. The three outermost teeth are small, the two outermost being fringed and the next simply hooked.

There are both salivary and ptyaline glands present on the buccal mass.

The penis and vagina are unarmed, but it is possible, since the genital organs bear a great resemblance to those of *Jorunna*, that the presence of a stylet may have been overlooked.

Sub-family: CHROMODORIDINÆ.

Chromodoris reticulatus, Pease.

One specimen of the above (= *Chromodoris alderi*, Collingwood) was taken at a depth of 45 fathoms in the Gulf of Manaar, in February, 1902.

The colour when living, as noted by Professor Herdman, was "white speckled with red-brown; bright yellow border. Gills dark red and white; long white tail."

The colour of the preserved specimen is a pale orange-yellow, with fine reddish markings and reticulations, the latter rather wider towards the margin. Branchiæ simply pinnate, light red, with two deep red lines running up the inside of the rachis. Rhinophores dark red. Margin of mantle with faint narrow orange line. General colour effect reddish-orange, darkest anteriorly. Length of preserved specimen 2·8 centims., width 1·8 centims., height 1·8 centims., width of foot 1·1 centims. The free margin of mantle is narrow, turned up posteriorly, with median posterior notch. Branchiæ 24, arranged in two spirals as in *Casella*. Pseudo-peritoneum tough, white, but without nodules.

The radula corresponds very well with the figures given by Bergh for *C. reticulatus*, and the labial armature is formed of bifid rods, as noted by him.

I think that there is little doubt but that this species is both the *C. reticulatus* of Pease (**6**, p. 205), and the *D. alderi* of Collingwood (**8**).

The figure given by Collingwood is more like it than that which Bergh gives after Garrett, and shows the notch at the end of the mantle which Bergh does not allude to. The number of branchiæ is given by Bergh as 9 to 15, and by Collingwood as 12, but this seems to be of no specific importance in the genus.

I have no drawing of the form assumed by the animal when alive, but the shape of the preserved specimen approaches so near to *Casella* that, taken with the manner of arrangement of the branchiæ, it raises a doubt as to whether the distinction between the genera *Chromodoris* and *Casella* can be preserved or rather whether the line of separation has not been drawn in the wrong place.

Chromodoris tenuilinearis, n. sp.—Plate III., figs. 11 to 15.

There is a single specimen of the above, taken on the Cheval Paar.

The length of the preserved specimen is 2·5 centims., its width 0·6 centim. and its height 0·8 centim. The mantle is smooth, long and narrow, slightly wider than the foot and not reaching as far as it posteriorly. The foot has its margins adpressed and extends behind the body for 0·4 centim.; width of the body 0·5 centim.

The ground colour is a dirty transparent white. The mantle is marked by intersecting diagonal broken lines of a pale greyish-green colour (Plate III., fig. 11). The sides of the foot are marked with traces of similar lines.

The branchiæ are 8 in number, long, slender and limp, simply pinnate, issuing from a collar about 1 millim. high. The rhinophores are long, slender and colourless.

The radula consists of 66 rows, formula 71–0–71. One or two of the innermost teeth on each side are trifid, the rest bifid. There is a trace of a median tooth on the rachis. The outermost tooth is a flat plate with median notch, the 2nd tooth is slightly hooked and distinctly bifid.

The jaws are strong, divided into 3 parts, one median and two lateral. They are made up of hooked plates regularly arranged in alternating rows.

There was no further examination of the animal made. The markings are of a rather unusual type in the genus *Chromodoris*, in which they usually consist of brightly-coloured lines parallel to the sides of the mantle or longitudinally arranged, or else of spots.

The armature of the jaws and radula are paralleled in several species, notably in *C. semperi*, Bgh. (**9**, p. 482, plate lii., figs. 1 and 2; plate liii., figs. 13 and 14), in which they are almost identical.

Casella cincta, Bgh.

One specimen from Muttuvaratu Paar, length 2·3 centims., has its colour fairly well preserved. It is of a dark claret or plum colour, fairly uniform, with a dark green margin to the mantle and, less evidently, to the foot.

The branchiæ are about 28 in number, simply pinnate, reddish with a dark green rachis. They are arranged apparently in two spirals, one on each side of the anus. Anterior to the anus is one gill plume distinctly larger than the rest.

The rhinophores are finely laminate, plum coloured, with a tinge of green at the tips.

The radula contains about 140 rows, formula about 63–1–63. The teeth are hooked, with from 8 to 10 fine lateral denticulations on the outer side. The innermost lateral tooth is denticulated on both sides.

The labial armature is formed of bent rods with pointed tips slightly hooked.

Professor HERDMAN'S notes contain a sketch of the animal in a living state which shows very well the characteristic shape, and very closely corresponds with the figure of *C. cincta* given by BERGH (**9**, plate lxxviii., fig. 9). Professor HERDMAN describes the colours in the living animal as follows :—" Pink with green edgings ; edge of foot and mantle white, then a marked green line, then inside that a yellow band, then a pink and white dotting covers the rest. Branchiæ in two spirally arranged tufts ; four large processes in front."

Ceratosoma cornigerum, GREY (?).

It is difficult to name with any certainty preserved specimens of *Ceratosoma* unless the colour of the living animal has been noted, as the radula and jaws of all the described species are almost identical and the external form is liable to a considerable amount of variation. There are in the collection three specimens of *Ceratosoma*, all very small, under 2 centims., which I have doubtfully referred to the above species. They vary considerably in the length of the dorsal horn, but agree in having the line of separation between the back and sides marked by a not very prominent ridge, which is not produced into lateral lobes. They are of a uniform cream colour, one specimen, from south-east of East Cheval, being distantly spotted with opaque white dots. The other two specimens were taken at Talaivillu Paar and $\frac{1}{2}$ mile south-east of Dutch Modragam Paar, respectively.

[**Ceratosoma ornatum**, BGH.]

In Professor HERDMAN'S notes there is a description with accompanying sketch of a species of *Ceratosoma*, but the specimen to which it refers has apparently not been preserved, or has disappeared from the collection. There is no doubt, however, that the species is *C. ornatum*, which has been described by BERGH from a specimen taken in Amboyna (**9**, p. 946).

Professor HERDMAN'S description, which is fuller than that given by BERGH, is as follows : " Spotted all over with yellow on a pale mauve ground, deeper on dorsum, getting to white on foot, with deep mauve or purple edgings to the front and lobes. Horn with mauve edgings on pale ground ; tail with yellow spots on mauve. Head with yellow spots on white. Front of foot with mauve spots on white. Rhinophores brown at base, violet at tip, laminated. Anus violet edged. Gills white at base, yellow in middle, brown at tip. Off Galle, 34 fathoms, February 18th, 1902."

The capture of a small violet-spotted specimen on March 8, 1902, towards the north of the Gulf of Manaar, is also noted, but the specimen is absent. This may be an undescribed species, as none of the described species are violet spotted, except as subsidiary to other coloration.

Doris, spp. ?

There are several small very much depressed Dorids from the east of the Gulf of Manaar and the south end of Cheval Paar which I have not been able to identify. They appear to belong to two closely allied species. One is represented by 8 specimens from the Gulf of Manaar and 2 from Cheval Paar. The largest specimen measures 1·1 centims. by 0·8 centim. The back is covered with uniform, blackish-brown, very minute marbling or reticulation. The ground colour of the Manaar specimens is a mahogany-brown, probably owing to the action of spirit; of the Cheval specimens, pale brownish-grey. The radula in the largest specimen consists of 45 rows of 18–0–18 teeth; in a specimen measuring 0·8 millim. by 0·5 millim. it is 39 rows of 16–0–16. The innermost 6 or 7 teeth are bifid at the apex, the rest are simply hooked. From the margin of the radula the first 4 teeth increase in size, and from the fourth to the centre again decrease regularly and rapidly.

The foot is moderately broad; its front margin not distinctly bilobed, but sharply folded inwards in the middle line, the fold being flattened and fitting into a recess in the under-surface of the notæum. The tentacles, which are minute and pointed, appear to be attached to the sides of this recess. The notæum is tough and densely spiculose; the branchial pore is small and 6-lobed. An examination of the gonads failed to show any armature.

The other species resembles the above in form and in structure of the front of the foot, but the markings are more minute and diffuse. It is represented by 2 specimens from Cheval Paar, the largest measuring 1·2 centims. by 1 centim., most of this size being taken up by the wide margin of the notæum.

The radula consists of 42 rows of 24–0–24 teeth, and, except for the inner teeth being simple instead of bifid, closely resembles the first-mentioned species.

Family: DORIOPSIDÆ.

Doriopsis aurea (Q. and G.).

The Doriopsidæ are only represented by a single species, *D. aurea*, of which one specimen was taken off Karativo on March 10th, 1902.

The colour, when alive, as noted by Professor Herdman, is "orange red with brown orange spots, those along margin of mantle pale blue." The same coloration, though much fainter, was noticeable in the spirit specimen, the orange red having become yellow.

Quoy and Gaimard, in the "Voyage de l'Astrolabe" (**1**, p. 265, plate xix., figs. 4 to 7), give a figure and description of *Doris aurea*. It is described as orange-red with white spots (blue spots ringed with white in the figure) scattered over the back, "parsemé en dessus" (in the figure they are represented as in three rows, one median and two lateral), branchiæ 5, compoundly pinnate; back elevated; smooth rhinophores with 15 lamellæ and a distinct longitudinal ridge (in figure); length a little over

2 inches. It was taken in fairly deep water off Jervis Bay, Tasmania. The description, though not perfectly in agreement with the Ceylon specimen, yet is sufficiently near to make the identification most probable.

Doris aurita, GOULD (**2**, p. 299, fig. 394), is similarly coloured, but has 8 branchiæ.

The same type of coloration is also found in a Tectibranch, *Pleurobranchus punctatus* and it would be interesting to discover whether these similar markings, occurring in different groups, were associated with a similar habitat, or were merely fortuitous.

FAMILY: PHYLLIDIIDÆ.

Phyllidia varicosa, LMK.

There is a single specimen of the above, taken on Muttuvaratu Paar. The colour of the spirit specimen is as follows:—Mantle of a deep bluish-black; tubercles with a halo of faint bluish-white; their tips with a purplish tinge. The tubercles are roughly of two sizes, large and small; there is a line of tubercles down the centre of the mantle, each large tubercle alternating with two small ones, the edges of their halos just touching. There are 2 ill-defined rows of more distinct large tubercles on either side, the smaller tubercles being scattered irregularly around them. The margin is occupied with very small crowded tubercles arranged irregularly 2 to 3 deep.

The underside of both mantle and foot is a dark greyish-black. There is no median black line on the sole of the foot.

This species is widely distributed throughout the Indian Ocean and has, according to BERGH, been recorded from Ceylon by KELAART (**3**) under the name of *Phyllidia ceylanica.*

Professor HERDMAN'S notes contain references to the capture of another *Phyllidia*, probably this species, at Periya Paar. It is described as being of a "rich dark green colour with prominent bright yellow papillæ; edge of mantle yellow all round; foot dark green."

Phyllidia nobilis, BGH. (?).—Plate III., figs. 16 and 17.

There is in the collection a small specimen of *Phyllidia* or *Phyllidiella*, taken off Talaivillu in April, 1902. I have been unable to distinguish satisfactorily between these two genera, and have been compelled to adopt Sir C. ELIOT'S view (**12**) that the distinction cannot be maintained.

The length of the spirit specimen is 2·5 centims., width 1·25 centims., width of foot 0·7 centim. The tentacles are short, pointed, placed close together at base, divergent, laterally grooved. The lateral branchial lamellæ are about 60 in number, triangular. The margin of the mantle is white, moderately narrow, bearing very small tubercles. Inside this is a very narrow black line bearing a few tubercles, entire in front, slightly broken behind. The centre of the mantle is of a bluish-white colour bearing white knobbed tubercles and marked by 3 black bands which take the form of a three-pronged fork directed backwards. The outer branches of the fork are parallel to the margin and on the outer side bear three short branches projecting at right angles and nearly reaching to the margin. The innermost prong of the fork is shorter than the 2 outer and bears 3 white tubercles. A very slight alteration of the white bands in *P. nobilis*, as figured by BERGH, would produce the pattern here described. It may be, however, that it should be referred to the variety of *P. varicosa* figured by BERGH (**9**, plate XXV., fig. 7). The underside of the Ceylon specimen is of a pale bluish-grey with 3 to 4 lateral ill-defined black spots.

(DORIDIDÆ PHANEROBRANCHIATÆ.)

SUB-FAMILY: POLYCERINÆ.

Aegires villosus, n. sp.—Plate III., figs. 18 to 22.

One specimen (Plate III., fig. 18) of the above, length 0·9 centim., was taken to the north-west of Cheval Paar. The body is elevated, with a medio-dorsal bunch of long clavate processes or elongated tubercles (Plate III., fig. 19) surrounding the branchial pore; two of these processes are slightly branched. There are two irregular lateral lines of slightly clavate tubercles on each side of the body, and small tubercles are crowded on the nape of the neck. There are longitudinal patches of purplish-brown pigment lying between the tubercles on the back and sides. The ends of the tubercles are shaded with brown. The ground colour is a dirty greyish-white. The surface of the body and tubercles is densely spiculose, the spicules projecting and giving the animal under slight magnification a densely pilose appearance.

Rhinophore sheaths (Plate III., fig. 20) with 3 outer moderately long tubercles, and 1 small inner tubercle. The radula shows that the specimen is evidently immature, it contains only 12 rows with 16 simply hooked teeth (Plate III., fig. 22) on each side. The jaws are not developed, but the chitinous collar shows slight lateral thickenings and a well-marked upper jaw (Plate III., fig. 21).

This genus has previously been known only from the Atlantic and Mediterranean.

Trevelyana bicolor, ALD. and HANC.

One specimen of what appears to be this species was found on Galle coral reefs in August, 1902; length, 1·2 centims. The colour has been lost and the skin is transparent, showing the internal organs. The liver occupies the posterior two-thirds of the body and is of a bluish-grey colour. The branchiæ are 12 in number arranged in a circle round the anus on the centre of the back. The area of skin surrounding the branchiæ is more opaque than elsewhere, which seems to suggest that it is of a different colour during life. There is a branching white arrangement, probably vascular, anteriorly on the surface of both sides of the body. The rhinophores are retracted. The size and number of branchiæ of this specimen seem to point to its being *T. bicolor*. The radula was not examined.

Kalinga ornata, Ald. and Hanc.—Plate III., figs. 23, 24.

A small specimen, length 2·5 centims., was taken 10 miles north of Cheval Paar. Professor Herdman has made the following note on its coloration when alive: "Pale grey, nearly transparent, with red internal organs showing through, and beautiful red papillæ on surface of body. Rhinophores lamellated at tip and coming from fringed sheaths. Colourless papillæ on body. Branchiæ tri-pinnate."

Bergh (**9**, pp. 959 to 962) has given a full account of the anatomy of this species with the exception of the radula, which was missing in his specimen owing to the pharynx having been everted through the front of the foot. Curiously enough, Professor Herdman's specimen had suffered an almost similar misfortune, the whole buccal mass having been everted through the mouth opening, so that the radula lay along the under-surface of the everted organ. The teeth (Plate III., figs. 23 to 24) are very numerous and all similar. Their shape is remarkable, each tooth having three long curved pointed cusps. They are arranged in about 130 rows, the radular formula being 90–0–90. There is no median tooth, but the rachis bears at intervals a few very small spurious teeth. The innermost tooth on each side differs slightly from the rest in having the inner spine slightly shortened; the outermost tooth is a flat plate, the 2nd and 3rd have traces of a single hook, the 4th has two hooks, and the 5th three. The teeth increase in size gradually from the margin inwards to the centre. The teeth in the specimen examined were widely separated from each other, perhaps owing to the stretching of the radula.

II. TECTIBRANCHIATA.

There are in the collection 17 species of Tectibranchs, 7 of which are here described as new to science.

Of those already known, two, *Philine aperta* and *Doridium depictum*, are well-known Atlantic or Mediterranean species; two, *Aplysia cornigera* and *Dolabrifera maillardi*, have been identified on the strength of the resemblances of the shells, as nothing seems to have been published on the animals themselves; the rest are fairly well-known Indian Ocean or Pacific species. The list of species is as follows:—

Philine aperta, Linn.
Doridium marmoratum, Smith.
„ *depictum* (Ren.), var.
Aplysia cornigera, Sow.
„ *elongata*, Pse.
„ *intermedia*, n. sp.
Phyllaplysia albomaculata, n. sp.
„ *pellucida*, n. sp.
Aplysiella mollis, n. sp.
Dolabrifera maillardi, Desh.
„ *marginata*, n. sp.
Dolabella scapula, Martyn.
Notarchus indicus, Schweig.
„ *ceylonicus*, n. sp.
Pleurobranchæa brocki, Bgh.
Pleurobranchus citrinus, R. and L.
„ *hornelli*, n. sp.

In an Appendix, I place:—

Onchidium verruculatum, Cuv., and *Marsenia perspicua* (Linn.).

Family: PHILINIDÆ.

Philine aperta, Linn.—Plate IV., fig. 1.

This is one of the most abundant species in the collection. It is represented from the Gulf of Manaar, Galle, deep water off Galle, Trincomalee, off Kaltura, the pearl banks off Aripu, and south of Modragam—in all 42 specimens, of which 33 came from the Gulf of Manaar. The specimens vary considerably in appearance owing to their different degrees of contraction, but the shells are identical in texture and almost so in shape. The shells (Plate IV., fig. 1) are of a moderately elongated oval form with a smooth somewhat opalescent surface, and agree with *P. angasi*, from Australia; but I do not think that the slight difference in form between these shells and those of British specimens of *P. aperta* can be regarded as amounting to a specific distinction. There was no constant difference to be noted between the gizzard plates and those of the typical *P. aperta*, though in most cases the ventral plate was more asymmetrical and the ends of the lateral plates more produced.

The radula was as in *P. aperta*.

Bergh (**12**) has recorded *P. aperta* as occurring not uncommonly in the Gulf of Siam, and it seems not improbable that it has a cosmopolitan distribution, and is represented by local races in many places; as such perhaps may be:—*P. vaillanti*, *P. erythræa* (though that species is said to be distinguished by the peculiar serration of its gizzard plates), *P. angasi*, *P. orientalis*, *P. caurina*, *P. vitrea* and *P. coreanica*.

Doridium marmoratum, Smith.

One specimen from the Gulf of Manaar should, I think, be referred to *D. marmoratum*. Its length is 2·2 centims., width 1·1 centims.; length of head shield 1·3 centims., width 1·1 centims. The ground colour is a dark brownish plum with numerous small pale oval or circular spots, those on the foot being rather larger than those on the rest of the body. The margins of the foot and the front margin of the head shield are marked with a bluish-black line. The sole of the foot is slightly darker than the rest of the body. The lateral margins of the foot are closely adpressed to the sides of the animal. The head shield appears to be emarginate posteriorly, owing to its posterior extremity being turned up. The gill protrudes through the mantle slit on the posterior end of the body, probably owing to an injury, as the specimen is in rather bad condition, the pharynx having been everted through a rupture in the front of the head shield and the shell crushed to fragments. *D. marmoratum* has only been recorded from Torres Straits (**7**).

Doridium depictum (Ren.), var.

A small specimen dredged on Periya Paar, in 9 fathoms, had the following coloration, as noted by Professor Herdman, while alive, "brown, mottled with pale green, and having two yellow lines from the head backwards; front edge of foot blue, lobe of mantle over gill paler, with edging of violet." In the spirit specimen the markings are as described, but the blue and green colours have disappeared; the ground colour is a pale brown.

The length of this specimen is 1·45 centims., width 1·05 centims., length of head shield 0·9 centim., width 0·85 centim. The shell was very much broken. The foot is pale, without markings, its margins are only slightly incurved.

There is nothing in the form of the animal to separate it from *D. depictum* of the Mediterranean, and, as that species is known to be extremely variable as regards coloration, I have recorded the Ceylon specimen as a variety.

Family: APLYSIIDÆ.

There appears to be a great amount of uncertainty as to the extent of the genera *Dolabrifera*, *Aplysiella* and *Phyllaplysia*, each author using the names with a different meaning. The distinctions have been based mainly on the form of the animal, which must vary considerably in the same species in preserved specimens. I have not material sufficient to throw any light on the matter, and have for convenience merely used the names in the following manner:—

Aplysiella.—Specimens with short median mantle slit, swollen body and broad foot.

Phyllaplysia.—Specimens with depressed body, median mantle slit and broad foot; shell in this and the preceding genus resembles that of *Aplysia*.

Dolabrifera.—Specimens with moderately depressed body, broad foot, posterior mantle slit and bat-shaped shell.

The circum-œsophageal nerve ring shows the same type in all, the commissures being short, the cerebro-pedal being almost as long as the cerebro-visceral. In the two species of *Dolabrifera* which occur in the collection there is a resemblance in the radulas in the fact that the inner cusp of the lateral teeth is always smaller than the outer.

Aplysia cornigera, Sow.—Plate IV., figs. 2 to 7.

It is impossible, on account of the many vague descriptions, with or without figures, which have been published, to say with certainty what name should be applied to what appears to be the common Ceylon species of *Aplysia*. I have identified it as *A. cornigera*, Sow, on account of the resemblance to the shell of that species, of which only the shell is known. It is represented in the collection by seven specimens, two from the Gulf of Manaar, two from the pearl banks off Aripu, one from the pearl banks off Manaar and two without definite locality.

The coloration of these specimens is a groundwork of fine reticulating brownish-olive lines, with clear spaces here and there, as in *A. punctata*. There are also small black spots, about 1 millim. in diameter, scattered over the surface of the body. The amount of pigment on the inner side of the pleuropodia varies; usually there is very little, and it is almost absent in some specimens.

The length of a well-preserved specimen was 6·3 centims. The pleuropodia were free to within from 5 millims. to 8 millims from the end of the foot. The excurrent mantle siphon was moderately produced, from 5 millims. to 10 millims. in length. The tentacle flaps were mostly flattened, but varied according to the amount of contraction. The mantle foramen was closed in some specimens, but the mark of its position was apparent; in others it was about 2 millims. in diameter. The markings and clear spots showed a sort of radial arrangement round the foramen. The hyaline gland (Plate IV., fig. 6) consisted of a group of large globular cells lying beneath the sub-dermal muscle layer and penetrating it at intervals. There was no sign of a single common duct. The gland in appearance resembled a bunch of grapes attached laterally to the muscle layer, and would seem to be intermediate in form between the two types of gland described by BLOCHMANN (6) as occurring in *Aplysia*, since the cells appeared to open separately on the surface or else two or three into a common opening.

The shell (Plate IV., fig. 4) is thin, with a fragile calcareous layer; the inside is opalescent, of a delicate pale pink tint; the outside is glossy, pale whitish-brown, with distant growth ridges.

The radula (Plate IV., figs. 2, 3, 5) consists of about 40 rows of 21–1–21 teeth of the usual form; the 16th and 17th from the centre have rudimentary hooks and the four outermost teeth consist of flat plates. The labial armature is made up of blunt rods.

A. pulmonica, GOULD, from Samoa, may perhaps prove to be the same as this species, but seems to be separated by having the pleuropodia fused for a larger proportion of their length.

Aplysia elongata, PEASE—Plate IV., figs. 9 to 12.

A specimen of the above was taken on Jokkenpiddi Paar in April, 1902.

The length of the preserved specimen is 1·2 centims., height 0·9 centim. The colour is an opaque whitish fawn with brownish markings irregularly arranged, leaving vacant spots, and in addition a fairly uniform but rather distant spotting of opaque white pigment. The eyes are distinctly visible, the skin over them being devoid of pigment. They lie lateral to and a short distance from the base of the rhinophores. The rhinophores (Plate IV., fig. 10) are tubular and split for about $\frac{3}{4}$ of their length; they resemble greatly a hare's ear in appearance. The tentacles are much shorter than the rhinophores and are split to the base. The inside of both rhinophores and tentacles is strongly pigmented. The pleuropodial lobes are short, meeting behind the mantle siphon; they are slightly pigmented with light brown on the inside. The mantle is transparent and colourless except for a black line along the margin of the mantle foramen. The latter is large and oval, measuring 5·5 millims. by 3·5 millims. The shell (Plate IV., figs. 11 and 12) is large, strong, opaque and deep, with well-marked growth ridges and overhanging adnate callus hood; it measures 9·5 millims. by 7 millims. Judging by the size of the shell and the way in which it has been forced out of the mantle cavity, the whole animal is very much contracted.

The radula (Plate IV., fig. 9) is of an orange-yellow colour and contains 34 rows of 13–1–13 teeth, the 4 outermost being imperfect.

This specimen agrees very closely with *A. elongata* from the Sandwich Islands, the very large mantle foramen and large strong shell with well marked callus being very characteristic.

Besides the above there are in the collection 2 specimens from Chilaw Paar which are most probably young examples of *A. elongata*. They resemble the Jokkenpiddi specimen in form, but differ in being semi-transparent and colourless except for a narrow black edge to the rhinophores, tentacles, front of foot, mantle foramen and posterior part of pleuropodia. The shell is membranous with a very delicate white calcareous layer which has mostly disappeared.

The radula has only 27 rows, the teeth being as in the larger specimen; the lengths of the two Chilaw specimens are 1·3 millims. and 1·1 millims. respectively.

Aplysia intermedia, n. sp.—Plate IV., fig. 8.

There is a single well-preserved specimen ot *Aplysia* from S. Cheval Paar which does not fit in with any of the published descriptions. It combines the opposite characters of a large mantle foramen and long free pleuropodia.

Length of the preserved specimen 1·8 centims., width 1·4 centims., height 1 centim., length of foot 1·6 centims., distance from fusion of pleuropodia to end of foot 2·4 millims., mantle pore 4·25 millims. by 3 millims., length of mantle siphon 2 millims. Colour of living animal, green; colour of spirit specimen, greyish; general effect made up of fine recticulating broken black lines of the usual *Aplysia* type, following no regular plan; mantle with black specks rather concentrically than radially arranged. The mantle foramen has not a black edge.

The tentacles are large, produced anteriorly into broad labial flaps. The shell is large (1·1 centims. long), thin and membranous; calcareous layer only present as a few small patches at the apex of the shell.

The radula (Plate IV., fig. 8) consists of 30 rows of 16–1–16 teeth, the 3 outermost being without hooks. The teeth resemble those of *A. elongata* in form.

Phyllaplysia albomaculata, n. sp.—Plate IV., figs. 13 to 16; Plate VI., fig. 6.

I have thought it best to create new species for this and the two following forms, rather than run the risk of identifying them incorrectly with any of the many vaguely described species which are in existence. The single specimen of *P. albomaculata* was taken south of Adam's Bridge, 30 fathoms, in March, 1902. Professor HERDMAN notes concerning it: "Olive brown spotted with white, foot paler, little spiky papillæ on mantle," accompanying his note with a sketch which shows the living animal in configuration and proportions almost exactly as in the preserved specimen.

The total length is 2·8 centims., width 1·5 centims., height 0·7 centim.

The form of the animal (Plate VI., fig. 6) is an oval, produced anteriorly to form the head. It is very much depressed. The foot is conterminous with the body laterally and posteriorly; anteriorly it extends beyond the head on either side.

The branchial slit is situated rather nearer the right side, the margins not closing over the slit. The tentacles and rhinophores are of moderate size, tubular and slit as usual. The eyes are distinctly visible in front of the rhinophores. The surface of the back is dotted with little spiky papillæ, simple or compound. The shell (Plate IV., fig. 15) is calcareous, very fragile, white with a slight brownish tinge, striated by growth lines and with a small but well-marked embryonic spine (Plate IV., fig. 16).

The radula (Plate IV., figs. 13 to 14) has 32 rows of 44–1–44 teeth. The teeth, as is usual in the genus, have two broad spatulate cusps and a small basal denticulation. In the 2nd and 3rd innermost teeth the inner cusp is distinctly larger than the outer; in the 4th they are about of equal size, and from the 5th outwards the outer cusp is the largest. The nature of the buccal armature was not noted.

Phyllaplysia pellucida, n. sp.—Plate IV., figs. 17 to 21; Plate VI., fig. 12.

There are, in the collection, 2 specimens of a smooth flattened *Phyllaplysia* from Chilaw Paar, for which I propose the above name. They are of a gelatinous consistency, semi-translucent and colourless. The length of the largest specimen (Plate VI., fig. 12) is 1·7 centims., width 1·5 centims., height 0·7 centim.

The foot is as wide as the body. The head is very much contracted, with short tentacles and rhinophores. The branchial slit, length 6 millims., lies rather nearer the right side, the right margin overlapping the left, except posteriorly, where the slit is open. The surface of the body is smooth. The eyes are not visible in the preserved specimens.

The radula (Plate IV., figs. 17, 19 to 21) consists of about 30 rows of 30–1–30 teeth. The teeth are of the usual form, with two main cusps and a smaller accessory one. From the 1st to the 10th tooth from the centre the innermost cusp is the largest, and from the 11th to the 25th the outermost. The five outermost teeth are slender, curved, and simple. The labial armature (Plate IV., fig. 18) is made up of square rods with denticulate inner margins.

The shell (Plate V., fig. 1) is of the same form as in *Aplysia*. It is thin and membranous, with a very slight calcareous layer which comes off at a touch. It measures 7·8 millims. by 5·3 millims. An embryonic spine was not noted, but it may have crumbled away.

Aplysiella mollis, n. sp.—Plate IV., figs. 22 to 26; Pl. V., figs. 2, 3; Pl. VI., fig. 11.

There are two specimens from South Cheval Paar.

The length of the larger specimen is 2·4 centims., width 1·2 centims., width of foot 1·3 centims., height 1·0 centim., length of branchial slit 1·0 centim., front of head to commencement of branchial slit 1·2 centims.

The colour of the preserved specimens is white, semi-opaque. They are of soft, wrinkled, and of a somewhat flabby consistency.

The animal (Plate VI., fig. 11) is moderately swollen, *Aplysia*-like in form, with short branchial slit. Over the surface of the back are scattered small spiky papillæ, much fewer in one specimen than in the other. The rhinophores are moderately long, of the usual form. The tentacles are short, split as usual, and flattened. There is a slight development of labial flaps. The eyes are distinctly visible.

The shell (Plate V., figs. 2 and 3) is shaped as in *Aplysia*. It is membranous, with a very brittle, opaque white calcareous layer covered with small nodules.

The radula (Plate IV., figs. 22 and 24 to 26) consists of 33 rows of 48–1–48 teeth, the inner cusp being the larger in the 1st to 4th tooth from the centre and the outer cusp the larger from the 5th tooth outwards. The outermost 5 or 6 teeth are narrow, curved, and simple. The labial armature (Plate IV., fig. 23) is made up of rods, bent and bifid at the tips.

Dolabrifera maillardi, Desh.—Plate V., figs. 4 to 10.

One specimen from Muttuvaratu Paar, 8 fathoms, March 1902.

The original species of Deshayes was only described from the shell which came from Réunion (5). His description and figure agree fairly accurately with the shell of the Ceylon specimen. The preserved specimen (Plate V., figs. 4 and 5) is smooth, somewhat plump, moderately elongate, of a dirty white colour. Its length is 1·9 centims., width 1·3 centims., height 0·9 centim. Professor Herdman's notes contain a sketch of the living animal and state, "Port-wine colour, with a limited number of white spots having each a spiky papilla rising from its centre."

The foot is as broad as the body, with its margins slightly frilled. It does not extend beyond the body posteriorly. The body is elevated posteriorly and slopes forward somewhat, as in *Dolabella*. The branchial slit is short and narrow, length 0·6 centim. It commences at about the posterior third of the body and runs backwards. The tentacles and rhinophores are tubular and slit externally.

The radula (Plate V., figs. 6, 7, and 10) consists of 35 rows of about 62–1–62 teeth. The median tooth has a central cusp, and two lateral cusps on each side. The innermost teeth of the lateral rows have two large hooked cusps, and a small basal cusp on the outer side. This basal cusp is found on about the 20 innermost teeth, after which it disappears. The outermost teeth are long, slender, and bifid at the tips.

The shell (Plate V., figs. 8 and 9), length 4·6 millims., has an embryonic spine just below the apex, the apex itself being formed by a flattened plate or callus.

The labial armature is made up of blunt rods.

This species may perhaps prove to be identical with one of the many forms described by PEASE from the South Pacific (**3**), (**4**).

Dolabrifera marginata, n. sp.—Plate V., figs. 11 to 15.

One specimen dredged on South Cheval Paar.

The length of the preserved specimen is 1·95 centims., width 1·3 centims., height 0·75 centim. The form of the body is ovate, somewhat narrower in front, the body passing into the head without a distinct neck (Plate V., fig. 11). The branchial slit is situated far back, about 4 millims. from the posterior end of the body. The slit is 7 millims. in length, open at both ends, the right pleuropodial margin being lapped over the left in the centre. The genital furrow is well marked. The margin of the foot extends beyond the body laterally and posteriorly, forming a frill 1·5 millims. wide. The body is smooth, the skin being somewhat tense. The rhinophores and tentacles are short, tubular, and slit as usual. The eyes are visible in front of the rhinophores.

The shell (Plate V., fig. 15) is very thin and membranous, of the same form as in *D. maillardi*, but perfectly transparent except for a chalky powder over parts of its surface which rubs off at a touch. The apex of the shell was injured in extraction, so it could not be ascertained whether an embryonic spine was present or not. It is probable that this species has not been already described, as the shell is not well fitted for preservation in a conchological cabinet.

The radula (Plate V., figs. 12, 13, 14) is of the same type as in *D. maillardi*, but the lateral teeth are not so slender. It consists of 37 rows of 57–1–57 teeth.

Dolabella scapula, MART.—Plate V., figs. 16 and 17.

There are three specimens of this, the common species of *Dolabella* of the Indian Ocean; one from South-east Modragam and two from south of Adam's Bridge.

The coloration of the preserved specimens consists in a faded yellowish-white ground colour mottled over the body and foot with irregular olive-brown blotches. Professor HERDMAN notes of another specimen from S. of Cheval, 6½ fathoms: "Chestnut brown in general effect, yellowish basis mottled with red and brown, many yellow tags or spines all over, broad flat foot rather paler." In the preserved specimens the body was covered sparsely with short fringed papillæ, longest on the margin of the posterior disc. These papillæ were most numerous in the largest specimen, which measured 4·8 centims. in length, and almost absent from the smallest.

Some of the published descriptions state that *D. scapula* is uniformly coloured, but this is probably a matter of individual variation. The shell of the Ceylon specimens agrees with that of *D. scapula*, having kindly been compared with specimens in the British Museum by Messrs. E. A. SMITH and E. R. SYKES.

The radula consists of 44 rows of about 120–1–120 teeth, those near the centre being simply hooked (Plate V., fig. 17), while towards the margin the hook becomes a long scythe-shaped blade (Plate V., fig. 16).

Notarchus indicus, Schweig.

I have, on account of the resemblance of the radula to the figures given by Bergh (**11**, plate vii.), referred to this species 20 little immature specimens of *Notarchus*, from Ceylon. The largest of these measured 1·2 centims. in length. The label indicating the exact locality where they had been taken has unfortunately been lost.

Notarchus ceylonicus, n. sp.—Plate V., figs. 18 to 23.

There is in the collection one specimen of *Notarchus*, from $\frac{1}{2}$ mile east of Dutch Modragam Paar, for which I propose the above name.

The form of the body (Plate V., fig. 18) is ovate, very plump, and inflated, except as regards the head. The foot is moderately wide and pointed behind. There is no shell. The branchial slit is short, length 6 millims. The length of the animal is 3·3 centims., width 2·1 centims., height 1·6 centims., width of foot 1·1 centims.

The surface of the body and head bears numerous small fringed papillæ which occur more thickly on the head, probably owing to its contraction. The rhinophores and tentacles are fringed with similar papillæ. Very small labial processes are present.

The radula (Plate V., figs. 20 to 23) consists of 30 rows of 33–1–33 teeth, the first 8 rows being imperfect. The first 5 teeth from the centre have four lateral denticles on the outer edge, the following 9 three denticles, the basal denticle being small and blunt, and becoming hard to recognise at a little distance from the centre. The next 4 teeth have two lateral denticles. From the 18th to the 24th tooth the distal denticle only persists, and the 9 outermost teeth are smooth and scythe-shaped, thus differing from those in *N. indicus*, which are serrulate.

Family: PLEUROBRANCHIDÆ.

Pleurobranchæa brocki, Bgh.—Plate V., figs. 24 to 28.

It is with some doubt that I refer to this species a well preserved specimen of *Pleurobranchæa*, which was taken 5 miles north of Cheval Paar in March, 1902.

The colour of the preserved specimen is an opaque brownish-yellow, due evidently to its preservation in spirit. On the mantle and upper surface of the hinder parts of the foot there are rusty-brown markings in coarse irregular reticulations, occupying to some extent the furrows on the mantle.

The form of the body (Plate V., figs. 24 and 25) approaches the Mediterranean species *P. meckelii*. The total length is 3·2 centims., width (of foot) 1·7 centims., height 1·1 centims., length of mantle 2·6 centims., width 1·5 centims., length of foot behind body 0·7 centim., length of gill from genital papilla 1·2 centims., height of caudal papilla 3·5 millims.

The mantle is not very large, reaching beyond the body, both laterally and posteriorly, for about 1 millim. and rather more over the gill. The foot is somewhat wider than the mantle laterally, and reaches considerably beyond it posteriorly. The tail is somewhat pointed and bent upwards, terminating in a little conical caudal papilla. The frontal margin of the mantle is beset with two rows of minutely tuberculate papillæ; there are 7 of these in the upper row and 6 in the lower. There are also very small scattered intermediate tubercles along the margin, which is laterally produced on either side into a tentacular appendage. The gill has 36 lamellæ, each of them pinnate; it reaches to the level of the end of the mantle.

The rhinophores as usual rise from the mantle and are split down the outer margin.

The surface of the mantle is not distinctly tubercular, but is furrowed and rough, owing perhaps to contraction. The foot, mantle and body walls are very muscular and tough. The intercrossing of the muscle bands gives the appearance of a woven material, particularly on the inner surface of the foot after removal of the viscera.

The genital openings are separate. The vaginal pore has a short tubular opening at the commencement of the gill rachis. The penis is retracted, its opening directed forwards and lying about 1 millim. in front of the female opening. The anus lies dorsal to the membrane which attaches the free end of the branchial plume.

The jaws are made up of hexagonal rods (Plate V., fig. 27), the edges of the inner marginal rods being very irregularly denticulate. Teeth of radula (Plate V., figs. 26 and 28) in about 29 rows, formula 56–0–56. No sign of a median tooth was seen. Form, as figured by BERGH for *P. brocki* (**11**). Shell absent.

The colour of the Ceylon specimen differs considerably from that described by BERGH, which was of a reddish-brown with darker reticulations. VAYSSIERE mentions a specimen of the same colour, but says that the pigment is superficial, and easily rubbed off, which may account for its absence on this occasion.

Pleurobranchus (Berthella) citrinus (RUPP and LEUCK.).—Plate VI., figs. 7 to 10.

There are 3 specimens of *Pleurobranchus* apparently belonging to this species which were taken at Jokkenpiddi Paar, Cheval Paar and to the South-east of East Cheval respectively. They differ slightly in colour and appearance, the Jokkenpiddi specimen being of an opaque brownish-yellow and considerably more contracted than the others, which are white, rather translucent and plump. The South-east of East Cheval Paar specimen, which is the best preserved of the 3, measures 1·7 centims. by 1·05 centims. Its height is 0·5 centim. The mantle is elevated, somewhat inflated, a little wider than the foot, covering the head, and slightly emarginate in front. Its colour is a transparent white with opaque white dots. When examined under a lens of moderate power, the white spots are seen to be subdermal opaque flask-shaped structures tapering towards the surface and surrounded by distinctly marked clear hexagonal areas. The surface of the mantle is smooth. The gill is short and compact, length 0·7 centim., without rachidian tubercles. The lamellæ number about 25. The front of the foot is divided into two lips by a transverse furrow, the lower lip being the largest. The furrow does not extend laterally. The labial flap is produced on either side into 2 very short tentacles split laterally at their extremities.

The rhinophores are close together and rather short, tubular and split as usual. The genital openings are close together at the commencement of the gill, but not surrounded by a common investment. The penis is retracted.

The shell, length 0·5 centim., lies well forward at about the anterior third of the body; the apex is pale, with embryonic spiral well marked; the expanded portion is of a horny yellow colour, strong, with well-marked longitudinal and transverse striæ. The teeth are of the usual type in *Berthella*, as defined by VAYSSIÈRE (9), knife-shaped, with strongly denticulated edges. They bear about 14 denticulations.

The colour of the living animal as noted by Professor HERDMAN is "brilliant orange, with white dots in little systems on the back." This differs somewhat from RUPPEL'S description of *P. citrinus* as "pale lemon yellow, with large whitish irregular spots," but as they agree otherwise there does not seem sufficient grounds for separating them. *P. angasi*, SMITH, from Port Jackson, agrees in many ways with this species, but has only 16 gill lamellæ. The figures of *P. oblongus*, AUD., given by SAVIGNY, are very like the Ceylon specimens and the figure of the shell of that species shows an evident attempt to represent an embryonic spiral.

KELAART (2) has recorded this species as being of common occurrence in Ceylon; he gives the colour as orange spotted with white.

Pleurobranchus hornelli, n. sp.—Plate VI., figs. 1 to 5.

There are in the collection some specimens of *Pleurobranchus* which I have not been able to identify with any of the described species, and for which I accordingly propose the above name. These are 7 specimens, 6 of which were taken by Mr. HORNELL from a buoy-rope at Galle in July, 1902, and one on Galle coral-reef in August, 1902. Their colour, as far as is preserved, is a dirty white ground colour, with the mantle covered with fairly close reticulations of brownish-purple. The length of the largest specimen is 1·8 centims., width 1·2 centims., height 1·0 centim. The mantle is about equal to the foot in front and behind, and a good deal wider laterally. It is tuberculate, but the tubercles are indistinct, being crowded together so as to produce a level surface (Plate VI., fig. 5), the margins of the tubercles being only noticeable on account of the previously mentioned purple reticulation which occupies the space between them. In the Galle coral-reef specimen, which seems in a different state of preservation from the rest, the apex of each tubercle is raised into a small papilla.

The foot is moderately broad, with the front margin divided into two lips by a transverse furrow. The upper lip is much thinner and somewhat shorter than the lower. The furrow is continued laterally down one margin as far as the commencement of the gill and to an equal distance on the other side. The pedal gland is well developed in the Galle coral-reef specimen, but hardly noticeable in the others.

The tentacular shield is well developed, but not produced into tentacles laterally. The anterior portion of the lateral margins is grooved. The rhinophores are moderately long and split as usual. The gill is moderately long, 1 centim. in the largest specimen, reaching to the end of the body, bipinnate, the rachis with two rows of tubercles, pinnæ 25–26, pinnules about 16.

The genital openings are close together at the base of the gill and appear to be surrounded by a common investment. The shell (Plate VI., fig. 1) is very thin, with an opaque white calcareous coating very fragile and easily rubbed off. It seems to be very faintly striated in the lines of growth. It is situated at about the anterior third of the mantle and is distinctly visible through it as a white patch ; its length in a specimen of 1·5 centims. is 2·9 millims. by 1·9 millims. The shell has an ill-defined membranous edge without calcareous coating. The radula in one specimen examined consisted of 46 rows of about 70–0–70 teeth, the inner teeth being simply hooked (Plate VI., fig. 3), the outermost rod-like (Plate VI., fig. 2), slightly bent. The jaws are rather broader than usual, measuring 1·12 millims. by 2·35 millims. ; they are made up of plates of the usual form (Plate VI., fig. 4), with two lateral denticles at the apex, a large distal and a smaller proximal one.

APPENDIX.

Family : ONCHIDIIDÆ.

Onchidium verruculatum, Cuv.—Plate VI., figs. 13 to 22.

There is one specimen of this widely distributed species, very well preserved, from the Gulf of Manaar. The length is 3·1 centims., width 3·4 centims., height 2 centims., width of foot 1·5 centims. The colour of the preserved specimen is grey, with irregular purplish-brown blotches over the back.

The back is completely covered with simple and compound tubercles of differing sizes. The simple tubercles are most numerous and vary in size from an extreme minuteness to about 1·2 millims. in diameter. The compound tubercles measure about 1·5 millims. in diameter and are made up of from 5 to 7 simple tubercles. On the posterior fourth of the back are about 10 branchial tubercles, which appear to be made up of from 20 to 40 short papillæ crowded together. These apparently represent frondose processes in the living animal. There are only 6 ocular tubercles in the Ceylon specimen, all situated on the anterior half of the body. They bear from 2 to 5 ocelli in a slightly depressed pit on their summit. The general effect of the tuberculation resembles that seen in *Archidoris tuberculata*.

The loop of the intestine follows the same course as figured by Plate for the species, being much less curved than in the closely allied *O. tumidum*.

The male gonads (Plate VI., fig. 17) agree fairly closely with PLATE's description. The penis rod is long and slender, the glans short and closely covered with minute hooks about 0·04 millim. in length.

The length of the "cartilaginous" rod is 16 millims., that of the spinulose glans 1·8 millims. The dart sac with its ampulla is of the usual form, the ampulla long and rather narrow and sharply curved at its anterior end, where it overlies the œsophagus. The length of the ampulla is 10 millims., the distance from the ampulla to the papilla of the dart sac 8 millims. The dart (Plate VI., fig. 13) is straight, regularly tapered; length 2·8 millims. Its free extremity shows a slight curve and has a solid lateral lip.

The radula (Plate VI., figs. 19 to 22) is of a pale yellow colour very slightly chitinised. It is made up of 60 rows of 83–1–83 teeth of the usual form. The central tooth is slightly broader than long; the lateral teeth, except those close to the middle line, are produced downwards into a broad adze-shaped hook and upwards into an irregular thin tongue, which takes part in their attachment to the radula ribbon.

The contents of the stomach consisted of quartz sand grains and a quantity of white flocculent matter, amongst which a few Foraminifera were noticed.

Onchidium verruculatum is very widely distributed in the Indian and Pacific Oceans, occurring from the East Coast of Africa and the Red Sea to Japan and Australia.

FAMILY: MARSENIADÆ.

Marsenia perspicua (LINN.)—Plate VI., figs. 23 to 26.

There are eleven specimens of *Marsenia* in the collection, most of them from Cheval Paar and its neighbourhood and the remainder from South-east Modragam, Gulf of Manaar, and Galle. Externally they are not to be distinguished from the common *M. perspicua* of European waters, with which species also the radula (Plate VI., figs. 24 to 26) and shell are in close agreement. The largest specimen, one of those from South-east Modragam, is a female, and measures 2·5 centims. by 2·2 centims., the shell (Plate VI., fig. 23) measuring 1·6 centims by 1·2 centims. These measurements are somewhat in excess of those usually attained by European specimens, but the difference in size and locality does not seem to warrant the use of a separate specific name.

EXPLANATION OF PLATES.

The figures, with the exception of Plate II., figs. 2, 3, 13, 14, 17, 20, and 21; Plate III., figs. 4, 11, 16, 17, and 20; Plate V., figs. 4, 5, 11, 18, 24, and 25; Plate VI., figs. 6, 8, 11, 12 and 14, were all drawn with the aid of a camera lucida.

PLATE I.

Fig. 1. *Herria ceylonica*, n. sp., side view of animal. × 9.
,, 2. ,, ,, 3 teeth from radula, dorso-lateral view. × 470.
,, 3. ,, ,, tooth from radula, seen from above. × 470.
,, 4. ,, ,, jaw plate. × 83.
,, 5. ,, ,, cutting edge of jaw plate. × 340.
,, 6. *Galvina producta*, n. sp., median tooth with one of side plates. × 700.
,, 7. ,, ,, 4 teeth from radula, with side plates, lateral view. × 350.
,, 8. ,, ,, view of under-side of head.
,, 9. ,, ,, jaw plate, restoration from crushed specimen. × 55.
,, 10. *Linguella cinerea*, n. sp., median and 2 lateral teeth from radula. × 340.
,, 11. ,, ,, jaw plate. × 16.
,, 12. ,, ,, lateral tooth from radula, 39th from median. × 340.
,, 13. ,, ,, 2 outermost teeth from radula. *a* = outermost. × 340.
,, 14. *Pleurophyllidia formosa*, Kel., jaw plate. × 8·3.
,, 15. ,, ,, outer tooth from radula. × 285.
,, 16. ,, ,, median and 2 lateral teeth from radula. × 285.
,, 17. *Discodoris labifera*, Abr., 4 outermost teeth from radula. × 330.
,, 18. ,, ,, innermost teeth, *a* = rachis of radula. × 330.

PLATE II.

Fig. 1. *Pleurophyllidia formosa*, Kel., lateral teeth from radula, 8th to 13th from middle. × 136.
,, 2. *Platydoris inframaculata* (Abr.), under-side, anterior.
,, 3. ,, ,, branchiæ and collar.
,, 4. ,, ,, teeth from radula, middle of lateral row. × 132.
,, 5. ,, ,, armature of penis. × 29.
,, 6. ,, ,, discs from vagina. × 29.
,, 7. ,, ,, upper part of penis.
,, 8. *Platydoris speciosa* (Abr.), lateral teeth from radula, 70th to 74th from middle. × 132.
,, 9. ,, ,, worn teeth from lateral row of radula. × 110.
,, 10. ,, ,, lateral tooth, side view. × 110.
,, 11. ,, ,, lower portion of penis, showing armature. × 35.
,, 12. ,, ,, upper portion of penis, with glans. × 35.
,, 13. *Platydoris herdmani*, n. sp., view of under-side, anterior. × 2.
,, 14. ,, ,, dorsal view. × 1·5.
,, 15. ,, ,, outermost teeth of radula, 15th and 16th rows. × 370.
,, 16. ,, ,, penis, upper portion. × 25.
,, 17. ,, ,, ,, and vagina.
,, 18. *Thordisa* (?) *caudata*, n. sp., innermost teeth of radula. *a* = rachis. × 305.
,, 19. ,, ,, 5 outermost teeth of radula. × 305.

Fig. 20. *Platydoris spinulosa*, n. sp., dorsal view of bulbus pharyngeus.
,, 21. ,, ,, stomach, dorsal view.
,, 22. ,, ,, vagina, after treatment with caustic potash. × 15.
,, 23. ,, ,, opposite plates from vagina. × 60.

PLATE III.

Fig. 1. *Platydoris spinulosa*, n. sp., lateral teeth from radula, 36th and 37th from middle. × 300.
,, 2. ,, ,, innermost 4 teeth. *a* = innermost. × 300.
,, 3. ,, ,, outermost 8 teeth. × 300.
,, 4. *Halgerda punctata*, n. sp., lateral view of animal. × 2.
,, 5. ,, ,, outermost 4 teeth from radula. × 300.
,, 6. ,, ,, arrangement of branchiæ.
,, 7. ,, ,, innermost teeth of radula. *a* = rachis. × 300.
,, 8. *Platydoris inframaculata* (Abr.), innermost teeth of radula. *a* = rachis. × 100.
,, 9. ,, ,, 3 outermost teeth. × 300.
,, 10. *Platydoris speciosa* (Abr.), 4 outermost teeth. × 300.
,, 11. *Chromodoris tenuilinearis*, n. sp., animal, dorsal view.
,, 12. ,, ,, median teeth from radula. *a* = rachis. × 480.
,, 13. ,, ,, 3 outermost teeth from radula. *a* = outermost. × 480.
,, 14. ,, ,, 3 teeth from middle of lateral row. × 480.
,, 15. ,, ,, elements of jaw plate. *a* = side view of one. × 480.
,, 16. *Phyllidia nobilis*, Bgh. (?), animal, dorsal view. × 2.
,, 17. ,, ,, head and front of foot.
,, 18. *Ægires villosus*, n. sp., animal, lateral view from right. × 7.
,, 19. ,, ,, tubercles surrounding branchial pore, from left side.
,, 20. ,, ,, rhinophore sheath.
,, 21. ,, ,, buccal collar. × 31.
,, 22. ,, ,, lateral teeth from radula. × 310.
,, 23. *Kalinga ornata*, A. and H., median teeth. *a* = rachis. × 310.
,, 24. ,, ,, lateral teeth. *a* = innermost. × 310.

PLATE IV.

Fig. 1. *Philine aperta*, Linn., shell. × 2.
,, 2. *Aplysia cornigera*, Sow., teeth from radula, median and 2 lateral. × 127.
,, 3. ,, ,, 5th and 6th teeth from centre of radula. × 127.
,, 4. ,, ,, shell. × 2.
,, 5. ,, ,, teeth from radula, 12th from centre to margin. × 127.
,, 6. ,, ,, section of hyaline gland. × 52.
,, 7. ,, ,, gill. × 2.
,, 8. *Aplysia intermedia*, n. sp., median tooth from radula. × 340.
,, 9. *Aplysia elongata*, Pse., median tooth from radula. × 340.
,, 10. ,, ,, lateral view of head.
,, 11. ,, ,, shell, ventral. × 7.
,, 12. ,, ,, shell, lateral. × 7.
,, 13. *Phyllaplysia albomaculata*, n. sp., teeth from radula, median to 6th lateral. × 310.
,, 14. ,, ,, 6 outermost teeth from radula. × 310.
,, 15. ,, ,, shell, ventral. × 7·5.
,, 16. ,, ,, apex of shell showing spire.

Fig. 17. *Phyllaplysia pellucida*, n. sp., 19th to 22nd lateral teeth from radula. × 320.
„ 18. „ „ rods from jaw plates. × 310.
„ 19. „ „ median and 2 lateral teeth from radula. × 320.
„ 20. „ „ 9th to 12th lateral teeth from radula. × 320.
„ 21. „ „ 7 outermost teeth from radula. × 310.
„ 22. *Aplysiella mollis*, n. sp., lateral teeth from radula, 6th and 7th from margin. × 310.
„ 23. „ „ rods from jaw plates.
„ 24. „ „ 3rd to 5th teeth from centre of radula. × 310.
„ 25. „ „ 32nd to 35th teeth from centre to radula. × 310.
„ 26. „ „ median and 1st lateral teeth from radula. × 310.

PLATE V.

Fig. 1. *Phyllaplysia pellucida*, n. sp., shell, dorsal view. × 7.
„ 2. *Aplysiella mollis*, n. sp., shell, ventral view. × 7·5.
„ 3. „ „ calcareous layer of shell, dorsal view. × 7·5.
„ 4. *Dolabrifera maillardi*, DESH., animal, dorsal view. × 2.
„ 5. „ „ , seen from right side. × 2.
„ 6. „ „ teeth from radula, middle of lateral row. × 315.
„ 7. „ „ lateral tooth from radula, 19th from centre. × 315.
„ 8. „ „ apex of shell showing spire.
„ 9. „ „ shell, ventral view. × 15.
„ 10. „ „ median and 1st lateral teeth from radula. × 315.
„ 11. *Dolabrifera marginata*, n. sp., animal, dorsal view. × 2.
„ 12. „ „ median and 1st to 3rd lateral teeth from radula. × 310.
„ 13. „ „ lateral tooth from radula, 3rd from margin. × 310.

REPORT

ON THE

OSTRACODA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

ANDREW SCOTT, A.L.S.,
RESIDENT FISHERIES ASSISTANT IN THE MARINE LABORATORY AT PIEL, BARROW-IN-FURNESS.

[WITH TWO PLATES.]

THE OSTRACODA forming the subject of this report were, with a few exceptions, found amongst the sand and *débris* washed out of the vessels containing other groups of the Ceylon collection. Pelagic species were occasionally taken in the tow-nettings made during the examination of the pearl banks, and also in the series of plankton collections taken during the outward and homeward journeys. Samples of mud and sand from various pearl banks were also examined, but these yielded no members of this group. Some of the material had been preserved in formol, which had apparently a bad effect on the delicate shells of these creatures. In some cases the lime salts had been partly or entirely dissolved out, making the identification a work of much difficulty.

The Ostracoda are represented by 77 species belonging to 22 genera. Thirty-five of the above number appear to be undescribed, and are now added to the Ceylon Fauna, and figured in the plates.

A considerable amount of work has already been done and a good deal of information published relating to the Ostracoda of Ceylon. Professor BRADY has one paper in 'The Journal of the Linnean Society' (vol. xix., No. 114, 1886) which deals entirely with Ceylonese Entomostraca. It contains descriptions of new and other marine species dredged in 2 fathoms off Kalpentyn, in the Gulf of Manaar. Descriptions of other species are given by Professor BRADY in reports published in the 'Transactions of the Zoological Society.' The valuable work on the Ostracoda collected by the "Challenger" is indispensable in dealing with tropical forms. 'The Monographs on the North Atlantic and North-Western European Ostracoda,' by Professor BRADY and Dr. NORMAN, are also of much service. The splendid work of Dr. G. W. MÜLLER, published by the Naples Zoological Station, is a mine of information, as the anatomical details of the animals are fully illustrated, and the positions of many hitherto incompletely described species are thus firmly established. Finally, every paper dealing with marine Ostracoda from foreign localities requires to be consulted, and this has been done as far as possible in the present case; but it is not considered necessary to give references under the species, or to add a list of the literature, as the authors named and the papers made use of are well known to all workers at the group.

I am much indebted to Professor BRADY, F.R.S., for looking over the identifications made and for assistance given with some doubtful species. My father, Dr. T. SCOTT, has also helped me greatly with the work of classifying the undescribed forms. Owing to the absence of the appendages, the exact positions of one or two of the new species, which happened to be only empty shells, are at present uncertain.

It is almost impossible to find good descriptive names in certain genera of Ostracoda which are not pre-occupied, and geographical terms are apt to prove misleading. So I have named the new species of *Cythere* and *Cytherella* in honour of some of the officials and naturalists connected with Ceylon and its pearl fisheries who were mentioned in Professor HERDMAN'S Introduction to these Reports.

SECTION I.: MYODOCOPA.

FAMILY: ASTEROPIDÆ.

Asterope oculata, BRADY.

In washings from young pearl oysters collected from Cheval Paar, February and March, 1902, and from Muttuvaratu Paar, November 19th, 1902; also in general washings from invertebrates from Gulf of Manaar. Ten females and four males were found altogether. Professor BRADY records it from the surface at Trincomalee, and from Cruz Bay.

Asterope quadrata, BRADY.

Three females were present in the washings from invertebrates dredged on the pearl banks. This species was described from specimens collected at Lyttelton Harbour, New Zealand.

Asterope arthuri, STEBBING.

Specimens of this fine species were taken by the tow-net in 6 to 10 fathoms at Karativo Paar on March 10th, 1902, and at 9 fathoms at 9 P.M. on Vankali Paar, March 13th, 1902. On the latter date there was much phosphorescence in the water. STEBBING describes it in Dr. ARTHUR WILLEY'S "Results," Crustacea, Part v.

Cyclasterope similis, BRADY.

Two females in general washings from dredged invertebrates from Gulf of Manaar. Java Sound is the only previous locality given for the species.

FAMILY: CYPRIDINIDÆ.

Cypridina faveolata, BRADY.

One specimen, from the pearl banks in the Gulf of Manaar. It has hitherto been recorded only from the China Sea, where a single example was found.

Pyrocypris chierchiæ, MÜLLER.

This species appeared to be generally distributed throughout the area investigated and has been found in the following places:—Muttuvaratu, West Cheval, South-south-west of Silavaturi, off Kalpentyn Island, at Galle, in washings from young pearl oysters, and from the general washings from dredged invertebrates from the Gulf of Manaar.

According to Professor BRADY, this and other species of *Pyrocypris* occur in immense numbers in tropical seas, and seem to contribute a very large share to the phosphorescence of these regions. MÜLLER states that as many as twenty thousand of the above species have been taken in a single haul, and attributes their light-producing power to the labial papillæ which so far appear to be peculiar to the genus.

Codonocera cruenta, BRADY.—Plate II., figs. 43 to 45.

A single specimen of this peculiar ostracod was taken in the collection made by Professor HERDMAN on the homeward journey when west of Minikoi, in the Indian Ocean. In Professor BRADY'S description of the animal it is stated that the post-abdominal laminæ have only three ungues. In the present specimen there are distinctly four, the fourth, however, being very small (Plate II., fig. 43). The specimen was a male. The peculiar filaments on the antennules ending in bell-shaped disks (fig. 44) and the muscular hand of the antenna (fig. 45) are noteworthy characters; size, 1·73 millims.

Professor BRADY'S single specimen was taken at Pulo Penang.

FAMILY: SARSIELLIDÆ.

Sarsiella ornithoides, BRADY.

One specimen of this distinct form was found in the collection made at Karativo Paar on March 10th, 1902.

The only other locality for the species is Trincomalee.

Sarsiella carinata, n. sp.—Plate I., figs. 1 and 2; Plate II., figs. 40 and 41.

Shell membranous, thin and flexible, seen from the side subrhomboidal, height equal to about two-thirds of the length. Anterior extremity truncate, and provided with a prominent protuberance at the beginning of the dorsal curve; posterior narrower, deeply excavated, bounded above and below by prominent projections; dorsal margin boldly arched, highest behind the middle, whence it slopes rapidly towards the large projection; ventral margin nearly flat, except at the posterior end, where it is deeply sinuated; seen from above elongated, widest in the middle, width considerably less than half the length; anterior extremity narrow, emarginate; posterior wide, terminating in one median and two lateral protuberances. The dorsal and ventral margins are in the form of a continuous ridge with radiating lines, two longitudinal ribs of a similar structure run parallel to, but at a considerable distance within the margins, both terminating posteriorly in protuberances; ventral margin adorned with four protuberances of various sizes; in addition to these, there are two between the ventral margin and the lower ridge and one on the surface of the lower posterior projection. Surface of the shell marked with numerous circular depressions, which have four or five short setæ round the outside; dorsal and ventral margins ciliated; size, 1·1 millims.

Three specimens, all males, were found in washings from deep-water dredgings off Galle. The antennules have the characteristic dense brush of long fine hairs; post-abdomen with five marginal ungues, increasing in length from the first to the last, which is about five times as long as the first; margins spinulose.

Sarsiella gracilis, n. sp.—Plate I., figs. 3 and 4; Plate II., fig. 37.

Shell membranous, thin and flexible; seen from the side subcircular, height equal to fully two-thirds of the length; anterior extremity broadly rounded, crenate, with a distinct notch near the middle; posterior truncate, with a wide triangular process above and below; dorsal and ventral margins rounded, the former sloping rapidly at its posterior end; seen from above, oblong subovate, widest near the posterior end, width slightly less than one-third of the length; anterior extremity obtusely rounded, posterior truncated, with a median process; surface of the shell slightly ciliated, covered with small impressed puncta; anterior and ventral margins ciliated; size, 1·34 millims.

Two specimens were found in a dredging from 100 fathoms, off Galle, and one in the general washings from invertebrates from Gulf of Manaar. All were mature females with ova. The postabdomen has three stout ungues with spinulose margins, and three short plumose setæ.

Sarsiella similis, n. sp.—Plate I., figs. 5 and 6; Plate II., fig. 38.

Shell thin and flexible, subcircular, height fully two-thirds of the length; seen from the side anterior extremity rounded, crenate, with a slight notch in the centre, posterior truncate, with distinct projections above and below; dorsal and ventral margins boldly convex; seen from above subovate, fully twice as long as broad, anterior extremity narrow, posterior widely truncate, with a small median process; for the greater part the sides are nearly parallel, converging rapidly towards the anterior end; surface of the shell slightly ciliated, covered with small impressed puncta, the valves have four or five longitudinal ribs at the posterior and a number of radiating lines at the anterior extremity; anterior and ventral margins ciliated; size, 0·93 millim.

A number of ova-bearing females were found in washings from Muttuvaratu Paar and in the general washings from Gulf of Manaar. The species resembles the last in general shape, but is distinguished by the longitudinal ribs. The postabdomen (Plate II., fig. 38) is much narrower, and the ungues more spinulose.

Sarsiella crispata, n. sp.—Plate I., figs. 7 and 8; Plate II., fig. 39.

Shell thin and flexible; seen from the side subcircular, broadly rounded in front, slightly narrowed and produced into a wide ciliated beak posteriorly; seen from above broadly ovate, widest just behind the middle, twice as long as broad; anterior extremity narrow, posterior truncate, with one median and two lateral projections; surface covered with large impressed puncta, valves with a number of conspicuous ridges, the two near the posterior end of the dorsal margin forming distinct projections, anterior and ventral margins crenate and ciliated, with a corrugated line a little within; size, 0·8 millim.

About a dozen mature females were obtained in the same material as the previous species. Postabdomen (fig. 39) with four stout spinulose ungues of different lengths.

Sarsiella tumida, n. sp.—Plate I., figs. 9 and 10; Plate II., fig. 42.

Shell membranous, thin and flexible. Seen from the side subcircular, slightly longer than wide; anterior extremity broadly rounded, with a small beak in the centre; posterior truncate and produced into a wide beak at the lower angle; dorsal and ventral margins boldly convex, the dorsal forming a distinct hump in the centre; seen from above broadly ovate, widest slightly in front of the middle, width equal to less than two-thirds of the length, narrow in front, rectangularly truncate behind, with a distinct median projection; surface of the shell devoid of sculpture, but having a large fold near the posterior end of the dorsal margin; anterior and ventral margins ciliated; size, 1·26 millims.

Two mature females of this species were found in the general washings from dredged invertebrates. The postabdomen is narrow and furnished with five spinulose ungues, the longest being about five and a half times the length of the shortest.

Future investigation may show this form to be the female of *Sarsiella carinata*, as the comparative lengths of the ungues on the postabdomen of both species are nearly alike, but in the meantime it is thought best to keep them separate.

Family: HALOCYPRIDÆ.

Conchœcia magna, Claus.

Two specimens belonging to this species were taken in the tow-netting collected in the Suez Canal, between Port Saïd and Suez, on the outward journey.

Conchœcia clausii, G. O. Sars (?).

Two specimens apparently belonging to this species occurred in the above collection, but their very poor condition makes their identity uncertain.

Conchœcetta acuminata, Claus.

One specimen in the above collection, one from near Perim Island in the Red Sea, and a third from the middle of the Indian Ocean.

Halocypris concha, Claus.

This species occurred in a number of the collections taken between the Mediterranean and Ceylon on both journeys, and also on the pearl banks in the Gulf of Manaar.

Section II.: PODOCOPA.

Family: CYPRIDÆ.

Macrocypris decora (Brady).

In general washings from invertebrata and in washings from sponges dredged in the Gulf of Manaar.

Macrocypris orientalis, Brady.

In general washings from invertebrata from the Gulf of Manaar.

Macrocypris similis, Brady.

Also in general washings from invertebrata from the Gulf of Manaar.

Macrocypris maculata (Brady).

In the general washings from the Gulf of Manaar and in washings from Cheval pearl oysters.

Pontocypris robusta, n. sp.—Plate I., figs. 17 and 18.

Shell seen from the side subtriangular, the height being equal to slightly more than half the length, anterior extremity moderately broad and obliquely rounded, posterior attenuated and almost acuminate; dorsal margin boldly arched, highest in the middle, sloping with a steep curve backwards, and more gently towards the front; ventral margin deeply sinuated well in front of the middle. Seen from above the outline is ovate, acuminate in front and rounded behind, greatest width in the middle and equal to fully two-fifths of the length; shell white, polished, with minute setæ and impressed puncta; the valves are marked with five lucid spots arranged in a semicircular manner; size, 0·82 millim.

A few specimens from the general washings from Gulf of Manaar; from Cheval pearl oyster washings; and from Gulf of Manaar sponges.

At first it was thought this might be a form of *Pontocypris trigonella*, G. O. Sars, but a comparison with the figures given in the '"Challenger" Report,' in the report 'On the Entomostraca from the Gulf of Guinea,' by my father, and in the 'Monograph on the North Atlantic and North-western European Ostracoda,' by Brady and Norman, shows that it is distinct.

Pontocypris elegans, n. sp.—Plate I., figs. 19 and 20.

Shell seen from the side oblong, compressed, subreniform, the height being equal to rather less than one-third of the length; anterior extremity obliquely rounded, posterior produced and subacute at the ventral angle; dorsal margin moderately arched, greatest height slightly in front of the middle, and sloping gently towards each extremity; ventral margin deeply sinuated in the middle; seen from above compressed, ovate, widest in the middle, width about one-fourth of the length, acuminate in front and slightly rounded behind; shell white, polished, with a few minute impressed puncta; the valves are marked with a circular patch of lucid spots and three smaller detached ones; size, 0·6 millim.

A few specimens were found in the same washings as the previous species.

Pontocypris rostrata, n. sp.—Plate I., figs. 21 and 22.

Shell seen from the side subtriangular, greatest height nearly equal to half the length; anterior extremity broadly rounded, almost truncate, posterior produced, subacute in the centre; dorsal margin boldly arched, highest slightly in front of the middle, sloping very gently towards the front, but rapidly to the posterior; ventral margin sinuated in front of the middle, becoming convex near the posterior end where it turns up to join the extremity; seen from above ovate, greatest width in the middle and about equal to one-third of the length, acuminate in front and behind, sides distinctly compressed in front, forming a beak-like process; shell white and polished, valves unequal, the right being slightly smaller than the left; size, 0·64 millim.

In washings from sponges dredged in the Gulf of Manaar.

Pontocypris tumida, n. sp.—Plate I., figs. 30 and 31.

Shell seen from the side subovate, the height being rather more than half the length; anterior extremity rounded, somewhat depressed, posterior subacute; dorsal margin boldly arched, highest in the middle, ventral slightly sinuated in front of the middle; seen from above ovate, widest behind the middle, length equal to two and a half times the width, right valve smaller than the left; shell white, smooth, and polished; size, 0·97 millim.

In general washings and in washings from Gulf of Manaar sponges.

Erythrocypris herdmani, n. sp.—Plate I., figs. 15 and 16.

Shell seen from the side subtriangular, the height being about equal to half of the length; anterior extremity broadly rounded, posterior attenuated and subacuminate; dorsal margin strongly arched, almost angular at its highest point, forming a distinct hump, greatest height considerably in front of the middle, and sloping with a steep curve to both extremities, ventral margin slightly sinuated; seen from above ovate, width fully two-fifths of the length, greatest width about one-third from the anterior extremity, extremities obtusely pointed, rather more acute in front than behind; valves yellowish, smooth, and shining, covered with numerous short rigid hairs, the left valve has a distinct tooth at its posterior end; size, 0·85 millim.

Specimens were found in general washings from Gulf of Manaar, in washings from Cheval pearl oysters, and Manaar sponges, and on Karativo Paar. This species, which is easily distinguished from any of those already described, is named in compliment to Professor Herdman, whose labours on the Ceylon pearl banks have added an extensive chapter to our knowledge of the tropical marine fauna.

Bairdia villosa, Brady.

In general washings from invertebrates from the Gulf of Manaar.

Bairdia attenuata, Brady.

In general washings from invertebrates from the Gulf of Manaar.

Bairdia woodwardiana, Brady.

In general washings from invertebrates from the Gulf of Manaar.

Bairdia amygdaloides, Brady.

In general washings from invertebrates from the Gulf of Manaar.

Bairdia faveolata, Brady.

In the general washings and in washings from Cheval pearl oysters.

Bairdia hirsuta, Brady.

In general washings, in washings from Cheval pearl oysters, and from Karativo Paar.

All these species of *Bairdia* are new to the fauna of Ceylon.

Bairdia inornata, n. sp.—Plate I., figs. 11 and 12.

Shell seen from the side subreniform, height equal to more than half the length;

anterior extremity obliquely rounded, posterior produced in the middle into an obtusely angular beak; dorsal margin boldly arched, highest in the middle and sloping steeply towards the extremities, slightly sinuated at the anterior and posterior ends, ventral margin deeply sinuated in the middle; seen from above compressed, ovate, widest in front of the middle and nearly three times longer than wide, extremities obtuse, subtruncate; colour almost black, with one or two lighter bands; surface of the valves covered with closely set, short, stiff setæ; posterior end of the ventral margin finely serrate; right valve smaller than the left; size, 0·74 millim.

A few specimens in general washings from invertebrates from Gulf of Manaar.

Bairdia robusta, n. sp.—Plate I., figs. 13 and 14.

Shell seen from the side subtriangular, height equal to fully two-thirds of the length; anterior extremity obliquely rounded, posterior produced in the middle into an obtusely angular beak; dorsal margin greatly arched, highest slightly in front of the middle, ventral nearly straight; seen from above broadly ovate, length fully one and a half times the width, extremities subacute, posterior more so than the anterior; shell white, polished, closely beset with black setæ; anterior and posterior extremities with a dense fringe of setæ; size, 0·87 millim.

In general washings from invertebrates from Gulf of Manaar. This species resembles *Bairdia villosa*, Brady, but is much more tumid and obtuse.

Anchistrocheles bradyi, n. sp.—Plate I., figs. 34 and 35.

Shell seen from the side reniform, height slightly less than half the length; anterior extremity wide, obliquely subtruncate, posterior broadly rounded, slightly produced in the middle; dorsal margin gently and evenly curved, highest behind the middle, ventral sinuated in front of the middle: seen from above the outline is elongated, with parallel sides, nearly four times longer than wide; both extremities acute, anterior more so than the posterior; shell smooth, thin and fragile; size, 0·9 millim.

In dredged material from 6 fathoms to 10 fathoms, Karativo Paar.

The species resembles *Anchistrocheles fumata*, Brady, in general appearance, but is easily recognised by the more acute extremities, as seen from the dorsal aspect. I have great pleasure in naming it after Professor Brady, to whom we remain indebted for much help both in this group and in the Copepoda.

Pseudocythere minuta, n. sp.—Plate I., figs. 28 and 29.

Shell seen from the side oblong, subquadrate, slightly higher in front than behind, height slightly less than half the length; anterior extremity rounded, with one or two tooth-like projections near the middle; posterior oblique, subtruncate, much compressed, produced at the upper angle into a broad, blunt beak, lower angle also produced, but the beak is much smaller: dorsal margin almost flat, highest near the anterior end, sloping very slightly towards the posterior, ventral margin slightly sinuated in front of the middle; seen from above ovate, widest in the middle, tapering to the extremities, both of which are acuminate, the posterior much attenuated; width equal to less than half the length; shell marked with numerous puncta arranged in fairly regular, slightly curved, longitudinal rows. Size, 0·35 millim.

A single specimen in general washings from dredged invertebrates from Gulf of Manaar.

Paradoxostoma cingalense, BRADY.

One or two specimens in general washings from dredged invertebrates from Gulf of Manaar. Off Kalpentyn is the only previous locality given for the species.

Paradoxostoma attenuatum, n. sp.—Plate I., figs. 32 and 33.

Seen from the side pear-shaped, about two and a half times longer than broad; anterior extremity very narrow, rounded, posterior broad and truncate, sloping inwards, forming a distinct tooth at the junction with the lower margin; dorsal margin boldly arched, highest considerably behind the middle, ventral margin sloping outwards from the anterior extremity; very slightly sinuated, convex at the widest part; seen from above much compressed, with acute extremities, greatest width in the middle, length four and a half times the width; shell amber coloured, smooth and transparent; size, 0·6 millim.

In washings from Gulf of Manaar sponges.

Paradoxostoma stebbingi, n. sp.—Plate II., figs. 1 and 2.

Shell seen from the side pear-shaped, two and a half times longer than broad; anterior extremity narrow, obliquely rounded, posterior subacute in the centre; dorsal margin boldly and evenly arched, highest slightly behind the middle; ventral margin sinuated near the anterior extremity; seen from above compressed, ovate, widest in the middle, and nearly four times longer than broad, extremities acute; shell smooth, white and semi-transparent; size, 0·6 millim.

In general washings from dredged invertebrates.

I name this species after the Rev. T. R. R. STEBBING.

Xestolebris margaritea, BRADY.

In the general washings, in washings from Cheval pearl oysters and Gulf of Manaar sponges, and in a dredging from Karativo Paar.

Xestolebris tumefacta, BRADY.

In the general washings from Gulf of Manaar.

Xestolebris aurantia, BAIRD.

Also in the general washings. The specimens were first identified as *Xestolebris* *margaritea*, but Professor Brady says he cannot distinguish them from our native *Xestolebris aurantia.*

Xestolebris variegata, Brady.

In the general washings, and in washings from Cheval pearl oysters.

Xestolebris faveolata, Brady.

In a dredging from Karativo Paar, 6 to 10 fathoms.

Xestolebris squamigera, n. sp.—Plate I., figs. 23 to 25; Plate II., figs. 28 and 29.

Shell seen from the side somewhat siliquose, two and a half times longer than broad. Anterior extremity very narrow, rounded, posterior subacute; dorsal margin boldly arched, highest a little behind the middle, sloping rapidly and evenly to the anterior end; posteriorly the slope is more abrupt and almost truncate; ventral margin nearly straight, slightly sinuated in front of the middle; seen from above the outline is broadly ovate; width about three-fifths of the length, and widest behind the middle; anterior extremity subacute, distinctly sinuated, and expanding rapidly; posterior extremity broadly rounded; seen from the posterior end the valves are deeply concave; valves slightly unequal; shell smooth, white and polished, with numerous whitish spots scattered over the surface; size, 0·52 millim.

In the general washings and in washings from Gulf of Manaar sponges. The drawings on Plate I. represent an ova-bearing female; the antennule and antenna are shown on Plate II., figs. 48 and 49.

Xestolebris irrasa, n. sp.—Plate II., figs. 5, 6 and 46, 47.

Shell seen from the side ovate, height fully two-thirds of the length; anterior extremity narrow, posterior broad, both well rounded; dorsal margin boldly arched, highest in the middle, ventral very slightly convex, with slight sinuations at the extremities; seen from above ovate, widest behind the middle, width fully two-thirds of the length, extremities obtusely pointed in front, wider and more rounded behind; surface of the shell marked with numerous concentric spinulose ridges, and clothed with short stiff setæ; colour yellowish; size, 0·53 millim.

In the general washings and in washings from Gulf of Manaar sponges. The figures represent a female shell, the antennule and antenna being shown by figs. 46 and 47.

Xestolebris tumida, n. sp.—Plate II., figs. 3 and 4.

Shell seen from the side broadly pear-shaped, scarcely one and a half times longer than broad, extremities well rounded, anterior much narrower than the posterior; dorsal margin greatly arched, highest behind the middle; ventral slightly sinuated in front and convex behind; seen from above broadly ovate, rather longer than broad, compressed and pointed in front, broadly rounded behind; greatest width behind the middle; shell smooth, white, with numerous whiter spots on its surface; size, 0·6 millim.

In general washings from the Gulf of Manaar.

The species resembles *Xestoleberis variegata*, but is much more tumid.

Paracytheridea perplexa, n. sp.—Plate I., figs. 26 and 27.

Shell seen from the side subrhomboidal, two and a half times longer than broad; anterior extremity obliquely rounded, with three median teeth; posterior produced into a median triangular beak; dorsal margin highest in front, sloping downwards towards the posterior in an irregularly sinuous line; ventral margin slightly convex in front, rising with a gentle slope posteriorly, deeply notched at the hinder end, and then suddenly produced into a curved triangular tooth-like process; seen from above the outline is much like that of a Trilobite, very wide and rounded in front; narrowing slightly posteriorly, then rapidly converging to form a wide triangular end; greatest width much in front of the middle, and equal to three-fourths of the length; surface of the shell marked with large puncta, and in side view with obliquely transverse ridges; size, 0·65 millim.

A few specimens in the general washings from dredged invertebrates from Gulf of Manaar.

The species resembles *Paracytheridea depressa*, G. W. Müller, but differs in the termination of the lateral margins as seen from above. In *P. depressa* the margins end in a distinct tooth projecting at nearly right angles to the sides.

Cytherura concinna, n. sp.—Plate II., figs. 7 and 8.

Shell seen from the side subrhomboidal, with a well-marked dorsal ridge, height equal to half the length; anterior extremity obliquely rounded, posterior broadly beaked above the middle; dorsal margin rugged, broken by a few small blunt projections, sloping gently upwards towards the posterior, ventral convex in the middle; seen from above broadly triangular, greatest width much behind the middle and equal to two-thirds of the length; anterior extremity rounded and produced into a blunt median beak; posterior very wide, subtruncate, and produced into a large median process, its margin forming a distinct flexuous ridge coursing between the outer and inner margins of each valve; surface of the shell marked with numerous puncta, and with a distinct depression in the centre of each valve; size, 0·53 millim.

One or two specimens in general washings from dredged invertebrates from Gulf of Manaar.

Loxoconcha anomala, Brady.

In general washings, in washings from Cheval pearl oysters, and in a dredging from Karativo Paar.

Loxoconcha alata, Brady.

From the same material as the previous species.

Loxoconcha papillosa, Brady.

In general washings from Gulf of Manaar.

Loxoconcha sculpta, Brady.

In washings from Gulf of Manaar sponges.

Loxoconcha australis, Brady.

In the general washings and in washings from Gulf of Manaar sponges.

Cythere bimammillata, Brady.

In washings from Gulf of Manaar sponges.

Cythere darwini, Brady.

In the general washings, in washings from Gulf of Manaar sponges, and in a dredging from Karativo Paar.

Cythere inconspicua, Brady.

In washings from Cheval pearl oysters.

Cythere ovalis, Brady.

In the general washings, in washings from Cheval pearl oysters, and in a dredging from Karativo Paar.

Cythere polytrema, Brady.

In general washings from Gulf of Manaar.

Cythere rectangularis, Brady.

In general washings from Gulf of Manaar.

Cythere ruperti, Brady.

In the general washings and in washings from Gulf of Manaar sponges.

Cythere stimpsoni, Brady.

In a dredging from Karativo Paar.

Cythere subcuneata, Brady.

In general washings from Gulf of Manaar.

Cythere knoxi, n. sp.—Plate II., figs. 9 and 10.

Shell seen from the side elongated, subsigmoid, height equal to half the length, extremities toothed; anterior extremity broad and obliquely rounded, posterior narrower, rounded off below, and obscurely angulated above; dorsal margin sinuated in the centre, highest in front and sloping towards the posterior, ventral sinuated in the middle; seen from above pear-shaped, greatest width near the posterior end, and equal to more than half the length, the outline between the widest point and the anterior end shows two distinct constrictions; shell surface marked with coarse impressed puncta; each valve seen from the side shows two distinct grooves; size, 0·56 millim.

In the general washings and in washings from Cheval pearl oysters.

Named after Captain Robert Knox, 20 years a captive in Ceylon in the seventeenth century.

Cythere chalmersi, n. sp.—Plate II., figs. 11 and 12.

Shell seen from the side subsigmoid, height equal to half the length, extremities corrugated but not toothed; anterior extremity very obliquely rounded, posterior narrower, and broadly rounded; dorsal margin highest at the anterior end, nearly flat, with a gentle slope towards the posterior; ventral sinuated in the middle; seen from above pear-shaped, outline irregular, and marked by three constrictions, widest near the posterior end, greatest width equal to about half the length; anterior and posterior ends with strong thickened lips, the posterior forming a distinct protuberance; surface of the shell marked with moderately coarse impressed puncta, and near the extremities with a row of circular depressions; seen from the side, the valves show three distinct grooves; size, 0·7 millim.

In the general washings and in washings from Gulf of Manaar sponges.

Named after Dr. A. J. Chalmers, Professor in the Medical College, Colombo.

Cythere imthurni, n. sp.—Plate II., figs. 13 and 14.

Shell seen from the side oblong, subquadrangular, height slightly less than halt the length; extremities smooth, anterior extremely broad and obliquely rounded, with an internal row of subcircular markings; posterior narrower, rounded above and truncate below; dorsal margin highest at the anterior end, nearly flat, with a gentle slope towards the posterior, ventral deeply sinuated near the middle; seen from above rather wedge shaped, with nearly parallel sides, deeply constricted near the posterior end, length about two and a half times the width; anterior margin acuminate with projecting thickened lips, posterior almost truncated, projecting slightly in the centre; surface of the shell marked with large irregular impressed puncta, and, when viewed from the side, with a deep hollow near the posterior; size, 0·5 millim.

In the general washings, in washings from Cheval pearl oysters, and from Gulf of Manaar sponges.

Named after the Honourable E. F. im Thurn, Lieutenant-Governor of Ceylon during the pearl oyster investigation in 1902.

Cythere thompsoni, n. sp.—Plate II., figs. 15 and 16.

Shell seen from the side oblong, subquadrangular, height rather more than half the length; anterior extremity wide and obliquely rounded, with about a dozen short thick teeth, posterior slightly narrower, almost truncate, with five or six short stout teeth; dorsal margin deeply sinuated in the middle, highest at the anterior end, ventral margin slightly sinuated near the anterior end; seen from above broadly ovate, with irregular outline, width rather more than half the length, widest near the posterior end; anterior extremity obtuse, with two mucronate processes, posterior wide, truncated, with broad, tooth-like median projections; surface of the shell marked with large regular ridges and deep depressions, which become very conspicuous in dead shells; size, 0·73 millim.

In the general washings and in washings from Gulf of Manaar sponges.

This well-marked species is named in memory of my friend and fellow-worker, the late Mr. Isaac C. Thompson, F.L.S., who was jointly responsible with me in the preparation of the "Report on the Copepoda," published in the first volume of this work.

Cythere donnani, n. sp.—Plate II., figs. 17 and 18.

Shell seen from the side subsigmoid, height equal to half the length; anterior extremity wide and very obliquely rounded, with about fourteen small teeth on the lower margin, posterior narrow, slightly produced in the centre, with four small teeth below the middle; dorsal margin sinuated in the middle, highest at the anterior and rounded off towards the posterior, ventral sinuated, convex in front and behind; seen from above broadly ovate, width slightly less than half the length, with rounded extremities, slightly produced into thickened lips, widest near the posterior, and slightly sinuated in the middle; surface of the shell marked with a number of fairly regular longitudinal ridges and rows of impressed puncta; size, 0·98 millim.

In washings from Cheval pearl oysters, and from Gulf of Manaar sponges.

Named after Captain Donnan, Inspector of the Pearl Banks in 1902.

Cythere willeyi, n. sp.—Plate II., figs. 19 and 20.

Shell seen from the side oblong, subquadrangular, height equal to rather more than half the length; anterior extremity wide and very obliquely rounded, with about seventeen short stout teeth, posterior much narrower, bluntly rounded, with four short teeth on the lower margin; dorsal margin very slightly sinuated in the middle, highest in front, and rounding off posteriorly, ventral sinuated slightly in front of the middle; seen from above broadly ovate, with irregular outline, width rather more than half the length, widest in front of the middle; anterior extremity obtuse, with two mucronate processes, posterior widely triangular; surface of the shell marked with large irregular puncta, and a distinct dorsal ridge; size, 0·8 millim.

In general washings from Gulf of Manaar.

Named after Dr. Arthur Willey, Director of the Museum at Colombo.

Cythere hornelli, n. sp.—Plate II., figs. 21 and 22.

Shell seen from the side siliquose, height rather less than half the length; anterior extremities narrowed and rounded, smooth; dorsal margin boldly arched, highest in the centre, ventral sinuated in the middle; seen from above wedge-shaped, width less than half the length, widest near the posterior; anterior extremity produced, with two mucronate processes, posterior margins truncate, and produced into a broad triangular projection; surface of the shell marked with a number of curved ridges and rows of impressed puncta; size, 0·53 millim.

In general washings from invertebrata from Gulf of Manaar. Named after Mr. James Hornell, now Inspector of the Pearl Banks.

Cythere halyi, n. sp.—Plate II., figs. 23 and 24.

Shell seen from the side oblong, quadrangular, height slightly less than half the length, widest in the middle; anterior extremity broadly rounded, with one tooth below the centre; posterior produced into a wide triangular beak; dorsal margin flat, with a corrugated margin, highest at the extremities, ventral slightly convex and irregular; seen from above narrowly ovate, with produced and thickened extremities, widest behind the middle, width considerably less than half the length; surface of the shell marked with numerous impressed puncta and studded with bluntly pointed spines; size, 0·55 millim.

In general washings from invertebrata from Gulf ot Manaar. Named after Mr. Haly, a former Director of the Colombo Museum.

Cythere kelaarti, n. sp.—Plate II., figs. 25 and 26.

Shell seen from the side oblong, subquadrangular, height scarcely equal to half the length; anterior extremity broadly and obliquely rounded, with about 21 short, stout teeth; posterior narrow and subtruncate, with seven short, thick spines; dorsal margin slightly sinuated, highest in front and sloping gently backwards, ventral nearly straight, much contracted at the posterior; seen from above doubly triangular, widest much behind the middle, where the outline is produced into a blunt tooth; width slightly more than half the length; anterior extremity with two, and the posterior with four, spines; surface of the shell marked with numerous impressed puncta, very rough and studded with short, aculeate spines, one triangular tooth near the posterior; size, 0·65 millim.

In general washings from dredged invertebrates from Gulf of Manaar. Named after Dr. Kelaart, who investigated the pearl banks in 1857.

Cythere willisi, n. sp.—Plate II., figs. 27 and 28.

Shell seen from the side subquadrangular, with compressed margins, height slightly less than two-thirds of the length; anterior extremity broad and very obliquely rounded, with seven short, stout teeth on the lower portion; posterior almost rectangularly truncated, produced below the middle, where it bears two teeth and one or two crenulations; dorsal margin highest in front, sloping with a sinuous curve gently backwards; ventral sinuated in front and convex behind; seen from above ovate, with produced emarginate extremities, sharply constricted in the middle and near the posterior end, width equal to half the length; surface of the shell covered with large irregularly angulated fossæ, marked with a strong marginal ridge and an obliquely transverse one, coursing from the posterior towards the anterior extremity; highest at the posterior end; size, 0·73 millim.

In the general washings, in washings from Gulf of Manaar sponges, and in a dredging from Karativo Paar. Named after Dr. J. C. Willis, Director of the celebrated Botanic Gardens at Peradeniya, Ceylon.

Cythere colletti, n. sp.—Plate II., figs. 29 and 30.

Shell seen from above subquadrangular with compressed margins, height equal to slightly less than two-thirds of the length; anterior extremity broad and obliquely rounded, with 10 short, stout teeth on the lower portion; posterior narrowed, truncated, produced near the middle into a quadri-crenulate projection; dorsal margin highest in front, sloping rather steeply to the posterior; ventral slightly sinuated in front, convex behind the middle, rising quickly near the posterior, where there is a strong, stout incurved tooth; seen from above doubly triangular, widest slightly behind the middle, width rather more than half the length, the margins near the posterior end are produced into strong teeth; anterior extremity blunt and produced into the mucronate processes, posterior truncate; surface of the shell marked with curved ridges and rows of impressed puncta; each valve has a strong tooth near the lower margin of the posterior end; size, 0·5 millim.

In washings from Gulf of Manaar sponges.

Named after the late Mr. Oliver Collett, a well-known naturalist in Ceylon.

Cythere holdsworthi, n. sp.—Plate II., figs. 31 and 32.

Shell seen from the side subrhomboidal, height equal to fully two-thirds of the length; anterior extremity broad and obliquely rounded, posterior truncated, with a small projection in the centre; dorsal margin boldly arched, highest in the middle; ventral convex in the middle; seen from above broadly ovate, widest near the middle, width equal to two-thirds of the length; anterior extremity narrowed and bluntly rounded; posterior broadly rounded, almost truncate; surface of the shell marked with concentric rows of impressed puncta; size, 0·5 millim.

In general washings from dredged invertebrata from Gulf of Manaar.

Named after Mr. Holdsworth, the naturalist who investigated the pearl banks in 1868.

Section III.: PLATYCOPA.

Family: CYTHERELLIDÆ.

Cytherella ondaatjei, n. sp.—Plate II., figs. 33 and 34.

Shell seen from the side subquadrangular, height rather less than two-thirds of the length; anterior extremity broadly rounded, posterior obliquely rounded, sloping steeply inwards; dorsal margin slightly arched, highest behind the middle, ventral deeply sinuated in the middle; seen from above elongate narrow, widest behind the middle, width equal to one-third of the length; anterior extremity bluntly rounded, posterior almost truncated, margins much hollowed above the middle; surface of the shell marked with numerous shining spots, and a conspicuous triangular groove; covered with fine spinules, anterior extremity and ventral margin finely spinulate; size, 0·6 millim.

In a dredging from Karativo Paar.

Named after Dr. Ondaatje, a former naturalist and collector in Ceylon.

Cytherella vraspillaii, n. sp.—Plate II., figs. 35 and 36.

Shell seen from the side subelliptical, height less than two-thirds of the length; valves unequal, left valve larger than the right; anterior extremity rounded, posterior rounded and slightly produced in the centre; dorsal margin slightly arched, highest in the centre; ventral flattened, slightly sinuated; seen from above pear shaped, widest behind the middle, width slightly less than two-thirds of the length, obtusely pointed in front, broadly rounded behind, lateral margins boldly convex; surface of the shell smooth and polished; size, 0·55 millim.

In general washings from dredged material from Gulf of Manaar.

This species is named in honour of Mr. V. Vraspillai, the well-known Adigar of Musali, who has rendered able service in connection with the pearl banks for many years.

CONTENTS OF PART IV.

PEARL OYSTER REPORT.

SUPPLEMENTARY REPORTS.

PREFACE.

When the last Part of this Report was issued, early in the present year, I still hoped that it would be possible to compress the remaining Supplementary Reports, along with the conclusion of the Pearl Oyster Report proper, within the limits of Part IV., and an intimation to that effect was made in the Preface. During the summer, however, when the Authors of the Supplementary Reports began to send in their manuscripts, it became plain that I had been too sanguine, and that a fifth and concluding Part would be necessary to finish the series. Under these circumstances I have decided to issue all the Supplementary Reports that are ready in the present Part—making it up to a volume of about the usual size of 300 pages and 30 plates—and to publish the few remaining Reports along with the several concluding sections of the Pearl-oyster work in Part V., early in 1906.

The Reports (all well advanced) which I still expect are:—On the Brachyura, by Mr. Douglas Laurie; on the Schizopoda and Stomatopoda, by Mr. Walter Tattersall; on the Anomura, and on the Actiniaria; on the Marine Insects, by Professor G. Carpenter; on the Tunicata, by myself; a list of the Molluscan Shells, by Mr. R. Standen and Mr. A. Leicester; and a list of the Foraminifera, by Mr. W. J. Dakin. There will be a further, and final, instalment on the Parasites of the Pearl Oyster, by Mr. Shipley and Mr. Hornell, and I propose to add a general discussion of the faunistic results. These sections, with the remainder of the Pearl-oyster work, and the Summary of Results and Recommendations as to the Conservation of the Banks, should then complete the Report.

The valuable memoirs in the present volume will speak for themselves, but I desire to express here my very cordial thanks to my friends the various contributors for their kindness in undertaking the work, and for their skill in carrying it out. The only case that calls for any further remark is the last in the volume. In order to prevent delay, I arranged with Dr. Willey that the proofs of the Report on the Polychæta should not be sent out to Ceylon. As the "copy" was supplied to me in the form of a corrected print marked "for press," and as Mr. Arnold Watson and Mr. Cyril Crossland—both familiar with the group—have kindly helped me to read the proofs, I hope that the chance of errors having escaped notice has been minimised. I have added at the last moment an interesting note by Mr. Arnold Watson on the Polychæte worm which is commensal with the sponge *Aulospongus* *tubulatus*—a familiar object on the pearl banks. This worm, when first found, was supposed to be an Oligochæte, but now proves, as Mr. Watson has shown, to be a Polychæte allied to the *Leucodore* that burrows in the pearl oyster shells.

During the present year, since the issue of Part III., important changes have taken place in Ceylon, both on the pearl banks and in the arrangements proposed for future fisheries. The recommendations made, on biological grounds, in the article on 'The Present Condition of the Pearl Banks' (Part III., p. 44) were not fully adopted by the Government of Ceylon.

The South Cheval Paar, which it was hoped would be left for another year, to supply a fishery in 1906, was stripped along with the Modragam Paars and some other sections of the Cheval—the result being that the great fishery in the Spring of 1905 now holds the record both for the total number of oysters fished and also for the amount of revenue brought in to the Government. The prices obtained were very high, and it is, of course, under such circumstances, a great temptation to a Government to fish and sell as many oysters as it is possible to obtain in the limited time permitted by the weather. It must always be a difficult matter to decide whether oysters present in abundance but admittedly immature should be secured at once or left to have an additional year of growth and probable pearl-formation. We can only hope that on the present occasion the decision has been a wise one, and that the clearing of the South Cheval Paar has not imperilled the success of next year's fishery.

Another factor which may have an important bearing upon the future history of the Ceylon Pearl Fisheries is the proposal that the pearl banks should be leased for a period of years to a Syndicate, which will be bound by the terms of the lease to expend a considerable sum annually in the cultivation and exploitation of the fishing grounds. It seems probable at the time of issuing this volume that the next Ceylon Pearl Fishery will be held under the auspices of the Syndicate.

W. A. HERDMAN.

The University, Liverpool.
November, 1905.

REPORT ON THE PEARL OYSTER FISHERIES OF THE GULF OF MANAAR.—PART IV.

THE GREAT PEARL FISHERY OF 1905.

(Drawn up from the Government Official Reports and Mr. Hornell's Letters, with Additions and Remarks.)

The Pearl Fishery which was held at Ceylon in the spring of 1905 may well be called "the great fishery." The temporary "fishery-town" erected at Marichchukaddi was larger than it is known to have ever been before, the inhabitants congregated there were at least 10,000 more than in the previous "record" fishery of 1904, the numbers of divers (4991) and their attendant manducks (4894) and the fleet of boats (318) were much greater, and the totals of oysters fished and of rupees obtained for the Government were far beyond all previous records. There were forty-seven fishing days as against thirty-three in 1904. The number of oysters collected (upwards of eighty-one and a half millions) is nearly double that obtained at any previous fishery, and the revenue derived from the Government share alone was nearly two and a half million rupees, which beats all other known fisheries with nearly 15 lacs of rupees to spare.

This is the last of a series of three highly successful fisheries in consecutive years, and it does not seem likely to be rivalled by any prospective fishery of the oysters now in sight upon the grounds. The fishery of 1903 yielded 41,180,137 oysters and the Government share of the revenue was about £55,303; in 1904 the oysters totalled 41,039,085 and the Government revenue £71,050; in 1905 the number of oysters was 81,580,716 and the revenue over £167,381. From these fisheries, taken together, the Government of Ceylon has derived fully £293,735, without taking into account the revenue derived from postal returns (which at these three fisheries were considerable), and other receipts indirectly connected with, but consequent upon, the industry.

These figures look magnificent, and they show what a valuable possession the

Ceylon Government has in the pearl banks, but it must be remembered that this series of three very profitable fisheries followed on an interval of eleven years during which there were no returns, and that the average yield for the last three years is far above that of the last hundred or so—the period for which we have any accurate record.

It may be of interest to quote here the results of the chief fisheries of that century:—

(1.)	1905	yielded	81,580,716	oysters.	Revenue =	2,510,727 Rs.
(2.)	1904	,,	41,039,085	,,	,, =	1,065,751 ,,
(3.)	1814		*		,, =	1,051,876 ,,
(4.)	1891	,,	44,311,441	,,	,, =	963,748 ,,
(5.)	1808		*		,, =	842,577 ,,
(6.)	1903	,,	41,180,137	,,	,, =	829,548 ,,
(7.)	1888	,,	22,052,769	,,	,, =	804,247 ,,

* Particulars as to number of oysters fished not available previous to 1835.

After that the revenue rapidly drops to seven, five, four, three, and two hundred-thousand rupees, and there are a number of fisheries on the list with between one and two hundred-thousand. As an example of a very poor fishery, we may take the one held in 1884 off Chilaw, yielding only 636,000 oysters and a revenue of 17,153 rupees. Many single days in the recent fishery far exceed the entire proceeds of certain previous fisheries.

The Report of Mr. G. P. Lewis, Government Agent, writing as Superintendent of the fishery, puts in this way "the extraordinary achievements of this fishery by comparison with the chief fisheries of former years, the fisheries of 1808 and 1903 were beaten in ten days, that of 1891 in eleven, and those of 1904 and 1814, which had hitherto occupied the first and second places respectively, in twelve." The fishery lasted for 35 days after that. Mr. Hornell, in his Report, puts it another way, and says that the total number fished "all but equals the combined totals of the two great fisheries of 1903 and 1904, and is not far from double the highest number taken in any other fishery concerning which we have authentic information, namely, 44,311,441 in 1891" ('Ceylon Sessional Papers,' 1905, p. 36).

Enough has been said to show the exceptional nature of the recent fishery, but it is quite a pertinent question whether this phenomenal success has not been attained, to some extent at least, at the expense of the next few years. It will be remembered that in the section of this Report entitled 'Present Condition of the Pearl Banks' (Part III., p. 37), written a year ago as the result of Mr. Hornell's inspection in November, 1904, certain reasons were given for fishing in 1905 the two Modragams and the sections of the Cheval defined as south-west, mid-east, and south-central (see fig. 1), leaving for 1906 the sixty-odd million oysters upon the South and South-

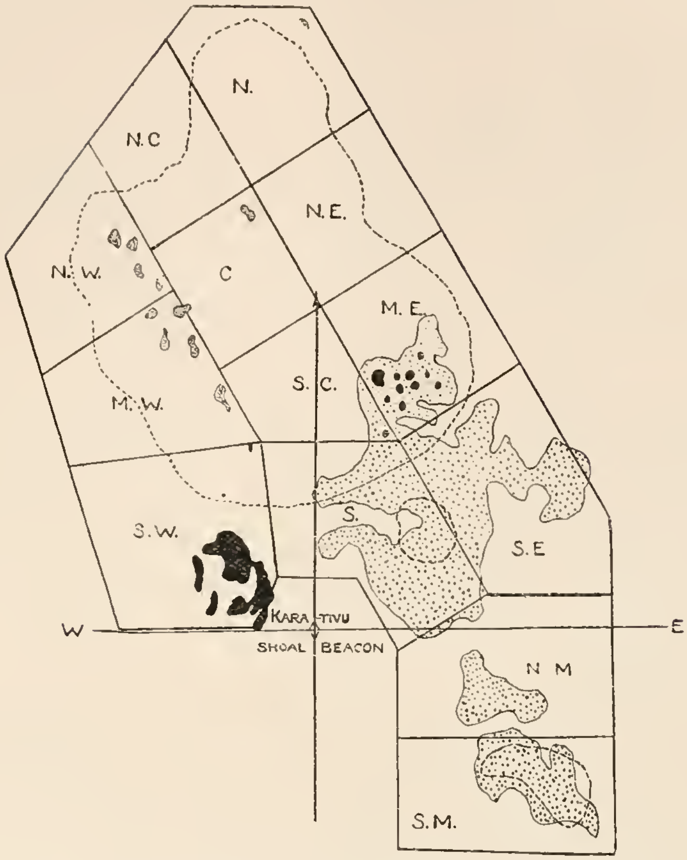

Fig. 1. Sketch-plan of the Cheval and Modragam paars, showing the distribution of pearl oysters in November, 1904. Scale: Half an inch to one nautical mile. The broken line surrounds the areas covered with spat a few months old, the dotted areas are those with oysters about 3 years old, the solid black indicates those beds of oysters over 5 years old.

east Cheval. The oysters on the banks in question were then estimated to be as follows :—

Paar.	Number of oysters.	Age in March, 1905.
South Modragam	21,000,000	Over 3 years.
North Modragam	4,700,000	„ 3 „
South-west Cheval	3,500,000	„ 5 „
Mid-east and South-central Cheval	13,750,000	3 to 6 „
South Cheval	40,220,000	Over 3 „
South-east Cheval	23,600,000	„ 3 „

Of these, the oysters on the two Modragam paars were thought to be unhealthy and liable to die off; those on the South-west Cheval were very old and clearly had to be secured at once or not at all; and those on the Mid-east and South-central Cheval were apparently being smothered by young oysters. Consequently the recommendation was that these forty-three million oysters should be fished first, leaving the rest which seemed healthy, vigorous, and safe for a further year of growth and pearl-production.

On the other hand, the November valuation of the pearls from the samples collected gave 24.65 Rs. per thousand to the South Cheval, as against 17.86 Rs. for the South Modragam which stood next. That fact was sure to cause pressure to be brought by the pearl merchants upon the Government in favour of fishing the South Cheval; and it is, of course, impossible to avoid sympathising with the view that 40 million oysters in the hand may be worth a good deal more than the chance of getting them next year at an enhanced value. Our recommendation of last year accordingly ended with these words:—"On the other hand, there is, of course, always a certain risk in leaving a fishable bed of oysters unfished, and, once the biological facts given above have been stated, it lies with the Government to decide what risk can be run and what course should be taken. If the 40,000,000 oysters on the South Cheval Paar, or a considerable number of them, can be fished in addition to the 43,000,000 which certainly ought to be secured first, there will, no doubt, be a large additional profit now—a present certainty in place of the prospect of a possibly much greater result next year" (Part III., p. 46).

The 'Gazette' of 16th December, 1904, gave notice, however, that the fishery, to begin on 20th February, 1905, would include the South Cheval, the South-west Cheval, the Mid-east Cheval, and the North and South Modragams. We can now only hope that the decision of Government to fish the South Cheval in 1905, in addition to the beds we had recommended, was a wise one, and that it has not too seriously affected the fishery prospects of the next few years. It is to be feared that the oysters fished from the South Cheval will scarcely maintain in pearl-yield the reputation of their bank, and it can scarcely be doubted that, had they been left, and had they survived, their value next year would have been much greater.

The inspection in February, immediately before the fishery, showed fortunately that no catastrophic change had taken place. The numbers for the South Cheval and North Modragam were increased, those for the Mid-east Cheval and South Modragam were reduced somewhat, while the very old oysters on the South-west Cheval, as was to be expected, had continued to dwindle and were now so few and so scattered as to be scarcely fishable.

The most noteworthy observation in this inspection was, as Mr. Hornell states, that on the south-east side of the South Modragam "the bed extended beyond the limit of the ground inspected, and there was therefore a probability that the actual numbers would prove considerably in excess of the estimate." I discuss this particular bed of oysters further on (see below, p. xi.).

The following statement of the numbers* estimated at the November and February inspections, and the actual numbers fished from the beds, may be worth recording:—

* The numbers recorded by Mr. Lewis and by Mr. Hornell respectively in their reports differ somewhat in detail on account of the methods adopted in assigning the oysters to their banks.

Paar.	November.	February.	Fished.
South Cheval	40,220,000	47,500,000	29,383,444
Adjacent part of South-east	—		1,503,590
Mid-east and South-central Cheval . .	13,750,000	9,000,000	2,975,849
North Modragam	4,700,000	10,000,000	7,280,817
South Modragam	21,000,000	19,700,000	Say, 10,000,000
Kutiramalai	Not estimated.	Not estimated.	„ 30,732,820
			81,876,520

Mr. Hornell estimates that about forty-one and a half millions of adult oysters are left on the banks. It is to be feared that a considerable number of these will die off during the year, but a solid bed of 10,000,000 remains on the South-east Cheval, and will probably be available for fishing next spring. There may be other patches on other parts of the Cheval still remaining in sufficient numbers to be worth fishing, and there ought to be a good many left on the South Modragam and the Kutiramalai paars, but these are said to be largely overgrown with a younger generation, and it is quite doubtful whether a sufficient number of the old will survive to yield a fishery in 1906 on these banks.

I now come to a question connected with the large number of oysters recorded in Mr. Lewis's report as fished from the South Modragam Paar, upon which I wish to make some observations. I shall quote first a couple of passages I find in Mr. Hornell's report (p. 38) in regard to the finding and fishing of these oysters :—

"34. On 22nd February a considerable number of boats fished on the ground to the south of that portion of the South Modragam inspected earlier in the month. The whole of this area is composed of purely sandy bottom, whereon lay oysters free from commingling with any of a younger generation ; all were a little over three years old. In some places they lay in loose bunches ranging from five to twelve individuals in each ; elsewhere the oysters clung to the projecting edges of large wedge-shaped shells of *Pinna bicolor*, rooted upright in the sand by the narrow end. The former condition delighted the hearts of the divers ; the latter gave those unprovided with protecting finger-stalls considerable trouble, the sharp edges of the Pinna shells inflicting frequent cuts and scratches on the hands tearing them from their sandy foothold. In both cases the divers filled their bags with remarkable celerity, 40 seconds in many cases sufficing to fill the diver's bag with 60, 70, or even 100 oysters. As a result, the day's catch, aggregating the enormous total of 4,574,460 oysters, broke every known record."

* * * * * *

"35. Work, on this sandy area, continued with feverish activity for the remainder of the week. The daily catches never fell below 4,000,000 per day, while on 24th February high-water mark was reached with the enormous take of 5,005,685 oysters.

Such a large total for one day's fishing establishes a record that is likely to remain unsurpassed for many years to come."

It is exceedingly interesting to find thus, from the official reports, that a considerable number of the oysters (from twenty-seven to thirty millions) credited (in the report of the Superintendent, p. 2) to the South Modragam Paar were really fished from an area extending to the south-east far beyond the usual limit of that paar. We must either conclude that the oysters have extended over the sandy ground lying between the South Modragam Paar and Kutiramalai point or that a new bed of oysters in this position has been fished. The difference may be considered to be unimportant, as being little more than a point in nomenclature. I notice that Mr. LEWIS in his report prefers to regard the whole of the large irregular-shaped area as being the South Modragam Paar; while Mr. HORNELL gives to this new southern part a new and quite appropriate name, "Kutiramalai Paar," on the analogy of Aripu Paar, Vankali Paar, Karativo Paar, Chilaw Paar, and others—all named after the land off which they lie. I think the latter course is the better simply because it does less violence to our existing ideas, charts and definitions. I reproduce here (fig. 2) a tracing from Captain DONNAN's chart with which I worked when on the pearl banks in 1902. It shows the North and South Modragams as two little areas of approximately equal size, and the South is certainly nothing like, either in shape or position, the area from which, judging from Mr. HORNELL's sketch-plan given as "Annexure I" on p. 49 of his report (Colombo, 1905), the oysters in question were obtained. In the definitions of these paars which I gave in the first volume of this Report I find that the North Modragam is described (Part I., 1903, p. 105) as lying "south-east of the central part of the Cheval Paar, at from $\frac{1}{2}$ mile to 1 mile distant, and is nearly 1 mile in diameter. It is about $8\frac{1}{2}$ miles west of Kallar tower. The depth is from $5\frac{3}{4}$ to $6\frac{3}{4}$ fathoms," &c. The description of the South Modragam runs (*loc. cit.*, p. 106): "This lies 1 mile south-south-east of the North Modragam, and is about $\frac{1}{2}$ to $\frac{3}{4}$ mile in diameter. It is about 7 miles north-north-west of Kodramallai Point, and has a depth of $5\frac{1}{2}$ to 6 fathoms. The bottom is rocky," &c. All this agrees with Captain DONNAN's chart and, I think, with previous records of these paars, but not with the area from which the thirty million oysters were fished this year, as shown in Mr. HORNELL's sketch-plan which I here reproduce (fig. 3) for comparison with fig. 2. Consequently I would favour the application of the new name "Kutiramalai Paar" to this very considerable southerly extension of the area hitherto known as the South Modragam Paar. It has this year proved itself to be of very much greater importance than many paars which have for long enjoyed distinctive names.

Now to turn to a more interesting point than mere nomenclature. Have these oysters on the Kutiramalai Paar, which had apparently not been inspected and estimated last year, but which have been fished this year along with those of the South Modragam, ever been seen before? *I believe they have*, and that I found them myself in March, 1902, when dredging along with Sir WILLIAM TWYNAM, Captain Donnan, and Mr. Hornell, in the "Lady Havelock." When I read of these oysters in the Reports of Mr. Lewis and Mr. Hornell, I at once recollected

Fig. 2. Captain Donnan's outlines and positions of the Modragams (N.M. and S.M.) and Cheval Paar (Ch.) in relation to Kutiramalai Point (K.P.), the Shoal Buoy (S.B.). The positions of the dredgings made from the "Lady Havelock" on March 17th, 1902, are shown by the four crosses lying to the south-east of the South Modragam. Scale one-fourth of an inch to the nautical mile.

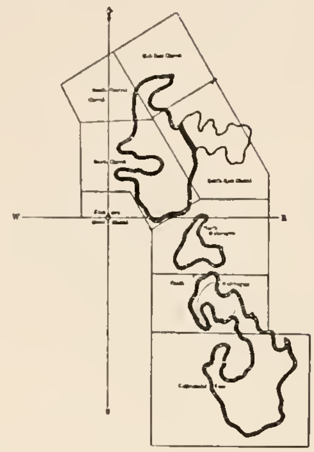

Fig. 3. Mr. Hornell's sketch-plan of the fishing ground of 1905, reduced to the same scale as fig. 2, one-fourth of an inch to the nautical mile. The thick lines show the areas fished, the thin line in the South-east Cheval the area with oysters over three years old left unfished, and the dotted line in the South Modragam the ground occupied by oysters six months old. Below that is the large area which Mr. Hornell has called the "Kutiramalai Paar."

the occasion, and on turning to my notes I find (see this Report, Part I., 'Narrative,' p. 84, published in 1903) :—

"After rejoining Captain Donnan and the inspection boats in the South Cheval district, we took four hauls of the dredge between the South Modragam Paar and Kodramallai Point. These may be united as Station LXIV. From between South Modragam and Jaggerboom Paars, along a line south-east towards Kodramallai Point; depth $4\frac{1}{2}$ to $5\frac{1}{2}$ fathoms; bottom coarse sand, with much fine green weed and small pearl oysters."

* * * * * *

"The fine green weed from the bottom had very young spat of pearl oysters on it. The small oysters dredged were 8 or 9 months old, and were in quantity at about $3\frac{1}{2}$ miles off Kodramallai Point." I had brought Sir W. Twynam from Jaffna that same morning (March 17th, 1902) and wished to show him how the dredge could bring up oysters or whatever else lay on the bottom, and I believe that these first dredged young oysters that we showed him "between South Modragam Paar and Kodramallai Point" were a sample of the oysters which have been fished this year from the "Kutiramalai Paar," and have contributed much to the success of the present fishery. The age of the oysters agrees, and the position on the chart is about right. The four little crosses on fig. 2 show the four dredgings united in the 'Narrative' as Station LXIV.

Finally, I would make a general remark upon paar-ground in the Gulf of Manaar. It is, that we need never be surprised to find that boundaries of banks alter, and that oysters appear on occasions in new spots. I have already pointed out in a previous part of this Report that the whole of the shallow shelf within, say, the 12-fathom line is potential paar-ground. The bottoms shift to some extent and may change their character, sand may be washed over a paar, or again may be swept away, leaving a hard bottom. One of my first observations when dredging on the "Lady Havelock" was that we found oysters in the Cheval district where they had no right to be, according to Captain DONNAN's outline of the paar. This statement may seem to cut at the root of my own charts and definitions; but it is not really so. The outlines of the paars are justifiable and, in fact, necessary as representing the normal, departures from which may be expected, but are exceptional.

It is evident that there is some difference of opinion amongst the authorities in Ceylon as to whether or not "dredging is economically a more sound method of fishing than is diving." I am inclined to think that the operation has not yet had a fair trial; but even though it may not, under the conditions in vogue in the East, be able to compete economically with native diving, I must emphasise what I have said elsewhere in this report, that the utility of dredging is by no means confined to obtaining a supply of adult oysters for the market, but is really fourfold, consisting as it does :—

(*a*) In fishing oysters;
(*b*) In cleaning the ground and removing enemies;
(*c*) In thinning out overcrowded beds; and
(*d*) In spat transplantation.

Its value is not properly assessed if account be taken of the first of these alone, or even of the first and the last. Finally, it must be remembered that several of these important operations can usually be carried on in the same series of dredgings.

Mr. HORNELL is acting in accordance with these views, and at the recent fishery it is evident that a good deal of transplanting, cleaning, and thinning out went on simultaneously with the fishing for oysters. I shall quote a few sentences in regard to this work in Mr. HORNELL's own words :—

"90. On 15th March enough of mature oysters had been removed by the divers from the central portion of the South Cheval to permit of the commencement of operations for the establishment there by transplantation of a bed of young ones. Accordingly, I instructed Captain Jelstrup to dredge for young oysters aged about six to seven months, which I knew to be in profusion in the South Modragam Paar, to convey them to the South Cheval and there to throw them overboard within the limits which I defined by a series of mark buoys.

"91. The method adopted was to bag all the young oysters taken, to keep them in a cool place covered with wet sacks, and to steam twice a day, noon and evening, to the South Cheval, throwing them out as the vessel manœuvred between the flags. The young oysters stood the treatment well; there was practically no mortality, as I ascertained by sending divers down from time to time to ascertain the condition of these young, and to bring me samples.

"92. The total quantity transplanted was upward of ten millions. I propose to concentrate attention upon this bed during the next season, in order to give the experiment fair treatment. I hope to transplant thereto in November next an additional 10 to 15 millions; after that we may hope that enough work shall have been accomplished to ensure a small fishery two years later—a result that would be due entirely to cultural methods, and not to the fortuitous interaction of currents and other natural influences.

"93. During the course of the dredging, a great amount of good was done by the capture and destruction of large numbers of starfishes and carnivorous gastropod molluscs, noted enemies of the pearl oyster. Frequently between 200 and 300 starfishes were taken and destroyed in one day. By my instructions these were retained on board for twenty-four hours in order to insure that life should of a certainty be extinct, when they were returned to the sea."

In regard to the bed of young transplanted oysters, Mr. Hornell adds:—

"109. Prior to leaving the banks, I directed the Government divers to examine the area in question. They reported young oysters apparently numerous, the individuals they brought up were in good health, exhibiting no ill-effects consequent on the transplanting operation. Some had attached to fragments of cultch rubble laid out during the course of the fishery.

"110. (*b*) *Thinning out.*—This operation went on concurrently with transplantation, the abundance of young oysters on the South Modragam being so inordinate as to constitute, through overcrowding, a grave danger to their own continued prosperity. Transplantation, by entailing a reduction in the numbers upon the South Modragam, should re-act favourably, and if the density of population be found still too great when next the bed is inspected, further transplantation should be resorted to. So great is the present profusion, that the numbers taken in the dredges upon the last day appeared as great as on the day transplantation was begun, and indicated no appreciable diminution in the fertility of the bed.

"111. (*c*) *Cultching.*—During the fishery a quantity of rubble obtained from the indurated limestone strata of Kayts, near Jaffna, was laid down, principally upon the sandy portion of the South-central Cheval, a region which has never yet yielded a pearl fishery. The quantity contracted for was 180 cubes; unfortunately the contractor experienced such difficulties in obtaining vessels to convey the stone to its destination that he was able to deliver less than half the specified quantity, although I helped him materially by extending the time limit by a week.

"112. The stone, on the whole, was satisfactory in quality, and likely to prove a durable cultch material. In size the blocks approximated $3\frac{1}{2}$ in. by $3\frac{1}{2}$ in. by $2\frac{1}{2}$ in., but several consignments contained a proportion of blocks of excessive dimensions, and these I rejected.

"113. The total amount laid down was just under 300 tons. Some 40 tons of the friable semi-calcareous sandstone of Kalpitiya was also used. The greater part was deposited on the South-central Cheval, some 20 tons on a sandy patch near the centre of the South Cheval, and about the same quantity on the north-east quarter of the South Modragam Paar, a locality where there is no outcropping rock on the bottom. Several times towards the end of the fishery I received fragments of this cultch from the divers with young oysters attached to the surface."

This fishery was phenomenal not only in the number of oysters obtained, but also in the prices that they fetched. While the valuation of the samples taken at the November and February inspections showed a range of from 8 to 24·65 rupees per 1000, the oysters at the fishery sold at very much higher prices—the lowest being 24 and the highest 124 rupees per 1000. The average price over the whole fishery was 48·89 rupees. Of these oysters sold by the Government, Mr. Lewis states that "India took a hundred times the quantity taken by Ceylon." It is to be hoped that India will not be sorry that it took them. Judging from the probable pearl-yield of these oysters, it is difficult to see how the business can be made to pay at such inflated prices. However, the Bombay pearl merchants, Kilakarai Moormen and Paumben Chetties probably know best what they are about, and the mysteries of the Indian pearl market may justify even more remarkable proceedings than the paying of 124 rupees for oysters valued by the experts at 12·70, 27·41, and 31·10 rupees per 1000.

REPORT

ON THE

ISOPODA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

THE REV. THOMAS R. R. STEBBING, M.A., F.R.S., SEC. L.S., F.Z.S.,
FELLOW OF KING'S COLLEGE, LONDON.

[WITH TWELVE PLATES.]

THE interest of the present collection is not to be measured by the number of species or the number of specimens, still less by the size of the animals. The species are not numerous, the examples in many cases are few, and of some the dimensions have proved to be afflictingly small. On the other hand, there is no want of variety, since the thirty-four species more or less definitely discriminated are spread over five very distinct tribes and divided among sixteen families. There is no want of novelty, since two of the families, three of the genera, and fourteen of the species are now added to science on what appear to be satisfactory grounds. Certainly the family AMESOPODIDÆ, founded on some small creatures allied to *Idotea*, must be thought well worthy of notice.

The only family illustrated by a rather large supply of specimens is that of the Sphæromidæ. But the supply has not thrown much convincing illumination on the difficulties of this group, which have of late years arrested the attention of several writers. Any person of impatient temper who has ever attempted, when pressed for time, to disentangle with unskilful fingers a knotted skein of string, may understand the plight of a busy naturalist who has Sphæromidæ to classify. There is always the chance in regard to this family that, after struggling with the complexities of the situation, one may have done more harm than good, by adding to the confusion instead of lessening it. It is, indeed, a general disadvantage attending the description of a local fauna, or of a special collection, that it may involve the fragmentary treatment of problems which can only properly be solved by a monographic survey.

The tribal division of the Isopoda is here accepted from the invaluable 'Crustacea of Norway,' by Professor G. O. SARS.

DESCRIPTION OF THE SPECIES.

ISOPODA ANOMALA.

Tribe: CHELIFERA.

Family: TANAIDÆ.

Tanais, Audouin and Milne-Edwards.

1828, **Tanais**, Audouin and Milne-Edwards, 'Résumé d'Entomologie,' p. 182, pl. 29, fig. 1, and 'Précis d'Entomologie,' vol. 1, p. 46, pl. 29, fig. 1.

The genus was named *Anisocheirus* by Westwood in 1832 ('Ann. Sci. Nat.,' vol. 27), *Zeuxo* by Templeton in 1836 ('Trans. Entom. Soc.;' vol. 2, p. 201), and *Crossurus* by Rathke in 1843 ('Fauna Norwegens,' p. 35). Sars, when defining it in 1896 ('Crustacea of Norway,' vol. 2, part i., p. 11), remarked that it was well distinguished from all the other genera of the family, especially by the circumstance that the pleon was composed of only five segments and carried only three pairs of pleopods. He assigned to it only four species: *T. tomentosus*, Kröyer; *T. cavolinii*, Milne-Edwards; *T. dulongii* (Audouin); and *T. novæ-zealandiæ*, Thomson. According to Dollfus ('Bull. Soc. Zool. France,' vol. 21, p. 207, 1897) the first of them is a synonym of the second. But several other species are on record, *T. macrocheles*, Nicolet, 1849; *T. brasiliensis*, Dana, 1849; *T. loricatus*, Bate, 1864; *T. gracilis*, Heller, 1866; *T. willemoesii*, Studer, 1884; *T. hirsutus*, Beddard, 1886; and since Sars wrote, several additions have been made to the list, namely, *T. robustus*, Moore, 1894; *T. grimaldii*, Dollfus, 1897; *T. chevreuxi*, Dollfus, 1897; *T. testudinicola*, Dollfus, 1897; *T. alascensis*, H. Richardson, 1899; *T. stamfordi*, H. Richardson, 1901; *T. philetærus*, Stebbing, 1904; *T. normani*, H. Richardson, 1905. In this group it must be noticed that *brasiliensis*, *gracilis*, *willemoesii*, *hirsutus*, *robustus*, *testudinicola*, *normani*, are all excluded from the genus, not as defined by Dana, but as restricted by Sars, since they all have six segments in the pleon instead of five. It is not improbable that other more or less correlated differences will be found to exist, but the material here at disposal would not justify interference in the matter. It may, however, be observed that *T. testudinicola*, Dollfus, is evidently the same species as *T. robustus*, Moore. *T. loricatus*, Bate, described from an imperfect specimen, still awaits fuller description. *T. novæ-zealandiæ*, G. M. Thomson ('Trans. N. Zealand Institute,' vol. 13, p. 207, plate 7, fig. 3), according to the figure, has the pleon distinctly six-jointed, but no notice of this is taken in the text, which includes in the generic definition the character "pleon five-jointed."

Tanais gracilis, Heller—Plate I. (D).

1866, **Tanais gracilis**, Heller, 'Novara Exp., Zool.,' vol. 2, pt. 3 (Crustacea), p. 133, pl. 12, fig. 3.

Heller's description is as follows:—"The head very short, the roundish black eyes placed forward on the somewhat projecting lateral angles, the front bluntly triangular. The lower antennæ five-jointed, thinner than, but almost as long as, the upper, which are three-jointed. The first [coalesced] peræon segment is the largest of all, narrowed forward, the second [first free] segment the shortest, the fifth, sixth and seventh sub-equal one to the other. The pleon narrows gradually backwards. The first three pleon segments shorter than those of the peræon, but longer than the fourth and fifth pleon segment, the last (sixth) again larger and apically rounded. The uropods (Schwanzanhänge) five-jointed, their basal joint thick, triangular, the first joint of the appendage (des Anhanges) tolerably long, towards the end somewhat thickened, the four following somewhat shorter than the first, among themselves subequal, cylindrical, the last blunt-ended, all the joints beset with long setæ. The first chelipeds large and strong. The legs little setose. The colour of the body on the surface yellowish or brownish, with dark points and markings. Locality:—St. Paul." Length, 3 millims.

In Heller's account there are one or two ambiguities, for, while he speaks of and figures six segments in the pleon, he uses the expression "fourth and fifth pleon segment" as if intending to mention a composite segment, and, while he distinctly says that the uropods are five-jointed, he appears to distinguish a peduncular joint from a five-jointed ramus. His figure shows only five joints in all, as in our specimen, which was not otherwise separable from Heller's. The mouth organs agree with those in the genus *Tanais*. The upper antennæ have a fourth joint in the shape of a tubercle, representing the flagellum. The finger in the hinder group of peræopods is strongly uncinate. The pleopods are delicate in structure. Whether there were more than three pairs I did not succeed in ascertaining.

Length of specimen, 2 millims.

Locality:—Gulf of Manaar.

In *T. brasiliensis* and *T. normani* the uropods are six-jointed, in *T. willemoesii* nine-jointed, in *T. hirsutus* about twelve-jointed, in *T. robustus* four-jointed.

Heterotanais, G. O. Sars.

1880, **Heterotanais**, Sars, 'Arch. Naturv. Kristian.,' vol. 7 (1881), separat., p. 28.

1886, **Heterotanais**, Sars, 'Arch. Naturv. Kristian.,' vol. 11, p. 333.

1886, **Heterotanais**, Norman and Stebbing, 'Trans. Zool. Soc. London,' vol. 12, pt. 4, p. 108.

1896, **Heterotanais**, Sars, 'Crustacea of Norway,' vol. 2, pt. 1, p. 13.

1897, **Heterotanais**, Dollfus, 'Mém. Soc. Zool. France,' vol. 11, p. 38.

1901, **Heterotanais**, H. Richardson, 'Proc. U.S. Mus.,' vol. 23, p. 501.

The leading feature in this genus is the sexual difference in the first gnathopods, which are small and normally chelate in the female, but large and complexly subchelate or not normally chelate in the male. It is, however, probable that up to a certain stage the males may not exhibit this distinction. The species referred to the genus by SARS are *H. örstedi* (KRÖYER), *H. limicola* (HARGER), *H. tenuis* (G. M. THOMSON), *H. anomalus*, SARS. To these DOLLFUS, in 1897, adds *H. algiricus* and *H. provincialis*, but, upon a comparison of the descriptions and figures of *H. algiricus* and *H. anomalus*, there is no character given by which they can be distinguished. H. V. HODGSON ('Nat. Hist. of the "Southern Cross,"' p. 240, 1902) remarks that but for the structure of the uropods he would have placed his own *Paratanais antarctica* and BEDDARD'S *P. dimorphus* in SARS' genus *Heterotanais*.

The species now offered as an additional member of the genus labours under the considerable disadvantage of not being represented by any adult male specimen, apart from which it is not easy to say whether junior or female specimens should be allotted to *Heterotanais* or *Leptochelia*. As will be seen by the description, if the minute character of the maxillary palp can be trusted, the species belongs to *Heterotanais*. As the first gnathopods are remarkably stout, one may be glad to rescue it from a genus like *Leptochelia* that derives its name from the slenderness of those appendages.

Heterotanais crassicornis, n. sp.—Plate I. (A).

In the cephalothorax the line of junction between the head and the first peræon segment is slightly indicated. The antepenultimate and penultimate segments of the peræon are the longest. The first five segments of the pleon are subequal, the telsonic segment not elongate.

The eyes are socketed, at apex in dorsal view apparently, but not really, acute, lenses about 12 in number.

First antennæ: first joint unusually stout, not twice as long as broad, more than twice as long as the second; third not longer than the second, very narrow, tapering, with three setæ, one of which is, perhaps, attached to a scarcely perceptible flagellar joint.

Second antennæ shorter and much narrower than the first, second joint the widest, fourth the longest, but not very long; a minute flagellar joint is tipped with a very long seta.

Mandibles nearly as figured by SARS (' Crustacea of Norway,' pl. 6) for *H. örstedi*, but on the left mandible the cutting edge and accessory plate are far less distinctly denticulate, and on the right the cutting edge shows a little tooth, the serration of the upper border being barely perceptible. There is no accessory plate on the right, and on both mandibles the molar is very prominent, as in the species described by SARS.

The first maxilla has the palp terminated by one seta, in accordance with the generic character given by SARS, whereas in the female of *Leptochelia* this organ is tipped with two setæ.

The first gnathopods are remarkably stout, the fifth joint being a little longer than broad, but almost quadrate, the sixth subequal to it in length but less broad, with the trunk a little longer than its rather broad thumb. The thumb has a slightly serrate inner margin, ends in a small tooth, and is furnished with a row of three setæ on the surface and one seta on the outer margin. The finger is more slender, with undulating inner margin.

The second gnathopods are very slender, with second joint scarcely longer than the fifth or sixth, which are subequal; the fourth joint is much shorter than these, but a little longer than the third; the slender curved finger is about as long as the sixth joint.

The peræopods are small, with the second joint decidedly longer and, especially in the last three pairs, broader than any of the other joints; the fourth and fifth joints differ little in length, each being shorter than the sixth, which is also considerably longer than the finger.

The pleopods resemble those of *Leptochelia*, having the inner margin of each oval ramus fringed with setæ, and the outer margin of the outer ramus carrying one seta placed high up.

The uropods have a six-jointed inner ramus, of which the first joint is the stoutest and the last the longest, carrying at its apex one seta as long as the ramus and one or two shorter setæ. The outer ramus, which is also tipped with a long and a short seta, is composed of two joints, the first very short, the second more than twice as long, the two together rather longer than the first joint of the inner ramus.

Length :—Of four specimens the largest measured a little over 2 millims., and the smallest a little over 1 millim. in length.

Locality :—Gulf of Manaar.

The specific name refers to the remarkable stoutness of the first antennæ, which appears to distinguish the species from any hitherto described in this genus or *Leptochelia*.

Leptochelia, Dana.

1849, **Leptochelia**, Dana, 'Amer. J. Sci.,' ser. 2, vol. 8, p. 425.
1900, **Leptochelia**, Stebbing, in Willey's 'Zoological Results,' pt. 5, p. 614.
1900, **Leptochelia**, Borradaile, 'Proc. Zool. Soc.,' London, p. 797.
1902, **Leptochelia**, H. F. Moore, 'Bull. U.S. Fish Comm.,' vol. 20 (for 1900), p. 165.
1902, **Leptochelia**, H. Richardson, 'Trans. Connecticut Ac. Sci.,' vol. 11, p. 279.

For a fuller synonymy of this genus down to 1900, Willey's 'Zoological Results' may be consulted. Mr. H. F. Moore's recently established Porto Rican species, *L. incerta*, is hesitatingly referred by Miss H. Richardson to *L. dubia* (Kröyer). The undesigned coincidence of dubiety and uncertainty in the specific names with the note of interrogation in the reference very appropriately marks the position of the systematist in dealing with this genus. When the generic name is justified by the presence of the extraordinarily elongated first gnathopods of the mature male, the standing ground is tolerably firm. This applies to four species, but in those leaves the determination of female and immature specimens in obscurity. In regard to the uropods the outer branch seems to vary not only in different species but even in the same species, being sometimes two-jointed and sometimes one-jointed. The inner branch has always more than three joints.

Leptochelia mirabilis, n. sp.—Plate I. (B).

While in many of its features resembling *L. minuta*, Dana, and *L. forresti* (Stebbing), the present species is easily distinguishable from them both and from *L. rapax*, Harger, by characters of the first and second antennæ, of the first gnathopods and the uropods, as well as by its much greater size.

The cephalothorax has the front rather broadly angled, not reaching beyond the eyes, the sides at first slightly concave, then considerably bulging. In the dorsal line the free segments of the peræon are successively longer to the antepenultimate, with a slight successive decrease in the remaining two. The first five segments of the pleon are subequally short, the telsonic segment equal to two of them combined, apically angular. The pleon at the centre is slightly wider than the peræon.

The eyes are movably socketed, dark, composed of a few large lenses.

The first antennæ are once and two-thirds as long as the body, the first joint a little swollen and bent at the base, about nine times as long as the third joint, the more slender second being about eight times the third; the flagellum of thirteen joints, carrying sensory filaments, is between two and three times as long as the third joint.

The second antennæ are about one-fourth as long as the first, the fourth joint of the peduncle longer than the three preceding joints combined and more than twice as long as the fifth joint, which is a little shorter than the two-jointed needle-like flagellum, not including its two or three long apical setæ attached to the minute second joint.

The first gnathopods are of very surprising length, being much more than twice as long as the whole body of the animal, and while, considered in themselves, they are very slender, on the other hand, when compared with the frame that carries them, their stoutness becomes a matter for wonder. The basal joints are short, but the three terminal joints are of enormous length. The pair are not symmetrical and both members are damaged, so that exact measurements cannot be given. In the larger one the slender, apically curved, movable finger is equal in length to the first joint of the first antennæ; it is shorter than the trunk of the hand, which widens to the hinge of the finger, and is produced to a long slender thumb or immovable finger, the apex of which is broken. The existing portion of the antepenultimate joint is longer than the trunk of the hand, and is narrower near the base than in the greater part of its length. In the shorter member the hand widens more abruptly and shows a little gap at the base of the fingers, the movable finger being sinuous, and having three little tubercles on the inner margin near the base.

Second gnathopods of quite insignificant size, agreeing in character with the first and second peræopods, but rather longer, all the joints slender, the third very short, the sixth shorter than the second, but longer than the fourth or fifth, these being subequal, each a little longer than the very slender slightly curved finger.

The third, fourth, and fifth peræopods are shorter and stouter than the preceding pairs, with curved spines round the apex of the fifth, and small setæ round that of the sixth joint; the finger tolerably stout.

The pleopods, as in the other species and in *Heterotanais*, have the two narrowly oval subequal rami fringed on the inner margin with long plumose setæ, the outer ramus having high up on its outer margin a single adpressed seta.

The uropods have the inner ramus seven-jointed, the joints carrying numerous setæ (the apex of the seventh broken); the outer ramus has two joints, longer than the first two of the inner ramus.

Length, 6 millims. to 7 millims. For *L. minuta* and *L. forresti* the recorded length does not exceed 2·5 millims.

Locality:—Gulf of Manaar.

Leptochelia lifuensis, Stebbing—Plate I. (C).

1900, **Leptochelia lifuensis**, Stebbing, in Willey's 'Zool. Results,' pt. 5, p. 616, pl. 64c, d, pl. 65b.

1900, **Leptochelia**, sp., Borradaile, 'Proc. Zool. Soc. London,' p. 797, pl. 51, figs. 2–2c.

This species has recently been described and figured, and the illustrations here given will, I think, show that the Ceylon specimens are in substantial agreement with those from Lifu. They also show the considerable contrast between the antennæ and gnathopods of the male in this species and those in *L. mirabilis*. The question, however, remains open as to a possible dimorphism in the males, which would diminish or destroy the contrast.

Specimens in the collection from eight stations are referred to this species.

Locality, &c.:—On baskets of oysters hung to buoy at Galle: Two specimens, female; one 3·35 millims. long with seven large eggs. From pearl oysters, East Cheval Paar, Gulf of Manaar: A male, 2 millims. long; the two teeth on the thumb of the cheliped rather close together, and on one of the chelipeds not fully formed; outer ramus of uropod one-jointed, inner five-jointed. Female from same station, 2·5 millims. long and agreeing with description in Willey's 'Zoological Results.' From pearl oysters, Gulf of Manaar: Male, 2·5 millims. long; two teeth on thumb of cheliped close together; outer ramus of uropod one-jointed, very short; inner ramus imperfect. Female, 3 millims. long. Off Mutwal Island, March 19, 1902: A female, 4 millims. long; outer ramus of uropod two-jointed, inner six-jointed. Cheval Paar, Gulf of Manaar: A female, 3 millims. long; outer ramus of uropod one-jointed, inner five-jointed, the last two joints rather long; the one-jointed ramus very short. Also a female, 1·75 millims. long; outer ramus one-jointed, inner four-jointed. At each of two other points in the Gulf of Manaar a female specimen was taken. By "female" should be understood specimens without any distinctively male characters.

ISOPODA GENUINA.

Tribe : FLABELLIFERA.

Family : ANTHURIDÆ.

Calathura, Norman and Stebbing.

1886, **Calathura,** Norman and Stebbing, 'Trans. Zool. Soc.,' London, vol. 12, pt. 4, p. 122.
1897, **Calathura,** Sars, 'Crustacea of Norway,' vol. 2, p. 44.
1901, **Calathura,** Whitelegge, 'Mem. Australian Mus.,' vol. 4, pt. 2, p. 225.
1901, **Calathura,** H. Richardson, 'Proc. U.S. Mus.,' vol. 23, p. 509.

To the species *Calathura brachiata* (Stimpson) Sars has added his *C. norvegica*, Whitelegge his *C. gigas*, and Miss Richardson her *C. crenulata*. Bonnier's *C. affinis* (1896) seems rather to belong to *Paranthura*.

Calathura, sp.

Two specimens occur in the collection, one from weed-bearing oysters off south-east of Modragam Paar, the other from north end of Chilaw Paar, February 2, 1902, 9 to 11 fathoms. Both have dark eyes. The former is about 14 millims. in length, the latter about 9 millims. They may be the species which Haswell has described in 'Proc. Linn. Soc. N. S. Wales,' vol. 5, p. 478, plate 10, fig. 5, 1881, as *Paranthura* (?) *crassicornis*, sp. nov. The Australian Anthuridæ will no doubt before long be more fully described, and I have therefore left over these specimens till a more favourable opportunity offers for their specific identification.

Family : GNATHIIDÆ.

Gnathia, Leach.

1814, **Gnathia,** Leach, 'Edinb. Encycl.,' vol. 7, p. 402.
1835, **Gnathia,** Westwood, Loudon's 'Mag. Nat. Hist.,' vol. 8, p. 273.
1885, **Anceus,** Haswell, 'Proc. Linn. Soc. N. S. Wales,' vol. 9, pt. 4, p. 1005.
1887, **Anceus,** H. J. Hansen, 'Dijmphna-Togtets Krebsdyr,' p. 205.
1896, **Gnathia,** Bonnier, 'Ann. Univ. Lyon,' vol. 26, p. 571.
1900, **Gnathia,** Stebbing, in Willey's 'Zoological Results,' pt. 5, p. 625.
1901, **Gnathia,** Ohlin, 'Bihang K. Svenska Vet.-Akad. Handlingar,' vol. 26, No. 12, p. 20.
1902, **Gnathia,** Hodgson, 'Nat. Hist. of the "Southern Cross,"' p. 241.

The references here given are supplementary to the much longer list supplied in Willey's 'Zoological Results.' As the material in the present collection is limited to a single small specimen, it would not be a suitable opportunity for an extended review of the genus. Especial attention, however, should be directed to *Gnathia ferox* (Haswell), since it is evidently a near ally of the species about to be described. The details of the mandibles are similar in the two, but by the relative size and position of these features the appendages in question are strongly distinguished. The maxillipeds and first gnathopods of *G. ferox* are as yet undescribed. It is not improbable that a separate genus will be thought desirable for these species, when they are more fully known.

Gnathia insolita, n. sp.—Plate XII. (B).

The head is very broad, markedly emarginate between the mandibles, the minute rostral point in the emargination only becoming visible after mounting, which involved some flattening of the frontal border. The telson is acutely triangular. Eyes small, dark, oval, slightly oblique in position, facets numerous.

Upper antennæ: Second joint shorter than first, first shorter than third, flagellum with very short first joint, long second, which is subequal to remaining three joints combined.

Lower antennæ: These are longer than the upper, with second joint of the four-jointed peduncle much the shortest; of the six-jointed flagellum the first joint is the longest.

The mandibles implanted wide apart are of uncommon pattern. There is no tooth on the outer margin; about midway on the inner is a quadrate process that might represent the molar; the apical part presents two strongly divergent teeth, with a small convex lamina at the bottom of the cavity between them.

The maxillipeds are of very delicate structure, except for the strong muscles in the second joint. This joint is broader than long, not showing any distinct apical lobe. In the four-jointed palp each joint is successively narrower than its predecessor. They have the outer margin fringed with setæ, 3 on the first, 5 on the second, 8 or 9 on the third, and 7 on the rounded incurved fourth joint.

The first gnathopods are very distinctive of the species, not having the ordinary tapering character, but the principal joint being as broad as it is long. Within are seen the chitinized areas, probably indicative of original joints now in coalescence. The middle area is the most extensive, the lowest has a feebly indicated companion. The upper half of the rounded margin is furnished with 21 graduated setæ. This margin is the upper and inner when these valve-like limbs are closed together, but it is not to be inferred that that is the proper description according to homology. There is a very small apical joint, with no trace of a division into two joints.

The second gnathopods are rather longer than the four pairs of peræopods, of which the second pair are slightly the shortest. In general character all five pairs of trunk-limbs agree.

The first pleopods have the rami rather longer than those of the other four pairs. All five agree with the uropods in carrying rather long setæ, which is contrary to custom in the adult male of this genus.

Length barely 2 millims., breadth a little less than half the length.

Locality:—Gulf of Manaar, off Karativo, from a sponge.

The specific name refers to the unusual characters of the mandibles and first gnathopods.

Family: EURYDICIDÆ.

(Cirolanidæ of Harger, Hansen, Bonnier, Stebbing, Norman, and others.)

Among the genera that have been assigned to this family, *Eurydice*, Leach, 1815, is beyond dispute the earliest, so that the name Cirolanidæ, notwithstanding the distinction conferred upon it as the title of Hansen's notable work in 1890, is bound to give way to Eurydicidæ. Another generic name has "page precedence" over *Cirolana*, since in 1818 Leach established *Nelocira* as his tenth genus of Cymothoadæ, and *Cirolana* as the eleventh, assigning a single species to each respectively, *Nelocira swainsoni* and *Cirolana cranchii*. These are now considered to be one and the same species. The only distinction between them which Leach supplied was that the pleon of *Nelocira* had five segments and that of *Cirolana* six. As, therefore, the generic character of *Nelocira* is erroneous, it is just that the preference should be given to the correctly described *Cirolana*, and this has been done by general consent. It is, moreover, convenient, because *Nelocira* is apt to be confused with the very similarly named but quite distinct genus which Leach at the same date called *Nerocila*.

The family at present includes seven closely connected genera, distinguished in the following synoptic table :—

1	Pleon forming only two distinct segments.	1. *Colopisthus*, H. Richardson, 1902.
	Pleon forming more than two distinct segments—2.	
2	Eyes absent; peduncle of uropods with inner apex not produced.	2. *Cirolanides*, Benedict, 1896.
	Eyes present; peduncle of uropods with inner apex produced—3.	
3	Peduncle of second antennæ four-jointed; maxillipeds without hooks on second joint.	3. *Eurydice*, Leach, 1815.
	Peduncle of second antennæ five-jointed;* maxillipeds with hooks on second joint—4.	
4	First pleopods with inner branch broad.	4. *Cirolana*, Leach, 1818.
	First pleopods with inner branch narrow—5.	
5	Head and trunk broad.	5. *Hansenolana*, Stebbing, 1900.
	Head and trunk narrow—6.	

* With regard to a sixth joint in this peduncle in *Cirolana*, *Conilera* and *Bathynomus*, see Hansen, 'Journ. Linn. Soc.,' vol. 29, p. 339.

6. First pleopods indurated; second with male appendix attached at base of inner ramus. — 6. *Conilera*, LEACH, 1818.
First pleopods not indurated; second with male appendix attached far from base of inner ramus. — 7. *Conilorpheus*, n. gen., 1905.

In addition to these some authors include in this family the huge-eyed *Bathynomus*, A. MILNE-EDWARDS, 1879, which has the two abnormal characters of an accessory branch on the first antennæ and supplementary branchiæ on the pleopods, the blind *Anuropus*, BEDDARD, 1886, in which the uropods resemble the pleopods in character, and the maxillipeds have a one-jointed palp, and *Branchuropus*, H. F. MOORE, 1902, which agrees with *Anuropus* in the characters just mentioned, but differs from it by possessing eyes and in the general habit of body. I am disposed to allot *Bathynomus* to a separate family Bathynomidæ, and the other two genera to a family Anuropidæ, as already suggested for the former of them in 1893.

A. DOLLFUS ('Ann. Sci. Nat.,' Zool., Ser. 8, vol. 20, p. 271) now transfers his genus *Sphæromides*, 1898, to the family Cirolanidæ, and institutes in that family a new genus *Faucheria* for *Cæcosphæroma faucheri*, DOLLFUS and VIRÉ, 1900, to which he believes that *Spelæosphæroma julium*, FERUGLIO, 1904, is nearly allied.

Cirolana, LEACH.

1818, **Cirolana**, LEACH, 'Dict. Sci. Nat.,' vol. 12, p. 347.
1881, **Cirolana**, MIERS, 'Ann. Nat. Hist.,' ser. 5, vol. 8, p. 369.
1896, **Cirolana**, BONNIER, "Edriophthalmes du 'Caudan,'" 'Ann. Univ. Lyon,' vol. 26, p. 574.
1900, **Cirolana**, STEBBING, in WILLEY'S 'Zoological Results,' part 5, p. 629.
1902, **Cirolana**, F. MOORE, 'Bull. U.S. Fish Commission,' vol. 20 (for 1900), pt. 2, p. 166.
1902, **Cirolana**, STEBBING, 'South African Crustacea,' part 2, p. 49.
1903, **Cirolana**, DOLLFUS, 'Bull. Soc. Zool. France,' vol. 28, p. 5.
1904, **Cirolana**, STEBBING, in WILLEY'S 'Spolia Zeylanica,' vol. 2, pt. 5, p. 11.
1904, **Cirolana**, STEBBING, in GARDINER'S 'Fauna, Maldive and Laccadive Archip.,' vol. 2, pt. 3, p. 701.
1904, **Cirolana**, H. RICHARDSON, 'Proc. U.S. Mus.,' vol. 27, p. 35.
1904, **Cirolana**, NORMAN, 'Ann. Nat. Hist.,' ser. 7, vol. 14, p. 437.
1905, **Cirolana**, HANSEN, 'Journ. Linn. Soc. London,' Zool., vol. 29, p. 339.

The species assigned to this genus are now very numerous, and it must be considered a fortunate circumstance that there is no necessity for transferring them to *Nelocira*, which lapses as practically a nomen nudum. The references above given will enable the student to trace a far longer list. The blind *C. cubensis*, W. P. HAY, 1903, needs to be compared with *C. cæca*, DOLLFUS, 1903.

Cirolana sulcaticauda, STEBBING.

1900, **Cirolana sulcaticauda**, STEBBING, in GARDINER'S 'Fauna, Maldive and Laccadive Archip.,' vol. 2, pt. 3, p. 701, pl. 49B.

Of this species a specimen measuring about 6 millims. in length was taken at

Cheval Paar, and five specimens occurred in a tow-net gathering off Marichchukaddi. With the five there were four young specimens, two of which did not certainly belong to the same species. In this latter gathering there were also two specimens of a young *Idotea*.

Cirolana parva, H. J. Hansen.

1890, **Cirolana parva**, Hansen, 'Vid. Selsk. Skr.,' ser. 6, vol. 3, pp. 321, 340, pl. 2, fig. 6–6*b*; pl. 3, fig. 1–1*d*.

1901, **Cirolana parva**, H. Richardson, 'Proc. U.S. Mus.,' vol. 23, p. 514 (Localities).

1902, **Cirolana parva**, H. F. Moore, 'Bull. U.S. Fish. Com.,' vol. 20 (for 1900), pt. 2, pp. 166, 167, pl. 8, figs. 6–8.

This species is known from both the East and West Indies, and is probably to some extent variable, since Hansen and Moore agree in saying that the broad, sub-triangular telsonic segment has the rounded apical margin furnished with about eight spines, while in our specimens the number appears to be uniformly six.

Moore describes the uropods as "short, reaching hardly to end of telson: rami subequal, narrow at ends, bifid, their margins furnished with spines and a few short setæ." But our specimens agree with Hansen's account, according to which the inner ramus reaches beyond the outer and is broader, and with his figure which shows it to be very much broader, so as to make the term subequal quite inapplicable.

The first antennæ have the third joint of the peduncle about as long as the composite first and second joint, the flagellum little shorter than the peduncle, nine-jointed in both adult male and female. Hansen gives it as eleven-jointed, much shorter than the peduncle, Moore as eleven- to twelve-jointed. The second antennæ have the first three joints of the peduncle very short, fourth a little shorter than the fifth, flagellum in male twenty-six-jointed, in female twenty- to twenty-two-jointed. A specimen not fully adult, having the fifth peræopods unarmed and much shorter than the fourth, had the flagellum of the first antennæ seven-jointed, that of the second fifteen-jointed.

In the maxillipeds the antepenultimate joint is furnished with only four or five setæ on the outer margin.

The first gnathopods have five blunt spines on the hind margin, the bluntness probably due to wear. At the apex of the inner margin the sixth joint in all the limbs has a rather strong spine.

The male appendix of the second pleopods is slender, the acute apex slightly incurved, reaching beyond the rami.

Length, male about 6·5 millims., breadth 2 millims.; female about the same size; specimen not adult, 3 millims. long, 1·25 millims. broad.

Localities:—Male, Chilaw Paar, Station LXIX., 8 to 11 fathoms; female with young, Muttuvaratu Paar, 10 fathoms. Specimen not adult, Talaivillu Paar.

Cirolana, sp.

The telsonic segment is smooth, triangular, with the apex almost acute, but not quite, since a high magnification shows it narrowly truncate, carrying two spines. Each side also carries two spines just above the apex.

The eyes are rather small, lateral. The first antennæ have the third joint about as long as the composite first and second, and the flagellum of seven joints, most of which carry sensory filaments. In the second antennæ the ultimate joint of the peduncle is slightly longer than the penultimate; the flagellum is rather long, fifteen-jointed. The mouth organs are of the pattern characteristic of *Cirolana*. The limbs are rather slender, not very strongly setose or spinose, the first gnathopods being, as usual, discriminated from the succeeding legs by the position of the fifth joint. The uropods, like the telson, have a fringing of fine spines and feathered setæ; the inner apex of the peduncle is rather sharply produced about to the middle of the broad inner ramus, which narrows apically and extends beyond the telsonic segment and the narrower inner ramus. The integument is covered with scale-like markings.

The length is 5 millims., with a breadth of about 2 millims. The specimen carried several young ones, still enclosed in membranous capsules, but with the eyes already visible. I hesitate about applying a specific name, whether new or old, to this small ovigerous specimen.

Locality:—Deep water, south of Galle, depth up to 100 fathoms.

Conilorpheus, n. gen.

Only the male known. Both first and second antennæ short. First maxillæ carrying four strong plumose setæ on the inner plate. The maxillipeds having the plate of the second joint furnished with hooked spines. The male appendix of the second pleopods is attached far down on the inner ramus. The uropods have the process of the peduncle very elongate and the outer ramus much smaller than the inner.

The body is almost cylindrical, with the basal segment of the short pleon covered by the laciniated seventh segment of the peræon. In the first pleopods the peduncle is not longer than broad, and neither ramus is hard.

The generic name refers to the combination of characters, here presented, partly pointing to the genus *Conilera* and partly to the genus *Eurydice*, which takes its name from the wife of Orpheus. The first maxillæ, like those of *Bathynomus*, show an unusual feature in carrying four setæ instead of three on the inner plate, and the laciniate border of the last peræon segment is also uncommon in this family.

Conilorpheus herdmani, n. sp.—Plate II. (A).

The head is produced into a narrow distally widened process between the first antennæ; its breadth is not much greater than its length. The second and third segments of the parallel-sided peræon are the shortest; the first segment even at the forward produced sides is not longer than the seventh, of which the postero-dorsal margin is cut into four acute lappets; between these the pleon segments, second to fifth, are partially seen. The telsonic segment narrows near the base, forming a broad oval, of which the serrate apical margin is beset with setæ and small spines.

The eyes are not large, wide apart, round.

The short stout first antennæ have the second joint of the peduncle as it were embedded in the broader first joint; the tapering flagellum is composed of seven short joints, most of them carrying sensory filaments. The second antennæ are about twice the length of the first. The third joint of the peduncle is the longest, and not much longer than broad, the fourth joint is of equal length and breadth, shorter but much broader than the fifth joint and on its obliquely truncate distal margin carrying some elongate setæ; one such seta is similarly situate on the fifth joint. The flagellum is shorter than the peduncle, nine-jointed.

The mouth-parts are as in *Cirolana*, except that the first maxillæ have four stout plumose setæ on the inner plate. The spines on the outer plate are slender. The maxillipeds are well furnished with setæ and spines, and the antepenultimate joint is large.

The first gnathopods have the second joint distally widened and the third still more so, the latter having the front apex and hind margin fringed with setæ. The fourth joint has four blunt spines on the hind margin and a long spine on the front apex; it entirely overlaps the small fifth joint which carries two blunt spines, one of them minute. The sixth joint has a stout spine between two thin ones, and some long setæ. The finger is slightly curved, nearly as long as the sixth joint, and, like the other limbs, has on the inner margin a small tooth or spine at the base of the short curved nail.

The fourth and fifth peræopods are nearly alike and about equal in length, but the second and fourth joints are longer and the fifth and sixth joints are shorter in the fifth pair than in the fourth. The side-plates are distally subquadrate in the sixth peræon segment, but are more produced and distally triangular in the seventh.

The first pleopods have the peduncle of equal length and breadth, with four delicate coupling spines. The inner ramus is rather shorter than the outer and less than half as broad. Both have the rounded distal margin fringed with plumose setæ. In the second pair the peduncle is broader than long; the inner ramus is almost as long as the outer and much more than half as broad. The male appendix is slender, apically acute, attached just above the middle of the inner margin of the inner ramus and extending considerably beyond both rami, which are armed as in the preceding pair. In all five pairs the outer ramus is broad, more or less vaulted and distally fringed with setæ. The inner ramus has some distal setæ in all but the last pair.

The uropods have the short base of the peduncle produced on the inner side into a very long process. The inner ramus is large, oval, reaching nearly to the end of the telsonic segment, and having all its free margin similarly serrate and armed with short spines and long plumose setæ. It has two or three dark markings. The outer ramus is only half as broad and half as long as the inner, with similar armature on the distal half.

Length 6 millims., breadth 1·5 millims.

Locality:—Station V., north end of Chilaw Paar, February 2, 1902, 9 to 11 fathoms.

The specific name is chosen out of respect to the president of the Linnean Society, to whose ever watchful activity in the interests of science the collection of species here described is due.

Hansenolana, STEBBING.

1900, **Hansenolana**, STEBBING, in WILLEY'S 'Zoological Results,' pt. 5, p. 634.

The species *H. anisopous*, for which this genus was originally established, shows, as I observed at the time, various points of resemblance to *Cirolana sphæromiformis*, HANSEN. While retaining the latter in the genus *Cirolana*, HANSEN himself forcibly calls attention to the singularity of its appearance. He had at command only one specimen, a female, not ovigerous, 4·25 millims. long, from St. Thomas, in the West Indies. The examination of a male specimen in Professor HERDMAN'S collection induces me now to transfer the species to *Hansenolana*, the definition of which will in consequence require to be modified as follows:—

Head transverse, produced into a process between the two pairs of antennæ; first five segments of pleon very short. Eyes small and wide apart. Mouth organs nearly as in *Cirolana*, but on the inner plate of the first maxillæ the three setæ are spine-like and not coarsely plumose. In the second maxillæ the outer pair of plates carry very few spines. First gnathopods with the sixth joint broad. First pleopods with narrow rami. Male appendix of the second pleopods attached at some distance from the base of the ramus.

The two species which at present fall under this definition are easily distinguished:—

Apex of telsonic segment broad. 1. *H. anisopous*, STEBBING.
Apex of telsonic segment narrow. 2. *H. sphæromiformis* (HANSEN).

Between these two may, perhaps, be placed *Cirolana hanseni*, BONNIER ('Ann. Univ. Lyon,' vol. 26, p. 574, 1896), originally described from an obviously juvenile specimen, and now (1905) re-described by HANSEN from specimens probably still immature. In this species the telsonic segment has an apex much less broad than that of *H. anisopous*, but considerably broader than that of *H. sphæromiformis*.

Hansenolana sphæromiformis (HANSEN)—Plate II. (B).

1890, **Cirolana sphæromiformis**, H. J. HANSEN, 'Vid. Selsk. Skr.,' ser. 6, vol. 5, pp. 319, 351, pl. 4, fig. 3–3*g*.
1900, **Cirolana sphæromiformis**, STEBBING, in WILLEY'S 'Zoological Results,' pt. 5, p. 634.
1901, **Cirolana sphæromiformis**, H. RICHARDSON, 'Proc. U.S. Mus.,' vol. 23, p. 512.

HANSEN'S full description, together with his figures of the female, and those here given of the male, leaves only a few points needing to be submitted or explained. The flagellum of the second antennæ has in our specimen ten joints instead of twelve. The epistome and upper lip I did not clearly make out. HANSEN does not call attention to the almost complete smoothness of the three setæ on the inner plate of the first maxillæ. The second maxillæ have three spines on the outermost plate and four on its companion. In the second pleopods the inner ramus is narrow and has the male appendix attached about one-third of its length from the base, reaching beyond both rami, and having apparently a bifid apex. The first four pairs of pleopods have setæ on both rami; the fifth pair escaped observation. In the telsonic segment, which is covered with squamose markings rather more conspicuously than the rest of the body, the three dorsal carinæ are clearly developed. But here the lateral pair appear to run without divergence and none of the three quite reach the margin of the segment, in these respects differing from the female represented by HANSEN. According to HANSEN the apex is not spinose, and he says the same of the uropods. In our specimen both the segment and its appendages carry several minute spines, which are only visible under high magnification. This is also the case in a specimen sent me from Antigua by W. R. FORREST, Esq.

In the first gnathopods the spines on the inner margin of the broad hand show a variety of minute denticulations. In this and the other limbs the point of junction between nail and finger is marked on the convex margin by a group of microscopic setules. The first gnathopods cannot claim to be subchelate, though otherwise by breadth and compactness they make some approach to the corresponding limbs in *H. anisopous*. But, whereas in that species the two following pairs are very differently and more slenderly constructed, here they show a very near agreement, in all three pairs the fifth joint underriding the sixth.

Length scarcely 3 millims., breadth 1·5 millims., the proportion being 27 : 14. HANSEN's specimen was 4·25 millims. long.

Locality :—Among compound Ascidians and with other Isopods at Reef, Galle.

The small size and deceptive appearance of this species, rather than any actual rarity or any marvel of distribution, may account for the fact that the East Indies have now revealed a solitary specimen of the male fourteen years after the West Indies had disclosed a solitary specimen of the female.

FAMILY: ARGATHONIDÆ, nov.

Mandibles, with cutting edge bidentate or simple; molar represented by a feeble blade, not serrate. First maxillæ with inner plate broadly truncate, outer strongly produced, ending in an unguis with a small curved spine at its base. Second maxillæ very short, ending in a broadly rounded single lobe. Maxillipeds six-jointed, second joint not elongate, fourth and fifth joints fused together, seventh well-developed, blunt. Male appendix of second pleopods affixed at the base of the ramus.

By the character of the mandibles this family offers a connecting link between the

Eurydicidæ and other neighbouring families, such as the Corallanidæ, but in every one of the mouth parts it presents some distinctive feature. It is at present represented only by a single specimen of a single species, so that it is not possible to say what amount of sexual dimorphism may occur.

Argathona, n. gen.

The characters of the family will at present suffice for those of the single genus. *Argathona* is a nymph or half-goddess, so recently sprung from the brain of Mr. Justin Huntly McCarthy, that her name is not likely to have been hitherto borrowed for scientific purposes.

Argathona normani, n. sp.—Plate III. (A).

The first peræon segment is rather the longest, and the last rather the shortest. The side-plates are diagonally furrowed, those of the second and third segments less deep than the rest, and not produced beyond their segments; the last four pairs are rhomboidal. The fourth pleon segment overlaps the fifth at the sides. The telsonic segment, with sinuous sides, becomes rather narrowly triangular as it approaches the rounded apex. The dorsal surface of the animal from one end to the other is beset with spines large or small, the only segment free from them being the first of the pleon, but also a basal area is left free where one segment slides under another, and a sinuous free area marks what is probably the boundary between the sixth pleon segment and the true telson. The sixth and seventh segments of the peræon have each six pale tubercles among the fringing spines of the hind margin; the fourth pleon segment has the same number, but less regularly spaced; the fifth has two that are submedian and much larger than those already mentioned, and the sixth segment has a pair which are quite near to the sides. The telson carries numerous spines in the serrate border besides those that belong to the dorsal cover, and is likewise fringed with long plumose setæ.

The eyes are dark, rather large, set wide apart.

The short first antennæ have the first and second joints apparently fused into one thick joint, not much longer than the following more slender joint; the flagellum, rather longer than the peduncle, is twelve-jointed.

The second antennæ have the fourth joint rather longer than the three preceding joints combined, and the fifth rather longer than the fourth; the twenty-nine-jointed flagellum is once and two-thirds the length of the peduncle.

The frontal lamina is pentagonal, not very large. The epistome forms two arms widely divergent, reaching beyond the membranaceous upper lip, in which a transverse area is perceptible of normal form, probably more highly chitinized than the remainder of the appendage.

The lower lip is longer than broad, the lobes elongate piriform, flattened on the confronting margins, the rounded apices not as usual fringed with setules, but carrying a short tooth or spine at the inner angle, and a longer one inserted a little behind and outside the other.

The mandibles are elongate, that on the left bidentate, that on the right with the cutting edge undivided; each has a narrow, transparent, apparently very feeble blade representing the molar, but devoid of the saw-teeth which are conspicuous in *Eurydice* and *Cirolana*. The palp is implanted near the base of the trunk, its second joint much longer either than the first or falciform third.

The maxillipeds are narrow, the three terminal joints setose, none very widely expanded.

The first gnathopods are moderately robust, with four short stout spines conspicuous on the stout fourth joint; the fifth joint short, not produced along the inner side of the sixth joint, which is very slightly armed; the finger curved, simple. The second gnathopods and first peræopods agree with the preceding limb. The four following pairs have a different character, with less tendency to geniculation, except between the second and third joints. There is little difference in length between the joints from the second to the sixth, the first three of these having the expanded distal margin beset with spines of varying length, and some of the spines, especially on the hinder apex of the fifth joint, are serrate. The finger shows a little projection at the base of the nail.

The pleopods have large rami. In the second pair the male appendix, affixed close to the base of the ramus, reaches a little beyond it, and is abruptly narrowed to a short linear apex; near the base its margin is fringed with minute setules.

The uropods have the peduncle considerably produced, spinose on its outer part, but dorsally almost clear, the long process having lateral and apical armature. The rami are strongly fringed like the telson, and the broad inner ramus, which reaches a little beyond the telson, is dorsally sprinkled with short spines, but the much narrower outer ramus has much of its dorsal surface smooth, evidently to suit its habit of folding underneath its companion.

The smooth ventral surface is orange-coloured, the spiny coating of the back dark brown, the limbs quite pale.

Length of the specimen in slightly bent position, 10 millims., which is about two and a-third times the breadth. A second specimen measured 12 millims. in length by 6 millims. in breadth.

Locality:—The smaller specimen was from coral reefs, Gulf of Manaar, the larger from Station XXXIX., south of Galle, up to 30 fathoms.

The clothing of this species gives it, when under the microscope, a very striking appearance; especially its caudal fan, by the grouping and variety of the spines and the addition of the long feathered setæ in more or less symmetrical arrangement, produces a particularly agreeable effect on the eye. I have named it in honour of my friend the Rev. A. M. Norman, D.C.L., F.R.S., whose services to the zoology of invertebrates are justly celebrated.

FAMILY: CORALLANIDÆ.

It is only necessary here to recall that the family embraces the genera *Corallana*, DANA, *Tachæa*, SCHIÖDTE and MEINERT, *Alcirona*, HANSEN, and *Lanocira*, HANSEN, with HANSEN'S definition of the family Alcironidæ transferred to the modified family Corallanidæ.

Lanocira, HANSEN.

1890, **Lanocira**, HANSEN, 'Vid. Selsk. Skr.,' ser. 6, vol. 5, pt. 3, pp. 287, 313, 391, 395.
1904, **Lanocira**, STEBBING, in GARDINER'S 'Fauna, Maldive and Laccadive Archip.,' vol. 2, pt. 3, p. 706.

The species may be distinguished as follows :—

1	The hinder part of the body not setigerous.	1. *L. kröyeri*, HANSEN.
	The hinder part of the body setigerous—2.	
2	Head (of male) with frontal horn.	2. *L. gardineri*, STEBBING.
	Head without frontal horn—3.	
3	Telsonic segment with broadly rounded apex.	3. *L. rotundicauda*, STEBBING.
	Telsonic segment with narrowly rounded apex.	4. *L. zeylanica*, n. sp.

Lanocira gardineri, STEBBING.

1904, **Lanocira gardineri**, STEBBING, in GARDINER'S 'Fauna, Maldive and Laccadive Archip.,' vol. 2, pt. 3, p. 706, pl. 51 A.

For the features which may apparently be relied on for distinguishing this species from *L. zeylanica*, see the next following account of the latter form.

Locality :—One specimen of *L. gardineri* was taken at the Galle reef, with compound Ascidians and some other Isopods. A second was taken along with some small sphæromids at Cheval Paar, and a third was labelled "Gulf of Manaar."

Lanocira zeylanica, n. sp.—Plate V. (B).

The general resemblance of this species to *L. gardineri*, which I have recently described from the Maldive-Laccadive Archipelagoes, is extremely close. The distinguishing features are that the present form has the body from the fifth peræon segment to the extremity of the pleon far more strongly setigerous ; that it has the front of the head with a well-marked margin and a faintly indicated longitudinal depression behind it, but no upturned frontal horn and no pair of dorsal tubercles between the eyes ; that the first maxillæ are stronger ; and that the fifth peræopods are armed on the third and fourth joints with far longer spines. As in the other species the second maxillæ are tipped with two setæ, but the difference in length between the two is greater here. The apical spine of the fourth joint in the first gnathopods is here stronger.

The eyes are dark. The first antennæ have a flagellum of five joints carrying sensory filaments. The mandibles with broad base and slender trunk exhibit an apical tooth, and alongside of the plate which carries this a thin membrane, which appears to be prolonged backward into a slightly curved lingual representative of the molar, the whole apparatus being somewhat obscured by entanglement with the lower lip. The upper lip is slightly emarginate.

The curved finger of the first gnathopod shows two minute prominences on the inner margin, and one such prominence is visible on the other limbs, faintly marking the base of the nail, but the feature is not peculiar to this species. The telsonic segment has six spines at the apex.

Length 6 millims., breadth 2·75 millims.

Locality:—The dissected specimen was a male from Jokkenpiddi Paar. Two other specimens, apparently of the same species, were obtained at the south end of Cheval Paar.

Family: ÆGIDÆ.

The accepted genera may be distinguished as follows:—

1	Pleon abruptly narrower than peræon.	1. *Syscenus*, Harger, 1880.
	Pleon not abruptly narrower than peræon—2.	
2	First antennæ with flagellum of not more than six joints; maxillipeds of not more than four joints.	2. *Rocinela*, Leach, 1818.
	First antennæ with flagellum of more than six joints; maxillipeds of not less than six joints.	3. *Æga*, Leach, 1815.

Syscenus agrees with *Rocinela* in respect to the maxillipeds. It is now recognised that the *Rocinela lilljeborgii* described by Bovallius in 1885 is identical with *Syscenus infelix*, Harger, 1880, but it seems to have been overlooked that Bovallius himself was the first to acknowledge the generic identity, and to point out the probability that *Harponyx pranizoides*, Sars, would prove to be a young *Syscenus* ('Bihang till k. Svenska Vet. Akad. Handl.,' vol. 11, No. 17, p. 17, 1887). *Ægiochus*, Bovallius, is not accepted as distinct from *Æga*. *Acherusia*, Lucas, 1849, and *Alitropus*, Milne-Edwards, 1840, are regarded as synonyms of *Rocinela*; *Pterelas*, Guérin, 1836, and *Ægacylla*, Dana, 1856, as synonyms of *Æga*.

Æga, Leach.

1815, **Æga**, Leach, 'Trans. Linn. Soc. London,' vol. 11, p. 369.
1879, **Æga**, Schiödte and Meinert, 'Naturhist. Tidsskr.,' ser. 3, vol. 12, p. 334.
1882, **Æga**, Haswell, 'Proc. Linn. Soc. N.S. Wales,' vol. 6, p. 11.
1890, **Æga**, H. J. Hansen, 'Vid.-Selsk. Skr.,' ser. 6, vol. 5, p. 316.
1897, **Æga**, Sars, 'Crustacea of Norway,' vol. 2, p. 58.

In recent years species have been added to this genus by Hansen, Whitelegge, H. Richardson and Norman. Many other references to it may be traced under those given above and in company with those given below for the genus *Rocinela*.

In defining the genus Leach laid stress on the ample development of the first two joints of the peduncle of the first antennæ. The dilatation of these joints is used as a character also by Schiödte and Meinert. Sars, however, employs the qualified statement, "the first two peduncular joints more or less expanded," and, in fact, describes the antennæ as very slender both in *Æga arctica*, Lütken, and *Æga ventrosa*, M. Sars. The absence of any expansion from the two peduncular joints in question is conspicuous in the figures given by Schiödte and Meinert of their species *Æga nodosa*. They further speak of the frontal lamina, that is, the plate above the upper lip between the bases of the second antennæ, as large or very large in *Æga*, but minute or evanescent in *Rocinela*. But, taking all the species of the two genera together, this distinction does not seem to be stable.

In the species about to be described the peduncular joints of the first antennæ are not specially dilated and the frontal lamina is not very large. But while in these respects it makes an approach to *Rocinela*, it is clearly separated from that genus by the flagellum of the first antennæ and by the maxillipeds. Its peculiarities tempted me to make it the type of a new genus, but I am content to leave it for the present as a very distinct unit among the many species of the genus *Æga*.

Æga ommatophylax, n. sp.—Plates IV., V. (A).

The very marked and at present seemingly unique feature of this species pertains to the first peræon segment of the male. The anterior border of this segment projects a sub-median pair of cylindrical processes over the large contiguous eyes. The specific name has been chosen to suggest that their function is protective to the organs of vision. In *Rocinela cornuta*, Richardson, the antero-lateral angles of the first peræon segment are extended straight forwards, probably with the same object. The defence obtained is presumably worth the interference with sight that must result from it.

Male. The head projects a distally widened round-ended frontal process slightly upturned, with the exception of this process having its dorsal surface almost completely and its ventral surface partially covered by the dark eyes. The first peræon segment, without including its slightly convergent antero-dorsal processes, is longer than any of the other segments, these varying little among themselves in length or breadth. The first five segments of the pleon are but little narrower than the peræon and are subequal one to the other, somewhat wider than the telsonic segment, which is broader than long, with its broadly rounded apical margin serrate, carrying spines and setæ and having the central point a little produced.

The eyes meet in the middle line of the head, leaving a little triangular interval above, but occupying all the hind margin.

The frontal lamina is not large. The bases of the first antennæ are concealed from above by the front of the head, and have a slender peduncle with flagellum thirteen- to fourteen-jointed. In the second pair the joints of the slender peduncle increase in length from the second to the fifth, and the flagellum is thirty-two-jointed.

The upper lip appears to be rounded, membranaceous. The mandibles have the palp planted near the base of the trunk, with the first joint nearly as long as the second, the third not very short. The first maxillæ are long and slender, the small apex carrying three hooked spines and four spinules. The second maxillæ are much broader than the first, having the inner margin of the apex armed with three little hooks, in addition to which a small, narrowly oval, movable inner plate is tipped with two hooks. The maxillipeds have an irregularly rounded epipod, as wide as the second joint, which is itself wide, elongate, and produced into a narrowly tapering process tipped with two setules. The third joint is short, distinct, the fourth and fifth have distinct outlines, but are, perhaps, only apically separate, the fifth carrying outward curved spines at its apex, its outer margin forming a continuous curve with the faintly separable sixth and seventh joints, which together have a free inner margin tipped with two outward curving spines. As will be seen from the figures, this account of the mouth organs in the male has been a little supplemented from the mouth organs of another specimen possibly of a different sex.

The first gnathopods have a few short finely plumose setæ along the front margin of the rather narrow second joint, and the same garniture seems to occur on the corresponding margin in the other limbs. The third joint is rather longer than the fourth and carries a single spine at its front apex. The fourth joint has two stout spines on the hind margin, the fifth is small, underriding the sixth, but not overlapped in front by the fourth; its spines like those of the hand are slight. The finger is nearly as long as the hand, with setules marking the base of the nail.

The second gnathopods are very similar to the first, but stronger and more spinose. The third joint has a stout spine on the hind margin, and the fourth has four or five such spines; the fifth joint does not underride the sixth. The first peræopod is of nearly the same appearance. On the left side of the specimen each of these limbs has, on the inner apex of the short fifth joint, an articulated obtuse process about twice as long as it is broad, giving the limb a subchelate character. On the right side of the specimen these processes are not present. Whether they are abnormal growths on the left side or are accidentally missing from the right I cannot determine.* The side-plates of the second gnathopods are round-ended. In the following limbs they tend to become less and less obtuse and those of the fifth peræopods are subacute, produced over the first segment of the pleon, of which, however, the angles are free.

In the last four pairs of peræopods the third joint attains a considerable length, this and the three following joints being armed with numerous well developed spines, of which a group on the hind apex of the fifth joint, though not very long, are

* It is worth noting for comparison that SARS ('Crustacea of Norway,' vol. 2, p. 61) describes the three anterior pairs of legs in *Æga crenulata*, LÜTKEN, as "distinguished by a very conspicuous cultriform spine, issuing from the end of the propodos, inside the base of the dactylus," and WHITELEGGE ('Mem. Australian Museum,' iv., pt. 2, p. 233) describes a similar process on first peræopods of his *Æga angustata*.

distinguished by their pectinate character. The genital papillæ on the ventral side of the last peræon segment are short and broad.

In the first pleopods the sinuous inner margin of the peduncle carries seven coupling spines and as many plumose setæ. The outer branch, as in the following pairs, is fringed round most of its margin with plumose setæ. The inner branch in this and the next pair has a fringe of setæ on the lower half of the inner margin and on the apical border. The second pair are distinguished by the extraordinary length of the slender male appendix, which is twice as long as the trunk of the supporting branch.

The uropods have the inner apex of the peduncle greatly produced into an acute process, of which the inner margin is setose. The broad inner ramus is mostly fringed with plumose setæ and carries eleven spines in the serrate part of its margin. The shorter and much narrower outer ramus is fringed also with plumose setæ and carries nine spines.

Length 14 millims., breadth about 6 millims.

Locality :—The single specimen, a male, was taken in "deep water off Galle."

A specimen which I deem to be the female or a younger form of the foregoing was "dredged off Mutwal Island," and measured 12 millims. in length, with a width of about 4·5 millims. It is devoid of the frontal process of the head, and the first peræon segment is without the two submedian dorsal processes. The last three segments of the peræon more decidedly surpass in length the preceding three segments than in the form already described; the first antennæ have twelve and the second antennæ have twenty-six joints to the flagellum. The peculiar process of the wrist in the second gnathopod and first peræopod is wanting. No male appendix could be discerned in the (undissected) pleon. Otherwise the agreement of the two specimens is extremely close. The remarkable eyes are alike in both, and though they agree with those of *Rocinela vigilans*, Haswell, that much larger species, if the figure of the maxillipeds can be trusted, must be generically distinct. The tenacity with which some of the mouth parts in this and kindred species cling together makes satisfactory dissection difficult. But there is little reason to doubt that the frontal lamina, epistome, and rounded membranaceous upper lip figured from the second specimen would equally well represent those parts in the first, had they there been in a condition for figuring. *Æga cyclops*, Haswell, is described as having the eyes confluent, the telsonic segment sub-triangular.

In 1898 Miss Harriet Richardson reckoned the then known species of this genus at nineteen, of which she provided a useful analytic key. Bonnier's blind species, *R. typhlops*, 1896, had probably at that time not come under her notice, as it is not included in the list. On the other hand, one of the accepted nineteen is the Tasmanian species which G. M. Thomson named *R. spongicola* in 1892 (1893). Since this has about fourteen joints to the flagellum of the first antennæ and a distinct third joint to the maxillipeds, it should be transferred to the genus *Æga*. In 1899 Miss Richardson made *R. alaskensis* (Lockington) a synonym of *R. belliceps*, which Stimpson had assigned to the genus *Æga*. In 1903 she described *R. hawaiiensis* as a new species, near to *R. orientalis*, and in 1904 established a new species, *R. affinis*, near to Harger's *R. oculata*, and gave the name *R. angustata* to a form which she had previously supposed identical with Hansen's *R. laticauda*. In 1902 Lanchester instituted *R. mundana* ('Proc. Zool. Soc. London,' p. 378, pl. 35, figs. 9–9*a*).

Rocinela orientalis, Schiödte and Meinert.—Plate VI. (C).

1879, **Rocinela orientalis**, Schiödte and Meinert, 'Naturhist. Tidsskr.,' ser. 3, vol. 12, pp. 383, 395, pl. 13, figs. 1, 2.

1898, **Rocinela orientalis**, H. Richardson, 'Proc. Amer. Philos. Soc.,' vol. 37, No. 157, pp. 9, 11.

This species belongs to a group distinguished by the Danish authors as having the eyes clearly separated, the flagellum of the second antennæ composed of fourteen to sixteen joints, and the sixth joint in the first three pairs of trunk-limbs armed with three or four spines. To distinguish it from its neighbours in this group, Miss Richardson notes that the frontal margin is not produced as it is in *R. dumerilii* (Lucas), and that, whereas Schiödte and Meinert's *R. maculata* and *R. americana* have the telsonic segment "linguate," and both branches of the uropods crenulate on their exterior margins, in the present species the telsonic segment is subtriangular and the branches of the uropods are not crenulate on their exterior margins. The Danish authors mention the crenulation in the two former species, but neither deny nor affirm it in regard to *R. orientalis*, the telsonic segment of which they describe as subtriangular, with rounded sides, a phraseology quite as applicable to their figures of that segment in *R. americana* and *R. maculata*. A more tangible distinction appears to lie in the proportions of the uropods, which in both the species last mentioned are said to have the inner branch a little longer and broader than the outer, while in the present species it is described as much longer and a little broader. Probably it was not the absolute length of each branch that was taken into comparison, but the inner branch was reckoned the longer by all that part of it which extended beyond the outer branch. It will be seen by the figures here given, that, if the specific determination is correct, the telsonic segment is subject to some variation, the apical margin passing from the subtriangular to a rather broadly rounded contour. In either case the margin is minutely serrate and fringed with minute spines and short plumose setæ. The uropods have the margins a little more strongly serrate and the armature rather stronger. Their peduncle is greatly produced at the inner apex, and the long process is rather strongly fringed with setæ.

In the first antennæ the flagellum is six-jointed, but in the smaller and perhaps not fully adult specimen five-jointed. The second antennæ have a long spine on the apex of the fourth joint of the peduncle, the flagellum in the male specimen with fourteen joints on one antenna and fifteen on the other, many of the joints fringed with setules. In the smaller specimen the flagella were twelve- and thirteen-jointed.

In the mandibles the first joint of the palp is the longest. The terminal joint of the maxillipeds has two outward curving apical spines, and a similar spine below the apex (this, however, not being clearly discerned in the male specimen).

The fingers of the prehensile legs are strongly hooked. The ambulatory legs have the third joint very elongate, especially in the last pair.

The first pleopods have both branches narrow, fringed with setæ, except on much of the outer border of the inner branch. The second pleopods have the outer branch longer and much broader than the inner. In both the margin is somewhat irregular and much of it fringed. The male appendix does not reach the end of the inner branch.

Length of largest specimen, male, 13 millims., with a breadth of 7 millims. The smaller specimen figured was 11·3 millims. long by 5 millims. broad. A specimen laden with eggs was 12 millims. long, 5·75 millims. broad.

Localities:—Station I., off Negombo, 20 fathoms; Station II., off Uluwitti, 8 fathoms; Station V., Chilaw Paar, 10 fathoms; on weed bearing oyster spat, S.E. of Modragam Paar.

Family: CYMOTHOIDÆ.

Anilocra, Leach.

1818, **Anilocra**, Leach, 'Dict. Sci. Nat.,' vol. 12, pp. 348, 350.

1900, **Anilocra**, Stebbing, in Willey's 'Zoological Results,' pt. 5, p. 639.

1901, **Anilocra**, H. Richardson, 'Proc. U.S. Mus.,' vol. 23, p. 528.

1902, **Anilocra**, H. F. Moore, 'Bull. U.S. Fish Comm.,' vol. 20 (for 1900), pt. 2, p. 172.

Anilocra dimidiata, Bleeker.

1857, **Anilocra dimidiata**, Bleeker, 'Acta Soc. Sci. Indo-Neerl.,' vol. 2, art. 5, pp. 30, 31.

1881, **Anilocra dimidiata**, Schiödte and Meinert, 'Nat. Tidsskr.,' ser. 3, vol. 13, p. 103, 111, pl. 8 (15), figs. 5, 6.

1900, **Anilocra dimidiata**, Stebbing, in Willey's 'Zoological Results,' pt. 5, p. 639.

The two specimens obtained agree closely with the description given by Schiödte and Meinert, having, in accordance with their conspectus of the species in this genus, the first antennæ geniculate, the coxæ not carinate but simple, and the fingers in the first four pairs of trunk-legs inflated in the middle, the inflation here forming a single nodule, not two or three nodules as in *A. leptosoma*, Bleeker. The colouring also agrees, not merely in being yellow, bespattered with minute dark specks, which is common to so many preserved species, but in the much more peculiar character of being very much darker on the right side of the animal than on the other, in accordance with Bleeker's description. Schiödte and Meinert write as though either side might be the darker.

The Danish authors speak of their specimens being more or less twisted to the right, whereas ours are quite straight as in Bleeker's figure. They attribute only nine joints to the second antennæ, while ours have these appendages ten-jointed. Both first and second antennæ, and the latter especially, are much compressed. In one specimen both members of the second pair, and in the other one member, have the antepenultimate joint shorter than either of its neighbours.

The fifth pleon segment has the postero-lateral angle produced a little over the telsonic segment, which is broader than represented by Schiödte and Meinert, but is, as they describe, obscurely carinate, with raised lateral margins. The peduncle of the uropods is only shortly produced on the inner apex; the long narrow rami are perfectly smooth, approximately equal in length, the outer a little the narrower.

One specimen, carrying elongate eggs, measured 24 millims. in length, the other being 22 millims. long. In each case the greatest breadth was 8 millims.

Locality :—Palk Bay, 6 fathoms.

Rhiothra, Schiödte and Meinert.

1884, **Rhiothra**, Schiödte and Meinert, 'Nat. Tidsskr.,' ser. 3, vol. 14, p. 223, 318.

This genus is placed by the Danish authors in the Cymothoinæ, the second tribe of their family Cymothoidæ. In the somewhat conjectural reference to it of a single specimen, a male not fully grown, it would be out of place to indulge in any long discussion of the characters, for which the original work should be consulted. It may be remarked that the generic definition refers to the female, not to the adolescent male, in which the second antennæ have a larger number of joints.

Rhiothra callipia, Schiödte and Meinert.—Plate VI. (A).

1884, **Rhiothra callipia**, Schiödte and Meinert, 'Nat. Tidsskr.,' ser. 3, vol. 14, p. 319, pl. 12, figs. 8–13.

The single specimen here available agrees with the account of the "mas adolescens" given by the Danish authors as well as could be expected considering its smaller size. The slender second antennæ, however, consist of thirteen joints instead of twelve. The eight-jointed first antennæ have the five joints of the flagellum each apically furnished with a spray of sensory filaments. The male appendix of the second pleopods, which the above-named authorities describe as very thin, hooked, scarcely reaching the end of the rami, is, in our example, only a third as long as the rami, not especially thin, and not showing any perceptible hook. The coupling spines of the peduncle are numerous. The delicately laminar rami of the uropods have fringes of finely plumose setæ and are scarcely, or not at all, shorter than the telsonic segment, the broadly rounded hind margin of which is fringed with very short but finely plumose setæ. Its base carries dorsally numerous setules, of which there are a few on the preceding segments. The pleopods are without setæ, according to the custom of the family Cymothoidæ.

A feature of our specimen, to which SCHIÖDTE and MEINERT make no allusion, is, that in all the limbs the fifth joint has the inner apex protruding, acutely in the first gnathopod, broadly in the fifth peræopod, where it is armed with three spines. The third joint is remarkably short in the former, but tolerably long in the latter pair of limbs. In all the limbs the finger is strongly uncinate.

Colour orange yellow, lightly sprinkled with small dark flecks, especially on the sides, the limbs pale.

Length about 6·75 millims., breadth about 2·75 millims.

Locality:—Station LVIII., off Karativo Paar, 9 to 26 fathoms.

Irona, SCHIÖDTE and MEINERT.

1884, **Irona**, SCHIÖDTE and MEINERT, 'Nat. Tidsskr.,' ser. 3, vol. 14, pp. 327, 381.
1897, **Irona**, H. J. HANSEN, 'Bull. Mus Comp. Zoöl. Harvard,' vol. 31, p. 110.
1901, **Irona**, H. RICHARDSON, 'Proc. U.S. Mus.,' vol. 23, pp. 525, 531.

This genus was placed by its authors in the Livonecinæ, the third tribe of their family Cymothoidæ. From the seven other genera which they assign to the same tribe it is distinguished by one or more of the following characters:—Segments of the pleon clearly separate, fifth peræopods subequal in length to the preceding legs, or a little longer, with uncinate fingers, the body all moderately convex, the front broadly or shortly rounded, the pleon deeply immersed in the peræon.

In the definition of the genus nothing is said as to the mouth organs or the character of the pleopods. Four species were placed in the genus, to which HANSEN has since added a fifth, *I. foveolata*. This last agrees with the species about to be described in a rather striking feature, of which HANSEN gives the following account:— The side-plates of the sixth, and especially of the seventh, segment are much broader and posteriorly much more produced than the others, besides on each side rising considerably above the more lateral part of the dorsal surface of the thorax [peræon], which is brought about by the curious fact that these epimera are turned outwards and somewhat upwards." In *Cterissa pterygota* (Koelbel) there is a similar expansion of the side plates, but it applies to all six of them on one side of the animal and to none on the other side.

Irona nanoides, n. sp.—Plate VI. (B).

The specimen, a female, having its pouch enormously distended with young ones, was slightly distorted so as to make the outline of the left side very convex. The middle of the back is raised considerably above the lateral parts of the segments. The head has a short, very broad front. The peræon is very broad, the side-plates of the fifth segment approaching the character of the two following pairs. The first two segments of the pleon are overlapped by the last segment of the peræon, the next three are very short but wider than the almost semicircular telsonic segment.

The eyes are wide apart, not very large, black. The first antennæ are rather stout, especially as to the first three of the eight joints. The ten-jointed second pair are slighter, subequal in length. The upper lip has a four-lobed margin as in *Anilocra curieri*, Leach, and in *Renocila periophthalmi*, Stebbing. The mandibles have a stout first joint to the palp, the second much thinner and a little shorter, the third shorter and thinner than the second, and armed with a few spines. The trunk thins out in advance of the palp, apparently carrying a quasi-molar not very remote from the pointed cutting-plate. The slender first maxilla is tipped with five spinules. The second maxilla appears to have a membranous apical margin accompanied by a process carrying small hooked spines. The maxillipeds have the composite second and third joints long and broad, followed by a joint which is about equal in length and breadth, narrowed at the rounded apex, to which is attached the narrow terminal bearing two outward bent hooks at its summit and one such hook on its side.

The gnathopods and peræopods are all very similar in appearance and structure, the hinder pairs having some superiority of size. The second joint is substantial, but not conspicuously expanded; the third in the gnathopods is as long as the hand, but in the hinder peræopod is longer than any one of the joints that follow it; the fourth joint is short but wide, being especially bulging in the fifth peræopod; the fifth joint is of insignificant size, tending slightly to underride the short curved hand, which does not exceed in length the simple but strongly hooked finger.

The pleopods are all of remarkable breadth, both branches similar in structure and devoid of setæ. The coupling spines of the short peduncles are small. The uropods are short, with two subequal oval branches, little longer than the stout peduncle, of which the inner apex is not produced. There are some tiny spinules on the branches, of which the inner is decidedly not longer than the outer. Colour in spirit yellow, with the upturned side-plates whitish.

Length 10 millims., greatest breadth 5·5 millims.

Locality:—Station XXXIX., Gallehogalle Bank, 16 to 20 fathoms.

The young ones taken from the mother's pouch have the broad front to the head as in the adults and the eight-jointed first antennæ. In the limbs the nail is rather more distinct from the trunk of the finger than it is in the full-grown animal. The seventh segment of the peræon is, as usual, without limbs, and resembling the segments of the pleon which at this stage are much narrower than the peræon. The telsonic segment shows a broadly rounded or very obtusely-angled apical margin, which like those of the uropods, and possibly also those of the pleopods, is feebly and microscopically fringed with setules. There is no subapical constriction of the telsonic segment as in the "pullus stadii primi" of *Irona foveolata*, and the inner branch of the uropod is broader than in the young of that species.

In *Irona nana*, Schiödte and Meinert, the adult female has the outer branch of the uropod much longer than the inner; in Hansen's species the inner is considerably longer than the outer, so that both species may be easily distinguished from the one here described.

Family: SPHÆROMIDÆ.

The genera that with more or less acceptance have maintained places in this family are *Sphæroma*, Bosc, 1802; *Campecopea*, Leach, 1813; *Cymodoce*, Leach, 1814; *Dynamene*, Leach, 1814; *Næsa*, Leach, 1815 (for *Nesæa*, Leach, 1813, preoccupied); *Cilicæa*, Leach, 1818; *Zuzara*, Leach, 1818; *Cerceis*, *Amphoroidea*, *Cassidina*, *Ancinus*, all four instituted by Milne-Edwards in 1840; *Monolistra*, Gerstaecker, 1856; *Isocladus*, Miers, 1876; *Ceratocephalus*, Woodward, 1877 (not preoccupied by *Ceratocephala*, Warder, 1838, and therefore taking precedence of *Bregmocerella*, Haswell, 1885); *Cycloidura*, Stebbing, 1878 (for *Cyclura*, Stebbing, 1874, preoccupied); *Scutuloidea*, Chilton, 1882; *Plakarthrium*, Chilton, 1883 (of which *Chelonidium*, Pfeffer, 1887, is a synonym, so that the family Chelonidiidæ if maintained must be named Plakarthriidæ); *Haswellia*, Miers, 1884 (for *Calyptura*, Haswell, 1881, preoccupied); *Cymodocella*, Pfeffer, 1887; *Næsicopea*, Stebbing, 1893; *Cæcosphæroma*, Dollfus, 1896 (part); *Tecticeps*, H. Richardson, 1897; *Exosphæroma*, Stebbing, 1900; *Cassidinella*, Whitelegge, 1901; *Chitonopsis*, Whitelegge, 1902; *Parasphæroma*, Stebbing, 1902; *Vireia*, Dollfus, 1905.

This rather unwieldy group suffers at present under various difficulties, towards the solution of which only a few suggestions can here be volunteered. Eugène Hesse in 1872 undertook to prove, with a reserve which he evidently scarcely entertained, that *Sphæroma* represented the female of *Cymodoce* and *Dynamene* the female of *Næsa*. The discovery of undoubted males in several species of *Sphæroma* has shown that the first part of his hypothesis is untenable, but for the second part there is much to be said. It is exceedingly probable that *Dynamene montagui*, Leach, is the young male, and that *Dynamene rubra* and *viridis*, Leach, are young forms, female or male, of *Næsa bidentata* (Adams), which is the adult male. The colouring, the general structure, and very frequent occurrence under similar conditions of these four forms give warrant to this belief (see 'Journ. Linn. Soc.,' London, vol. 12, p. 148, 1874). From acceptance of this view will follow the necessity of cancelling one of the generic names. *Nesæa*, LEACH, has priority, but is preoccupied. *Næsa* was substituted for it. But *Dynamene* has priority over *Næsa*, although its title is a little peculiar. It was indeed defined in advance of the substituted naming of *Næsa*, but the species for which it was defined were not specified by name until 1818. The simplest issue out of the complication seems to be by reducing the two genera and their four representative species to a single genus and species under the name *Dynamene bidentata* (ADAMS). Thus *Næsa* disappears, and *Dynamene* in its place acquires an intelligible status.

The relief, however, is not very great, because there are several other species that have been assigned to this dimorphic genus before its dimorphism was understood, and of these the true generic position remains uncertain.

Although sexual dimorphism is not conspicuous in *Sphæroma*, *Exosphæroma*, or *Parasphæroma*, in many other genera of the family it has been more or less clearly established, and there exists at least a possibility that the females of different genera may be much less divergent in appearance than the males. The latter sex is distinguished in *Dynamene* and *Campecopea* by having the sixth segment of the peræon dorsally produced, in *Zuzara*, *Cycloidura*, *Isocladus*, and *Haswellia* by having the peræon's seventh segment so produced. In *Dynamene*, *Campecopea*, *Cilicæa*, and *Næsicopea* the males have the inner ramus of the uropods degraded (with an exception subsequently mentioned). In *Ancinus* that ramus is wanting, but the sexes have not as yet been discriminated either in that genus or in *Tecticeps*, which shows a near relationship to it. The uropods in *Tecticeps* are biramose, with the inner branch much the shorter.

In regard to some isolated members of the family, it may be suggested that *Sphæroma algoense*, STEBBING, 1875, *Cymodocella tubicauda*, PFEFFER, 1887, and *Sphæroma* (?) *egregia*, CHILTON, 1891, must all belong to the same genus, and may possibly deserve to be united under the name *Cymodocella algoensis*. *Cymodocea antarctica*, HODGSON, 1902, also appears to approach *Cymodocella* more nearly than *Cymodoce*. *Exosphæroma amplifrons*, STEBBING, would, according to my present view, stand better in the genus *Cymodoce*, and, in any case, I agree with my friend Dr. H. J. HANSEN that it cannot properly be retained under *Exosphæroma*.

Since the above was written, Mr. HOLMES has kindly sent me his interesting essay on the sexes of Sphæromids ('Proc. California Ac. Sci.,' ser. 3, Zool., vol. 3, p. 295). He takes the view that the name *Dynamene* should be accepted in place of *Næsa*, but further extends it to supersede *Cilicæa*, a procedure which can scarcely be accepted without more consideration and argument. As regards the male sex, *Cymodoce* seems fairly distinguishable by superficial characters from *Dynamene* and both sections of *Cilicæa*, but whether there are stable and sufficient marks for separating either the female or the juvenile forms of *Cymodoce* and *Cilicæa* in all cases is less clear. The addition of new species without tolerably full description and figures is rather to be deprecated than welcomed.

Sphæroma, Bosc.

1904, **Sphæroma**, Stebbing, in Gardiner's 'Fauna, Maldive and Laccadive Archip.,' vol. 2, pt. 3, p. 710.

The definition of the restricted genus may be formulated as follows:—Sexual dimorphism not conspicuous. Telsonic segment without apical sinus. Maxillipeds having the fourth and fifth joints fringed on the inner margin with long setæ, but neither these two joints nor the sixth produced into lobes. First and second gnathopods having the third and fourth joints fringed on the front margin with long setæ. Uropods with subequal rami.

Conforming to these characters are the type species, *S. serratum* (Fabricius), *S. terebrans*, Bate, *S. quadridentatum*, Say, and *S. walkeri*, n. sp. In the multitude of species which from early dates down to the last two or three years have been assigned to *Sphæroma*, there are many which are obviously excluded from that genus as above defined. But there are several of which not enough is known to enable us to say whether they belong to it or not. There is a presumption in favour of *S. quoianum*, Milne-Edwards, since Heller in re-describing that species says that the first three pairs of feet have the middle joints fringed on the outer side with long hairs, and there is a similar presumption in regard to *S. sieboldii*, Dollfus, 1889, and *S. pentodon*, H. Richardson, 1904. On the other hand, Whitelegge, describing *S. australe*, *S. latifrons*, and *S. plumosum* in 1902, speaks of the lobes in the palp of the maxillipeds as well developed. At least the first of these three may be referred with some certainty to *Exosphæroma*.

Sphæroma walkeri, n. sp.—Plate VII.

Head not very broad or long. Peræon convex, its segments not greatly differing in length, although a contrary impression may be produced by the telescoping or extension of a particular segment. The unsutured side-plates of the first segment are as usual much the longest, being subacutely outdrawn backwards and forwards. The next two pairs are apically narrowed, the following three somewhat squared, and the seventh pair with a rather deep trituberculate hind margin. The transverse tuberculation of the segments, which is scarcely perceptible on the first segment, gradually increases in prominence, and fringes the seventh segment in a very pronounced manner. In the front division of the pleon, representing five faintly distinguishable segments consolidated into one, there is a curved transverse row of tubercles, belonging chiefly to the fourth segment. The telsonic segment is only moderately convex, and becomes slightly concave near the broadly rounded, slightly crenulate apical margin. This shield is ornamented by four longitudinal rows of tubercles, two submedian, of about eight tubercles apiece, and two sublateral of four, which lead to an encircling apical ridge, the sloping sides of the shield carrying at the upper part short divergent lines of tubercles, and usually a little tubercle outside each sublateral line.

The eyes are dark, deeply inserted in the front margin of the peræon.

The first antennæ have a broad basal joint, probably representing two joints consolidated. The following joint is small, scarcely as long as broad. The flagellum in the specimen examined consisted of fourteen joints, the first much the longest, as long as the basal and twice as long as the terminal joint of the peduncle.

The slender second antennæ are rather longer than the first; the fourth and fifth joints of the peduncle are equal in length; the flagellum is fourteen-jointed, rather longer than the peduncle.

The epistome is somewhat longer than broad; the upper lip has a feebly trilobed margin.

The gastric spines on the folds of the stomach at its entrance display a variety of shapes, which, however, may be customary.

The mandibles have the molar strong and prominent, the palp less slight than usual. In both pairs of maxillæ the plates appear to be somewhat broader than is usually the case.

The maxillipeds have the plate of the second joint broad, strongly setose round the convex distal margin and down the surface at some distance from the inner margin. The latter is armed with an exceptionally long and slender upward-bent coupling spine. The third joint is exceedingly small, the fourth as broad as long, with inner margin narrower than the outer, the fifth about square, like the preceding joint having its inner margin densely fringed with long setæ; the sixth and seventh joints are subequal, apically setose, considerably longer and narrower than the fifth joint.

The first gnathopods have the hind margin of the second joint setose in its upper part, the third joint nearly as long, with the plumose setæ of the front margin very long; the much shorter fourth joint has long plumose setæ on the convex front margin; the triangular fifth joint is quite small; the sixth joint is about as long as the fourth, with short plumose setæ distally on the front margin and a serrate spine at apex of hind margin; the finger has minute setules along the concave hind margin.

The second gnathopod differs from the first chiefly by the cylindrical fifth joint, which is nearly as long as the sixth, the former carrying plumose setæ at its front apex, and both being setose along the hind margin.

The peræopods are fringed with setæ on the front margin of the second, third, and fourth joints, and on the hind margin of all joints from the second or third to the sixth in the first two pairs, and on the corresponding but inverted margins of the other three pairs. The second and third joints are more robust than in the gnathopods.

The fifth joint is uniformly shorter than the sixth, which in the fifth pair is considerably elongated, being as long, though not as broad, as the third joint.

The fixed inner branch of the uropods has two or three tubercles on its upper surface; the outer branch is fringed with setæ along the inner margin and has the outer divided into six or seven teeth.

The colouring (as preserved) is a symmetrical dark-grey mottling on a pale ground.

The specimen figured was 9 millims. long and 5 millims. broad. The second pleopods showed no trace of a male appendix.

Numerous examples were obtained at Jokkenpiddi Paar, one in tow-net gathering at Marichchukaddi, two at Cheval Paar, one in Galle Harbour, and one elsewhere.

The tuberculation of the dorsal surface is not incapable of being regarded as forming a series of transverse lines, but the general effect produced is that of a striking contrast between longitudinal lines on the telsonic segment and transverse lines on the rest of the body. I name this prettily sculptured species in honour of A. O. Walker, Esq., F.L.S., a carcinological colleague whose cheering friendship I have for many years enjoyed.

To include the numerous species now assigned to this genus, the following definition is offered :—

Sexual dimorphism conspicuous. Segments of peræon devoid of dorsal processes. Telsonic segment with an apical sinus. Maxillipeds with fourth, fifth, and sixth joints produced into apically setose lobes. Gnathopods without fringes of long plumose setæ. Uropods of male (except in *C. spinulosa*) having only the outer ramus strongly developed.

LEACH having only *C. latreillii* on which to found his genus, availed himself of characters which would exclude many of the forms now grouped under this generic name. The four marks which he used for distinguishing *Cilicæa* among the Sphæromidæ were: first, the approximate equality of the sixth and seventh segments of the peræon; second, the prolonged medio-dorsal process on the anterior division of the pleon; third, the apical sinus with central lobe in the hinder division of the pleon; and fourth, the rudimentary character of the inner ramus of the uropods. The second of these characters is conspicuous in fewer than half the species at present assigned to the genus.

The lobe within the apical sinus of the pleon is found in only four of the species, and the fourth character is subject to one curious exception, since in *C. spinulosa* the inner ramus of the uropods is rather longer than the outer. LEACH himself evidently suspected that the long process of the pleon might be peculiar to the male, and this has proved to be the case. But the females, so far as is known, besides being without the dorsal process, have the apical sinus, at least usually, simple, and the rami of the uropods subequal. WHITELEGGE, however, says that "the sexual differences in *C. hystrix* are very slight," and that in *C. stylifera* "the female does not differ materially from the male." He thinks it highly probable that the form figured by HASWELL as the female of *C. hystrix* may really be the female of *C. spinulosa*, HASWELL in his text leaving the point ambiguous. MIERS regards *Sphæroma pubescens*, MILNE-EDWARDS, the *Cymodocea pubescens* of HASWELL, as with scarcely any doubt the female of *C. latreillii*. H. F. MOORE explains *Cymodocea bermudensis*, IVES, as female of *C. caudata* (SAY), and suggests that *Dynamene nodulosa*, RICHARDSON, is the female of *C. caudata-gilliana*, RICHARDSON, *nodulosa* being apparently named by a slip of the pen instead of *tuberculosa*. But S. J. HOLMES makes it fairly certain that *Dynamene tuberculosa* is the female of *Cilicæa cordata*, RICHARDSON. As *tuberculosa* has page precedence, it will supersede *cordata*, and not without advantage to the genus, since to many ears *cordata* and *caudata* are indistinguishable. The confusion caused by the sexual dimorphism in this genus will not, perhaps, be very easily disentangled.

The following synoptic view of the species rather suggests that, for practical convenience, those which are devoid of the great dorsal process might be grouped under a separate generic name:—

1	Anterior division of pleon in male with long medio-dorsal process—2.
	Anterior division of pleon in male without such process—11.

2	Apical sinus in male with prominent central lobe—3.	
	Apical sinus in male with central lobe very small or absent—5.	
3	The medio-dorsal process with apex simple.	1. *C. latreillii*, Leach, 1818.
	The medio-dorsal process with apex bifid—4.	
4	Outer ramus of uropods sub-apically notched.	2. *C. crassa*, Haswell, 1882.
	Outer ramus of uropods not notched.	3. *C. longispina*, Miers, 1884.
5	Apical sinus of pleon in male with very small central lobe.	4. *C. antennalis*, Miers, 1884.
	Apical sinus of pleon in male without central lobe—6.	
6	Surface of peræon conspicuously spinulose—7.	
	Surface of peræon smooth or moderately granular—8.	
7	Inner ramus of the uropods in male not shorter than the outer.	5. *C. spinulosa*, Haswell, 1882.
	Inner ramus of the uropods in male shorter than the outer.	6. *C. hystrix*, Haswell, 1882.
8	Apex of medio-dorsal process not distinctly bifid—9.	
	Apex of medio-dorsal process distinctly bifid—10.	
9	Apex of medio-dorsal process truncate, slightly indented.	7. *C. caniculata* (Thomson), 1879.
	Apex of medio-dorsal process truncate, slightly trifid.	8. *C. granulata*, Whitelegge, 1902.
10	Outer ramus of uropods in male with bifurcate apex.	9. *C. tenuicaudata*, Haswell, 1881.
	Outer ramus of uropods in male with simple apex.	10. *C. whiteleggei*, n. sp., 1905.
11	Apical sinus of pleon in male with minute central lobe.	11. *C. sculpta* (Holmes), 1904.
	Apical sinus of pleon in male with large central lobe—12.	
	Apical sinus of pleon in male without central lobe—13.	

12	Central lobe with the flanking apices bifid.	12. *C. granulosa*, H. Richardson, 1899.
	Central lobe with the flanking apices simple.	13. *C. linguicauda*, H. Richardson, 1901.
13	Apical sinus in male simple—14.	
	Apical sinus in male sculptured—17.	
14	Apical sinus visible from above—15.	
	Apical sinus dorsally concealed—16.	
15	Movable ramus of uropods in male stiliform.	14. *C. stylifera*, Whitelegge, 1902.
	Movable ramus of uropods in male uncinate.	15. *C. carinata*, H. Richardson, 1900.
16	Apical sinus concealed by a trilobed process.	16. *C. curtispina*, Haswell, 1882.
	Apical sinus concealed by a simple acute process.	17. *C. ornata*, Whitelegge, 1902.
17	Apical sinus with two teeth in the border.	18. *C. beddardi*, n. sp., 1905.
	Apical sinus with four teeth in the border.	19. *C. caudata* (Say), 1818.
	Apical sinus with six teeth in the border—18.	
18	Teeth in the sinus boldly cut.	20. *C. tuberculosa* (H. Richardson), 1899.
	Teeth in the sinus minute.	21. *C. gilliana*, H. Richardson, 1899.

In regard to this list it should be mentioned that Miers treats Haswell's *C. crassicaudata* and his own *C. longispina* as two varieties of *C. latreillii.* The specific name of *C. antennalis* he adopts from White, who published it in 1847 without a description. The species described by G. M. Thomson, in 1879, as *Nesea caniculata* was recorded by Thomson and Chilton, in 1886, as *Næsa canaliculata*, with a notice that Miers supposed it to belong to *Cilicæa*, and that the type specimen had apparently been lost. Miss Richardson's *C. gilliana* was described by her under the name *C. caudata gilliana*, as a new sub-species of *C. caudata* (Say). Species that may belong to the genus, but which have as yet only been described in the female form, are not included in the list.

Male.—Miers says, "the segments of the body are covered with a very short stiff pubescence." In the Ceylon specimen the integument is clothed with plumose setules accompanied by thin pellucid undulating fringes, the precise character of which is not easy to determine. Their function may be to retain a concealing coverlet of mud on the animal's coat, as suggested by Doflein ('Brachyura of the "Valdivia,"' p. 203), for the "leaf-hairs" of the Dromiacea and Oxyrrhyncha. The hind region of the last three peræon segments is ornamented with transverse rows of small granules. The long unsutured side-plates of the first segment have the narrowly-squared front apex commonly found in this and some other genera. In contrast to these, the side-plates of the next three segments are extremely short, those of the third segment ending acutely, with the points less produced than those of their neighbours on either side. The anterior division of the pleon projects a thick, apically obtuse, medio-dorsal process over and beyond the telsonic segment, leaving exposed to view the pair of sub-lateral bosses on that segment, but covering both the central lobe and the sides of its apical notch.

The first antennæ in the specimen figured have a flagellum of twenty-one joints. The second antennæ in the same specimen show a want of symmetry, in one member of the pair the fourth and fifth joints of the peduncle being considerably longer than any of the preceding joints, the flagellum ten-jointed, shorter than the peduncle, while in the other member the fourth and fifth joints of the peduncle are each shorter than the second, and the flagellum is twelve-jointed, longer than the peduncle. Normally, as shown by another specimen, and in Desmarest's figure, the first antennæ are not, as in this instance, longer, but shorter than the second.

Mandibles with dark horn-coloured cutting edge with dentation obscure, accessory plate bidentate on one mandible, simple on the other, a tuft of spines between this and the prominent molar, palp slender.

Maxillipeds: The second joint has a sinuous outer margin to the stem, its plate is of moderate breadth, and the ultimate joint of the palp reaches well beyond the lobe of the penultimate joint.

First gnathopods: Third joint elongate, hind margin carrying many little groups of spinules, front distally channeled and above the groove produced into an obtuse spine-tipped process, fourth joint broader than long, its spine-tipped front apex overlapping the fifth joint, with seven spines along the hind margin; small fifth joint with five, and sixth joint with six spines along the hind margin, of the last set the sixth being shorter than the one before it, but with this exception, the three successive sets of slightly serrate spines beginning with smaller and ending with larger forms. The finger is strong, as long as the stout sixth joint, ending in two horny nails, of which the short inner one is serrate on its inner margin.

The second gnathopods are less robust, the spines of the front margin more developed, those of the hind margin more numerous, but for the most part not so strong, the fifth joint not differing greatly in size and character from the fourth, the finger not quite so long as the sixth joint, and its inner nail showing no serration.

The fifth peræopod is the longest of the limbs, the process of the third joint by successive reduction in prominence here almost disappearing, the fourth, fifth, and sixth joints attaining their greatest elongation, and the finger being decidedly shorter than the preceding joint.

The first pleopods exhibit an interesting feature of the inner branch in that its inner margin, instead of joining the outer either by a continuous straight line or a convex curve, here makes a slightly concave sweep from the point where the fringe of long, feathered setæ begins. The second pleopods, as already described and figured by Mr. WHITELEGGE, are remarkable for the great length and corrugated appearance of the male stilet. This in our specimen, as in that described by Mr. WHITELEGGE, was stiffened into a strongly bent position. The three following pairs have the covering branch sutured and lying very close to the branchial plate. In the fifth pair the short, but broad, portion beyond the suture is bilobed, and from the junction of the lobes rises a forward-pointing lappet, this, with the border of the inner lobe, and two tubercles just in advance of the suture, being also closely beset with little teeth or prickles in regular arrangement.

The uropods have the short stout peduncle produced on the inner side to a short thick process representing the inner ramus, of which the appearance varies considerably with the point of view. The stout, blunt outer ramus has a tooth on the outer margin at some distance from the apex, often obscure, and, according to MIERS, occasionally obsolete.

Length, 11 millims. to 13 millims. From the tendency of the specimens to fold up, the exact length is not very easily measured.

Localities :—South of Manaar ; Coral reef, Gulf of Manaar ; Pearl banks, Palk Bay. One specimen was obtained at each station.

Cilicæa latreillii, LEACH, juv.—Plate III. (B).

This small specimen is remarkable for its coat. This may be described as thickly beset with short, stiff, irregularly blunt setæ covering all the dorsal surface, except such parts as are adapted for sliding under neighbouring parts. In the 'Zoology of H.M.S. "Alert,"' pp. 308–310, 1884, Mr. E. J. MIERS makes *Sphæroma pubescens*, MILNE-EDWARDS, 1840, doubtfully, a synonym of *Cilicæa latreillii*, and HASWELL'S *Cymodocea pubescens*, 1881, with conviction, another synonym. His remarks on the variations of this species according to age, sex, and individuality, should be carefully studied by anyone interested in the subject. HASWELL gives the length of his longest specimen of *Cymodocea pubescens* as 1 inch. That the setose covering should be worn down in large specimens might be easily explained, but it is less easy to understand in an evidently young specimen, such as that in the present collection. Probably, therefore, the peculiar setæ are not stumps due to attrition, but an inchoate stage of the undulating fringes noticed above. It will be observed that the spines of the first gnathopod are not blunted, and the finger clearly shows a delicate serration of the inner margin and small setules on the outer. In the adult male the serration is less easy to observe, the finger having become thicker and coarser.

Length 6 millims., breadth 3 millims.

Locality :—Coast of Ceylon, under 100 fathoms.

Cilicæa whiteleggei, n. sp.—Plate IX. (A), (B).

Male.—This species is easily distinguished from *C. latreillii* by its much slighter general structure, as well as by the character of the very elongate dorsal process in the front division of the pleon, the terminal part of which is not conical but almost parallel-sided and sharply bifid at the apex. Also, the apical notch of the telsonic segment is simply semicircular without median lobe. The three species which make a nearer approach are *C. tenuicaudata*, HASWELL, distinguished by the bifid apices of the uropods ; *C. caniculata* (G. M. THOMSON), with practically truncate apex to the dorsal process and the free ramus of the uropods short and thick ; and lastly *C. granulata*, WHITELEGGE, which also has the dorsal process truncate, "with three small terminal subspiniform granules." This last species attains a length of 13 millims., therefore greatly exceeding in size that which I am here naming after Mr. WHITELEGGE out of respect for his useful researches in this group.

The surface is very inconspicuously granular and hairy, only on the pleon and uropods showing these characters at all distinctly. The side-plates are similar to those of the preceding species, but having in addition a subcarinate appearance along the upper portion. The pleon, which is as long as head and peræon combined, has a rounded tooth or projection on either side of the dorsal process at its base, which must be regarded as an additional distinction between this species and *C. granulata*. It has "a submedian pair of tubercles transversely disposed behind the middle of the terminal segment," such as WHITELEGGE considers distinctive of the female in his species.

The first antennæ have the flagellum consisting of ten or eleven unequal joints, with sensory filaments on the last five. The longer second antennæ have the last joint of the peduncle decidedly longer than the penultimate, the flagellum longer than the peduncle, fifteen-jointed.

In the mouth organs it was probably a casual abnormality that the first maxilla had only three setæ instead of the usual four on the inner plate.

The maxillipeds differ from those of *C. latreillii* by the stronger stem of the second joint, which has a straight outer margin and carries a much wider plate ; also the lobes of the fifth and sixth joints are longer than in the older species.

First gnathopods : The third joint projects and carries a spine at the middle of the front margin, but has no process. The fourth joint has a spine at the front apex and three on the hind margin, the small triangular fifth has two spines, and the sixth three on the hind margin ; the finger has a horny principal nail, but the accessory nail is only represented by a small pellucid spine.

The second gnathopods have similar fingers, but the four preceding joints more elongate, the fifth joint being of the same character as in the peræopods. Most of these limbs show a fur-like clothing of the inner margin of the fourth and two following joints ; the spines are quite small and not very numerous ; the proportions of the joints are variable, in the long fifth peræopods the fourth joint being as long as the third or the sixth and a little longer than the fifth.

The first pleopods have the inner branch triangular with no distal emargination of the inner border. Both branches are covered with scale-like markings. The male appendix of the second pair is produced only a little way beyond the branches and is subapically widened but apically narrowed to a short obtuse point, thus differing from the longer, not subapically widened, stilet in *C. granulata*. The third pleopods differ from those of *C. latreillii* by having the inner branch considerably shorter than the outer, and the part of the outer branch below the suture with a breadth much less in excess of its length.

The uropods have a dorsal tubercle on the peduncle ; the peduncle is widened above on the inner side, and is still more widened below into the short unjointed inner ramus. The outer ramus is very long and nearly straight, the tolerably acute tip tending to bend outwards.

Length at full stretch from front of head to end of dorsal process of pleon, 8·5 millims. The uropods reach little beyond the dorsal process.

Localities :—Cheval Paar, Gulf of Manaar ; deep water off Galle ; off Foul Point, Trincomalee, Station XXIV.

Female.—The form which I regard as the female of this species is devoid of the long dorsal process and has the rami of the uropods subequal. It is also considerably smaller than the male. But in other respects the agreement between the two forms is so close as to leave little room for doubt that they are the same species. The maxillipeds are especially characteristic. The antennæ, first gnathopods, and fifth peræopods, as will be seen by the illustrative figures, are in close agreement. The pleopods, in addition to agreement in shape, show the same scale-like markings.

The uropods have the fixed branch squarely truncate, the outer narrowly ovate, with its apex acute, turned slightly outward. The front division of the pleon has a faintly marked medio-dorsal projection of its hind margin. The telsonic segment has two prominent submedian bosses and a semicircular apical notch.

Localities :—Trincomalee, Station XXIV., off Foul Point ; deep water off Galle.

Cilicæa beddardi, n. sp.—Plate X. (A), (B).

Male.—This species is nearly related to *C. caudata* (Say), but, according to the more recent descriptions and figures of the latter by Ives ('Proc. Ac. Sci., Philad.,' 1891, pp. 188, 194, pl. 6, figs. 11–16), and by H. F. Moore ('Bull. U.S. Fish. Comm.,' vol. 20 for 1900, p. 172, pl. 10, figs. 5–8, 1902), the present form must be considered distinct. Say, in his original account, speaks of the telsonic segment as "marked by a deep sinus, within which are two or four small teeth." Ives, who had six male specimens from Bermudas, takes no notice of the alternative two teeth, but says, "there appears to be a tendency in the four spines within the sinus of the posterior abdominal segment to become double." Moore says, "the apical notch is furnished with four teeth, two small ones at the base, and two larger ones outside of them and at a slightly lower level. The two limbs forming the borders of the notch are notched at their tips and furnished with a tuft of setæ." These notches at the tips are also very clearly shown in the figure given by Ives. In the Ceylon species there are decidedly only two teeth within the sinus, and the tips of the sinus are not notched, but carry dorsally an upright tuft of setules seemingly seated on a tubercle.

A few setules rise from the dorsal surface throughout the length of the animal. There is little difference in length between the segments of the peræon, except in regard to the seventh, which is the shortest, and has its side-plates rounded, less produced than the rest. The anterior division of the pleon has a transverse row of five small setulose tubercles. To these succeed on the telsonic segment three longitudinal ridges divided into tubercles, some of which carry setules. Behind the ridges the segment is depressed and has a group of setules in advance of the sinus which has been above described.

The first antennæ have an eight-jointed flagellum. In the second antennæ one member had the flagellum ten-jointed, while in the other it was seven-jointed.

The epistome is conspicuously tri-lobed above. The distal margin of the upper lip is evenly convex.

One of the mandibles has both cutting edge and accessory plate tri-dentate. On the other the dentation of these parts is obscure. They are succeeded by a bunch of spines. The molar is well developed; the palp slender, with its first joint not much longer than the second or third.

The first maxillæ have the usual four feathered setæ on the inner plate, the apical spines of the outer plate slender.

The maxillipeds are slightly constructed, with the last four joints apically setiferous, the three preceding the terminal joint being produced into narrow lobes.

The limbs are very similar to those of *Cilicæa whiteleggei*, but rather less robust. The second peræopod on the right side of the specimen figured has the sixth joint reduced to an oval stump, carrying no finger.

The first pleopods are remarkable for having the inner ramus twice as broad as it is long, agreeing with the same appendage as described by Whitelegge for *Zuzara emarginata*, Haswell. The second pleopods also have the inner ramus much broader than long, with the male appendix a little longer than the breadth of the ramus, transparent, smooth, of uniform width, with the apex turned a little away from the ramus. The outer ramus has the serration of its distal outer margin produced into prominent teeth. The third pleopods have the portion of the outer ramus beyond the suture nearly as long as it is broad. The fourth and fifth pairs have branchial folds on both rami.

The uropods are very hairy. The short peduncle is produced into a quadrate process representing the inner ramus, which has its lower angle a little acutely produced and beset with short feathered setæ. The movable ramus is long, cylindrical, slightly curved, the outer margin being convex.

Length 5 millims., breadth 2·5 millims.

Locality :—Cheval Paar; Muttuvaratu Paar.

Cilicæa (?), sp. juv.—Plate IX. (C).

The small specimen figured is no doubt immature, as may be judged from the unfurnished condition of the maxillipeds. The pleon differs little from that of the female or young *C. whiteleggei*, except that the outer ramus of the uropods shows no outward curving. The first antennæ have a massive peduncle and a flagellum of eight joints or, perhaps, more. The flagellum of the second antennæ is twelve-jointed. In the finger of the gnathopods the little spine or tooth at the base of the nail is comparatively strong.

Length, in a somewhat bent position, about 5·5 millims.

Locality :—Palk Bay.

Cymodoce, Leach.

1814, **Cymodoce**, Leach, 'Edinburgh Encycl.,' vol. 7, p. 433.
1902, **Cymodoce**, Stebbing, 'South African Crustacea,' part 2, p. 73.
1904, **Cymodoce**, Stebbing, in Gardiner's 'Fauna, Maldive and Laccadive Archip.,' vol. 2, pt. 3, p. 712.

Cymodoce bicarinata, Stebbing—Plate X. (C).

1904, **Cymodoce bicarinata**, Stebbing, in Gardiner's 'Fauna, Maldive and Laccadive Archip.,' vol. 2, pt. 3, p. 712, pl. 52B.

The specimen here figured differed from the type by its greater proportionate breadth, being 4 millims. broad by 6 millims. long, while the flagellum of the first antennæ was only eleven-jointed, and that of the second fourteen-jointed. But the long genital papillæ* of the seventh peræon segment and the greatly produced inward curving male appendix of the second pleopods and various other features showed close agreement. To judge by other specimens, the breadth is variable.

Milne-Edwards, 'Hist. Nat. Crust.,' vol. 3, p. 213, 1840, describes *C. pilosa* as

* This term is introduced by Dr. H. C. Williamson in the 'Twenty-second Annual Report of the Fishery Board for Scotland,' part iii., p. 101, 1904. For an earlier vague use of it by v. Willemoes Suhm, see '"Challenger" Amphipoda,' p. 438.

follows:—"Body very flexible and almost smooth in front, but granular and setose in the hinder half. Front obtuse as in *Sphæroma*; hind margin of the first pleon segment furnished with two rounded tubercles; two tubercles similar but much larger, more salient and above all more elongated, situated on the last pleon segment and separated by a longitudinal furrow, at the extremity of which is found a boss furnished with a pencil of long setæ. Terminal incision of the pleon very wide; the elongate median process almost cylindrical, rounded at the end, and terminating at the level of the extremity of the two teeth formed by the sides of the incision. Terminal plates of the uropods reaching much beyond the extremity of the pleon; the inner large and obtuse; the outer much broader, thin on the inner side, but very thick towards the outer margin and armed with a conical tooth at its extremity. Length about 6 lines. Habitat, the Mediterranean." A length of 12·5 millims., compared with 6 millims., makes the difference in size very considerable, but in other respects there is a close resemblance between the Pacific species and that described from the Mediterranean.

Localities:—East of Shoal buoy; off Chilavaturai; on trap sunk to bottom, Shoal buoy.

Cymodoce inornata, Whitelegge.

1902, **Cymodoce inornata**, Whitelegge, 'Mem. Australian Mus.,' iv., pt. 4, p. 263, fig. in text.

The specimen referred to this species agrees well with Mr. Whitelegge's account and figure. It has the body minutely hairy, the pigmented area of the eyes with the narrow end directed backwards, the process in the apical sinus of the telsonic segment small and rounded, the outer ramus of the uropods bidentate, with the outer tooth smaller and higher up than the inner.

On the other hand, it should be stated that the apical sinus is much more marked than that which Mr. Whitelegge represents, and the tip of the median process scarcely reaches the level of the apices of the sinus. The outer ramus of the uropods is not so forcibly bidentate as in Mr. Whitelegge's figure, and above the semicircular depression, which that author mentions as extending from one uropod to the other, the telsonic segment is here bilobed. In the Australian memoir it is spoken of simply as convex.

Length about 12 millims., equal to twice the breadth. The specimen was crowded with young ones, in which the eyes were already visible.

Locality:—Coral reefs, Gulf of Manaar. A second specimen was taken south of Adam's Bridge.

Tribe: VALVIFERA.

To the tribe, in 1897, Sars assigned the three families Idotheidæ (synonymous with Idoteidæ), Arcturidæ (with suggestion of Astacillidæ as the proper substitute), and Chætiliidæ. The late Axel Ohlin in 1901 added a new family, Pseudidotheidæ, to receive the three species, *Idothea miersii*, Studer, *Pseudidothea bonnieri*, Ohlin, and *Arcturides cornutus*, Studer. He was, however, almost convinced that the first two were identical, and suspected that in any case both would have to be transferred to *Arcturides*, the genus of the third. He recognised that in the latter event the family name would have to be changed. It would rather inconveniently become Arcturididæ. Another family, likewise intermediate between the Idoteidæ and Astacillidæ, is now required. This is remarkable for the negative character in which it agrees with the Amphipoda Caprellidea, a common result being no doubt referable not to any close tie of consanguinity, but to the simple fact that in each instance nature has enabled a species to get rid of limbs for which it had no further use. For the genera *Antarcturus* and *Pseudoprion*, zur Strassen, see 'Zool. Anzeiger,' vol. 25, p. 686; vol. 26, p. 31; 1902–03.

Family: AMESOPODIDÆ, nov.

Body not geniculate, but antennæ, mouth organs, first gnathopods, and appendages of pleon nearly as in the Astacillidæ. Second gnathopods ambulatory, not setose, not fully jointed. First and second pairs of peræopods unrepresented, except by the marsupial plates in the female.

Amesopous, n. gen.

To the characters of the family none can be added for generic distinction, so long as the family contains but a single genus. It may be noticed that the first segment of the peræon is coalesced with the head, that all the segments of the pleon are fused into one, and that the wrist and hand of the first gnathopods are fringed with conspicuously trifid setæ.

The name is framed to express the default of the median pairs of legs. In *Cleantis*, Dana, a genus of the Idoteidæ, which in general facies makes some approach to the present, the second peræopods are the smallest of the limbs. In *Arcturides* the head is only incompletely separated from the first peræon segment, but Ohlin finds this fusion complete in his *Astacilla falclandica*, and nearly so in *A. magellanica*.

Amesopous richardsonæ, n. sp.—Plate XI. (A).

Head united to first peræon segment without apparent suture, rostral point minute, lateral lobes produced about to the end of the first joint of the upper antennæ. Body in male narrowly cylindrical, the limbless segments of the peræon the smallest, but in the ovigerous female the cephalothorax widens distally, and the second, third, and fourth peræon segments which carry large marsupial plates are much wider, the third and fourth being also considerably longer than any of the three following segments. The pleon is narrowly ovoid, narrowly rounded at the apex. In lateral view the dorsal outline is corrugated, and the female has a pair of dorso-lateral tubercles on each of the second, third, and fourth peræon segments.

The eyes are dark, laterally protuberant just below the frontal lobes of the head. The facets are small and numerous.

The first antennæ reach some way along the third joint of the second pair which they overlie. The first joint is stout, a little longer than broad, the second and third shorter and much narrower, together as long as the one-jointed flagellum, which carries three apical sensory filaments.

The second antennæ have a very short first joint, the second not long, the fifth rather longer than the third and rather shorter than the fourth, the three-jointed flagellum being as long as the peduncle's third joint. The very short apical joint is tipped with a curved spine.

The upper lip appears to be rounded. The lower lip forms two broadly rounded lobes.

The mandibles are without palp, with small tridentate cutting plate and narrow accessory plate, close to which is a strong but not elongate molar with finely denticulate crown.

The first maxillæ show only two plumose setæ on the apex of the inner plate, and nine not very elongate spines on that of the outer plate.

The second maxillæ are remarkably short, with short comparatively broad plates, the outermost tipped with two long setæ, the middle one with four that are not so long, and the innermost with five that are shorter and more spine-like.

The maxillipeds have the lobe of the second joint produced about to the end of the fifth joint and armed on the inner margin with setæ and with three or sometimes only two hooks. The third joint is small, the fifth broadly oval, the sixth much shorter, nearly as broad as long, the seventh almost tubercular; the fifth and sixth are well fringed with setæ on the inner margin. The epipod is quadrately oval in the female, but in the male balloon-like, being very narrow at the base.

The first gnathopods are closely applied to the mouth. They have the fourth joint somewhat cup-like, much broader than the third, the fifth joint longer but not so wide, the sixth narrower than the fifth but subequal to it in length, and both of these notable for the trifid setæ along the inner margin. The middle branch of the setæ is the longest. The narrowed apical part of the sixth joint has curved setæ on the outer margin. The finger is short and conical, and tipped with a spine.

The second gnathopods display only five joints. The finger has its inner margin denticulate and ends in a very small curved unguis, agreeing with the finger in the third, fourth, and fifth peræopods. The two preceding joints have the inner margin denticulate or serrate. Of the four joints preceding the finger the second is not longer than broad, the third is shorter than the first, and the first than the fourth. Whether the first represents a coalescence of the first and second or of the second and third joints, or whether the fourth may be a fusion of the true fifth and sixth joints it is, perhaps, vain to speculate.

The three hinder peræopods are almost exactly alike, the second joint in the female decidedly longer than the sixth, but scarcely so in the male. The third joint is longer than the fourth and the fourth than the fifth.

The first and second pleopods have two slender branches with long apical setæ.

The others appear to be simply branchial, narrowly oval, without setæ. A male pleopod figured shows one of the branches apically divided for a short distance. The smooth inner division is probably the male stilet in preparation.

The uropods are elongate, the narrowly triangular terminal division being about a quarter as long as the peduncle. Within it is a plate about two-thirds as long and half as broad, with a long seta on its rounded apex.

The female is brown, with numerous conspicuous white spots, and three dorsal longitudinal dark bands. The males did not exhibit any white spots, and had two dorso-lateral dark bands.

The length of the female was 6 millims., not including the second antennæ which were 2·75 millims. long. The longest male was 4 millims. From this the detail figures of the male are taken. The male figured measured 2·5 millims. in length. The sex of the female specimen was beyond question, as it was provided with fourteen large eggs. As to the other much smaller specimens one must speak with more reserve, as they might be young ones of either sex.

Locality :—From pearl oysters, East Cheval Paar.

The specific name is given out of respect to the assiduous work which Miss Harriet Richardson has devoted to this tribe of the Isopoda.

Family: IDOTEIDÆ.

Idotea, Fabricius.

1798, **Idotea**, Fabricius, 'Supplementum Ent. Syst.,' p. 302.

Idotea sp.

In a tow-net gathering off Marichchukaddi there were two specimens of a young *Idotea*, 2 millims. long, in which the last pair of peræopods were not yet visible.

Family: ASTACILLIDÆ.

Astacilla, Cordiner.

1795, **Astacilla**, Cordiner, 'Remarkable Ruins . . . and Singular Subjects of Natural History.' Section, "Astacillæ," etc.

1893, **Astacilla**, Stebbing, 'History of Crustacea,' p. 370.

1897, **Astacilla**, Sars, 'Crustacea of Norway,' vol. 2, p. 87.

1904, **Astacilla**, Norman, 'Ann. Nat. Hist.,' ser. 7, vol. 14, p. 447.

Astacilla amblyura, n. sp.—Plate XI. (B).

The head has a minute rostral point and the usual broad lateral lobes in advance of the dark protuberant eyes; it is rather gibbous between the eyes and apparently has a pair of tubercles wide apart in advance of the hump. The specimen was rather foul with adhesive extraneous matter, by which the excrescences were in part obscured, in part exaggerated, and there was some risk, in clearing away what was adventitious, of removing what really belonged to the animal. A strong groove (but not necessarily an articulation) separates the first segment of the peræon from the head. The long fourth segment has a dorsal hump in advance of the middle and a small medio-dorsal tubercle closely flanked by two others a little to the rear of it on the hind margin. The sixth peræon segment appears to have two lateral tubercles, the fifth and seventh segments each one such tubercle on either side. No transverse dorsal divisions of the pleon could be discerned, but on each lateral margin there are three projections; to the last and most prominent of these a short obtusely ending apical triangle succeeds, very different from the acute ending of the pleon in the four Norwegian species figured by Professor G. O. Sars, but agreeing with the apex in *A. granulata*, Sars, and *A. marionensis*, Beddard.

The first antennæ are normal, with stout first joint, the second and third successively narrower, the one-jointed flagellum fringed with thirteen or fourteen sensory filaments.

The second antennæ are very little shorter than the body, the third joint much stouter distally than at its base, the fourth joint the longest of all, but much narrower than the third and curving to a little conspicuous tooth not far from the base; the fifth joint is narrower, intermediate in length between the third and fourth, about twice as long as the three-jointed flagellum.

In the mouth parts and limbs there is scarcely any tangible difference from the corresponding structures figured by Sars for *A. longicornis* (Sowerby).

On one of the mandibles, between the accessory plate and the strong molar, in this species two or three short spines are to be seen crowded into a very narrow space. The cutting edge has three or four close-set teeth. The first maxillæ have three setæ on the inner plate, nine very short spines on the outer. The second maxillæ have the inner plate much broader and more setose than the other two plates. In the maxillipeds the broad plate of the second joint is armed with a remarkably large coupling hook; the seventh joint is well developed, not unguiform.

The first gnathopods, of which the last four joints are by no means unlike the corresponding four of the maxillipeds, have serrate spines on the broad fifth joint. The seventh joint has one conspicuous spine among many that are smaller. The second gnathopods and the first and second peræopods are, as usual, alike, very slender, with the seventh joint minute, this and the three preceding joints being furnished with very long setæ. The fourth, fifth and sixth joints are subequal in length. The third peræopods are a little longer than the fourth or fifth, all three pairs being stoutly built, with the second and sixth joints longest, but none very elongate or conspicuously armed, except the finger which has a stout apical tooth on the inner margin in addition to the short curved nail. The finger is also tuberculate on the inner margin, and this is perhaps the case with some of the preceding joints.

The pleopods agree very nearly with those which have been figured by Sars for the male of *A. longicornis* and *A. granulata*, the first two pairs having slender rami, with the setæ of the apical border elongate, and the masculine appendix of the second pair forming a narrow stilet which reaches to the end of the ramus and carries two long apical setæ.

The uropods are rounded above, widest below the middle, then rather rapidly narrowed to the rami, of which the external is very small, acutely triangular, and reaching to the apex of the pleon. The internal ramus is still smaller. Colour in spirit a dull yellowish.

Length 9 millims., apart from the antennæ, the lower of which are nearly as long as the body, about 8·5 millims.

Locality :—Periya Paar, Gulf of Manaar.

A specimen, 4 millims. long, delicately pink in colour, from East Cheval Paar, is no doubt the young of this species. It has the first peræon segment not marked off from the head, the fourth segment very elongate and smooth. The flagellum of the first antennæ is armed about the apex with only three or four sensory filaments. The fifth peræopods are still imperfectly articulated, very small, ending obtusely without a nail.

Another specimen, from East Cheval Paar, is only 3 millims. long, with the fifth peræopods in a still more inchoate condition. Here, however, the fourth segment of the peræon is not especially elongate and shows traces of median and terminal tuberculation. The colour is a delicate pink. Neither in this nor the other juvenile specimen is there a tooth on the fourth joint of the lower antennæ.

The specific name is from the Greek ἀμβλύς, blunt, and οὐρά, tail. Apart from size and arrangement of tubercles, the distinguishing characters of this species depend on the antennal tooth just mentioned, the decided groove between head and peræon, the solidarity of the pleon, and the extension of the uropods further back than appears to be the case in any of the species hitherto described.

Tribe: ASELLOTA.

Family: JANIRIDÆ.

Sars, when separating this family in 1897 from the Asellidæ, incidentally mentioned *Stenetrium* as belonging to the latter. Miss Richardson, in 1902, without comment transferred the genus to the newer division within the Asellota. It certainly seems to conform in many important respects to the following definition which Sars himself gives of the Janiridæ :—

"General habitus that of the Asellidæ, but the lateral parts of the cephalon always lamellarly expanded. Eyes, when present, subdorsal. Superior antennæ sometimes well developed, with the flagellum multiarticulate, sometimes very small, with rudimentary flagellum. Inferior antennæ always longer than the superior, with the peduncle six-articulate, and generally carrying a small accessory appendage (scale) outside the third joint. Oral parts normal. Legs subequal in length, with the dactylus generally bi- or tri-unguiculate ; first pair sometimes differing from the others in being prehensile. First pair of uropoda [pleopoda] in female transformed into a single, large, opercular plate; in male, constituting the median piece of the compound operculum, the lateral pieces of which are formed by the copulative appendages. The three succeeding pairs very delicate, the last pair forming simple, smooth lamellæ, the two preceding ones with the outer ramus narrow and confluent with the basal part. Uropoda biramous, more or less developed."

From this characterization Miss Richardson's account varies in one or two respects, assigning to the Asellidæ and Janiridæ in common a feature which Sars only attributes to the former, namely, that the first antennæ issue close together, which cannot be predicated of all the Janiridæ, and omitting a feature on which Sars lays stress, namely, that the peduncle of the second antenna is six-jointed. In two species of *Stenetrium* the small fourth joint of this peduncle has been clearly observed, but in three of the species, including the one first assigned to the genus, it is either not present or has been overlooked.

Sars speaks of nine or ten genera as being included in the family, and since he wrote, the genus *Carpias*, Richardson, 1902, has been added. In 1901, Dr. Ortmann ('Proc. Ac. Philad.,' p. 157) introduced the new generic name *Tole* to take the place of "*Janthe*, Bovallius," on the ground of preoccupation. In this he is followed by Miss Richardson in 1905. But the genus which Bovallius instituted in 1881 is *Ianthe*, not *Janthe*, so that no change is required. Moreover, in his key to the species of *Tole*, the first species which Dr. Ortmann mentions is "*J. bovallii* (Studer)," which was named *Ianthopsis bovallii* by Beddard in 1886 ('"Challenger" Isopoda,' vol. 17, pt. 48, p. 15, pl. 5, fig. 5). Seeing that Dr. Ortmann expressly adopts the type species of *Ianthe* as the type of *Tole*, that name must lapse as a synonym, and could not properly be revived in case either *Tole libbeyi*, Ortmann, or *Tole holmesi*, Richardson, should in future be transferred from *Ianthe* to a distinct genus.

Janira, Leach.

1814, **Janira**, Leach, 'Edinburgh Encycl.,' vol. 7, p. 434.
1886, **Janira**, Beddard, '"Challenger," Isopoda, Reports,' vol. 17, part 48, p. 5.
1897, **Janira**, Sars, 'Crustacea of Norway,' vol. 2, p. 98.
1898, **Janira**, A. O. Walker, 'Trans. Biol. Soc. Liverpool,' vol. 12, p. 280.

The species about to be described agrees in many respects with this genus as defined by Sars, but the fifth joint or wrist of the first gnathopods is not subfusiform; it is distally expanded, so as to form a kind of bidentate palm. The single specimen in the collection appears to be an adult male. It was, however, so exceedingly small and defective, having lost most parts of the second antennæ, all the last three pairs of peræopods, and the uropods, that it was not well suited for initiating a new genus. The parallel-sided peræon agrees with what is found in *Jæropsis*, *Stenetrium*, and *Iais*. Haswell's *Stenetrium inerme* may be congeneric, but the great difference in size makes specific agreement very unlikely.

Janira (?) nana, n. sp.—Plate III. (C).

The general appearance agrees with that of *Jæropsis curvicornis*, in company with which the specimen was taken, but the segments of the peræon are not so markedly separated. The pleon is nearly circular, not serrate, with a small apical convexity, on either side of which the uropods probably protrude.

The eyes are pale orange coloured, differing from those of *Iais pubescens* by having not two but thirty-eight components.

The first antennæ have a stout basal joint, the second much smaller, and the third almost like a flagellar joint; the flagellum is longer than the peduncle, its seven joints unequal in length, all slender, the last tipped with a couple of long setæ or filaments.

The upper lip is rounded, and seemed to be projected forward with the lower lip. The mandibles have a prominent cutting-plate divided into five teeth, the accessory plate on the left similarly divided, but bidentate on the right. The spine-row has five or six spines. The molar is prominent, denticulate. The three joints of the palp are subequal in length. The first maxillæ have a slender inner plate, and nine, mostly denticulate, spines on the outer. The outer and middle plates of the second maxillæ carry each three setæ. In the maxillipeds the plate of the second joint is rather large, with several plumose setæ on the distal margin, and one hook on the inner margin; the third, fourth, and fifth joints are broad, the fifth having its outer margin longer than the inner; the sixth and seventh joints are narrow.

The first gnathopods have the fifth joint much broader but not longer than the sixth, which in closing down would reach much beyond the palmar margin. The finger is much the same in all the known limbs of the peræon, having a short trunk with two distinct nails. The second gnathopods agree with the first and second peræopods in structure, but are longer, especially in the second, fifth, and sixth joints; the sixth joint is narrower than the preceding joint.

The male operculum is composed of the first two pairs of pleopods. The first pair are narrow and more or less tapering, but with a constriction below the middle. They end in two pairs of overlapping shortly lanceolate lobes. The second pair are semicircular, with a long sinuous almost filiform masculine appendix.

Length 1·5 millims. HASWELL'S *Stenetrium inerme* is described as $\frac{5}{16}$ths of an inch in length.

Locality :—Gulf of Manaar.

Jæropsis, KOEHLER.

1885, **Jæropsis**, KOEHLER, 'Ann. Sci. Nat.,' sér. 6, Zool., vol. 19, Art. 1, p. 2.
1886, **Jæropsis**, BEDDARD, '"Challenger," Isopoda, Reports,' vol. 17, p. 20.
1891, **Jæropsis**, CHILTON, 'Trans. New Zealand Inst.,' vol. 24, p. 267.
1893, **Jæropsis**, STEBBING, 'History of Crustacea,' p. 379.
1899, **Jæropsis**, H. RICHARDSON, 'Proc. U.S. Mus.,' vol. 21, p. 857.

1899, **Jæropsis**, NORMAN, 'Ann. Nat. Hist.,' ser. 7, vol. 4, p. 291.
1900, **Jæropsis**, H. RICHARDSON, 'Amer. Naturalist,' vol. 34, No. 400, p. 298.
1902, **Jæropsis**, H. RICHARDSON, 'Trans. Connect. Acad. Sci.,' vol. 11, p. 298.

By the addition, which is well justified, of *Jæra curvicornis*, NICOLET, Miss RICHARDSON is able to say in 1902 that "six species of this genus have been heretofore described." They are *J. curvicornis* (NICOLET); *J. brevicornis*, KOEHLER; *J. marionis*, BEDDARD; *J. neo-zelanica*, CHILTON; *J. lobata*, RICHARDSON; *J. dollfusi*, NORMAN; to which on the same occasion Miss RICHARDSON adds *J. rathbunæ*. *Jæra antarctica*, PFEFFER, may perhaps belong to the group, but the description and figures leave its generic location quite uncertain. All the species have many features in common. They range in size from 2 millims. to a little over 4 millims. The sides of the middle body or peræon are nearly or quite parallel, with the segments very distinctly separated. Both pairs of antennæ are short. The appendages of the peræon are truly isopodous, without any real distinction between gnathopods and peræopods. The uropods are small, carrying two minute dissimilar rami, and occupying emarginations in the distal border of the caudal shield. In the second antennæ the joint numbered second by KOEHLER, third by CHILTON, BEDDARD, and RICHARDSON, fourth by Canon NORMAN, is broadly expanded, unless *J. marionis* be an exception, for in that species the joint is figured as cylindrical rather than laminar.

It may perhaps be objected that there is a want of authority for the statement that the uropods occupy emarginations in the telsonic segment. Miss RICHARDSON indeed says that her species, *J. lobata*, differs from KOEHLER'S "in the shape of the terminal segment, which is perfectly rounded in *J. brevicornis*," while in *J. lobata* "there are two posterior incisions for the reception of the uropods." But one may easily press too far the differences shown in the habitus figures of very minute animals. When the highly magnified figure of the uropod of *J. brevicornis* is considered, it will be noticed that the outer margin is serrate, and this makes it probable that here as in other species it has its share in completing the curve of the tail-piece.

Jæropsis curvicornis (NICOLET)—Plate XI. (C).

1849, **Jæra curvicornis**, NICOLET, in GAY'S 'Hist. fis. y pol. de Chile,' Zool., vol. 3, p. 263, pl. 3, fig. 10.
1891, **Jæropsis neo-zelanica**, CHILTON, 'Trans. New Zealand Instit.,' p. 267.
1902, **Jæropsis curvicornis**, H. RICHARDSON, 'Trans. Connect. Acad. Sci.,' vol. 11, p. 298.

The body, as described by NICOLET, forms a rounded longitudinal medio-dorsal elevation. This is not particularly easy to see, but, when the specimen is placed back downwards, its rolling from side to side is evidence of the shape in question. The head corresponds with CHILTON'S description as being "produced slightly into a rostrum between the bases of the antennæ; end of rostrum emarginate, and with a rounded lobe fitting into the emargination." NORMAN says of the head in *J. dollfusi* "the anterior margin is emarginate, and in front of this the buccal organs are conspicuously projected," but his figure also shows the rounded lobe in the emargination. The figure of *J. dollfusi* shows the pleon more sharply contracted towards the apex and the sides more deeply serrate than is the case with the present species.

The eyes are not large, not dark, placed near the front angles of the head. The first antennæ have a broad basal joint, seemingly denticulate at the front corners. The second joint is much shorter and much narrower, the third smaller than the second, and the two remaining joints very insignificant, but tipped with two long filaments.

The second antennæ are of the typical form, seemingly with three short basal joints, followed by the characteristic large dilated joint with thin outer margin slightly crenulate, not strongly as in *J. dollfusi*; to this succeeds a much smaller, apically expanded joint, helping to form a double geniculation. The five remaining joints, perhaps, constitute the flagellum, but the first, which is very far the largest of them, has usually been accounted the terminal joint of the peduncle. It is, however, not very usual for the penultimate joint of the peduncle to be shorter than the joint preceding as well as the joint following it.

The upper lip has a rounded distal margin. The mandibles have the cutting edge cut into five teeth, eight spines in the spine-row, the three-jointed palp very small. The first maxillæ have three short spine-like setæ on the inner plate, and nine to eleven spines, mostly denticulate, on the outer plate. The second maxillæ are notable for the shortness of the inner plate; each of the three plates carries four apical setæ. The maxillipeds have a very large second joint with extremely broad plate, the distal margin slightly and irregularly crenulate with a gentle curvature or sinuosity, distinct from the quadrate character displayed in *J. dollfusi*. The coupling hooks are two. The fourth joint is distally produced on the inner margin, the sixth joint is very narrow and the seventh minute.

The limbs of the peræon differ but little, the fourth joint being shorter than the third, fifth, or sixth. The finger has two conspicuous nails and one that is inconspicuous.

The operculum of the pleopods in the female is broadly rounded for nearly two-thirds of its length, and then contracts to a narrowly truncate apex carrying four setules. It does not show marks of a longitudinal or a transverse suture, such as are said by Dr. CHILTON to be indistinctly visible in his specimen.

The uropods fill the emarginations of the pleon. The peduncle is more strongly serrate on the inner than on the outer margin. The inner ramus is hook-like; the outer, which is even smaller than the inner, carries a bunch of setæ.

Length 2 millims. NICOLET gives 2 lines for the length of his specimen; CHILTON about 2·5 millims. for his.

Locality :—Gulf of Manaar.

Family: STENETRIIDÆ*

Stenetrium, Haswell.

1902, **Stenetrium**, H. Richardson, 'Trans. Connect. Ac. Sci.,' vol. 11, p. 295.
1905, **Stenetrium**, Hansen, 'Proc. Zool. Soc. London,' pp. 303, 316.

Five species have been assigned to this genus, *S. armatum*, Haswell, *S. inerme*, Haswell, *S. fractum*, Chilton, *S. haswelli*, Beddard, and *S. stebbingi*, Richardson. But Haswell's *S. inerme* differs from his other species in having rounded lateral eyes, the antepenultimate joint of the maxillipeds distally narrowed, and perhaps, also by having the rostrum subacute. It appears to belong to the genus *Notasellus*, Pfeffer, 1887. The union of the other four species in a single genus is probably justifiable, though in each case some important evidence is wanting. For *S. armatum* Haswell has twice figured the mandible, and on each occasion gives no indication of its possessing a molar. In *S. haswelli*, and in the species about to be described from Ceylon, this part of the mandible is strongly developed and too conspicuous to be overlooked. In the descriptions of *S. fractum* and *S. stebbingi* the presence or absence of this structure is not discussed. For the last-mentioned species no account is given of the pleopods, and for the other species the accounts of these organs are variable or uncertain. Including the new species, which is nearly allied to what is known of *S. fractum*, the genus may be defined as follows:—

Body depressed, parallel-sided. Pleon consolidated. Head bluntly rostrate. Eyes obliquely dorsal. First antennæ short, inserted close to the rostrum on either side of it. Second antennæ elongate, with exopod on the third joint. Mandible with palp. Maxillipeds with third to fifth joints broad, sixth and seventh narrow. First gnathopods simply or complexly subchelate. Second gnathopods and all the peræopods slender, ambulatory, biunguiculate. Pleopods not in every case biramose. Uropods biramose, not adjacent, inserted apically on the telsonic segment.

The uncertainty attending the characters in some of the species makes it difficult to

* After the manuscript of this paper had passed out of my hands, I received the luminous essay, "On the Morphology and Classification of the *Asellota*-group of Crustaceans, with Descriptions of the Genus *Stenetrium*, Hasw., and its Species," by Dr. H. J. Hansen ('Proc. Zool. Soc. London,' p. 302, April 18, 1905). In this the new family Stenetriidæ is defined (*loc. cit.*, p. 315), and nine species of *Stenetrium* are described, with illustrative figures of several and a conspectus of them all. Five are new, *S. mediterraneum*, *S. serratum*, *S. occidentale*, *S. antillense*, *S. siamense*. For a more accurate account of the pleopods than I had myself arrived at I am now indebted to Hansen's instructive treatise.

produce a useful synoptic table. The following is offered, therefore, with all necessary reserves :—

	Telsonic segment without lateral notch.	1. *S. haswelli*, BEDDARD.
	Telsonic segment with lateral notch—2.	
2	First gnathopod with hind margin of wrist produced.	2. *S. stebbingi*, RICHARDSON.
	First gnathopod with hind margin of wrist not produced—3.	
3	First antenna, second joint as long as first.	3. *S. fractum*, CHILTON.
	First antenna, second joint shorter than first—4.	
4	Margin of head convex between rostrum and antero-lateral angles.	4. *S. armatum*, HASWELL.
	Margin of head angular between rostrum and antero-lateral angles.	5. *S. chiltoni*, n. sp.

In the adult male the first gnathopods strikingly distinguish *S. haswelli*, *S. stebbingi*, *S. armatum*. But in the female of the last-named species these gnathopods do not appear to differ from those of *S. fractum*, and from those of *S. chiltoni* only by the greater robustness of the hands.

Stenetrium chiltoni, n. sp.—Plate XII. (A).

The whole body, dorsally and at the sides, is beset with rather long stiff setæ. The head has a rather broad, blunt rostrum not reaching so far forward as the broad epistome. The antero-lateral angles of the head are acutely incurved, and between each of these and the rostrum the margin is produced to a point, thus forming sockets for the first antennæ. The segments of the peræon differ but little in length or breadth ; the sides are nearly straight, with the anterior angles of the first four pointing acutely forwards. The telsonic segment has the lateral margins regularly but quite microscopically serrate, and, as in all the species except *S. haswelli*, each of these margins far down is produced into a tooth. The indentation or pocket thus formed is followed lower down by a small setiferous indent, to which succeed the rounded corners of the broad apical margin, with its shallow convex projection between the uropods.

The eyes are narrowly bean-shaped, placed obliquely near the middle of the convex lateral ridges that run below the anterior lobes of the head.

The first antennæ agree closely with those of *S. armatum*, the second joint being much shorter than the first and not so long as the third ; the flagellum is obscurely six-jointed. The second antennæ have the first joint acutely produced on the outer side, but the short second joint and the longer third are not produced on either side. The exopod is conical, having its truncate point tipped with a pencil of setæ. HASWELL has apparently overlooked the second joint and described the third as produced like the first externally and distally into a slender acute process, the process ending in a hair-like appendage. He does not mention the articulated scale or exopod. For *S. fractum* CHILTON describes and figures the third joint as "produced acutely at its antero-distal angle, bearing on the outer edge an articulated appendage, which has the end rounded and supplied with a few long setæ." The small fourth joint, which is seen in the present species and in *S. haswelli*, is not noticed or figured in connexion with the other three species, as noted in the discussion of the family. The fifth and sixth joints of the peduncle are elongate, the sixth slightly longer than the fifth, the flagellum three times as long as the sixth joint, rather longer than the whole peduncle, composed of very many little scarcely separated joints, setose.

The upper lip is apically rounded. The two broad lobes of the lower lip have the usual armature of minute spines.

Left mandible with dentate accessory plate like the cutting edge but smaller, spine-row of five serrate spines; right mandible without accessory plate, unless it be represented by the first of the five spines in the spine-row; cutting edge with four or five crowded teeth, but within the mandible the new teeth in preparation for the moult are spread out in one plane; molar long and prominent; palp of three long joints, the second carrying five short spines between two long ones, the third falciform, with long spines at apex, short ones fringing the margin.

First maxilla with three spines, a little tooth and some setules on apex of inner plate, and nine more or less denticulate spines on apex of outer plate.

Second maxilla with about four slender spines on apex of outer plate, and also on that of the middle one, the rather broader and more oval inner plate carrying several spines along the inner margin.

Maxillipeds with large distally narrowed epipods reaching nearly to the apical border of the broad lobes which surmount the second joint and considerably overtop the fourth joint; the third joint is short but broad, the fourth larger than the fifth, both of them broad and widened distally, the sixth and seventh being abruptly much narrower.

The first gnathopods have the second joint moderately long, the three following joints short, the fourth subacutely produced on the front margin; the fifth joint is setose on the hind margin; the sixth joint is less than twice as long as its greatest breadth; the front margin is curved and carries a few setules, the hind margin straight, furnished with many setæ; the palm, defined by a long spine, carries several smaller pectinate spines sloping towards this palmar spine; the finger, which curves over the palm and ends in a small simple nail (broken in the specimen), has a few setules on the convex margin and several microscopical spines on the concave border. CHILTON speaks of the palm of his species as "armed with strong serrated setæ," and the finger as having the "inner edge thickly fringed with strong denticulated setæ," but these expressions may refer to the armature as it appears when very highly magnified.

The second gnathopods appear to have a round-lobed first joint; the second joint is about as long as the third and fourth combined, the third being much longer than the fourth, nearly as long as the sixth, which is slightly shorter than the fifth. The finger is less than half as long as the sixth joint; it curves to a sharp apical point, which is overhung by an unguis-like spine, while on the concave margin of the finger there is a small spine. The peræopods differ little in character from the second gnathopods, except that the second joint is less elongated and the third joint is more nearly subequal in length to the sixth. To the first and second gnathopods and first and second peræopods in one of the specimens four pairs of marsupial plates were attached, the third pair being the largest, but the fourth also of considerable size. In dissection of the pleon there came away a linear ring, which, perhaps, represents a degraded first pleon segment. Dorsally two such segments are indicated.* A small unpaired plate, square above and triangular below, without any trace of longitudinal or other suture, must be regarded as representing the first pair of pleopods.† The second pleopods are wanting, as in other females of this tribe. The third pleopods form a very large pair of biramose appendages, the peduncle small, the inner ramus branchial, with three or four setæ on the narrow apex, the outer ramus of great size, with slightly oblique transverse suture below the middle, but starting just above the apex of the inner ramus. The fourth pair are biramose, and have the oval inner branchial ramus much broader and not shorter than the outer ramus, which shows a transverse suture above the middle and has the tapering lower division fringed with several long setæ. In the fifth pair each pleopod consists of a single branchial ramus, possibly representing a coalescence of two rami, the outer margin raised and distally fringed with setæ.‡

The uropods are inserted a little within the distal margin of the telsonic segment, separated by the convexity which may be considered an equivalent of the actual telson. The peduncle is rather stout, shorter than the rami, of which the inner is the larger, both being well furnished with tufts of long setæ on sides and apex.

Description of the uropods and the complete second antennæ is based on a specimen of the same dimensions as the one figured, but which did not come to light till after the less complete example had been figured. This second specimen was straight, but a third, rather smaller specimen with it had a distortion similar to that shown in the plate.

Length 4·5 millims., breadth 1·5 millims.

Locality :—Reef, Galle, with Ascidians; and Coral banks, Gulf of Manaar.

* For the genus at large HANSEN says, "two rudimentary segments are observed in front of the large abdominal shield" (*loc. cit.*, p. 304).

† HASWELL (*loc. cit.*, p. 1010) says: "The bases of the first pair of abdominal appendages are covered in both cases by a broad plate, with a bifid apex attached to the posterior border of the last thoracic segment." By "both cases" no doubt the two sexes are intended, and "the first pair of abdominal appendages" are really the third pair of pleopods.

‡ HANSEN in his character of the family says in regard to the pleopods, "fifth pair with only one ramus, in all probability the exopod" (*loc. cit.*, p. 315).

The specific name is given out of respect to my friend Dr. Charles Chilton, whose *Stenetrium fractum* has a name only too suggestive of the mishaps to which these delicate isopods are liable. Haswell's species is described as half-an-inch long, Chilton's as about a sixth of an inch. Though it remains a little doubtful whether the species here described belongs to Haswell's genus, the possibility is also open that *S. armatum*, *S. fractum*, and *S. chiltoni* may all be the same species.

Family: MUNNIDÆ.

Pleurocope, A. O. Walker.

1901, **Pleurocope**, Walker, 'Journ. Linn. Soc.,' London, vol. 28, p. 297.

Mr. Walker remarks that "this genus differs from *Pleurogonium*, its nearest ally, in the large size and peculiar appendages of the head, the different relative proportion and structure of the antennæ, in the form of the caudal segment, and in the position and size of the uropods, which are unusually large for the family." It may, however, be observed that in the genus *Dendrotion*, Sars, the uropods are larger and more conspicuous than in the present genus.

Pleurocope dasyura, Walker.

1901, **Pleurocope dasyura**, Walker, 'Journ. Linn. Soc.,' vol. 28, p. 297, pl. 27, figs. 12 to 18.

The description by Mr. A. O. Walker, and the excellent figures by Mr. Andrew Scott which accompany it, place the identification of this species beyond doubt. Beyond verification I have nothing to add, except that the peræon displayed four stiff upstanding dorsal setæ. A point of interest would have been to ascertain the character of the mandibles. But at the very moment when I was arranging the specimen for dissection, it disappeared like a dream, and defied all the efforts made for its re-discovery.

The length was a little over 1 millim., therefore approximately the same as Mr. Walker's type specimen from the Mediterranean. It came into my hands already named by Mr. A. Scott.

Locality:—Gulf of Manaar.

Tribe: ONISCIDEA.

Family: LIGIIDÆ.

Ligia, Fabricius.

1798, **Ligia**, Fabricius, 'Supplementum Ent. Syst.,' p. 301.

INDEX.

EXPLANATION OF PLATES.

PLATE I.

A. *Heterotanais crassicornis*, n. sp.—*n.s.*, natural size of specimen figured in lateral and in dorsal view; *a.s.*, *a.i.*, upper and lower antennæ more highly magnified; *gn.* 1, *gn.* 2, first and second gnathopods; *prp.* 1, *prp.* 3, first and third peræopods; *urp.*, uropod.

All the details are to the same scale, except the separate thumb and finger of *gn.* 1, and the separate outer branch of the uropod, which are more magnified than the other parts.

B. *Leptochelia mirabilis*, n. sp.—*A.n.s.*, natural size of specimen figured in dorso-lateral view, with first gnathopod of the right side supplied from fragments; *gn.* 1, part of first gnathopod of the left side, probably belonging to the above specimen and drawn to the same scale; *a.s.*, *a.i.*, third joint of peduncle and the flagellum of upper antenna, and the lower antenna—these and the following details on a higher scale of magnification; *gn.* 2, *prp.* 5, second gnathopod and part of fifth peræopod; *plp.*, *urp.*, one of the pleopods and a uropod; *B.n.s.*, natural size of specimen figured in dorsal view, showing lower antennæ and base of right upper antenna; uropods broken.

C. *Leptochelia lifuensis*.—*a.s.* ♀, *a.i.* ♀, upper and lower antennæ of female; *gn.* 1, ♀, *gn.* 2, ♀, first and second gnathopods of female; *urp.* ♀, uropod of female; *a.s.* ♂, *a.i.* ♂, upper and lower antennæ of male; *gn.* 1, ♂, first gnathopod of male; *urp.*, uropod of male.

All the above are magnified to the same scale as the general details in Plate I., A, except the separate ramus of the male uropod, which is magnified on the same scale as the corresponding ramus in Plate I., A.

D. *Tanais gracilis*, Heller.—*n.s.*, natural size of specimen figured in lateral and dorsal views; *a.s.*, *a.i.*, upper and lower antennæ very highly magnified; *gn.* 1, *gn.* 2, *prp.* 4, first and second gnathopods and fourth peræopod; *Pl.*, *urp.*, dorsal view of pleon and uropods, to the same scale as the preceding details; *m.*, *mxp.*, mandible and maxillipeds, exopod of the latter detached and incomplete. These and the separate portions of the second gnathopod and fourth peræopod are more magnified than the other details.

PLATE II.

A. *Conilorpheus herdmani*, n. gen. et sp.—*n.s.*, lines indicating natural size of specimen figured below in dorsal and lateral view; *C.*, dorsal view of the head; *Per.s.* 7, seventh segment of peræon in dorsal view, and in lateral view with the fifth peræopod and pleopods showing below; *Pl.*, pleon in dorsal view; *a.s.*, *a.i.*, first and second antennæ; *m.*, *m.*, *mx.* 1, *mx.* 2, *mxp.*, the two mandibles, first and second maxillæ, and maxillipeds, the mandible on the right figured from the inner side; *gn.* 1, *prp.* 4, *prp.* 5, *plp.* 1, *plp.* 2, *urp.*, first gnathopod, fourth and fifth peræopods, first and second pleopods, and uropods, the last in ventral view.

The mouth organs are magnified on a higher scale than the other appendages.

B. *Hansenolana sphæromiformis* (Hansen).—*n.s.*, lines indicating natural size of specimen figured in dorsal view; *Pl.*, pleon in dorsal view; *a.s.*, *a.i.*, first and second antennæ; *m.*, *mx.* 1, *mx.* 2, *mxp.*, mandible, first and second maxillæ, maxillipeds; *gn.* 1, *gn.* 2, *prp.* 5, *plp.* 1, *plp.* 2, *plp.* 4, *urp.*, first and second gnathopods, part of fifth peræopod, first, second, and fourth pleopods, and uropods. Below the full figure of *gn.* 1 from the outside is given a more enlarged figure of the other member of the pair from the inner side. The portion of this *gn.* 1 and the portion of *prp.* 5 are enlarged on the same scale as the mouth organs.

PLATE III.

A. *Argathona normani*, n. gen. et sp.—*n.s.*, lines indicating natural size of the specimen represented by the adjoining figures in dorsal and lateral views; *Pl.*, pleon in dorsal view, more highly magnified; *a.s.*, *a.i.*, the first and second antennæ; *l.s.*, the upper lip, with the epistome surmounted by the frontal lamina; *l.i.*, the lower lip; *m.*, *m.*, the left mandible entire, and part of the right mandible; *mx.* 1, *mx.* 2, *mxp.*, the first and second maxillæ and the maxillipeds; *gn.* 1, *gn.* 2, *prp.* 5, the first gnathopod without side-plate, the second gnathopod and fifth peræopod each with its side-plate; *plp.* 2, the second pleopod.

The mouth parts are magnified on a higher scale than the other appendages, but the uropods figured in attachment to the pleon are enlarged on a lower scale than the rest.

B. *Cilicæa latreillii*, Leach, juv.—*n.s.*, lines indicating natural size of specimen figured below in dorsal and dorso-lateral aspects; *Pl.*, pleon in dorsal view; *a.s.*, *a.i.*, first and second antennæ; *l.s.*, upper lip with epistome; *mxp.*, maxillipeds; *gn.* 1, first gnathopod.

The mouth parts are more highly magnified than the other appendages.

C. *Janira* (?) *nana*, n. sp.—*n.s.*, line indicating natural size of the specimen; *Pl.*, pleon, without appendages; *a.s.*, *a.i.*, first antenna and four basal joints of second; *l.s.*, *l.i.*, upper and lower lips; *m.*, *m.*, *mx.* 1, *mx.* 2, *mxp.*, the mandibles, first and second maxillæ, and a maxilliped; *gn.* 1, *gn.* 2, *prp.* 1, first and second gnathopods and first peræopod, the finger of the first gnathopod and that of the first peræopod more enlarged; *plp.* 1, *plp.* 2, the first and (one of the) second pleopods, the two pairs together forming the male operculum.

The mouth parts are more highly magnified than the other appendages, being on the same scale as the more enlarged finger of the first gnathopod.

PLATE IV.

Æga ommatophylax, n. sp., ♂.—*n.s.*, lines indicating natural size of the specimen figured in dorsal aspect; *C.*, the head in dorsal aspect; *C.L.*, lateral view of the head in conjunction with the first two segments of the peræon; *Per.s.* 1., anterior part of first segment of peræon in dorsal view; *g.p.*, ventral plate of the seventh peræon segment, with the genital papillæ also more highly magnified; *Pl.*, Pleon in ventral view, after removal of the pleopods; *a.s.*, *a.i.*, first and second antennæ; *m.*, *mx.* 1, *mx.* 2, *mx.* 2, *mxp.*, mandible, first maxilla, second maxilla in two positions, maxillipeds in ventral aspect. These organs are magnified on a higher scale than the other details in general, and the distal parts of mandible, first maxilla, and maxillipeds are again more highly magnified. In the mandible the third joint of the palp is missing. The further enlargement of the maxillipeds is from the dorsal aspect. *gn.* 1, *gn.* 2, *gn.* 2, *prp.* 3, *prp.* 5, *plp.* 1, 2, 5, *urp.*, the first and second gnathopods, third and fifth peræopods, first, second and fifth pleopods, and the uropod. The portions of these appendages which required further enlargement are on the same scale as the principal figures of the mouth organs. Both members of the second pair of gnathopods are figured, to show the difference mentioned in the text.

PLATE V.

A. *Æga ommatophylax*, n. sp., ♀ (?).—*n.s.*, lines indicating natural size of specimen figured above in dorsal view; *C.*, ventral view of the head; *l.s.*, upper lip surmounted by the epistome and frontal lamina; *m.*, *m.*, the two mandibles, with higher magnification of a seta from second joint of palp, and of apical portion of the trunk. In both mandibles a rounded lobe is shown below the apical margin, but this lobe was only indefinitely made out. *mx.* 1, *mx.* 2, *mxp.*, first and second maxillæ, with the apices more highly magnified, and the maxillipeds.

B. *Lanocira zeylanica*, n. sp.—*n.s.*, lines indicating natural size of specimen figured above in dorsal view; *Pl.*, dorsal view of pleon more highly magnified; *a.s.*, *a.i.*, first and second antennæ; *l.s.*, upper lip; *m.*, *m.*, *mx.* 1, *mx.* 1, *mx.* 2, *mxp.* the mandibles, first maxillæ, one of the second maxillæ, and the maxillipeds; *gn.* 1, *prp.* 5, first gnathopod and fifth peræopod; *plp.* 1, *plp.* 2, first and second pleopods.

The mouth organs are more highly magnified than the other appendages.

PLATE VI.

A. *Rhiothra callipia*, Schiödte and Meinert.—*n.s.*, lines indicating natural size of male specimen figured above in dorsal view; *C.*, the head, stripped of its appendages, in dorsal view; *a.s.*, *a.i.*, the first and second antennæ, with the terminal portion of each more highly magnified; *m.*, a mandible in connexion with the epistome; *mx.* 1, *mx.* 2, *mxp.*, the first and second maxillæ and the maxillipeds; *gn.* 1, *prp.* 5, the first gnathopod and the fifth peræopod; *plp.* 2, the second pleopod, a more highly magnified portion showing the numerous coupling-spines of the peduncle and the male appendix of the inner branch. *urp.*, one of the uropods.

The mouth organs are more highly magnified than the full figures of the other appendages.

B. *Irona nanoides*, n. sp.—*n.s.*, lines indicating natural size of the female specimen figured at the centre in dorsal view; *C.*, the head, stripped of its appendages, in dorsal view; *a.s.*, *a.i.*, the first and second antennæ; *m.*, the mandible in connexion with the upper lip; *mx.* 1, *mxp.*, the first maxilla and a maxilliped; *gn.* 1, *prp.* 5, first gnathopod and fifth peræopod; *plp.*, *urp.*, a pleopod and one of the uropods.

The mouth organs are more highly magnified than the other parts.

C. *Rocinela orientalis*, Schiödte and Meinert.—*n.s.*, lines indicating natural size of specimen figured at the centre in dorsal view; *n.s.* ♂, lines indicating natural size of a full-grown male specimen, from which the figures marked ♂ are taken; *a.s.*, *a.s.* ♂, first antenna of each specimen; *mxp.*, *mxp.* ♂, one maxilliped of the smaller specimen and both maxillipeds of the larger; *gn.* 1, *gn.* 2, *prp.* 5, first and second gnathopods and fifth peræopod from the smaller specimen; *plp.* 2, second pleopod of the full-grown male; *Pl. urp.*, dorsal view of the pleon of the smaller specimen, much of the right side omitted for want of space; *Pl.* ♂, *urp.*, telsonic segment and left uropod of the full-grown male in dorsal view. The unsymmetrical right margin of the segment is seen through the figure of the transparent pleopod placed above it for convenience.

The maxillipeds are more highly magnified than the other parts.

PLATE VII.

Sphæroma walkeri, n. sp.—*n.s.*, *n.s.*, curved line indicating natural size of partially rolled specimen figured above in lateral view, crossed lines showing length and breadth of the same specimen unrolled and figured below in dorsal view; *a.s.*, *a.i.*, first and second antennæ; *l.s.*, epistome and upper lip; *m.*, *m.*, the mandibles, the palp of one separately figured on the right to display relative length of the first joint; *mx.* 1, *mx.* 2, *mxp.*, *mxp.*, first and second maxillæ, and one of the maxillipeds figured from the outer and the inner surface; *gn.* 1, *gn.* 2, the first and second gnathopods, with a more enlarged figure of the terminal part of the first; *prp.* 1, 4, 5, first, fourth and fifth peræopods; *g.sp.*, gastric spines, more highly magnified than the other details, among which the mouth organs are on a higher scale than the antennæ and limbs.

PLATE VIII.

Cilicæa latreillii, Leach.—*n.s.*, outline indicating natural size of specimen figured below in partially bent position and in lateral view; *Pl.V.*, ventral view of the pleon, omitting the pleopods; *Pl.D.*, dorsal view of the pleon with seventh segment of the peræon; *a.s.*, upper antenna; *a.i.*, *a.i.*, both members of the lower pair of antennæ, to show the casual want of symmetry; *l.s.*, upper lip and epistome from the upper (inner) side; *l.i.*, lower lip; *m.*, *m.*, the two mandibles; *mx.* 1, *mx.* 2, *mxp.*, the first and second maxillæ and the maxillipeds; *gn.* 1, *prp.* 5, the first gnathopod and the fifth peræopod; *plp.* 1, 2, 4, 5, the first, second and fifth pleopods, and part of the fourth; *int.*, a small piece of the integument from side-plate of seventh peræon segment.

The antennæ, mouth organs, and limbs in detail are drawn to a uniform scale. The fragment of the integument is more highly magnified.

PLATE IX.

A. *Cilicæa whiteleggei*, n. sp., ♂.—*n.s.*, line indicating natural size of specimen figured above in partially bent position and in lateral view; *C.D.*, dorsal view of head with first two segments of peræon not flattened out; *Pl.D.*, *Pl.V.*, dorsal and ventral views of pleon to the same scale as preceding figure; *mx.* 1, *mxp.*, first maxilla and maxillipeds more highly magnified than the other figures, with one exception; *a.s.*, *a.i.*, *l.s.*, first and second antennæ with epistome and upper lip; *gn.* 1, *prp.* 5, first gnathopod and fifth peræopod; *plp.* 1, 2, 3, *plp.* 2, *m.s.*, first, second and third pleopods, to the same scale as the antennæ and trunk limbs, but the separate male stilet of *plp.* 2 to the same scale as the maxillipeds.

B. *Cilicæa whiteleggei*, n. sp., ♀.—*n.s.*, line indicating natural size of specimen figured above, much bent and in lateral view; *Pl.*, pleon in dorsal view, with last segment of peræon and parts of the two preceding segments; *a.s.*, *a.i.*, first and second antennæ; *mx.* 1, *mxp.*, first maxilla and maxillipeds. These are more highly magnified than the other details, and more highly than the corresponding parts of the male; *gn.* 1, *prp.* 5, *plp.* 1, first gnathopod, fifth peræopod, and first pleopod.

C. *Cilicæa* sp., juv.—*n.s.*, line indicating natural size of specimen figured above, slightly bent, and in lateral view; *mxp.*, maxillipeds magnified to the same scale as those in Plate IX., B; *gn.* 1, *urp.*, first gnathopod and uropod.

PLATE X.

A. *Cilicæa beddardi*, n. sp. ♂.—*n.s.*, line indicating natural size of male specimen figured above in dorsal view; *a.s.*, *a.i.*, first and second antennæ; *l.s.*, upper lip with epistome; *l.i.*, lower lip; *m.*, *m.*, complete mandible on the right of the plate, and on the left the cutting edges and spine row of its companion; *mx.* 1, *mxp.*, first maxilla and maxillipeds; *gn.* 1, 2, *prp.* 1, 2, 3, 4, 5, the first and second gnathopods and the five peræopods in lateral view, connected together; *plp.* 1, 2, 5, the first, second, and fifth pleopods; *urp.*, uropod.

Of the details, the mouth parts are magnified on a higher scale than the other appendages.

B. *Cilicæa beddardi*, n. sp. ♀.—*n.s.*, line indicating natural size of female specimen figured above in dorsal view and not quite flat. Some of the details are from another female specimen; *juv.*, dorsal view of a young one taken out of the specimen of which the mouth organs and pleon are figured; *a.s.*, *a.i.*, first and second antennæ; *m.*, *l.i.*, *mx.* 1, 2, *mxp.*, mandible, lower lip, first and second maxillæ, and maxilliped, rather more highly magnified than the antennæ and limbs; *gn.* 1, *prp.* 1, first gnathopod and first peræopod; *Pl.*, telsonic segment and uropods.

C. *Cymodoce bicarinata*, STEBBING.—*n.s.*, lines indicating natural size of specimen figured above in dorsal view; *Pl.*, ventral view of pleon, the pleopods removed; *g.*, part of the gastric apparatus; *a.s.*, *a.i.*, first and second antennæ; *l.s.*, *l.i.*, *mxp.*, upper and lower lips and maxillipeds; *gn.* 1, *prp.* 5, first gnathopod and fifth peræopod; *g.p.*, genital papillæ from seventh peræon segment; *plp.* 2, second pleopod, with apical part of male appendix more highly magnified.

PLATE XI.

A. *Amesopous richardsonæ*, n. gen. et sp.—*n.s.* ♀, line indicating length of body and second antennæ of the female specimen figured above in lateral and below in dorsal view; *n.s.* ♂, line indicating length of body of a young, probably male, specimen figured in dorsal view. *C.T.*, *a.s.*, *a.i.*, cephalothorax (head and first peræon segment), with a first antenna and part of the second as far as base of fourth joint; the flagellum shown separately; *l.i.*, *m.*, *mx.* 1, *mx.* 2, *mxp.*, lower lip, a mandible (with part more enlarged), first and second maxillæ, and maxillipeds; *gn.* 1, *gn.* 2, first and second gnathopods. All these details are from the female specimen, the mouth organs more highly magnified than the other appendages. *prp.* 4 ♂, *plp.* ♂, *urp.* ♂, fourth peræopod, second pleopod, and uropod from a male specimen 4 millims. long. The figures drawn to the same scale as that used for the limbs of the female.

B. *Astacilla amblyura*, n. sp.—*n.s.*, line indicating length of body and second antennæ of the specimen figured in lateral view; *C.*, part of head; *Pl.*, dorsal view of pleon, showing one of the valvular uropods thrown open; *a.s.*, *a.i.*, first and second antennæ; *m.*, *mx.* 1, *mx.* 2, *mxp.*, mandible (with part more enlarged), first and second maxillæ, maxillipeds; *gn.* 1, *gn.* 2, *prp.* 5, first and second gnathopods and fifth peræopod, with the finger of each more enlarged; *plp.* 2, *urp.*, second pleopod and uropod.

C. *Jæropsis curvicornis* (NICOLET).—*n.s.*, line indicating length of specimen figured above in dorsal view; *C.*, dorsal view of head, with upper lip and one of the mandibles projecting in front; *Pl.*, ventral view of pleon, without the pleopods; one uropod more highly magnified; *operc.*, opercular plate formed by the first pleopods; *a.s.*, *a.i.*, upper and lower antennæ, with most of the lower antenna more enlarged; *m.*, *m.*, *mx.* 1, *mx.* 2, *mxp.*, the mandibles, first and second maxillæ, and maxillipeds, with the cutting plates of the mandibles and one palp of the maxillipeds more highly magnified; *gn.* 1, *gn.* 2, *prp.* 5, first and second gnathopods and fifth peræopod, with the fingers of first gnathopod and fifth peræopod more enlarged.

All the detail figures are enlarged to the same scale, but are accompanied in some instances by parts more highly magnified.

PLATE XII.

A. *Stenetrium chiltoni*, n. sp.—*n.s.*, lines indicating natural size of specimen figured below in dorsal view; *C.*, *a.s.*, *a.i.*, dorsal view of head more enlarged, with the eyes, the first antenna of the left side, part of that on the right, and parts of the second antennæ, ending with the third joint on the left, with the fourth on the right. *Pl.*, terminal part of pleon; this, with the legs and pleopods, is enlarged to the same scale as the preceding figure, while the mouth organs are more highly magnified, and the spines of the first gnathopod still more highly. *l.s.*, *l.i.*, upper and lower lips; *m.*, *m.*, *mx.* 1, *mx.* 2, *mxp.*, *ep.*, mandibles, first and second maxillæ, maxillipeds, with one epipod detached; *gn.* 1, *gn.* 2, *prp.* 1, first gnathopod, with some of the spines of the palm and finger very highly magnified; second gnathopod; first peræopod; *plp.* 1, 3, 4, 5, the first, third, fourth and fifth pleopods; *a.i'.*, second antenna from a different specimen, to which the following parts also belong;

gn. 1′, first gnathopod, showing the marsupial plate; *prp.* 5′, terminal part of fifth peræopod; *urp.*′, the uropods.

B. *Gnathia insolita*, n. sp.—*n.s.*, lines indicating natural size of specimen figured in dorsal view; *C.*, cephalic region, showing the muscles belonging to the mandibles; *Pl.*, pleon in dorsal view, with rudimentary seventh segment of peræon; *a.s.*, *a.i.*, first and second antennæ; *m.*, *mxp.*, a mandible and the maxillipeds; *gn.* 1, 2, first and second gnathopods; *plp.* 1, *plp.*, first pleopod, and one of the following pairs.

All the details are magnified to the same scale.

REPORT

ON THE

MACRURA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

JOSEPH PEARSON, B.Sc.,

DEMONSTRATOR AND ASSISTANT LECTURER IN ZOOLOGY, UNIVERSITY OF LIVERPOOL.

[WITH TWO PLATES.]

PROFESSOR HERDMAN'S collection of Macrurous Crustaceans from Ceylon consists of 53 species, of which 4 are new to science.

With the probable exception of 3 species the collection is entirely typical of a representative Indo-Pacific shallow-water fauna. *Bithynis savignyi* (SP. BATE), *Athanas nitescens*, LEACH, and *Urocaris longicaudata*, STIMPSON, appear hitherto to have had a known distribution limited to the Atlantic and the Mediterranean.

The following is a list of the species described in this Report :—

TRIBE: PENÆIDEA.

FAMILY: Penæidæ.

Penæus canaliculatus (OLIVIER).
,, *monodon*, FABRICIUS.
,, *indicus*, MILNE-EDW.
Parapenæus anchoralis (SP. BATE).
,, *incisipes* (SP. BATE).
,, *dalei*, RATHBUN.
,, *mogiensis*, RATHBUN.
,, *acclivis*, RATHBUN.
gallensis, n. sp.
Philonicus pectinatus, SP. BATE.
Sicyonia lancifer (OLIVIER).
,, *cristata* (DE HAAN).
,, *sculpta*, MILNE-EDW.

FAMILY: Sergestidæ.

Acetes indicus (MILNE-EDW.).
Leucifer typus (VAUGH. THOMPS.).

TRIBE: CARIDEA.

FAMILY: Atyidæ.

Caradina vitiensis, BORRADAILE.

FAMILY: Pontoniidæ.

Periclimenes vitiensis, BORRADAILE.
,, *danæ* (STIMPSON).
Conchodytes meleagrinæ, PETERS.
Anchistus inermis (MIERS).

FAMILY: Palæmonidæ.

Bithynis savignyi (SP. BATE).
Urocaris longicaudata, STIMPSON.

FAMILY: Latreutidæ.

Nauticaris futilirostris, SP. BATE.
,, *unirecedens*, SP. BATE.
,, *grandirostris*, n. sp.
Latreutes ceylonensis, n. sp.

FAMILY: Alpheidæ.

Alpheus idiocheles, COUTIÈRE.
,, *phrygianus*, COUTIÈRE.
,, *paraculcipes*, COUTIÈRE.
,, *paralcyone*, COUTIÈRE.
,, *miersi*, COUTIÈRE.
,, *pareucheirus*, COUTIÈRE.
,, *bis-incisus*, var. *malensis*, COUTIÈRE.
,, ,, ,, *stylirostris*, COUTIÈRE.
,, *audouini*, COUTIÈRE.
,, *macrodactylus*, ORTMANN.
,, *spongiarum*, COUTIÈRE.
,, *lævis*, RANDALL.
Synalpheus gravieri, COUTIÈRE.
Synalpheus laticeps, COUTIÈRE.
,, *biunguiculatus*, STIMPSON.
,, *comatulorum*, HASWELL.
,, *neomeris*, DE MAN.
,, *carinatus*, DE MAN.
Athanas nitescens, LEACH.
,, *orientalis*, n. sp.

FAMILY: Crangonidæ.

Ægeon cataphractus (OLIVIER).

FAMILY: Processidæ.

Processa canaliculata, LEACH.

TRIBE: SCYLLARIDEA.

FAMILY: Scyllaridæ.

Scyllarus tuberculatus (SP. BATE).
,, *sordidus* (STIMPSON).

TRIBE: THALASSINIDEA.

FAMILY: Callianassidæ.

Callianassa rotundicaudata, STEBBING.
,, *maldivensis*, BORRADAILE.
Upogebia intermedia (DE MAN).

In addition to the above species, two fresh-water forms—*Bithynis lar* and *Bithynis grandimanus*—were obtained from the River Gin Ganga. They are not included in this Report.

LIST OF STATIONS

at which Macrura were obtained, with the species collected in each:—

STATION I.—Five miles west and south-west of Negombo; 12 to 20 fathoms; bottom coarse yellow sand with a few dead shells.

Parapenæus mogiensis.

STATION III.—Two and a-half to four miles off Chilaw; 9 to 14 fathoms; bottom coarse sand and small corals.

Penæus canaliculatus, Parapenæus anchoralis, Parapenæus dalei, Parapenæus mogiensis, Parapenæus acclivis, Philonicus pectinatus, Sicyonia lancifer, Anchistus inermis, Periclimenes danæ, Alpheus miersi, Alpheus phrygianus, Alpheus audouini, Synalpheus gravieri, Synalpheus neomeris, Processa canaliculata, Callianassa maldivensis.

STATION VI.—Across Muttuvaratu Paar; depth 6 to 9 fathoms; bottom sand, with hard patches of "rock" at intervals.

Leucifer typus, Bithynis savignyi, Alpheus idiocheles, Athanas orientalis, Processa canaliculata, Upogebia intermedia.

STATION XVIII.—South-west part of Palk Bay, off Rameswaram Island and Adam's Bridge; 7 to 9 miles off shore; bottom fine soft bluish-grey mud containing casts of various Molluscan shells; depth 7 to 8 fathoms.

Penæus monodon, Parapenæus mogiensis, Leucifer typus.

STATION XX.—North part of Back Bay, Trincomalee; depth 11 to 13 fathoms; bottom hard.

Parapenæus anchoralis, Parapenæus dalei, Parapenæus acclivis, Sicyonia sculpta.

STATION XXXV.—Entrance to Galle Harbour; depth 4½ to 7 fathoms; bottom coarse sand.

Nauticaris unirecedens, Nauticaris grandirostris, Ægeon cataphractus, Scyllarus tuberculatus.

STATION XXXVI.—Galle Harbour, off Gibbet Island; depth 2 to 4¾ fathoms; bottom fine sand and mud.

Parapenæus dalei, Leucifer typus, Acetes indicus, Caradina vitiensis, Nauticaris futilirostris.

STATIONS XXXIX. to XLII.—Deep water off Galle; depth up to 100-fathom line; bottom sand, shells, nullipores.

Parapenæus dalei, Parapenæus mogiensis, Parapenæus acclivis, Parapenæus gallensis, Synalpheus laticeps, Synalpheus biunguiculatus, Synalpheus carinatus, Alpheus lævis.

STATION XLIII.—Six miles west of Kaltura; depth 22 fathoms; bottom hard sand and nullipores.

Parapenæus anchoralis, Philonicus pectinatus.

STATIONS XLVII. to XLIX.—Cheval Paar; depth 6½ to 13 fathoms; bottom sand, nullipores and dead shells.

Penæus indicus, Parapenæus anchoralis, Leucifer typus, Periclimenes vitiensis, Periclimenes danæ, Conchodytes meleagrinæ, Anchistus inermis, Alpheus phrygianus, Alpheus paraculeipes, Alpheus miersi, Alpheus spongiarum, Alpheus bis-incisus, var. *malensis, Synalpheus gravieri, Synalpheus comatulorum, Athanas nitescens, Athanas orientalis, Processa canaliculata, Callianassa rotundicaudata.*

STATION LIII.—Ten to twelve miles north of Cheval Paar, and 12 miles west of Vankali Church; depth 7½ to 9 fathoms; bottom muddy sand with dead shells.

Latreutes ceylonensis.

STATION LIV.—South of Adam's Bridge; depth 4 to 40 fathoms; bottom varied, from sand to living coral.

Conchodytes meleagrinæ, Alpheus pareucheirus, Upogebia intermedia.

STATIONS LV. to LX.—Coral reefs and pearl banks, Gulf of Manaar; depths varying from 9 to 36 fathoms; bottom nullipores and dead coral.

Parapenæus mogiensis, Sicyonia cristata, Conchodytes meleagrinæ, Alpheus miersi, Alpheus bis-incisus, var. *stylirostris, Alpheus audouini, Synalpheus gravieri, Synalpheus comatulorum, Synalpheus laticeps, Synalpheus biunguiculatus, Athanas orientalis, Scyllarus sordidus.*

STATION LXI.—Northern end of Periya Paar; depth 12 to 14 fathoms; bottom sand, nullipores and coral.

Leucifer typus, Sicyonia cristata, Synalpheus gravieri, Athanas orientalis.

STATION LXIV.—From between South Modragam and Jagerboom paars along a line south-west towards Kodramallai Point; depth $4\frac{1}{2}$ to $5\frac{1}{2}$ fathoms; bottom coarse sand, with much fine green weed and small pearl oysters.

Periclimenes vitiensis, Processa canaliculata.

Aripu Reef; depth 5 fathoms.

Parapenæus acclivis, Parapenæus anchoralis, Philonicus pectinatus, Urocaris longicaudata, Scyllarus tuberculatus.

STATION LXVII.—Off south end of Mutwal Island; depth 10 to 14 fathoms; bottom dead coral and nullipore.

Synalpheus gravieri, Alpheus paralcyone, Alpheus miersi, Alpheus macrodactylus.

STATION LXVIII.—From off Coppeluddi southwards to Navakaddua Paar; depth 8 to $18\frac{1}{2}$ fathoms; bottom nullipores, coral and muddy orbitolites sand.

Synalpheus comatulorum.

STATION LXIX.—North end of Chilaw Paar; depth 8 to 11 fathoms; bottom yellow quartz sand with some coral fragments.

Synalpheus biunguiculatus, Synalpheus comatulorum, Nauticaris unirecedens.

MACRURA.

TRIBE: PENÆIDEA.

FAMILY: PENÆIDÆ.

Penæus, FABRICIUS, 1798.

Penæus canaliculatus (OLIVIER).

Palæmon canaliculatus, OLIVIER, 'Ency. Méthod.,' VIII., p. 660, 1811.
Penæus canaliculatus, MILNE-EDWARDS, 'Hist. Nat. Crust.,' II., p. 414, 1837.
Penæus canaliculatus, var. **japonicus,** SP. BATE, '"Challenger" Macrura,' p. 245, 1888.

Locality:—Pearl banks, Gulf of Manaar (Station III.), 1 specimen very much damaged.

General distribution:—Japan, Mauritius, Figi, Australia, Ceylon.

Penæus monodon, Fabricius.

Penæus monodon, Fabricius, 'Suppl. Ent. Syst.,' p. 408, 1798.

Penæus semisulcatus, de Haan, 'Fauna Japonica,' p. 191, 1849.

Penæus carinatus, Dana, 'U.S. Expl. Exp.,' p. 602, 1852.

Locality :—Palk Strait (Station XVIII.), several specimens.

Measurements of two males and two females :—

	Males.		Females.	
From end of telson to tip of rostrum . .	162 millims.,	131 millims.	195 millims.,	135 millims.
Length of carapace and rostrum . .	52 ,,	41 ,,	60 ,,	43 ,,

Both male and female specimens possess a well-marked median groove extending from behind the rostrum to the posterior end of the carapace. Spence Bate found this groove absent in the single male which he examined. There is no doubt that the position of the ventral rostral teeth relative to the upper rostral teeth is subject to variation.

General distribution :—India, Ceylon, Singapore, Japan, Pacific and South Africa.

Penæus indicus, Milne-Edw.—Plate I., fig. 1.

Penæus indicus, Milne-Edw., 'Hist. Nat. Crust.,' II., p. 415, 1837.

(?) **Penæus merguiensis**, de Man, 'Journ. Linn. Soc.' (Zool.), vol. 22, p. 287, 1888.

Locality :—Gulf of Manaar (Station XLIX.), 5 specimens. Lengths varying from 14 millims. to 40 millims. All immature.

The rostrum in these specimens differs from the type species and has a formula $\frac{1+(6 \text{ to } 7)}{6}$. The anterior half of the rostrum bears no teeth dorsally. The rostrum is very slender and extends in front of the antennular peduncle a distance equal to half the length of the peduncle. In spite of these differences from the type species, I have referred these specimens to the above species, because there seems to be little doubt that the rostrum is subject to a great deal of variation in this form. The "Challenger" specimens differed in the form of the rostrum from Milne-Edward's species, and de Man's species, *P. merguiensis*, appears to differ in no important respects from *P. indicus*.

An examination of the various forms grouped together under this species would be valuable and instructive, and would throw some light on the value of the rostrum in classification.

General distribution :—India, Philippines, Mergui (?), Ceylon.

Parapenæus, Smith, 1885.

I have followed Smith* in separating certain species from the genus *Penæus.* The characters of the genus *Parapenæus,* which distinguish it from the genus *Penæus,* are:—(1) Endopodite of 1st maxilla is short and unsegmented; (2) 3rd maxilliped without an epipodite, and (3) the absence of branchiæ from the last thoracic segment.

Parapenæus anchoralis (Sp. Bate).

Penæus anchoralis, Sp. Bate, '"Challenger" Macrura,' p. 258, 1888.

Localities:—Pearl banks, Gulf of Manaar (Station III.), 1 specimen (♀); Trincomalee (Station XX.), 1 specimen (♀); off Kaltura (Station XLIII.), 1 ♂; Galle (Station XXXVII.), 1 ♀; Aripu Reef (Station XLIV.), 1 ♂ and 2 ♀.

Male:—Total length 40 millims., carapace and rostrum 15 millims.

Female:—Total length 64 millims., carapace and rostrum 23 millims.

Rostral formula is $\frac{(8 \text{ to } 9)+1}{0}$.

The rostrum in the females appears to be slightly longer than in the males. The female rostrum reaches to the end of the second antennular segment. In the male it only reaches slightly past the first segment.

The dorsal groove of the telson appears to be deeper in the female than in the male.

General distribution:—Pacific, Japan, Ceylon.

Parapenæus incisipes (Sp. Bate).

Penæus incisipes, Sp. Bate, '"Challenger" Macrura,' p. 257, 1888.
Parapenæus incisipes, Rathbun, 'Proc. U.S. Nat. Mus.,' vol. xxvi., p. 38, 1902.

Locality:—Gulf of Manaar, 1 specimen, ♂.

The rostrum is straight and not so deep as in the preceding species. It extends to the middle of the 3rd joint of the antennular peduncle. Rostral formula is $\frac{9+1}{0}$.

The flagella of the antennule are short and equal in length to the 2nd and 3rd joints of the peduncle.

Two obliquely longitudinal grooves cross each side of the carapace. The anterior groove becomes comparatively deep ventrally. The carapace tends to become much shallower dorso-ventrally at the anterior end.

The meropodite of the 5th pereiopod is notched at its proximal end. There is a tubercle present on the endopodite of the 2nd abdominal appendage. The 6th abdominal segment is $1\frac{1}{2}$ times as long as the 5th. The uropods are slightly notched at their outer proximal margins.

General distribution:—Philippines, Japan, Ceylon.

* Smith, 'Proc. U.S. Nat. Mus.,' VIII., p. 170, 1885.

Parapenæus dalei, RATHBUN.*

Parapenæus dalei, M. RATHBUN, 'Proc. U.S. Nat. Mus.,' vol. xxvi., p. 40, 1902.

Localities:—Pearl banks, Gulf of Manaar (Station III.), 1 ♂; Galle (Station XXXVI.), 2 ♂; south of Galle (Station XXXIX.), 1 ♂; Trincomalee (Station XX.), 1 ♂.

These specimens appear to agree with Miss RATHBUN'S diagnosis of the species. The antennular flagella are thicker than in the other species of the *velutinus* group.

Length of largest specimen (♂):—

Total length from end of rostrum to tip of telson . .	40 millims.
From tip of rostrum to end of carapace	11 ,,
Side length of carapace	9 ,,

Rostral formula $\frac{6+1}{0}$.

General distribution:—Japan, Ceylon.

Parapenæus mogiensis, RATHBUN—Plate I., fig. 2.

Parapenæus mogiensis, M. RATHBUN, 'Proc. U.S. Nat. Mus.,' vol. xxvi., p. 39, 1902.

Localities:—Pearl banks, Gulf of Manaar (Station III.), 31 specimens; west of Negombo, hauls 1 to 4 (Station I.), 15 specimens; Palk Straits (Station XVIII.), 2 specimens; south of Galle (Station XXXIX.), 1 specimen; Coral reef, Gulf of Manaar (Station LIV.), 7 specimens.

The petasma agrees with the type, but the thelycum in all the specimens shows a slight difference (see fig. 2). The appendages are more richly setose than is the case with the other species of this group. The 3rd maxillipeds do not extend as far as the tips of the antennal scales, but are situated behind them a distance equal to the length of the distal joint of the 3rd maxilliped. The antennal scale is slightly longer than the antennular peduncle.

Dimensions of males (3 specimens):—

Total length	56 millims.,	48 millims.,	61 millims.
Length of rostrum and carapace . .	18 ,,	15 ,,	19 ,,
Lateral length of carapace . . .	15 ,,	12 ,,	14 ,,

Dimensions of females (3 specimens):—

Total length	75 millims.,	67 millims.,	61 millims.
Length of rostrum and carapace . .	24 ,,	23 ,,	20 ,,
Lateral length of carapace . . .	19 ,,	18 ,,	16 ,,

Rostral formula $\frac{8+1}{0}$.

General distribution:—Japan, Ceylon.

* This and the three following species belong to the *Parapenæus velutinus* group. This collection of Ceylon Crustaceans has given me an opportunity of examining a large number of specimens belonging to

Parapenæus acclivis, Rathbun.

Parapenæus acclivis, Rathbun, 'Proc. U.S. Nat. Mus.,' vol. xxvi., p. 41, 1902.

Localities:—Pearl banks, Gulf of Manaar (Station III.), 1 specimen; Trincomalee (Station XX.), 1 specimen; south of Galle (Station XXXIX.), 1 specimen; Aripu Reef (Station LXIV.), 1 specimen.

The 3rd maxillipeds do not extend as far as the ends of the antennal scales, but they are longer than those of *Parapenæus mogiensis*. The antennal scale is slightly shorter than the antennular peduncle.

Dimensions of two females:—

Total length	88 millims.,	80 millims.
Length of rostrum and carapace	29 ,,	26 ,,
Lateral length of carapace	25 ,,	21 ,,

Rostral formula $\frac{(7 \text{ to } 8)+1}{0}$.

General distribution:—Japan, Ceylon.

Parapenæus gallensis, n. sp.—Plate I., fig. 3.

Locality:—South of Galle (Station XXXIX.), many specimens.

This species is of the *velutinus* type, and possesses certain characters which distinguish it from Dana's species and also from the species formed by Miss Rathbun.

In the form of the rostrum this species resembles somewhat closely *P. dalei*. The length of the rostrum, however, is slightly shorter than in the latter species. In typical specimens the rostrum reaches to the end of the 1st segment of the antennular peduncle. In *P. dalei* the rostrum reaches to the middle of the 2nd segment. The rostrum in *P. gallensis* is generally less toothed than in *P. dalei*, having a formula of $\frac{(5 \text{ to } 6)+1}{0}$. The anterior tooth is much smaller than the others, and in some cases is hardly perceptible. But in the form of the petasma and thelycum it differs distinctly from *P. dalei*, and approaches nearer to *P. akayebi*, showing, however, distinct differences from the latter species. The rostrum is much shorter than in *P. akayebi* and has fewer teeth. The left branch of the petasma is much more delicate and slightly longer than the right branch, and ends in a few small denticles, which, however, are only observed when the petasma is examined under a microscope. The antennal scale reaches as far forward as the extremity of the antennular peduncle. The 3rd maxillipeds are slightly longer than those of the three previous species, reaching almost to the end of the antennal scale. There is a pair of well-developed

to the *velutinus* group, and I think Miss Rathbun is justified in separating from the old species certain forms possessing various definite and distinctive characters. But it is doubtful whether these characters are of sufficient importance to warrant the formation of new *species*, and I am not sure whether their separation from *Parapenæus velutinus* merely as new varieties would not have been preferable.

spines present between the bases of the feet of the second pair. These only appear to be present in the female. The last four abdominal segments have a dorsal carina which ends in a well-developed tooth at the posterior end of the 6th segment. The sixth abdominal segment is about $1\frac{1}{2}$ times as long as the fifth and slightly shorter than the telson. The telson is slightly shorter than the uropods and has the usual number of spines, which is characteristic of the *velutinus* group. The anterior pair of spines are much smaller than the posterior three pairs, and in some specimens are only observed with difficulty.

The general surface of the body is smooth. The dimensions are :—

	millims.	millims.	millims.	millims.	millims.	millims.
Total length along mid-dorsal line from tip of rostrum to end of telson . .	49	43	50	48	59	40
Length of carapace and rostrum along mid-dorsal line	15	13	15	14	17	10·5
Side length of carapace to tip of antennular tooth	13	10	12	12	15	9
Length of sixth segment of abdomen, mid-dorsal line	7	6	7	6	7·5	5
Sex	♀	♀	♀	♀	♀	♂

It would appear that this species is in an intermediate position between *Parapenæus akayebi* and *P. dalei*.

The characters of the rostrum and of the petasma and thelycum appear to be the most reliable characters on which to base the identification of the various species of this group. Of these characters the former is not altogether trustworthy, as it is subject to some variation, and it is not impossible to obtain a series based upon the length of the rostrum and the number of rostral teeth which will connect all the species of this group. Still, in a broad manner, Miss Rathbun's method of separation holds good.

The form of the genital opercula appears to be much more constant, and each of the species is quite distinct in this respect.

The comparative length of the sixth abdominal segment does not seem to be constant enough to be of value as a basis of identification.

So that, as I have already suggested, it is, perhaps, placing too high a value upon the distinguishing characters of the various forms of the *velutinus* group to give these forms the rank of species. For the present, however, I follow Miss Rathbun.

Philonicus, Spence Bate, 1888.

Philonicus pectinatus, Sp. Bate.

Philonicus pectinatus, Sp. Bate, '"Challenger," Macrura,' p. 279, 1888.

Localities :—Deep water off Galle (Station XL.), 1 specimen ♀, 35 millims.; off

Kaltura (Station XLIII.), 2 ♀, 35 millims. and 48 millims.; Pearl banks, Gulf of Manaar (Station III.), 1 ♀, 48 millims.; Aripu Reef (Station LXIV.), 1 ♂, 35 millims.

All the specimens are much damaged, the exoskeleton apparently being poorly calcified. In all the female specimens the thoracic legs are incomplete.

In the male the petasma is comb-like as described by Sp. Bate. The antennular flagella, which were absent in the "Challenger" specimen, are typical of the genus. There are two long flagella on each antennular peduncle, the upper one being thin and the lower being very broad. The antennal scale is well developed and is longer than the antennular peduncle and twice as long as the antennal peduncle. The antennal flagellum is long and is slightly thicker than the upper antennular flagellum. The form of the rostrum and carapace agrees with Spence Bate's description. In the "Challenger" specimen the 3rd maxillipeds and the thoracic legs were absent.

In the Ceylon specimens the 3rd maxillipeds are very long, reaching well in front of the antennal scale. The distal end of the propodite is about on a level with the end of the antennal scale. All the joints are richly covered with setæ, some of which are so robust as to have the appearance of long slender spines. Of the thoracic legs the first is the shortest and only reaches to the end of the carpos of the 3rd maxilliped. The second leg reaches to the end of the propodite of the 3rd maxilliped. The third pair is missing. The fourth is very long and slender, reaching almost as far forward as the end of the 3rd maxilliped. The last pair of thoracic legs are short, being only slightly longer than the 1st pair and more slender.

Comparative lengths of appendages in male specimen:—

3rd maxilliped	12 millims.
1st thoracic leg	9 ,,
2nd ,, ,, ...	11·5 ,,
3rd (wanting)	—
4th thoracic leg	14 millims.
5th ,, ,, ...	10 ,,

General distribution:—Papua, Ceylon.

Sicyonia, Milne-Edw., 1830.

Sicyonia lancifer (Olivier).

Palæmon lancifer, Olivier, 'Encyclop.,' t. vi., p. 664.
Sicyonia lancifer, de Haan, 'Fauna Japonica,' p. 194, 1849.
Sicyonia lancifer, Sp. Bate, '"Challenger" Macrura,' p. 297, 1888.

Locality:—Pearl banks, Gulf of Manaar (Station III.), 3 ♀ and 1 ♂, average length 40 millims.

There is very little to add to Spence Bate's description and figures.

In the male the petasma is symmetrical, and there is a conspicuous triangular plate between the bases of the last three pairs of thoracic legs, having the apex produced into a long pointed tooth anteriorly like the thelycum in the female. As in the female, there is a pair of spines present at the base of each of the first two pairs of walking legs. The 3rd maxillipeds are similar in both sexes, and are more massive than the thoracic walking legs and extend slightly further forward than the tip of the antennal scale. They are richly setose and have the joints somewhat flattened. The first three pairs of walking legs are chelate and the carpopodite is only slightly longer than the propodite. The fingers are slightly longer than the palm.

General distribution :—New Guinea, Japan, Indian Ocean.

Sicyonia cristata (DE HAAN) (?).

Hippolyte cristatus, DE HAAN, 'Fauna Japonica,' pl. xlv., 1849.
Sicyonia cristata, DE HAAN, 'Fauna Japonica,' p. 194, 1849.

Localities :—West of Periya Paar (Station LXI.), 1 ♂, 25 millims. ; off Dutch Modragam (Station LVII.), 1 ♂, 25 millims. ; Coral reef, Gulf of Manaar (Station LIV.), 1 ♀, 35 millims.

I refer these specimens to the above species, although a little doubtful as to their identity. I have not been able to see figures of DE HAAN'S species, but these specimens agree closely with the description. SP. BATE evidently considered this species to be identical with *Sicyonia lancifer*. The Ceylon specimens resemble the latter species closely, but they possess characters differing from *S. lancifer*. The carapace is more arched than in *S. lancifer*. The rostrum does not turn up at the end and only reaches to the end of the eyes. The abdomen differs only from that of *S. lancifer* in not having pleural spines on each segment. The three distal joints of the 3rd maxillipeds appear to be more flattened than in *S. lancifer*, and the hepatic spine on the carapace is not so well developed as in that species.

General distribution :—Japan, Ceylon.

Sicyonia sculpta, MILNE-EDW.

Sicyonia sculpta, MILNE-EDW., 'Ann. des Sci. Nat.,' sér. 1, t. 19, p. 339, 1830.

Locality :—Trincomalee (Station XX.), 1 ♀, 17 millims.

General distribution :—Atlantic, Mediterranean, Ceylon.

FAMILY: SERGESTIDÆ.

Acetes, MILNE-EDW., 1830.

Acetes indicus, MILNE-EDW.

Acetes indicus, MILNE-EDW., 'Ann. des Sci. Nat.,' t. 19, p. 350, 1830.

Locality :—Galle Harbour (Station XXXVI.), 1 specimen, 14 millims. long, in a damaged condition, but evidently belonging to this species.

This species is generally found either in fresh water or in the brackish water of estuaries.

Distribution :—Mouth of River Ganges, Ceylon.

Leucifer, MILNE-EDW., 1837 (= **Lucifer**, VAUGHAN THOMPSON, 1829).

Leucifer typus (VAUGHAN THOMPSON).

Lucifer typus, VAUGHAN THOMPSON, 'Zool. Researches,' p. 58, 1829.
Leucifer typus, MILNE-EDW., 'Hist. Nat. Crust.,' t. ii., p. 469, 1837.

Localities:—Muttuvaratu Paar (Station VI.); Palk Strait (Station XVIII.); Galle Harbour (Station XXXVI.); south of Cheval (Station XLVII.); Cheval Paar (Station XLIX.); Periya Paar (Station LXI.). A large number of specimens from the various localities. It is probable that most of these specimens were taken in the tow-net, although the labels do not definitely say so, except in one instance.

Altogether there are some hundreds of specimens, and I am satisfied that they all belong to this species. It is worthy of note that in the separate gatherings the specimens are almost entirely of one sex.

The differences from SPENCE BATE'S description are very slight. In the male the eyes do not quite reach to the end of the 1st segment of the antennular peduncle. BATE describes them as reaching nearly to the end of the 2nd segment.

The antennal scale is shorter than the 1st segment of the antennular peduncle and about equal in length to the eye. In the females the eyes are slightly shorter than in the male, and in the females the spines at the base of the abdominal appendages are not so well developed as in SP. BATE'S figures.

General distribution:—North and South Atlantic, Pacific, Australia, Ceylon.

TRIBE: CARIDEA.

FAMILY: ATYIDÆ.

Caradina, MILNE-EDW., 1837.

Caradina vitiensis, BORRADAILE—Plate I., fig. 4.

Caradina vitiensis, BORRADAILE, 'P.Z.S.,' 1898, p. 1003.

Locality:—Galle (Station XXXVI.), 5 specimens, average length 13 millims.

These specimens appear to agree closely with BORRADAILE'S description, but the rostrum is not quite so richly toothed, having a formula $\frac{18-20}{6}$. The ventral rostral teeth are smaller than the dorsal ones. The anterior border of the eyes appears to be slightly concave in all the specimens. The chelæ of the first two pairs of thoracic legs are typical of the genus. The distal joint of the last thoracic legs has a large number of closely packed spines on its posterior border. The sixth abdominal segment is almost twice as long as the fifth, and the telson is equal in length to the sixth segment. The telson bears five pairs of small spines on its dorsal side. Each corner of the posterior border bears a small spine, and there are four pairs of longer spines arranged along the posterior border.

The Ceylon specimens are marine. BORRADAILE's Figi specimens were obtained from fresh water.

General distribution :—Figi and Ceylon.

FAMILY: PONTONIIDÆ.

Conchodytes, PETERS, 1851.

Conchodytes meleagrinæ, PETERS.

Conchodytes meleagrinæ, PETERS, 'Ges. naturf. Freunde, Berlin,' 1851.

Pontonia meleagrinæ, BATE, '"Challenger" Macrura,' p. 707, 1888.

Localities :—Cheval Paar (Station XLVIII.), four ♂; Cheval Paar (Station LIV.), two ♂ and two ♀ within *Pinna*; West Cheval (Station LVIII.) two ♂ and two ♀ from shell of *Pinna*.

The mouth parts agree with SPENCE BATE's description of the thoracic legs, the second pair are very massive and are longer than the body. The ischium, meros and carpos are subequal in length, and the three together are shorter than the palm, which is long and massive and more than twice as long as the fingers. The 1st, 3rd, 4th and 5th pairs are small, decreasing slightly in length from before backwards. The distal joint of the last three pairs is triunguiculate.

Dimensions of male specimen :—

Total length from rostrum to end of telson	24 millims.
Length of carapace and rostrum	10 ,,
1st thoracic leg	12 ,,
2nd ,, ...	27 ,,
3rd ,, ...	11 ,,
4th ,, ...	10 ,,
5th ,, ...	10 ,,

General distribution :—East Africa, Torres Straits, New Guinea, Pacific, Ceylon.

Anchistus, BORRADAILE, 1898.

Anchistus inermis (MIERS).

Harpilus inermis, MIERS, 'Zool. Coll. of "Alert,"' 1884.

Anchistus inermis, BORRADAILE, 'Ann. Mag. Nat. Hist.' (7), ii., 1898.

Localities :—Pearl banks, Gulf of Manaar (Station III.), three ♂ and two ♀; Cheval Paar (Station XLVIII), three ♂ and three ♀.

There is nothing to add to the original description. In most of the specimens the sides of the carapace and abdomen are only very slightly calcified.

General distribution :—West Australia, Ceylon.

Periclimenes, Costa, 1844.

Periclimenes vitiensis, Borradaile.

Periclimenes vitientis, Borradaide, 'Ann. Mag. Nat. Hist.' (7) ii., p. 383, 1898.

Localities:—Cheval Paar (Station XLVIII.), 1 specimen; south-east of Modragam (Station LXIV.), 1 specimen "on weed bearing oyster spat," length 18 millims.

General distribution:—Pacific, Ceylon.

Family: PALÆMONIDÆ.

Bithynis, Philippi, 1860.

Bithynis savignyi (Sp. Bate).

Brachycarpus savignyi, Sp. Bate, '"Challenger" Macrura,' p. 798, 1888.
Bithynis savignyi, Rathbun, 'Bull. U.S. Fish Comm.,' vol. 2, p. 124, 1900.

Locality:—Muttuvaratu Paar (Station VI.), 1 specimen, 12 millims.

Rostrum reaching to the end of the antennular peduncle and having a formula $\frac{7}{3}$. The antennular peduncle has the 1st joint broad and much flattened and equal in length to the sum of the 2nd and 3rd joints, which are cylindrical. The flagella are slightly longer than the peduncle. The scale of the antenna is as long as the rostrum. Thoracic legs are mostly missing, but the specimen agrees closely with Bate's description.

Up to the present this species appears to have only been recorded from the Atlantic.

General distribution:—Bermudas, West Indies, Ceylon.

Urocaris, Stimpson, 1860.

Urocaris longicaudata, Stimpson—Plate I., fig. 5.

Urocaris longicaudata, Stimpson, 'Proc. Ac. Nat. Sci. Phil.,' XII., p. 39, 1860.
Urocaris longicaudata, Rathbun, 'Bull. U.S. Fish Com.,' vol. 2, p. 126, 1900.

Locality:—Aripu Paar (Station LXIV.), 1 specimen. Female bearing eggs.

Dimensions:—

Total length from tip of rostrum to end of telson					32	millims.
Length of carapace and rostrum along mid-dorsal line					8	,,
,, ,, along mid-dorsal line					4·5	,,
,, 1st abdominal segment along mid-dorsal line					2	,,

The rostrum is straight and slightly arched, semi-transparent except on the ventral side, which is strengthened by a thick ridge. There are nine dorsal teeth, the posterior of which is a little remote from the others and is situated on the carapace. There are two minute teeth at the tip of the rostrum on the ventral side. The rostrum reaches almost to the end of the 2nd segment of the antennular peduncle. The antennular peduncle has the 1st joint broad and flattened and equal to the sum of the 2nd and 3rd. There are two flagella, the outer of which is thicker and shows signs of bifurcation at its distal extremity. The flagella are slightly longer than the peduncle. The antennal peduncle is half as long as the 1st joint of the antennular peduncle. The flagellum is about as long as the body. The antennal scale is slightly longer than the antennular peduncle. The eye stalks are long and the eyes project laterally. The carapace bears on its anterior margin a well-developed spine below the eye and also a smaller spine ventral to this. There is also a large hepatic spine. Running along the carapace are two slight grooves. The dorsal groove starts behind the antennal spine and extends half the length of the carapace. The ventral groove starts at the anterior ventral border and traverses the entire length of the carapace in a sinuous manner. The first two pairs of legs are chelate, the second pair being longer and stouter than the first. The last three pairs are long and slender and have the dactylos biunguiculate. The abdomen is more than three-fourths the length of the body and is suddenly bent at right angles at the 3rd segment, the dorsal part of which is much swollen. The dorsal side of the last three abdominal segments forms a straight line. The 6th segment is long, being about one and a half times as long as the 5th, and equal in length to the telson. The telson is slightly shorter than the uropods and ends in two spines.

General distribution :—Atlantic coasts of North America, Ceylon.

Family: LATREUTIDÆ.

Nauticaris, Sp. Bate, 1888.

Nauticaris grandirostris, n. sp.—Plate I., fig. 6.

Locality :—Galle (Station XXXV.), 2 males.

The carapace has a prominent antennal spine and a spine at the antero-lateral border. as well as a spine on the anterior border half-way between these two spines. The median dorsal surface of the carapace is occupied by well-marked teeth, which are continued on to the rostrum. There is a well-developed rostrum, two-thirds as long as the carapace. The rostrum is deep and is turned upwards at the tip. There are six teeth occupying the whole of the mid-dorsal line of the carapace and the posterior half of the rostrum. Of these teeth the posterior one is very small and not easily made out. The others are well developed, the anterior tooth being slightly smaller than the rest. Only the first two of these teeth are situated on the rostrum. The anterior half of the rostrum bears no dorsal teeth. The extremity is marked by three small teeth. On the ventral side there are six teeth, the posterior four being exceptionally well marked and deep. The antennular peduncle is short, and is only half the length of the rostrum. Its proximal joint is the largest, being equal to the sum of the other two. There are two branches to the flagellum. The inner branch reaches slightly beyond the rostrum, and the outer branch, which is slightly shorter, is much thicker and plumose, and shows signs of bifurcation at the tip. The antennular scale is almost as long as the peduncle. The antennal peduncle is as long as that of the antennule. The flagella are broken in both specimens. The scale is stout and reaches to the end of the rostrum. The mouth parts are similar in all important respects to those of *Nauticaris marionis*.

The 3rd maxillipeds reach past the end of the rostrum and have the distal joint tipped by about five well-marked spines. The proportionate lengths of the joints are similar to those of *N. marionis*. There are only four joints, and the second bears a large spine at its distal end. The 3rd joint is richly setose on its anterior face. The legs are robust, excepting the 2nd pair. The 1st pair are chelate and reach a little past the end of the antennal peduncle. The 2nd pair are long and slender and have a multi-articulate wrist. They reach to the extremity of the rostrum, the 3rd, 4th, and 5th pairs are similar to one another in form, decreasing slightly in length from before backwards. The 5th leg reaches to the base of the antennal scale. The carpos of each of the last three pairs bears a blunt process at the anterior distal border. The dactylos ends in two larger spines, and bears several smaller spines on its posterior border. The abdomen is robust and bent at right angles at the 3rd segment. There are two spines on the ventral side of each of the first four abdominal segments, and on the ventral side of the 5th and 6th segments there is a long median spine pointing backwards. The 6th abdominal segment has a well-marked movable spine at each of its posterior lateral borders, and also bears two well-marked spinous processes on its posterior border overhanging the telson. The uropods are slightly longer than the telson. The 2nd abdominal segment has a small transverse groove in the mid-dorsal line.

The telson tapers somewhat posteriorly and has a slightly grooved dorsal surface carrying two pairs of spines. The posterior border bears two pairs of spines and numerous long hairs.

Dimensions (measured along mid-dorsal line):—

From tip of rostrum to end of telson	50	millims.
Rostrum and carapace	20	,,
Carapace	11	,,
1st abdominal segment	2	,,
2nd ,, ,,	4	,,
3rd ,, ,,	8	,,
4th ,, ,,	$5\frac{1}{2}$	,,
5th ,, ,,	2	,,
6th ,, ,,	$3\frac{1}{2}$	,,
Telson	$5\frac{1}{2}$	,,

Nauticaris unirecedens, Sp. Bate.

Nauticaris unirecedens, Sp. Bate, '"Challenger" Macrura,' p. 608, 1888.

Localities:—Galle (Station XXXV.), 5 specimens; Jokkenpiddi Paar, 1 specimen.

These specimens agree closely with Sp. Bate's description, but the rostral formula is slightly different. The Ceylon specimens are not so richly toothed as the "Challenger" specimens.

Rostral formula $\frac{5+1}{2}$.

Average length 35 millims. (3 males and 3 females).

General distribution:—Hong Kong, Ceylon.

Nauticaris futilirostris, Sp. Bate—Plate II., fig. 8.

Nauticaris futilirostris, Sp. Bate, '"Challenger" Macrura,' p. 606, 1888.

Locality:—Galle Harbour (Station XXXVI.), 4 specimens taken in the tow-net. Average length 11 millims.

These specimens agree with Spence Bate's description; the posterior rostral tooth is slightly more remote from the others than in Bate's figure.

General distribution:—Off Japan, Ceylon.

Latreutes, Stimpson, 1860.

Latreutes ceylonensis, n. sp.—Plate II., fig. 7.

Locality:—Cheval Paar (Station LIII.), 1 specimen, 8 millims. long.

The latero-anterior edge of the carapace is furnished with 4 spines at each side. There is a deep rostrum, almost equal in length to the carapace. The carapace and rostrum together equal half the length of the body. The rostrum dips slightly downwards and bears dorsally two prominent teeth above the eyes and a tooth of equal size slightly behind the pointed anterior extremity. In addition to these there are about a dozen smaller teeth on the dorsal side which are only detected under a microscope. The under side of the rostrum is smooth. Each antennular peduncle is short, the proximal joint being as long as the sum of the other two. Each antennule has two flagella which reach to the end of the rostrum, and are slightly longer than the peduncle. The inner flagellum is slightly thicker and shorter than the outer. The antennal peduncles are slightly longer than those of the antennules. The antennal scale is large and broad, and extends slightly beyond the rostrum. Each scale is furnished with half-a-dozen small spines along its outer border. The antennal flagella are missing.

The first two pairs of thoracic legs are chelate. The 2nd pair are longer than the 1st pair and have the wrist 3-jointed. The remaining three pairs of legs are more strongly made, the meros and carpos being very broad. The dactylos terminates in two very robust spines.

The 3rd, 4th, and 5th abdominal segments each has the posterior part of its dorsal surface raised into a blunt keel. The abdominal segments are all subequal. The telson is long and narrow, and is twice as long as the 6th abdominal segment. It ends posteriorly in a blunt median spine, and is furnished with a lateral spine halfway along each side. The uropods are as long as the telson.

Family: ALPHEIDÆ.

Synalpheus, Sp. Bate, 1888.

Synalpheus gravieri, Coutière.

Synalpheus gravieri, H. Coutière, 'Fauna of Maldives and Laccadives,' p. 870, 1905.

Localities:—Pearl banks, Gulf of Manaar (Station III.), 7 specimens; Cheval Paar (Station XLVIII.), 19 specimens; Coral reef, Gulf of Manaar (Station LIV.), 2 specimens; west of Periya Paar (Station LXI.), 2 specimens, "commensal with dendritic Alcyonarian;" off Mutwal Island (Station LXVII.), 2 specimens.

The rostral and orbital spines are equal in length, the latter sometimes being slightly divergent. The rostrum does not reach the end of the 1st joint of the antennular peduncle. The 1st joint of the antennular peduncle is equal to the sum of the other two, the 2nd joint is twice as long as the 3rd. The antennular scale is a little longer than the 1st joint of the peduncle. The antennal peduncle is one and one-third times as long as the antennular peduncle. The outer spine of the antennal scale is as long as the antennular peduncle.

The 3rd pair of legs has a small spine on the dorsal side of the dactylos. The meros has 4 spines on its ventral posterior border. The propodite has about 8 spines on its posterior border.

General distribution:—Maldives, Ceylon.

Synalpheus laticeps, Coutière.

Synalpheus laticeps, Coutière, 'Fauna of Mald. and Lacc.,' p. 874, 1905.

Localities:—Coral reef, Gulf of Manaar (Station LIV.), 1 specimen; deep water off Galle (Station XL.), 4 specimens.

Orbital spines equal in length to rostrum, but slightly broader. Rostrum shorter than 1st joint of antennular peduncle. First joint of antennal peduncle longest, the 2nd and 3rd joints subequal. Antennular scale a little longer than the 1st joint of the antennular peduncle. The antennal peduncle one and one-fifth times as long as the antennular peduncle. Antennal scale as long as antennal peduncle.

Third legs having the dactylos biunguiculate, posterior border of propodite armed with about a dozen spines.

This species approaches closely to *S. biunguiculatus*.

General distribution:—Maldives, Ceylon.

Synalpheus biunguiculatus, Stimpson.

Synalpheus biunguiculatus, Stimpson, 'Proc. Acad. Phil.,' p. 31, 1860.

Localities :—Deep water off Galle (Station XL.), 2 specimens; Coral reef, Gulf of Manaar (Station LIV.), 14 specimens; Chilaw Paar (Station LXIX.), 1 specimen.

This species differs principally from the preceding species in (1) the rostrum and orbital spines being shorter in comparison with the 1st joint of the antennular peduncle; (2) the antennal scale is shorter, and only reaches to the end of the antennular peduncle; (3) the posterior border of the telson has a deeper curve.

General distribution :—Maldives, Philippines, Pacific, Ceylon.

Synalpheus carinatus, de Man—Plate II., fig. 9.

Synalpheus carinatus, de Man, 'Arch. f. Naturg.,' I., 1887.
Synalpheus carinatus, Coutière, 'Ann. des Sci. Nat.,' (8), t. ix., 1899.

Locality :—Deep water off Galle (Station XLI.), 2 specimens.

The rostral spine is more than twice the length of the orbital spines and reaches nearly to the end of the 1st segment of the antennular peduncle. The rostrum and the orbital spines point slightly upwards. The 1st segment of the antennular peduncle is slightly longer than the 2nd and twice as long as the 3rd. The antennular spine reaches to the end of the 1st peduncular segment. The antennal peduncle is slightly longer than the antennular peduncle. The antennal scale reaches to the end of the antennular peduncle. The large chela is on the left side. The carpopodite has a strong ventral spine. The dorsal side of the palm ends in a fairly prominent spine, immediately in front of the digits. This spine seems more strongly developed than in the type species.

In the 3rd pair of legs there is a spine on the ischiopodite, the meros is almost as long as the carpos and propodite combined, and bears 8 well-developed spines on the posterior border. The carpos bears a single spine at the distal end of its posterior border. The propodite has 8 spines on the posterior border. The dactylos is bifid.

In the male each of the abdominal pleura is produced posteriorly into a spine. In the female the pleura are rounded. The telson is as long as the uropods and tapers slightly. It carries two pairs of spines on the dorsal side and there are 3 spines at each of the posterior corners.

General distribution :—Indian Ocean.

Synalpheus comatulorum, Haswell.

Synalpheus comatulorum, Haswell, 'Cat. Austr. Crust.,' p. 187, 1882.
Synalpheus falcatus, Sp. Bate, '"Challenger" Macrura,' p. 574, 1888.

Localities :—Navakaddua Paar (Station LXVIII.), 4 specimens; Gulf of Manaar (Station LIV.), 3 specimens; Chilaw Paar (Station LXIX.), 1 specimen "on *Antedon*"; south end of Cheval Paar (Station XLVIII.), 1 specimen.

Rostrum twice as long as the orbital spines, and reaching to end of the 2nd segment of antennular peduncle. Antennular scale reaching past the middle of the 2nd peduncular joint. The antennal peduncle is longer than the antennular peduncle. The antennal scale is as long as the antennular peduncle.

General distribution :—Australia, Maldives, Ceylon, Pacific.

Synalpheus neomeris, DE MAN.

Synalpheus neomeris, DE MAN, 'Zool. Jahr.,' 9. Bd., p. 734, 1897.

Locality :—Gulf of Manaar (Station III.), 1 specimen.

I have referred the single specimen to the above species. It appears to differ but slightly from *Synalpheus gravieri*.

General distribution :—Red Sea, Bay of Bengal, Madagascar, Australia, Japan, Maldives, Pacific, Ceylon.

Alpheus, FABRICIUS, 1778.

Alpheus idiocheles, COUTIÈRE.

Alpheus idiocheles, H. COUTIÈRE, 'Fauna of Mald. and Lacc.,' p. 883, 1905.

Locality :—Muttuvaratu Paar (Station VI.), 3 specimens.

Carapace deep. Rostrum short, and separated from the orbits by deep grooves. The orbits are well formed and unarmed. In the antennule the 1st and 3rd segments of the peduncle are subequal, each being half as long as the 2nd segment. The antennular scale reaches to the middle of the 1st peduncular segment. The antenna is short, only reaching three-fourths of the way along the 2nd joint of the antennular peduncle. The antennal scale is nearly as long as the antennal peduncle. The large chela is peculiar, having the dactylos portion of the digit hammer-shaped, and the propodite part short as in *Alpheus malleodigitatus*. The 3rd and 4th legs are robust and have the propodite armed with 5 spines, and end in a simple dactylopodite.

General distribution :—Maldives, Ceylon.

Alpheus phrygianus, COUTIÈRE.

Alpheus phrygianus, COUTIÈRE, 'Fauna of Mald. and Lacc.,' p. 886, 1905.

Localities :—Gulf of Manaar (Station III.), 2 specimens; Cheval Paar (Station XLVIII.), 2 specimens.

Somewhat similar to *A. idiocheles*. The eyes are not so prominent. The antennæ are comparatively longer, reaching to the end of the 2nd segment of the antennular peduncle. The antennal scale reaches to the middle of the 2nd segment of the antennular peduncle. The digits of the large chela are similar in shape to the preceding species, but the palm is broader.

General distribution :—Maldives, Ceylon.

Alpheus paraculeipes, COUTIÈRE.

Alpheus paraculeipes, COUTIÈRE, 'Fauna of Mald. and Lacc.,' p. 894, 1905.

Locality :—Cheval Paar (Station XLVIII.), 1 specimen.

Rostrum poorly developed. Orbits unarmed. 1st and 3rd segment of the antennular peduncle equal. 2nd segment twice as long as each of the others. Antennular scale not reaching to the end of the 1st segment. Antennal peduncle one and one-fourth times as long as the antennular peduncle. Spine of antennal scale as long as antennular peduncle.

The 3rd legs have the ischiopodite unarmed. The posterior border of the meropodite is fringed with about 20 very delicate spines and ends distally in a strong spine. The carpopodite has on its posterior external border 1 spine and about 5 hairs, and on its internal border about 15 long, fine spines. The propodite has 7 pairs of spines on its posterior border and is fringed with hairs anteriorly. The dactylos is slightly biunguiculate.

General distribution :—Maldives, Ceylon.

Alpheus spongiarum, Coutière.

Alpheus spongiarum, Coutière, 'Fauna of Mald. and Lacc.,' p. 895, 1905.

Locality :—Cheval Paar (Station XLVIII.), 1 specimen.

This species is very closely allied to *A. paraculeipes*, but differs in the form of the 3rd pair of legs. The meropodite is not so stout as in the latter species. Along the posterior border of the meropodite there are 7 very long hairs with about 15 short hairs between. The carpopodite has no spine on the posterior border and the dactylos is not bifid.

General distribution :—Maldives and Ceylon.

Alpheus paralcyone, Coutière.

Alpheus paralcyone, Coutière, 'Fauna of Mald. and Lacc.,' p. 895, 1905.

Locality :—Off Mutwal Island (Station LXVII.), 2 specimens.

Rostrum is well defined and slightly carinated behind. The 1st and 3rd segments of the antennular peduncle are subequal, and the 2nd segment is one and a half times as long as each of the others. Antennular scale very small, antennal peduncle one and one-third times as long as the antennular peduncle. The spine of the antennal scale reaches past the end of the antennular peduncle. The palm of the large chela is massive, narrowing distally, and the digits are very short.

In the 3rd pair of legs the ischiopodite is armed with a single spine, the meropodite is large and ends distally at the posterior border in a large spine. The carpopodite has about 4 spines on its posterior border, and the propodite has 8 pairs of spines. The dactylos is bifid.

General distribution :—Maldives, Ceylon.

Alpheus miersi, Coutière.

Alpheus miersi, Coutière, 'Fauna of Mald. and Lacc.,' p. 903, 1905.
Alpheus rapax, var. **miersi**, Coutière, 'Bull. Soc. Entom. de France,' No. 7, p. 166, 1898.

Localities :—Pearl banks, Gulf of Manaar (Station III.), 3 specimens; Cheval Paar

(Station XLVIII.), 3 specimens; Coral reef, Manaar (Station LIV.), 2 specimens; off Mutwal Island (Station LXVII.), 1 specimen.

Rostrum well developed, reaching to the end of the 1st segment of the antennular peduncle. The 2nd segment of the antennular peduncle is slightly longer than the 1st or 3rd, which are subequal. The antennal peduncle and scale are equal in length and slightly longer than the antennular peduncle. In the Ceylon specimens the large chela is massive and the palm is broad. The meropodite is spiny on its inferior border.

The 3rd pair of legs has the ischiopodite with a single spine. The meros is smooth except for a small spine at the posterior distal border. The carpos is smooth. The propodite bears five pairs of spines. The dactylopodite is half the length of the propodite and slightly curved.

General distribution :—Pacific, Japan, Maldives, Ceylon.

Alpheus pareucheirus, Coutière.

Alpheus pareucheirus, Coutière, 'Fauna of Mald. and Lacc.,' p. 906, 1905.

Locality :—Haul 6, south of Adam's Bridge (Station LIV.), 1 specimen.

The antennules and antennæ do not differ greatly from those of the preceding species. Their peduncles are not so stout. The rostrum is only two-thirds as long as the 1st segment of the antennular peduncle. The large chela differs in having the palm grooved on both sides. The meropodite is smooth. In the 3rd legs the ischiopodite does not bear a spine. The meropodite is smooth and not so robust as in the previous species. The carpos is smooth and the propodite bears 8 long spines on the posterior border. The dactylopodite is long and slightly curved.

General distribution :—Maldives and Ceylon.

Alpheus bis-incisus, var. **malensis**, Coutière.

Alpheus bis-incisus, var. **malensis**, Coutière, 'Fauna of Mald. and Lacc.,' p. 910, 1905.

Locality :—Cheval Paar (Station LXIX.), 1 specimen.

The rostrum is triangular, and separated from the orbits by two well-marked grooves. It reaches to the middle of the 1st segment of the antennular peduncle. The 1st and 2nd segments of the antennular peduncle are subequal and slightly longer than the 3rd. The antennular scale almost as long as the 1st peduncular segment. The peduncle and scale of the antennal are equal in length and slightly longer than the antennular peduncle.

I have placed this specimen in Coutière's variety merely on the characters of the rostrum and antennæ. The large chela and most of the legs are missing.

General distribution :—Maldives and Ceylon.

Alpheus bis-incisus, var. **stylisostris**, Coutière.

Alpheus bis-incisus, var. **stylisostris**, Coutière, 'Fauna of Mald. and Lacc.,' p. 911, 1905.

Locality :—Coral reef, Gulf of Manaar (Station LIV.), 1 specimen.

This specimen appears to differ mainly from the variety *malensis* in the form of the rostrum, which is much narrower in proportion to its length.

General distribution :—Maldives and Ceylon.

Alpheus audouini, Coutière.

Alpheus edwardsi, Audouin (see Coutiere, 'Fauna of Mald. and Lacc.,' p. 911).
Alpheus audouini, Coutière, 'Fauna of Mald. and Lacc.,' p. 911, 1905.

Localities :—Off Mutwal Island (Station LXVII.), 2 specimens; Pearl banks, Gulf of Manaar (Station III.), 6 specimens; Coral reef, Manaar (Station LIV.), 3 specimens.

This species, which Coutière has separated from *Alpheus edwardsi*, resembles the latter species in the form of the rostrum and in the appearance of the antennæ. The large chela has the dorsal and ventral projections of the palm rounded, thus differing from those of *A. edwardsi*, which are spiny.

General distribution :—Red Sea, Indian Ocean, Malay Archipelago, New Zealand, Sandwich Islands.

Alpheus macrodactylus, Ortmann.

Alpheus macrodactylus, Ortmann, 'Zool. Jahrb.,' V., p. 473, 1890.

Locality :—Off Mutwal Island (Station LXVII.), 1 specimen. Related to *A. edwardsi* and *A. euphrosyne*.

The rostrum is well pronounced and more than half as long as the 1st segment of the antennular peduncle. Of the joints of the antennular peduncle the 2nd is the longest, being twice as long as the 3rd and nearly twice as long as the 1st. The antennular scale is broad and reaches nearly to the end of the 1st segment of the peduncle. The antennal peduncle and scale are equal in length and extend as far forward as the end of the antennular peduncle. The large chela differs from that of *A. edwardsi* in the absence of a dorsal spine and in the comparatively greater length of the digits.

General distribution :—Australia, Ceylon.

Alpheus lævis, Randall.

Alpheus lævis, Randall, 'Journ. Acad. Nat. Sci. Phil.,' vol. viii., p. 141.

Localities :—Galle (Station XXXV.), 4 specimens; Coral reef near Galle (Station XL.), 5 specimens.

Well-developed rostrum reaching to the end of the 1st segment of the antennular peduncle. Orbits armed with two small spines. Segments of the antennular peduncle subequal. Antennular scale slightly longer than the 1st peduncular segment. Antennal peduncle and scale equal to one another and slightly longer than the antennular peduncle. The large chela has a massive palm, laterally compressed, with no dorsal or ventral notches. The carapace is deep.

General distribution :—Indian Ocean, Pacific, Australia.

Athanas, Leach, 1813.

Athanas nitescens, Leach.

Athanas nitescens, Leach, 'Edin. Encycl.,' vol. vii., p. 432, 1813.

Athanas veloculus, Sp. Bate, '"Challenger" Macrura,' p. 529, 1888.

Locality :—Cheval Paar (Station XLVII.), 1 specimen.

This specimen clearly belongs to the well-known species in which must be included—according to Coutière—Bate's species *Athanas veloculus.*

This record is of interest, inasmuch as the distribution of this species up to the present has been limited, so far as I can ascertain, to the Atlantic and Mediterranean.

General distribution :—Atlantic coasts of America, Cape Verd Islands, north-west Europe, Mediterranean, Ceylon.

Athanas orientalis, n. sp.—Plate II., fig. 10.

Localities :—Cheval Paar (Station XLVIII.), 2 specimens; Muttuvaratu Paar (Station VI.), 1 specimen; Coral reef, Gulf of Manaar (Station LIV.), 2 specimens; west of Periya Paar (Station LXI.), 2 specimens.

This species is in many respects very closely allied to *Athanas dimorphus*, Ortmann, and *A. minikoensis*, Coutière, but there are differences in the form of the extra- and infra-orbital spines, as well as in the form of the 1st pair of legs which lead me to place it in a new species.

The rostrum extends as far as the end of the 2nd joint of the antennular peduncle. The infra-corneal spine reaches slightly beyond the eye, and the extra-corneal spine just reaches to the anterior end of the eye, so that it is difficult to make out in side view. There is no supra-corneal spine.

The antennule has the 3 joints of its peduncle subequal, and its scale reaches as far forward as the end of the 2nd peduncular joint and the tip of the rostrum. The antennal peduncle reaches to the end of the 2nd joint of the antennular peduncle, and its scale, which is very broad, reaches slightly beyond the end of the antennular peduncle. In the small leg of the female the carpopodite and the propodite are about equal in length, but the latter is more robust. The meropodite is one and a half times as long as the carpopodite. The ischiopodite has a long delicate spine at the distal end of its dorsal border, and there are five smaller spines along the same border. This is the only specimen bearing the 1st pair of legs, so that it is not possible to compare these appendages in the male.

This species differs from the two allied species in the length of the rostrum and also in the relative lengths of the extra- and infra-orbital spines, as well as in the length and robustness of the joints of the small leg. The other two species are devoid of spines on the ischiopodite of that limb.

Family: CRANGONIDÆ.

Ægeon, Guérin-Méneville, 1835
(= Egeon, Risso, 1816).

Ægeon cataphractus (Olivier).

> **Cancer cataphractus**, Olivier, 'Zool. Adriatica,' p. 30, 1792.
> **Egeon loricatus**, Risso, 'Crust. de Nice,' p. 100, 1816.
> **Crangon cataphractus**, Milne-Edw., 'Hist. Nat. Crust.,' vol. 2, p. 343, 1837.
> **Ægeon cataphractus**, Ortmann, 'Zool. Jahrb.,' vol. 5, p. 535, 1890.

Locality :—Galle (Station XXXV.), 1 specimen.

This single specimen agrees closely with the type species, and also with Henderson's species, *Ægeon orientalis*,* in most respects. The latter species differs from the above species only slightly with regard to the teeth present on the carapace, and in the absence of the small hepatic groove on the sides of the carapace. Since the Indian species was formed from the characters of a single specimen, it is by no means improbable that this specimen merely represents an extreme variation of the parent species. In all other characters, excepting the two above mentioned, *Ægeon orientalis* agrees with *Ægeon cataphractus.*

General distribution :—Mediterranean, Senegambia, South Africa, Ceylon.

Family: PROCESSIDÆ.

Processa, Leach, 1815
(= Nika, Risso, 1816).

Processa canaliculata, Leach.

> **Processa canaliculata**, Leach, 'Malac. Podoph. Brit.,' p. 641, 1815.
> **Nika edulis**, Risso, 'Crustacés de Nice,' p. 85, 1816.
> **Nika canaliculata**, Desmaret, 'Consid. gén. Crust.,' p. 231, 1825.
> **Nika bermudensis**, Rankin, 'Ann. N.Y. Acad. Sci.,' XII., p. 536, 1900.

Localities :—Pearl banks, Gulf of Manaar (Station III.), 6 specimens; Muttuvaratu Paar (Station VI.), 1 specimen; 10 miles west of Cheval (Station XLVII.), 2 specimens; Cheval Paar (Station XLVIII.), 4 specimens; south-east of Modragam (Station LXIV.), 2 specimens.

None of these specimens appear to differ in any marked degree from the ordinary characters of the species.

General distribution :—Madeira, Japan, West Indies, Gulf of Mexico, South Africa, North-west Europe, Ceylon.

* J. R. Henderson, 'Trans. Linn. Soc.,' 2nd series (Zoology), vol. v., part 10, p. 446, and plate 40, figs. 16 and 17, 1893.

Tribe : SCYLLARIDEA.

Family : SCYLLARIDÆ.

Scyllarus, Fabricius, 1793
(= **Arctus**, Dana, 1852).

Scyllarus tuberculatus (Sp. Bate).

Arctus tuberculatus, Sp. Bate, '"Challenger" Macrura,' p. 70, 1888.

Localities :—Pearl banks, Gulf of Manaar (Station III.), 1 specimen, female ; Galle (Station XXXV.), 3 females and 1 male ; Aripu Reef (Station LXIV.), 1 specimen.

Characterised by large tuberculations on the mid-dorsal line of the carapace and of the first 3 pairs of abdominal segments. Those of the second abdominal segment are very distinctive of the species.

In this genus all the legs of the male end in a simple dactylos, and in the female there is a poor developed chela on each of the 5th legs. The propodite digit is not very well developed.

General distribution :—Australia and Ceylon.

Scyllarus sordidus (Stimpson).

Arctus sordidus, Stimpson, 'Proc. Acad. Nat. Sci., Phil.,' p. 8, 1860.

Locality :—Coral reef, Gulf of Manaar (Station LIV.), 3 females and 1 male.

General distribution :—Pacific and Ceylon.

Tribe : THALASSINIDEA.

Family : CALLIANASSIDÆ.

Callianassa, Leach, 1813.

Callianassa rotundicaudata, Stebbing.

Callianassa rotundicaudata, Stebbing, 'Marine Invest. of S. Africa.' Crust., ii., p. 41, 1903.

Locality :—Cheval Paar (Station XLVIII.), 1 specimen, 18 millims. long.

General distribution :—South Africa, Ceylon.

Callianassa maldivensis, Borradaile.

Callianassa maldivensis, Borradaile, 'Fauna of Mald. and Lacc.,' vol. ii., part 3, p. 753.

Locality :—Gulf of Manaar (Station III.), 1 specimen, 24 millims. long.

This specimen is imperfect, but it agrees closely with the above species.

General distribution :—Maldives and Ceylon.

Upogebia, Leach, 1813.

Upogebia intermedia (de Man).

Gebiopsis intermedia, de Man, 'Journ. Linn. Soc.,' vol. 22 (Zool.), 1888.

Localities :—Haul 6, south of Adam's Bridge (Station LIV.), 2 males and 1 female; Muttuvaratu Paar (Station VI.), 1 male.

This species is characterised by the possession of a large number of denticulations on the cephalic portion of the carapace, and also by the anterior thoracic legs being richly clothed with long and very fine setæ.

The anterior portion of the carapace covers the small eyes and projects almost to the end of the antennular peduncle. The peduncle of the antennule is 3-jointed, the 3rd being slightly longer than the 1st and two and a half times as long as the 2nd. The 3rd joint is more slender than the other two. There are 2 flagella one and a half times as long as the peduncle. The inner flagellum is slightly longer and less robust than the outer. The antennal peduncle is slightly longer than that of the antennule and is also 3-jointed. The 1st and 2nd joints are equal and slightly longer than the 3rd joint, which is also less robust than the other two. The 1st and 2nd joints are richly clothed with long fine setæ. The eyes are small and project nearly to the end of the 2nd antennular peduncle. The middle of the carpos of the 1st legs reaches to the end of the rostrum. The appendages agree with de Man's description. The abdomen is large, being twice as long as the carapace and proportionally broad. The segments are subequal, the 2nd and 6th being slightly longer than the others. The telson is broader than long and equal in length to the uropods.

General distribution :—Mergui, Ceylon.

REPORT

ON THE

ANTIPATHARIA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

PROFESSOR J. ARTHUR THOMSON, M.A., UNIVERSITY OF ABERDEEN,

AND

JAMES J. SIMPSON, M.A., UNIVERSITY OF ABERDEEN.

[WITH ONE PLATE.]

THE collection of Ceylonese Antipatharians here reported on was made in 1902 from the Pearl Oyster Banks in the Gulf of Manaar, by dredging within the 100-fathom line off Trincomalee and off Galle. The localities are more precisely referred to in Professor HERDMAN'S "Narrative" in Part I. of the General Report (1903).

The collection is a small one, including thirteen species, but nine at least of these seem to be new. The list is as follows:—

FAMILY: ANTIPATHIDÆ.

SUB-FAMILY: CIRRIPATHINÆ.

**Cirripathes* (?), n. sp.

SUB-FAMILY: ANTIPATHINÆ.

**Antipathes gallensis*, n. sp.
**Antipathes gracilis*, n. sp.†
Antipathes abies, GRAY.
**Stichopathes ceylonensis*, n. sp.
**Stichopathes contorta*, n. sp.
**Stichopathes papillosa*, n. sp.
Stichopathes gracilis, GRAY, var. *spiralis*, nov.
Stichopathes echinulata, BROOK.
**Antipathella rugosa*, n. sp.
**Antipathella elegans*, n. sp.
**Antipathella irregularis*, n. sp.
**Antipathella ceylonensis*, n. sp.

* Those marked with an asterisk are reported as new.

† NON *Antipathes gracilis*, GRAY (1860) = *Antipathella gracilis*, GRAY;
NON *Antipathes gracilis*, KOCH (1889) = *Antipathes mediterranea*, BROOK (1889).

Before proceeding to the systematic report, we would make a few general observations:—

(*a*) In the detailed classification of Antipatharia much importance has been attached to the form and distribution of the spines on the axis. But it does not seem to have been sufficiently emphasised that there is considerable variation in both of these characters in the different parts of the colony. Thus in the branched forms the nature of the spines, the number seen from one aspect, and the arrangement of these in spirals or longitudinal rows in no way correspond on the larger branches and on the pinnules (Plate, fig. 2). In the simple colonies this is even more emphasised, *e.g.*, in *Cirripathes* (?) (Plate, fig. 8) those at the base are arranged irregularly (*a*), those about the middle of the colony have a distinct linear arrangement (*b*), while those near the tip are disposed in whorls around the stem (*c*). This distinction has been illustrated relative to the species described, in the figures on the Plate, where two views, and in one case three, have been given. This is of great importance where species are determined from fragmentary specimens.

(*b*) This difference between stem, branches, and pinnules is also borne out with regard to the size and shape of the polyps. In many of the specimens, on the stem and larger branches, the polyps are almost circular and disposed irregularly, their diameter being less than that of the axis, while on the pinnules they are elongated and rectangular, exceeding in breadth the diameter of the axis. Their distribution also varies in the different portions of the colony; they are often separated by considerable intervals on the older parts, while on the pinnules they may be closely apposed. The length and degree of transparency of the tentacles does not seem to be a safe criterion, varying as it does with the degree of contraction and the mode of preservation.

(*c*) Of some general interest and deserving further investigation is the extraordinary modification shown in the spines of several species. The general Antipatharian spine is simple or papillose, but in some species they pass from an elongated sinuous form through a series of gradations to an antler-like growth and eventually simulate a tree-like structure (Plate, fig. 1, *a–f*). This has been previously noted, *e.g.*, by Carter for *Antipathes spinosa* (Carter), but no interpretation has been suggested. It may be due to a pathological condition, and in some cases where branched spines were observed it was noted that a sponge-like growth surrounded the axis, or it may be the result of irregular regeneration of broken spines. It is particularly well seen at the base of *Antipathes gracilis*, n. sp., and on *Antipathella rugosa*, n. sp. In *Antipathes abies*, Gray, a forking of the spines was occasionally observed.

(*d*) The polyps of *Antipathes abies*, Gray, which were unknown when Mr. George Brook described the "Challenger" Antipatharia, are very well preserved in some of Herdman's specimens, and we have therefore given a full description and figures of their external features (Plate, fig. 4).

(*e*) A fact which may yet prove to be of some importance is that in *Stichopathes papillosa*, n. sp., belonging to a genus typically simple, a knob-like projection, about 6 centims. from the base, indicates, without doubt, the remains of a branch.

(*f*) The various specimens show a considerable number of epizoic animals:—*e.g.*, Sponges, Polyzoa, Serpula-tubes, Spirorbis-tubes, Cirripede-galls, stalked Barnacles, Corals, and in one case a young pearl oyster.

Cirripathes (?) n. sp.—Plate, fig. 8.

A very large simple colony, 135 centims. long, with a diameter varying from 3·75 millims. at the base to 0·75 millim. at the top. The basal portion, which is attached to a stone, is expanded into a circular disc 16 millims. in diameter. The stem is sinuous for the first 35 centims., but after that it is coiled into three distinct spirals, with diameters of 10 centims., 9 centims., and 8 centims. respectively—the corresponding heights being 10 centims., 8 centims., and 7 centims. The total height of the colony is 65 centims. The colour of the axis at the base is jet black, changing gradually to a golden brown. It is hollow, at least in the upper region, and is covered with distinctly papillose spines, which are 0·1 millim. in height near the top of the colony, but shorter and thicker further down. They are arranged irregularly near the base, where twenty can be counted from one aspect, but further up a linear arrangement seems to predominate. Near the top they are disposed in verticils round the stem, about one and a half to two lengths apart, and the number from one aspect diminishes to nine. They are of a paler colour than the stem.

As there are no polyps on the specimen, it is impossible to decide its position with security, beyond saying that it is either a *Stichopathes* or a *Cirripathes*, but the arrangement of the spines and the general nature of the colony would point towards its being a new species of *Cirripathes*, which we would refrain from naming. The specimen was trawled at Station XXIV., off Foul Point, outside Trincomalee, 46 fathoms.

Antipathes gallensis, n. sp.—Plate, fig. 15.

A fragmentary portion of a colony, 8 centims. high and 4·5 centims. broad. The branching is irregular, giving the whole a shrub-like appearance, suggestive of the broom. The main stem is short and sinuous, but a large branch arises about midway up and constitutes the greater part of the colony. The general colour is black towards the base, but rusty brown in the smaller branches, which are long and slightly flexed. The diameter of the axis is 1 millim. at the base and tapers very gradually.

The spines on the main branch are low and conical, standing perpendicularly and arranged irregularly, so that no definite number could be counted from any one aspect. Those on the smaller branches are compressed and thorn-like—the upper margin being sub-horizontal, while the lower is convex. They are comparatively short, about one-third the diameter of the branch, and are disposed in fairly steep sinistrorse spirals and longitudinal rows, those in a row being about two lengths apart. The rows do not consistently alternate, but a quincuncial arrangement is infrequent. Five can be clearly seen from one aspect, while the tip of another is visible, seven making a complete revolution.

The polyps on the stem are large and circular, with a low truncated oral cone and prominent mouth opening, which is also circular. The tentacles are arranged radially and slightly distant on the branches, the polyps are arranged in a single longitudinal row and are elongated in the direction of the axis—this being specially marked on the smaller branchlets. They are very large and prominent, measuring 1·5 millims. in length. The projection bearing the circular oral opening is large and cylindrical. The tentacles when fully expanded are very long, but in most of the polyps they are contracted—being then thick set and conical. They are disposed in three pairs, the sagittal pair being inserted low down in the polyp. On the larger branches the distance between the polyps is equal to about one-half their length, but this diminishes considerably on the branchlets, where the polyps are more elongated though still of the same general character.

This species differs from any known form both in its mode of branching and in the arrangement of the spines.

Locality :—Station XLI., deep water off Galle.

Antipathes gracilis, n. sp.—Plate, figs. 7 and 14.

A small, complete, delicate whin-like colony, 6 centims. high and 1 centim. in diameter, attached by a small expansion. It consists of a main axis, 1 millim. in diameter at the base, tapering gradually to a fine point. The lower 13 millims. of the stem are devoid of branches. On the next 2 centims. small branches bearing pinnules arise sub-horizontally from three sides. These are almost straight and taper to a point, the longest being 8 millims. The remainder of the stem bears branches arising on all sides, but apparently in no definite order. The branches gradually diminish in length towards the apex of the colony. The colour of the axis is golden yellow when seen with transmitted light.

The spines on the bare part of the axis are slightly elongated, compressed, and triangular, the upper margin being sub-horizontal, the lower convex. They are arranged irregularly, about nine being visible from one aspect, at intervals of about one length. Many of the basal spines show an antler-like or dendriform mode of branching. On the upper part of the stem they are disposed in more regular longitudinal lines, five being now visible from one aspect. On the pinnules they are still of the same type, but more elongated, and with a greater slope towards the axis. They seem to be arranged irregularly, but a closer examination reveals a hint of a steep dextrorse spiral. They are about one and a half lengths apart, and seven is a typical number from one aspect.

The polyps are all arranged so as to face in one direction, and it is worthy of note that this is away from the bare portion of the axis mentioned before. On the stem they are disposed irregularly and are somewhat circular, the tentacles being inserted almost equidistant from the mouth opening. The oral projection is very prominent and cylindrical, and the mouth opening is circular. On the branches and pinnules they are very much elongated, and the tentacles are disposed in three pairs, the sagittal pair being inserted slightly below the level of the others; but apart from this the structure is much the same as in those on the stem. On the branches they are separated by intervals about equal to their breadth, but on the pinnules this distinct demarcation disappears.

This species approaches most closely to *Antipathes spinosa* (Carter) (*Hydradendrium spinosum*, Carter), but differs from it both in the mode of branching and in the character of the spines. In *A. spinosa* (Carter) the polyps had not been observed when Mr. Brook described the "Challenger" Antipatharia.

Locality :—Deep water off Galle.

Antipathes abies, Gray—Plate, fig. 4.

Several very fine specimens of this species are included in the Ceylon collection. All are of the bottle-brush, or, more correctly, fir-tree type.

One magnificent colony (A) is 65 centims. in height, the breadth varying at the different parts. At 20 centims. from the base the diameter is 15 centims., but this gradually diminishes to 10 centims. at 40 centims. from the base, and tapers almost to a point at the top of the colony. It is attached to a stone, and for the first 11 centims. the axis is bare. Above this there are about a hundred principal branches of varying sizes. The colour of the axis is black, but owing to the thin cœnenchyma it presents a greyish surface. The branches have a superficial rusty or reddish-brown tint, getting paler towards the top of the colony. The diameter of the axis at the base is 5 millims.; it gradually tapers upwards.

A smaller colony (B) is also very perfect and compact. It is 30 centims. high and 15 centims. in diameter about half way up. From that point it ascends in a symmetrical cone. From the first 9 centims. of the stem the branches have been broken off, but the knob-like ends have been quite overgrown by the cœnenchyma.

The axis is 7 millims. in diameter at the base and tapers to a point. The colour is identical with that of (A).

The main stem is slightly curved and the branches are longest on the concave surface, so that in contour the colony is symmetrical.

The mode of branching is by no means regular. At some places there are signs of a spiral arrangement, but this is often interrupted by extra offshoots. The branches arise very close together, often only 2 millims. apart. They are mostly in planes at right angles to the main stem, but some are turned upwards and others downwards, interlocking, so that no two overlap. At their point of origin they are about 2 millims. in diameter and present the crescentic shape characteristic of the species. A typical branch from the concave side of the stem has a chord of 10 centims., a perpendicular height of 2 centims., and a breadth of 5 centims. The branches bear branchlets, and even secondary and tertiary branchlets, extending in a plane at right angles to the long axis of the branch. The secondary branches arise in a distinctly alternate manner, the planes bearing them enclosing an angle of 60°. The branches do not all curve in one direction, but for the most part they diverge in pairs, so that the tips of two approximate, enclosing an ellipse. The secondary branches arise in a similar manner, so that the maximum of surface is exposed on the contour of the colony.

The spines vary greatly in the different parts of the colony. On the black main stem they are disposed very irregularly, and are very small and abundant. This is also the case on the paler branches, and owing to the conical form the whole gives the impression of a moss-rose stem. They are horny in colour and have a black broadened part where they arise from the stem. The smaller branchlets are transparent and hollow, being of a golden-brown colour with a faint reddish tinge. Here the spines are much longer, being bluntly conical and pointing slightly upwards. They are arranged in distinct longitudinal lines, which in reality are the result of steep sinistrorse spirals, five or six being seen from one aspect. They are almost equal to the radius of the pinnule and are about one length apart.

The polyps, which were unknown when Mr. Brook described the "Challenger" Antipatharia, are of two kinds, according to the position in the colony. On the main stem and larger branches they are scattered irregularly on the concave surface, being thus within the general network of the circumference. They are visible to the naked eye and appear as six-rayed stars. They are almost circular, the tentacles being disposed on six radii. The tentacles vary considerably in size, according to the state of retraction. On the pinnules the polyps are arranged on the convex surface and thus all face outwards. They are more rectangular in shape than on the stem, being elongated in the direction of the long axis of the pinnule. The tentacles are disposed in three pairs, those in the sagittal axis being inserted very far down and standing mostly perpendicular to the polyp. The distance between the polyps is approximately the same as the length of a polyp, viz., 0·9 millim. In all cases the mouth is situated on a prominent cylindrical projection, the oral cavity being elongated in the direction of the sagittal axis.

Cirripede galls are of frequent occurrence, and these are overgrown with the mud-coloured cœnenchyma, also bearing spines. Numerous barnacles are attached to the larger branches.

Another almost complete colony (C), without the basal attachment, is 22 centims. in height and 9 centims. in diameter at the widest portion. The main stem is bent so as to form two arcs. The length of the branches on the concave surface of the stem greatly exceeds that on the convex, so that the contour is symmetrical.

The spines are typical both as to size and arrangement. A few are bifurcated, but as this is only of local occurrence it does not justify the dignity of a new species. The polyps are also typical, but in some, owing to contraction, the tentacles are very inconspicuous.

A beautiful complete colony (D), closely resembling a young larch tree, was attached to a stone by a disc-like expansion. It is 30 centims. in height, the greatest width being 10 centims. The first 10 centims. are bare, owing to the branches having been broken off, and the next 6 centims. bear branches only on one side. The diameter of the axis at the base is 2 millims. The spines and polyps are typical. A great number of barnacles are attached to the branches.

Another complete colony (E) was more of the bottle-brush type. It is 13·5 centims. high, with branches down to the very base—breadth 6·5 centims. The diameter of the axis at the base is 1·5 millims., tapering to 0·5 millim. The branching is not so regular as in the others, but in no case do the branches overlap. The spines and polyps agree closely with the typical forms, but the colour of the branches is slightly darker.

Localities:—Station LXIII., west of Periya Paar, in the Gulf of Manaar, 40 fathoms; and Station XXIV., off Foul Point, outside Trincomalee, 46 fathoms.

Stichopathes ceylonensis, n. sp.—Plate, fig. 9.

A small, complete, simple colony attached to a piece of stone by an almost spherical expansion. It is 8·5 centims. long, but only reaches a height of 6 centims. owing to its spiral course.

The diameter at the base is 1 millim., and this diminishes to 0·75 millim. at the tip of the colony, so that the tapering is very slight. The stem is translucent, golden brown near the base, becoming paler upwards; it is hollow throughout its entire length. The first 4 centims. are straight, followed by two open sinistrorse spirals 1·3 centims. in diameter.

The spines near the base are short, triangular, and compressed, standing at right angles to the stem, disposed irregularly, but mostly one to two lengths apart. Four may be seen from one aspect. On the upper half of the colony the spines are of the same type, but considerably longer in proportion to the thickness of the stem, being equal to about one-third of the diameter. They are arranged in steep sinistrorse spirals and longitudinal rows about two to three lengths apart. Four can be distinctly seen from one aspect, while the tips of two others are visible, so that there are eight altogether in a spiral.

The polyps are typical and prominent. The tentacles are very long and transparent, and the sagittal pair are inserted almost diametrically opposite. They are separated by a distance of about one-half the length of a polyp. Towards the top of the colony they are alternately large and small—the smaller forms being probably younger. They are also separated by greater intervals.

This specimen comes nearest to *S. pourtalesi*, Brook, but cannot be identified with it. It differs, for instance, in not having "crowded" polyps, and the arrangement of the spines is also different.

Locality :—Station LV., outside the pearl banks, Gulf of Manaar.

Stichopathes contorta, n. sp.—Plate, fig. 3.

A simple slender colony, 40 centims. long, attached to a piece of rock. It is very sinuous, growing first upwards, then coiling and turning downwards, again twisting and starting on an upward course. Thus the total height is only 7 centims., and the growing point is but 3 centims. above the base. The diameter of the axis is 1 millim. and is uniform throughout. The colour is blackish with a brown tinge, the axis is hollow down to the disc of attachment.

The spines are of a pale horny colour, and are slightly but distinctly papillose. They are arranged in longitudinal rows in the lower portion about two to two and a half lengths apart, seven being seen from one aspect. Further up, a distinct steep spiral arrangement may be seen—seven being required to form one revolution. Those in one longitudinal row are about two lengths apart.

The polyps are arranged on one side of the axis at intervals of about 1 millim., which is also the length of a polyp.

The oral cone is prominent and the mouth opening circular. The tentacles are about 0·5 millim. in length even in a contracted state. Young polyps are frequent between the larger older forms.

This species is nearest *S. lutkeni* (Brook), but differs from it both in the number and arrangement of the spines.

Locality :—From off Galle and onwards up West Coast of Ceylon.

Stichopathes papillosa, n. sp.—Plate, figs. 6 and 13.

A complete, simple, robust colony attached to a piece of rock. It is 38 centims. long and attains a height of 18 centims.

The first 4 centims. are almost straight, the remainder coiled into ten distinct dextrorse spirals, 13 millims. in diameter and averaging 14 millims. high. The axis is 1·25 millims. in diameter at the base and tapers gradually to 0·5 millim. at the top. At a distance of 6 centims. from the base there is a projection which indicates the remains of a branch. The colour is black at the lower part, becoming lighter towards the apex.

The spines are slightly but distinctly papillose, and vary in number in the different parts of the colony; thus at the base fourteen can be counted from one aspect, whereas at the top only ten and points of two are visible. Those near the base are conical and covered throughout their whole length with small papillæ, but on the upper part of the colony the papillæ are confined to the apex of the spines, which in this region are more flattened and triangular. They are arranged in distinct dextrorse spirals, and are about one length apart.

The cœnenchyma is very thick on the side devoid of polyps.

The polyps are about 1 millim. in diameter and almost form a square—the directive tentacles being inserted at the corners and the sagittal pair at a slightly lower level. The tentacles are very long when expanded, but on contraction form low, broad cones. The oral cavity is large and elliptical, being elongated transversely. The oral cone is large and prominent. The polyps in the upper part of the colony are close together, but lower down they are separated by a distinct groove. Smaller polyps, probably young forms, are of not infrequent occurrence.

The lower part of the stem is covered with Polyzoa.

The distinctive features of this new species are: the thickness of the cœnenchyma, the papillose character of the spines, together with the dextrorse spiral arrangement, and the distance between the spines as compared with their length.

Locality:—Deep water off Galle and onwards up West Coast of Ceylon.

Stichopathes gracilis, Gray, var. **spiralis**, nov.

A very slender, simple colony, 58 centims. in length. Owing to its sinuous and spiral course, it only attains a height of 20 centims. It is attached by a broadened basal expansion. The first 5 centims. are straight; succeeding this there is a sinuous portion 17 centims. long, followed by two distinct spirals 6 centims. in diameter and about 6 centims. high. The diameter at the base of the stem is 1 millim. and this measurement scarcely diminishes even at the tip. The colour appears black, but when viewed with transmitted light has a decided reddish-brown tinge. The stem is hollow to the very base.

The spines near the base are very much damaged, but appear to be short, somewhat flattened cones, irregularly arranged, a comparatively small number (about 5) being visible from one aspect. About the middle portion of the colony they are short and triangular, standing perpendicularly to the axis, and disposed in irregular longitudinal rows and dextrorse spirals. The spines in a longitudinal row are separated by about two lengths. Six can be counted from one aspect.

Near the top of the colony the spines are much smaller and inclined to the axis, the upper margin being concave and the lower convex. They are arranged in very steep dextrorse spirals, nine in one spiral being seen from one aspect.

The distance between any two varies greatly—from two to four lengths. The polyps are arranged in a single longitudinal row, and are very large and prominent, measuring about 2 millims. in length. They are slightly elongated, the oral cone being low but distinct. The tentacles are disposed in three pairs, the sagittal pair being inserted at a considerably lower level than the others. They are very long when fully expanded, but when contracted are low, broad and conical; others are like large spheres with a small filiform projection. They arise from somewhat spherical bases. The polyps are separated by a very small interval, but an annular constriction between each pair seems to pass round the stem.

This specimen agrees on the whole with *Stichopathes gracilis*, but as it differs in some details regarding the spines, and conspicuously in having a spiral course, it has seemed convenient to name a new variety.

Locality :—Deep water off Galle.

Stichopathes echinulata, Brook.

This species is represented by a simple colony, incomplete at the base, 26 centims. long, very irregular and sinuous, so that the total height is only 8 centims. The growing point is turned downwards and is only 5 centims. above the lowest portion. The colony tapers very markedly from 1·5 millims. to 0·5 millim. The colour of the axis is almost black.

The spines are very short, compressed and directed upwards. They are arranged in very steep spirals, the distance between two rows being almost the same as that between any two on a spiral, so that they show a quincunx grouping. The distance between any two is equal to about four lengths of a spine.

The polyps are typical, but the sagittal tentacles are relatively distant from the oral cone. They are separated by a distance about two-thirds of the length of the polyp.

This species has been previously recorded from Mauritius.

Locality :—Station LX., outside the pearl banks, Gulf of Manaar.

Antipathella rugosa, n. sp.—Plate, figs. 5 and 11.

There are two specimens of this new species in the collection, both slightly damaged. The larger of these is 19 centims. high and 13 centims. broad. It is branched mostly in one plane, and consists of two main branches which arise dichotomously from a short main stem 1 centim. long. One branch arises at 60°, while the second after a short distance at right angles to the stem bends upwards and runs closely parallel to it. The first is broken off about 7·5 centims. from its origin, and the second at a slightly lower level. At the point of fracture large secondary branches are given off, and it is noteworthy that the angles of inclination are the same as for the first two, viz., 60° and 90°. The primary and secondary branches give off pinnæ in a strictly alternate manner, and these again bear pinnules. The pinnæ converge slightly. The whole plane of branching is slightly curved and the polyps arise on the convex surface.

Near the base the axis is opaque and black in colour, but this passes gradually into a transparent horny yellow in the upper parts of the colony. The smaller branches and pinnules are hollow.

The spines on the large branches are short and slender, tapering in a marked degree. They are slightly inclined to the axis, and are arranged irregularly, about fifteen being visible from one aspect. Those on the pinnules are very thin and delicate, fairly long, conical in shape, and inclined to the axis at an acute angle. They are arranged in distinct longitudinal lines which are the expression of steep dextrorse spirals. Five can be seen from one aspect. The distance between two in a longitudinal line is equal to about two lengths.

On the main branches the polyps are arranged irregularly, and are almost circular, the tentacles, which are moderately long, being equidistant from the oral cavity. On the pinnules the polyps are arranged on the convex surface and are elongated in the direction of the axis. The distance between the polyps varies. In some places they are crowded together, while in others they are separated by a distance equal to their breadth. In all cases the body of the polyp is large. The oral cavity is circular and borne on a very prominent cylindrical projection. The tentacles are large and inclined outwards, being very rugose in appearance, due probably to the state of retraction. They are arranged in three rows of two each—the sagittal tentacles being inserted far down.

The colony bears numerous epizoic animals :—Cirriped galls and stalked barnacles, tubes of *Spirorbis*, several Polyzoa, a Sponge, and a young pearl oyster shell. It is worthy of note that the majority of these are overgrown by the cœnenchyma and bear both polyps and spines.

A second specimen of this species—also slightly damaged—is 14·5 centims. in height and 8 centims. in breadth. It consists of a main stem with a basal attachment from which three branches arise on one side at about 60°. These are slightly arched, and the longest, which is 12 centims. in length, has a diameter of 1 millim., tapering to a point. The whole colony is flabellate. In its spines, polyps, and colour it agrees with the other specimen.

This species should be included in Brook's Group A ("Challenger" Report), but it does not approach closely to any of species already included in that group.

Localities :—Deep water off Galle, and Station VIII., deep water, in Gulf of Manaar.

Antipathella elegans, n. sp.—Plate, fig. 10.

A complete, very graceful colony, 13 centims. in height, with a maximum breadth of 5·5 centims. at a distance of 9·5 centims. from the base, which is expanded into a disc-like attachment. At a distance of 3 centims. from the base the main stem bifurcates and the two subsidiaries develop almost equally. The mode of branching is not uniform. The general appearance is dichotomous, but this breaks down in several places where three or four branches arise on one side. The stem and branches are black at the base, gradually passing into golden brown near the apex. All the branches and pinnules are hollow. The diameter of the branches varies very little in the different parts, and the gentle tapering gives the whole colony a very graceful appearance. The axis is 1 millim. in diameter at the base. The spines are short and very much compressed, being somewhat triangular with a very broad base. The upper margin is sub-horizontal, while the lower is convex. They are arranged in very steep sinistrorse spirals and longitudinal rows, the distance between two in a row being four lengths, while that between two in a spiral is one length. From one aspect five can be seen quite distinctly along with the tips of other two, making in all eight spines in a circumference. The spines near the base are shorter, smaller and more conical. They are disposed in sinistrorse spirals and distinct rows, the distance between two in a row being about four lengths.

The polyps are typical. They are situated in a single row on the branches and branchlets, and are very much elongated in the direction of the axis. The distance between the polyps varies in the different parts; they are in some places close together, in others separated by intervals equal to half their length. Very often a line passing through the oral cones is a line of spines, and the polyps occupy a length corresponding to four spines in a longitudinal row. The oral cone is very prominent and the mouth opening is circular. The tentacles vary in different parts according to their state of contraction. The sagittal pair are inserted rather far down, corresponding to spines 1 and 5 on a circumference. In some cases the tentacles have spherical terminations.

This species is chiefly distinguished by the nature and arrangement of the spines, which are markedly different from those of other species, but also by the polyps, which, though typical of the genus, nevertheless bear specific characters.

Locality :—Station LX., outside pearl banks, Gulf of Manaar.

Antipathella irregularis, n. sp.—Plate, fig. 12.

This species is represented by a small complete colony and a fragment. The former is 4 centims. in height and 6 centims. in breadth, the general shape being sub-flabelliform. The branches arise mostly in two planes, but occasionally in a third, leaving one quadrant bare. Frequent fusions occur.

The other specimen consists of a short main stem with a disc of attachment at the base. The stem is only 2 centims. high, and the axis tapers from 1 millim. at the base to a very fine point at the apex. The branches are longer than the main stem and constitute the greater part of the colony. They arise on three sides at a very large angle, so that the expansion is mostly lateral.

The colour of the axis near the base is black, but it passes through a dark amber to a horny yellow in the branchlets. The secondary branches are somewhat elongate and slender and appear slightly flabellate.

The spines near the base of the stem are short, conical, and irregularly disposed; but on the branches a definite arrangement can be traced. There they are compressed and triangular in form, arranged sometimes in a dextrorse and sometimes in a sinistrorse spiral. They are about two lengths apart and five can be seen from one aspect.

The polyps are rather small and are disposed on one side of the stem and branches, so that none appear on the quadrant devoid of branches. They are oval in shape, being elongated in the direction of the axis. The oral cone is low but definite; the mouth is scarcely discernible. The tentacles are comparatively long and delicate, having a broad base and tapering markedly. The distance between the polyps varies, but in most cases there is a valley-like depression between them, giving the surface an undulating appearance.

The distinctive features of the species are the irregular mode of branching, the character and arrangement of the spines, and the nature of the polyps.

Locality:—Station XXIV., off Foul Point, outside Trincomalee, 46 fathoms.

Antipathella ceylonensis, n. sp.—Plate, fig. 2.

Of this species there are two specimens—one complete colony and a broken part of another.

The former is a small, graceful, delicate colony, complete but for the tips of some of the branches. It is 7 centims. in height and 5 centims. in breadth. The main stem is 5 centims. long, and the axis is about 1 millim. in diameter above the disc of attachment, which is 1 centim. broad. The branching is approximately in one plane, and there are signs of fusion in three places. About 1 centim. from the base two branches arise, almost of the same diameter as the main stem. One of these is 4 centims. long, the other is 6 centims. and bears a comparatively large secondary branch. The branching is irregular, but nearly alternate. The branchlets are very slender and arise at different angles, very seldom at an angle less than 60°, and most frequently at right angles.

The spines near the base are short, conical, and distant; those on the pinnules are larger and thorn-like, the lower margin of the compressed triangle being convex. They are equal to about half the diameter of the pinnule and are about three lengths apart. The arrangement is in steep sinistrorse spirals, four being seen from one aspect.

The polyps are disposed on one side of the branches and are elongated in the direction of the long axis. The tentacles are short and are arranged in three pairs, the sagittal pair being inserted at a level slightly lower than the others. The oral opening is circular, and is elevated on a prominent cylindrical projection.

This species comes nearest to *A. tristis* (Duch.), but is distinguishable from it both in spines and polyps.

Locality:—Station XXIV., off Foul Point, outside Trincomalee, 46 fathoms.

REPORT

ON THE

POLYZOA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

LAURA ROSCOE THORNELY
(ZOOLOGY DEPARTMENT, UNIVERSITY OF LIVERPOOL).

[WITH ONE PLATE.]

INTRODUCTORY.

THERE are at least 116 species of Polyzoa in this collection from Ceylon. Of these, 31 had already been found in Indian seas, 32 of the remainder have been reported from Australian waters, 13 from the China Sea, and several from neighbouring but outlying waters to the east, west, and south of the Indian Ocean. Of the rest, some have not been, I believe, recorded from nearer than Florida (7 species), the Queen Charlotte Islands (1), and the Mediterranean Sea (2). Several are cosmopolitan in their distribution, and 19 are British species. Finally there are 16 species and 1 variety which I consider to be new, and which will be described below as :—

Onychocella cucullata, n. sp.
Schizoporella avicularis, n. sp.
,, *viridis*, n. sp.
,, *collaris*, n. sp.
Rhyncopora incisor, n. sp.
,, *corrugata*, n. sp.
Gemellipora protrusa, n. sp.
Lepralia multidentata, n. sp.
,, *purpurea*, n. sp.
Lepralia nitida, n. sp.
,, *ceylonica*, n. sp.
,, *fissa*, n. sp.
,, *triangula*, n. sp.
Smittia trispinosa, var. *protecta*, n.
Phylactella spiralis, n. sp.
Retepora pocillum, n. sp.
Cellepora compacta, n. sp.

Polyzoa are well distributed round the coast of Ceylon. No less than 89 species were found in the Gulf of Manaar, and 32 off Galle. Many of them were obtained in several distinct localities and in great abundance, while other species are represented by one colony each. From the large number of specimens obtained, and the manner in which the colonies are crowded together on the foreign bodies to which they are attached, it may be inferred that the Ceylon seas are a favourable locality for the Polyzoa; but at the same time, from the multiplication of avicularia and of spinous processes of various sorts which characterise these Ceylonese specimens, the impression is derived that there is severe competition and that the colonies have a struggle to hold their own. It is possible that the avicularia, spines and other roughnesses on the surface of the zoarium may protect such species from being smothered by overgrowths of colonies of their own kind; and this seems a very necessary protection in this case, and the need may account for some of the extraordinary calcareous outgrowths of the zoœcia which I have to describe below.

Comparatively few collections of Polyzoa have been made in Indian seas. HINCKS (**16**) reported in 1887 upon a collection made by Dr. ANDERSON in the Mergui Archipelago. KIRKPATRICK (**22**) described in 1895 a collection made by Mr. THURSTON in the Gulf of Manaar. Among HINCKS's series of papers, entitled "Contributions towards a History of the Marine Polyzoa," in the 'Annals and Magazine of Natural History' (**8**), there is a report upon a small collection from Indian seas, and here and there among other papers of this series may be found descriptions of a specimen or two from Ceylon. In all, perhaps, 45 species have been previously described from the seas around Ceylon. Of these, 31 are represented in the present collection; and 85 additional species, including 16 new to science, are now recorded for the first time.

The work has been carried out chiefly in Liverpool, but it is a pleasure to record the help that has been freely given to me in Cambridge and in London. Dr. S. F. HARMER has kindly allowed me to consult his private collections of specimens and notes, and Mr. R. KIRKPATRICK has helped me with those at the British Museum; to both gentlemen I am indebted for advice and suggestions. In conclusion, I should like to express my gratitude to Professor HERDMAN for the privilege of being allowed to handle and name his valuable collection of Polyzoa.

ORDER: ECTOPROCTA.

SUB-ORDER: CHEILOSTOMATA.

FAMILY: ÆTEIDÆ.

Ætea anguina, LINN.

Localities:—Station I., off Negombo, 12 to 20 fathoms; and Station XLVI., off Mount Lavinia, 7 to 12 fathoms.

FAMILY: CATENARIIDÆ.

Catenaria lafontii (AUD.).

Locality:—North of Cheval Paar, 7 to 10 fathoms.

Catenicella elegans, Busk (1).

Locality : Gulf of Manaar (attached to floating oyster cages).

Family : CELLULARIIDÆ.

Scrupocellaria cervicornis, Busk (2).

Locality :—Navakaddu Paar, Gulf of Manaar.

Scrupocellaria diadema, Busk (2).

Localities :—North of Cheval Paar, in Gulf of Manaar, 7 to 10 fathoms ; and Station LXIII., west of Periya Paar, 17 to 55 fathoms (large quantities).

Scrupocellaria scrupea, Busk (2).

Locality :—Gulf of Manaar.

Caberea retiformis (Pourtalès).

The peculiar, unequal development of the fornix, mentioned by Miss Phillips (25), is a characteristic of these Ceylon specimens. The upper half is developed into a long, sharp process, while the lower is scarcely produced below the stem by which it is attached to the zoœcium. Avicularia are present both along the median line and on the oœcia.

Locality :—Off Galle in deep water.

Family : BICELLARIIDÆ.

Diplœcium simplex, Kirkpatrick (20).

Localities :—North of Cheval Paar, 7 to 10 fathoms ; off Manaar ; and off Galle.

Bugula neritina, Linn.

There is one specimen in the present collection which differs from the others, being lighter in colour, less rigid in growth, and with avicularia. Hincks (12) mentions these last as present on some of his specimens, therefore there does not seem sufficient reason for separating the two forms. The avicularia are large, placed on the outer sides of the zoœcia, and have long mandibles. Oœcia are present in the position usual for the species.

Localities :—Palk Bay ; and Gulf of Manaar.

Beania mirabilis, Johnston.

Locality :—Cheval Paar.

Family : CELLARIIDÆ.

Cellaria johnsoni, Busk.

Localities :—Gulf of Manaar ; off Galle, deep water ; and Station XL., 10 miles off Watering Point, 34 fathoms.

Nellia oculata, Busk (2).

Locality :—Gulf of Manaar.

Family : TUBUCELLARIIDÆ.

Tubucellaria cereoides (Ellis and Sol.).

Localities :—Off Galle and onwards up the West Coast of Ceylon, deep water; Navakaddu Paar, Gulf of Manaar (several colonies).

Family : MEMBRANIPORIDÆ.

Membranipora favus, Hincks (8).

There are tubercles between some of the zoœcia in the colonies of this species which otherwise agree with Hincks's description of the species.

Locality :—Gulf of Manaar (on *Conus* shells).

Membranipora irregularis, D'Orbigny.

Locality :—Gulf of Manaar.

Membranipora hastilis, Kirkpatrick (21).

Locality :—Gulf of Manaar.

Amphiblestrum cervicorne, Busk (2).

Locality :—Off Manaar Island (several colonies).

Amphiblestrum papillatum, Busk (1).

Localities :—Station XLVI., off Mount Lavinia, 25 to 30 fathoms; Navakaddu Paar, Gulf of Manaar.

Amphiblestrum granuliferum (Hincks, 3).

Localities :—Gulf of Manaar; off Galle; and off Mount Lavinia (several colonies).

Amphiblestrum marginella (Hincks, 8).

The lateral avicularia of these specimens are more pointed than in Hincks's description, and are directed upwards instead of downwards. The large avicularia occupying a whole zoœcial area are present.

Locality :—Gulf of Manaar.

Amphiblestrum delicatulum (Busk).

The Ceylon specimens show the serrated denticle of this form and have no avicularia. The zoœcia are not quadrangular but of a diamond shape, resembling *one* of the zoœcia in Hincks's figure (3, plate xi.) of this species. There are no knobs such as Hincks describes on his specimens. Oœcia are present, not described before; they are sunk below the membrane of the zoœcium, above the one to which they belong, are finely punctured and have a calcareous arch above the zoœcial orifice. The colony is of a brownish colour and adheres closely to the bivalve shell on which it is growing.

Locality :—Gulf of Manaar.

Siphonoporella bursaria (MacGillivray, **23**).

The Ceylon colonies of this species have avicularia with spatulate mandibles, interspersed here and there among the zoœcia, on separate areas. In old specimens the front wall of the zoœcium is distinctly punctured. With these slight differences the specimens have all the appearance of *Membranipora rossellii* (Aud.) which MacGillivray (**23**, plate xxvi., fig. 4) later named *Amphiblestrum bursarium*. There is even an indication, in his drawing of one of the zoœcia, of a siphon, which is clearly present in the Ceylon specimens. I believe the specimens undoubtedly belong to MacGillivray's species.

Localities :—Off Galle ; off Trincomalee ; and from the Gulf of Manaar (several good colonies).

Family : ONYCHOCELLIDÆ.

Onychocella antiqua (Busk).

Locality :—East Cheval Paar, Gulf of Manaar.

Onychocella abyssicola (Smitt, **26**).

Localities :—Gulf of Manaar ; and off Galle at Station XL., 10 miles off Watering Point, 34 fathoms.

Onychocella cucullata, n. sp.—Plate, fig. 1.

Zoarium incrusting or erect, branching and bilaminar. Zoœcia large and irregularly oval, raised towards the upper end, where the margin is often coarsely beaded. Operculum large and horse-shoe shaped, bent forward along with the raised portion of the zoœcium. Cryptocyst coarsely granular and punctured on the front wall, descending as in *Steganoporella lateralis*, MacGillivray (**24**), to the basal wall of the zoœcium and pierced by a tubular orifice which has an everted rim. Avicularia curved over the top of the zoœcium, usually branched on one side and having the tips of the branches more or less forked. A triangular swollen area, probably œcial, is seen above some zoœcia, having an oval opening covered by a membranous operculum, situated in the centre of the beaded upper margin of the zoœcium to which it belongs.

Localities :—Gulf of Manaar ; and off Trincomalee.

This species appears to be closely allied to *Steganoporella* in the form of zoœcium, but has a smaller operculum and avicularia of the *Onychocella* type. The two forms present in this collection, incrusting and erect, have the same zoœcial and avicularian characters, and cannot therefore be separated. The erect form is represented by broken specimens of about 2 centims. in height, flat and branched in various ways and of a grey colour. The incrusting form has all the appearance of a *Steganoporella* to the naked eye.

FAMILY: MICROPORIDÆ.

Steganoporella buskii, HARMER (17).

There is a large colony of this species measuring about 10 square centims. It is growing in a loose honeycomb-like form and is of a remarkably light and brittle texture. Another colony, the same in detail, is incrusting a seaweed and is much smaller in every way.

Locality :—Cheval Paar, Gulf of Manaar.

Steganoporella sulcata, HARMER (17).

Locality :—Gulf of Manaar.

Steganoporella simplex, HARMER (17).

Localities :—Gulf of Manaar ; and off Trincomalee.

Thalamoporella rozieri (AUD.), form **indica**, HINCKS (3).

Localities :—Gulf of Manaar ; Palk Bay ; and off Galle.

Thalamoporella rozieri (AUD.), form **falcifera**, HINCKS (3).

Locality :—Generally distributed round the Ceylon coast.

FAMILY: CRIBRILINIDÆ.

Cribrilina radiata, MOLL.

Localities :—Off Galle ; Gulf of Manaar ; off Mount Lavinia ; and Station XL., 10 miles off Watering Point, 34 fathoms.

FAMILY: MICROPORELLIDÆ.

Microporella violacea, JOHNSTON, form **plagiopora**, BUSK.

Locality :—Gulf of Manaar.

Microporella ciliata (PALLAS).

Locality :—North of Cheval Paar, 7 to 10 fathoms.

Microporella ciliata, var. **personata**, BUSK (2).

The avicularia on the Ceylon specimens have wing-like membranous extensions of the sides of the mandible. Two of the colonies are of a pink colour.

Localities :—Gulf of Manaar ; and Station XXXIII., south-east of Ceylon, 18 fathoms.

Microporella decorata, Reuss.

Locality :—Gulf of Manaar.

Berenicea prominens, Lx. [= **Chorizopora brongniartii** (Aud.)].

Localities :—Gulf of Manaar ; off Galle, deep water ; and Station XL., off Watering Point, 34 fathoms.

Family : PORINIDÆ.

Porina magnirostris (MacGillivray, 23).

Locality :—Gulf of Manaar.

Gigantopora fenestrata, Ridley.

On the most perfect of the few, small, incrusting colonies of this form there are little branched spines, in between the perforations of the front wall of the zoœcia. The secondary, tubular orifice has a 4-toothed margin and avicularia are very long, reaching from the base of the tube and extending beyond its margin. Where an avicularium is absent the tube has a fissure in its place. Oœcia are present, low down at the back of the tubular orifice, and perforated like the front wall of the zoœcia.

Localities :—Gulf of Manaar ; and off Galle.

Lagenipora spinulosa, Hincks (8).

Locality :—Gulf of Manaar.

Lagenipora tuberculata, MacGillivray (23).

There are several colonies corresponding to MacGillivray's description of this species, but there are also among them some that have the hollow tubercles very much lengthened, ending in points, or being jagged and irregular in outline. These specimens have also simple or branched spines round the margin of the much raised peristome. The front walls of the zoœcia have punctures in between the spines ; the peristome is granular. There are no avicularia, and no oœcia are present.

Locality :—Off Galle.

Family : MONOPORELLIDÆ.

Monoporella albicans, Hincks (6).

An interesting point in the present example of this form is that the oœcia are in most cases set a little "awry," a fact that Hincks thought merely a peculiarity of the colony in his collection. There are none of the large avicularia present here.

Locality :—Gulf of Manaar.

Monoporella lepida, Hincks (5).

Locality :—Station LIII., north of Cheval Paar, 7 to 10 fathoms.

Family: MYRIOZOIDÆ, Smitt.

Schizoporella spongitis (Pallas).

Localities :—Gulf of Manaar ; and off Mount Lavinia.

Schizoporella ampla, Kirkpatrick (20).

Localities :—Gulf of Manaar ; and Navakaddu Paar.

Schizoporella argentea, Hincks (6).

In the single small colony of this species the sinus is wider than Hincks describes and there are no oval avicularia, but in their place the elongated kind as in some of his specimens. There are the two spines above and the granular, silvery surface of the zoœcia with foramina between the granulations.

Locality :—Gulf of Manaar.

Schizoporella aperta, Hincks (6).

There are two spines on the upper margin of some of the orifices of these specimens not described before. No oœcia are present, but in other points the characters agree with those of the species.

Localities :—Gulf of Manaar ; and Navakaddu Paar.

Schizoporella cecilia (Aud.).

The one small colony of this species has raised, irregular-shaped ridges of calcareous matter on the oœcium, and a decided arch above the orifice at the base of the oœcium, also a screen-like process on the front of the zoœcium.

Locality :—Gulf of Manaar.

Schizoporella unicornis, Johnston.

The present specimen has the peculiar long avicularia of the form *longirostris*, Hincks (11), but not the more important feature of that variety, namely the loop-shaped sinus.

Locality :—Navakaddu Paar.

Schizoporella nivea, Busk (1).

There are numerous colonies of this species, loosely attached, being, as it were, folded round the stems of the large zoophyte, *Campanularia juncea*, and having the opposed edges of the zoarium adhering to one another. (See Part II., p. 115, fig. 2.)

Locality :—Gulf of Manaar.

Schizoporella circinata, MacGillivray (23).

The zoœcia of these specimens have the ridge-like mucro of Hincks's (10) species, but not the avicularium. There is a single row of large punctures at the edge of the zoœcium. No oœcia are present on the two small colonies in the Ceylon collection.

Localities :—Off Mount Lavinia ; and off Galle.

Schizoporella sanguinea (Norman).

Avicularia are usually present on these specimens. They are long and pointed and raised, a pair on each zoœcium, situated at their extreme upper angles, above the orifice and directed downwards and inwards.

Locality :—Off Galle.

Schizoporella magnifica, Hincks (11).

The peculiar distinctive oœcia of this species are not present on the one colony in this collection, which is deep red in colour. The long pointed sinus, the pairs of upward pointing avicularia, and the reticulate front wall of the zoœcium, without a raised margin, accord with Hincks's description of the spécies.

Locality :—Off Galle.

Schizoporella depressa, Phillips (25).

There are some colonies of a pink colour corresponding with the figure and description of this species. The orifice of the zoœcium is deeply sunk, the front wall rising into almost an umbo below it, and calcareous ridges radiate from this to the margin, leaving large, loop-shaped areolations between them. The small rounded avicularia, on one or both sides of the orifice, are sunk below the surface, together with the orifice. Oœcia are smooth and hyaline or ridged, and have an oval area on either side of them.

Localities :—Gulf of Manaar ; and off Mount Lavinia.

Schizoporella triangula, Hincks (5).

The specimens of this form in the present collection have the triangular orifice, the raised margins and punctured surface of the zoœcium, with small avicularium pointing downwards from just below the orifice, although this last is smaller and never raised on an elevation. There is a second avicularium lying transversely on a separate area above the orifice. Busk (1) mentions, but does not figure, a second avicularium with a slender, spear-shaped mandible which corresponds with these, with the exception that his are described as lying vertically and these are transversely placed. Where oœcia are present, they take the place of these. They are large, covering nearly the whole of the zoœcium above the one to which they belong, as described by Busk, but are sub-immersed and have no nodules, being punctured like the zoœcium.

Localities :—Gulf of Manaar ; and East Cheval Paar.

Schizoporella subsinuata (Hincks, 9).

There are a few colonies of a grey-white colour, incrusting pieces of broken shell, having the zoœcial characters of this form with the addition of numerous avicularia, which in Hincks's specimens did not exist and which were rare in MacGillivray's (23). They have long, pointed mandibles, and are usually pointing downwards, like those in

MacGillivray's figure (plate cxxxviii., fig. 5), from an upper angle of the zoœcium; but are sometimes below the orifice, transversely placed, or they may be on separate, raised areas.

Localities:—Gulf of Manaar; and Navakaddu Paar.

Schizoporella avicularis, n. sp.—Plate, fig. 2.

Zoarium adnate, of a pink colour; zoœcium punctured, with slightly raised margins. Orifice with a broad sinus and umbo below it. Avicularia here and there large and spatulate, starting from above the umbo, covering over the oral aperture and resting on an extended portion of the zoœcium above. Oœcia large, more finely punctured than the zoœcium and with a calcareous arch over its summit.

Locality:—Gulf of Manaar.

I do not know of any species having an avicularium in the position described above. When the mandible is removed, the zoœcial orifice, with its operculum, appears beneath, in its usual form. There is a specimen, in this collection too, of *S. triangula*, which has apparently a similar arrangement of the avicularium and zoœcial orifice, but it will be necessary to examine more material before coming to a definite conclusion as to the exact relations of these parts.

Schizoporella collaris, n. sp.—Plate, fig. 4.

Zoarium incrusting, of a dull white colour. Zoœcia rhomboidal, punctured, the upper portion slightly narrowed to a neck and bent forward. Orifice with a broad shallow sinus, peristome thickened and forming a triangular bracket-like process in front. Oœcia punctured like the zoœcia, the sides extending to form with the peristome a collar round the orifice.

Locality:—Station XLVI., off Mount Lavinia.

Schizoporella pulcherrima (MacGillivray, 23).

There is a strong resemblance between the "small colony," described by MacGillivray, of this species and the large specimens from Ceylon, although the former has no punctures on the zoœcium, nor is it coloured, while the latter have punctures as well as radiating lines and are coloured a deep red, excepting for one colony, probably old, which is white. The raised margins of the broad zoœcia, the shallow sinus and avicularia on either side of the orifice are the same; these are sometimes quite up to the edge and in an angle of the zoœcium. Oœcia, not described before, are large, covering almost entirely the zoœcium above and embedded in it, punctured like the zoœcium. The orifices of the zoœcia which bear oœcia are larger than those of the others. It is a very striking species.

Localities:—East Cheval Paar; off Galle; off Mount Lavinia.

Schizoporella viridis, n. sp.—Plate, fig. 3.

Zoarium incrusting and forming very large colonies, extending to nearly two feet (50 centims. or upwards) across.

It has a coarse looking, roughened surface and is of a greenish colour, somewhat obscured by a brownish surface layer or membrane; zoœcium prostrate, irregularly oval, ventricose and punctured closely all over the front wall; often with an umbo in its centre, or to one side, which may become tall and massive. Orifice with a deeply rounded sinus, peristome raised above.

Avicularia small and pointed, one or two transversely placed below the orifice, and a few long and sword-shaped, on separate areas, scattered over the zoarium.

Locality :—Coral banks, Gulf of Manaar.

This fine species forms thick massive colonies of many superimposed layers, and spreads over other objects to form very large masses; one colony measures upwards of 53 centims. in length by 18 centims. in breadth and 23 millims. in thickness. The verdigris-green colour is a striking feature, best seen in the thickness of the superimposed layers at the edges of broken pieces; a brown membrane which envelops the zoarium conceals it, somewhat, on the surface. The large ventricose zoœcia and oœcia can be seen by the naked eye as small pimples covering the irregularly undulating surface of the zoarium. The zoœcia are always prostrate, but are heaped and turned in various ways and are seen at various levels.

Schizoporella incrassata, HINCKS (6).

The great variety in appearance of the zoœcia in different parts of one colony is quite as marked in the present specimens as it was in HINCKS's, and, although the variations do not always agree with his, the differences seem to belong to unimportant characters. The primary orifice has, here, sometimes from 2 to 4 spines on its upper margin. A large process, bearing an avicularium, is sometimes to be seen on both sides of the orifice instead of on one side only. The surface of the zoœcium is usually grooved, the grooves radiating towards the centre. Avicularia on raised processes are scattered irregularly over the zoœcia. The peristome forms sometimes a spinous collar, open in front, or the points of the edges of the opening join and leave the opening below like an oval pore. The oœcium agrees with that of HINCKS's species, but that the flat plate covering its aperture is of a dead white, contrasting with the glassy appearance of the rest of the zoarium.

Localities :—Gulf of Manaar; Station XL., 10 miles off Galle, 34 fathoms.

Mastigophora dutertrei, var. **pes-anseris** (SMITT, 26).

Locality :—Station XL., 10 miles off Galle, 34 fathoms.

Rhyncopora bispinosa, JOHNSTON.

The primary orifice of this species varies in one specimen from the usual shallow sinus form to one with a deeper, narrower sinus, which variety has also a crenulated margin as in *Rhyncopora crenulata*, WATERS (27), a species which has, however, no sinus.

Localities :—Gulf of Manaar; and Station XLVI., off Mount Lavinia.

Rhyncopora corrugata, n. sp.—Plate, fig. 5.

Zoarium incrusting, yellow-white in colour. Zoœcia large, distinct throughout, with the secondary orifice prolonged into a tube, widening from the base up and with an uneven margin. An uncinate process at the base of the tube a little to one side of the centre, and an avicularium of small size on the corresponding other side, its beak pointed and forming with the uncinate process a loop-shaped sinus.

Locality :—Gulf of Manaar.

The raised secondary orifice of this species gives it the appearance of a *Lagenipora*, but that the tube is irregularly fluted in outline. It is a good deal smaller than *Rhyncopora incisor*, n. sp., although at first taken to be the same when the two were growing together.

Rhyncopora incisor, n. sp.—Plate, fig. 6.

Zoarium incrusting, of a white colour. Zoœcia crowded, hexagonal, with a deeply areolated margin, a long tubular peristome and even rim.

Primary orifice orbicular with a transversely placed avicularium a little to one side of the centre, an uncinate process on the opposite side becoming very long and pointed. Oœcia behind the tubular orifice, smooth with a circular area on either side.

Localities :—Gulf of Manaar ; and off Galle, 34 fathoms.

The characters of this species are very simple and constant ; the most striking feature is the elongated uncinate process which sometimes projects almost across the orifice, so as to bar the entrance to the tube, and has a curved needle-like point. There is no avicularium to be seen when this stage is reached.

One perfectly preserved colony has the appearance to the naked eye of the pile of white velvet ; the zoœcia almost approach those of *Lagenipora tuberculata* in size and appearance.

Hippothoa flagellum, MANZONI.

Locality :—Chilaw Paar.

Gemellipora glabra, form **striatula**, SMITT (**26**).

Localities :—Gulf of Manaar ; Trincomalee ; and off Mount Lavinia.

Gemellipora lata (SMITT, **26**).

The Ceylon specimens of this form have the yellow colour of the colony, the dark colour of the opercula, more brown than green in these specimens, the conspicuous pores of the zoœcia, the form of orifice and peculiar fold of the peristome below this, as figured by SMITT (**26**, plate vii., fig. 157).

Avicularia are distributed among the zoœcia, on separate areas, but are much larger than he describes and spatulate, not oval.

Oœcia, not described before, are more broad than high, perforated like the zoœcia, with, sometimes, an umbo. The orifices of fertile zoœcia are much larger than those of the others.

Locality :—Gulf of Manaar.

Gemellipora protrusa, n. sp.—Plate, fig. 7.

Zoarium incrusting, of a pale brown colour. Zoœcia rhomboidal, smooth or slightly roughened, front wall much raised, punctured round the margin. Orifice of the usual *Gemellipora* form, sometimes much elongated; peristome often raised above and irregularly lobed. A large avicularium on the front of the zoœcium, directed across it, supported on a raised process; mandible wide at the base, becoming long and pointed; a small avicularium, with rounded mandible, on a raised process on one or both sides of the orifice. Oœcia granular and minutely punctured, open in front, and leaning forward over the orifice.

Locality :—Gulf of Manaar (numerous colonies on Nullipore balls).

There are sometimes two avicularia, in place of the one large transversely placed one; they point outwards to either side of the zoœcium. There is some resemblance in the appearance of this species to *Schizoporella ampla*, Kirkpatrick (20).

Family: ESCHARIDÆ.

Lepralia robusta, Hincks (8).

The central circular pore, alluded to by Hincks, is quite evident on the present specimens, and is sometimes multiplied to three or more of irregular shapes, as seen in an old, worn specimen.

Locality :—Gulf of Manaar (in large quantity on broken shells).

Lepralia poissonii, Audouin.

Localities :—Navakaddu Paar; off Galle and onwards up West Coast, deep water.

Lepralia mortoni, Haswell (19).

Localities :—Gulf of Manaar; off Trincomalee; north end of East Cheval Paar.

Lepralia triangula, n. sp.—Plate, fig. 8.

Zoarium incrusting. Zoœcia punctured all over, covered by a yellow membrane. There are usually scattered spinous processes on the front wall of the zoœcium and also two curved horn-like processes, one on either side below the orifice, which may be avicularia. Orifice longer than broad, with a much raised, thin, often irregularly pointed peristome, forming a collar round it. Operculum with a triangular excrescence having its base attached to the base of the operculum. No oœcia.

Locality :—Gulf of Manaar.

It is possible this species may be a variety of *L. pallasiana*, Moll., as it resembles *L. canthariformis*, Busk, which is probably a variety of *L. pallasiana*, but the peculiar processes on the cell wall and that on the operculum give it a distinctive character.

Lepralia turrita, SMITT (26).

The fresher looking colonies of this species are pink in colour and have pointed tubercles round the margin of the orifice; with age they become white and the tubercles worn down into blunt knobs. There are large spatulate avicularia on the sides of large massive tubercles and small oval ones on more slender tubercles, and also scattered over the zoœcia.

There are very few oœcia, and I have not been able to see perforations on them. They have a semicircular, marked area in front.

Localities:—Gulf of Manaar; Station XL., 10 miles off Galle, 34 fathoms; Navakaddu Paar.

Lepralia multidentata, n. sp.—Plate, fig. 9.

Zoarium incrusting, white. Zoœcia very small, rotund, irregularly placed, usually lying flat, but occasionally standing upright, surface roughened. Orifice arched above, sides widening downwards, base slightly convex, six long slender spines on the upper margin and a long, pointed rostrum below. Sometimes avicularia with rounded mandibles are present on either side of the orifice. Oœcia granular above, smooth in front, with an arched rib between the rough and the smooth portions.

Localities:—Gulf of Manaar; and off Trincomalee.

Lepralia cucullata, BUSK (2).

Localities:—Cheval Paar, Navakaddu Paar and elsewhere in Gulf of Manaar (common on Ascidians and pearl oyster shells).

Lepralia depressa, BUSK (2).

Avicularia in various forms, long and seta-like, or thick and spear-like, or the mandible branched, looking like the leg and foot of a bird.

Localities:—Gulf of Manaar and off Galle.

Lepralia gigas, HINCKS (10).

Localities:—Station LIII., north of Cheval Paar, 7 to 10 fathoms; Palk Bay; Trincomalee (many large colonies, up to 3 inches across); Welligam Bay; and various parts of Gulf of Manaar (growing on pearl oyster shells).

Lepralia purpurea, n. sp.—Plate, fig. 13.

Zoarium forming purplish grey patches, incrusting. Zoœcia small with thick walls, sub-immersed, diamond-shaped, occasionally heaped and upright, smooth and shining or slightly roughened. Orifice arched above, widening downwards, with an almost straight lower lip, peristome slightly thickened with five marginal spines and a sub-oral mucro below the orifice. The tip of this, the bases of the spines and the peristome are of a purple tint. Sometimes an avicularium on a raised process at one side of the zoœcium, varying in size, spatulate and large or small and pointed. Oœcia small, narrow, open in front, two of the spines showing in front.

Locality :—Gulf of Manaar.

Lepralia nitida, n. sp.—Plate, fig. 10.

Zoarium closely adhering, with a shining surface, pale yellow in colour. Zoœcia flat but rising to a prominent umbo situated below the orifice, granular, the granules radiating from the umbo to the margin of the zoœcium which is punctured there. Orifice arched above, narrowing, then widening, and with a convex lower lip. A small round avicularium on either side on a level with the lower margin of the orifice. Oœcia small, rising to a prominent umbo, orifice of the fertile zoœcium much larger than the usual orifice.

Locality :—Gulf of Manaar.

This is a small neat species with little variation of form. The oœcia are merely like a triangular extension of the zoœcium above the orifice.

Lepralia adpressa, Busk (**2**).

The surface of the zoœcium in the present specimen is granular, punctured round the margins only ; the upper portion of the zoœcium is considerably raised ; the lateral lumps carry small round avicularia ; when in old specimens these are absent the lateral processes are seen to be hollow tubes. Sometimes two or three of these processes are present above the orifice and one below in addition.

Locality :—Off Galle, deep water.

Lepralia feegeensis, Busk (**2**).

The oœcium of this species has not been described before. There is one well preserved oœcium on the Ceylon specimen. It is large and irregular in shape, the front wall is marked with large circular pitted areas, punctured in their centres, giving the oœcia a much coarser appearance than the zoœcia, the reverse of what is seen in *Lepralia gigas*, Hincks (**10**). The orifices of fertile zoœcia are broader at their bases than those of others. Avicularia of the usual type, and in the usual position for *L. feegeensis*, are often present in pairs, but usually singly, or there may be none.

Locality :—Gulf of Manaar.

Lepralia cleidostoma, Smitt (**26**).

There is one small colony of this species. It has no oœcia to show the characteristic striæ as a help to identification, and the avicularia are always directed upwards, not outwards. On one of the zoœcia, on the outside of the colony, jointed spines are to be seen, as in Smitt's (**26**), plate xi., fig. 217. A larger, loosely incrusting colony from another locality resembles this so nearly as to make it probable it is one of the same species. The zooecia are larger, avicularia are smaller and turned sideways, as in SMITT's figures. Oœcia are present here, but are punctured, not striated, and they are often half buried in the calcification of the zoarium. There is still a third variety, smaller than either of the above, and with a smooth and glistening surface, with avicularia turned sideways and oœcia faintly striated, but with a small arched area in front. As all these three specimens have the same key-shaped orifice and pointed avicularia I am inclined to think them varieties of the one species.

Localities :—Gulf of Manaar ; and off Galle.

Lepralia ceylonica, n. sp.—Plate, fig. 11.

Zoarium adhering, of a yellowish-white colour. Zooecia in linear series closely set, becoming upright in places, with glistening front walls, pitted and punctured and lumpy. Orifice arched above, with straight sides and slightly concave lower lip, six long sharp spines above and several bosses below the orifice, carrying small avicularia with pointed mandibles on their summits. Oœcia roughened like the zooecia and having scattered raised avicularia upon them.

Locality :—Gulf of Manaar.

Lepralia fissa, n. sp.—Plate, fig. 12.

Zoarium incrusting, forming brown patches. Zooecia finely punctured at the outside of the colony, becoming coarsely ridged further in and having a large umbo occupying most of the area, and a large avicularium on its outer side, with the mandible directed upwards. Orifice broader than long, with a pouting lower lip. Oœcia rounded, smooth, with a large cone-shaped fissure in front.

Locality :—Off Galle, deep water.

Lepralia subimmersa, MACGILLIVRAY (23).

There is one colony, greyish-white in colour, and covering the shell of a univalve mollusc inhabited by a hermit crab. Another colony is of a deep red colour, from a membranous covering still adhering to the zoarium.

Locality :—Gulf of Manaar.

Escharoides verruculata (SMITT, 26).

Localities :—Gulf of Manaar ; and off Mount Lavinia.

Porella malleolus, HINCKS (8).

Localities :—Gulf of Manaar ; off Galle ; Navakaddu Paar.

Smittia trispinosa (JOHNSTON).

There is great variety in the form of zooecia and avicularia among the Ceylon specimens of this species. It is widely distributed around the coast, and apparently very abundant.

Localities :—Gulf of Manaar ; off Galle ; off Mount Lavinia ; and Navakaddu Paar.

Smittia trispinosa, var. **spatulata** (SMITT, 26).

Locality :—Station XLVI., off Mount Lavinia.

Smittia trispinosa, var. **protecta**, nov.

This large variety has the peristome raised and in front, below the orifice, produced into a long spout-like extension. Avicularia, not on every zoœcium, are of enormous size, reaching from above the orifice and bending and spreading so as to cover the whole front wall of the zoœcium, and having a blunt extremity.

There are sometimes two small raised avicularia, one on either side of the orifice. The finely punctured oœcium has a narrow, prominent arched rib across the front.

Locality :—Gulf of Manaar.

Smittia tubula, KIRKPATRICK (20).

The present specimens of this form are of a pink colour. There are usually two avicularia, one on either side of the tubular secondary orifice, pointing upwards. Two of the oral spines, of which there are six, remain in front of the oœcium when present.

Locality :—Gulf of Manaar.

Smittia rostriformis, KIRKPATRICK (20).

Avicularia on these specimens are sometimes pointing downwards, as figured by KIRKPATRICK, but sometimes upwards with the appearance of a spine on either side of the orifice. In both cases the peculiar serrated edge of the beak is plainly visible. Oral spines vary in number from two to six. In other respects the specimens agree with the original description of the species.

Locality :—Station XLVI., off Mount Lavinia.

Phylactella spiralis, n. sp.—Plate, fig. 14.

Zoarium forming small pink patches on shells. Zoœcia arranged in radiating lines, smooth or slightly roughened, areolated round the margin, with a much raised tubular peristome and an avicularium raised to the margin of this on a semi-spiral tube. Primary orifice, having a very wide denticle with sharp lateral points. Secondary orifice, with from two to four spines above. Oœcium behind the tubular peristome, smooth or slightly roughened like the zoœcium.

Localities :—Gulf of Manaar ; off Mount Lavinia ; and off Galle.

This species approaches most nearly to *Phylactella geometrica*, KIRKPATRICK (21), in form, but the one broad denticle instead of three and the difference in the position of the avicularium, which resembles that of *Lagenipora nitens* (MACGILLIVRAY, 23), makes it impossible to mistake the two species.

Mucronella coccinea, ABILD.

Localities :—Gulf of Manaar ; and off Galle.

Mucronella tubulosa, HINCKS (3).

In the Ceylon specimens, which I believe to belong to this species, there is an enormous development of the central mucro, which is here long and spinous ; there is also an avicularium on the inner side of this, either at its base, lying in front of the primary orifice, or at varying heights up this process, always transversely placed and with a sharp curved beak, but varying in size.

These points add to the resemblance between *M. tubulosa* and *Rhyncopora longispinosa,* which Miss JELLY regards as synonymous, but there is missing still, in these specimens, the uncinate process of *Rhyncopora,* unless the curved beak of the avicularium takes the place of this. In the faint indication of a sinus of the primary orifice, the spinous mucro and markings of the oœcia, there is a likeness to a species of quite another genus, *i.e., Cellepora longirostris,* MACGILLIVRAY, as described by Miss PHILIPPS (25).

Localities :—Off Trincomalee ; off Mount Lavinia ; Navakaddu Paar and elsewhere in the Gulf of Manaar.

Mucronella thenardii, AUD.—Plate, fig. 15.

The cross-shaped process, situated below the orifice of the zoœcium in this species, is greatly developed (see fig. 15). Its upright portion is often occupied by a large spatulate avicularium, and, where this is so, one of the arms of the cross is missing, giving a one-sided appearance to the process. Sometimes the arms are duplicated, one pair below the other, and they are always much branched, each branch bearing a small, rounded avicularium on its summit. Slender, spinous processes, resembling the branches in size, are scattered over the front wall and round the margin of the orifice of the zoœcium, and there are sometimes ordinary spines, from two to five in number.

There is a strong resemblance between the characters of this species and those of *M. aviculifera,* HINCKS (14). The slender, spinous, aviculiferous processes are present there, but the cross-shaped mucro is only represented by a small simple mucro, and there are large, lateral avicularia. There is, however, much variation in form and position of the avicularia and of the processes which carry them, even in one small specimen of the present collection, so that it seems possible that the differences represent various stages in the development of one and the same species.

Localities :—Gulf of Manaar ; and off Galle.

Mucronella vultur, HINCKS (7).

There are in the present collection specimens having all the important characteristics of *M. vultur,* as described by HINCKS (7) and MACGILLIVRAY (23) with this exception, that the avicularium on the central mucro has a rounded, instead of a pointed, mandible. There are sometimes small, raised, rounded avicularia scattered over the front wall of the zoœcium in great profusion. Some of the specimens have spinous knobs in front of the oœcia and also one on the summit of this.

Altogether, with the addition of the usual six long marginal spines of the orifice, the colony has a formidable appearance, especially in specimens where the zoœcia are crowded together. The largest colony is partly incrusting and partly sends off free expansions. It measures 8 centims. by 4 centims. and is of a dull pale brown colour and of a very brittle and light substance.

Locality :—Gulf of Manaar (growing over a colony of *Lepralia gigas*, Hincks).

Retepora tubulata, Busk (1).

Locality :—Gulf of Manaar.

Retepora simplex, Busk (1).

Locality :—Off Galle and onwards up west coast of Ceylon.

Retepora apiculata, Busk (1).

Locality :—Ceylon seas.

Retepora pocillum, n. sp.—Plate, fig. 16.

These colonies correspond with *Retepora avicularis*, MacGillivray (23), in size, and the zoœcia in having triangular teeth within the orifice, and below this a loop-shaped fissure, but there are some other additional marked characteristics in these specimens. The zoœcia are rhomboidal in form and have slightly tubular necks crowned by about six spines, which are beautifully jointed in the Equisetum-like form described for *R. monilifera*, MacGillivray (23). These are often broken, but their bases, which, united, form the tubular neck, are visible, and when oœcia are present two are to be seen in front of it, not always of the jointed form. The oœcia have a fissure faintly visible. There is generally a small avicularium with a rounded mandible below the orifice, more or less in the middle of the zoœcium; sometimes there are two of these, one below the other, or rarely one large spear-shaped one, lying across the zoœcium and pointing upwards.

Locality :—Gulf of Manaar.

Family: ADEONIDÆ.

Adeonella subsulcata (Smitt, 26).

The largest colonies of this species in the present collection are about 8 centims. in height. They correspond entirely with Smitt's description, but that there is also a serrated denticle within the orifice, corresponding to that of *A. pectinata*, Busk (1).

Localities :—Station I., off Negombo, Gulf of Manaar; Station XXIX., Trincomalee; Station XLVI., off Mount Lavinia, 25 to 30 fathoms; Station XL., 10 miles off Watering Point, 34 fathoms; and off Galle, deep water.

FAMILY: CELLEPORIDÆ.

Cellepora albirostris (SMITT, 26).

Localities:—Gulf of Manaar; off Mount Lavinia; off Kaltura; and off Galle, deep water. There are large quantities of this species.

Cellepora megasoma, MACGILLIVRAY (23).

There is usually a raised avicularium to one or both sides of the orifice on the present specimens and large scattered spatulate ones here and there. The zoœcia are smooth or slightly ridged. Oœcia thickly punctured all over, with no marked area.

Localities:—Off Galle and onwards up west coast of Ceylon, deep water; Gulf of Manaar (several colonies on worm tubes and stems of Zoophytes); Station XXXII., off south-east coast of Ceylon (on Sponge).

Cellepora rota, MACGILLIVRAY (23).

Localities:—Station LIII., north of Cheval Paar, 7 to 10 fathoms; and elsewhere in Gulf of Manaar.

Cellepora cidaris, MACGILLIVRAY (23).

There is a large quantity of material resembling the description of this form excepting that the columnar processes in between the zoœcia are solid instead of hollow. *C. albirostris*, SMITT, has, in the "Challenger" collection, occasional, solid columns of this sort on the older parts of a colony, but, although the two species *C. albirostris* and *C. cidaris* of the present collection resemble each other pretty closely in some points, neither the long pointed rostrum, nor the broad one with serrated beak, nor the dark operculum, characteristic of *C. albirostris*, are present on the specimens I have considered to be *C. cidaris*. Oœcia, said in *C. cidaris* to be globular and immersed, have an arched area in front, which, being often absent, leaves a cave-like space. There are occasional large spatulate avicularia to be found on raised areas in between the zoœcia, but these are the only points of difference to be seen between the present specimens and MACGILLIVRAY's description of *C. cidaris*.

Localities:—Off Mount Lavinia; Station XL., off Galle, 34 fathoms; and in Gulf of Manaar.

Cellepora compacta, n. sp.—Plate, fig. 17.

Zoarium incrusting, white or purplish in colour. Zoœcia small, upright, rounded, smooth, with a few marginal punctures.

Orifice rounded, with a loop-shaped sinus, and below, rather to one side, a large thick rostrum, sometimes pointed above, having a long pointed avicularium on its side; often other slenderer processes round the orifice and long hollow columns in between the zœcia. Oœcia standing upright, smooth and shining, with a narrow arched ridge in front.

Locality:—Gulf of Manaar.

Sub-order: CYCLOSTOMATA.

Family: CRISIIDÆ.

Crisia holdsworthii, Busk (2).

Localities:—Station LIII., north of Cheval Paar, 7 to 10 fathoms; Station I., and elsewhere in Gulf of Manaar; and Palk Bay.

Family: TUBULIPORIDÆ.

Idmonea milneana, D'Orb.

Localities:—Navakaddu Paar; and Station XL., 10 miles off Watering Point, 34 fathoms.

Family: LICHENOPORIDÆ.

Lichenopora hispida, Fleming.

Localities:—Navakaddu Paar, and elsewhere in Gulf of Manaar.

Lichenopora novæ-zelandiæ, Busk (2).

Locality:—Navakaddu Paar.

Sub-order III.: CTENOSTOMATA.

Family: ALCYONIDIIDÆ.

Alcyonidium mytili, Dalyell.

Locality:—Gulf of Manaar.

Pherusa tubulosa, Lx.

The largest colony among the few present in the present collection is about 3 centims. in height, and its branches spread to about the same in width. Zoœcia are on both sides of the branch, not as in the original description only on one surface.

Locality:—Station LIII., north of Cheval Paar, 7 to 10 fathoms.

Family: ARACHNIDIIDÆ.

Arachnidium fibrosum, Hincks (15).

Locality:—Gulf of Manaar.

Family: VESICULARIIDÆ.

Amathia distans, Busk (1).

Locality :—Gulf of Manaar.

Farrella atlantica, Busk (1).

Locality :—North of Cheval Paar.

Family: BUSKIIDÆ.

Buskia setigera, Hincks (16).

Localities :—Station LIII., north of Cheval Paar, 7 to 10 fathoms; and Palk Bay.

Family: CYLINDRŒCIIDÆ.

Cylindrœcium dilatatum, Hincks (15).

Localities :—Station LIII., north of Cheval Paar, 7 to 10 fathoms; off Galle; and Station I., off Negombo.

Family: VALKERIIDÆ.

Valkeria uva, Linn.

Locality :—Station LIII., north of Cheval Paar, 7 to 10 fathoms.

Order: ENTOPROCTA.

Family: PEDICELLINIDÆ.

Ascopodaria discreta, Busk (1).

One small colony of a reddish colour, growing on a sponge.
Locality :—Navakaddu Paar.

REPORT

ON THE

MEDUSÆ

(HYDROMEDUSÆ, SCYPHOMEDUSÆ AND CTENOPHORA)

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

EDWARD T. BROWNE, B.A.,

ZOOLOGICAL RESEARCH LABORATORY, UNIVERSITY COLLEGE, LONDON.

[WITH FOUR PLATES.]

INTRODUCTION.

THE collection of Medusæ brought back by Professor HERDMAN from Ceylon and another forwarded by Mr. JAMES HORNELL were kindly sent to me by Professor HERDMAN for examination. So far as I know there are no previous records relating to the medusæ of Ceylon, except for the Siphonophora which have been specially studied on the spot by HAECKEL. Unfortunately none of his beautiful species occur in the collection.

The specimens come chiefly from two places—Galle, at the south of Ceylon, and the Pearl Banks in the Gulf of Manaar. It is distinctly a littoral collection from shallow water, and the littoral character is shown by the number of Anthomedusæ and Leptomedusæ. The collection has not brought to light any new genera, nor are the species in any way very remarkable, considering that they live within a tropical region, in a sea at about 80° F. From a geographical point of view the collection is a valuable one, as it has increased our knowledge of the distribution of genera.

Some of the specimens had been splendidly preserved and were a pleasure to work with, but many were in bad condition, more or less broken up, and these gave me endless trouble. I have endeavoured, as far as possible, to give such details as I hope will lead to the recognition of the species again, but should any doubt arise when comparing a description or figure with living specimens, I would suggest that it would be better to amend my work rather than describe another species.

[After this report had been sent to the printer I received intimation from Professor OTTO MAAS, of Munich, that he was preparing for publication his account of the Hydromedusæ of the Dutch "Siboga" Expedition. As our respective reports were likely to be published about the same time we agreed to exchange proofs. I wish here to express my thanks to Professor MAAS for his kindness in allowing me to make use of his work, which must be regarded as a valuable contribution towards our knowledge of the Hydromedusæ.

A few of the species in the Ceylon collection were also taken by the "Siboga" in the East Indies, namely:—*Irenopsis hexanemalis*, *Octocanna polynema*, *Mesonema pensile*, *Liriope tetraphylla*, and *Solmundella bitentaculata*.]

The following is a classified list of the species described in this report:—

HYDROMEDUSÆ.

ANTHOMEDUSÆ.

Dipurena sp.?

Cytæis herdmani, n. sp.

Proboscidactyla minima, n. sp.

LEPTOMEDUSÆ.

Laodice indica, n. sp.

Mitrocomium assimile, n. sp.

Eutima curva, n. sp.

Octorchis orientalis, n. sp.

Irene ceylonensis, n. sp.

Irene palkensis, n. sp.

Irenopsis hexanemalis, GOETTE.

Octocanna polynema (HAECKEL).

Æquorea conica, n. sp.

,, *parva*, n. sp.

Mesonema pensile (MODEER).

TRACHOMEDUSÆ.

Gonionemus hornelli, n. sp.

Olindias sp.?

Liriope tetraphylla (CHAM. ET EYS.).

NARCOMEDUSÆ.

Solmundella bitentaculata (QUOY ET GAIM.).

SIPHONOPHORA.

Diphyes chamissonis, HUXLEY.

Cupulita sp.?

Agalmopsis sp.?

Physalia utriculus, ESCH.

Porpita sp.?

SCYPHOMEDUSÆ.

Charybdea sp.?

Nausithoe punctata, KOLL.

Pelagia sp.?

Crambessa sp.?

CTENOPHORA.

Pleurobrachia globosa, MOSER, var. *ceylonensis*, n.

Beroe flemingi (ESCH.).

A Comparison between the Medusæ of Ceylon and those of the Maldives.

It is somewhat hazardous to draw a comparison between the medusoid fauna of Ceylon and that of the Maldives. About that of Ceylon I feel that we at present know but little, in fact, we have just made a beginning in our observations. We know, perhaps, a little more about the medusæ of the Maldives, which have recently been visited by two expeditions—the first under the leadership of Mr. Stanley Gardiner, and the second, which soon followed the first, under the guidance of Professor Alexander Agassiz.

Leaving out the oceanic medusæ, which have usually a wide geographical range, and limiting the comparison to the Anthomedusæ and Leptomedusæ, Mr. Gardiner's collection contained 5 genera and 5 species (3 of which were new species). Professor Agassiz's collection contained 10 genera (1 new genus) and 11 species (6 of which were new species and 3 were not named). With the possible exception of one of the Æquoriidæ, the genera and species were quite distinct in the two collections. Taking the two collections, without any limitations, there is a well-marked difference between them, which is quite as great as if they had come from localities a thousand miles apart. It is difficult to assign a correct reason for such a difference, but probably a different season of the year and the localities visited had much to do with it.

The two Maldive collections contain altogether 14 genera and 15 species of Anthomedusæ and Leptomedusæ. The Ceylon collection contains 12 genera and 14 species (10 of which are regarded as new species). A comparison between the Maldive and Ceylon collections shows that 6 genera (*Dipurena?*, *Proboscidactyla*, *Irene*, *Irenopsis*, *Mesonema* and *Æquorea*) are common to both, but only 2 species (*Irenopsis hexanemalis* and *Mesonema pensile;* the former also occurs at Zanzibar and the latter in the Red Sea). I think that these figures show clearly that the medusoid fauna of Ceylon is quite distinct from that of the Maldives.

HYDROMEDUSÆ.

Order: ANTHOMEDUSÆ.

Family: SARSIIDÆ, Forbes, 1848.

Dipurena, McCrady, 1858.

Dipurena, sp. ?—Plate II., figs. 1 and 2.

Description.—Umbrella about as high as broad. Manubrium extending beyond the margin of the umbrella. Mouth circular. Gonads arranged in several large isolated clusters upon the manubrium. Four tentacles with globular basal bulbs, and with numerous small clusters of nematocysts. Ocellus upon the outer side of each basal bulb.

Size :—Umbrella about 3 millims. in width and height.

Locality :—Galle Bay, one specimen on June 12 and two on August 25.

Notes.—The umbrella of the three specimens is so badly out of shape that a figure of it cannot be given. The manubrium (fig. 2) is a long thin tube, about two to three times the length of the cavity of the umbrella, with an apical knob in the jelly of the umbrella, and with a large terminal stomach which has a circular mouth. The gonads are situated on the manubrium in large roundish clusters, and their size makes them conspicuous. One specimen has four clusters of gonads, another has two clusters. The third specimen has lost its manubrium. The stomach itself also appears to be surrounded with generative cells. The tentacles (fig. 1) are long and flexible, and are closely studded with clusters of nematocysts, except for a short distance next to the basal bulb. The upper half of the basal bulb is globular and embedded in the jelly of the umbrella, the lower part is like a circular band round the tentacle, broader on the inner side than on the outer side. In this band, on the outer side, the ocellus is situated. The ocellus is circular, of a yellowish colour in formalin, and has a small lens.

I have placed this species in the genus *Dipurena* and follow at present HAECKEL'S classification, though I think that this species and *Dipurena ophiogaster* will ultimately have to be removed to another genus. All the other species have the nematocysts on the tentacles confined to a large conspicuous terminal knob, and some in addition have a few large swellings containing nematocysts just above the terminal knob. *Dipurena ophiogaster* has the nematocysts on the tentacles arranged in quite a different manner. They form numerous semi-circular or three-quarter spiral loops round the tentacle when it is in a contracted or semi-contracted state. When the tentacle is fully expanded the nematocysts form minute globular clusters which give a moniliform appearance to the tentacle. The terminal cluster of nematocysts is very small and inconspicuous. The arrangement of the nematocysts of this species from Ceylon is similar to that of *Dipurena ophiogaster* and to that found in the genus *Sarsia.*

The specimens from Ceylon are very much like *Dipurena ophiogaster* which belongs to the British fauna, and it is not possible to point out a character in the structure of the tentacles or the manubrium with its gonads by which they can be specifically separated. As the specimens are in bad condition, I think it is best to leave the specific name in abeyance. They may differ from the *Dipurena ophiogaster* in the shape of the umbrella, in colour, and perhaps in other details.

BIGELOW (1904) found at the Maldives a *Dipurena* which he was not able to clearly distinguish from *Dipurena fragilis*, MAYER, belonging to the fauna of the Tortugas in the West Indies.

Family: MARGELIIDÆ, Haeckel, 1877.

Cytæis, Eschscholtz, 1829.

Margeliidæ with four single perradial marginal tentacles, and with unbranched oral tentacles.

Cytæis herdmani, n. sp.—Plate I., fig. 1; Plate IV., fig. 12.

Description.—Umbrella somewhat bell-shaped, about as high as broad, with fairly thick walls. Velum narrow. Stomach large, about as long as wide, situated on a short peduncle, and extending a little over half-way down the cavity of the umbrella. Mouth circular (expanded) with about 50 to 60 oral tentacles, which are unbranched and evenly distributed. Four broad radial canals. Gonads forming four large perradial swellings, and extending the whole length of the stomach. Four thick tentacles, perradial, with very large basal bulbs, which are somewhat triangular in shape.

Size:—Umbrella about $3\frac{1}{2}$ millims. in width and height.

Locality:—One specimen from Chilaw Paar on March 20, and one from Cheval Paar on November 11.

Notes.—Of these two specimens, one is an adult and the other is an intermediate stage. The stomach is cross-shaped in transverse section, and the gonads occupy the sides of the cross. The oral tentacles have a small round terminal cluster of nematocysts. The four marginal tentacles are thick and have a dark central band of pigment (perhaps a brilliant colour in the sea). A transverse section (fig. 12) shows that the pigment granules are confined to the endoderm cells, which form a solid central band of cells along the tentacle. The pigment granules form a dense layer round the periphery of the endoderm, and are also scattered along the walls of the cells. There is a fairly thick layer of mesoglœa and an extra thick ectoderm which contains an enormous number of nematocysts, closely packed together. The basal bulbs are very large and extend some way up the umbrella. There is a layer of dark pigment along the inner side of the bulb, and a thick whitish mass of cells on the outer side. Sections were not cut of the basal bulb, but the dark pigment granules would probably denote the endoderm and the external whitish cells the ectoderm. The specimen at the intermediate stage in development is about 2 millims. in width and height. It has four marginal tentacles, fewer oral tentacles, and smaller gonads than the adults.

This species is nearly related to *Cytæis nigritina* and *Cytæis macrogaster* of Haeckel. It differs from them in having many more oral tentacles, in the shape of the basal bulbs, and in the structure of the tentacles.

Family: WILLIIDÆ, Forbes, 1848.

Proboscidactyla, Brandt, 1835, ex Browne, 1904.

Williidæ with four radial canals leaving the stomach.

Proboscidactyla minima, n. sp.—Plate II., fig. 3.

Description.—Umbrella fairly thin and probably hemispherical in shape. Stomach divided into four longitudinal lobes. Mouth with a sinuous margin. Four radial canals with lateral branches. Gonads upon the lobes of the stomach. Tentacles short, about 16 to 20, with globular basal bulbs.

Size :—Umbrella about 1 millim. in diameter.

Locality :—Marichchukaddi, on the Gulf of Manaar, in February.

Notes.—There are 12 specimens, but their condition does not permit the production of a figure. I was unable to trace out the branching of the radial canal system, owing to the umbrella of all the specimens being more or less contracted, and to their fragile condition. The stomach is divided longitudinally into four lateral lobes and appears cross-shaped in transverse section. The gonads form lateral swellings upon the sides of the lobes, which do not extend along the top of the umbrella. The tentacles (fig. 3) are very short, about 0·25 millim. in length, and have a globular basal bulb situated in the jelly of the umbrella. On the ex-umbrella, not far from the margin, there are circular clusters of nematocysts, one between every two tentacles. The velum is very narrow. A few of the specimens are about 0·75 millim. in diameter and have 10 to 12 tentacles. Others, a little older, have 14 to 16 tentacles. One specimen has 18 tentacles. A full-grown adult has probably 20 tentacles. This species may be distinguished by the smallness of its size and the position of the gonads on the stomach.

Order : LEPTOMEDUSÆ.

Family : THAUMANTIIDÆ, Gegenbaur, 1856.

Laodice, Lesson, 1843.

Laodice indica, n. sp.—Plate I., fig. 5; Plate IV., figs. 7 to 11.

Description.—Umbrella slightly curved, about two to four times as broad as high, with moderately thick walls. Stomach cross-shaped, fairly large. Mouth with four short lips, having a slightly folded margin. Gonads extending from the stomach to about half-way or close to the margin of the umbrella, forming a large hollow sac upon each of the four radial canals. Tentacles about 60 to 80, with blackish basal bulbs, and without spurs. A large black ocellus upon the inner side of nearly all the basal bulbs. A single cordylus between every two tentacles. Cirri present.

Size :—Umbrella up to 6 millims. in diameter.

Locality :—Off Mutwal Island, West Coast of Ceylon, 12 specimens on March 19; and Galle, 3 specimens, on July 15.

Notes.—The collection contains 15 specimens which are about 5 millims. to 6 millims. in diameter and about the same age. The distance to which the gonads extend from the stomach along the radial canals varies in different specimens. Some have the gonads on the proximal half of the canals, whilst in others the gonads reach nearly to the margin of the umbrella. The gonads first arise in the proximal part of the canals quite close to the stomach, and grow outwards towards the periphery of the umbrella. Owing to the great extension of the walls of the radial canals in the region occupied by the gonads, it is difficult in some specimens to mark the spot where the stomach ends and the canals begin. The gonads look as if they were situated upon lobes of the stomach. The length of the gonads is independent of the development of the generative cells, as a gonad extending over only half the radial canal has large ripe ova. Sections show (fig. 10) that the ova at an early stage in their development are among the endoderm cells, and that later on they move outwards to the ectoderm. The section figured shows an ovum leaving the ovary and breaking through the ectoderm.

The tentacles are closely packed together round the margin of the umbrella, and apparently form two alternating series, one projecting outwards and the other hanging down. Although similar in structure, only those belonging to the former have a conspicuous blackish basal bulb with a conspicuous black ocellus. The latter series have a smaller basal bulb, either colourless or slightly pigmented, and either without an ocellus or with a very small one. The basal bulb is on the inner side of the tentacle ; it is a semi-circular thickening containing nematocysts and granules of pigment, which cover the exterior of the bulb and also extend in radiating lines into the interior. There is no spur-like projection at the base of the tentacles. The cirri (fig. 9) are capable of extending to a great length. There is probably one between every two tentacles, but very few were seen on the specimens. The free end terminates in an oval knob containing large nematocysts (fig. 11). The ocellus is situated on the margin of the basal bulb just below the velum. It is of an intense black colour, spherical in shape, with a circular pit penetrating nearly to the centre (fig. 8).

The cordylus is very small and club-shaped (fig. 9). The interior of club is composed of endoderm cells which are connected with endoderm cells of the circular canal (fig. 7). The structure of the cordylus resembles that of *Laodice calcarata* (see Brooks, 1895).

The specimens from Ceylon come nearest to *Laodice calcarata* which inhabits the North Atlantic. They differ from it in having no spur at the base of the tentacles, in having larger ocelli, and perhaps in colour and in size.

Family: EUCOPIDÆ, Gegenbaur, 1856.

Mitrocomium, Haeckel, 1879.

Mitrocomium assimile, n. sp.—Plate I., fig. 3.

Description.—Umbrella fairly thick, a little broader than high. Velum narrow. Stomach short, with a quadrangular base. Four radial canals. Gonads upon the outer half of the radial canals, forming large oval sacs. Four perradial tentacles.

About 5 to 7 marginal bulbs in each quadrant; the central, interradial, bulb being much larger than the others. A cluster of cirri adjacent to and on each side of the tentacles. About five marginal sensory vesicles, each with two (occasionally three) otoliths, in each quadrant of the umbrella.

Size:—Umbrella 2 millims. in width and $1\frac{1}{2}$ millims. in height.

Locality:—Cheval Paar, in February.

Notes.—There is only one specimen of this little medusa in the collection. It is rather opaque with a yellowish stain, and its margin is badly curled inwards. The umbrella is somewhat contracted, so that it may not be quite so highly arched as figured. The stomach is contracted back. The mouth is wide open and quadrangular in outline, but has probably four lips when closed. The gonads (male) are very large for the size of the medusa. Each gonad is divided into two by a median longitudinal line. The tentacles have large basal bulbs and transverse bands of nematocysts. The cirri are more or less contracted, and have a small terminal cluster of nematocysts. The cirri are apparently confined to the proximity of the tentacles and none were seen scattered along the margin of the umbrella.

As there is only one specimen, I place the species provisionally in the genus *Mitrocomium*. It bears a resemblance to *Mitrocomium cirratum* in having cirri clustered at the base of each tentacle. According to HAECKEL'S definition of the genus it should have 8 tentacles and 16 sense-organs.

Eutima, McCRADY, 1858.

Eutima curva, n. sp.—Plate III., figs. 1 to 3.

Description.—Umbrella probably hemispherical, nearly twice as broad as high, moderately thick. Peduncle of the stomach long, quadrangular in transverse section, and with a conical base. Stomach small, about twice as long as broad. Mouth with four small lips, and sinuous margin. Four radial canals. Gonads along nearly the whole length of the peduncle, one on each radial canal, beginning a little way below the conical base of the peduncle and terminating not far from the stomach. Four perradial tentacles, with long tapering cone-shaped basal bulbs, which are laterally compressed and curve over the margin of the umbrella. About 30 to 35 marginal bulbs in each quadrant of the umbrella, and alongside each bulb usually one, occasionally two cirri. Eight adradial marginal sensory vesicles, each with about 8 to 10 otoliths, which are arranged in a semicircle.

Size:—Umbrella 10 millims. in width and 6 millims. in height. Peduncle about 10 millims. in length.

Locality:—Off Mutwal Island, West Coast of Ceylon, on March 19.

Notes.—The single specimen, although in a good state of preservation, has the umbrella badly compressed and folded, so that it is impossible to figure the whole medusa. It is an adult, as the gonads contain large ova. The basal bulbs of the tentacles are attached to a slight thickening of the umbrella and curl over the margin. The nematocysts along the tentacle are arranged in transverse bands which do not quite meet on the inner side of the tentacle, so that a shallow groove is formed along the inner side, running the whole length of the tentacle. The marginal bulbs have a patch of blackish pigment at their apex.

This species comes nearest to *Eutima mira* and *Eutima insignis*, but is distinguished from them by the shape of the basal bulbs.

Octorchis, Haeckel, 1864.

Octorchis orientalis, n. sp.—Plate III., fig. 4.

Description.—Umbrella probably hemispherical, a little broader than high, and moderately thick. Peduncle of the stomach long, quadrangular in transverse section, and with a broad roundish base. The length of the peduncle is about twice the diameter of the umbrella. Stomach small, about as long as broad. Mouth with four short lips and a deeply folded margin. Gonads upon the peduncle of the stomach and also upon the sub-umbrella. The gonads occupy the greater length of the peduncle, extending along the radial canals, beginning a little way below the base of the peduncle and terminating close to the stomach. The gonads upon the sub-umbrella usually occupy the central third of the radial canals, or the outer half, but do not reach to the margin of the umbrella. Four long perradial tentacles, with long tapering cylindrical basal bulbs. About 18 to 20 marginal bulbs in each quadrant of the umbrella, each one with a lateral cirrus. Eight marginal sensory vesicles.

Size :—Umbrella about 5 millims. to 6 millims. in diameter.

Locality :—Galle Bay, one specimen on June 5, seven on June 12, and two on August 21.

Notes.—None of the specimens are in good condition, the umbrella being so flattened out and crumpled that it is not possible to draw a figure of it. Some of the largest specimens have the gonads upon the peduncle in a series of folds (fig. 4), but it is possible that the folding may be due to the contraction of the peduncle. The gonads upon the peduncle are much larger and longer than those upon the sub-umbrella, the latter forming merely a thin narrow band along the radial canals. The marginal bulbs are very small and inconspicuous. The cirri are very slender and have a small terminal cluster of nematocysts. The sense-organs are situated near the tentacles. They are very small and globular in shape, their otoliths not visible.

Notes on Intermediate Stages.

(*a.*) Umbrella about 2 millims. in diameter. Peduncle about 5 millims. in length, with gonads just appearing upon it. Four tentacles. Cirri present. About 9 marginal bulbs in each quadrant. Eight sense-organs.

(*b.*) Umbrella about 3 millims. in diameter. Peduncle about 6 millims. in length. Gonads just appearing upon the peduncle and sub-umbrella. About 12 marginal bulbs in each quadrant.

This species does not agree with HAECKEL's definition of the genus *Octorchis*, since it has only 4 instead of 8 tentacles, but in other respects it conforms to the generic character. *Octorchis gegenbauri* has been frequently taken by me in British seas. Early and intermediate stages (the latter often with gonads) have 4 tentacles, whereas the fully developed adult has 8 tentacles. I think it would be better to enlarge the generic character so as to include species with 4 and 8 tentacles, than to establish a new genus for species which have only 4 tentacles.

HAECKEL, in his monograph, mentions two species of *Octorchis*—*O. gegenbauri* and *O. campanulatus*, both occurring in the Mediterranean, but probably there is only one species. The specimens from Ceylon are distinguished from the Mediterranean species by the greater length of the gonads on the peduncle.

Irene, ESCHSCHOLTZ, 1829.

Irene ceylonensis, n. sp.—Plate III., figs. 9 to 11.

Description.—Umbrella probably watchglass-shaped, much broader than high, with thin walls. Velum narrow. Stomach short, situated upon a long cylindrical peduncle. Mouth with four lips, which have a folded margin. Four radial canals. Gonads linear, extending from the base of the peduncle to near the margin of the umbrella. Tentacles about 100. Cirri absent. Sensory vesicles, one between every two tentacles, each vesicle with a single otolith.

Size: Umbrella up to about 25 millims. in diameter.

Locality: Galle Bay, one specimen on July 15; Cheval Paar, five in November.

Notes.—The collection contains six specimens differing in age and size, the smallest being about 5 millims. in diameter. All the specimens are more or less damaged. They are in a fair state of preservation, but are stained dead black, probably owing to the use of osmic acid.

The umbrella is flat and thin, but is no doubt slightly curved when the medusa is alive. Only one specimen shows the peduncle fairly well, the others have either lost it or have it twisted up. The gonads form thin narrow bands, either straight or sinuous, extending along the radial canals over the sub-umbrella. In the largest specimens the ova are large and clearly visible. Some of the specimens have a marginal bulb between some of the tentacles, and these bulbs I believe to be the origin of new additional tentacles, and not warts or tubercles, which do not develop tentacles. I am doubtful about the presence of excretory pores at the back of the basal bulbs, as there were no indications of papillæ, but they may be contracted.

The sensory vesicles have one otolith, but occasionally a vesicle was seen with two otoliths, which may have been caused by twinning.

(*a*)	Umbrella about	5	millims. in diameter.	About	28 tentacles.
(*b*)	,, ,,	7	,, ,,	,,	36 ,,
(*c*)	,, ,,	15	,, ,,	,,	72 ,,

Irene palkensis, n. sp.—Plate III., figs. 12 to 16.

Description.—Umbrella watchglass-shaped, about four times as broad as high. Velum narrow. Stomach short, situated upon a long cylindrical peduncle. Mouth with four short lips, which have a folded margin. Four radial canals. Gonads linear, extending from the base of the peduncle to near the margin of the umbrella. Tentacles about 50. Usually two or three marginal bulbs between every two tentacles. Excretory pores opposite the basal bulbs of the tentacles and all the marginal bulbs. Sensory vesicles about 2 to 4 between every two tentacles, each vesicle with two otoliths (variation 1 to 4).

Size :—Umbrella up to 20 millims. in diameter.

Locality :—Palk Bay, north of Ceylon, five specimens on March 16.

Notes.—The five specimens are all in a damaged condition, especially as to the gonads and the margin of the umbrella. The smallest is about 15 millims. in diameter and the largest about 20 millims. The gonads are upon the sub-umbrella along the radial canals. One specimen has the gonads extending from near the margin of the umbrella up to the peduncle, and for a short distance down the peduncle. The number of tentacles is only given from an estimation, as not one specimen has even a quadrant of the margin of the umbrella in a perfect condition. The basal bulb of the tentacle is somewhat globular when the tentacle is contracted, and more cone-shaped and tapering when the tentacle is expanded. On the inner side of the basal bulb just above the velum there projects an excretory pore. These pores are conspicuous and clearly visible when expanded, but almost invisible when contracted. Cirri were specially searched for, but none were seen. The marginal bulbs are small, and to judge from their appearance in one of the specimens, I think that some are capable of developing tentacles. Their number between every two tentacles is variable, usually two or three, sometimes only one. All these bulbs have excretory pores, similar to the pores opposite the basal bulbs of the tentacles. The sense-organs are closed vesicles with generally two otoliths (fig. 14), occasionally three to four otoliths, rarely one. The otoliths possess well-marked eccentric zones, which are conspicuous in specimens which have been apparently killed with a re-agent containing osmic acid.

At first sight *Irene palkensis* and *Irene ceylonensis* look very much alike, but after an examination of the organs on the margin of the umbrella I came to the conclusion that they were distinct species. *Irene ceylonensis* has about twice as many tentacles without a series of marginal bulbs in between them, and there is a difference in the shape of the basal bulbs of the tentacles, but I attach more importance to the sense-organs as a better means of distinguishing between the two species. *Irene ceylonensis* has only one sense-organ between every two tentacles, each sense-organ with a single otolith. *Irene palkensis* has two to four sense-organs between every two tentacles, and each sense-organ usually has two otoliths, occasionally three to four, and rarely one. There is also a difference in the structure of the otoliths.

Irenopsis, GOETTE, 1886.

Eucopidæ with numerous sensory vesicles, and with numerous tentacles. Six gonads in the course of six radial canals. Stomach upon a peduncle.

Irenopsis hexanemalis, GOETTE, 1886.—Plate I., fig. 4; Plate III., figs. 5 to 8.

Irenopsis hexanemalis, GOETTE, 1886, p. 832; CHUN, 1896, p. 5.

Phialidium tenue, BROWNE, 1904, p. 730, plate liv., fig. 4; plate lvii., fig. 16.

Description.—Umbrella like an inverted basin in shape, with a flattened top, about twice as broad as high. Velum narrow. Stomach short, with six lateral lobes, situated upon a short, broad, cone-shaped or semi-globular peduncle. Mouth with six lips, having a deeply-folded margin. Six radial canals. Gonads linear, on the distal part of the radial canals, close to the margin of the umbrella. Tentacles, about 30 to 40. Marginal bulbs about three or more between every two tentacles. Excretory pores opposite the basal and marginal bulbs. Sensory vesicles, usually one, sometimes two, between every two bulbs, each vesicle containing a single otolith (occasionally about two to four). Cirri absent.

Size:—Umbrella up to about 18 millims. in diameter.

Locality:—Palk Bay, 18 specimens on March 16; Cheval Paar, 9 specimens.

Notes.—The collection contains about two dozen specimens and nearly all are in bad condition. The smallest is an intermediate stage measuring 5 millims. in diameter. The stomach is situated upon a short peduncle which is about 2 millims. to 4 millims. in length. The peduncle is variable in shape. In some specimens it is conspicuous, but in others hardly noticeable. When semi-globular, or like a broad inverted cone, it is quite recognisable. In some of the specimens the peduncle is flattened out (whether this is natural or due to preservation I am unable to say), and in this condition the roof of the sub-umbrella appears convex, and the top of the umbrella is very thick. The stomach (fig. 8) is divided into six lobes, and its base seen aborally is like a six-rayed star. It is very short, about 1 millim. in length, and about twice as broad as long. The mouth has six conspicuous lips, which are continuous with the lobes of the stomach, and the margin of the lips is deeply and closely indented with a series of folds. In some specimens the stomach and its peduncle are within the cavity of the sub-umbrella, but those specimens which have an extra thick umbrella may have the stomach projecting a little way outside the cavity.

When a medusa has normally six radial canals, a variation in number may be expected. Medusæ with six radial canals have been derived from a form with four canals, and are much more liable to variation than those with four canals. There are altogether 27 specimens of *Irenopsis*, and six show a numerical variation in the radial canals, their numbers being as follows;—4, 7, 8, 8, 9, 11. The number of gonads also varies with the radial canals. The gonads vary very much in size, and are always situated upon the distal or outer half of the radial canals. Most of the specimens have very short linear or spindle-shaped gonads, about 1 millim. or little more in length, and situated near the margin of the umbrella. Three specimens have the gonads extending over nearly the whole of the distal half of the canals, but not quite reaching to the margin of the umbrella.

The tentacles vary in number according to the size and age of the specimens. The exact number in any one specimen could not be ascertained, as all the specimens have the margin of the umbrella more or less damaged. As a rule, in the largest specimens, there are about five or six tentacles (one specimen has six or seven) between every two radial canals. I estimated the number of tentacles in several large specimens to be about 36, and in one specimen at about 40. About the exact shape of the basal bulbs of the tentacles I am uncertain. In a contracted state they look somewhat globular, but are probably more conical when the tentacle is expanded. The marginal bulbs between the tentacles are very minute and their number is variable. Usually about three are present, but occasionally only one between every two tentacles. There are excretory pores opening above the velum, opposite every basal and marginal bulb. In nearly every specimen these pores are so contracted that their presence is not noticeable. In a few specimens they are well expanded (fig. 5) and form long papillæ. The marginal sense-organs (fig. 7) are closed vesicles, usually with a single otolith, but occasionally with two or three otoliths, rarely with four. There is generally only one between every two marginal bulbs, or about two to four between every two tentacles.

The genus *Irenopsis* was established by Goette for *Irenopsis hexanemalis*, found at Zanzibar. The original description is rather brief and there is no figure. Chun, however, has given a fuller account of some specimens taken at Tumbatu, off Zanzibar. The genus clearly belongs to the sub-family Irenidæ, and is readily distinguished by the presence of six radial canals. As the specimens from Ceylon agree with the descriptions given by Goette and by Chun, I have presumed that they are *Irenopsis hexanemalis*, though I should have liked to see a figure for comparison.

After seeing these specimens of *Irenopsis* I again examined *Phialidium tenue*, which was described by me as a new species in the Report on the Hydromedusæ of the Maldive Islands. The description of this species, based upon a single specimen, was given as follows:—" Umbrella watch glass-shaped and thin. Stomach small, quadrangular in shape, and situated on a semi-globular thickening of the umbrella.

Mouth with four lips and a sinuous margin. Four gonads extending over the outer half of each radial canal. Tentacles 25 in number. One or two minute marginal bulbs between every two tentacles. Sense-organs numerous, one or two, rarely three, between every two tentacles, with a single otolith. Umbrella 15 millims. in diameter." I clearly pointed out that I did not regard the thickening of the umbrella as a definite peduncle, and consequently placed the species in the genus *Phialidium* instead of in *Irene*. The result of the second examination, with specimens of *Irenopsis* for a comparison, leaves no doubt that the thickening of the umbrella must be regarded as a peduncle, so that the species does not belong to the genus *Phialidium*. It resembles *Irenopsis* in the shape of the peduncle, in the position of the gonads, in the number of tentacles, marginal bulbs and sense-organs. The basal bulbs of the tentacles are slightly larger. But it has only four radial canals, four gonads, and a mouth with four lips. If the specimen had been in this collection I should certainly have considered it to be an abnormal *Irenopsis*, having four instead of six radial canals. With four radial canals one would expect to see a mouth with four lips. I think that *Phialidium tenue* had better be regarded as an abnormal *Irenopsis*.

Octocanna, Haeckel, 1879.

Octocanna polynema (Haeckel)—Plate II., figs. 8, 9, 10.

Description.—Umbrella about twice to three times as broad as high, and thick. Stomach flat, octagonal base with eight lateral lobes, about 2 millims. in diameter. Mouth with eight small lips. Eight radial canals. Gonads linear, extending over the outer half of the radial canals and nearly reaching to the margin of the umbrella. Sixteen tentacles. About three to four marginal bulbs between every two tentacles, each having an excretory pore. One marginal sensory vesicle (seldom two) between every two bulbs, each vesicle with two otoliths (rarely with one or three).

Size :—Umbrella up to 12 millims. in diameter.

Locality :—Palk Bay, one on March 16 ; off Mutwal Island, one on March 19 ; Galle, one on August 25.

Notes.—The umbrella of two specimens is plano-convex in shape, fairly thick, and its margin is curled inwards. The third specimen has a very thick umbrella, which is more highly curved than those of the other two specimens, and the cavity of the umbrella is very shallow. The stomach has eight lobes, from which run the radial canals. The mouth is expanded in all the specimens and has eight small lips, corresponding in position to the radial canals. The gonads, in two of the specimens, are on the outer half of the radial canals, but in the third specimen they are more central, occupying the central third of the radial canals. They are linear in shape, increasing in thickness towards the distal end, and show fairly large ova. There are eight tentacles in the smallest specimen (8 millims. in diameter), one opposite each radial canal, and eight large marginal bulbs, one midway between every two tentacles. A few of these bulbs are just beginning to develop tentacles. The tentacles are long and slender, and their basal bulbs are somewhat globular. The excretory papillæ are plainly visible, and project out just above the velum. All the basal bulbs and the small marginal bulbs have excretory pores. The small marginal bulbs are more or less conical in shape, and some look as if they were capable of developing tentacles.

I place this species provisionally in the genus *Octocanna*, as it does not possess all the characters according to HAECKEL'S definition. There are two species of *Octocanna*, both of which were described, without figures, by HAECKEL, and have not since been recorded.

Octocanna octonema has 8 tentacles. Gonads reaching along the whole length of the radial canals. Sixteen sense-organs, each with a single otolith. Umbrella 10 millims. in diameter. Red Sea.

Octocanna polynema has 32 tentacles. Gonads not along the whole length of the radial canals. 60 to 80 sense-organs, each with two otoliths. Umbrella 15 millims. in diameter. Singapore.

Both the above species have four very long oral lips, which HAECKEL includes in the generic characters. The Ceylon specimens have eight small lips. They also possess marginal bulbs and excretory pores which are not mentioned by HAECKEL.

[In the report upon the Hydromedusæ of the "Siboga" Expedition, Professor MAAS describes under the name of *Octocanna polynema*, HAECKEL, some medusæ which appear to me to be identical with the specimens in the Ceylon collection. These specimens I had described in manuscript as a new species of *Octocanna*. As MAAS has emended HAECKEL'S description and transfers the genus from the Æquoriidæ to the Eucopidæ, he has prevented me from introducing a superfluous new species. I quite agree with him as to the desirability of the removal of the genus to the Eucopidæ and have adopted the classification here.]

FAMILY: ÆQUORIIDÆ, ESCHSCHOLTZ, 1829.

Æquorea, PÉRON et LESUEUR, 1809; ex BROWNE, 1904.

Æquoriidæ with numerous simple unbranched radial canals. Stomach circular, with the lower wall fully developed. Mouth capable of closing up.

Æquorea conica, n. sp.—Plate I., fig. 2; Plate II., figs. 16, 17, 18.

Description.—Umbrella somewhat cone-shaped, with a rounded summit, a little higher than broad, and very thick. Velum narrow. Stomach flat and circular, about half the diameter of the umbrella. Oral lips about 16 in number, long and slender. About 16 radial canals. Gonads upon the proximal half of the radial canals, very much laterally compressed. Tentacles about 26 to 30, small and slender; their basal bulbs small and somewhat cone-shaped. Between every two tentacles a very minute marginal bulb and two sensory vesicles (sometimes only one), each with two small otoliths.

Size :—Umbrella up to 7 millims. in width and 8 millims. in height.

Locality :—Pearl banks, Gulf of Manaar.

Notes.—The collection contains six specimens, which are mostly about the same size (5 millims. in width and 6 millims. in height) and age. Some are males and others are females having gonads with large ova. The oral lips have an external rib, with an internal groove which is probably ciliated. In this species the gonads are confined to the proximal half of the radial canals, and hang down as laterally compressed sacs. It is upon the position and shape of the gonads that I base the specific character. Excretory pores along the circular canal are not visible. Four of the specimens have 16 radial canals and 16 oral lips, one specimen has 15 canals and another 18 canals.

Æquorea parva, n. sp.—Plate II., figs. 5, 6, 7.

Description.—Umbrella plano-convex in shape, a little broader than high, very thick. Velum of moderate width. Stomach flat and circular, about one-third the diameter of the umbrella. Oral lips 13 to 16 in number, of moderate length and width. Radial canals 13 to 16. Gonads sac-like, in the central third of the radial canals. Four (perhaps eight) tentacles, with large basal bulbs. About 12 or more marginal bulbs between every two tentacles. About 10 or more marginal sensory vesicles between every two tentacles, or usually one between every two bulbs; each vesicle with two small otoliths.

Size :—Umbrella up to 6 millims. in width and 4 millims. in height.

Locality :—Galle Bay, one on June 5 and two on June 12.

Notes.—The three specimens are about the same size and age. One is a female and the other two are males. The stomach is about 2 millims. in diameter, and its lower wall about 1 millim. in width; the oral lips do not exceed 1 millim. in length. The gonads have lost their original shape, as they have been crushed down by the folding in of the margin of the umbrella. They occupy the central part of the radial canals, and are slightly nearer to the margin of the umbrella than to the stomach. The gonads hang down as sacs, somewhat laterally compressed. The female has large ova. One specimen has 13 radial canals, gonads and oral lips; the other two have 16 radial canals, gonads and lips. Two specimens have only four tentacles, but the third specimen has one interradial bulb which is just developing a tentacle. The interradial bulbs are much larger than the other bulbs and probably have tentacles in a fully developed specimen. The marginal bulbs, which are very variable in size, are somewhat cone-shaped and contain nematocysts. Some of the bulbs have an excretory pore opening on the sub-umbrella just above the velum. One specimen is badly infested with Cercaria.

This little *Æquorea* differs from the other species of the genus in the small numbers of its tentacles, and in the shape and position of the gonads upon the radial canals.

Mesonema, Eschscholtz, 1829; ex Browne, 1904.

Æquoriidæ with numerous simple, unbranched radial canals. Stomach circular, with lower wall quite rudimentary. Mouth nearly as large as the diameter of the stomach and cannot be closed.

Mesonema pensile (Modeer), 1791—Plate II., figs. 11 to 15.

Medusa sp., Forskål (1776, p. 9, tab. xxviii. b.).
Mesonema cœlem pensile, Modeer (1791, p. 32).
Mesonema pensile, Haeckel (1879); Browne (1904, p. 733, pl. lv., fig. 4; pl. lvii., figs. 2–9).

In my Report upon the Hydromedusæ of the Maldive Islands I gave a description of *Mesonema pensile* (Modeer). In this Ceylon collection there are fragments of a specimen which I believe belongs to this species. The specimen is from the Cheval Paar, Gulf of Manaar, and is broken up into about twenty-five pieces, which together represent only a portion of the whole medusa. Fortunately some of the fragments contain all the organs of the medusa, and it is possible, within certain limits, to give a description and to identify the species.

This medusa is so peculiarly constructed that all the organs lie close to the margin of the umbrella. The umbrella is rather like a plano-convex lens in shape and of great thickness. Around its periphery lie the mouth, stomach, radial canals, marginal tentacles, and sense-organs. These organs are all close together, the distance from the oral lips to the margin of the umbrella is only about 20 millims. To judge from the curvatures of the stomach and the margin of the umbrella on the three largest fragments (the largest fragment which contained all the organs measures 35 millims. in length), the diameter of the umbrella should be much larger than that of the largest Maldive specimen, which measured about 60 millims. in diameter. I think that this medusa when alive was probably about twice the size of the largest Maldive specimen.

The stomach (fig. 14) is rudimentary, and its lower wall is about 4 millims. in length. The margin of the mouth is furnished with a large number of long narrow lips, which are strengthened by an external rib. The length of the longest lips is about 4 millims. Among the lips there are many small ones in the course of development. In structure and shape the oral lips are exactly like those of the Maldive *Mesonema*, but they are a little longer. The lower wall of the stomach is also longer, twice the length.

The radial canals are very numerous, and very short; the distance from margin of the stomach to the circular canal is about 9 millims. The radial canals usually run straight from the stomach to the circular canal, and in one fragment the canal system is quite normal, but some fragments show that the short portion of the canals, between the termination of the gonads and the circular canal, has a strong tendency to curve and to send out lateral branches, which occasionally unite with lateral branches from an adjacent canal, or the union of two or three canals may occur, so that just near the margin of the umbrella the radial canal system appears to be very irregular.

The gonads are situated upon the radial canals and extend almost from the stomach to within a short distance of the circular canal, the distance from the termination of the gonad to the circular canal being about 2 millims. to 3 millims. The gonads are arranged in a lateral band along each side of the radial canals. At first a radial canal is merely a narrow, slender, inconspicuous tube (fig. 14, *R.*), then when the gonads begin to develop, the wall of the canal becomes thicker and increases in size. In this specimen the gonads are much larger than in the Maldive specimens. They have the appearance of cylindrical sacs, about 6 millims. in length and 1 millim. in diameter, with the wall slightly crumbled. Between the canals bearing the fully-developed gonads there are, here and there, canals which are of much later growth showing gonads in various stages of development. Some of these canals are at about the same stage as those in the Maldive specimens, showing that the Maldive specimens had not reached their full development.

The tentacles (fig. 12) belong to the same type as those of the Maldive specimens, but the basal bulbs have not such a long lateral extension along the margin of the umbrella. I have again examined the tentacles of the Maldive specimens, and find the extension along the margin to be slightly variable. The tentacles are also much longer and larger than those in the Maldive specimens, but they have the nematocysts arranged in the same manner. The nematocysts are in large clusters, which are laterally situated, on both sides, along the whole of the tentacle (fig. 13).

The marginal bulbs, like the basal bulb, at first sight, as shown by the figures in this Report and in the Maldive Report, do not appear to be similar, but I believe that the difference in general appearance is due to a lateral contraction of the margin of the umbrella of the specimen in this collection. The bulbs are closely packed together, touching one another, and the sense-organs are squeezed out on to the inner margin of the umbrella (fig. 15). This lateral contraction would also explain the shortness of the basal bulbs of the tentacles upon the margin. In the genus *Æquorea*, excretory pores are present upon the inner side of the circular canals, one opposite each tentacle or bulb. In my description of this species in the Maldive Report I did not mention the excretory pores, for the simple reason that I could not see any. But I have now cut a series of sections of a marginal bulb and found the pore in the usual place just above the velum. There is no trace of any external papilla or swelling, but simply a slender, narrow tube running from the circular canal to the exterior. It is just like a slit in the wall of the circular canal.

The sense-organs (fig. 15) are on the inner side of the margin of the umbrella, and are arranged in groups These groups are placed midway between the marginal bulbs. Between two tentacles I counted the number of bulbs and sense-organs, and found that there were 10 bulbs and 20 sense organs. The latter were arranged in numbers thus: 1.1.2.3.1.1.1.2.2.2.2.2. From the examination of other groups of sense-organs it may be said that there are either one or two, rarely three sense-organs between every two bulbs. A sense-organ contains two otoliths. The figure (11) shows the shape of the vesicle and the position of the otoliths, but the minute details of structure are somewhat diagrammatic.

It is impossible to estimate the number of tentacles, radial canals, &c., which the specimen should have, as the fragments are only a portion of the whole medusa. The tentacles are about 5 millims. to 8 millims. apart, and between them there are about 8 to 12 marginal bulbs, and about 4 to 8 radial canals.

Distribution :—Indian Ocean.

Order : TRACHOMEDUSÆ.

Family : OLINDIIDÆ, Haeckel, 1877 ; ex Browne, 1904.

Gonionemus, A. Agassiz, 1862.

Gonionemus hornelli, n. sp.—Plate I., fig. 6 ; Plate II., fig. 4.

Description.—Umbrella hemispherical, with moderately thick walls, about twice as broad as high. Velum fairly broad. Stomach cross-shaped, having four perradial lobes, situated upon a short, broad, cone-shaped peduncle. Mouth with four short lips. Four broad radial canals, upon which are situated the gonads. Gonads small in size, deeply folded and lobed, extending laterally from the canals and close to the velum. Tentacles about 70, arranged in 16 groups, and all have an adhesive disc about half-way down. Sixteen internal sense-organs, oval in shape, with a single otolith.

Size :—Umbrella 6 millims. in width and 3 millims. in height.

Locality :—Pearl Banks, Gulf of Manaar.

Notes.—The single specimen is in an excellent state of preservation and in perfect condition. The gonads are not papilliform, but are deeply folded and extend outwards on both sides of the radial canals. They are about twice as broad as high, and contain ova of a fair size. On one of the radial canals there is an additional gonad, smaller in size, and not far from the stomach. It may be regarded as an abnormal growth, as the other three canals show no signs of a gonad in that position.

The tentacles are arranged in 16 groups, but the grouping is not so well marked as in the genus *Gossea.* The tentacles forming a group are not of the same size, which is due to development. The perradial and interradial groups each contain five tentacles, the adradial four tentacles. The central tentacle in each group is the largest, the tentacles on each side of the central one come next in size; the two outside tentacles vary very much in size, one is always very small. The attachment of the basal part of the tentacle to the ex-umbrella varies in length according to the age of the tentacle. It proceeds furthest up the umbrella in the oldest tentacles and less far in the other tentacles, showing well the arrangement of the tentacles in groups. There is a semi-globular basal bulb on the inner side of each tentacle, and for a short distance the base of the tentacle is attached on its outer side to the margin of the ex-umbrella, being partly embedded in a groove. The tentacles are covered with nematocysts, which are arranged in transverse bands. The adhesive disc is on the outer side of the tentacle, forming a slightly raised elongated loop, and as it extends about half-way across the tentacle it is easily seen. All the tentacles of this specimen are contracted, and in this condition the adhesive disc is about half-way down the tentacle.

The sense-organs are inside the margin of the umbrella, adjacent to the circular canal, and their position is between the groups of tentacles.

Olindias, F. Müller, 1861.

Olindias, sp. ?

There is only one specimen, which is in bad condition. The umbrella is about 6 millims. in diameter. The stomach is fairly large and cross-shaped. The mouth has four lips and its margin is slightly folded. Four perradial canals, and about three centripetal canals in each quadrant. The gonads extend over the outer half of the radial canals and are arranged in papilliform clusters. The margin of the umbrella is torn and damaged. There are two kinds of tentacles; the primary tentacles have a few spiral bands of nematocysts and a horseshoe-shaped terminal cluster, the secondary tentacles have numerous bands of nematocysts. Upon the margin of the umbrella there are a number of large bulbs which look like the basal bulbs of the secondary tentacles which have been broken off, and also a number of small bulbs. An internal sense-organ lies at the base of some of the primary tentacles, but this could only be seen here and there, owing to the opaqueness and damaged condition of the margin.

The specimen may be *Olindias singularis*, found at the Maldives, but it is not in a condition suitable for an accurate determination of the species. It was found amongst sea-weed at Galle, on February 17.

Note on the Olindiidæ.

In my Report on the Hydromedusæ of the Maldive Islands I revised the genera of the Olindiidæ, but did not know till too late that Professor Seitaro Goto had published a paper on "The Craspedote medusa *Olindias* and some of its Natural Allies" in the 'Mark Anniversary Volume.' It was not until several months after the publication of my paper that I was able to obtain a copy of the volume, and later on Professor Goto kindly sent me a reprint of his paper.

Goto has also revised the Olindiidæ, but excludes from the family the genera

Aglauropsis and *Gossea*, which have not an adhesive disc on the tentacles. About the genus *Olindias* we differ, and it is quite likely that I may be in the wrong. We both examined specimens sent out from the Zoological Station at Naples. I came to the conclusion that the primary (ex-umbrellar) tentacles had not a terminal adhesive disc, but GOTO has expressed an opposite opinion. It is an important point in the classification and could, no doubt, be quickly settled by watching the habits of *Olindias* in the aquarium at Naples.

GOTO has investigated the development of the sense-organs of *Olindioides formosa*, GOTO, and has come to the conclusion that they are entirely derived from the ectoderm. On the ground that the sense-organ is ectodermal, GOTO transfers the Olindiidæ from the Trachomedusæ to the Leptomedusæ and places them under the Eucopidæ. In this Report I have left the Olindiidæ in their old place for convenience sake, not that I dispute GOTO's account of the development of the sense-organs, but rather that I am doubtful about their being true Leptomedusæ.

In 1901, when I was examining the medusæ brought back from the Falkland Islands by Mr. RUPERT VALLENTIN (I regret that the report on the collection is still unfinished, but hope to finish it next year), I cut some sections of the sense-organs of *Aglauropsis conantii*. The sense-organ lies in a corner, formed on one side by the ectoderm containing nematocysts on the margin of the umbrella, and on the other side by the endoderm of the circular canal. It is a globular vesicle containing an otolith upon a short stalk. The wall of the vesicle is composed of a single layer of cells which are in contact with the ectoderm, but isolated from the endoderm by what looks like a layer of mesoglœa. As this layer took a definite shape and stained a much deeper colour than the mesoglœa seen elsewhere, I, not knowing its origin, was doubtful about its really being mesoglœa. I was puzzled for a time over the sense-organ, not being sure whether the cells of the vesicle were ectoderm or endoderm, but finally came to the conclusion that the deeply-stained layer between the vesicle and the endoderm had some connection with the sense-organ and regarded the whole sense-organ as endodermal. As the sections showed that the preservation was not suitable for histological work (the specimens were preserved in formalin), I did not attempt to trace the development of the sense-organ.

After reading GOTO's description of the development of the sense-organ of *Olindioides*, I again examined the sections of *Aglauropsis*. I am now inclined towards the view that the vesicle is ectodermal, and that it is cut off from the endoderm by mesoglœa, but before coming to a definite conclusion I should like to see earlier stages in development.

FAMILY: GERYONIIDÆ, ESCHSCHOLTZ, 1829; ex MAAS, 1893.

Trachomedusæ, with four or six radial canals, in the course of which are situated leaf-shaped gonads. Blind centripetal canals. Stomach on a long peduncle. Internal sensory vesicles.

Liriope, Lesson, 1843 ; ex Maas, 1893.

Geryoniidæ, with four radial canals and with four or eight tentacles.

Liriope tetraphylla (Chamisso et Eysenhardt), 1820.

Geryonia tetraphylla, Chamisso et Eysenhardt (1820, p. 357, plate xxvii.).
Liriantha tetraphylla, Haeckel (1879).
Liriope tetraphylla, Vanhöffen (1902, p. 82, taf. x.); Browne (1904, p. 738, pl. liv., fig. 3).

The collection contains 19 specimens; only a few are in fairly good condition There are a few early and intermediate stages, but their condition is not satisfactory for a description. The largest specimens are similar to a figure given by Vanhöffen.

When I wrote the 'Report on the Hydromedusæ of the Maldive Islands' I was not quite certain about the correctness of the identification of a *Liriope* which I called *L. tetraphylla* (1904, plate liv.). I have again examined this specimen (there was only one in that collection) and have come to the conclusion that it must be regarded as *Liriope tetraphylla.* I have failed to find a character by which it could be specifically separated from those in the collection from Ceylon.

Notes on the Largest Specimens.—The shape of the umbrella is similar to that in the figure given by Vanhöffen, and is not so thick or so rounded as in that figured by me in the Maldive Report. The peduncle of the stomach is long and tapering; its length in the largest specimen is about 13 millims. Along the peduncle run four interradial, longitudinal muscle bands, which bifurcate at the base of the peduncle and the two ends curve outwards. The stomach is large and sac-shaped. The gonads vary very slightly in shape. They resemble Vanhöffen's figure, and measure 7 millims. in width and 5 millims. in length. The space between the gonads (measured from the upper margins) is about 2 millims. The radial canals are fairly broad, and that part of the canal between the gonad and the circular canal is much broader than as figured by Vanhöffen and myself. Most of the specimens have three centripetal canals in each quadrant. They are broader and less tapering than those shown in the figures mentioned above. One of the specimens has only one or two centripetal canals in each quadrant. A few of the specimens have eight tentacles, but the majority have only the four perradial tentacles.

Size :—The largest specimen measures 15 millims. in width and 7 millims. in height.

Locality :—Cheval Paar, off Mutwal Island and Chilaw Paar, various dates in March and November; Galle Bay, in June and July.

Distribution :—Atlantic and Indian Oceans.

Order : NARCOMEDUSÆ.

Family : ÆGINIDÆ, Gegenbaur, 1856 ; ex Maas, 1904.

Solmundella, Haeckel, 1879 ; ex Maas, 1904.

Æginidæ with two tentacles and with a stomach having eight pouches.

Solmundella bitentaculata (Quoy et Gaimard), 1833—Plate IV., figs. 1 to 6.

Charybdea bitentaculata, Quoy et Gaimard (1833, tome v., p. 295, plate xxv., figs. 4 and 5).
Æginella bitentaculata, Haeckel (1879).
Solmundella bitentaculata, Browne (1904, p. 741, plate lvi., fig. 3).

Description of the Adult.—Umbrella cone-shaped, usually a little broader than high. Stomach circular and flat, nearly as wide as the umbrella, having eight lateral pouches which are rectangular in shape and about twice as broad as high. Mouth circular, with an everted rim. Gonads on the inner wall of the pouches and also extending over the outer half of the lower wall of the stomach, forming a continuous band. Two opposite tentacles, which are situated above the stomach, and are about two to three times longer than the diameter of the umbrella. Peronial bands and grooves present. Sense-organs 24, perhaps more, usually three in each octant.

Size :—Umbrella up to 9 millims. in height and width.

Locality :—Galle, in February and August ; Modragam Paar and Cheval Paar, in November ; and Trincomalee.

Distribution :—Australasian seas ; Amboina Island (Quoy et Gaimard). Singapore (Bedford ; in Coll. E.T.B.). Indian Ocean ; Maldive Islands (Bigelow, 1904, p. 261, under the name of *Æginella dissonema* ; and Browne).

Notes.—The collection contains 39 specimens ; only a few are in good condition, and most of them are about 3 millims. to 5 millims. in diameter.

The umbrella is cone-shaped and nearly as high as broad. There is a slight variation in its shape, as the apex is more rounded in some specimens than in others. All the specimens have the apex of the umbrella more or less battered down so that it is impossible to note its exact shape, but it is not so pointed as that shown in the figure given by Quoy and Gaimard. The peronial groove below each tentacle is very deep, and goes right back to the wall of the sub-umbrella. The stomach is circular and flat and has eight lateral pouches. The upper wall of the stomach is either flat or slightly convex. The lower wall is also flat, with a circular mouth in the centre. The mouth, when fully expanded, is almost as wide as the diameter of the stomach. Its natural size is apparently about one-third to one-quarter the diameter of the stomach, but when closed the opening is very small. The margin of the mouth has an everted rim, and it does not usually hang down so low as in the specimen figured by me in the Maldive Report.

Haeckel, in his description of *Æginella dissonema*, and also Mayer (1900, p. 66, plate xiv.) state that there are four double perradial canals, each canal being divided into two by a longitudinal septum (called by Haeckel the peronium). The appearance of a double radial canal was seen in the two Maldive specimens, and also very plainly in some of the specimens in this collection, especially when the umbrella had been lightly stained. Transverse sections, however, do not confirm the presence of radial canals, and, after cutting several complete series, I have come to the conclusion that they are a delusion.

Description of the Peronia.—It is in the perradii, without the tentacles, that the appearance of a double canal is best seen, and transverse section in this position shows the "septum" but no canals (fig. 1).

In the two perradii, which have the tentacles, there is a longitudinal groove, the peronial groove, running from the margin of the umbrella up to the tentacle. This groove is very deep, running back to the wall of the sub-umbrella, cutting the wall of the sub-umbrella nearly in two (fig. 2). At the bottom of this groove is the peronial band (figs. 2 and 6), which runs from the margin of the umbrella to the base of the tentacle. The peronial band is a solid cord of ectoderm cells, nearly circular in transverse section, and surrounded by mesoglœa, except on the side facing the peronial groove. In the lower wall of the stomach there are two little funnel-shaped pockets, one under the root of each tentacle. Sections show that the ectoderm of the lower wall of the stomach, at the apex of the pocket, unites with the peronial band, and is continuous with the ectoderm of the tentacle. In the ectoderm of the tentacles there are large round nematocysts. These nematocysts form a conspicuous band along the under or lower side of the tentacle near its base (fig. 6) and then, a little further along, spread all round the tentacle. I have found similar nematocysts in the ectoderm of the pockets in the lower wall of the stomach and scattered among the generative cells (fig. 2) adjacent to the pockets. They are also in the strand of ectoderm between the apex of the pocket and the tentacle, but not in the peronial band, which is between this point and the margin of the umbrella. It seems to me that the nematocysts develop in the lower wall of the stomach in the neighbourhood of the pockets, then migrate into the ectoderm of the pocket and pass along the strand to the ectoderm of the tentacle.

The "septum" in the perradii, without tentacles, has the same structure as the peronial bands connected with the tentacles, but there is no peronial groove and the band ("septum") is completely surrounded with mesoglœa. It starts from the margin of the umbrella, runs up the side of the wall of the sub-umbrella, and at the level of the lower wall of the stomach it curves outwards and passes through the jelly to the ex-umbrella. In its passage through the jelly it tapers out almost to a point, and in some specimens stops a little way short of the ex-umbrella. Its presence marks the former existence of a tentacle, and shows that *Solmundella* is descended from a medusa which had four perradial tentacles.

The appearance of radial canals on each side of a "septum" is, in my opinion, due to the transparent mesoglœa in the short interval between the gastric pouches.

Sections across the margin of the umbrella do not show the existence of a definite circular canal.

Gonads.—Some of the specimens have the gonads confined to the inner wall of the gastric pouches, where they lie in the ectoderm (figs. 1 and 2). The gonads may extend over the lower half of each gastric pouch or over the whole pouch. Some of the large specimens have the gonads not only over the gastric pouches but also over a part of the lower wall of the stomach, forming a continuous ring round the lower wall of the stomach just like the genital ring of a Solmaris. One specimen has the outer half of the lower wall of the stomach covered with ova, which are large and clearly visible ; other specimens have only one quarter or one third of the wall of the stomach occupied with gonads. It appears from the specimens that the gonads first start developing at the bottom of the pouches, and then spread upwards and finally reach the lower wall of the stomach. The smallest specimens have the gonads confined to the pouches, but it is only in the largest specimens that the gonads are on the wall of the stomach.

Tentacles.—My figure of *Solmundella* in the Maldive Report shows that the base or root of the tentacles is curved outwards towards the ex-umbrella. This I now find is not the normal position, but the position occasionally taken when a specimen is in a contracted condition. As a rule the root of the tentacle points towards the centre of the umbrella (fig. 6), and in specimens which do not show signs of contraction it is sometimes clear of the upper wall of the stomach and the curve is scarcely visible. The tentacles have numerous internal transverse septa (fig. 5) which are connected in the centre by an elongated endoderm cell, containing usually two nuclei. The lower part of the tentacle (fig. 4) is somewhat triangular in shape ; along this portion there is a longitudinal muscle band.

Sense-organs.—The smaller specimens have two sense-organs and the largest ones three and perhaps more in each octant. In certain octants I have seen extra bulbs without sense-organs, and these may be the bases of sense-organs which have lost the otolithic part through injury.

A few of the specimens are infested with a Cercaria.

SIPHONOPHORA.

Order : CALYCOPHORÆ, Leuckart.

Family : DIPHYIDÆ, Eschscholtz, 1829.

Diphyes, Cuvier, 1817.

Diphyes chamissonis, Huxley, 1859.

Diphyes chamissonis, Huxley (1859, p. 36, pl. i., fig. 3) ; Browne (1904, p. 742, pl. liv., fig. 6).

The collection contains eleven anterior nectophores, some of which are in very good condition. The specimens are similar to those which were described and figured by me in the 'Report on the Hydromedusæ of the Maldive Islands.'

One specimen is from Galle, in July, but all the rest were from the Gulf of Manaar, mostly in February and March.

The nectophores measure about 8 millims. to 11 millims. in length. The somatocyst shows considerable variation in length and thickness. Some of the specimens have the somatocyst similar in shape and size to that shown in my figure of the species, whereas in other specimens it is longer (the length varies from 2 millims. to $3\frac{1}{2}$ millims.) and much thinner. The length of the hydrœcium is also variable, about one-third to half the length of the umbrella.

ORDER: PHYSOPHORÆ, ESCHSCHOLTZ, 1829.

FAMILY: AGALMIDÆ, BRANDT, 1835.

Cupulita, QUOY et GAIMARD, 1824.

There is one small specimen of a *Cupulita*, from the Cheval Paar, which is very much broken up. I am unable to determine the species.

Agalmopsis, SARS, 1846.

There are two small specimens, from the Cheval Paar, both of which are badly contracted and broken. The nectophores have all disappeared with the exception of a few minute buds, and only one damaged bract remains. The tricornuate tentilla are large and in excellent condition.

FAMILY: PHYSALIIDÆ, BRANDT, 1835.

Physalia, LAMARCK, 1801.

Physalia utriculus, ESCHSCHOLTZ, 1829.

Physalia utriculus, HUXLEY (1859, p. 101, pl. x., pl. xii., fig. 12); BROWNE (1904, p. 744).

Two small specimens were caught off Watering Point, Galle. The float is about 15 millims. in length. There is one main tentacle and several very small secondary tentacles. The gonophores are beginning to develop.

FAMILY: PORPITIDÆ, BRANDT, 1835.

Porpita, LAMARCK, 1801.

Porpita is represented by the remains of a single float, obtained on the Pearl Banks, Gulf of Manaar, and measuring about 35 millims. in diameter. The upper surface of the float has numerous radial rows of stigmata on the back of prominent ridges. It resembles the float of *Porpita umbella*, which is figured by HAECKEL (1888, plate xlv., fig. 5).

SCYPHOMEDUSÆ.

CHARYBDEIDA.

Charybdea, Péron et Lesueur, 1809.

Charybdea, sp. ?

There is a single specimen in the collection from the pearl banks, and it is not in a first rate condition. The umbrella has become soft and limp, consequently it has collapsed and lost its natural shape. The umbrella measures about 75 millims. in length, and is probably cone-shaped. The stomach is very short and flat; the mouth has small lips. The gastric filaments appear to be perradial in position (the top of the umbrella is damaged and crushed in). Each of the four groups is composed of about six tufts of filaments packed so close together as to form a continuous row. The sense-organs are about 10 millims. away from the margin of the umbrella. There are four ocelli on the inner side of each tentaculocyst. The principal ocellus is very large and semi-globular in shape. Above it, a little nearer the base of the tentaculocyst, is a transverse ocellus, forming a narrow pigmented band. The other two ocelli are more lateral in position, and situated between the semi-globular and the transverse ocelli. The ocelli are of a reddish brown colour in formalin. The velarium contains seven unbranched canals between every two tentacles. The gonads form very narrow bands, and appear to be quite immature. The pedalia are about 20 millims. in length and 15 millims. in width. The shape of their wings and the tentacle resemble the figure of *Charybdea grandis* (Agassiz and Mayer, 1902, plate vi.).

This may be an immature specimen of *Charybdea grandis*, but I remain uncertain. A second specimen would have been an advantage for comparison.

CORONATA.

Family: NAUSITHOIDÆ, Haeckel, 1879; ex Vanhöffen, 1902.

Nausithoe, Kölliker, 1853.

Nausithoe punctata, Kölliker, 1853.

Nausithoe punctata, Vanhöffen, 1892, p. 13, Taf. iii., figs. 8 and 9; Mayer, 1900, p. 67, plate xxiii., figs. 67 and 68, plate xxvi., figs. 87 and 88; Vanhöffen, 1902, p. 29; Bigelow, 1904, p. 263, plate vi., fig. 21.

Description.—The umbrella is somewhat hemispherical in shape. At the top of the umbrella there is a distinct hemispherical crown which is separated off from the rest of the umbrella by a conspicuous circular furrow. Just below the circular furrow the radial furrows begin. There are 16 deep radial furrows on the ex-umbrella, one midway between every tentacle and sense organ, terminating at the base of the marginal lobes. The bottom of each furrow is attached to the wall of the sub-umbrella by a septum which divides the distal portion of the stomach into 16 pouches (8 ocular and 8 tentacular). The septum is continued for a little way down the middle of each marginal lobe, separating the prolongation of the stomach in each lobe into two parts. But as the septum does not proceed along the whole length of the gastric prolongation, two completely isolated pouches are not formed. The whole of the ex-umbrella, including the marginal lobes, is closely granulated.

The gastric filaments are arranged in four distinct groups, which are isolated from each other by the four basal angles of the cross-shaped mouth. There are about 10 to 12 filaments in each group arranged in a single row. Each group occupies the whole space between the angles of the mouth.

The mouth is large and cross-shaped, about 3 millims. in length and width.

The gonads vary in shape, and, looked at from the sub-umbrella, appear circular or oval. The largest are about 1 millim. in length and 0·75 millim. in width. Three specimens in one bottle have rose-red gonads, and two in another bottle are of an orange colour. All the specimens are in formalin. One is a male and four are females with large ova.

There are 16 marginal lobes, which are about as broad as long (2 millims.), and have a rounded edge. Between these lobes are the eight tentacles and eight sense-organs, which alternate with each other. The tentacles are of moderate length (about 5 millims.), stiff, and taper to a fine point. The sense-organs have an otolithic sac and a circular reddish pigmented ocellus.

The collection contains five specimens, three of which are in splendid condition. Two were from off Mutwal Island on March 19, and three from Muttuvaratu Paar on March 29. The largest measures 9 millims. in width and 7 millims. in height. Two specimens are 9 millims. in width and 5 millims. in height. The others are slightly smaller.

I have compared these specimens with *Nausithoe punctata* obtained from the Zoological Laboratory at Naples, and feel certain that they belong to this species; in fact, they agree in every detail except in the shape of the ocellus. The Naples specimens have a circular pigmented ocellus on a semi-circular or convex bulb, whereas in the Ceylon specimens the ocellus forms a pigmented ring on a bulb with a flat surface.

The results obtained by the "Valdivia" and "Siboga" Expeditions show that *Nausithoe punctata* has a very wide geographical distribution. It occurs in all the oceans. It was taken by the "Valdivia" off the east coast of Ceylon, and by BIGELOW at the Maldives.

DISCOPHORA.

SEMÆOSTOMATA.

Pelagia.

Pelagia, sp. ?

There are nine very young stages, the smallest 4 millims. in diameter and the largest 8 millims. They have eight tentacles and eight sense-organs. These specimens are too immature for me to identify, as they have not long passed through the Ephyra stage. They are all from the Cheval Paar, Gulf of Manaar.

RHIZOSTOMATA.

Family: LYCHNORHIZIDÆ, Maas, 1903.

Crambessa.

Crambessa, sp. ?

The collection contains two specimens, both from Galle Bay, June and August; one is in fairly good condition and the other is damaged.

Umbrella.—The umbrella is semi-globular, about twice as broad as high, and measures about 75 millims. in width and about 40 millims. in height. The ex-umbrella looks smooth, but a close examination with a lens shows that the surface is closely covered with very minute papillæ, which give it a granulated appearance. The ex-umbrella of one specimen has fine markings which look like a pattern produced by pressure against a tow-net. The pattern forms a network with a mesh of about half a millimetre.

Canal System.—There are eight ocular canals and eight adradial canals. The ocular canals run to the sense-organs, but the adradial canals stop at the circular canal and do not proceed to the margin. The circular canal, which is broad and conspicuous, is situated about 10 millims. from the margin of the umbrella. Between the circular canal and the margin of the umbrella the canal system forms a network of fine meshes. The ocular canals pass through this network and anastomose with it. On the inner side of the circular canal and between the radial canals there is a very coarse network of canals. This network is in communication with the circular canal, but not with the stomach. In one specimen there is a slight anastomosis of the inner network with some of the radial canals, but in the other specimen there is no union.

Margin of the Umbrella.—Some of the velar lobes are about as long as broad, somewhat quadrangular in shape, with rounded corners, and some are narrow and more pointed. There are about eight velar lobes between every two ocular lobes.

Sense-organs.—Eight sense-organs are present. The outer sensory pit is triangular in outline and its surface is folded. The principal folds radiate outwards from the bottom of the pit. The tentaculocyst is apparently without an ocellus, as there is no trace of any pigment. The ocular lobes are much smaller than the velar lobes, and are pointed.

Sub-umbrella Muscles.—In one specimen the sub-umbrella muscles have become detached and a clear view of the canal system is obtained. In the other specimen the muscles are present, and they form a circular band between the periphery of the oral disc and the margin of the umbrella. The circular muscle band is continuous and is not radially interrupted.

Sub-genital Cavity.—The four sub-genital ostia open into a common continuous cavity. The ostia are very large, forming long but narrow slits, about 20 millims. in width, and about as wide as the columns. The entrance is partly blocked in the centre by a large triangular gelatinous knob on the sub-umbrella, and just inside there is another median knob and also two small lateral ones.

Oral Arms.—In a normal specimen there should be eight oral arms of equal length, but in both of these specimens the oral arms are abnormal in number and in length. One specimen has ten oral arms, the four columns bearing respectively 2.2.3.3. arms. The arms show a great difference in size, the largest is about 80 millims., and the smallest about 25 millims. As one arm is much longer than the others, which are all of different lengths, it is probable that the medusa received an injury in the oral arms, and regeneration has followed. The upper arm is very short and is somewhat laterally compressed. In the arm, measuring 80 millims. in length, the upper arm is about 15 millims. and the lower arm about 65 millims. The lower arm has three thin wings bearing oral mouths along the outer edges down to the distal end, which does not bear a gelatinous knob. The oral mouths on the ventral wings are continued along the upper arms to the oral disc, where they meet and form a cross-shaped pattern. There are no special appendages of any kind upon the arms or the oral disc. In the second specimen the arms are broken off close to the arm disc and there are stumps of nine, possibly ten, arms.

Stomach.—The stomach is cross-shaped. The gastric filaments run round the margin of the stomach and also curve downwards and inwards, forming a loop in the base of the columns. It is at the end of the loop that the canal from the oral arm enters the stomach.

The gonads are immature.

The specimens are of a whitish colour in formalin.

So far as I can make out, these specimens belong to the genus *Crambessa*, but I am not able to determine the species. As they are immature they are probably at an intermediate stage in growth and may develop into a species which has already been described.

CTENOPHORA.

ORDER: CYDIPPIDEA, LESSON.

FAMILY: PLEUROBRACHIIDÆ, CHUN, 1880.

Pleurobrachia, FLEMING, 1822.

Pleurobrachia globosa, MOSER, var. **ceylonensis**, nov.

Pleurobrachia globosa, MOSER (1903, p. 7, taf. i., figs. 1–4).

The collection contains about 900 specimens, varying in size from about 2 millims. up to 8 millims. in length. The largest specimen measures 8 millims. in length and 7 millims. in width.

A few are preserved in formalin and these have been used for examination, as they have retained their shape better than those in alcohol. The specimens in alcohol suffer more or less from contraction and shrinkage. When contraction or shrinkage is considerable, the position of the various organs changes so much that it would be quite possible to make two or more species out of a hundred specimens.

Locality :—A few were obtained on the Cheval Paar in March and Modragam Paar in November; the great majority were from Galle Bay in June, July and August.

Description.—The body is egg-shaped, sloping towards the oral pole, and almost circular in a transverse section. There are eight rows (costæ) of ciliated plates, of moderate length, extending over half, or a little more than half, of the meridional surface, beginning and terminating at about equal distances from the aboral and oral poles respectively. Each row contains about twenty narrow ciliated plates (combs). The meridional canals are just as long as the costæ. The two tentacles and their sheaths lie above the level of the stomach. The base of the sheath is in the first fork of the gastrovascular canals, on a level with the funnel. The sheath is like a long cone, tapering from the base, and lying at an angle of about 45 degrees from the perpendicular axis of the body and pointing towards the aboral end of the body. The opening of the sheath on the surface of the body is just under the aboral boundary line of the costæ. At the bottom of the sheath is the base of the tentacle, which is somewhat concave. The tentacles have lateral filaments, but no eolidiform appendages were seen. The transverse canals from the funnel to the meridional canals slope slightly in the aboral direction and join the meridional canals in the middle of their length, slightly above the level of the funnel. The base of the tentacle lies a little way from the funnel, but in a large number of specimens, owing to contraction or shrinkage, the base of the tentacle is adjacent to the funnel. It has contracted back on to the funnel and the top of the stomach.

On comparing the specimens with the figures of *Pleurobrachia globosa* (MOSER, 1903, taf. i., figs. 1–3), I find that they differ mainly in the length of the costæ, which are about half as long again. There is a slight difference in the shape of the body, the specimens from Ceylon taper more towards the oral pole. The position of the tentacular sheath is identical and so also is its sheath opening. As the chief difference lies in the length of the costæ, I hesitate to add a new species to the genus, but prefer to mark the difference by establishing a new variety.

The "Siboga" specimens were obtained in the Malay Archipelago.

ORDER: BEROIDEA, LESSON.

FAMILY: BEROIDÆ, ESCHSCHOLTZ, 1829.

Beroe, P. BROWNE, 1756.

Beroe flemingi (ESCHSCHOLTZ), 1829.

Pandora flemingii, ESCHSCHOLTZ (1829, p. 39, taf. ii., fig. 7).
Beroe pandora, MOSER (1903, p. 23, taf. ii., figs. 8 and 9; taf. iii., figs. 9 and 10).

There are about a dozen specimens in the collection, four of which are in fair condition and the others in fragments.

Description.—The body is conical, compressed in the funnel (transverse) plane, a little longer than wide, and rounded at the aboral end. The mouth is wide and has a fairly thin margin. The costæ are of unequal length; the sub-transversal costæ are about twice or nearly twice as long as the sub-ventral costæ. The meridional canals do not unite with the stomodæal canals. The lateral canals of the meridional canals meander without uniting in the smaller specimens, while in the larger specimens they unite with those from the adjacent meridional canals, forming a coarse irregular network in the outer wall of the body. Short blind canals also proceed from the circular canal around the mouth. The meridional canals on their outer surface are sparsely sprinkled with minute reddish-brown spots of pigment. The gonads are along the walls of the meridional canals, male and female on opposite sides of the canals.

Size:—8 millims. long and 6 millims. wide, 10 millims. long and 10 millims. wide, 12 millims. long and 8 millims. wide. Larger specimens broken into fragments.

Locality:—Off Mutwal Island, March 19, twelve specimens; Galle Bay, July 15, one specimen.

Distribution:—N. Pacific, east of Japan. Malay Archipelago.

Miss MOSER, in her 'Report on the Ctenophora of the "Siboga" Expedition,' has revised the Pleurobrachiidæ and Beroidæ, and has given a useful key for the identification of the species. I have tried to identify these specimens with the aid of the key, but remain somewhat doubtful about the result. The difficulty of the identification is no doubt increased by my want of experience in the group and by the fact that the best specimens are early stages. Taking the unequal length of the costæ and the absence of cilia round the mouth as a guide, the specimens come nearest to *Beroe flemingii.* They do not, however, quite agree in shape, and the lateral canals from the meridional canals do not communicate with the stomodæal canals. Miss MOSER states that the Siboga specimens are identical with *Pandora flemingii* of ESCHSCHOLTZ. This species ESCHSCHOLTZ named after the English zoologist JOHN FLEMING. Miss MOSER, however, has changed the specific name to *pandora,* wishing to retain the generic name *Pandora* as a specific name in honour of ESCHSCHOLTZ. The changing of the specific name of this species is certainly contrary to the International Rules on Nomenclature, and consequently the specific name *pandora* is invalid.

APPENDIX TO THE REPORT

ON THE

ALCYONARIA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

PROFESSOR J. ARTHUR THOMSON, M.A., UNIVERSITY OF ABERDEEN.

[WITH ONE PLATE AND TWO TEXT-FIGURES.]

A REVISION of the collection of Ceylonese Alcyonarians has enabled me to add to the list given in Supplementary Report No. XX., by Mr. W. D. HENDERSON and myself.*

The additions are :—

Spongodes cervicornis, WRIGHT and STUDER.
,, *involuta*, KÜKENTHAL.
,, *pütteri*, KÜKENTHAL.
,, *microspiculata*, PÜTTER.
,, ,, var. *ceylonensis*, nov.
Chironephthya indica, n. sp.
Suberogorgia köllikeri, WRIGHT and STUDER, var. *ceylonensis*, nov.
,, *rubra*, n. sp.
Caligorgia versluysi, n. sp.
Bebryce indica, n. sp.
Acamptogorgia gracilis, n. sp.
,, *rubra*, n. sp.
Muricella rubra, n. sp.
Virgularia elegans, GRAY.
,, *calycina*, n. sp.
,, *indica*, n. sp.
Fusticularia herdmani, n. gen. et sp., SIMPSON.

One of these (*Caligorgia versluysi*) is hardly an addition, since it replaces *Primnoa ellisii*, VON KOCH (= *Caligorgia ellisii*, = *C. verticillata*). For this correction I have to thank Dr. J. VERSLUYS, Amsterdam. The last on the list, *Fusticularia herdmani*, represents an interesting new genus, which has been separately described by Mr. J. J. SIMPSON, M.A. ('Annals and Magazine of Natural History,' June, 1905).

* By an oversight the two species of *Xenia* (Part III., pp. 271, 273) were misplaced; they should come first in the order Alcyonacea. On p. 289, the title of the family Muriceidæ was omitted in front of *Acanthogorgia*.

Family: NEPHTHYIDÆ.

Spongodes cervicornis, Wright and Studer.

A much weathered specimen, expanded in one plane, 10·5 centims. in height, by 10 centims. in breadth, and 1·8 centims. in thickness. The general colour is yellowish-white, but the polyp stalks and the polyps are covered with orange-red spicules. The polyps themselves are white in colour, but there appear to be minute orange-red spicules on the tentacles.

The polyp stalk is about 2 millims. in length and is covered by longitudinally disposed spicules. At the base of the polyp, which stands at right angles to the Stützbündel, there is a double ring of transverse spicules, from which there arise eight converging triangles, each composed of two pairs of spicules, the basal pair converging at an obtuse angle.

As the colony is markedly flattened, with an irregular outline, with leaf-like lowermost branches, the specimen must be referred to Kükenthal's *cervicornis* group, and among those species in which the polyps have long stalks.

The specimen agrees, on the whole, with *Sp. cervicornis*, Wright and Studer, which seems to be a very variable species, including, according to Kükenthal, *Spongodes rhodosticta*, Wright and Studer.

Locality :—Ceylon seas.

Spongodes involuta, Kükenthal.

A beautiful divaricate colony, without the stalk, but otherwise almost complete. The general surface of the cœnenchyma is white, near the polyps the colour is strengthened by golden-yellow spicules; the spicules supporting the white polyps are deep rose-pink. The dimensions of height, maximum breadth and average thickness are 45, 40, and 12 millims. As the divaricate polyparium has no regular outline and is markedly flattened, the specimen is referable to Kükenthal's *cervicornis* group. As the polyps are borne on stalks 1·5 millims. to 2 millims. in length, the specimen must be included near *Sp. cervicornis*, Wright and Studer. The eight double rows of polyp spicules consist of five pairs of spindles, and thus our attention may be restricted to Kükenthal's *Dendronephthya involuta*.*

Our specimen agrees with this species in the following features :—(1) there are five pairs of polyp spicules in each double row; (2) one of the uppermost in each row projects above the polyp; (3) the polyp stalk is about 2 millims. in length.

Locality :—Ceylon seas.

Spongodes pütteri, Kükenthal.

A divaricate form, with a regular outline, a slightly flattened polyparium, and

* Kükenthal has referred all typical *Spongodes* species to his new genus *Dendronephthya*, but we see little advantage in this.

foliate lower branches, is referable to Kükenthal's *rigida* group, and closely approaches *Sp. pütteri.* Thus the polyparium is a slightly flattened cylinder; the lateral branches are almost cylindrical and sometimes dichotomous; the groups of polyps, usually seven in number, are borne by stalks about 2 millims. to 3 millims. in length; the polyps are supported by eight pairs of converging spicules, one of which projects farther than the others; the longest Stützbündel spicule exceeds 3 millims., is covered with minute thorns, and projects for a little over a millimetre. The spicules closely resemble those of *Sp. pütteri* in form and size, but are of a bright orange colour around the polyps and on the polyp stalks. It seems warrantable to regard this specimen as a colour variety of *Sp. pütteri.*

Locality:—Ceylon seas.

Spongodes microspiculata, Pütter.

This species is represented by a very beautiful small colony,—6·5 centims. in height and 5·5 centims. in maximum breadth. The stalk by which it is attached is 2·5 centims. long and 1·3 centims. in diameter. The lower branches are foliaceous, but above this there are three main branches, one central and two lateral, in length 3 centims., 2·5 centims., and 2 centims. respectively, with an average diameter of 0·8 centim. From these, smaller branches arise on all sides almost perpendicularly, the lateral ones being the longest, so that the whole colony presents a somewhat flattened appearance, the tips so arranged that the contour is regular. The general colour of the colony is orange-red.

The polyps are in clusters of five to eight, seven being the most typical number. They arise from tertiary branches, except on the lower foliaceous part, which is the expanded portion of primary branches. The polyps are almost globular, standing at right angles to a short stalk 1 millim. in length. The Stützbündel is fairly well developed, one long spindle projecting about 0·8 millim. beyond the insertion of the polyp. On the outside of the anthocodia the spicules have a very definite arrangement, consisting of eight double rows of 6 to 7 converging pale yellow spicules, the terminal pairs projecting a little beyond the anthocodia. Between these groups small colourless spindles are scattered irregularly. On the tentacles the spicules are arranged in a biserial manner, approximately at right angles to the long axis.

The spicules are warty spindles of very varied proportions, some long and slender, others short and thick. On the main stem they are of the second type, the following being typical measurements:—1·2 millims. × 0·5 millim.; 1·3 millims. × 0·4 millim.; 2 millims. × 0·4 millim. On the secondary branches they become more elongated and slender, and have a slight yellow tinge. Further up the colour becomes more marked and there is a distinct orange-coloured core. The following measurements were taken:—2·5 millims. × 0·1 millim.; 1·9 millims. × 0·1 millim. Scattered irregularly amongst these there are small elongated thin spindles of a bright red colour of the following sizes :—0·3 millim. × 0·02 millim. ; 0·35 millim. × 0·02 millim. The spicules of the polyps are very minute and are pale yellow or colourless, 0·15 millim. × 0·01 millim.

Locality :—Ceylon seas.

Spongodes microspiculata, var. **ceylonensis,** nov.

Another colony, 8·5 centims. high and 5 centims. broad, belongs to the same species, but as it differs markedly in general form and colour it seems advisable to record a distinct variety. The chief points of difference are :—

(1) It does not extend so markedly in one plane, one of the branches arising more or less at right angles to the plane of expansion ;

(2) The general contour is more rugged ;

(3) The colour approaches purple, even on the main branches, owing to the presence of faintly purplish spicules ;

(4) The spicules are arranged on the main stem and branches more transversely ;

(5) The spicules are long, slender, warty spindles, with a light purple tint in the older parts, becoming darker on the smaller branches which bear the polyps. Those of the polyps are transparent and colourless. Measurements :—On the main stem, 2·2 millims. × 0·2 millim. and 1·2 millims. × 0·2 millim. ; on the smaller branches, 1·4 millims. × 0·1 millim., 1·5 millims. × 0·1 millim. ; around the polyps, 0·6 millim. × 0·01 millim.

The architecture of the polyps is essentially the same as in the former specimen, so that this form must be classed in the species *microspiculata*, though the characters enumerated above justify its position as a new variety.

Locality :—Ceylon seas.

Family: SIPHONOGORGIIDÆ.

Chironephthya indica, n. sp.—Plate, figs. 1 and 14.

A specimen of a reddish-brown colour, consisting of two small branches, about 4 centims. in height and 4 millims. in thickness.

The polyps occur on all sides and a frequent interval is 1 millim. Each is about 0·5 millim. in diameter. The anthocodiæ are almost without exception nearly flush with the general surface of the branch.

The opercular covering consists of eight triangular portions or "points" converging over the tentacles, and at the bases of the triangles there are numerous (5) rows of horizontal spicules forming a circlet or "crown." Each triangular "point" consists of three diverging pairs of spicules arranged *en chevron*, the two outermost enclosing the others. The spicules of the "points" and of the "crown" are reddish-brown to orange-red in colour.

The whole cœnenchyma is covered with large rough spindles, mostly curved in a slightly **S**-shaped manner, some reddish-brown and others very light in colour. Similar internal spicules constitute the rigid substance of the branch around the longitudinal canals, of which four were seen in a cross-section. The knobbed tubercles often present a spiral arrangement.

The following measurements were taken in millimetres :—(*a*) Long stout spindles, 2·3 × 0·2, 2·5 × 0·175, 2·7 × 0·3 ; (*b*) slender smaller spindles, 1·1 × 0·03, 1·3 × 0·04, 1·5 × 0·025 ; (*c*) very small spindles, 0·2 × 0·025 ; (*d*) canal-wall spicules, uncoloured, with relatively long spines, 0·2 × 0·01, 0·16 × 0·01, 0·14 × 0·02, including the spines.

It seems difficult at present to distinguish between the genera *Chironephthya* and *Siphonogorgia*, if indeed they are not one. Hickson has suggested that the name *Chironephthya* be retained for species or facies with a form and mode of branching like *Nephthya*, with anthocodiæ rarely retracted, and with four principal spicules *en chevron* in the points of the anthocodiæ ; and that the name *Siphonogorgia* be retained for species or facies of more massive *Gorgonia*-like form of growth, with anthocodiæ capable of complete retraction within the general cœnenchyma, and with spicules irregularly placed or arranged in a fan-like manner in the points of the anthocodiæ ('Alcyonaria of the Maldives,' Part I., p. 491).

If we apply these distinctions to the present specimen, we find that it agrees with *Chironephthya* in having triangular opercular coverings, but disagrees in having almost all the anthocodiæ completely retracted, and in having, as far as we can judge, a more massive mode of growth. As the minute architecture of the polyps is probably the most distinctive feature, we have referred the specimen to *Chironephthya*.

Locality :—Ceylon seas.

Family : SCLEROGORGIIDÆ.

Suberogorgia köllikeri, Wright and Studer, var. **ceylonensis**, nov.

Several fragments, including a basal piece, of a yellowish colony or colonies with a sclerogorgic axis. The stem is 3 millims. in diameter at the base, and 1 millim. in the thinnest branch of the chief specimen. The greatest length is 8·5 centims.

Verrucæ may arise on all sides, but they are, for the most part, lateral. In the smaller fragments they are altogether lateral and regularly alternate. Their diameter is about 1 millim. Here and there the aperture shows an eight-rayed figure in the fully retracted state of the polyp.

The thin cœnenchyma is marked on opposite sides by two shallow winding grooves.

The spicules include the following forms :—(*a*) Numerous warty spindles, 0·175 millim. × 0·075 millim., 0·225 millim. × 0·075 millim ; (*b*) a few very slender spindles, 0·1 millim. × 0·02 millim.; (*c*) almost orbicular forms, 0·1 millim. × 0·1 millim.; and (*d*) small spindles (0·1 millim. × 0·03 millim.) on the aboral surface of the tentacles, forming in retraction an opercular covering with eight points.

This form closely approaches *S. köllikeri*, Wright and Studer, but there the verrucæ have a diameter of 2 millims. to 3 millims., the polyps are large and prominent, the verrucæ have eight-rayed margins, and the colour is yellowish-brown. But as the differences are hardly more than quantitative, we rank the Ceylonese specimens simply as a variety of the "Challenger" species.

Locality:—Ceylon seas.

Suberogorgia rubra, n. sp.—Plate, fig. 4.

Half-a-dozen fragments of a red colony, with a sclerogorgic very horny axis (1·5 millims. in diameter), with a nutrient canal on each side, with thin friable cœnenchyma, and with close-set, lateral, alternate verrucæ, about 1 millim. in diameter. The completely retractile polyps are white with a slight yellowish sheen, and are supported by groups of small colourless spicules. It is difficult to make out with certainty what the precise arrangement of these spicules is, but in two or three cases eight triangular groups were seen on the polyp wall. In the fully retracted state of the polyps the verruca appears as a rounded hillock beset with somewhat blunt spindles.

The spicules of the cœnenchyma are warty spindles of very varied dimensions. The following measurements were taken in millimetres:—(*a*) yellow spindles, 0·45 × 0·1, 0·3 × 0·1; (*b*) colourless spindles, 0·175 × 0·07, 0·2 × 0·08.

The colour when first examined was a bright red, but it has since become paler and shows a tint of orange. We note this change because it is unusual in Alcyonarians.

The fragments in question most closely approach *S. köllikeri*, Wright and Studer, var. *ceylonensis*, n., but the polyps are much more crowded and decidedly smaller, and both colour and spiculation are different. One of the fragments bore a very minute pearl oyster.

Locality:—Ceylon seas.

Family: PRIMNOIDÆ.

Caligorgia versluysi, n. sp.—Plate, figs. 6 and 15.

The beautiful form which we recorded (Part III., p. 289) as *Primnoa ellisii*, von Koch, appeared to us to agree with the description given by von Koch, and so up to a certain point it does. But Dr. J. Versluys has been good enough to point out to me that von Koch's description is not sufficiently minute to enable one to discriminate between *Primnoa* (or better *Caligorgia*) *ellisii* and other species which have since been defined off. Dr. Versluys was kind enough to examine the specimen from the Ceylonese collection and another from the Indian Museum collection (see Part III., p. 289). He regards them as representatives of two new species, distinct from von Koch's, and closely related to a new species (*C. similis*) which will be described in Versluys' memoir on the Primnoidæ of the "Siboga" Collection. In the "Siboga" material he found that the number and arrangement of the sclerites in the polyps afforded a constant and reliable basis for specific diagnosis.

We have therefore to withdraw the remarks we made on the geographical distribution of *Primnoa ellisii* (= *Caligorgia verticillata*), and we have to record from Ceylon the new species *Caligorgia versluysi*, the particular features of which are discussed in the following note which Dr. Versluys has generously supplied:—

Note by Dr. Versluys.

"I find that the Primnoid collected by Professor Herdman at Ceylon is not referable to *Primnoa ellisii*, von Koch. As it seems to me that von Koch was not justified in separating his species from *Caligorgia verticillata* (Pallas), I shall use the older name in comparing it with Herdman's species.*

The Ceylonese species is decidedly more delicate than *C. verticillata*, and the type of ramification is different. The more important differences are stated in the following table:—

1. Characters of Herdman's Species.	2. Characters of *Caligorgia verticillata*.
(*a*) The colony is dichotomously branched.	(*a*) The colony is pinnately branched.
(*b*) The polyps are arranged in whorls of 3 and occasionally of 2; no higher number was observed.	(*b*) On the thinnest twigs the polyps are arranged in whorls of 3, very rarely of 2; on the thicker branches the whorls mostly consist of 4 polyps.
(*c*) On a centimetre of the twigs about 8 whorls of polyps are found.	(*c*) On a centimetre there are only 5 or 6 whorls.
(*d*) The length of the contracted polyps is less than 0·75 millim.	(*d*) The length of the contracted polyps is 1 millim. to 1·25 millims.
(*e*) The distance between two successive whorls generally varies between 0·6 millim. and 0·75 millim.; sometimes, however, it rises up to 1 millim.	(*e*) This distance is 1 millim. to 1·5 millims.

Of the 8 longitudinal rows of scales, which formed the covering of the polyps in the typical primitive Primnoinæ, viz., a pair of adaxial, inner lateral, outer lateral and abaxial rows, only four rows, the abaxial and outer lateral pair, are well developed in both species. The inner lateral rows are each reduced to a single large distal

* Compare Versluys, 'Primnoidæ; "Siboga" Expeditie, Monograph XIII,' second part, which is in the press.

scale in Herdman's species, against two large distal scales in *C. verticillata.* The outer lateral rows are somewhat reduced in Herdman's species, as they number only 5 scales, against 7 (or 6 if the most basal scale is considered as belonging to the cœnenchyma) in *C. verticillata.* The abaxial rows in this last species consist of 9 scales each, all of nearly the same rounded form, and not extending over the sides of the polyps, which are entirely covered by the scales of the well-developed outer lateral rows. In Herdman's species the abaxial rows are formed by 10 or 11 scales of rather diverse form, as 2 or 3 are somewhat prolonged laterally over the sides of the polyps between the scales of the somewhat reduced outer lateral rows. The upper margin of the polyp scales in Herdman's species is not strongly toothed, but these teeth are well developed and more numerous in *C. verticillata.* In this last species the operculum forms a higher and, consequently, more pointed cone on the top of the polyp. The scales in the cœnenchyma are of the same type, polygonal scales with strongly toothed irregular borders, and with the outer surface covered with radiating and anastomosing prominences.

The species collected by Professor Herdman may also be easily distinguished from all the previously described dichotomously branched species of *Caligorgia*, viz., *C. ventilabrum*, *modesta* and *compressa.** It is more delicate, with smaller polyps, and none of these three species has so few polyps in each whorl, even on its thinnest twigs.

There are, however, two new species in the collection made by the "Siboga" Expedition in the Malay Archipelago, which in their habit, the dimensions of their polyps, and the small number of polyps in each whorl very closely resemble Herdman's species. They will be described in my paper on the Primnoidæ of the "Siboga" Expedition; in this note I can only point out the more important differences between these two species and Herdman's.

One of them, *C. minuta*, is easily distinguished by the much less numerous and proportionately much larger scales in its polyps. The abaxial rows consist of only 5 scales, of which the 4 proximal ones extend over the sides of the polyps, where they replace the outer lateral rows, of which only one large distal scale in the upper margin of the polyps is left.

The other new form, *C. similis*, is more closely allied to Herdman's species. But while its polyps are arranged in whorls of 3, very rarely 2, on the thinnest twigs, on the thicker branches the whorls number 4, perhaps even sometimes 5 polyps. On one centimetre length of the twigs the same number of whorls (8) is found. But the polyps are somewhat larger, measuring from 0·75 millim. to 0·8 millim. in length, sometimes even 1 millim., against 0·75 millim. or less in Herdman's species, and consequently the distance of the successive whorls is on an average somewhat less. The most important differences, however, are found in the polyps; they are shown in the following table:—

* *C. elegans*, Gray, is insufficiently described and a doubtful species.

1. Polyps of Herdman's Species.	2. Polyps of *Caligorgia similis.*
(*a*) The abaxial rows are formed by 10 (or 11) scales each.	(*a*) The abaxial rows are formed by 7 scales.
(*b*) The outer lateral rows are but little reduced, consisting of 5 scales each.	(*b*) Of the outer lateral rows only one large distal scale is left.
(*c*) When the polyps are seen from the side, the distal scale of the inner lateral row is clearly visible.	(*c*) No scale of the inner lateral row is visible when the polyps are seen from the side.
(*d*) The abaxial scales show no well-developed extensions over the sides of the polyps, though such an extension is clearly indicated in some of them.	(*d*) The 5 proximal abaxial scales are produced laterally and replace the missing outer lateral scales.
(*e*) The outer surface of the scales of the polyps is covered with prominences radiating from the nucleus and partly ending in teeth at the upper border of the scales.	(*e*) No prominences are developed; the teeth are few and feeble.

In both species the outer surface of the scales of the cœnenchyma is covered with anastomosing prominences, many of which end in a tooth at the border of the scales. These prominences give a typical appearance to the scales of the cœnenchyma; they are more strongly developed in Herdman's species than in *C. similis.* They are also found in some pinnately branched species of *Caligorgia*, for instance, *C. verticillata* and *C. sertosa.*

From this comparison it may be concluded that the *Caligorgia* in the collection made by Professor Herdman is a new species, recognisable by its dichotomous ramification, its delicate habit, the small number of polyps in each whorl, its very small polyps, and by the comparatively large number of scales covering the polyps.

I have to thank Professor Herdman and Professor J. Arthur Thomson for their kindness in sending me some material to study this species. In many respects it resembles *C. verticillata.* The description given of this last species under the name *Primnoa ellisii*, by von Koch, though excellent and valuable in many respects, does not give many morphological details, especially in regard to the arrangement and form of the scales in the polyps. A renewed investigation was necessary to make out how far it is different from Herdman's specimen. This investigation has shown conclusively that the two are different species, but it is readily comprehensible that Professor Thomson was led by von Koch's description to consider the species as identical."

Locality:—Deep water off Galle.

Family: MURICEIDÆ.

Bebryce indica, n. sp.—Plate, fig. 3.

The collection included several specimens of a Muriceid, which we have, with some hesitation, referred to the genus *Bebryce*. It agrees with this genus in its general features, but differs considerably in its spiculation from *B. mollis*, von Koch, *B. studeri*, Whitelegge, *B. philippi*, Studer, and *B. hicksoni* already described by us (Part III., p. 294). In our account of *B. hicksoni* we referred to what might be regarded as varieties of that species, but some additional specimens which we have studied cannot so be dealt with.

All are dark-coloured irregularly branched colonies, disguised by a growth of monaxonial siliceous sponge, and with one exception spreading in one plane. The exception has seven alternate branches, terminally clavate, on an average 2 millims. in diameter, and is 8 centims. in height by the same in maximum breadth. One of the specimens attained a height of 18 centims.

The verrucæ are prominent truncated cones, usually on all sides of the main stem and branches, but sometimes almost restricted to the sides in the plane of branching. They are about 1·5 millims. in height and breadth, and are separated along one line by intervals of 1·5 millims to 2 millims. Except in a few cases, the polyps are completely retracted and the verrucæ are thickly beset with sponge spicules.

The axis is non-calcareous, light brown in colour, very soft and flexible, and traversed by twisted longitudinal grooves whose depth has doubtless been increased by shrinkage of the core. The diameter of the axis is about 1·25 millims.

When the sponge spicules are carefully removed, the surface of the cœnenchyma exhibits the characteristic *Bebryce* appearance. There is a coherent mosaic of interlocked tuberculate discs, and large pieces can be separated off after slight heating without any loosening of the component spicules. The average thickness of the cœnenchyma is about 0·3 millim.

On the few polyps which could be satisfactorily seen, there were relatively large tuberculate spindles.

The following types of spicules occur :—

(*a*) Almost regular tuberculate quadriradiate forms, with more or less pronounced cruciate arms, and sometimes at least with an internal boss at right angles to the expanded disc, 0·15 millim. × 0·125 millim. in length and breadth of the disc.

(*b*) Irregular quadriradiate forms, with the arms to one side longer and stronger than those to the other side; 0·25 millim. between the tips of the longest arms, 0·15 millim. between a long and a short arm, 0·1 millim. between the two short arms.

(*c*) Approximately square forms, suggestive of amphicœlous vertebræ, with slightly prolonged corners and slightly concave sides, 0·175 millim. × 0·175 millim.; and transitional forms connecting these with the pronounced quadriradiate types.

(*d*) Tuberculate "capstans," with a very slightly marked middle zone, separating two equal portions; and a variety of this "double-club" type with the part to one side of the waist much smaller than the other—a feature prominent in the spicules of some other species of this genus; 0·125 millim. × 0·1 millim. in height and breadth.

(*e*) Small tuberculate forms, more like "double wheels" than capstans; 0·1 millim. × 0·1 millim. in length and breadth, and 0·04 millim. across the "waist."

(*f*) Bent, warty spindles from the polyps, including (1) short, thin, rough forms with relatively long, irregularly disposed tubercles, *e.g.*, 0·35 millim. in length by 0·075 millim. at the broadest part, and (2) longer, smoother forms with relatively shorter, more regular tubercles, 0·5 millim. to 0·6 millim. in length by 0·05 millim. in maximum breadth.

It is unsatisfactory that we have not been able to study the polyps of this species, but there is no doubt that some of the spicules are flattened tuberculate discs with an internal boss, approaching the so-called "scales" of *Bebryce*. If we are right in our diagnosis, *B. indica* is nearest *B. hicksoni*, but there the "scales" were numerous and unmistakable, and quadriradiate or cruciate forms, which are here characteristic, were not seen.

Locality :—West of Periya Paar, Gulf of Manaar.

Acamptogorgia gracilis, n. sp.—Plate, figs. 12 and 13.

A weathered and yet distinctive specimen, 6 centims. in height by 4 centims. in breadth. From a short distance the branches appear pinkish red, and the verrucæ stand out like white papillæ. Closer examination with the lens shows an exquisite mingling of red and colourless spicules, the former producing a somewhat characteristic punctate appearance.

The verrucæ may occur on all sides of the branches, but are for the most part lateral in position; they stand out almost at right angles to a height of about 1 millim. ; they are sometimes opposite, sometimes alternate, and the branch terminates in a pair.

The cœnenchyma presents a rough surface owing to the projecting sharp points of the continuous layer of spicules. The characteristic spicules of the cœnenchyma are continued without marked change up the sides of the verrucæ, the projecting tips being all directed upwards. At the top of the verruca there is a ring of horizontal spicules in two rows, and on this is based an opercular covering of eight parts, each composed of two curved foliaceous spindles.

The axis is brown in colour, non-calcareous, 1·5 millims. in diameter at the base, and rather less than 0·5 millim. in the delicate twigs, where it becomes much paler in colour, almost approaching yellow. It shows at places the chambered appearance seen in some other species of this varied genus.

The spicules include the following types :—

(*a*) Curved warty spindles with a bidentate or otherwise toothed foliaceous expansion from the middle of the curve, 0·3 millim. between the tips by 0·1 millim. at the broadest part ;

(*b*) Clubs with irregularly expanded divaricate ends, 0·25 millim. in extreme length by 0·15 millim. at the broadest part ;

(*c*) Small irregularly stellate forms, 0·1 millim. × 0·1 millim. ; and

(*d*) Forms with four or more rays, 0·3 millim. × 0·2 millim.

Locality :—Ceylon seas.

Acamptogorgia rubra, n. sp.—Plate, fig. 5, and text-fig. 1.

A deep crimson, incomplete colony, 5 centims. in height, giving off in one plane three lateral branches which have an average thickness of about 1 millim. There is also a fragment about 2 centims. in length, with four twigs arising almost at right angles from the main branch, which is slightly over 1 millim. in breadth.

Fig. 1.
Acamptogorgia rubra, n. sp. × 15.

The verrucæ, 0·5 millim. in height by 1 millim. in breadth, are alternate or sub-opposite, and arise at right angles to the axis. Two occur side by side at the end of a branch. The cœnenchyma is thin and presents a very prickly appearance, due to the projecting folia and spines of the beautiful crimson spicules. The axis is yellowish, 0·3 millim. to 0·4 millim. in diameter.

The spicules show considerable diversity of form :—

(*a*) Straight, warty spindles, 0·6 millim. × 0·1 millim. ;

(*b*) Narrow, curved spindles, smooth terminally, warty about the middle, 0·6 millim. × 0·05 millim.

(*c*) Large triradiate forms in which the shortest, almost smooth ray projects externally and often bears a foliaceous expansion, while the two larger rays are denticulate or branched to a very varied degree ; 0·6 millim. in breadth between the tips of the longest rays and 0·4 millim. in height between a line joining these internal tips and the tip of the external ray.

(*d*) Smaller and often simpler triradiate forms, 0·45 millim. in breadth and 0·25 millim. in height, and much smaller.

(*e*) Small, very warty spindles with a foliaceous expansion about the middle, 0·2 millim. × 0·1 millim.

Locality :—Ceylon seas.

Muricella complanata, Wright and Studer.

Reference has already been made (Part III., p. 303) to varietal forms of this species, which seem to vary considerably in detail. Another form deserves to be recorded. It differs from the type in the coloration of the spicules, large yellowish spindles covering smaller transparent ones, and others still smaller which are rose-coloured. Thus the rubbed base of the specimen is bright rose, while the upper parts are ochreous yellow—a difference which seems to be wholly due to the degree of abrasion.

The verrucæ show the characteristic longitudinal grouping of small spindles in eight triangles, but it may be noted that in some cases they occur opposite one another, instead of alternately as in the type, and that the diameter of their base can hardly be said to exceed a millimetre, while that in the type was 2 millims.

Muricella rubra, n. sp.—Plate, figs. 2 and 7.

A minute fragment of a bright-red colony with a relatively thin cœnenchyma filled with long warty spindles.

The verrucæ are crowded and alternate, low and subconical, arising at right angles to the surface, and covered with spindles smaller than those of the cœnenchyma. The polyps are white and stand out conspicuously. The axis is light yellow, non-calcareous, flexible, 0·5 millim. in diameter.

The general spicules of the cœnenchyma are (*a*) large warty spindles, straight or slightly **S**-shaped, 1·2 × 0·2, 0·95 × 0·175 millims.; and (*b*) small warty spindles, 0·5 × 0·1, 0·4 × 0·075 millim. In the polyps the spicules are transparent, slightly warty spindles, 0·25 × 0·04, 0·2 × 0·03 millim.

Locality :—Ceylon seas.

Family: VIRGULARIIDÆ.

Virgularia loveni, Kölliker.

We have already recorded the occurrence of representatives of *V. loveni* in this collection, but another specimen has come to hand which deserves notice, especially as that on which Kölliker based his species was very imperfect.

This is also an incomplete specimen, but very well preserved, and presenting several features which make us hesitate in referring it to *V. loveni* unless Kölliker's diagnosis be somewhat modified. It is about 90 millims. in length, 5 millims. to 9 millims. in breadth, and is altogether pinnule-bearing, except 15 millims. at the broken basal part. The lower pinnules are closely crowded without visible intervals; those on the upper portion are separated on the prorachidial surface by intervals of 1 millim. to 1·5 millims., and overlap on the metarachidial surface. There is a bare tract, 2·5 millims. in breadth, along the prorachidial surface, and up the middle of this there runs a well-marked narrow groove.

The free margin of the pinnule curves like an elongated **S**, and its prorachidial insertion is higher than the other. Most of the pinnules are turned markedly downwards. There were 30 polyps on the pinnules counted, and a single row of zooids extends transversely in the interspace between the pinnules. The polyps are very distinct, but the indentations between the calices are shallow.

The axis, which measures 2·25 millims. in diameter at the base, is cylindrical, whitish, and covered with remarkable indentations and irregular ridges.

This form agrees with *V. loveni* in having up to 30 polyps on the pinnules, an indented ridged axis, the zooids in a single row, and so on; but in Kölliker's specimen the pinnules were 3 millims. to 4 millims. apart, the shape was approximately fan-like, and the calices were scarcely distinct.

Locality :—Ceylon seas.

Virgularia elegans, GRAY.

To this imperfectly described species we refer an imperfect specimen, and if the reference be correct we can make GRAY'S diagnosis a little more definite.

The rachis bears 106 pairs of pinnules; it is 145 millims. in length, including 15 millims. of exposed axis at the broken basal end; its breadth is 2 millims. to 3 millims., and that of the axis 1·25 millims.

The pinnules have a breadth and height of 2·75 millims. × 0·5 millim., 2·75 millims. × 2 millims., 2·25 millims. × 0·75 millim., at the base, middle portion, and top of the rachis. The interval between them is 0·25 millim. at the base and 2 millims. at the top. They bear 18 polyps in a single row.

Locality:—Ceylon seas.

Virgularia calycina, n. sp.—Plate, figs. 8, 9, 10, 11.

An incomplete specimen, 57 millims. in length by 3 millims. to 4 millims. in breadth, altogether pinnule-bearing, except 5 millims. of bare axis at the broken basal end.

The lower pinnules are closely crowded, with no intervals between them, but in the upper portion of the rachis they become distant, being separated by intervals of 1·75 millims. There is a bare streak, about 0·75 millim. in breadth, along the prorachidial surface.

The pinnules are substantial and distinct, though relatively narrow, and their prorachidial insertion is very markedly higher than the other. The curve of their free margin is a crescent. On each of those counted there were 18 very distinct calices, with conspicuous longitudinal grooves. When the polyps are retracted, the calices are ovoid in shape, about 1 millim. in height, with a minute circular aperture. The polyps appear to be arranged, except the first three or four at the prorachidial side, in two alternating rows, but this is simply due to the fact that they are alternately shunted to opposite sides along the margin of the pinnule. The inferior surface of the pinnule is strongly marked by eighteen parallel ridges, each corresponding to a calyx or polyp. On the upper surface there are similar markings, but less pronounced. Some of the polyps contain ova. Here and there a few minute lateral zooids were seen in a row about halfway between two pinnules.

The axis is white and cylindrical, with somewhat delicate and complex markings.

This form should be ranked among those species of *Virgularia* which KÖLLIKER described as having distinct pinnules, distinct calices, zooids in one row or in two rows, with the ventral insertion higher than the dorsal, with non-transparent, crescent-shaped pinnules,—that is to the artificial section including *V. mirabilis* (O. F. MÜLLER) (with 6 to 9 polyps), *V. multiflora*, KNER (with 11 to 15 polyps), and some uncertain forms. But from *V. multiflora* this new form is at once distinguishable by the markedly separate calices, and also by their number, &c. In *V. juncea*, again, the pinnules are very slight, and the calices are not separate; in

V. reinwardtii there are 18 polyps, but the calices are not separate. The present specimen appears to be nearest *V. elegans*, GRAY, but in that species the pinnules are much less distinct, the number of calices is 14 to 24, and the calices are "scarcely separate at the margin."

Locality :—Ceylon seas.

Virgularia indica, n. sp.

Several incomplete specimens, about 12 centims. in length by 5 millims. to 6 millims. in breadth, bearing over 120 pairs of pinnules. About a fourth of these are well developed and are separated by intervals of 0·75 millim. On the upper region of the prorachidial surface there is a bare streak 2 millims. in breadth, which becomes a narrow line in the lower half of the colony. On the lower half of the metarachidial surface there is a deep channel left up the middle between the two rows of pinnules, but higher up this is lost, since the opposite pinnules meet or regularly overlap. There were 15 polyps on all the pinnules counted and the siphonozooids occur in equal number in a row midway between two pinnules or near the base of the upper pinnule. The ovoid calices are distinctly marked off from one another and the translucent pinnule shows grooves and ridges corresponding in number to the polyps. Several ova were seen in the pinnules.

The axis is cylindrical, about 1 millim. in diameter, and covered by a reddish-brown investment. As regards the number of polyps on a pinnule, this form resembles *V. multiflora*, KNER, which JUNGERSEN regards as merely a variety of *V. mirabilis* (O. F. MÜLLER). But the pinnules are much closer together, they often show an S-shaped curve, and they are translucent; the calices are distinctly separated from one another; the axis is flexible and covered with a reddish investment.

It therefore seems necessary to establish a new species.

Locality :—Modragam Paar, Gulf of Manaar.

It may seem remarkable that Professor HERDMAN should have found in a short time within a limited area no fewer than six species of *Virgularia*. This is the more extraordinary since the rich collection of deep-water Alcyonarians made by the "Investigator" in the Indian Ocean does not include a single representative of the genus.

It seems extraordinary, almost suspicious, that the handful of *Virgulariæ* before us should include three new species, in spite of our endeavours to unite these with others previously described. We would therefore note that :—

(1) *V. tuberculata* is conspicuously characterised by its red tuberculated axis and by the six, relatively large, very distinct, barrel-shaped polyps on each small pinnule;

(2) *V. calycina* is conspicuously characterised by its 18 very distinct ovoid calices on each prominently ridged pinnule;

(3) *V. indica* approaches *V. multiflora*, but differs in having the pinnules much

closer, often S-shaped, translucent, with distinctly separated calices, and in other characters.

Family: CAVERNULARIIDÆ.

Fusticularia herdmani, Simpson—Plate, figs. 16 to 22, and text-fig. 2.

I entrusted to Mr. J. J. Simpson, M.A., my private assistant, a small club-like specimen which had been overlooked in the first study of Professor Herdman's collection. It had, indeed, so much resemblance to a corticate sponge that it was originally sent for examination to Professor Dendy. The accompanying text-figure (fig. 2) is a reproduction of a drawing of the colony made by Professor Dendy.

Fig. 2. *Fusticularia herdmani*, Simpson. ×2.

Mr. Simpson has published an account of this interesting form in the 'Annals and Magazine of Natural History,' xv. (1905), pp. 561–5, 1 plate, and has named it appropriately *Fusticularia herdmani*, gen. et sp. n.

The specimen is a small free-living sponge-like colony, 3·7 centims. in length, 1·7 centims. in breadth, and 1 centim. thick. It consists of a flattened ovoid stock separated by a constriction from a comparatively slender trunk 1·2 centims. long and 0·6 centim. in breadth.

The general colour is a dark brown, approaching chocolate.

The zooids are dimorphic, the smaller siphonozooids being scattered irregularly among the larger autozooids, which are separated by distances varying from 1 millim. to 3 millims. The zooids are completely retractile into pit-like depressions, about 0·5 millim. in diameter. The length of a fully expanded autozooid is about 0·75 millim. to 1 millim. and the tentacles measure 0·7 millim.

Three longitudinal canals traverse the colony throughout its entire length.

The cœnenchyma is densely spiculose. The spicules, which vary greatly in form and size in the different parts of the colony, are arranged in bundles supporting the polyp cavities. All are hyaline and smooth and the majority bear blunt digitiform terminations which are often marked by characteristic annulations. The most frequent types are the following: blunt spindles, cylinders, clubs, double barrels and palmate forms. They vary in size from 0·3 × 0·05 millim. in the cortical layer of the stock to 0·45 × 0·025 millim. in the trunk. Among the characteristic features of this genus the following are most noteworthy: (*a*) the minuteness of the zooids; (*b*) the absence of an axis; (*c*) the broadly palmate spicules; (*d*) the elliptical trunk; (*e*) the constriction between stock and trunk; (*f*) the number (3) of canals in the stock; (*g*) the small number of autozooids.

The diagnosis reads:—"A somewhat sponge-like cavernularid, with a flattened ovoid stock separated by a constriction from a comparatively slender sterile trunk; with dimorphic retractile polyps, the autozooids not exceeding 1 millim. in length, the much smaller siphonozooids scattered irregularly among the autozooids; with abundant densely spiculate cœnenchyma, traversed by three longitudinal central canals passing down into the trunk; with smooth hyaline spicules bearing peculiar digitiform terminal processes and showing very characteristic annulations, especially near the ends."

Locality:—Cheval Paar, Gulf of Manaar, 6 fathoms.

Note.—Further inquiry into the history of the specimen listed by Professor Herdman and Mr. Hornell in their diaries as a possible *Corallium* sp. has shown that this tentative identification was mistaken. We therefore withdraw the paragraph referring to this specimen on p. 289 of Part III. of this Report.—J. A. T.

REPORT

ON THE

SOLITARY CORALS

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

GILBERT C. BOURNE, M.A., D.Sc., F.L.S.,
FELLOW AND TUTOR OF NEW COLLEGE, OXFORD.

[WITH FOUR PLATES AND FIVE FIGURES IN THE TEXT.]

THE following paper contains an account of a small but remarkably interesting collection of Solitary Corals from Ceylon, which Professor HERDMAN has kindly entrusted to me for identification and description. The collection includes five species of Turbinolidæ, of which two are apparently new to science, three species of Flabellidæ, six species of Fungiidæ and seven species of Eupsammiidæ. There are, in addition, some specimens of *Cyathohelia*, sp. *incert.*, and other colonial corals, but as it is my intention to confine myself to a description of the solitary corals and to species closely related to them, these compound forms will not be included in the present memoir.

As every student of corals knows, the classification and identification of the Turbinolidæ and Eupsammiidæ is attended with no inconsiderable difficulties. The greater number of the genera and species described by MILNE-EDWARDS and HAIME (**35** and **36**) were fossil and the type specimens have been inaccessible to me. The researches of the last forty years have added a considerable number of recent, as well as fossil species, some of which are undoubtedly identical with forms described by older authors; others are undoubtedly new, but many must be regarded as doubtful, for there is ample evidence that varieties have frequently been classed as species, and the identity of recently discovered living genera and species with previously described fossil species has in several cases been overlooked. Hence one cannot deal with any collection of Turbinolidæ and Eupsammiidæ, however small, without entering upon a criticism of these families, and, unfortunately, my claims to undertake such a criticism are limited. A short study of the literature of the subject is sufficient to convince one that no sufficient degree of exactitude can be attained without a study of the original specimens on which the genera and species were founded. But these are largely contained in foreign museums, which I have been unable to visit, or were included in private collections which have been dispersed and are no longer traceable. The British Museum is rich in the possession of the "Challenger" collections and in duplicates of species collected by Pourtalès, but it is singularly poor in Eupsammiidæ, and a careful search among the named specimens of this family failed to bring to light anything that was of assistance in disentangling the difficulties attendant on its classification. I have, therefore, had to rely chiefly on published descriptions and illustrations, and these are, in many cases, too vague and inaccurate to be of material assistance.

I wished, when I undertook this piece of work at Professor Herdman's request, to make a thorough examination of the anatomy of the soft parts as well as of the coralla of the specimens he entrusted to me, but this I found was impossible, as several of the more important species were represented only by a single specimen and it was necessary to dissolve away the soft parts in order to identify the coralla. I have, however, made a tolerably thorough investigation of the anatomy of three forms, *Heterocyathus æquicostatus*, *Heteropsammia michelinii*, and *Dendrophyllia gracilis*. As a matter of convenience this paper will be divided into two sections, the first dealing with the systematic description of the coralla contained in Professor Herdman's collection, the second with the details of the anatomy of the three above-mentioned species.

PART I.—SYSTEMATIC.

Family: TURBINOLIDÆ (*pars.*), M. Edwards and Haime.*

M. Edwards and Haime divided the Turbinolidæ into the two sub-families Caryophyllinæ, with one or more crowns of pali, and Turbinolinæ, without pali. The Caryophyllinæ were further subdivided into Caryophylliaceæ, with a single circle of pali, and Trochocyathaceæ, with more than one circle of pali. The Turbinolinæ were subdivided into the Turbinoliaceæ, destitute of epitheca, and Flabellaceæ, in which "the wall is completely covered by a pellicular epitheca." Martin Duncan, in his revision of the families and genera of the Madreporaria (**13**), abolished the sub-families

* 'Ann. des Sci. Nat.,' 3e sér., t. ix., 1848, and 'Hist. Nat. des Corall.,' t. ii., p. 7, 1857; P. M. Duncan, "Revision of the Madreporaria," 'Journ. Linn. Soc.,' vol. xviii., "Zoology," 1885.

of M. Edwards and Haime depending on the presence or absence of pali, and created in their stead three sub-families Turbinolidæ simplices, Turbinolidæ gemmantes and Turbinolidæ reptantes. The first of these includes nearly the whole of the Caryophyllinæ and Turbinolinæ of M. Edwards and Haime and is divided into seven alliances, viz., Smilotrochoida, Flabelloida, Placotrochoida, Turbinoloida, Trochocyathoida, Discocyathoida and Haplophylloida. Want of space and want of material forbid my entering upon a criticism of Duncan's classification, and I must content myself with remarking that it has been of no great assistance to systematists, and that the older classification of M. Edwards and Haime has been generally preferred to it by recent writers. Both classifications agree in placing the genus *Flabellum* and its allies as a subordinate group of the Turbinolidæ, and the most recent writer on the genus *Flabellum*, Mr. J. Stanley Gardiner (**22**), adopts the classification of Duncan, giving, however, a definition of the "Flabelloida," which I cannot find anywhere in Duncan's paper. As I shall have to enter more fully into the structure and classification of *Flabellum* and its allies in a subsequent part of this paper, I need only say here that I am of the opinion that they differ from all other Turbinolidæ in several important characters, but chiefly in the fact that their wall is a persistent prototheca (Bernard, **4**), which is not thickened externally by a secondary deposit of calcareous substance laid down by an "edge zone" or "perisarc," this latter structure being, indeed, absent. They must, therefore, be classified apart in a family Flabellidæ, and the Turbinolidæ, after the removal of the Flabellidæ, may be defined as follows:—

Corallum simple, or forming colonies by gemmation from the wall or from stoloniform basal outgrowths. The wall is thickened externally by the secondary deposit of calcareous tissue formed by the edge-zone, and is solid, variously ornamented with costæ, granules and spines, the spaces between the costæ sometimes filled up by the deposit. The upper part of the wall commonly formed by the union of the enlarged outer ends of the septa. Epitheca, when present, pellicular or lamellar, closely adherent. The septa commonly exsert and solid. Septal loculi open to the base. Pali may or may not be present. Columella present or absent; when present it may be essential or parietal and of very various shape and composition.

Paracyathus, M. Edwards and Haime.*

This genus is easily recognised by its numerous lobate pali, scarcely distinguishable from the prominences of the columella. The pali, however, should more correctly be described as paliform lobes, as they are clearly thickenings of the inner ends of the septa, and the outermost of the several crowns, at any rate, do not extend to the base. The original definition of the genus given by M. Edwards and Haime, in

* 'Ann. des Sci. Nat. Zool.,' 3e sér., t. ix., p. 318, 1848; 'Hist. Nat. des Cor.,' t. ii., p. 52, 1857; P. M. Duncan, "Rev. Madrep.," 'Journ. Linn. Soc.,' vol. xviii., "Zool.," p. 24, 1885.

1848, was amended in the 'Hist. Nat. des Coralliaires'; in the former the columella was described as "très developpée," the pali as "très élevés," but both these characters are exceedingly variable, and in the 'Hist. Nat. des Coralliaires' the definition of the structures in question runs thus: "La columelle est formée des tigelles qui paraissent naître du bord interne et inférieur des cloisons, et qui sont d'autant plus élevées qu'elles sont plus éxtérieures; sa surface est papilleuse et concave. Les palis paraissent se detacher également de la partie inférieure des cloisons, et se distinguent à peine des tigelles columellaires." The species of the genus are not easy to determine with certainty. LACAZE DUTHIERS (**33**) gives excellent photographs of *P. striatus*, and DUNCAN (**11**) gives several species from different parts of the world, but all these are obviously different from the specimens in Professor HERDMAN'S collection. It should be observed that the initial and therefore solitary corallites of the arborescent *Cyathohelia* closely resemble *Paracyathus*, the septal pali and columella being almost identical, and I am inclined to think that several of the described species of *Paracyathus* are nothing more than young Cyathoheliæ.

Paracyathus stokesi, M. EDW. and H.

There are three specimens of *Paracyathus* in Professor HERDMAN'S collection; they were taken at different times from different localities and differ from one another in details, but their resemblance is sufficiently close to lead me to refer them all to *P. stokesi*, M. EDW. and H. (**35**, plate x., figs. 7 and 7A).

Specimen *a* is from Trincomalee. The corallum is 17 millims. in height; the calice elliptical, its longer axis measuring 13 millims., its shorter axis 8 millims. The calice is depressed at either end of the long axis. The septa correspond very closely with M. EDWARDS and HAIME'S description of *P. stokesi*, but the fifth cycle is incomplete, and the outer ends of the primary and secondary septa are scarcely, if at all, thickened. The costæ differ from those of *P. stokesi*, in being so slightly developed that they are scarcely distinguishable at a short distance below the level of the calice.

Specimen *b* is from Galle. Height of corallum 14 millims.; longer axis of the calice 12 millims.; shorter axis 9 millims. Septal arrangement as in specimen *a*, but the septa are rather thicker externally. The calicular fossa is deeper, the columella less developed, and the septal pali stouter and more prominent than in *a*. The costæ agree exactly with M. EDWARDS and HAIME'S description of *P. stokesi;* they are rather broad, distinct to the base, and thickly covered with granules.

Specimen *c* is from deep water near Galle. Height of corallum 14 millims.; longer axis of calice 7 millims.; shorter axis 6 millims. This specimen resembles *P. procumbens*, M. EDW. and H., from the Eocene of Hauteville, in the following characters. The corallum is curved and the calice inclined to one side; the calice is subcircular and rather deep; the septa are somewhat exsert and their external ends project beyond the lip of the calice; the costæ are somewhat slender and form sharp ridges projecting unequally at different levels, but never prominently. On the other hand, it resembles *P. caryophyllus*, from the Eocene of Sheppey, in having only four cycles of septa. (It seems very probable that these two Eocene species are identical, the presence or absence of a fifth cycle of septa not being sufficient to distinguish them.)

I have no hesitation in referring *a* and *b* to *P. stokesi*, but I am more uncertain about *c*. If it cannot be referred to this species, it cannot be anything else than *P. procumbens;* but a comparison of M. EDWARDS and HAIME's figures (**35**, plate x., figs. 6 and 7) lead me to believe that the latter species is only a variety of *P. stokesi*, and that the three Ceylonese specimens are local varieties of that species.

Paracyathus striatus, PHILIPPI.

Cyathina striata, PHILIPPI, 'Arch. für Natur.,' 1842, vol. 1, p. 48.
Paracyathus striatus, M. EDWARDS and HAIME, 'Pol. foss. des terr. palæoz.,' 1851, p. 25.

A single specimen, from deep water off Galle, which only came into my hands after this paper was written, must clearly be referred to this species.

Rhodocyathus, n. gen.

Corallum simple, free, saucer-shaped, with signs of former adherence. Calice subcircular, wide, shallow. Columella essential, well developed, composed of numerous oblique thin overlapping lamellæ whose upper edges are produced into numerous flattened spines. Septa in six systems and five cycles, the last cycle incomplete. The primary and secondary septa subequal, very exsert, arched at their outer ends and sloping inwards to join the columella; their upper margins furnished with blunt spines; their outer margins produced into sharp and prominent spines where they pass into the costæ; the surfaces of the septa marked with broad radiating ridges corresponding to the marginal spines, the whole surface finely granular. Tertiary septa similar to the primaries and secondaries, but smaller and less exsert. The quaternary much smaller than the tertiary septa, and bending inwards to join the latter near the columella. The quinary septa mostly very small and free at their inner ends; where they are longer they generally become attached to an adjacent septum, usually to a quaternary, but in some cases to a primary, secondary, or tertiary; the inner ends of the quinary and quaternary septa are very thin and cribriform. The costæ corresponding to the first four cycles of septa form distinct fairly prominent ridges covered with fine granulations; those corresponding to the fifth cycle very small; the costæ of opposite ends meet below and cover in the basal scar of attachment.

Rhodocyathus ceylonensis, n. sp.—Plate I., figs. 1 and 1A.

The characters are those of the genus. A single specimen from Trincomalee.

The dry corallum is of a yellowish colour, and measures about 18 millims. in height from the rounded base to the top of a primary septum. The calice is subcircular, measuring 35 millims. in its longer and 33 millims. in its shorter diameter. The columella is oval, measuring 10 millims. × 6 millims., and has a horizontal surface. The specimen was evidently fixed in early life and has become detached, the scar of detachment being healed over in a peculiar manner by the continuation of sixteen costæ round the bottom of the corallum, to meet and fuse with their fellows of the opposite side. These costæ belong to the septal systems at either end of the longer axis of the calice; the costæ of the lateral systems converge below and unite to form two somewhat irregular and not very conspicuous lateral basal prominences. The specimen was completely covered by soft tissues, but these had to be removed to facilitate the study of the corallum.

I have been unable to refer this specimen to any known genus, and have therefore made the new genus *Rhodocyathus* to contain it. The name is descriptive of the shape of the calice, which bears a resemblance to a conventional rose. It differs from all the members of DUNCAN'S Turbinoloida in the characters of the columella. It is distinguished from the majority of the Trochocyathoid alliance by the absence of pali, and its shape and the character of its septa and costæ mark it off from the somewhat vague and all-embracing genus *Ceratotrochus*, as defined by DUNCAN. It cannot be placed in any genus of the Discocyathoid alliance, nor yet among the Haplophylloida. The presence of a columella separates it from all the Smilotrochoida; the character of the columella prevents its being placed among the Placotrochoida; and it certainly is not a Flabelloid. The genus shows most affinity to *Ceratotrochus* and *Deltocyathus*, and may be described as a Trochocyathoid without pali.

Cyathotrochus, n. gen.

Corallum simple, free, without a trace of adherence, forming a short, laterally compressed cone. Costæ moderately prominent near the lip of the calice, but scarcely distinguishable below and indistinguishable near the bluntly pointed base; the primary and secondary costæ somewhat more prominent than the tertiaries, which in turn are rather more prominent than the quaternaries; the costæ corresponding to the primary septum at each end of the longer axis of the calice much more prominent than the rest and continued as sharp ridges about half-way down the corallum, but not forming aliform expansions. Calice elliptical, subplane. Columella essential, with a papillary upper surface, projecting slightly in the calice. Septa in six systems and four regular cycles; the primary and secondary septa subequal, moderately exsert, arched above, with nearly vertical inner margins, their surfaces ornamented with rows of relatively large granules, arranged nearly parallel to the inner margins. Paliform lobes, separated from the septa by a deep but narrow notch, stand in front of the first three cycles of septa and connect them with the columella; those in front of the tertiaries are the largest, but they do not form chevrons or deltas.

Cyathotrochus herdmani, n. sp.—Plate I., figs. 2 and 2A.

Height of corallum, 7 millims.; longer axis of calice, 10 millims.; shorter axis, 7·5 millims. The characters are those of the genus. The septa and the bluntly pointed basal part of the corallum are white, the rest of the wall of a dull Indian-red colour. The wall and costæ are covered with close-set but very fine granules, which can only be distinguished by the aid of a strong lens. A single specimen from the west of Periya Paar.

After some hesitation I have founded a new genus to receive this species, which does not correspond exactly with any described genus of the Turbinolidæ. It is undoubtedly closely allied to *Trochocyathus*, from which it differs only in the form of the pali, which should perhaps be described as paliform lobes rather than true pali, as they are evidently the thickened inner continuations of the septa, separated from the latter by a notch which, although fairly deep, does not extend to the bottom of the septum. These pali, or paliform lobes, form a single crown, not two crowns as in *Trochocyathus*, and they do not form chevrons as in *Tropidocyathus*. The characteristic feature of the species is the keel-like projection of the costæ at each end of the long axis of the corallum, suggesting an affinity to *Tropidocyathus* (*Trochocyathus*) *lessoni*. But in this latter species, as MICHELINS' (34) and ALCOCK'S (3) figures show very clearly, the corresponding costæ are very much enlarged and form aliform expansions extending round the base of the corallum, whereas in *Cyathotrochus* they are but slightly enlarged to form ridges extending scarcely half way to the base.

Heterocyathus, M. EDWARDS and HAIME (35).

Heterocyathus æquicostatus, M. EDW. and H.

Stephanoseris rousseaui, M. EDW. and H., 'Hist. Nat. des Cor.,' t. iii., p. 56, 1860.
H. philippinensis, SEMPER, 'Zeit. Wiss. Zool.,' xxii., p. 254, 1872.
H. parasiticus, SEMPER, *loc. cit.*
H. pulchellus, REHBERG, 'Abh. Ver. Hamb.,' xii., p. 8, 1892.
H. oblongatus, REHBERG, *loc. cit.*
H. æquicostatus, J. C. GARDINER, 'Mar. Invest. in South Africa,' "Turbinolid Corals," 1904.

Professor HERDMAN'S collection contains numerous specimens of this interesting species, of all sizes, and apparently collected from all the localities in which he dredged.

Mr. STANLEY GARDINER has recently shown how very variable this species is, and has absorbed the various species of SEMPER and REHBERG. The Ceylonese specimens also show great variety, and, though I have not as large a collection for comparison as Mr. GARDINER, I have no doubt of the identity of these specimens with *H. æquicostatus*, and further, I have no doubt that the forms first described by

M. Edwards and Haime as *H. rousseaui* and afterwards as *Stephanoseris rousseaui* are identical with *H. æquicostatus*.

The genus *Stephanoseris* was created, M. Edwards and Haime tell us, to contain the species first described by them as *H. rousseaui*, but subsequently found to possess synapticula, the presence of which involved its removal to the Fungiidæ. Subsequent authors, including Duncan, have accepted the genus *Stephanoseris*, the last-named remarking that he places it with much doubt among the Fungiidæ, for he could not find synapticula in any of his specimens. Omitting for the moment any reference to synapticula, we find that *S. rousseaui* differs from *H. æquicostatus* (1) in having costæ of unequal size, the tertiaries being particularly large; (2) in having four instead of five cycles of septa; (3) in the fact that the septa do not project externally.

Among the specimens in Professor Herdman's collection there are individuals with all the characters of *H. æquicostatus*, and every intermediate grade between these and individuals identical with *S. rousseaui*. Further, I have found well-marked synapticular structures in every individual that I have examined, so there can be no doubt that the forms described as *Stephanoseris rousseaui* are only varieties of the forms described as *Heterocyathus æquicostatus*, and for reasons that I will explain in the latter half of this paper I prefer to retain the latter name and to place the genus among the Turbinolidæ. Synapticula have been found to be common to so many different kinds of corals that their presence is no longer a reason for including any given form among the Fungiidæ. It should be mentioned that the synapticula of *Heterocyathus* cannot be seen on mere inspection of the corallum, as they are hidden by the swollen upper ends of the septa. In order to see them it is necessary to make sections or to grind down the corallum below the level of the exsert septa, when they are at once apparent, as is seen in fig. II. Thus one can easily understand how both M. Edwards and Haime and Duncan, as well as other authors, have failed to recognise their presence. The genus *Psammoseris* is described by M. Edwards and Haime as resembling *Stephanoseris* (*Heterocyathus*) in almost every respect, except that it has no pali. Not having access to the type specimens of *Psammoseris*, I cannot speak with certainty on this subject, but I am inclined to think that the genus was founded upon a variety of *Heterocyathus*, in which the pali are so slightly developed as to be indistinguishable from the papilliform columella. An inspection of Gardiner's excellent photographs of *Heterocyathus* (**23**, plate iii., figs. 13 to 19) shows that such a reduction of the pali is not uncommon. *Psammoseris*, like *Heterocyathus* and *Heteropsammia*, fixes itself in the young state on a gastropod shell, which it subsequently envelops, and in the adult the shell, and the spiral basal cavity continuous with it, is tenanted by a Sipunculid of the genus *Aspidosiphon*. I shall refer to this interesting association in a subsequent part of this paper, and I give in the second part a detailed account of the anatomy and minute structure of the corallum of *Heterocyathus*.

Family: FLABELLIDÆ.

Simple corals, multiplying asexually by transverse fission from a fixed nurse-stock. Corallum more or less compressed and flabelliform or cuneiform. Calice elongated; elliptical or angular at the extremities of the long axis. Septa numerous, increasing in number during the growth of the corallum, chiefly by the addition of new septa in the systems contiguous to the directive septa, in such a manner as to appear to be arranged in a variable number of ternary systems. The columella may be essential and lamellar, or parietal and formed by the union of spines or trabeculæ projecting from the lower ends of the principal septa. The wall is protothecal, and increases in thickness only by addition to the inside surface. There is no edge-zone. Costæ rudimentary or absent. Protothecal spines commonly present. Genera :—*Flabellum*, Lesson, and *Placotrochus*, M. Edwards and Haime.

The Flabellidæ, as characterised above, differ from all the other Turbinolidæ, among which they have hitherto been placed, in the absence of an edge-zone, that is, of soft tissues external to the wall. The wall, as von Koch pointed out (**30**), is an "epitheca," or, if we adopt the more exact nomenclature of Bernard, a "prototheca," that is to say, it is a direct upward continuation of the primitive basal cup common to all Madreporarian corals, of which the development has been carefully described by von Koch (**28**), de Lacaze Duthiers (**33**), and Duerden (**10**). As there are no soft tissues external to the prototheca, it can only increase in thickness by addition from within, and a section of the wall of *Flabellum* shows that the "dark line of growth," which lies in or near the middle of the theca of other corals, is here on the outside. As the wall does not increase in thickness externally, the costæ are very feebly developed, and there is an absence of the ridges, spines, and other external ornamentations formed by the deposit of additional calcareous matter on the outside of the wall by the activity of the calicoblasts of the edge-zone. The spinous processes and rootlets found in most members of the Flabellidæ are hollow, and only become solid by the secondary deposit of calcareous matter within. Thus they differ from ordinary costal spines, and their mode of formation, by local extensions of the lip of the calice, has been indicated by de Lacaze Duthiers (**33**). In all the Turbinolidæ, as here limited, there is a distinct and usually well-developed edge-zone. Hence the wall increases in thickness, both externally and internally, and there are well-developed costal ridges, variously ornamented with granules, tubercles, or spines, or sometimes the furrows between the costal ridges may be filled up by a secondary deposit of an "epithecal" character, formed by the calicoblastic layer of the edge-zone. Moreover, in the typical Turbinolidæ, the septa grow in height well beyond the limits of the protothecal cup, and are either prominently exsert or their peripheral margins are thickened and become attached to one another, forming the so-called pseudotheca of Ortmann. The marked difference in the structure and growth of the wall seems a sufficient reason for separating *Flabellum* and its allies from the rest of the Turbinolidæ, and placing them in a separate family, Flabellidæ, and the septal arrangements and the peculiar mode of multiplication by transverse fission, characteristic of the family, are additional reasons for keeping it apart. GARDINER (**23**) has shown that the genera *Blastotrochus*, M. EDW. and H., and *Rhizotrochus*, M. EDW. and H., must be absorbed. I have not been able to examine DUNCAN'S fossil genus *Thysanus*, and I do not include it in the family Flabellidæ, as here defined, because it has well developed granular and minutely spined costæ, which seem to indicate an external thickening of the wall.

The genus *Placotrochus* was not included by DUNCAN (**13**) in his alliance Flabelloida, but was placed, along with *Sphenotrochus*, *Nototrochus*, *Placocyathus*, and *Platytrochus* in an alliance Placotrochoida, characterised by the presence of an essential lamellar columella. For this I can find no justification whatever. *Placotrochus* has no edge-zone; its wall is protothecal and devoid of costæ; it has the compressed flabelliform or cuneiform shape characteristic of *Flabellum;* it reproduces itself asexually by transverse fission from a nurse-stock, and the truncated free forms have a basal scar exactly like that of *Flabellum;* it has protothecal spines; its septal arrangements are those of *Flabellum*. The only point of difference is the essential lamellar columella, but this cannot outweigh the other characters, and the well-preserved specimens of this genus in Professor HERDMAN'S collection show that the general anatomy of the polyp is the same as that of *Flabellum*, though I have not yet completed my study of its microscopic structure. I have no hesitation in placing it in the family Flabellidæ.

Flabellum, LESSON (1831).

A detailed criticism of this genus has recently been given by GARDINER (**22**), to which the reader is referred. The subdivisions *Subpedicellata truncata* and *fixa*, of M. EDWARDS and HAIME, were shown by SEMPER (**49**) to be purely artificial, and DUNCAN'S subdivisions of the genus (**13**, p. 13) are still more arbitrary and unnatural. SEMPER, and more particularly GARDINER, have shown that most of the living species enumerated in the 'Hist. Nat. des Coralliaires,' must be regarded as varieties of a few distinct species, and the latter author has reduced most of M. EDW. and HAIME'S, as well as SEMPER'S species to varieties of either *F. pavoninum*, LESSON, or *F. rubrum*, QUOY and GAIMARD, the latter species being apparently protean in its characters. I speak with all diffidence, for I have not had the opportunity of comparing a large number of specimens, but I am inclined to think that GARDINER has gone too far.

Flabellum crassum, M. EDW. and H.—Plate I., figs. 3 and 3A.

There are in Professor HERDMAN'S collection two specimens of *Flabellum*, from the pearl banks in the Gulf of Manaar, which agree in almost every respect with SEMPER'S description and figures of *F. irregulare*. Both specimens were preserved in spirit; one I have decalcified, the corallum of the other when cleaned and dried measures

30 millims. in height. The longer axis of the calice measures 16 millims., the shorter axis 8 millims.; the small scar at the base 4 millims. × 2 millims.; thus the ratio of the axes is 2 : 1, agreeing with SEMPER'S description. The corallum is compressed, with rounded directive edges, whose sides form an angle of 23° in the dry specimen, but a considerably wider angle in the decalcified specimen. The wall is constricted at tolerably regular intervals and there are three short and stout spines at varying heights on the directive faces, and two short and corroded spines near the basal scar. The costæ, especially those corresponding to the principal septa, are distinct and are recognisable nearly down to the basal scar. The corallum is tall, and the directive margins of the calice are nearly level with the lateral margins. The fossa is very deep (6 millims.), narrow and slit-like. The parietal columella is formed by the union of trabeculæ given off from the lower ends of the principal septa. There are in all sixty-six septa; the primaries and the secondaries are of equal size and unite in the columella. The twelve tertiaries are nearly equal in size to the primaries and secondaries and also join the columella. The fourth cycle septa are short, excepting those nearest the two directive septa at opposite ends of the long axis of the calice; these are nearly as large as the tertiaries and join the columella. Fifth cycle septa are developed in the chambers between the primary and secondary septa on both sides of the two directive septa, and are equal in size to the lateral tertiary septa. In one chamber nearest to a directive, two sixth-cycle septa are developed, one on either side of a quinary septum (see fig. 3A). (This interpretation of the septal succession differs from SEMPER'S, who explained an exactly similar arrangement by supposing that additional second-cycle septa were developed in each of the terminal systems, but it is clear that what he describes as additional secondary septa are nothing more than third-cycle septa, which have grown to the same size as the primaries and secondaries.) The result of this arrangement is that there appear to be sixteen ternary systems, and, in addition, two small septa in one of the systems. The principal septa have very slightly arched, or nearly horizontal, upper edges; their inner edges descend vertically to the columella, and they are distinctly, though slightly, notched near their insertions on the wall. The surfaces of the septa are thickly covered with fine spinose granules, which have an obscurely radial arrangement. The dry corallum is brilliantly white in colour, and the lower five-sixths of the wall is encrusted by a secondary calcareous deposit, which, on decalcification, proves to be formed by interlacing algal filaments, as described by FOWLER for *F. patagonichum* (14). It is noteworthy that the costæ are more conspicuous in the region of this secondary deposit than they are at the upper end of the corallum.

These Ceylonese specimens are so similar in all respects to the figures and description of SEMPER'S *F. irregulare* that there can be no doubt of their identity. According to GARDINER (22), *F. irregulare*, SEMPER = *F. rubrum*, QUOY and GAIMARD, and there is certainly some resemblance between his (not wholly satisfactory) figs. 26, 30, 31 and the Ceylonese specimens, while the latter can certainly be included in the amended definition of *F. rubrum* given by GARDINER on p. 28. It is further stated that *F. variabile*, SEMPER, is connected with *F. rubrum* by individuals, SEMPER'S species being identified by MOSELEY with *F. stokesi*, M. EDWARDS and H., which in turn is identical with *F. oweni*, *aculeatum*, *spinosum*, *debile*, *sumatrense* and *candeanum*. I must take leave to doubt whether these identifications are correct. That *F. variabile*, SEMPER, is identical with *Flabellum* (*Turbinolia*) *rubrum*, QUOY and GAIMARD, I have no doubt. The characters of the corallum are similar and a comparison of SEMPER'S figure of the expanded polyps (**49**, plate xviii., fig. 1) of *F. variabile* with QUOY and GAIMARD'S figure of *F. rubrum* (**46**, plate xiv., figs. 5 to 9) show a very close correspondence in the coloration of the living animal; in both there are the same six alternating radial bands of deeper red and lighter red or yellow. On the other hand, *F. irregulare*, as described by SEMPER, is red with as many radial white lines as there are principal septa. The colour, no doubt, is variable to some degree, but it must be taken into account, and what I wish to point out here is, that SEMPER is the only author who has paid special attention to the colour of the living polyp; that he had at least as many specimens for comparison as GARDINER; that he found a constant colour-difference between his *F. variabile* and *F. irregulare*, and that the colour of the former, and not that of the latter, corresponds to QUOY and GAIMARD'S figure of *F. rubrum*. It follows, therefore, that *F. variabile* = *F. rubrum*, and, as SEMPER showed beyond all cavil, *F. stokesi*, *oweni*, *aculeatum*, *spinosum*, *debile* and *sumatrense*, all M. EDW. and H., are synonyms of *F. variabile*.

The Ceylonese specimen, which I identify with *F. irregulare*, SEMPER, agrees very closely with *F. crassum*, M. EDW. and H., especially in the characters of the septa, which are notched near their insertion on the wall (**38**, plate viii., fig. 8A), and have thickened and rugose internal borders. SEMPER observes that the two species are very closely allied, differing chiefly in the height of the corallum. There can be no doubt that they are identical; the specific name *crassum* has the priority, and I therefore identify the Ceylonese specimen above described as *F. crassum*, M. EDW. and H.

Flabellum rubrum, Q. and G.—Plate I., fig. 4.

There are three other specimens of *Flabellum* in Professor HERDMAN'S collection: *a* and *b* (locality not recorded), and *c* from deep water near Galle. These are all truncate forms with a fairly large basal scar; their measurements correspond closely, their calices are elliptical, their calicular fossæ wider, and the septa are thinner, and their inner margins less vertical than those of *F. crassum*, and the spines on the surfaces of the septa are longer, further apart, and definitely arranged along radial thickenings of the septa. Their walls are thinner than in *F. crassum*, the costæ are of equal size and very slightly developed, and the corallum is not constricted at intervals as in that species, but only exhibits a succession of somewhat sinuous lines of growth parallel to the curved margin of the calice. The three specimens differ from one another in colour, in the characters of the lower edges of the septa, and of the trabeculæ forming the parietal columella, but their resemblances are so great that I must refer them to one species, viz., *F. rubrum*, QUOY and GAIMARD.

Specimen *a*.—Height, 12 millims.; calice, 15 millims. × 8·5 millims.; scar, 6 millims. × 3·5 millims.; depth of calice, 5 millims. Angle formed by the directive faces of the wall, 37°. The dry corallum is white and has a small directive spine at each end of the scar. The margin of the calice is entire, the directive ends of the calice 2 millims. lower than the sides. There are eighty-two septa, whose character and arrangement are shown in fig. 4. The lower margins of the septa are furnished with sharp spines, but are not sinuous; the septal trabeculæ uniting to form the columella are large and spiniform. The character of the trabecular columella approximates this specimen to *F. profundum*, M. EDW. and H., which is a variety of *F. rubrum*.

Specimen *b*.—Height, 13 millims.; calice, 17 millims. × 8·5 millims.; scar, 7 millims. × 3·5 millims.; depth of calice, 4·5 millims. Angle formed by directive faces of wall, 45°. The dry corallum is of a brownish-grey colour and bears short protothecal spines at either end of the scar. The calicular margin is crenulate, the directive ends of the calice about 2 millims. lower than the sides. There are eighty septa arranged in twenty apparent ternary systems. Eight of the tertiary septa are equal in size to the primaries and secondaries and unite with them in the columella, but four of the laterally placed tertiaries are of smaller size, and either barely reach, or do not reach, the columella. The principal septa are thin, their inner margins slope obliquely into the fossa, their lower edges are expanded and slightly sinuous and terminate in nodular trabeculæ, which unite to form the columella. The septal surfaces bear distinct radial ridges ornamented with spiniform granules. This specimen is clearly identical with *F. crenulatum*, M. EDW. and H., which is a variety of *F. rubrum*.

Specimen *c*.—Height, 13 millims.; calice, 15 millims. × 9 millims.; scar, 8·5 millims. × 4 millims.; depth of calice, 5 millims. Angle formed by the directive faces of the wall, 35°. The wall in the dry corallum is of a deep reddish-brown colour, and the same colour extends half way across the septa, a peculiarity which SEMPER (**49**, p. 250, footnote) says is confined to *F. pavoninum* and *F. distinctum*. The concentric lines of growth on the wall are distinct, the costæ are scarcely recognisable, and there are no protothecal spines. The calicular margin is entire, the directive ends of the calice are about 1½ millims. below the lateral margins. There are seventy-two septa, the tertiaries equal in size to the primaries and secondaries and meeting them in the columella. The fifth cycle is complete in the terminal systems, but incomplete in the lateral systems. The septa resemble those of specimen *b*, but their inner edges are more vertical and their lower ends more decidedly sinuous.

The calicular fossa is rather narrow, and the septal trabeculæ forming the columella short and bluntly spiniform. This specimen might be referred either to *F. rubrum* or *F. stokesi*, M. Edw. and H.; but it cannot be either *F. pavoninum* or *distinctum*, the colour of the septa notwithstanding. These three specimens, therefore, are varieties of *F. rubrum*, Quoy and Gaimard, which is synonymous with *F. variabile*, Semper, but is, in my opinion, distinct from *F. crassum*, M. Edw. and H. (= *F. irregulare*, Semper).

I differ, with some hesitation, from Mr. Gardiner, but I feel bound to point out that his reasons for uniting nearly all the described species of *Flabellum* under *F. rubrum* are not satisfactory. He relies very much on certain numbers and measurements, and he appears to think that if one form is connected with another by some individuals, the two must be reckoned as constituting one species. Now, in the first place, much depends on the numbers or measurements that are chosen for comparison. Two of his characters, viz., the number of septa fusing by trabeculæ and the total number of septa, are characters depending on the age of the coral, and are therefore of little value. His third character, the relation of the length to the breadth of the calicle, is tolerably constant at all ages after maturity, and is therefore better. But whatever characters are chosen, it is not sufficient to set out the results of the measurements in a simple table and to say that, since the average measurements of a number of unequal groups of individuals can be arranged in a continuous series, all the specimens measured must belong to one species. To deal with the statistics of a number of individual forms, proper statistical methods must be employed, or systematic zoology will be thrown into confusion. The extreme measurements—the characters that vary most widely from the mean—of two closely allied species may be expected to overlap, but the fact of their overlapping does not break down the distinction between two species whose mean is different. We have at present no data for determining the range of variation in the species of *Flabellum* by statistical methods, and until such data are available I prefer to place reliance as much upon such characters as the shape of the columellar trabeculæ, the shape and thickness of the septa and the kind and arrangement of the granules on their surfaces, the visibility or otherwise of the costæ, &c., as upon measurements which have been shown to vary very widely according to the age and condition (whether recently liberated or not) of the individual.

Placotrochus, M. Edwards and Haime (1848).

The reasons for placing this genus in the family Flabellidæ have been given above.

Placotrochus lævis, M. Edw. and H.—Plate I., fig. 5.

Three specimens from Periya Paar are referable to this species. Two were preserved with the polyps partly extended, one is dead and corroded. The three specimens vary between the following limits: Height 16 millims. to 12 millims. Calicle from 16 millims. × 7 millims. to 14 millims. × 6 millims. Scar from 6 millims. × 2 millims. to 7 millims. × 2·5 millims. (the smallest specimen has the largest scar). Angle formed by the directive faces of the wall 33° to 40°. They correspond exactly with M. EDWARDS and HAIME'S description, except that the directive faces of the wall show only the merest traces of wing-like expansions, in this respect agreeing with SEMPER'S specimens. This appears to be a very rare species. It is remarkable among the Flabellidæ for the perfectly regular development of the septa, the first, second, and third cycles are equal in size, and appear to form with the intermediate quaternary and quinary cycles twenty-four regular systems (Plate I., fig. 5).

FAMILY: FUNGIIDÆ, M. EDWARDS and HAIME.

Fungia (*pars.*) LAMARCK.

Fungia danai, M. EDWARDS and HAIME (1851).

Two specimens from the pearl banks, Gulf of Manaar, are referable to this species. The larger specimen is subcircular, measuring 18 centims. × 19 centims., and the central part of the upper surface is raised into a prominent convexity. The smaller specimen has no central prominence, but is evenly convex above and concave below.

Fungia dentigera, LEUCKART, 1841.

A single specimen, measuring 16·5 centims. in length, 11 centims. in breadth, and 5·5 centims. in height. According to DÖDERLEIN this is a variety of *F. scutaria*, LINK, but GARDINER (20) has given a sufficient criticism of this author's varieties.

Locality :—Gulf of Manaar.

Cycloseris, MICHELIN (*pars.*) (34).

Cycloseris cyclolites, LAMARCK

Fungia cyclolites, LAMARCK, 'Hist. des Anim. sans Vert.,' ii., p. 236, 1816.
Cycloseris cyclolites, M. EDW. and H., 'Ann. des Sci. Nat.,' 3e sér., xv., p. 112, 1851.

Professor HERDMAN'S collection contains thirty-two specimens of this species, twenty-five of which come from the pearl banks in the Gulf of Manaar, four from south of Modragam, one from off Mutwal Island, two from Trincomalee. The range of variation in this species is considerable. In the thirty-two specimens the diameter of the corallum varies from 42 millims. to 27 millims., the height from 19 millims. to 10 millims., the depth of the basal concavity from 9·5 millims. to 1 millim., the length of the fossa from 15 millims. to 6 millims. There is also a considerable amount of variety in the granulation of the costæ, but the septal characters are closely similar in all the specimens.

Cycloseris tenuis, DANA.

> **Fungia tenuis**, DANA, 'Zoophytes,' p. 290, 1846.
> **Cycloseris sinensis**, M. EDW. and H., 'Ann. des Sci. Nat.,' 3e sér., xv., p. 112, 1851.
> **Cycloseris hexagonalis**, M. EDWARDS and HAIME, *loc. cit.*
> **Cycloseris hexagonalis**, GARDINER, WILLEY'S 'Zool. Results. Solitary Corals,' 1899.

Professor HERDMAN'S collection contains seven specimens, of which the largest measures 40 millims. in diameter, while the smaller specimens vary from 22 millims. to 9 millims. in diameter. The smaller individuals, among which are two somewhat hexagonal forms, agree in all respects with the definition of *C. hexagonalis*, M. EDW. and H., and, allowing for individual variation, with GARDINER'S excellent photographs of this species (**20**, plate xx.). Two of them have definite basal scars, not yet filled up by secondary deposit, and the costæ reach to the edges of the scars; in the other specimens the costæ, and the extent of the central basal granulation, differ to a considerable extent, but the septal characters are quite uniform and none of the septa are fenestrated. In the largest specimen the two last cycles of septa are fenestrated, a character which would attach it to *C. sinensis*, M. EDW. and H. This species however is synonymous with *Cycloseris* (*Fungia*) *tenuis*, DANA, and the latter name has the priority. Except for the fenestration of the lower cycles of septa there is absolutely no difference between the largest and the smaller specimens in Professor HERDMAN'S collection, hence I am of opinion that *hexagonalis* and *sinensis* are merely varieties of DANA'S species *tenuis*, and must be absorbed into it.

Diaseris, M. EDWARDS and HAIME (**37**).

QUELCH (**45**, p. 121) has expressed his opinion that the specimens referred to this genus are nothing more than broken and distorted individuals of *Cycloseris tenuis*, but I cannot agree with him. Professor HERDMAN'S collection contains a specimen of *C. cyclolites*, which has been broken and repaired, and shows considerable distortion and re-arrangement of the septa, but its characters are widely different from *Diaseris*. It is true that the structure of the wall, the septa, and even of the rudimentary columella of *Diaseris* are very similar indeed to that of *Cycloseris*, as M. EDWARDS and HAIME pointed out, but the former genus is sufficiently distinguished by its peculiar method of reproduction by radial division, whence the corallum has the appearance of being composed of a number of lobes with rounded edges, or is divided into wedge-shaped fragments. This method of reproduction has been so sufficiently and clearly described by SEMPER (**49**) that I can add nothing to his account, which is fully borne out by a study of the Ceylon specimens.

Diaseris distorta, MICHELIN.

> **Fungia distorta**, MICHELIN, 'Mag. de Zool. V. Zooph.,' pl. 5, 1843.
> **Diaseris distorta**, 'Ann. des Sci. Nat.,' 3e sér., xv., p. 118, 1851.

Numerous specimens and cuneiform fragments from off Mutwal Island, and some small fragments and specimens from deep water off Galle and from Kaltura.

Diaseris freycineti, M. Edwards and Haime (**37**).

A number of petaloid fragments from the Gulf of Manaar and from off Kaltura appear to belong to this species. As described by M. Edwards and Haime, the septa are of less height, much more closely packed, and have thicker edges than in *D. distorta*. I may add that all the septa are more or less fenestrate. The spirit specimens are of a rich red-brown colour, the upper surface exhibiting black spots near the inner ends of the septa. These spots probably indicate the position of the tentacles, but the specimens are so contracted that I cannot speak with certainty on this point.*

Family: EUPSAMMIIDÆ.

As Semper has remarked (**49**, p. 256), the difficulty of determining the species and even the genera of the Eupsammiidæ is very great. In order to relieve himself of the difficulty, he founded the genus *Rhodopsammia* to include his Philippine specimens, and the genus has been accepted by most subsequent authors, even by Duncan in his critical revision of the genera of the Madreporaria, and this in spite of the fact that, as I shall show, Semper's genus was confessedly provisional.

Semper's definition of the genus *Rhodopsammia* runs as follows:—"Polypary simple or with lateral buds, free or attached, sometimes cylindro-conical, sometimes compressed (not, as Duncan gives it, 'Corallum simple or colonial, free or attached, with lateral buds'). Epitheca absent or rudimentary. Costæ simple, visible from the base upwards, similar, thickly granulated. Calicular fossa rather deep, with a more or less prominent columella consisting of curled leaflets (aus gewundenen Blättchen). The septa narrow, with sharp edges, scarcely rising above the lip of the calice: those of the first cycles equal, extending right down to the columella; those of the third cycle smaller, and also united to the columella; the septa of the remaining—often irregular—cycles much narrower and invariably united to those of the preceding cycle."

This definition differs from M. Edwards and Haime's description of any genus of Eupsammiidæ, as it includes both single and compound, free and attached, forms, but it embraces all members of the genera *Eupsammia*, *Balanophyllia*, *Leptopsammia*, and *Endosammia*, and possibly some species of the genus *Dendrophyllia* as defined by the authors of the 'Histoire Naturelle des Coralliaires,' and it is quite clear, from what Semper says, that he meant at least the first four of these genera to be included in his new genus. Thus (*loc. cit.*, p. 256) he says: "Da mir nun leider das fossile Material fehlt, welches nöthig wäre, um diese Incongruenzen gründlich ausgleichen zu können, so ziehe ich es vor, hier die von mir bei Bohol aufgefundenen 8 Arten ohne

* Professor Herdman's "Field-notes" contain the following colour record of this species when alive:—Station XLIII., off Kaltura, 22 fathoms, "also a living group of four 'flabellums' having upper side dark purple on the outer margin and dark green within, mottled with paler yellowish-green, grey, and deep drab-purple, the septa especially being of the latter colour—the under side is white." The accompanying sketches show that the Coral is a *Diaseris*.

Rücksicht auf ihre Basis als Species einer neuen Gattung zu beschreiben, wobei ich es Anderen überlassen muss, die schon beschriebenen lebenden und fossilen Eupsammidæ nach den durch die philippinischen Formen sich ergebenden Andeutungen zu untersuchen, und mit diesen in systematischen Zusammenhang zu stellen." Notwithstanding SEMPER'S hope that one of his successors would show the proper systematic relation between his Philippine specimens and previously described fossil and living forms, DUNCAN, in his 'Revision of the Madreporaria,' retains SEMPER'S genus *Rhodopsammia*, but removes it from the "alliance" Balanophylloida, to which, on its author's own testimony, it belongs, and places it apart as a genus which cannot be included in any alliance!

The Eupsammiidæ in Professor HERDMAN'S collection include free and fixed, solitary and colonial forms, and most of them resemble one another very closely in such distinctive characters as septal arrangement, columella, and costæ. The solitary forms (with the exception of *Heteropsammia*) must, without doubt, be referred to a single genus, and they agree in all respects with SEMPER'S definition of the genus *Rhodopsammia*. But if we agree with SEMPER and ignore, as we must after the study of a sufficient number of specimens, such variable characters as attachment or its contrary, the presence or absence or the completeness or incompleteness of a fifth cycle of septa, or the relative thickness of the septa, we must recognise that the genus *Rhodopsammia*, SEMPER, includes *Eupsammia*, M. EDWARDS and HAIME; *Balanophyllia*, SEARLES WOOD; *Leptopsammia*, M. EDW. and HAIME; *Endopsammia*, M. EDW. and HAIME, and it becomes a question as to what name shall be used to denote the single genus into which all the other genera are absorbed. The genus *Balanophyllia* was founded by SEARLES WOOD in 1844, and there is no objection to be taken to it on the score of indefiniteness. Therefore, by the rules of nomenclature, it has the priority over the genera founded by M. EDWARDS and HAIME in 1848, and *à fortiori* over SEMPER'S genus *Rhodopsammia* founded in 1872. Hence I suggest the amendment of the definition of *Balanophyllia* in the terms of SEMPER'S definition of *Rhodopsammia*, the latter name being dropped and *Eupsammia*, *Leptopsammia*, and *Endopsammia* merged into *Balanophyllia*.

It is a characteristic, though not a peculiarity of the Eupsammiidæ, that the septa of the later cycles curve towards and are usually united to those of the preceding cycle, and it commonly happens that the septa of what on the ordinary system of reckoning would be called the last cycle are larger than those of the preceding cycle. SEMPER, many years ago (**49**, p. 259), called attention to the inapplicability of M. EDWARDS and HAIME'S law of septal sequence to the Eupsammiidæ as well as to other Madreporaria described in his well-known memoir, but until recently there has been no satisfactory explanation of the apparent irregularity in the septal sequence of these forms, and it has been necessary, in spite of its obvious disadvantages, to retain M. EDWARDS and HAIME'S system of notation in describing the septa of all Madreporaria. But as long ago as 1871, POURTALÈS (**43**) gave a description of the development of *Balanophyllia floridana* which, if it had received the attention it deserved, would have given a full explanation of the peculiarities of the septal arrangement in this genus. POURTALÈS' description is as follows: "The youngest individuals observed have the shape of a truncated cone attached by the base. The wall is quite smooth, imperforate, and the septa, twelve in number, equal and not quite extending to the centre, where the rudiments of the columella are already visible. . . . . The next step is the formation of costæ on the upward prolongation of the wall. They first appear in the shape of sharp points grouped about the origin of the septa. At the same time an opening appears on the border and rather outside of the calicle, opposite each of the secondary septa, which gradually widens inwards, apparently dividing the septum in two. The two borders of that opening become the tertiary septa; the secondary septum is gradually pushed inwards and is replaced by a new one growing out on the same radius from the wall, and but loosely connected with the jointed tertiaries and original secondary. . . . . The interior part of the tertiary septum is now to all intents and purposes a palus. . . . . As the growth proceeds the point of junction of the tertiaries and secondaries moves further into the calicle until it reaches the columella. At this period the older or internal part of the secondary septum has nearly entirely disappeared and the same process of growth goes on with the septa of the fourth cycle which become joined to those of the third." In these few sentences POURTALÈS anticipates the discoveries of several recent authors. The imperforate wall is clearly the basal plate of VON KOCH (= prototheca, BERNARD). The description of the formation of costæ on the upward prolongation of the prototheca agrees exactly with DE LACAZE DUTHIER'S description and figures of the development of these structures in *Balanophyllia regia* (**33**, plate x., figs. 20 and 21). The description of the bifurcation of the peripheral ends of each secondary septum, and the formation of a new secondary septum on the same radius, is in exact agreement with DUERDEN'S (**9** and **10**) account of the septal sequence in *Siderastræa radians*. But, although the credit of priority must rest with POURTALÈS, it is the last-named author who has given a full and perfectly intelligible account of this mode of septal sequence, and has shown in detail the relation between the order of appearance of the septa and that of the mesenteries. In his valuable and beautifully illustrated memoir, DUERDEN has shown that in *Siderastræa radians* the six septa comprised in the first cycle appear simultaneously, and are situated within the entocœles of the six primary pairs of mesenteries. The six septa of the second cycle make their appearance later and occupy the six exocœlic chambers, thus alternating with the six primaries. As growth proceeds the peripheral ends of all the septa become bifurcated, as a consequence of the continuous addition of skeletal nodules to their outer ends, but the angle formed by the bifurcating limbs is much larger in the secondary (exocœlic) than in the primary (entocœlic) septa. The bifurcations become filled up and disappear in the primary septa, but in the secondaries they continue to extend, and presently a second mesenterial cycle is developed, each mesenterial pair being situated within the angle formed by the bifurcated peripheral extremities of the secondary septa. After a time a new cycle of entocœlic septa is formed, each septum within a mesenterial pair of the second cycle, and as growth proceeds these secondary entocœlic septa grow centripetally, and fuse with inner portions of the septa which originally constituted the exocœlic cycle. Thus a stage

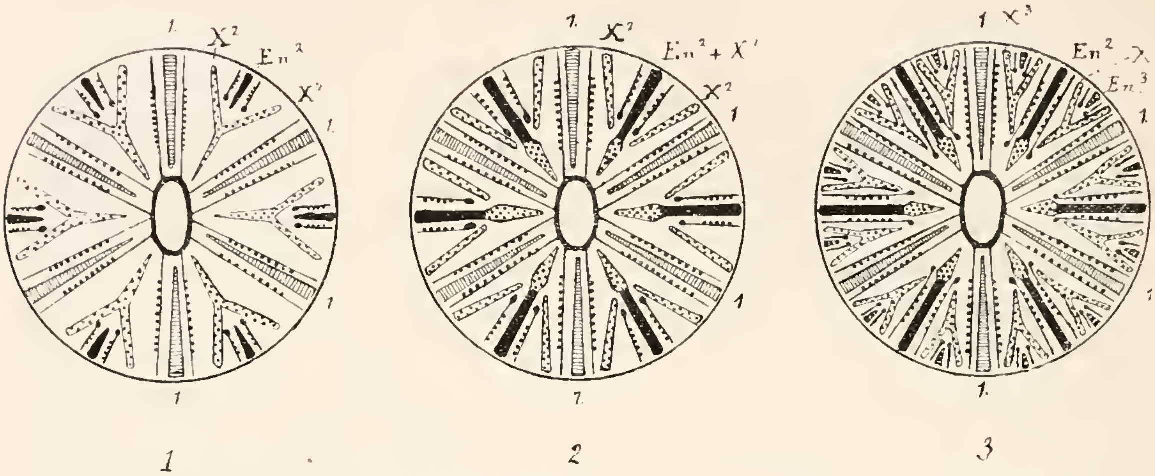

Fig. I. Diagram illustrating the development of the septa, and their relation to the mesenteries in *Balanophyllia floridana* (POURTALÈS), and *Siderastræa radians* (DUERDEN). The primary entocœlic septa are shaded with cross lines; the exocœlic septa are dotted; the secondary entocœlic septa are black; the tertiary entocœlic septa are banded black and white. In fig. 1 the outer ends of the six exocœlic septa have bifurcated to form the secondary exocœlic septa X^2; within each bifurcation a new mesenterial cycle of the second order has been formed, embracing an entocœlic septum of the second order $En.^2$. In fig. 2 the secondary entocœlic septa have grown inwards and fused with the inner limbs of the first formed exocœlic septa, thus forming the *apparent* second cycle of septa $En.^2 + X^1$. In fig. 3 the secondary exocœlic septa X^2 have in turn bifurcated, and in each of the twelve bifurcations a mesenterial pair of the third order is developed, embracing a tertiary entocœlic septum $En.^3$. The primary entocœlic septa are denoted by 1, 1 in all the figures.

is reached in which there are three cycles of septa; two cycles, namely those which are ordinarily reckoned as the first and second, are entocœlic, the remaining cycle, which would ordinarily be reckoned as the third, is exocœlic. But it is clear that each apparently secondary entocœlic septum is a compound structure, its inner end formed of a septum which was actually second in order of appearance, its outer end of a septum which was actually third in order of appearance. And it is further clear that the exocœlic septa, which appear to constitute the third cycle, are really the forked peripheral ends of the septa that were second in order of appearance. The formation of the next cycle of mesenteries and septa follows the same rule. The exocœlic septa become bifurcated at their extremities; new mesenterial pairs of the third cycle are formed within the bifurcations; a new cycle of entocœlic septa is formed within the pairs of third-cycle mesenteries, and these grow centripetally and unite with the inner limbs of the apparently third-cycle septa of the previous stage, the bifurcated outer ends of these same septa constituting the apparent fourth cycle. The further development has not been followed, but it probably continues on the same plan. Thus it appears, as is shown in the diagram above, that at any given stage in the growth of the coral, all the entocœlic septa, after the first cycle, are composite structures, but all the exocœlic septa, forming the apparently last cycle, are the derivatives of the original exocœlic septa which were second in order of appearance. One can scarcely imagine anything more at variance with M. EDWARDS and HAIME's law of septal sequence. DUERDEN has further shown that there is a regular dorsi-ventrality in the mesenterial, and therefore in the septal succession of *Siderastræa radians*. New mesenterial pairs appear first in the dorsal member of the two exocœles of each system. This fact may be of assistance in explaining the irregularities in the apparently last cycle of septa which are so common in the Eupsammiidæ and other corals, but, as I shall show, the same sequence does not seem to obtain in *Balanophyllia* as in *Siderastræa*, and it is quite probable that the dorsi-ventral order of the appearance of the mesenteries varies as much in the Scleractiniæ as it does in the Malakactiniæ.

The convergence and union of the inner ends of the lower orders of septa is a much more common phenomenon than is generally supposed. In the collection of corals forming the subject of this paper, such septal unions occur in *Rhodocyathus*, *Heterocyathus*, and *Paracyathus* among the Turbinolidæ. They are characteristic of the genera *Cycloseris* and *Diaseris*, and, as I have shown elsewhere (6), they are well marked in the anthoblast of *Fungia*. But they are above all characteristic of the Eupsammiidæ, in which the septal arrangement of the adult appears to retain its embryonic character, and it may be inferred from the septal characters of the adults that the septal sequence in the course of development has followed the law of POURTALÈS and DUERDEN. It is obvious that, if this inference is correct, all the adult septa of the apparently last cycle will be exocœlic, while those of the apparently penultimate cycle will be entocœlic and contained within the mesenterial pairs of the last formed, and therefore smallest, mesenterial cycle. In the second part of this paper I shall show that this is the case, not only in *Heteropsammia* and a species of *Dendrophyllia*, among the Eupsammiidæ, but also in *Heterocyathus* among the Turbinolidæ.

It might seem desirable to amend MILNE-EDWARDS and HAIME's method of enumerating the septa, and to adopt a system more consistent with the facts of developmental sequence as now ascertained. But after several attempts to invent a new notation, I have decided to retain the old method. After all, we have only POURTALÈS' and DUERDEN's accounts to go by, and we are by no means certain that what is true of the species they describe is true of all Madreporaria. Future researches may bring to light considerable differences in the septal sequences of different groups, and it would be premature to invent a system of notation that might prove to be inapplicable to new cases. I have therefore retained the old system in describing the

Eupsammiidæ in Professor HERDMAN'S collection, leaving it to be understood that the words "secondary," "tertiary," &c., indicate only the size of the septa, and not their order of succession. And in this connection it may be noted that DE LACAZE DUTHIER'S account (**33**) of the septal succession in *Balanophyllia regia* differs widely from that of POURTALÈS' account of *B. floridana*, and therefore from DUERDEN'S. I am inclined to think, however, that DE LACAZE DUTHIERS missed the actual succession of the development of the septa. An inspection of his figures (Plate x., figs. 23 and 29) will show that they are not inconsistent with DUERDEN'S and POURTALÈS' accounts. In fig. 23, the septa marked 2 are clearly bifurcated at their distal ends, and the sclerite lying within each bifurcation gives every appearance of having been formed independently and having become secondarily united with the inner limb of the bifurcated secondary. In fig. 29 the septum marked 3 is equal in size to, and clearly continuous with, the inner end of the septum marked 2, the latter thinning out very much towards its point of union with the angle of the **Y**. And in the same figure the "tertiary" septum occupies the position of a "quaternary," and the septa that occupy the positions of "tertiaries" are described as subsequent formations. They are clearly the new entocœlic septa formed between the bifurcated peripheral ends of the exocœlic septa marked 3.

Balanophyllia parallela, SEMPER—Plate I., figs. 6 and 6A.

Rhodopsammia parallela, SEMPER, 'Zeit. für Wiss. Zool.,' xx., 1872.
Rhodopsammia parallela, FOWLER, 'Quart. Jour. Micr. Sci.,' xxv., new ser., 1885.

A single specimen from the pearl banks, Gulf of Manaar. Height of corallum 29 millims.; longer axis of calice 18 millims.; shorter axis 13 millims.; depth of calice 8 millims. In this specimen the outline of the calice is not so hexagonal as in the Philippine form described by SEMPER, and the base is narrow and pedicellate, whereas the Philippine forms are free and pointed below. Septa in six systems and five cycles, the fifth cycle being incomplete. The primary and secondary septa are equal in size, similar and somewhat exsert; their outer ends are thickened and porous, their inner ends sharp, entire, and descend nearly vertically to unite with the columella; their sides are ornamented with radiating rows of very small granules; their upper ends more or less fenestrate. The tertiary septa are smaller and their inner ends become thickened and trabecular and pass into the columella; each is joined at two-thirds of its length from the lip of the calice by the quaternary septa. There is an incomplete cycle of quinary septa, which can best be described by saying that the peripheral ends of the quaternaries bifurcate and a small septum is developed between their bifurcated ends in each directive moiety of the four primary systems adjoining the directive septa, and the same arrangement is present in all but one of the four outer moieties of the same systems. The quaternary septa are not bifurcated in the lateral primary system on one side of the coral, and on the other side only one is bifurcated and contains an entocœlic septum in each of the moieties of the system.

In other words, the formation of a new cycle of entocœlic septa has progressed more rapidly at the two directive ends than at the sides, and the sequence is therefore different from that observed by DUERDEN in *Siderastræa radians.*

This specimen is in many respects intermediate between SEMPER'S *Rhodopsammia carinata* and *R. parallela*, and I am inclined to think that these two and *R. amœna* are only varieties of one species. The Ceylonese specimen agrees with *R. parallela* in having vertical inner edges of the primary and secondary septa, in the costæ being of equal size, in the presence of a fifth incomplete cycle of septa, and in the depth of the fossa. In all these respects it differs from *carinata*, but such characters are clearly variable. The calice is less compressed and more regularly oval than in SEMPER'S figures of *parallela*, but FOWLER (**14**) gives a figure of the calice of this species in which the difference between the longer and shorter axes is even less than in the specimen here described, and the septal arrangement is almost identical.

Balanophyllia cumingi, M. EDWARDS and HAIME (**36**)—Plate II., figs. 7 and 7A.

Rhodopsammia ovalis, SEMPER, 'Zeit. für Wiss. Zool.,' xxii., p. 262, 1872.

There are three specimens in Professor HERDMAN'S collection, of which one, from deep water off Galle, so closely agrees with M. EDWARDS and HAIME'S description and figure of *B. cumingi* that I have no hesitation in referring it to this species. It is somewhat larger than the type specimen (the height being 12 millims., the calice 19 millims. × 12 millims.) and the fifth cycle of septa is well developed and nearly complete. The second specimen is from Trincomalee and is a small colony, or rather an aggregation consisting of three dead and decayed corallites, one small and one large living corallite. Of the living corallites the larger measures: height 30 millims., calice 19 millims. × 12 millims., depth of calice 12 millims. Smaller corallite: height 12 millims., calice 8 millims. × 6 millims., depth of calice 5 millims. The larger corallite is identical with the specimen of *B. cumingi*, from Galle, in septal characters, the columella, and the costæ, differing from it only in being longer and turbinate in shape with a narrow base, whereas the Galle specimen is short with a broad base. The septal arrangement is shown in fig. 7A, and it agrees very exactly with SEMPER'S description of *Rhodopsammia ovalis.* The tertiary septa are continued below into the columella, but, as the figure shows, their lower ends converge distinctly towards the secondary septa. The "quaternaries" are inserted very low down on the tertiaries and the quinary cycle is nearly complete, but in the two lateral systems three of the quaternaries adjoining the secondary septa are not bifurcated, nor is the quaternary adjoining a secondary in one of the remaining systems. The smaller corallite in the Trincomalee specimen has a nearly circular calice. The six primary septa are conspicuously larger than the others and pass straight to the columella. The secondary septa are joined just above the columella by the "tertiaries," and the latter bifurcate in all but two instances and a new cycle of entocœlic septa is formed in the bifurcations. This shows that the secondary septa have been formed in the manner described by POURTALÈS and DUERDEN, and that it is only at a later stage of growth that the extension of the columellar trabeculæ overspreads the union of the tertiaries with the secondaries and causes the latter to appear as if they sprung directly from the columella. The primary and secondary septa are much thickened and porous towards their thecal ends.

Balanophyllia socialis, SEMPER.—Plate II., figs. 8 and 8A.

Rhodopsammia socialis, SEMPER, 'Zeit. für wiss. Zool.,' xxii., p. 260, 1872.

A beautiful cornuate specimen from the pearl banks, Gulf of Manaar, clearly belongs to this species, as is shown by its subcircular calice, deep fossa, well-developed and projecting columella, and four fully developed cycles of septa. Its measurements are: height 27 millims.; calice 10 millims. × 9 millims.; depth of calice 6 millims. There are no buds, but a small outgrowth of the theca 3 millims. below the lip of the calice on the opposite side to that drawn in fig. 8 is evidently the commencement of a bud. The primary and secondary septa are equal in size, as described by SEMPER, and their surfaces are covered with very fine granules ("äusserst fein gekörnelt"), but they are only very slightly thickened peripherally, and in this respect resemble *Rhodopsammia affinis*, which, as SEMPER himself says, is probably nothing more than a variety of *R. socialis*. *R. dubia* and *R. incerta*, both SEMPER, again are almost certainly nothing more than varieties of the same species. SEMPER describes the quaternary septa as uniting with the tertiaries close to the columella. In the Ceylonese specimen, as is shown in fig. 8A, the quaternaries do not invariably unite with the tertiaries, and indeed they follow M. EDWARDS and HAIME'S law very closely, the quaternaries nearest the primary septa being, as a rule, the best developed. The infrequent union between the third and fourth cycle septa, however, does not indicate that the septa have not been developed according to POURTALÈS' and DUERDEN'S law, for the latter author shows (**10**, p. 103, fig. 12, *c*) how the bifurcated external limbs of the lower cycles of septa commonly become detached from the inner limb.

A dead and corroded specimen from deep water off Galle seems to belong to this species. The calice was broken so much that its characters were indistinguishable, but a section taken lower down shows that it is peculiar in having a tetrameral instead of a hexameral arrangement. There are four systems: the primary septa are the largest, the secondaries are smaller, but pass direct to the columella, the tertiaries also join the columella, but converge in a marked manner towards the secondaries, and there is a complete fourth cycle uniting with the tertiaries. There is no indication of this arrangement being derived from an originally hexameral arrangement, and it must be regarded as a remarkable variation from the normal.

Balanophyllia taprobanæ, n. sp.—Plate II., figs. 9 and 9A.

Height of corallum 15 millims.; calice 6 millims. × 5 millims.; depth of calice, 3 millims. The six primary septa are much larger than the others, considerably thickened at their thecal ends, and they, and the two septa adjacent to them, are exsert, forming a crown of six prominent points round the edge of the calice. The edges of the primary septa slope rather steeply inwards and then descend vertically into the depth of the fossa without joining the columella; the inner half of the surface of each primary septum is nearly smooth, the outer half bears a number of spinose granules. There are five septa of lower orders in five of the systems and seven in the sixth system (adjoining one of the directive septa), those adjacent to the primary septa being the largest and most exsert; the smaller septa join the columella very deep down in the fossa. Costæ of the six primary septa larger and more prominent than the rest, forming ridges extending nearly half-way down the corallum; the remaining costæ subequal, extending to the base, the perforations between the costæ numerous and relatively large. Columella oval, very prominent, spongy in texture. Buds are formed on opposite sides a little way below the margin of the calice, each bud being astride of a primary costa.

A single specimen from deep water off Galle.

I have founded this species to receive a small and remarkably beautiful coral, which resembles *B. rediviva*, MOSELEY, in the costæ and arrangement of the septa, but differs from it in size, in colour (*B. rediviva* is "reddish coloured," *B. taprobanæ* a brilliant white), and in the fact that the secondary septa are not exsert. These differences can hardly be due to immaturity, as the specimen of *B. taprobanæ* bears two fairly advanced lateral buds.

The septal characters are particularly interesting as being wholly unintelligible unless interpreted in the light of POURTALÈS' and DUERDEN'S work. In fig. 9A it is evident that, in the lateral system on the left hand of the drawing, the inner ends of the septa marked $X.^2$, $X.^3$, are the bifurcated arms of the exocœlic septa of the cycle second in order of appearance; these arms unite together and with the columella very low down in the calice. The septum marked $En.^2$ is clearly the entocœlic septum of the cycle third in order of appearance. In the upper half of the system the exocœlic septum has bifurcated to form the secondary exocœlic septa $X.^3$, $X.^3$, and a new entocœlic septum $En.^3$ is formed in the bifurcation. A precisely similar arrangement obtains in four of the remaining systems, and in each it is the upper member of the exocœlic septa that has bifurcated, giving a dorsiventral arrangement entirely consistent with DUERDEN'S description of the septal succession in *Siderastræa radians*. In the left-hand lower terminal system both exocœlic members have bifurcated and an entocœlic septum is present within each bifurcation. In *B. rediviva* all the systems are similar to this single system in *B. taprobanæ*, and the arrangement would obviously be that which is normal in the Eupsammiidæ, if it were not for the preponderant size of the apparent quaternaries, whose outer ends become more or less intimately united to the primary septa. The condition in *B. taprobanæ* is a step towards the septal arrangement in *B. verrucaria*, PALLAS, and *B. cornu*, MOSELEY. SEMPER (**49**, p. 263), in discussing the validity of his genus *Rhodopsammia*, makes reference to the difference in the septal characters of the former species as shown in MILNE-EDWARDS and HAIME'S figure (**36**, plate i., figs. 6, 6A), but it requires no great amount of ingenuity to show that the difference, great as it may appear at first sight, is really nothing more than a slight variation of the grouping of septa developed according to the sequence established by POURTALÈS and DUERDEN.

It is possible that the specimen here referred to *Balanophyllia*, is nothing more than the initial individual of a colony of *Dendrophyllia*, and the two lateral buds lend some support to this view. On the other hand, the buds, both from their position and character, might very well be similar to those of *B. socialis* or *parallela*, and as the specimen is a solitary one, I have preferred to refer it, provisionally, to the same genus.

Lobopsammia, M. EDWARDS and HAIME (**36**).

The small colony shown in Plate II., fig. 10, agrees very closely with the definition of this genus, hitherto represented only by fossil forms. The structure of the corallites, however, is so similar to that of *Balanophyllia cumingi* that it is hard to draw any distinction between them; the septa and columella are almost identical, and the most that can be said is that the costæ are smaller and the theca decidedly thinner than in the latter species. If this specimen must be separated from *Balanophyllia* on account of its colonial habit, it must be placed with *Lobopsammia* rather than with *Cœnopsammia* because of its elliptical calices and because the mode of aggregation of the colony suggests that it has been formed by fissiparity rather than by gemmation. Moreover, its likeness to *L. cariosa*, GOLDFUSS (**25**, taf. xiii., fig. 7), is sufficient to establish its generic position.

Lobopsammia robusta, n. sp.—Plate II., figs. 10 and 10A.

Colony consisting of a few corallites borne on a very thick and short stem. The individual corallites short, radiating outwards from the stem. Calices oval, somewhat irregular in outline; calicular fossæ deep; columella spongy, with a flat upper surface, not projecting into the calice. Five cycles of septa; the primaries and secondaries subequal, not exsert, with nearly vertical inner edges. The quaternaries are united with the tertiaries near the columella; the fifth cycle is complete except in the lateral systems, and the quinary septa unite with the quaternaries high up in the calice; the lower orders of septa fenestrate with serrated or denticulated margins. Costæ fine, of equal size, extending to the base of the stem.

Height of colony 27 millims.; the largest calice measures 15 millims. × 11 millims.; depth of calice 7 millims.; smallest calice 11 millims. × 8 millims.

A single specimen from deep water off Galle.

Dendrophyllia, de Blainville ('Dict. des. Sci. Nat.,' lx., p. 319, 1830).

Dendrophyllia gracilis, M. Edwards and Haime (**36**).

A portion of a colony, from deep water off Galle, appears to belong to this species. The fragment only included three mature corallites, two of which, with the buds attached to them, were decalcified for the study of the soft parts. The remaining corallite is somewhat broken, but the size, septal characters and mode of budding appear to be those of *D. gracilis*.

Dendrophyllia minuscula, n. sp.—Plate II., figs. 11 and 11a.

Colony arborescent; the trunk and branches slender; the lateral corallites disposed in alternate and opposite pairs. Costæ of equal size, rather prominent, finely granulated. Calice circular, with a fairly deep fossa. Columella formed of a few calcareous trabeculæ, moderately prominent in the fossa. Septa in six systems and three cycles, with traces of a fourth. The primary septa exsert, forming a crown of six points at the edge of the calice. The apparent tertiary septa next in size closely applied to the primaries at their outer ends, their inner ends converging and uniting deep in the calice just before joining the columella. The apparent secondaries short, usually not united to the inner ends of the tertiaries. Height of colony 25 millims.; diameter of calices 2 millims.

A single small colony and a fragment of this very elegant species from deep water off Galle. The large exsert primary septa recall those of *Balanophyllia taprobanæ*, but the corallites are much smaller, the primary costæ are not prominent, and there are three cycles of septa with traces of a fourth in one system only, in the corallite depicted in fig. 11a. This figure shows very clearly that the apparent tertiaries are the exocœlic bifurcated ends of the original secondary cycle, and that the apparent secondaries are the entocœlic septa formed in the angles of the secondaries, and, therefore, are the third cycle in order of appearance.

Heteropsammia, M. Edwards and Haime (**36**).

Heteropsammia michelini, M. Edwards and Haime (**36**).

Numerous specimens from nearly all stations. The septal arrangement and anatomy of this genus are fully described in the second part of this paper.

PART II.—ANATOMY.

1. Heterocyathus æquicostatus, M. Edwards and Haime.

(Plates III. and IV., figs. 12 to 21.)

Gardiner (**23**) has given a short account of the anatomy of this species, but he does not deal with the minute structure of the corallum, and I am able to supplement his description of the anatomy of the polyp in many particulars.

The Corallum.—In the majority of specimens there are forty-eight septa, which, according to MILNE-EDWARDS and HAIME'S system of notation, would be described as being regularly arranged in six systems and four cycles. It will become obvious, however, that the septa have been developed according to DUERDEN'S and POURTALÈS' law, and that what are apparently the quaternary septa are really exocœlic septa belonging to the second cycle in order of appearance. In some few specimens the normal regularity of the septal arrangement is disturbed by the development of one or two additional septa in one or more of the systems. These additional septa are always inserted between the apparent tertiaries and the apparent quaternaries adjacent to them, and suggest the commencement of a fifth septal cycle, but in every system in which they occur there is so much irregularity in the septal arrangement that I attribute their presence to a process of re-growth and repair rather than to the formation of a new cycle. The normal arrangement of the septa is shown in fig. II. There are three cycles of endosepta. The six primaries are prominently exsert and their inner ends bear large paliform lobes just before they unite with the columella. The secondary endosepta are likewise prominent and exsert, and there are two or three prominent vertical pali at the inner extremity of each. The innermost of these pali can with difficulty be distinguished from the vertical upgrowths of the columella, and the outermost is fused to the inner free margin of the septum, so that there is a transition between "true pali" and "paliform lobes." I am inclined to think that the sharp distinction drawn between these paliform structures is artificial and untenable. The inner ends of the third cycle of endosepta converge towards the secondaries and unite with them just outside the columella through the intervention of palial upgrowths. In specimens that have been rubbed down, the pali in front of the secondary and tertiary septa are seen to unite to form a chevron, similar to the chevrons characteristic of *Deltocyathus*.

Between every two endosepta there is an exoseptum, and in the deeper parts of the corallum, *i.e.*, below the level of the exsert portions of the septa, these exosepta are seen to be united to the adjacent endosepta by tangential bars which, although they do not exactly correspond to the similarly named structures of the Fungiidæ, must be described as synapticula. Their arrangement is very regular and characteristic. Each primary endoseptum is joined to the exoseptum on either side of it by a synapticulum which curves downwards and inwards to the fossa. These primary synapticula, as they may be called, are equidistant from the centre of the coral, and are situated nearer the centre than the others, so they form a sort of inner synapticular ring. Each secondary endoseptum is similarly joined to the two adjacent exosepta by synapticula which are situated somewhat further from the centre than the primary synapticula, and similarly the tertiary endosepta are joined to the adjacent exosepta by synapticula still further from the centre and forming an outer ring. Thus there is only one synapticular bar in each interseptal loculus. In longitudinal section the synapticula are seen to be narrow curved bars or partitions, in shape and

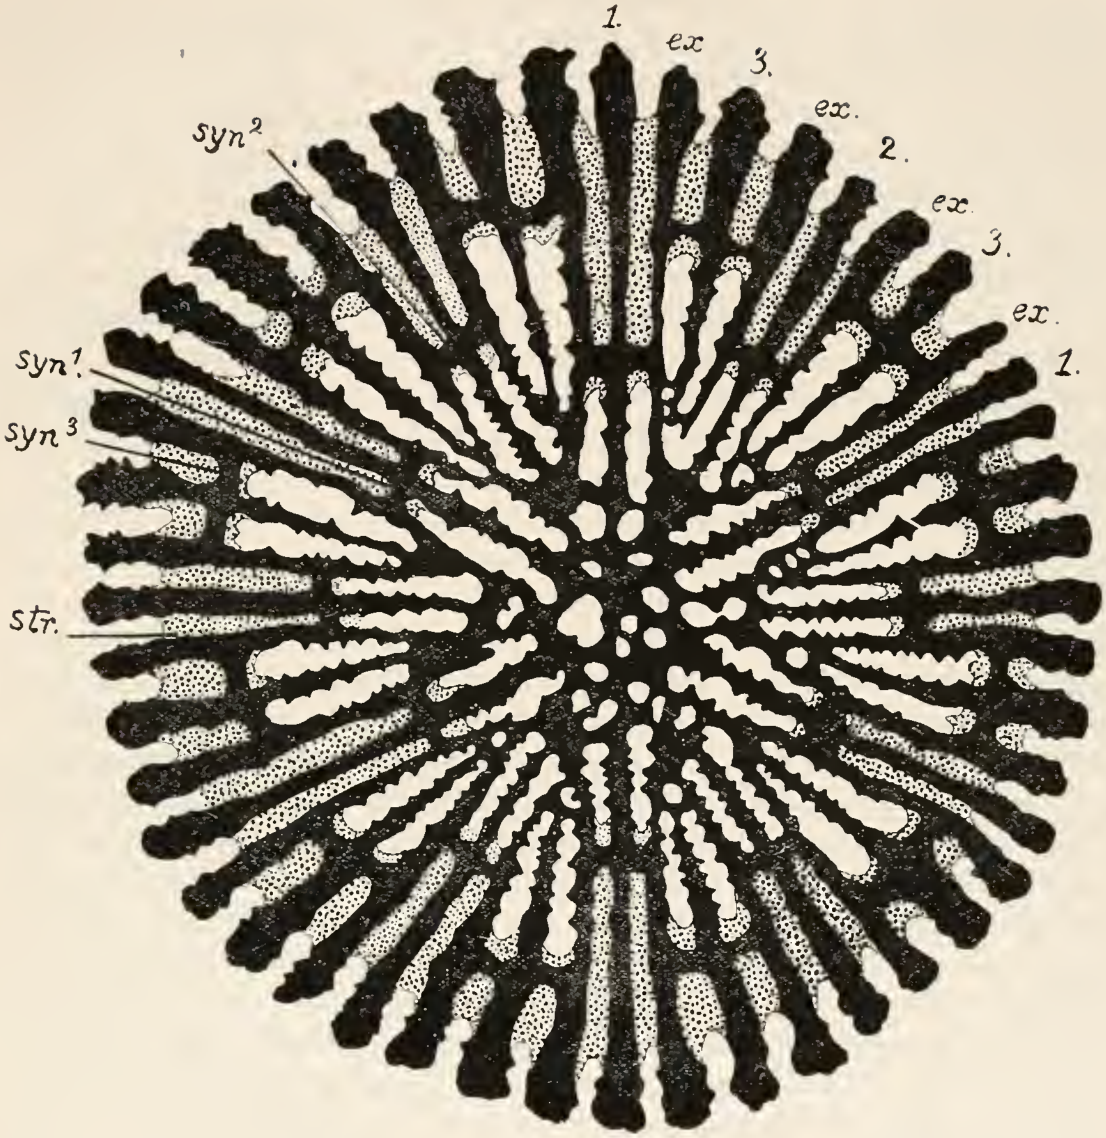

Fig. II. Diagram of a section through the corallum of *Heterocyathus aequicostatus* taken a short distance above the *Aspidosiphon* chamber. The septa and synapticula are black, the stereoplasm is shaded with dots. 1, 2, 3, endosepta of three cycles. *ex.*, exosepta. *str.*, stereoplasm. *syn.*[1], synapticulum connecting a primary endoseptum with an exoseptum. *syn.*[2], *syn.*[3], synapticula connecting secondary and tertiary endosepta with adjacent exosepta.

structure resembling any single synapticulum of *Fungia*. Their lower ends pass into the secondary calcareous deposit in the neighbourhood of the *Aspidosiphon* chamber; their upper extremities end in free margins at heights varying according as they connect a primary, a secondary or a tertiary endoseptum with an adjacent exoseptum.

The exosepta, in addition to this synapticular union, converge towards, and their inner ends unite with, the tertiary endosepta.

In the upper parts of the corallum the synapticula form the only union between adjacent septa, but a little distance lower down, and at some height above the *Aspidosiphon* chamber, the interseptal loculi become largely filled up by a secondary calcareous deposit, which, being of a dark colour from the presence of an abundant brown pigment, stands in sharp contrast to the white septa and synapticula in a rubbed down specimen. This deposit is crystalline in structure, and as it appears to have been formed independently of and subsequent to the original septa and synapticula, it has all the characters of a "stereoplasm," *i.e.*, a thickening on either side of every septum filling up the interseptal loculi. It should be observed that this deposit is most abundant and extends furthest towards the centre in the interseptal loculi adjacent to the primary endosepta; it is abundant, but does not extend so far towards the centre in the loculi adjacent to the secondary endosepta; it is least abundant in the loculi adjacent to the tertiary endosepta (fig. II.).

The structure of the septa is somewhat complicated, and different to anything that has hitherto been carefully figured or described. Each septum is very thin at its inner end and gradually thickens towards its outer or costal extremity. As is shown in Plate III., fig. 12, its inner edge is produced into a number of irregularly shaped teeth or paliform lobes, which merge into the columella, and the impossibility of distinguishing between these paliform septal offsets and true pali has been alluded to above. The faces of the septa are covered with small spiniform granulations which seem to radiate from a centre situated just within the lower end of the synapticulum. These spiniform granules are shown by longitudinal, horizontal and tangential sections to be the extremities of the radiating trabeculæ (using this term in PRATZ's sense) of which the septum is composed. Plate III., fig. 13, is a careful drawing of a horizontal microscopical section through the middle of the corallum, above the level of the *Aspidosiphon* chamber. The thin inner ends of the septa are shown to consist of a series of trabeculæ, standing in a single line, but at intervals diverging from the centre to end in a spiniform granule on the septal surface. Passing from the centre towards the periphery, the thickening of the middle and outermost parts of each septum is seen to be due to the multiplication of the trabeculæ, which no longer form a single line but stand in rows, first two, then three, and finally, at the costal extremity, five or six deep. It can be seen clearly enough in the horizontal section that these trabeculæ radiate not only towards the central and the peripheral ends of each septum, but also outwards towards the two septal surfaces, on which they emerge as the spiniform granules already described. The septum, then, is formed of a number of trabeculæ which radiate in all directions from an imaginary centre situated low down and nearer to the inner than the outer (costal) margin of the septum, and it is apparent that the centrifugal growth of the septum is effected by the addition of new trabeculæ on the outside of those first formed, these new trabeculæ being at first in single series, but in the more peripheral parts becoming arranged in curved rows, two, three, and more abreast. The curved growth lines, showing the successive additions to the septum, and their relations to the rows of trabeculæ, are well shown in the figure, as well as the way in which the outermost trabeculæ in each row from place to place bend sharply towards the surface and end in a spiniform granule.

It will be observed that there is no dark central line and no dark "centres of calcification." The centre of each trabecula is clearer than the surrounding calcareous deposit, and the latter, which appears white by reflected but dark by transmitted light, seems to have a very fine fibrous rather than a crystalline structure, but I could not make out the details clearly in the thinnest sections that I was able to prepare. In longitudinal sections each septum is clearly seen to be made up of a number of trabeculæ radiating like a fan from a centre, and each trabecula appears to be made up of a number of growth segments joined end to end, each segment formed by the fascicle of diverging fibres described by PRATZ and Miss OGILVIE as characteristic of the minute structure of the Madreporarian corallum.

But if no definite crystalline structure can be discovered in the septa themselves, or in the synapticula, the case is different for the "stereoplasm" in the interseptal loculi. This stereoplasm, except where it is heavily charged with brown pigment, appears dark by reflected and light by transmitted light, and, as is indicated in fig. 13, it is clearly made up of coarse crystalline fibres. The orientation of these fibres should be carefully studied, as it affords a proof that the stereoplasm is a secondary structure, and not a simple addition to the thickness of the septa. At the thin innermost ends of the septa the secondary fibro-crystals are disposed at right angles to the long axis of the septum (as seen in transverse, *i.e.*, horizontal section), and here we seem to have the characteristic structure of the Madreporarian septum with a middle dark line or "centre of calcification," &c. But where the stereoplasm is thick and completely fills the interseptal loculus, it displays a number of curved lines of growth, generally emphasized by the deposition of curved bands of dark brown pigment, and it should be noted that, whereas the curved growth-lines of the septa have their convexities directed outwards, the reverse is the case with the growth-lines of the stereoplasm. The fibro-crystals of the latter, as is shown in fig. 13, are arranged in diverging bundles, conformably to the curved lines of growth, in such a manner as to appear to diverge from a stereoplasmic "centre of calcification" which is more apparent in tangential than in horizontal sections. It is obvious that, after the septa and synapticula have been formed, the soft tissues in the deeper parts of the corallum shrink away from the septal and synapticular surfaces both externally and internally, and as they shrink away the calicoblastic layer again enters into activity and deposits the coarsely fibro-crystalline stereoplasm that eventually fills up the interseptal loculi to a greater or less extent.

Concerning the brown pigment, I have very little to say. It appears to be deposited in the form of minute granules between the fibro-crystals, but I found it impossible to make sections sufficiently thin to admit of an accurate study of it.

I have entered at some length into this question of secondary deposit or "stereoplasm," as there appears to be unquestionable evidence of its existence in *Heteroeyathus*, and the minute structure of the corallum of this genus may prove serviceable in the interpretation of the structure of some fossil corals. Miss OGILVIE (**41**, pp. 93–99) denies the existence of a "stereoplasm" in both recent and fossil corals, and she was perfectly right as regards the corals that she describes. There is, however, a close analogy between the secondary thickening or stereoplasm described by VON KOCH (**29**) in *Pholidophyllum* and that of *Heterocyathus*, and it is possible that the structure of *Lonsdaleia indica*, as described and figured by WAAGEN (**51**), may be referred to the same type, but in neither case are the authors' figures sufficiently detailed to enable one to speak with certainty. The description given by FRECH (**19**) of *Idastræa profunda*, and quoted at length by Miss OGILVIE (**41**, p. 99), might be applied with very little correction to *Heteroeyathus*, but in this case again the author's figure is on too small a scale to enable one to judge whether the structure is identical or not with that here described.

General Anatomy of the Polyp.—As described by GARDINER (**23**), the corallum is completely invested by the tissues of the polyp, the latter being interrupted only at the mouth of the *Aspidosiphon* chamber. It must be borne in mind that the young *Heteroeyathus* is attached to and grows round a gastropod shell (usually a *Cerithium*) tenanted by an *Aspidosiphon*, and that the growth of the coral and the Sipunculid proceed *pari passu* till we get the intimate association between the two forms characteristic of their adult condition. The shell, which served for the original habitation of the Sipunculid and the surface of attachment for the coral, is completely overgrown and eventually greatly exceeded in size by the latter. It is evident, then, that as the coral grows, its soft tissues must be folded down all round the edge of the cup to form a "perisarc," using that term in the restricted sense given to it by BERNARD (**4**, p. 21). As the corallum grew round the shell, the perisarc must have kept pace with it; indeed, it would be more correct to say that the soft tissues enveloped the shell, and that their innermost ectodermic or calicoblastic layer secreted the corallum which eventually enclosed the shell, and, growing beyond its limits, formed the *Aspidosiphon* chamber. Eventually the edges of the perisarc, growing round the shell on all sides, meet and unite below, excepting in the region of the mouth of the shell. Thus we get a basal union of the perisarc similar to that observed in *Fungia*, and as in the last-named genus we find that the mesenteries are prolonged into the cavity of the perisarc and divide up the extra-thecal cœlenteron into as many entocœlic and exocœlic chambers as there are mesenteries. The mesenteries, however, do not extend to the centre of the base of the coral. They may be traced as far as the costæ, but die out where the costæ pass into the central irregular basal granulations, and here the soft tissues appear to be supported on the granulations in the manner described by FOWLER (**16**). Above the level of the synapticula, which not only physiologically replace but are in some respects morphologically equivalent to a true theca, the external portions of the exocœles and endocœles are continued into the corresponding internal chambers, and when the polyp is fully expanded the depth of these intermesenterial chambers must be considerable, owing to the relatively great height of the exsert septa. Spirit specimens are, of course, very much contracted, and the soft tissues are everywhere stretched over and down in between the septa, pali and columella to an extent that makes the interpretation of sections a matter of considerable difficulty.

The Tentacles.—These, as stated by GARDINER, are twenty-four in number, one corresponding to each endocœle. Owing to contraction it is somewhat difficult to determine the position of the tentacles in an expanded polyp, but it appears that the twelve tertiary tentacles form an external circlet situated quite at the edge or even outside the margin of the calyx. The six primary and six secondary tentacles form an inner circle within the margin of the calyx; they alternate with one another and the primaries are nearer to, but still at some considerable distance from, the mouth. The tentacles are thickly covered with knob-like batteries of nematocysts, which are conspicuous in sections. Each tentacle is attached at its base to the two members of a mesenterial pair, and the longitudinal muscle fibres of the mesenteries are continued up into and may be traced to the tip of the tentacle. In contraction the tentacles are completely introverted by the action of the muscle fibres, and in spirit specimens, owing to the excessive contraction of the mesenteries themselves, the invaginated tentacles are doubled over the endocœlic septa and each appears in sections to be prolonged downwards into two pockets, one in each mesentery of the pair to which it belongs (fig. III.).

The Peristome and Mouth.—Owing to the distance of the tentacles from the mouth, the peristome is of considerable extent. It is closely contracted against the numerous pali and paliform lobes at the inner edges of the septa, and its contours are scarcely distinguishable in spirit specimens. The mouth is an oval aperture whose size varies very much in spirit specimens; in some it is contracted to a narrow oval, in others it is widely open, giving a clear view of the soft tissues investing the columella. The mouth, according to all received ideas on Actinian anatomy, should open into a stomodæum, but in *Heterocyathus* there is no definite stomodæum, in the sense of a longer or shorter tube lined by a modified epithelium. The ectoderm of the peristome is very thin, and at the lips of the mouth it is somewhat thickened, and, as described below, there is evidence of a distinct sphincter oris and a distinct dilator oris (radiating fibres) muscle in this region. Immediately within the lips, but not uniting to form a complete tube, are the large gutter-shaped "filaments" of the six primary mesenterial pairs which undoubtedly perform the functions of a stomodæum, and may be described as twelve discontinuous portions of the stomodæum, united only by the thickened but not modified ectoderm of the lips. There is no trace of a sulcus or sulculus (gonidial grooves). The reduction of the stomodæum seems to be clearly due to the great development of the pali and the

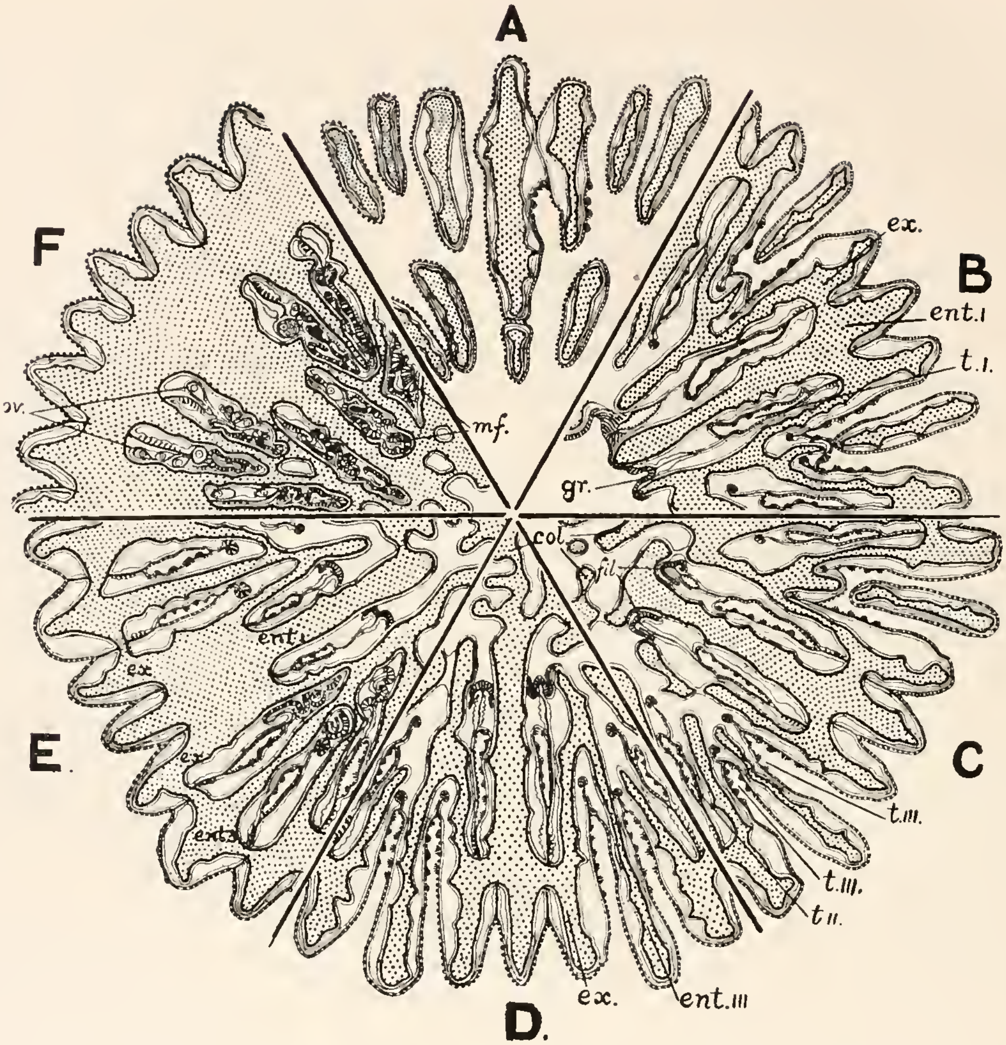

Fig. III. Semi-diagrammatic representation of six successive horizontal sections through the same sextant of *Heterocyathus æquicostatus.* The corallum is shaded with dots; the mesoglœa is represented by a black line, the endoderm by a contour line following the mesoglœa; the ectoderm is blocked. A passes through the exsert portion of the septa, B through the mouth, C and D are sections about 0·25 millim. apart and below the mouth; the interseptal loculi in these sections are not reduced by the formation of secondary calcareous deposit or "stereoplasm." In E a considerable amount of stereoplasm has been deposited in the loculi adjacent to the primary endoseptum. In F all the loculi are reduced by the deposit of stereoplasm and the mesenteries contain ova. *ent.*I., *ent.*II., endosepta of the first and third cycles; portions of the second-cycle endosepta may be seen at the edges of each sextant. *ex.*, exosepta. *fil.*, band-like primary mesenterial filaments. *gr.*, groove leading from the mouth to one of the primary mesenterial filaments. *m.f.*, coiled mesenterial filaments. *t.'*, *t.''*, *t.'''*, introverted tentacles of three cycles doubled over the corresponding endosepta. *col.*, columella.

columellar upgrowths. There is not, in fact, room for a stomodæum in the contracted polyp.

The Mesenteries.—These are of the normal Actinian character and are forty-eight in number, consisting of six primary, six secondary, and twelve tertiary pairs. The muscle banners are well developed, and the directive pairs, as is usual, have the muscle banners on their outer faces. The general arrangement of the mesenteries and their relations to the septa, mouth, and peristome are shown in the diagram, fig. III., A, B, C, D, E, F, which represent six sections of the same sextant of a decalcified specimen of *Heterocyathus* taken at different levels. The six pairs of primary mesenteries extend further inwards than the rest, and they alone reach the mouth. The six secondary pairs are intermediate in length, and the twelve tertiary pairs are the shortest of all. As stated above, the free edges of the primary mesenteries at and below the lip of the mouth are broadened out to form a T-shaped or Y-shaped "filament" (fig. III., D, *fil.*). The inner face (*i.e.*, the face directed towards the central cavity of the polyp) is covered with a very thick ciliated epithelium which passes somewhat abruptly into the thinner but still thick epithelium of the lips. Below the level of the mouth the arms of the T- or Y-shaped filament become free from adjacent tissues and may be traced as broad ciliated bands, which in section appear T-shaped, or Y-shaped, or W-shaped, for a considerable distance below the level of the mouth into the gastro-vascular cavity. As long as they retain this size and shape, they are composed almost exclusively of very long attenuated ciliated epithelial cells, whose nuclei stain deeply and are closely crowded together; there are few glandular elements interspersed among the attenuated cells, and no nematocysts. Towards the bottom of the gastrovascular cavity these bands become smaller, and gradually assume the normal shape of a mesenterial filament; gland cells become more abundant and large nematocysts make their appearance. At the bottom of the cavity the filament is thrown into a complex coil, and is loaded both with gland cells and nematocysts of the large type. It is impossible to say, from a study of sections alone, whether the coiled masses at the bottom of the intermesenterial chambers are acontia, *i.e.*, free offsets of the edges of the mesentery, or simply coiled filaments. GARDINER (21) describes acontia in *Cœnopsammia*, but I am inclined to the opinion that in *Heterocyathus* the structures that might be mistaken for acontia are only coiled mesenterial filaments.

The filaments of the secondary and tertiary mesenteries do not reach the axial gastrovascular cavity, and are easily distinguished from the primary filaments. They are much smaller, especially in the upper part of their course, and have the usual kidney-shaped outline in section. Like the primary filaments they appear to consist almost exclusively of ciliated cells in the upper part of their course, but they soon show glandular cells and large nematocysts (Plate III., fig. 15). At the bottom of the gastrovascular cavity the filaments of the secondary and tertiary mesenteries are thickened and coiled like those of the primaries.

The absence of a definite stomodæum and the extent and importance of the ciliated bands forming the upper ends of the primary mesenterial filaments are features which, though peculiar, are readily explained by a consideration of their relations to the palial and columellar structures. As may be seen in fig. III., C, the hammer-shaped palial process at the inner end of the primary septum cuts off the filaments of the primary mesenteries from the axial space, and in D the palus is seen to have contracted unions with the columellar pillars, cutting off the interseptal loculi from the axial space. It is evident that the broad ciliated filaments, extending far down in these nearly isolated loculi, are the chief if not the only agents in maintaining the circulation in the deeper parts of the loculi. Fig. III., F, shows how much the interseptal loculi become narrowed and isolated in the deeper parts of the coral in consequence of the abundant secondary thickening or stereoplasm.

All the mesenteries are fertile. In female polyps the ripe ova are large, and filled with granules of deutoplasm. I have been unable to make out details to my satisfaction, but the ova, when young, appear to become enclosed in the mesoglœa, and as they increase in size they project from the sides of the mesenteries, still enclosed in a thin mesoglœal envelope, outside of which is a layer of endoderm, forming a sort of follicle. The ripe ova are pyriform and hang in bunches from the sides of the mesenteries, each ovum attached by a slender stalk of mesoglœa and surrounded by its follicle of endoderm cells.

The relation of the mesenteries to the septa affords a strong presumption in favour of the view that these structures have been formed according to Pourtalès and Duerden's law. As has been shown, the septa are alternately exocœlic and endocœlic. The exocœlic septa, which on the usual system of notation would be called quaternaries, are larger than the endocœlic tertiaries, and, as is shown in fig. III., B and C, their inner ends meet and unite in front of the latter. Further than this, in each system the exocœlic septa adjacent to the primaries converge and meet together in front of the secondaries, forming the more or less distinct chevron-shaped pali described above. This union can best be seen in fig. II. As the tertiary endocœlic septa are enclosed within the smallest and therefore the most recently developed mesenterial pairs, and as they are themselves the smallest and least exsert of all the septa, and only unite with the Y-shaped figures formed by the exocœlic septa low down in the corallum (fig. III., B, C, and D), the evidence that they are the most recent in point of formation, and that they and the mesenterial pairs embracing them originated between the diverging Y-shaped outer ends of the exocœlic septa, in the manner described by Pourtalès and Duerden, is sufficiently convincing.

The little canals or tubes, running inwards from the lateral walls of the coral and opening into the *Aspidosiphon* chamber, have been described and figured by several authors, but their minute characters have not yet been investigated. They are almost exactly like the similar tubes in *Heteropsammia*, and the transverse section, Plate IV., fig. 24, of a tube of the latter genus serves equally well for *Heterocyathus*. The resemblance is the more striking because in *Heterocyathus*, an imperforate Turbinolid, there are endodermal canals, usually twelve in number, closely attached to the whole length of the tube, which is itself lined by an invagination of the ectoderm. In *Heteropsammia* these canals form part of the system of endodermic canals characteristic of perforate corals, but their presence in *Heterocyathus* is remarkable. The transverse section has a curious resemblance to a section through a young Actinian with twelve mesenteries and a very wide stomodæum. The ectoderm lining the central tube is curiously modified at its inner end, as will be described below. The tubes vary in number and position. There may be from five to nine of them, and they are not, as a rule, in the same plane, but in the majority of specimens they are more numerous and more closely set together on the side furthest from the mouth of the *Aspidosiphon* chamber. Tangential sections of the corallum show that the tubes are interseptal, and that the stereoplasm filling up the interseptal loculi is interrupted by their presence. Being interseptal, their external openings are always between the costæ.

Histology.—Though Professor HERDMAN'S specimens are exceptionally well preserved, histological details are, as is usual in corals, difficult to determine to one's satisfaction. In what follows I do not profess to give a complete account of the histology of the different tissues, but will confine myself to such details as I have been able to make out to my own satisfaction.

The Ectoderm.—As is shown in fig. III., the ectoderm of the body-wall is more or less deeply infolded between the costæ in spirit specimens. It is thinner where it is stretched over the edges of the costæ and thicker in the furrows between, and this does not seem to be due to contraction in spirit and the consequent stretching of the tissue over the costal edges, but to a differentiation of the ectoderm, which is not only thicker, but more glandular and more richly provided with nematocysts in longitudinal stripes, corresponding to the attachments of the mesenteries. In the thinner stripes of ectoderm corresponding to the costæ the tissue consists almost entirely of columnar or cubical epithelial cells. There are very few gland cells, and few, if any, nematocysts. In the thicker stripes opposite the attachments of the mesenteries the epithelial cells are longer, and there are numerous gland cells and nematocysts of the kind shown in Plate III., fig. 18. The gland cells are of an elongated goblet form, with a compressed nucleus at the base of the goblet and a very thin protoplasmic stalk passing from the nucleus to the mesoglœa. They contain a number of yellowish-brown highly refractive granules, which do not stain with any of the ordinary aniline dyes, or with hæmatoxylin. Similar gland cells are very abundant in the ectoderm of the tentacles. The nematocysts, two of which are shown everted in fig. 16, are elongate oval in shape with a somewhat coarse thread coiled loosely within. The everted threads are covered with long barbs disposed in a spiral. Before eversion these nematocysts contain a flocculent substance which stains bright blue in picro-indigo-carmine, and therefore probably belongs to the class of hyalogens, all of which stain similarly with this dye.

The ectoderm lining the outer moieties of the tubes leading into the *Aspidosiphon* chamber is of the same character as that of the thickened stripes of the body-wall, but it is remarkably modified in the inner moieties of these tubes. It becomes much thicker (Plate III., fig. 17) and has a vacuolated appearance, and in place of the gland cells described above we find elongated pyriform gland cells filled with round granules, which stain deeply in hæmatoxylin. But the most striking feature is afforded by the nematocysts. These are very numerous, closely crowded together, are ovoid in shape and very large, with a thick thread covered with barbs arranged in a double spiral. They contain coarse, closely-packed granules, which stain intensely blue in picro-indigo-carmine. In spite of their much larger size (figs. 16 and 17 are drawn to the same scale) and their different shape, I regard these as modifications of the ordinary nematocysts of the ectoderm of the body-wall. But they are certainly very strikingly modified, and I am at a loss to explain their function, situated as they are at the deeper end of tubes whose function is also problematical.

The ectoderm of the tentacles is raised into a great number of the well-known knob-like "batteries," crowded with small nematocysts of the usual form with a closely coiled spiral thread. Interspersed among these are larger nematocysts resembling those of the body-wall, but usually much longer and narrower. The ectoderm of the peristome is extremely thin, and consists of a cubical epithelium with very few gland cells, and, as far as I could ascertain, no nematocysts. At the lips of the mouth, however, the ectoderm is thickened, and shows some special features not visible in the ectoderm of the body-wall. There are very few gland cells, those which are present containing coarse granules staining blue in picro-indigo-carmine. I could not detect any nematocysts. Muscle fibres, which were scarcely distinguishable in the peristome, are here well developed and arranged radially so as to form a more or less distinct dilator oris muscle. In many sections the epithelio-muscular character of the ectoderm cells becomes evident. The layer of nerve fibres at and between the bases of the ectoderm cells is distinct, and among the epithelio-muscular cells very small attenuated, spindle-shaped cells may be distinguished which may be interpreted as sense cells. This thickened ectoderm passes insensibly into the endoderm at the lower margin of the lips, except at the places where the twelve primary mesenteries reach the mouth. Here it is continued into the very thick ectoderm of the Y- or T-shaped filaments of these mesenteries. In these filaments, as mentioned above, the ectoderm consists almost exclusively of very long attenuated, ciliated, epithelial cells, whose character is sufficiently indicated in fig. 14. There are very few glandular elements and no nematocysts. The coiled filaments of the bases of the primary mesenteries, and nearly the whole extent of the filaments of the secondary and tertiary mesenteries, consist of closely-packed, attenuated, epithelial cells, among which numerous gland cells and nematocysts are wedged in. The gland cells are of two kinds: (1) ovoid vesicular cells with clear contents; (2) pyriform cells containing coarse granules staining deeply in picro-indigo-carmine or hæmatoxylin. The nematocysts are all of the type shown in fig. 18. They are very large, measuring

0·06 millim. in length, and the central thread stains intensely blue in picro-indigo-carmine. They are clearly of the same type as, but somewhat larger than, the mesenterial nematocysts described by GARDINER (21) in *Cœnopsammia*.

As regards the layer of calicoblasts and the desmocytes, they are of the usual character, and I have nothing to add to what I have published concerning these structures in a previous paper (7).

The Endoderm.—As is usual in corals, the highly vacuolated endoderm cells are so badly preserved that nothing very definite can be said of their structure. They differ, however, in different regions of the body. The endoderm cells covering the muscle-banners and the extrathecal continuations of the mesenteries, and also those of the tentacular endoderm, are very long and columnar, and are crowded with Zooxanthellæ. As a rule there is a similar modification just within the mesenterial filaments, this modification being most pronounced in the primary mesenteries. Elsewhere the endoderm consists of a rather low columnar or cubical epithelium, and Zooxanthellæ are more scarce or, in some places, absent. GARDINER (21) lays great stress on the absence of glandular elements in the endoderm, but my observations do not support his conclusions. Glandular elements, it is true, are few or altogether absent, not only in the elongated endoderm above referred to, but in the whole or the greater part of the endodermic investment of the mesenteries. But in *Heterocyathus* the endoderm of the axial gastrovascular cavity, that is to say the tissue investing the pali and columellar upgrowths, is invested by a moderately thick cubical endoderm in which there are few Zooxanthellæ, but numerous ovoid or bean-shaped cells containing clear refractive granules which do not stain with any of the aniline dyes used, nor with hæmatoxylin. These cells are shown in Plate IV., fig. 19. It is, of course, possible that they may be modified nematocysts. Similar cells are found, though not so abundantly, in the endoderm wherever it is opposite a layer of calicoblast, and this would seem to suggest that the function of the cells in question is to elaborate material which is passed through the thin mesoglœal lamina to the layer of calicoblasts and converted into calcareous tissue by the agency of the latter. This view has a certain probability, because the calicoblasts form so thin a layer, and are themselves so retrograde in structure that it is difficult to believe that they are the only agents in the active growth of the corallum. On the other hand, I have observed fragments of copepods and diatoms in the intermesenterial chambers, at some distance from the filaments, and as these have evidently been or are being digested, it is equally possible that these glandular-looking cells in the endoderm may secrete a digestive fluid. At all events the facts do not warrant so sweeping an assertion as that of GARDINER, that the endoderm is excretory but not glandular, or the conclusions as to the homology of the Anthozoan layers that he has founded on it.

In some, but not in all my series of sections, the endoderm, in addition to the glandular elements described above, contained a number of large amœboid cells of various shape, two of which are shown in fig. 20. They were very abundant in one series, but entirely absent in another, and in a third they were rare. They are filled with large refracting granules, which generally stain crimson in picro-indigo-carmine, but in some cases they stain a deep indigo blue. They can be nothing else than amœbocytes, and are probably excretory in function. Their abundance in one specimen and their rarity or absence in others is probably attributable to the different conditions of nutrition of the polyps in question. It is well known that the endoderm of Cœlenterates, *e.g.*, of *Hydra*, presents very different appearances according as the animal has been recently fed or starved, and I have found the most diverse appearances, particularly in the matter of the presence or absence of endoderm cells loaded with granules, in the endoderm of *Hydræ*, according as they had been fed abundantly or starved.

Finally, it may be noted that at the bottom of the axial cavity there are large spaces, and frequently there is a single large central space in the axial gastro-vascular cavity. The endoderm lining these spaces or space is invariably devoid of Zooxanthellæ and gland cells, and has the simple columnar form depicted in fig. 21.

As regards the occurrence of nematocysts in the endoderm, I occasionally found large nematocysts, of the second type characteristic of the tentacular batteries, in the tentacular endoderm, but invariably in close proximity to one of the batteries. I conclude, therefore, that these nematocysts were not formed in the endoderm, but have been forced through the mesoglœa into the endoderm during the violent contraction produced by the action of reagents. Elsewhere I could find no trace of nematocysts of any kind in the endoderm.

2. **Heteropsammia michelini**, M. Edw. and H.

(Plate IV., figs. 22 to 25.)

The remarkable analogies between this coral and *Heterocyathus æquicostatus* have been commented on by several authors. Both are built up round a gastropod shell tenanted by an *Aspidosiphon*, both have an exactly similar spiral *Aspidosiphon* chamber in the adult state. In both there is a minute Lamellibranch commensal with the *Aspidosiphon* within the chamber, and in both there is a number of minute tubes lined by ectoderm leading from the lateral walls of the coral into the chamber in question. The shape and general appearance of the two corals is closely similar, but whereas *Heterocyathus* is always a simple coral, *Heteropsammia michelini* generally exhibits two calices produced by fission of the parent calicle, and *H. multi-lobata* exhibits several calicles. The anatomy of the last-named species has been described by Fowler (18), who notes the following features. The external soft tissues rest on the echinulations of the cœnenchyme; the tentacles are simple, without nematocyst batteries, and are apparently both exocœlic and endocœlic; exosepta and endosepta are present, and certain of the septa fuse centrally, as in *Rhodopsammia*

(*Balanophyllia*); the number of mesenterial pairs is very variable and there are no directive mesenteries; the tubes leading into the *Aspidosiphon* chamber are lined by ingrowths of the body-wall consisting of ectoderm, mesoglœa, and endoderm. No account is given of the histology.

H. multilobata is a well-marked colonial form with several calices, whereas *H. michelini* usually has two calices only, and some of the differences between my observations and Fowler's are no doubt attributable to the difference in habit of the two species. In older specimens of *H. michelini* the septal arrangement is sometimes very irregular, but in young specimens with a single undivided calicle the septa are arranged in a normal manner in six systems and four complete cycles, and their relations are practically identical with those described in *Balanophyllia*, and with a little trouble one may select a considerable proportion of adult specimens, in which two calicles have been formed by fissiparity, in which the septal arrangement differs very little from the normal.

The most interesting results, however, are obtained from specimens with a single elongated but as yet undivided calicle. I made a series of sections through one such specimen and another series through an obviously regular calicle of a specimen in which fissiparity was complete. The sections show that the septa are alternately exocœlic and endocœlic. In the first specimen with an undivided calicle there are two pairs of directive mesenteries defining the primary septa at each end of the long axis of the calicle. A portion of one side of the specimen was destroyed by the ravages of a boring sponge, but in the complete half I was able to count three systems and twenty-six endosepta arranged in four complete cycles, and a single septum of a fifth cycle in the chambers adjoining the directive septa. I have given a diagram of this specimen in fig. IV. The diagram is carefully constructed with reference to a camera drawing of the actual section, but the complexity of the actual drawing is so great, owing to the porous nature of the corallum, and the details are so minute that it is impossible to get them all into any figure of reasonable size other than a diagram.

It will be observed that the arrangement of the septa and their relations to the mesenteries are practically identical to what has been described in *Heterocyathus*. But particular attention should be paid to the exocœlic septa, which are shaded with lines to distinguish them from the endosepta. Nothing can be more clear than the fact that their peripheral ends have been thickened; that chambers have been formed in the thickened ends, whereby the septa became Y-shaped. And, finally, that the quaternary endosepta have been formed between the mesenterial pairs arising in the forks of the endosepta, and in some cases they have and in some they have not united with the inner ends of the exosepta. Moreover it is clear, from the manner in which the inner ends of the exosepta unite in the columella, that the tertiary endocœles must have been formed in exactly the same manner as the quaternaries obviously have been. There could not be a more striking demonstration of the validity of

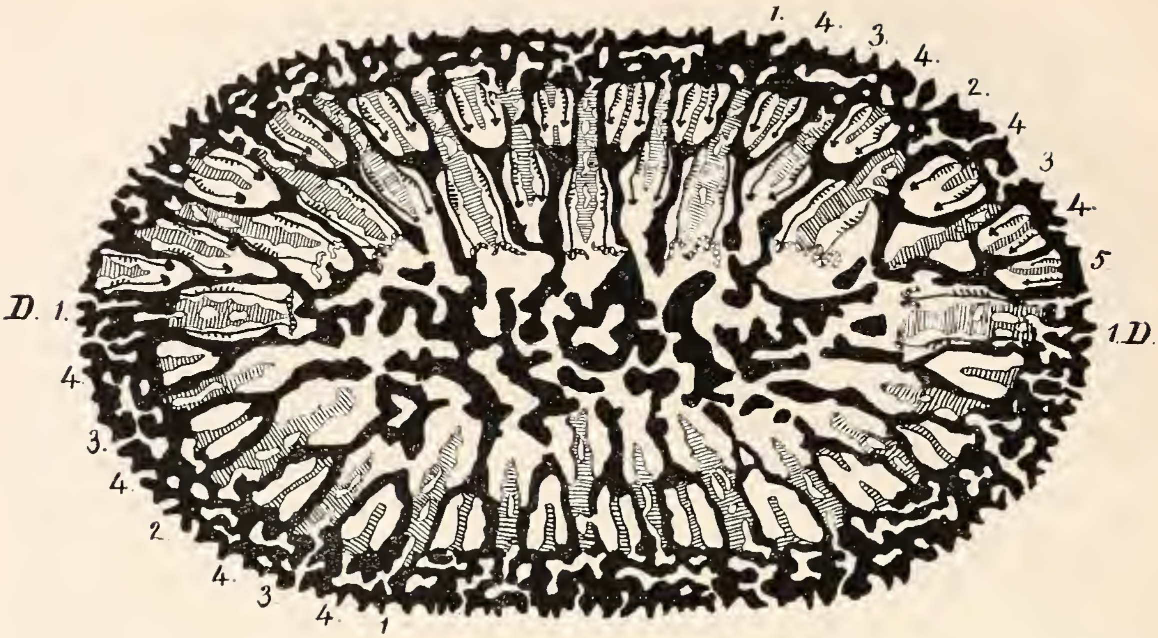

Fig. IV. Diagram of a specimen of *Heteropsammia michelini* in which the calice has not yet divided by transverse fission. The endosepta are cross-shaded, the exosepta, the porous theca, and the columella are black. The mesenteries are indicated in the upper half of the figure but not in the lower. *D*, *D*, directive mesenterial pairs. 1, 2, 3, endosepta of the first, second, and third cycles. 4, 4, fourth-cycle endosepta, each enclosed in a chamber formed by the forked peripheral ends of an exoseptum. In several cases the inner ends of the exosepta may be seen to unite in front of a tertiary endoseptum and to be prolonged beyond the point of union into the columella. 5, an endoseptum of the fifth cycle formed in a bifurcation of an exoseptum adjoining one of the directive endosepta.

Pourtalès and Duerden's law in the case of Eupsammid corals. It should be noted, however, that the quinary mesenterial pairs do not arise according to the sequence observed by Duerden in *Siderastræa*, but are contiguous to the sulcar (dorsal) and sulcular (ventral) primary septa.

My second series of sections, through a polyp which had been formed by transverse division from the original single parent polyp, gave some interesting results. A tracing of a section taken a little above the level of the stomodæum is given in fig. 22. The arrangement of the septa and mesenteries is remarkably regular. There are apparently six systems and three cycles of endosepta, with an additional quaternary septum in the chamber on the right side of the directive septum, that is to say, there is just half the number of endosepta that there was in the elongated and undivided specimen. The endosepta may be classified according to size and relations as primaries, secondaries, and tertiaries, but they cannot have made their appearance in this order, as they were derived from the pre-existing septa of the parent polyp. The number of parental mesenteries has evidently been halved in the process of division. No new septa have been added, but the quaternaries of the parent have become the tertiaries of the offspring.

Another singular fact is the presence of only one pair of directive mesenteries, the absence of the second pair being obviously explained by the division of the parent at right angles to the long axis of the calicle, whereby one pair of directives remained in the one, and the other pair in the other of the offspring. The existence of the single pair of directives in a coral which has doubled itself by a single act of fissiparity confirms the conclusion I arrived at in an earlier paper (**5**), that the absence of directives in many corals is to be explained by the fact that they have multiplied by fission.

To deal briefly with other points in the anatomy of the polyp. The external body wall, as Fowler describes, rests upon the echinulations of the cœnenchyma, and there are no peripheral continuations of the mesenteries. The tentacles are all endocœlic, and therefore correspond in number to the endosepta. In contraction they are introverted, and in this condition are doubled over the inner edges of the endosepta. Thus they are situated nearer the mouth than in *Heterocyathus*, and the peristomial area is correspondingly reduced. The primary and secondary tentacles form a circle nearest to the mouth, the remaining orders form circles at greater distances from it, and it follows from their relations to the endosepta that the tentacles of different orders alternate with one another. In *H. michelini* the tentacles are covered with well-developed batteries of nematocysts; in *H. multilobata*, according to Fowler, they are not.

There is a short, but distinct stomodæum, and I think that I found traces of a sulcus (gonidial groove), but of this I cannot be certain, as both my specimens suffered partly from the attacks of boring sponges, and partly from the fact that grains of quartz sand were lodged in the angles of the mouth and produced imperfections in my sections in those regions. However this may be, the circulation of water in the complex chambers in which the lower parts of the mesenteries are lodged is provided for by means similar to that described in *Heterocyathus*. The filaments of the primary and secondary mesenteries form broad sinuous bands in the upper part of their courses, and it is only deep down in the coral that one meets with the characteristic kidney-shaped sections of mesenterial filaments. The number and arrangement of the mesenteries has been sufficiently described. As far as I could determine, all the mesenteries are fertile, but in the undivided specimen of which I made sections the quaternary mesenteries, especially those in the lateral chambers, were in advance of the remaining orders as regards the maturity of ova contained in them. The ova, and as far as I could make out in a series of longitudinal sections the testes also, are embedded in the mesoglœa of the mesenteries in the manner figured by the Hertwigs for *Actinia*, and do not hang from the sides of the mesenteries in follicles as in *Heterocyathus*.

Histology.—The external tissues were very well preserved, but the reagents had not penetrated well, and the endoderm and mesenterial filaments were in consequence macerated and of little use for histological examination.

The Ectoderm (fig. 23) of the body-wall is relatively much thicker than in *Heterocyathus*, and is richly supplied with gland cells and nematocysts. The character of the epithelial cells is well shown in the figure. The gland cells are of three kinds:—(1) Goblet cells with a central nucleus and filiform internal ends, the wider external end filled with small granules staining deeply in hæmatoxylin or picro-indigo-carmine. (2) Flask-shaped cells with broad internal ends and a narrow neck opening at the surface; these cells are filled with coarse granules which stain in the same way as those of the first variety. (3) A few large vacuolated sac-shaped cells whose contents stain with eosin, but remain colourless in picro-indigo-carmine.

The nematocysts are of two kinds. The small spiral-thread variety is fairly abundant, and here and there are large torpedo-shaped nematocysts with barbed threads, similar to those described for *Heterocyathus*.

The ectoderm lining the small canals leading into the *Aspidosiphon* chamber is not modified as in *Heterocyathus*, but contrariwise, it loses its glandular character and consists almost exclusively of ciliated columnar cells, among which nematocysts of the larger variety with barbed threads are to be found. In some of my sections the lumina of the tubes are packed with everted nematocysts of this kind, which have evidently been discharged when the polyp was killed, and this suggests that these canals serve in some manner as special batteries of nematocysts protecting the commensal Sipunculid. In fig. 25 I have given a representation of the manner in which these chamber canals pass through the general mass of cœnenchymal canals into the *Aspidosiphon* chamber. It will be observed that the endoderm canals, generally twelve or thirteen in number, surrounding them are specially related to the chamber canals and lie parallel to them.

The tentacular ectoderm is raised into large and broad nematocyst batteries containing numerous small spiral nematocysts and a lesser number of those of the larger type. In the peristomial region the ectoderm becomes thinner, less glandular, and contains but few nematocysts. At the lips it again becomes thick, and in this region the nervous layer is thicker than elsewhere, and I was able to observe a few large pale nuclei embedded in the layer of nerve fibrils which appear to belong to gland cells. In this region, as in *Heterocyathus*, the radially disposed muscular fibres of the ectoderm cells are very conspicuous, and one can equally well recognise the circular layer of endodermic fibres forming a sphincter oris.

The ectoderm of the lips passes without any abrupt change into the stomodæum. Here the same elements may be recognised, but in different proportions. The epithelial cells are elongated filiform, and their deeply staining elongated nuclei are closely crowded together. Nematocysts of the spiral and barbed types are fairly abundant, especially the latter variety. The glandular cells are much increased in number, especially the eosinophile cells of the third type. The layer of nerve fibrils at the bases of the cells is relatively thick. This structure is continued without much change into the broad filaments of the primary and secondary mesenteries, but in the lower part of their courses the spiral nematocysts and the basophile gland cells become less numerous, and the number of eosinophile gland cells is correspondingly increased. The coiled mesenterial filaments were too much macerated to admit of accurate observation. I was only able to satisfy myself that they contain numerous large barbed nematocysts, but none of the spiral variety; that the epithelial cells are attenuated and closely packed together in groups, and that there are numerous very large eosinophile gland cells between the groups.

The endoderm was too much macerated to admit of careful study. The cells are evidently highly vacuolated, and their nuclei are unusually small. Zooxanthellæ are abundant in the most external cœnenchymal canals, but are scantily distributed in the deeper parts. In one of my specimens the endoderm was full of granular amœbocytes similar to those described in *Heterocyathus*.

3. Dendrophyllia gracilis, M. Edw. and Haime.

(Plate IV., figs. 26 to 28.)

The anatomy and histology of *D. ramea* has been fully described by von Heider (26), whose observations are so careful and accurate that I have little to add to them. He has given a very full account of the relations of the perisarc (edge-zone or "Randplatte"), and has fully realized the importance of the exosepta and the manner in which the tertiary mesenterial pairs, and the exosepta embraced by them, are formed in the Y-shaped peripheral extremities of these exosepta. The full significance of this observation of course escaped him, as he was unacquainted with Pourtalès' account of the development of *Balanophyllia*, and his memoir was many years anterior to Duerden's recent work.

Dendrophyllia is an arborescent genus propagating by lateral buds. The soft tissues extend for a considerable distance below the lip of the calicle, forming a well-marked edge-zone or perisarc. The septa and theca are thin and fragile, and there are well-marked external costæ corresponding to the septa. Correlated with the presence of costæ is the existence of peripheral continuations of the mesenteries in the perisarc, as has been correctly described and figured by von Heider. There is practically no difference between the septal arrangement of *D. gracilis* and *D. ramea*. In both there are three cycles of endosepta, and the exosepta alternate with the endosepta, forming an apparent quaternary cycle. Von Heider has given an excellent account of the manner in which the apparent quaternary exosepta meet and unite in front of the short tertiary endosepta, and his diagram (*loc. cit.*, plate xxxi., fig. 7) leaves nothing to be desired in clearness and accuracy. It is evident that the septa and mesenteries are formed in strict accordance with Pourtalès' and Duerden's law, and I am able to add this much in confirmation. I made a series of sections through a small lateral bud measuring about 2 millims. in diameter. In this bud there are only twelve pairs of mesenteries. Six pairs, of which two are directives, are well developed and reach the stomodæum; they embrace the primary endosepta, the latter being tolerably well developed as narrow, ridge-like projections in the calicle, but with branched peripheral ends passing into the network of trabeculæ forming the cœnenchyme. Alternating with the endosepta are six exosepta of approximately the same size, whose peripheral ends bifurcate and enclose chambers in which are the mesenterial pairs of the second cycle. These secondary mesenteries are unequally developed, but not, as far as I could determine, according to any regular sequence. Each pair embraces an endoseptum, which in some cases is very rudimentary, but in other cases has grown centipetally and has united with the inner limb of the Y-shaped exoseptum (fig. V). Thus we see that in the bud the

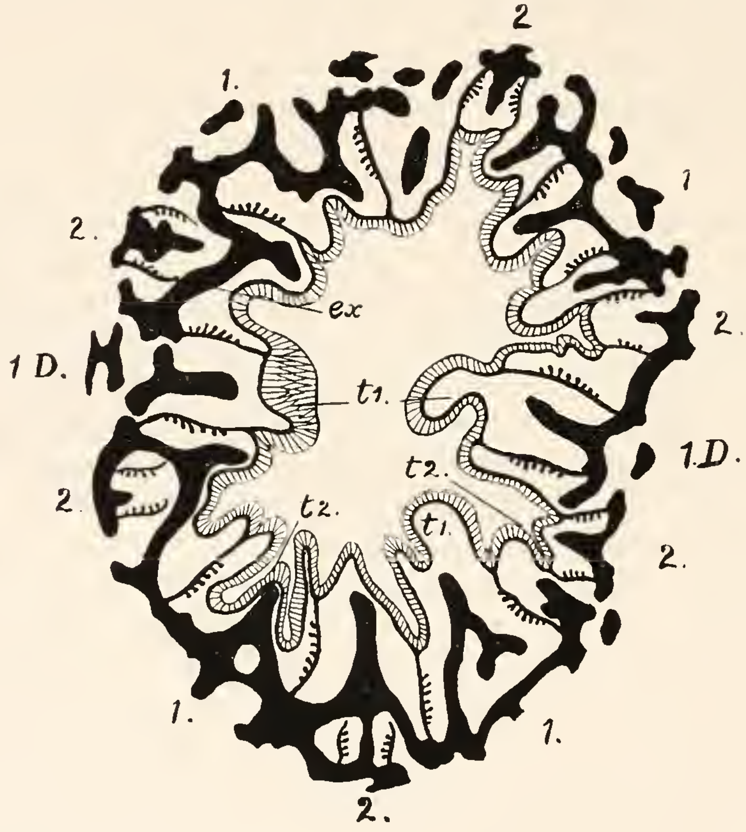

Fig. V. Semi-diagrammatic section through a young bud of *Dendrophyllia gracilis*. 1, 2, the primary and secondary cycles of endosepta embraced by the corresponding mesenterial pairs. *D*, *D*, the two pairs of directive mesenteries. *ex*, an exoseptum with forked peripheral ends, within which a pair of secondary mesenteries enclosing a secondary endoseptum is developed. t^1, t^2, tentacles of the first and second cycles corresponding to the endosepta.

secondary mesenteries, and the endosepta embraced by them, are formed between the bifurcated outer ends of the exosepta, and show the same relations to the latter that the tertiary endosepta show in the adult. This is a clear proof of the nature of the septal sequence.

Von Heider counted eighteen tentacles in one-half of a specimen of *D. ramea.* My specimens of *D. gracilis* were too much contracted to enable me to count with certainty, but I found, both in the bud and in the adult, indications of a cycle of exotentacles alternating with the primary and secondary endotentacles. The exotentacles appear to be simply introverted, and do not enter into close relations with the mesenteries. The endotentacles, as in *Heteropsammia,* are introverted and doubled over the inner edges of the endosepta. As far as I could determine, there are twelve exotentacles in the adult, alternating with the primary and secondary endotentacles. Thus there would be thirty-six tentacles of both kinds, and my observations agree with von Heider's.

The stomodæum is relatively longer than in *Heteropsammia,* measuring fully 1 millim. in length in the contracted spirit specimen, and in the expanded polyp it is probably much longer. I could find no trace of sulcus or sulculus. The stomodæal ectoderm extends some little way down the free edges of the primary and secondary mesenteries, as in *Heterocyathus* and *Heteropsammia,* but not so far as in these two genera, and eventually it gives place to a normal mesenterial filament.

As regards the histology, I have not very much to add to what has been published by von Heider. In *D. gracilis* the ectoderm of the body-wall is peculiar, and unlike anything that I have seen in any other coral. It is difficult to obtain a clear idea of its structure in sections, but it appears, as shown in fig. 26, that the cells are large and vacuolated, and form a thickened cell-wall, which, from its staining properties, seems to be of the nature of an intercellular substance. The walls of adjacent cells cohering together give a semi-cartilaginous consistency to the whole tissue, which no doubt forms an efficient protection against the numerous sponges and other organisms that infest the majority of corals. Embedded in the ectoderm cells are nematocysts of three kinds: (1) the common spiral-thread nematocyst measuring 0·02 millim. in length, more or less; these are very scantily distributed. (2) Medium-sized elongated nematocysts, about 0·028 millim. long and 0·005 millim. broad (fig. 27B) with a loosely and irregularly coiled thread; these are abundant. (3) Large elongate oval nematocysts about 0·035 millim. long and 0·01 millim. broad. According to Gardiner (**21**) the medium-sized nematocysts are developing stages of the spiral 0·02-millim. nematocysts, and this may be the case. It is not easy to speak with certainty on this point from a study of sections only, but there is some reason to think that the medium-sized nematocyst, as I have figured it, is really a third variety. In the first place they are very abundant in the ectoderm of the body-wall, whereas the small spiral nematocysts are very scantily represented there; in the second place they occur in the stomodæum in which no other nematocysts are to be found. Von Heider found two kinds of nematocysts in the ectoderm of *D. ramea,* the small spiral 0·02-millim. variety, and the large elongate oval variety, measuring in this case 0·05 millim. in length. He describes the latter as filled with a coarsely granular material, but without a thread, and a large proportion of these nematocysts in *D. gracilis* present this appearance; but others may be found in which a thick thread loosely wound in a spiral of few turns is clearly distinguishable, and it is scarcely open to doubt that the forms filled with granular material are simply unripe. In fig. 27C I have drawn a nematocyst of this variety which seems to throw some light on the development of the thread. In the centre of the capsule is the pointed end of the thread (much longer than in *Cœnopsammia*) surrounded by a granular sheath which seems to be differentiating to form the eversible portion of the capsule. At the base of the capsule the granular sheath widens out and forms a rounded mass in which an irregularly and imperfectly formed coil can be distinguished: this I take to be the middle portion of the thread in course of formation. Near the point of the thread, and outside the granular sheath surrounding it, is a spiral of five turns closely wound round the granular sheath: this must be the terminal portion of the thread differentiated from the granular sheath at the same time that the latter gave rise to the eversible portion of the capsule. The capsule itself is lined by a rather thick granular layer. It should be observed that in these nematocysts the terminal part of the thread is wound round the eversible sheath near the aperture for the extrusion of the latter. GARDINER (*loc. cit.*, plate xxxiv., fig. 14) figures it at the opposite end of the capsule, but in *Cœnopsammia* the eversible sheath is only one-third the length of the capsule. In *Dendrophyllia*, moreover (VON HEIDER agreeing with me in this), there is a distinct spearhead-shaped tip to the thread, as in *Euphyllia*, whereas GARDINER found no such armature in *Cœnopsammia*.

In the "batteries" of the tentacles there are, as usual, very numerous and closely crowded nematocysts of the small spiral variety, and among them a considerable number of the second variety described above, which, if GARDINER is right, are to be regarded as early stages of the spiral variety. I think, however, that they are really a different form of nematocyst. I was able to distinguish a fine fibril passing inwards from the bases of many of the small spiral nematocysts, and in some cases I could observe that this fibril passed into a fine layer of protoplasm surrounding an oval nucleus, and that from this a fine branching fibril passed into the layer of nerve fibres overlying the mesoglœa (fig. 27A). The ectoderm of the peristome is very thick as compared with *Heteropsammia* and *Heterocyathus*, and contains a large proportion of gland cells and the same nematocysts as the ectoderm of the body wall. The stomodæal ectoderm, as VON HEIDER remarked, is composed almost exclusively of elongated cells of the columnar type; they are almost certainly ciliated, but the cilia had been destroyed by the action of alcohol. There are few gland cells, those that are present being of the flask-shaped finely granular type, in the stomodæum and very few nematocysts. All the nematocysts that I was able to recognise belong to the second variety described above.

The mesenterial filaments are crowded with gland cells and nematocysts, the latter all of the same medium-sized variety as those of the stomodæum, and this fact leads me to think that GARDINER was in error in describing this form as a stage in the development of the small spiral variety. The mesenterial filaments are relatively small, and the absence of the largest ectodermal nematocysts is explained by the fact that there is no room for bodies of such size.

The endoderm is remarkable chiefly for the fact that Zooxanthellæ are very sparingly distributed in the mesenterial epithelium, and the epithelio-muscular cells are for the most part clearly defined and but little vacuolated. The muscular processes of the cells are remarkably well developed. Scattered through the endoderm, but somewhat sparingly, are minute nematocysts, about 0·01 millim. long, containing a loosely and irregularly coiled spiral thread. Each is contained in a transparent cuticle, and there is a flattened nucleus to one side of and *outside* the nematocyst itself. In the somewhat similar endodermic nematocysts of *Flabellum*, GARDINER (22) figures the nucleus inside the capsule of the nematocyst. The mesoglœa of *D. gracilis* is relatively thick, no doubt in correlation with the unusually great development of the musculature, but I could find no trace of structure in it. The desmocytes, described by VON HEIDER as calicoblasts, are well developed and form tassel-like groups at the points of attachment of the mesenteries to the theca, but otherwise present the usual features.

It is evident that the three forms whose anatomy is described in this memoir do not differ in any important points of anatomical or histological structure from the normal Actinian type, which has been shown by many authors to be characteristic of the polyps of Madreporarian corals. There are, indeed, minor characters, both anatomical and histological, which have a certain interest, but none of them can be regarded as having any classificatory value. One's attention is arrested by the presence of both endotentacles and exotentacles in some genera and of endotentacles only in others. But when we see that in the Eupsamniidæ, a well-defined family, only endotentacles exist in *Heteropsammia* while *Dendrophyllia* possesses both endo- and exotentacles, this character does not appear to be of much value. Moreover, owing to the great difficulty experienced in counting and localising the tentacles in spirit specimens, the information we possess on this point is not altogether trustworthy, and before any attempt is made to use the tentacles as an aid in determining the affinities of different genera of corals, it will be necessary to accumulate a large number of facts based on the study of living or well-preserved expanded polyps.

But a much more promising field is offered to the future investigator by the study of the relations of the septa to the mesenteries, especially by the developmental sequence of the endosepta and their connections with the exosepta, if present. My chief object in this paper has been to show that it is possible, by a study of the relations of hard and soft parts in the adult corals, to determine whether the septal sequence follows the rule established for *Balanophyllia* by POURTALÈS and *Siderastræa* by DUERDEN, and I have given sufficient evidence to show that the peculiar septal arrangement of the Eupsammiidæ, which has been commented upon by many authors, is due to the sequence in question. I have further shown that the septal arrangement in *Heterocyathus*, an imperforate coral, can only be interpreted upon the same principle, and DUERDEN'S account of the development of *Siderastræa* is of itself sufficient evidence that a similar mode of septal sequence prevails both in perforate and imperforate corals.

On the other hand, it is clear from VON KOCH'S (32) and DE LACAZE DUTHIER'S (33) account of the development of *Caryophyllia*, that POURTALÈS and DUERDEN'S rule is by no means applicable to all corals, but that, contrariwise, there is another and distinct mode of septal sequence which is either independent of the formation of exosepta, or in which the part played by the exosepta is very different.

It is tempting to suppose that there are two principal modes of septal development among corals, typified by the Eupsammiidæ, *Heterocyathus* and *Siderastræa* on the one hand, and *Caryophyllia* on the other hand, and that the presence or absence of exosepta will indicate the group to which any given coral belongs. But while I think that it is very possible that a solution of many classificatory difficulties may be found by extensive investigations on the lines laid down by DUERDEN, I must recognise that it would be premature to make any positive statements in the present state of our knowledge. There can, I think, be very little doubt that forms like *Mussa*, *Euphyllia*, and *Galaxea*, which have endosepta only, cannot have been developed on the same plan as *Siderastræa*, but must have followed the mode described by VON KOCH for *Caryophyllia*. But this statement cannot be extended to all forms known to possess endosepta only. GARDINER (22) has shown that in *Flabellum* the new cycles of septa are at first exocœlic, and that in the course of growth a pair of mesenteries is formed in connection with each exoseptum, in consequence of which the exosepta become endosepta. I have shown (6) that the same rule holds good for the anthoblasts of *Fungia*. Though our evidence is not complete upon this point, I believe that this will be found to be the usual mode of septal formation in all corals which have only endosepta in the adult condition. It must be borne in mind that a coral in the course of growth increases not only in height but in diameter. As a consequence of its constantly expanding perimeter, the peripheral ends of the original radial structures (the primary and secondary septa) become further and further removed from one another, and the polyp forms new radial folds between which new radial calcareous structures are formed to fill up the gaps between the diverging septal extremities. These new radial structures are the exosepta or their equivalents. In those cases in which the exoseptal formations acquire a very intimate union at the time of their appearance with the adjacent endosepta, further peripheral growth is accompanied by a bifurcation or splitting of the peripheral ends of the exosepta, and a newer set of radial folds with corresponding calcareous structures is formed within their bifurcated extremities, as in the Eupsammiidæ, *Siderastræa*, &c. In other cases further peripheral growth is provided for by the formation of new radial folds *on* *either side of* instead of between the forked peripheral ends of the exosepta, and these latter, as a consequence of the formation of new mesenterial pairs embracing them, become in their turn endosepta. But, whichever the mode of peripheral growth, it is obvious that the so-called "theca," about which so much discussion has taken place, is really the result of the formation of radial structures in connection with peripheral growth, and is not a circumferential structure. An examination of the figure in the text, fig. IV., will make this clear. Here the different stages of peripheral growth are clearly marked by the different distances from the centre of the insertions of the primary, secondary, tertiary, and quaternary mesenteries. The wall or theca must at each stage have been formed by the trabecular offsets of the peripheral ends of the exosepta united to the endosepta, and it is clear that the perforate "theca" of the adult is nothing more than a network of trabeculæ formed by the peripheral ends of the exosepta and endosepta. In *Heterocyathus* the wall is formed by the intervention of the synapticula, which must be regarded as being formed simply by very short radial folds between the outer ends of the septa, and are therefore quasi-septal structures, as has been pointed out for *Fungia* by Miss OGILVIE. In many corals the wall is formed by simple apposition of the thickened peripheral ends of the septa, giving rise to the so-called "pseudotheca." In others it is formed by the so-called "euthecal" pieces, which are really nothing more than very short radial structures intervening between the peripheral ends of the septa, but not produced internally so as to form septa. In the present state of our knowledge it would be unprofitable to pursue the subject further, but I may repeat that the whole tendency of recent investigation has been to show that a true theca, that is to say, a circumferential structure independent of the radial growths, or septa, is always to be referred to the prototheca, as defined by BERNARD, and that all other so-called "thecal" structures are in reality radial growths, formed in radial folds of the polypal walls, between previously existing radial structures. Further, it would seem from the most recent embryological investigations, which are confirmed by a study of adult structure, that there are two ways in which the new radial growth may take place: (1) by the simple formation of new radial folds between every pre-existing radial fold (*Caryophyllia*, &c.); (2) by the bifurcation of every alternate radial fold and the formation of a new radial fold in every space formed by such bifurcation (*Siderastræa*, *Balanophyllia*, *Heterocyathus*, &c.).

It is possible, but it would be rash to make a positive assertion at present, that these two modes of peripheral growth will be found to be of primary value to the systematist.

It may be worth while, in conclusion, to observe that the following corals have been found to have endosepta only:—*Mussa*, *Euphyllia*, *Madrepora durvillei*, *Madracis asperula*, *Duncania*, *Galaxea*, the lateral polyps of *Madrepora variabilis*. The following have been found to possess both exosepta and endosepta:—*Astroides*, *Stephanotrochus*, *Balanophyllia*, *Heteropsammia*, *Dendrophyllia*, *Heterocyathus*, *Madrepora aspera*, the apical polyps of *Madrepora variabilis, Lophohelia, Seriatopora, Amphihelia, Stephanophyllia, Stephanaria, Sphenotrochus, Caryophyllia, Trochocyathus, Bathyactis.*

In *Flabellum* and *Fungia* there are both endosepta and exosepta, but the latter eventually become endosepta on the formation of mesenterial pairs embracing them. The list is incomplete, but it suffices to show that little reliance can be placed on the mere presence or absence of exosepta. On the other hand, I believe that it is of importance to discover in every coral whether the new endosepta are formed in the forked peripheral extremities of the exosepta, or simply by the formation of a new pair of mesenteries in connection with a radial upgrowth.

,, 8. *Balanophyllia socialis*, Semper. Profile view of the corallum.

,, 8A. ,, Diagram of the septal arrangement.

,, 9. *Balanophyllia taprobanæ*, n. sp. Profile view of the corallum, showing the enlarged primary costæ and one of the lateral buds, *b*.

,, 9A. *Balanophyllia taprobanæ*, n. sp. Calice viewed from above. 1, 1, the enlarged primary entocœlic septa. *X.*^{2}, the secondary exocœlic septum of the left-hand lateral system. *X.*^{3}, *X.*^{3}, tertiary exocœlic septa of the same system. *En.*^{2}, secondary entocœlic septum; and *En.*^{3}, tertiary entocœlic septum of the same system.

,, 10. *Lobopsammia robusta*, n. sp. Lateral view of the colony.

,, 10A. ,, ,, Diagram of the septal arrangement. The numerals indicate the cycles of septa.

,, 11. *Dendrophyllia minuscula*, n. sp. Profile view of the colony. × 2.

,, 11A. ,, ,, A calice viewed from above. 1, 1, primary entocœlic septa. *En.*^{2}, secondary entocœlic septum. *X.*^{2}, *X.*^{2}, secondary exocœlic septa (largely magnified).

,, 12. Side view of a primary septum of *Heterocyathus æquicostatus*, showing the septal trabeculæ emerging on the surface as spiniform granulations. *A.c.*, *Aspidosiphon* chamber. *p.*, pali and paliform lobes. *str.*, stereoplasm represented by cross shading. *syn.*, synapticulum.

,, 13. Portion of a horizontal section through the corallum of *Heterocyathus æquicostatus*, showing the diverging trabeculæ of which the septa are composed and the pigmented stereoplasm largely filling up the interseptal loculi. *S.*, *S.*, septa. *str.*, stereoplasm external to, and *str.*^{1}, stereoplasm internal to *syn.*, the synapticula.

,, 14. Section through a band-shaped primary mesenterial filament of *Heterocyathus*, some little way below the lip of the mouth. *c.e.*, ciliated epithelio-muscular cells of the filament. *en.*, endoderm. *mg.*, mesoglœa. Zeiss. Obj. D, Oc. 4.

,, 15. Section through a convoluted mesenterial filament of *Heterocyathus*. *en.*, endoderm. *gl*^{1}., *gl*^{2}., two varieties of gland cells. *n.*, nematocyst. Zeiss. Obj. D, Oc. 4.

Fig. 16. Section through the ectoderm of the body-wall of *Heterocyathus*. *gl.*, gland cells. *mg.*, mesoglœa. *n.*, *n.*, nematocysts. *nv.*, nervous layer. Zeiss. Imm. $\frac{1}{12}$. Comp. Oc. 4.

„ 17. Section through the inner end of one of the canals leading into the *Aspidosiphon* chamber in *Heterocyathus*. *gl.*, gland cells. *n.*, *n.*, ovoid nematocysts with granular contents. Zeiss. Imm. $\frac{1}{12}$. Comp. Oc. 4.

„ 18. A nematocyst 0·06 millim. in length from the convoluted mesenterial filaments of *Heterocyathus*.

„ 19. Endoderm covering the septa of *Heterocyathus* showing *gl.*, glandular looking cells, which may be degenerate nematocysts. An isolated cell is shown to the right of the figure. *zo.*, zooxanthellæ. Zeiss. Imm. $\frac{1}{12}$. Comp. Oc. 4.

„ 20. Endoderm of *Heterocyathus* showing *am.*, amœboid cells full of granules. *cal.*, calicoblasts. Zeiss. Imm. $\frac{1}{12}$. Comp. Oc. 4.

„ 21. Columnar endoderm from the axial gastro-vascular cavity of *Heterocyathus*.

„ 22. Semi-diagrammatic representation of a horizontal section through *Heteropsammia michelini* a little above the stomodæum. The corallum is black. The mesenteries, peristomial, tentacular and external ectoderm are represented by red lines. 1, 2, 3, the several cycles of endosepta. 4, a single endoseptum of the 4th cycle. *D.*, the single pair of directive mesenteries. $t.^1$, $t.^2$, $t.^3$, the several orders of tentacles, introverted and doubled over the endosepta.

„ 23. Ectoderm of the body-wall of *Heteropsammia michelini*. *en.*, endoderm. *gl.*1, goblet-shaped gland cells with granular contents. *gl.*2, flask-shaped gland cell. *mg.*, mesoglœa. $n.^1$, spiral nematocysts. $n.^2$, large nematocyst. *zo.*, zooxanthellæ. Zeiss. Imm. $\frac{1}{12}$. Comp. Oc. 4.

„ 24. Transverse section through a canal leading into the *Aspidosiphon* chamber in *Heteropsammia*. The histological details are indicated diagrammatically. *ec.*, ectoderm lining the canal. *en.c.*, endoderm canals surrounding the central ectodermic canal. *mg.*, mesoglœa. Zeiss D. Oc. 2.

„ 25. Modified ectoderm of the body-wall of *Dendrophyllia gracilis*, showing the thickened walls of the ectodermic epithelium. *mg.*, mesoglœa. n^2, medium sized nematocysts, 0·028 millim. in length n^3, large nematocysts, 0·035 millim. in length. Zeiss. Imm. $\frac{1}{12}$. Comp. Oc. 4.

„ 26. Nematocysts of *D. gracilis*. Zeiss. Imm. $\frac{1}{12}$. Comp. Oc. 4.

„ 26a. A spiral 0·02-millim. tentacular nematocyst, its inner end prolonged into a fine nerve fibril.

„ 26b. Nematocyst from the stomodæum or mesenterial filament.

„ 26c. Developing nematocyst from the external ectoderm (see text).

„ 26d. A ripe nematocyst from the external ectoderm.

„ 26e. The same diagrammatically represented.

„ 27. Four endoderm cells from a mesentery of *D. gracilis*, showing *n*, an endodermic nematocyst. *m.p.*, muscular processes. Zeiss. Imm. $\frac{1}{12}$. Comp. Oc. 4.

REPORT

ON THE

POLYCHÆTA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

ARTHUR WILLEY, F.R.S.,

DIRECTOR OF THE COLOMBO MUSEUM.*

[WITH EIGHT PLATES.]

THIS collection of Polychæta is the most extensive which has been brought together from the coast of Ceylon. There are only three older collections of any magnitude from Ceylon upon which reports have been published, namely, that of SCHMARDA, worked out by the traveller himself and published in 1861 ('Neue Wirbellose Thiere'); a small series gathered by Mr. HOLDSWORTH and described by GRUBE in 1874 ('P. Zool. Soc., London'); lastly, another small series collected by Dr. HANS DRIESCH and described by MICHAELSEN in 1892 ('J. B. Hamb. Anst.,' ix. 2). Of these older collections the most important was the Schmarda collection, which included the discovery of the remarkable genera *Gastrolepidia* and *Bhawania*, the latter not being represented in Professor HERDMAN's collection.

The material was handed over to me at Professor HERDMAN's suggestion by Mr. JAMES HORNELL in September, 1904. A further consignment which had been

* EDITORIAL NOTE.—In order to save delay, I have, with Dr. WILLEY's consent, undertaken to see this Report through the press without sending proofs to Ceylon. I have to thank Mr. ARNOLD WATSON and Mr. CYRIL CROSSLAND, both of whom are familiar with the group, for their kindness in reading the proofs along with me. The only change of any importance we have had to make is the name of the new genus on p. 251. Dr. WILLEY had proposed *Hololepidia*, but we regarded this as being practically the same as MOORE's name *Hololepida* ('Proc. Acad. N.S. Philad.,' 1905) applied to an allied but distinct Polychæte, so we altered the title of WILLEY's genus to *Hololepidella*.—W. A. HERDMAN.

taken to England, consisting mostly, but not entirely, of duplicates of some of the species contained in the first set, was sent out to me by Professor HERDMAN. These had also passed through the hands of Mr. ARNOLD T. WATSON, who kindly forwarded to me such notes and drawings as he had made, some of the latter being reproduced on Plate VIII. A species of *Polydora* which attacks the pearl oyster was subsequently forwarded by Mr. HORNELL.

Some new facts of systematic importance relating to previously described species are recorded here. Among the species described as new are some of considerable interest, *e.g.*, *Autolytus orientalis*, *Branchiomma quadrioculatum*, *Ceratonereis falcaria*, *Grymæa cespitosa*, *Halosydna zeylanica*, *Leprea inversa*, *Paramarphysa orientalis*, *Serpula watsoni*, *Thalenessa stylolepis*.

The occurrence of *Onuphis conchylega* and the recovery of *Harmothoe dictyophora* are also noteworthy features of the collection.

FAMILY: AMPHINOMIDÆ.

Chlœia flava (PALLAS)—Plate I., figs. 1 and 2.

Chlœia ceylonica, GRUBE, 1874, "Ann. Ceylon," 'P. Zool. Soc.,' p. 326.
Chlœia flava (SAV.), GRUBE, 'Ann. Semp.,' 1878, p. 10.

Four rather small specimens from Station LVI., Dutch Modragam Paar, 9 fathoms; average length about 28 millims., with 24 setigerous segments. Another smaller specimen is also in the collection.

Examples of dorsal and ventral bayonet setæ, the former barbed, are shown in Plate I., figs. 1 and 2. The branchiæ commence on the fourth segment; mediad of the violet tinted dorsal cirrus of the first four segments there is an accessory cirrus, that on the fourth segment being very slender. The caruncle of this well-known species is attached to the first two segments, and is produced backwards over the next two; it consists of an upper and lower series of lamellæ, those of each series united together in a zigzag manner by their lower ends; those of the upper series are further united together in couples along the crest of the caruncle.

The Amphinomidæ are not, I believe, as a rule, rapacious Annelids, but swallow sand and small stones, &c. Probably they are preyed upon by the Aphroditidæ, since the small specimen (No. 64) was penetrated by some of the enormously long barbed spines of *Hermione*.

A small worm taken in 24 fathoms, at Station LXIII., west of Periya Paar, seems to be a form of the same species; it is 9 millims. long, 20 segments. The tentaculum impar is nearly as long as the caruncle, and, like the dorsal cirri and the stems of the gills, deep purplish crimson in colour. No colour marks were observed along the back, and the crimson cirri stood out prominently from the midst of the very long and delicate setæ. Branchiæ commence as usual on the fourth segment; accessory dorsal cirrus observed on the first three segments only, as described by GRUBE; the folds of the caruncle are more open, less closely set than in older worms. No barbed setæ were found. Unlike *Hesione ceylonica* (q. v.), young individuals of *Chlœia flava* do not possess the full number of segments characteristic of the adult.

Eurythoe complanata (Pallas).

Several examples of this species, whose distribution coincides with that of coral reefs, were obtained from Aripu Reef and at Galle, ranging in length up to 200 millims. and in breadth up to 17 millims. over the setæ. Branchiæ commence on the second setigerous segment and there is one dorsal cirrus to each parapodium. The caruncle is inserted into the first three setigerous segments.

Eurythoe latissima (Schmarda, *op. cit.*, p. 141) is a synonym of this species.

Eurythoe longicirra (Schmarda).

(See Schmarda, 'Neue Wirbellose Thiere,' ii., 1861, p. 142.)

Whether or not this is an exceptional form of *E. complanata* I am unable to decide, but it is certain that the caruncle is inserted upon the first four setigerous segments and overlaps the fifth.* The branchiæ commence on the second setigerous segment, and there is one dorsal cirrus to each parapodium.

Length 40 millims., width 5·5 millims. One specimen, from Aripu Reef.

Family: APHRODITIDÆ.

Hermione malleata, Grube—Plate I., figs. 3 and 4.

Hermione malleata, Grube, 'Ann. Semp.,' 1878, p. 17.
Hermione ridgewayi, Hornell, 'Ceylon Pearl Oyst. Rep.,' Part I., 1903, pp. 16 and 74.

Two specimens from old Dutch Modragam Paar, 9 fathoms, Station LVI.; one specimen from Aripu Reef, 18th March, 1902.

The malleiform processes described by Grube are clearly not definite morphological structures, but merely dermal folds associated with the elytrophores and branchial tubercles, the latter being transversely elongate.

This species is the Oriental form representing the Mediterranean species *Hermione hystrix*. I have satisfied myself on this point by actual comparison of the material from Ceylon with specimens of *H. hystrix* procured from the Stazione Zoologica at Naples for the special purpose of this investigation. The only serious divergence in Grube's description relates to the palps, which he describes as being smooth. His specimen only measured 16 millims. in length, and the palps, when examined under low magnification by transmitted light, appear smooth, though in reality they are beset with minute papillæ. The Neapolitan specimens of *H. hystrix* are larger and darker than the Ceylon worms; the elytra thicker and more opaque.

A complete Ceylon worm measures 30 millims. long by a width of 12 millims. over

* For further remarks on this point see Ehlers, 'Florida-Anneliden,' 1887, p. 30.

the neuropodia; fifteen pairs of elytra covering the back; length of dorsal glochideal spines up to 10 millims. (Plate I., fig. 3). Eye-peduncles rounded. Cirrophores and neuropodia thickly covered with minute rounded papillæ; neuropodia 3 millims. long. Ventral surface beset with similar papillæ. Tentaculum impar, tentacular cirri, dorsal cirri and first ventral cirrus with distal clavate tip articulated to the main shaft, which is expanded at this point. Palps 13 millims long, beset with six longitudinal rows of minute spiniform papillæ. The elytral segments carry on each side a flabellum of curved smooth-tipped setæ radiating dorsad and a backwardly directed fascicle of long brown glochideal setæ; below the dorsal setæ there is a tuft of fine silken threads. The neuropodia carry furcate setæ with or without an accessory tooth (Plate I., fig. 4). The portion of the notopodium from which the flabellum arises is adnate to the elytrophore.

Pontogenia indica, Grube—Plate I., fig. 5.

Grube, 'Ann. Semp.,' 1878, p. 18; Herdman, "*Palmyra aurifera,*" 'Ceylon Pearl Oyster Report,' Part I., Narrative, 1903, p. 75.

The close resemblance between *Pontogenia indica* and *Palmyra aurifera* (see Grube, *op. cit.*, pp. 13–14) is one of the remarkable facts of Polychæt taxonomy.

The specimen was obtained from a living coral block in 6½ fathoms, one mile north of Muttuvaratu Paar, Station LIX. It measures 20 millims. in length and has 45 segments. The head is retracted within the anterior segments and beneath the anterior elytra, the second pair of elytra overlapping the ommatophores. The ceratophore is marked off from the frontal border of the prostomium and the ommatophores extend to this level. The palps are beset with longitudinal rows of delicate recurved papillæ. By pressing the ceratophore back a tuberculum faciale with granulated surface may be seen extending from the prostomium to the anterior border of the mouth. Each ommatophore carries two eyes, but as the pigmented areas overlap there appears to be only one eye in certain lights (Plate I., fig. 5). The paleæ which form flabella projecting over the elytra are utrinquedentate, as described by Grube. The dorsal setæ which occur in addition to the paleæ are long, delicate, colourless and numerous, and constitute a tela tomentosa over the elytra, concealing the latter, but not felted together so as to form an inextricable tangle. The two rows of distantly placed denticulations with their points directed towards the apices of the paleæ are not always visible in one view, and the paleæ then appear to be denticulate along one side only.

Family: POLYNOIDÆ.

Iphione muricata, Savigny—Plate I., fig. 6.

Polynoe peronea, Schmarda, 1861; 'Neue Wirbellose Thiere,' ii., p. 157.

Locality:—Gulf of Manaar. One specimen of the typical yellowish brown colour; length 17·5 millims., breadth over the setæ 8·5 millims. The head is withdrawn between the anterior segments to such an extent that four pairs of elytra had to be removed in order to expose it (Plate I., fig. 6). The antennæ converge from the anterior pinnacles of the head towards the middle line, and then run side by side close together; one of them may sink down at a lower level, and then one only remains in view. They are subglabrous, being very sparsely and minutely papillose. SCHMARDA observed one antenna only, which he described as a tentaculum impar erroneously. There is no doubt as to the identification of the present specimen with SCHMARDA's species; the only question is whether it is co-specific with SAVIGNY's *I. muricata* (GRUBE, 'Ann. Semp.,' 1878, p. 21).

An elytron from the mid-body shows a concave anterior border, a large gold-coloured outer surface and a smaller pale inner portion directed obliquely forwards and overlapped by neighbouring scales. The whole surface of the elytron is divided up into polygonal, mostly hexagonal areas, and these again into numerous secondary areoles. The main areolation resembles that of *Harmothoe dictyophora*, but differs in some details; the areas are largest on the inner (mesial) portion of the scale, smaller along the outer and posterior borders; the secondary areolation is highly characteristic and was noted by SCHMARDA. Focussing through the superficial secondary areolation, another reticulum, which may be called the interstitial reticulum, comes into view, the meshes of which do not coincide with the former. The interstitial mesh-work shows nodal dilatations with a refringent body in each, like a nucleus, very clear in caustic potash. Proceeding to the pigmented portion of the scale, the surface enclosed by the secondary areoles becomes elevated to form low papillæ, which, near the outer border, assume the form of inclined spines. Posteriorly, certain of the primary areas become elevated to form long stout aculeate spines terminating distally in a pair of prominent horns and covered by numerous secondary spines, as figured by SCHMARDA. The secondary spines become larger distally, so that the main spine sometimes presents a more or less trifid appearance at the summit. The dorsal setæ are excessively numerous and bipinnate. The ventral setæ show a well-marked subterminal dilatation, a verticillate tract, and a smooth curved apical portion.

As for *Iphione muricata*, GRUBE makes no mention of the secondary areolation of the elytra, a highly remarkable feature; and he states that the outer and posterior margin of the scale is fimbriated, which is not so in *I. peronea*. Across the major diameter of the scale I counted about 30 primary meshes, and across one of the latter about nine sharply defined secondary areoles. There are 29 segments, 13 pairs of elytra. The anus is dorsal and is bordered by the last pair of elytra. SCHMARDA says the last segment has "zwei kleine Endfortsätze," but I cannot see them. The dorsal and ventral cirri, the palps and tentacular cirri are papillose. The tentacular cirri are concealed below the palps in dorsal view.

A smaller specimen, 5 millims. wide, shows a wide membranous fringe round the outer and posterior border, not yet areolated; there are no fimbriæ; about 17 primary meshes across the scale. The antennæ adhered together and broke away from their peduncles.

Lepidonotus carinulatus, Grube (1869)—Plate I., figs. 7 to 11.

(See Grube, 'Ann. Semp.,' 1887, p. 26.)

Localities:—South-west Cheval Paar, one specimen, broken in half, and several specimens mostly fragmentary; Chilaw Paar, Station LXIX., one specimen.

The antennæ and dorsal cirri show a very slight distal dilatation followed by a flagelliform terminal process. The cirri and palps are smooth; dorsal setæ more slender than ventral, 20 to 30 in number, disposed in three concentric arcs, the setæ of the dorsal arc being shorter than the rest. Ventral setæ about 25, bidentate and fringed (Plate I., fig. 11).

Elytral papillæ carinulate and spheroidal on the surface, echinulate and stellate near the fimbriated border; in some elytra the echinulate papillæ extend over the surface to the region of the scar. Elytra deciduous and body fragile; twelve pairs of elytra. Exserted pharynx with fringe of nine dorsal and nine ventral marginal papillæ. Some elytra become narrower towards the inner side than at the outer side, others are nearly equally wide throughout, with concave anterior border. Patches of dark brown pigment are scattered over the surface. The fimbriæ of the outer border are densely placed, those at the posterior border are sparser. Some scales are much less papillose than others; in a highly tuberculate scale the carinulate papillæ occupy the anterior and inner (mesial) portions; the echinulate papillæ occur at the posterior border, extending thence over the scar, this region being somewhat elevated; the echinulate papillæ near the outer border are smaller and less hirsute than those of the posterior border, sometimes presenting a more or less stellate appearance (Plate I., fig. 10). The prostomium (cephalic lobes) with eyes and antennary bases (ceratophores) is shown on Plate I., fig. 7.

Observations on a larger specimen, in which some of the elytra were better preserved in position, show that the dominant macroscopic character of the species lies in the difference between the elytra of the anterior region and those of the middle and posterior regions. The anterior scales (only those of the fourth and fifth segments are present in the specimen) are much smaller than the rest, they are placed subtransversely and their surface appears verrucose under low magnification. The more posterior scales show a finely granulose surface, they are about twice the size of the anterior scales (excluding the scales of the first pair, which are generally small and round, and are absent from this specimen), and they are longitudinally elongate, the anterior end narrower. All scales show a large opaque whitish patch in the region of the scar, and all are fimbriated externally. The length of the specimen is 17 millims.; total width over the setæ 5 millims. Along the posterior border of the elytra there are small saucer-shaped elevations which appear to be the bases of deciduous fimbriæ.

Microscopic examination shows that the verrucose appearance of the anterior scales is due to the presence of large numbers of spheroidal echinulate papillæ (Plate I., fig. 9). These papillæ do not occur on the posterior scales, which owe their granulose appearance to the ordinary carinulate papillæ (Plate I., fig. 8), small stellate papillæ and smooth globoidal papillæ.

The elytra of this species show an analogy with those of Marenzeller's *Lepidonotus pleiolepis* from Japan, which, however, possesses fifteen pairs instead of the usual twelve pairs. Some individuals show a narrow black ring round the lower part of the subterminal dilatation of the dorsal cirri. In a specimen with extruded proboscis the outline of the prostomium was nearly circular.

This species appears to be the most abundant and typical representative of the genus *Lepidonotus* on the Ceylon pearl banks.

Lepidonotus cristatus, Grube.

Grube, 'Ann. Semp.,' 1878, p. 27; Gravier, 'Ann. Mer Rouge,' 1901, p. 212.

A fine example of this species, 43·5 millims. in length, 17 millims. wide over the setæ, was taken on the Galle Reef under a boulder, 7th June, 1902.

The smooth-bordered elytra show a large tumid bilobed transverse crest. The ventral setæ have the usual laciniate fringes on the region of the subterminal dilatation and end in a smooth curved tip. The distal portions of the antennæ, tentacular cirri, dorsal cirri and first ventral cirrus, up to the subterminal bulb, are coloured black.

Gravier describes for the first time the modified ventral setæ of the second segment, which are characterised by the possession of a very long verticillate tract.

Lepidonotus trissochætus, Grube.

Grube, 'Ann. Roth. Meer.' (Ehrenberg coll.), 1869; 'Ann. Semp.,' 1878, p. 25.

Locality:—South-east Cheval Paar. Length of the specimen 12 millims., breadth over the setæ 5 millims.

This species is distinguished by the possession of two kinds of setæ in the dorsal ramus of the parapodium, and these setæ are very numerous. There are rather short, stout, transversely spinulose setæ of a common type, and enclosed by these are numerous fine smooth capillary setæ ending in a point, a short distance below which there is a delicate dilatation, as in a spear-head without barbs; these may be called hastate setæ. In the anterior half of the body the hastate setæ do not project beyond the spinulose setæ which surround them, and cannot therefore be seen without adopting special measures. In the posterior half the hastate setæ project far beyond the short spinulose setæ, which occur like a sheath at the base of the bundle; they project here as far outwards as the ventral setæ. The resulting difference between the anterior and posterior dorsal fascicles as seen under low magnification is very pronounced. It is, however, probably due to a temporary protrusion of the setæ, but it may serve to account for the alleged difference between *L. trissochætus*, GR., and *L. indicus*, KINBERG. The hastate setæ can clearly be retracted and protruded at will. In one segment they are projecting on one side, retracted on the other. The elytra are sparsely covered with smooth obtuse pustules of varying sizes, the smaller and more numerous occupying a submarginal position. The margin of the elytron is quite smooth.

As indicated by GRUBE in 1869, this species presents a cryptocephalous condition, as in the later described species *L. cryptocephalus*, the head being concealed below a projecting collar formed by the second segment. The dorsal cirri are smooth, with a terminal flagellum and a subterminal swelling. The palps are beset with conical papillæ, and terminate in a smooth attenuate extremity (seen in one of the palps only). The ventral setæ have simple hamulate extremities (not bidentate) with the usual subterminal fringes.

Halosydna zeylanica, n. sp.—Plate I., figs. 12 and 13.

Total length about 15 millims., width 2 millims. to 2·5 millims. Commensal on Astropecten, Ceylon seas.

Body much flattened, extremely fragile, elytra smooth, colourless, covering the dorsum, leaving parapodia exposed, lightly attached to the elytrophores. The prostomium is divided by a shallow linear groove into two halves, upon which no eyes were observed, and the bases of antennæ and tentaculum are somewhat concealed below the frontal border of the head, though arising at one level, as seen in frontal view. The number of segments may be as many as 50, but this will depend upon age and variation, and the same applies to the number of the elytra, the highest number observed being 24 pairs.

The chief character is presented by the distribution of the elytra on the following segments :—II., IV., V., VII., IX., XI., XIII., XV., XVII., XIX., XXI., XXIII., XXVI., XXIX., XXXII., XXXIII., XXXV., XXXVII., XXXIX., XLI., XLIII., XLV., XLVII., XLIX. The peculiarity here is the occurrence of successive elytra on segments XXXII. and XXXIII., a point which I have verified on three specimens. In the specimen of which the elytral formula is given above, the elytra were lost from a number of the posterior segments but present on No. XLIX.

The dorsal ramus of the parapodium is very small, and the setæ which issue from it are few in number, plain and hyaline. Foreign particles adhere to all the setæ individually throughout their exposed portions. The ventral setæ have the form shown in Plate I., fig. 13, a plain apex slightly curved, and at some distance removed from it a dilatation with a projecting semilunar cusp. The number of ventral setæ varies, but is about 12.

The ventral cirri are shorter than the ventral ramus, arising from a prominent base. The dorsal cirri are plain structures occurring on the segmenta nuda, arising from a projecting base which lies obliquely outwards and backwards when seen from above. The dorsal cirri are highly deciduous. They exceed the length of the parapodium (Plate I., fig. 12). The dorsal ramus and elytrophore of a foot from an elytra-bearing segment appear to carry long vibratile cilia. No tubercles were observed on the segmenta nuda. The ventral ramus is richly furnished with decussating muscles. The elytra are orbicular, glabrous, with few "veins" ramifying out from the scar.

Harmothoe dictyophora (Grube)—Plate I., figs. 14 to 16.

Polynoe dictyophorus, Grube, 'Ann. Semp.,' 1878, p. 44.

Locality:—East side of Cheval Paar. Length 12 millims., breadth over the setæ 4·75 millims.

Prostomium normal, anterior eyes placed in the centre of the lateral border (Plate I., fig. 15). Antennæ ciliate; palps beset with numerous minute blunt papillæ; dorsal cirri densely ciliate, the long filiform papillæ ceasing at the base of the terminal filament; no dilatation below the terminal filament. Dorsal setæ numerous, verticillate spinulose, but the whorls are not complete, only occupying three parts of the circumference of the setæ; the shorter setæ of the dorsal bundle are distinctly stouter than the ventral setæ; ventral setæ without exception conspicuously bidentate, dilated at a point variously remote from the apex and spinulose thereafter (Plate I., fig. 16). The spinulose tract of the superior ventral setæ is much longer than that of the inferior.

Thirty-five segments; fifteen pairs of elytra covering the back. Exposed portions of the elytra divided into polygonal areoles carrying chitinous spines and filiform papillæ; some of the areoles are densely pigmented dark brown. Some of the spines are bifurcated, such spines being particularly prominent on the round elytra of the first pair. The outer fimbriæ of the elytra are longest and densest, these are followed posteriorly by a group of papillæ with globular tips, and these again by shorter filiform papillæ (Plate I., fig. 14). It should be noted further that the ventral cirri also carry short blunt papillæ, scattered and not very numerous.

Grube founded the species upon a single elytron.

Hololepidella, n. gen.

A Polynoid; antennæ arising at a lower level than the tentaculum impar; segments and elytra numerous.

Hololepidella commensalis, n. sp.—Plate I., figs. 17 to 20.

Station I., off Negombo, 12 to 20 fathoms, on *Clypeaster humilis*.

This species appears to be allied to *Polynoe venosa*, Grube ('Ann. Semp.,' p. 43), in which however there were only 18 pairs of elytra and 42 segments in the single individual examined. The number 18 is a generic character of *Acanthicolepis*, McInt. (= *Dasylepis*, Mgn.), but it seems likely, though not certain, that a polymeric Polynoid with more than 18 pairs of elytra will pass through a stage with 18 only. At any rate, *Polynoe venosa*, Gr., does not belong to the genus *Acanthicolepis*.

Those polymeric Polynoidæ in which the paired antennæ arise at a lower level than the tentaculum impar appear to be inadequately classified. Malmgren's genera *Nemidia* and *Enipo* are at most only sub-genera of Schmarda's *Hemilepidia*.

All Polynoidæ (*s. str.*) in which the antennæ arise at a lower level than the tentaculum are placed in the sub-family Harmothoina. The genus *Polynoe* (*s. str.*) is polymeric, having more than 45 segments in the fully formed condition. It comprises two sections:—(1.) *Hemilepidia*, Schmarda, in which there are 15 pairs of elytra restricted to the anterior region of the body. This section comprises the following species:—*Polynoe scolopendrina*, *Hemilepidia erythrotænia*, *Nemidia torelli*, and *Enipo kinbergi*. (2.) *Hololepidella*, *n.g.*, in which the elytra are not so restricted. Very possibly Grube's *Polynoe venosa* belongs here in spite of its few segments. The species now described also belongs to this section.

In *Hololepidella commensalis* the small antennæ clearly arise at a lower level than the tentaculum (Plate I., fig. 20). The elytra are pale, delicate, translucent, smooth, large, orbicular, covering the back; the first pair with central insertion, the others with excentric insertion near the anterior margin becoming submarginal in the posterior region; there is an indication of nervures radiating out from the scar of insertion, as in *P. venosa*. The elytra are inserted upon segments II., IV., V., VII., IX. * * * * * XXI., XXIII., XXVI., XXIX., XXXI., XXXIV., XXXVI., XXXVIII., XL., XLII., XLV.; segment XLIV. has an elytrophore on the left side, a branchial tubercle and cirrophore on the right side. There are 46 segments present, incomplete behind; in a fragment of the posterior end the alternation of cirrophores and elytrophores, the former sometimes skipping one segment, sometimes two, seems to be continued to the end of the body, but it is not always easy in this region to distinguish between a cirrophore and an elytrophore.

Head hexagonal; ground colour of body nearly black (becoming brown after a length of time in spirit) with a pale ridge across each segment between elytrophores and branchial tubercles respectively. Palps, antennæ, tentacle and cirri smooth; first ventral cirrus long, the rest short, with swollen basal portion and terminal flagellum. Dorsal cirri dark brown, tapering to a pale blunt point which may be slightly swollen, but without subterminal dilatation. The setæ are pale; dorsal setæ, about 8, broad parce-serrulate, much shorter than the ventral setæ; superior ventral setæ obliquely laciniate towards apex, giving the appearance of alternate serrulations, inferior ventral setæ with subterminal dilatation, curved simple tip and normal fringes (Plate I., figs. 17 to 19).

This species is one of those which easily undergo fragmentation, so that the length cannot be given; the width is 2 millims.

Gastrolepidia clavigera, SCHMARDA.

(SCHMARDA, 1861, 'Neue Wirbellose Thiere,' ii., p. 159.)
Gastrolepidia amblyphyllus, GRUBE, 'Ann. Semp.,' 1878, p. 46.
Gastrolepidia clavigera, HERDMAN, 'Ceylon Pearl Oyster Report,' Part I., 1903, pp. 29, 79.

Localities:—Station XVIII., off Rameswaram, 7 to 8 fathoms; Station LXI., off Periya Paar, 12 to 14 fathoms.

The lateral portions of the sterna of the segments are produced into conspicuous imbricating lamellæ, arching below the bases of the parapodia. They are semilunar folds, but if a segment is detached from the body and looked at from behind, they appear to be subcordate, as figured by SCHMARDA. The dorsal elytra are inserted upon segments II., IV., V., VII. * * * * * * * XXIII., XXVI., XXIX., XXXII., XXXV., XXXVI., XXXVIII., XXXIX., XLI., XLIII., XLV., this enumeration being based upon one specimen from which all the elytra had fallen off; the other specimens were smaller and showed fewer elytrophores, so that the peculiar distribution of the posterior elytra could not be confirmed. Dorsal setæ curved, stout, shorter than the ventral setæ, with as many as forty serrulations along the convex border; superior ventral setæ with not less than fifteen laciniate fringes; inferior ventral setæ stronger than the rest, with curved simple tips, subterminal dilatations and about eight fringes. The antennæ are inserted at a slightly lower level than the tentaculum. Dorsal cirri clavate, mostly lost. Beyond the club there is a terminal flagellum shown by GRUBE, omitted by SCHMARDA.

FAMILY: ACOËTIDÆ.

Panthalis, KINBERG.

This is a genus of Acoëtidæ characterised by the reversed imbrication of the anterior scales.

The family to which it belongs agrees with the Aphroditidæ (*s.str.*) in having pedunculate eyes; with the Sigalionidæ in the polymeric body; with Polynoidæ in having only setæ simplices; with Iphionidæ in having serrated jaws. It is clearly a family of composite affinities and its members possess an extraordinary interest, regarded from bionomical and anatomical points of view. They manufacture a felted tube woven from chitinous silken fibres which appear to be homologous with the fibres composing the dorsal felt of *Aphrodite*, that is to say, modified setæ which issue from the dorsal ramus of the parapodium and are contained within a convoluted sac intruding into the body cavity. The tube-forming habits of *Panthalis œrstedi* have been admirably described by Mr. ARNOLD T. WATSON in the 'Transactions of the Liverpool Biological Society,' vol. ix., 1895, pp. 169 to 188.

Two species of *Panthalis* were described by GRUBE from the Philippines, and very fortunately both of these are represented in Professor HERDMAN'S material from Ceylon, so that I am able to supplement GRUBE'S diagnoses with additional facts and figures.

Panthalis melanonotus, Grube—Plate I., figs. 21 to 27.

Grube, 'Ann. Semp.,' 1878, p. 48; also Part I., 'Ceylon Pearl Oyster Report,' p. 71.

Locality:—Station LIV., south of Rameswaram, 40 fathoms. One specimen.

A typical cirrus-bearing parapodium from the anterior region has the following structure:—(i.) A short dorsal cirrus consisting of a stout basal portion and an acuminate apical portion; (ii.) the dorsal ramus supported by a flexible acicula and penetrated by the tomentose setæ which are employed in weaving the tube; (iii.) the ventral ramus with four kinds of setæ, dorsally a small bundle of very fine serrulate setæ, then a bundle of long delicate penicillate setæ, then a central group of stout so-called aristate setæ; lastly, a ventral bundle of long spinulose setæ (Plate II., figs. 24 to 27). At the tip of the aristate setæ there is an alveolus. From the 28th segment the peduncle upon which the dorsal cirrus is inserted acquires a geniculate appendix, containing a prolongation of the internal tissues, possibly a diverticulum of the gut, but of this I cannot be certain without transverse sections. A few segments farther back an ovate or subcylindrical appendix appears on the squamiferous segments, in the same position as that occupied by the cirriform branchia of the Sigalionidæ, also containing the same kind of tissue as that which occurs in the geniculate process above described. The surface of these processes is not ciliated (Plate I., figs. 22 and 23).

Panthalis melanonotus appears to be an Indo-Pacific representative of the Mediterranean and Atlantic *P. œrstedi*. The accounts given of the eyes of the latter are rather puzzling. Von Marenzeller* denies the existence of eyes, although the ocular peduncles are present. Mr. Watson, in the article referred to above, has omitted to note the presence or absence of black pigment,† stating that the sight of the animal is good, each reddish-coloured eyestalk being faced with a clear lens, and having at its tip a rounded papillated appearance.

In *Panthalis melanonotus* the stalked eyes are very large and provided with abundant black pigment, in the centre of which is a lens; the eyes are subspherical, occupying the extremity of the clavate peduncles. In addition there is, as described by Grube, an eye-spot on each side of the prostomium behind the ocular peduncle; between and slightly behind the sessile eye-spots the median tentacle arises. The antennæ are small and largely concealed by the eye-stalks and were not seen by Grube (Plate I., fig. 21).

The extruded pharynx bears distally thirteen papillæ above and the same number below, forming a terminal crown; the median dorsal papilla is enlarged and the median ventral is lost from the specimen. The palps show pigment spots and appear glabrous with a simple lens, although minute papillæ can be found with the microscope, especially towards the apex, but there is no marked distinction between apical and

* V. Marenzeller, 'Polychæten des Grundes,' Vienna, 1893, p. 28.

† Mr. Watson informs me that no black pigment is visible in the eyes of the specimens of *P. œrstedi* now in his possession.—W. A. Herdman.

basal portions, such as occurs in the next species. The body is incomplete behind, upwards of fifty segments being preserved; total width of anterior region 6 millims. The specimen is well preserved.

Panthalis nigromaculata, Grube—Plate I., figs. 28 to 32.

(Grube, 'Ann. Semp.,' 1878, p. 50.)

Locality:—Station II., North of Negombo, 9 fathoms. One specimen.

Antennæ arising from the frontal margin of the prostomium; the tentaculum impar of about the same length, from the occipital margin. Only one pair of eyes observed on the slightly protuberant lateral borders. Palps short and stout, the anterior half densely fimbriate. Dorsal cirri short, ventral cirri subarticulate at tip. Each foot (after the first few pairs) is provided with a silk-producing gland which is apt to remain in the body after the extraction of the parapodium, the silken strands being drawn through the orifice of the notopodium.

The anterior elytra are inversely imbricate, inserted upon the elytrophores near the posterior border; the third elytra touch in the middle line behind the head (Plate I., figs. 28 to 31). The elytra were observed on segments II., IV., V., VII. and all subsequent odd segments up to XXXI., after which the body was quite flaccid and collapsed, full of the gold-coloured glistening silken coils and firmly attached to the tube at the posterior end.

The anterior portion of the tube was mostly free from the body of the worm, though slightly connected therewith by loose silken strands. The elytra are subtranslucent, colourless. The extruded proboscis carries a crown of marginal papillæ, eleven above, thirteen below; the median dorsal papilla is barely larger than the others. The setæ differ from those of *P. melanonotus* considerably. The dorsal group of setæ in the ventral ramus consists of small spinulose setæ, the spinules arranged in three remote whorls, below which the seta is slightly dilated; next a few fringed setæ; then the strong aristate setæ in two groups above and below the acicula; finally the ventral group of spinose setæ (Plate I., fig. 32). There are no penicillate setæ.

Length of anterior portion, including the proboscis, 13 millims.; width about 3 millims. Length of the posterior flaccid portion about 13 millims.

Family: SIGALIONIDÆ.

Psammolyce zeylanica, n. sp.—Plates I. and II., figs. 33 to 43.

Locality:—Ceylon Seas. One specimen, incomplete.

A fragment comprising about thirty setigerous segments, length 17 millims., body width 5 millims., 8 millims. over the setæ. The dorsum is completely encrusted with fine particles, chiefly calcareous débris, leaving the setæ exposed at the sides. The elytra are thin, transparent and triangular, the base of the triangle directed forwards. The basal area is clear, but the hinder area bears a luxurious growth of club-shaped and capitate papillæ to which the foreign particles adhere. The anterior pair of elytra probably meet or overlap, but in general the elytra are confined to the sides of the body, leaving the mid-dorsum free. Nevertheless the latter is covered with sand grains which adhere to dermal capitate papillæ (Plate I., fig. 33).

The prostomium, carrying two pairs of eyes, is overshadowed by the massive ceratophore. There are no paired antennæ on the prostomium, these having become adnate to the cirrophores of the buccal segment which carry the tentacular cirri and bundles of plumose setæ (Plate I., fig. 34). The lower side of the ceratophore carries a pair of dermal folds or lobes, which project from the sides below and inwards. The ventral surface is not encrusted, but is thickly beset in each segment with transverse rows of not very long acuminate papillæ which are continued upon the ventral surface of the parapodia. The ventral middle line is depressed. Amongst the bases of the acuminate papillæ are scattered minute globular papillæ reminding of those present in *Hermione*. The cirrophores (appendages of buccal segment) lie between the palps and the head, so that it is difficult to remove a cirrophore without the palp of the same side; the palps are glabrous.

The simple plumose setæ of the buccal segment have been mentioned above. In the second segment in addition to the plumose setæ there are compound setæ of the form represented in Plate II., fig. 36, with filiform apex of the appendix, the shaft being plumose. The ventral cirrus of the second segment is stout and long, nearly twice as long as the parapodium, and arises from a distinct basal joint. In the third segment compound setæ of more usual form appear, the shafts being stout and smooth except towards the extremity where they are squamose (Plate II., fig. 37); the appendices are lost. The dorsal cirrus of this segment has the articulated structure shown in Plate II., fig. 35. In the fourth segment the shafts of the compound setæ are still squamose distally; the appendix is elongated, curved at apex with a slight truncation jutting out below the apex. In a parapodium of a normal body-segment (anterior third of body) there is a dense dorsal fascicle of finely plumose capillary setæ, followed by a superior ventral group of moderately stout compound falcigerous setæ with subelongate appendices; then a central group of stout compound setæ with shorter appendices; finally an inferior ventral group of slender setæ with elongate appendices (Plate II., figs. 38 and 39). Sometimes the apex of the appendix is clearly bidentate, varying from this condition to smooth (Plate II., fig. 40). The ventral border of the parapodium is beset with acuminate filiform papillæ and some spheroidal papillæ (Plate II., fig. 41). The elytra are notched and lobed, especially at the inner border (Plate II., fig. 42).

Psammolyce rigida, GRUBE—Plate II., figs. 44 to 47.

GRUBE, 1868, 'Ann. Roth. Meer.' (Frauenfeld); 'Verh. zool.-botan. Ges. Wien,' p. 631, 1878; 'Ann. Semp.' (Philippines), p. 55.

Locality:—Station LIII., 10 miles north of West Cheval Paar. Three specimens, one complete, 115 millims. long, tapering gradually behind; 8 millims. wide over the setæ.

This species has the same general appearance as the *Psammolyce arenosa* of the Mediterranean. It is probably distinct in minor points, though I cannot specify what these points are without comparing actual specimens.

It differs from the preceding species in the following superficial respects:—

Ps. zeylanica.	*Ps. rigida.*
1. Colour fuscous.	Colour fulvous.
2. Calcareous grains predominate.	Quartz grains predominate.
3. Venter beset with capillary papillæ, *i.e.*, Venter hairy.	Venter beset with globular papillæ, *i.e.*, Venter tuberous.
4. Terminal portion of dorsal cirrus of third segment slenderer and shorter than its peduncle.	Terminal portion of same cirrus tapering and longer than its peduncle.

The parapodial armature of the two species shows such close correspondence that the slight differences which are observable could easily be attributed to individual variation, but the differences noted above under Nos. 3 and 4 would seem to preclude the possibility of regarding them as co-specific. Unfortunately I have no information as to the precise locality of the *Psammolyce zeylanica*. In Professor HERDMAN'S 'Narrative' of his expedition, *Psammolyce* is recorded from two stations, LII. and LIII. The latter is that from which the present species was dredged in 7½ to 9 fathoms, "bottom muddy sand with some dead shells;" the former station may be the locality of the other species, "between north of Cheval Paar and Vankali reef; depth 3 to 6 fathoms; bottom sand."

The difference noted above in respect of the adventitious coating of sand-grains is only of local significance as indicating a difference of habitat. The tuberculation of the ventral surface of the body is the most obvious character of this species. The low rounded dermal tubercles are placed close together without reference to segmental limits and not in rows, forming an even, elastic sole on each side of the depressed neural tract. The dermal tubercles are continued upon the parapodia, especially in the posterior two-thirds of the body, where they are thickly covered. Besides these spheroidal dermal tubercles there are tufts of filiform papillæ like those shown on Plate II., fig. 41. These occur on the base and summit of the parapodia, at the base of the ventral cirrus, and there is a ventro-lateral tuft on each segment between the tubercular tract and the parapodia.

Other substantial differences between the two species are shown in the figures. The elytra are formed upon the same model in both, and they are not safe objects for comparison, since they vary from segment to segment. Those of *Ps. rigida* have a concave anterior border, those of *Ps. zeylanica* are straight. The scar of insertion is short in the former, elongated in the latter (Plate II., fig. 46). The setæ of the second segment have a shorter appendix (Plate II., fig. 47). An important difference appears in the stout setæ from the centre of the ventral fascicle. In Plate II., figs. 43 and 44, two of these setæ, one from the right sixteenth foot of each species, are shown side by side. In *Ps. zeylanica* the declivity of the articular surface of the shaft is greater, and below the apex of the shaft there is a very distinct semilunar cusp which is not present in the seta of the same order in *Ps. rigida*. The other setæ show close correspondence, and here, as there, some of them are distinctly bidentate, but the difference noted appears to be constant.

Sthenelais zeylanica, n. sp.—Plate II., fig. 48.

A fragment with extruded proboscis, 15 millims. long, 5 millims. wide, in company with *Hyalinœcia camiguina*, was dredged off Foul Point, Trincomalee, Station XXV., 8 fathoms.

This species is closely allied to *Sthenelais boa*, but differs in several well-marked points. The prostomium carries four eyes in front, two on either side of the stout ceratophore with its aliform lobes (characteristic of the genus); the tentaculum impar borne upon the ceratophore is not very long, about as long as the ceratophore and the prostomium together; the palps are long, nearly as long as the extruded proboscis. The free margin of the latter carries both dorsally and ventrally a row of eleven evenly disposed papillæ.

The scales are carried on the usual segments II., IV., V., VII., IX. * * * * * * * * XXVII., XXVIII., XXIX., &c., becoming consecutive at segment XXVII. In the condition of extruded proboscis the dorsum of the third segment hardly shows, and the first two scales appear to occur on consecutive segments until they are pressed apart. The general character of the scales (their pronounced reniform shape, the tuberculation of the surface and the fimbriation of the margin) resembles that described and figured by Professor McIntosh for *Sthenelais boa* ('Ray Soc. Mon.,' 1900); the fimbriæ of the outer margin are acuminate, others which occur on the posterior margin are blunt; the tubercles are thickly scattered over the whole surface except near the anterior border of the inner lobe and near the corresponding border of the outer lobe; brownish pigment occurs all over the exposed portion of the scale.

The characters upon which I rely for specific differentiation are presented by the parapodia of the body-segments. In *Sthenelais boa* there are four principal groups of setæ, the dorsal plumose capillary setæ, the superior ventral plumose spiniform setæ, the mid-ventral compound bidentate falcigerous setæ, and the inferior ventral compound setæ with articulate bidentate appendix (*cf.* McIntosh, *op. cit.*, 1900). In *Sth. zeylanica* instead of the group of superior ventral spiniform setæ we have, composing this group, a few of the same kind of slender compound setæ with articulate appendix as occur in the inferior ventral group, and the spiniform setæ are not represented in the ventral ramus of the parapodium. The setæ themselves are not sensibly different from those of the corresponding forms in *Sth. boa* (Plate II., fig. 48). The ciliated cushions or ctenidia (McIntosh) on the upper surface of the foot beneath the cirriform branchia are the same as in *Sth. boa*, but the disposition of stylodes is different, particularly as regards the two long stylodes which proceed from the base of the ventral cirrus in *Sth. zeylanica* (Plate II., fig. 48).

Sthenolepis, n. gen.

The genera *Thalenessa* and *Leanira* are characterised by the presence of a very small tentaculum impar inserted directly upon the prostomium, not borne upon a ceratophore. The compound setæ of *Thalenessa* are a variety of the falcigerous type with bidentate appendices; those of *Leanira* are spinigerous.

Sthenelais and *Sthenolepis*, n. gen., are characterised by the presence of a long tentaculum impar borne upon a ceratophore which is provided with a pair of spatulate appendages. The compound setæ of *Sthenelais* are falcigerous like those of *Thalenessa;* those of *Sthenolepis* are spinigerous as in *Leanira*.

All the species of *Leanira* described by Professor McIntosh in the "Challenger" collection are to be ranged in the genus *Sthenolepis*. In this genus the scales are generally smooth.

Sthenolepis japonica (McIntosh)—Plate II., fig. 49.

Leanira japonica, McIntosh, '"Challenger" Polychæta,' 1885, p. 154.

A headless posterior fragment of a Sigalionid worm, labelled "*Leanira* sp.," was dredged at Station XXXV., off Galle, 7 fathoms. An anterior fragment of the same species with same locality and date was contained in another bottle in company with *Glycera lancadivæ*.

The different preservation of the two pieces gives them a different aspect, but the structure of the parapodia shows that they belong to the same species. The thin translucent smooth elytra embrace the body so closely as to be inconspicuous; in front they meet in the middle line and overhang the head; further back they leave the mid-dorsum exposed and then approximate again.

The long tentaculum, accompanied by a pair of equally long tentacular cirri, projects straightly and stiffly forwards; the spatulate appendages are nearly as long as the ceratophore; at the base of the latter on each side of the prostomium a small eye is visible from above. The ends of the parapodial rami are furnished with a rich growth of stylodes; the dorsal setæ are very numerous, long, slender, and transversely fringed; from the dorsal end of the ventral ramus a compact tuft of about 20 spinulose simple setæ issues; the rest of the ventral setæ are compound spinigerous, the appendices are not very long and present a peculiar intrinsic laminated structure. Between the cirriform gill and the dorsal fascicle are three ctenidia. The ventral cirrus has a rounded protuberance some distance beyond its insertion (Plate II., fig. 49). The body is slender, the anterior region having a width of 2·5 millims. across the body, 4 millims. across the setæ.

A much smaller complete specimen from the same locality is also contained in the collection and shows to perfection a feature which is present in the larger individual. The anterior setæ of the buccal segment are exceedingly long and slender, as long as the tentaculum and tentacular cirri, and they embrace these appendages in such a manner that the whole complex bears the appearance of a compact flabellum.

There is a great quantity of mucus surrounding the specimens which was apparently produced by the Glycerids with which they were preserved, and this no doubt binds the setæ and tentacles fortuitously together, but the extremely delicate porrect fascicles of long hair-like setæ are highly characteristic. Another point which should be noted is the greater length of the appendices of the compound setæ in the anterior segments. In the smaller specimen there are fewer spinulose or verticillate setæ in the superior fascicle of the ventral ramus, and the stylodes appear to be less numerous; in fact, in a parapodium from the mid-body I only see one verticillate seta as in *Leanira japonica*, McInt. Although the Japanese worm retained no scales, yet it seems probable that the Ceylon specimens are co-specific. In these the scales adhere firmly to the body.

Thalenessa digitata, McIntosh—Plate II., figs. 50 to 52.

> **Thalenessa digitata**, McIntosh, "Polychæta," '"Challenger" Rep.,' 1885, p. 140 (off the Admiralty Islands in 16–25 fathoms).
>
> **Thalenessa im-thurni**, Hornell, 'Ceylon Pearl Oyster Report,' Part I., 1903, pp. 16, 49, and 52.

Taken off Galle (Station XXXVIII.) and off Panadure (Station XLV.) down to 25 fathoms.

Three small frontal antennæ; the lips of the anterior four pairs of setigerous parapodia are produced into conspicuous membranellæ and also carry numerous stylodes; the first five setigers contain setæ with long, jointed appendices, such setæ being numerous in the first four feet, scarce in the fifth, and thereafter absent, only setæ with unjointed appendices being found (Plate II., fig. 50). All these points correspond closely with Professor McIntosh's description and figures.

The elytra do not cover the back; the first two elytra are smaller than the rest, and the first has a smooth margin, destitute of fimbriæ; a typical elytron is subtriangular in shape, the outer border provided with about a dozen compound fimbriæ, more frequently with four divisions each (Plate II., fig. 51), but there may be as many as six branches, or only three, two, or one. The elytra are attached to segments II., IV., V., VII., IX., * * * * * * * XXV., XXVII., XXVIII., XXIX., &c., becoming continuous at segment XXVII. Cirriform branchiæ are present in all setigerous segments, two clear ctenidia on the dorsal surface of the foot, one attached to the peduncle of the gill. Ventral cirrus long, projecting beyond the foot. No papillæ on the ventral division of a typical foot from the middle region.

Thalenessa oculata, McIntosh, is apparently another form of *digitata*, slightly differing from the type. It is interesting to take note of the differential shifting of parts which has taken place, for example in such genera as *Thalenessa* and *Iphione.* In the former the palps are concealed below the cirrophores of the tentacular cirri (Plate II., fig. 52); in the latter the cirrophores of the tentacular cirri are concealed below the palps (Plate I., fig. 6).

Thalenessa stylolepis, n. sp.—Plate III., figs. 53 to 56.

Localities:—Station LVII., 11½ to 36 fathoms; and Station LVI., Dutch Modragam Paar, 9 fathoms; specimen incomplete behind; taken out of coral block.

This must be the worm referred to on p. 74 of the 'Ceylon Pearl Oyster Report,' Part I., as *Sigalion mathildæ.**

The chief characters, which typify a new section of the genus *Thalenessa*, are the possession of a pair of small frontal antennæ and an equally small median occipital antenna; the insertion of the elytra upon high peduncles; and, in the anterior region, the absence of the cirriform branchiæ from the scaleless segments.

Prostomium large, flattened, shield-shaped, with three notches or emarginations, two at the frontal border from which the paired antennæ arise, one at the occipital border from which the tentaculum impar arises (Plate III., fig. 53). Only one pair of eyes was observed occupying a central position behind the frontal emarginations. The cirrophores of the buccal segment are porrect, sub-median and adnate to the prostomium. The line of division between the frontal border and the cirrophores is at the same time the line of concrescence of these structures, so that the antennæ are virtually inserted into the base of the cirrophores, a condition leading to that found in *Sthenelais, Sthenolepis* and *Psammolyce.* The palps are long and smooth.

The elytra are pedunculate, the elytrophores rising like stout pillars from the dorsum, as in *Eulepis;* the elytra are firmly attached to the elytrophores; proceeding outwards from the latter below each elytron is a rather long cirriform appendage which does not occur on the intervening segments (segmenta nuda); the latter show a small tubercle in the line of the elytrophores. The elytra are placed on the usual segments up to the 27th, when they begin to be continuously successive. They carry 12 to 13 (or fewer) plumose fimbriæ (Plate III., fig. 56), which project straight outwards from the outer border, followed by a few simple filiform papillæ. The elytra of the first pair are smaller than the following, rounded, not accompanied by cirriform appendage. The remaining elytra cover the dorsum, their inner borders meeting so as to form a tunnel along the length of the body; on the inner side of each elytrophore a small ctenidium projects into the tunnel, a pair of these ctenidia being inclined towards one another in each body-segment (Plate III., fig. 54). As mentioned above, the cirriform branchiæ of *Thalenessa stylolepis* are confined to the elytrophores. The dorsal ramus of the parapodium (Plate III., fig. 54) carries a bundle of numerous long simple fringed setæ, the fringes appearing in side view as a

* The plumose fimbriæ of the elytra exactly resemble those of *Sigalion mathildæ* as figured by Professor McIntosh (1900).

series of projecting overlapping scales; mediad of the dorsal fascicle the simple setæ are shorter and hyaline. The ventral ramus carries a superior bundle of simple whorled setæ, the verticillate tract short. All the remaining ventral setæ are of the compound falcigerous type, bearing very long, many-jointed, tapering, bidentate appendices, the number of joints being as many as ten. The compound setæ of the middle group are characterised by the possession of squamose (fringed) shafts, while the more slender setæ of the inferior group have plain shafts. A parapodium from the posterior region (near the 60th segment) shows the dorsal ramus projecting clearly beyond the ventral, and in the ventral fascicle, in addition to the compound setæ with the long, jointed, flexible appendices, there are two stout setæ with short unjointed appendices provided with a gaping beak (Plate III., fig. 55). Between 50 and 60 segments are present in the imperfect specimen described above, which is 35 millims. long with width of 3 millims. without the setæ, 4 millims. over the setæ.

Family: PHYLLODOCIDÆ.

Anaitis zeylanica, n. sp.—Plate III., figs. 57 to 60.

Locality:—South of Manaar Island, 8 to 9 fathoms. One specimen, proboscis retracted.

The dorsal phyllodes are broadly ovate (cordate-lanceolate) and pedunculate, as they are in a dozen other species. Head rounded; eyes large; tentacular cirri normal, elongate. Proboscis (dissected) consists of two well-separated portions, a thin-walled proximal or adoral portion densely crowded with papillæ not serially disposed; a thick-walled distal portion with six prominent rows of large subtriangular papillæ, six or seven in a row.

Setæ, ten in a parapodium, the shaft terminating in a triangular apex fringed at the sides and articulating on one side with a long flagelliform strongly serrulate appendix (Plate III., fig. 57). Anal cirri (one preserved) of moderate length, acuminate with stout basal portion. Body slender, length 38 millims.; total width under 2 millims.

The setæ appear heterogomph in side view, homogomph in frontal view (Plate III., fig. 58). I am afraid they offer no reliable diagnostic character, unless it is their size. In this, however, as in other points they resemble the setæ of *Phyllodoce sancti-josephi*. The shape of the head and of the phyllodes is shown on Plate III., figs. 59 and 60.

Carobia castanea, Marenzeller.

Marenzeller, 'Südjapan. Ann.,' i., 1879, p. 127 (p. 19 of reprint).

This species is distinguished from other Oriental Phyllodocidæ by its deep red colour.

The red dorsal phyllodes are cordate and the setæ are distinguished from all others in this collection by their rather short appendices destitute of serrulations and the wide, nearly horizontal articular end of the shaft, as figured by von Marenzeller.

Notophyllum laciniatum, n. sp.—Plate III., figs. 61 and 62.

Station V., off Chilaw Paar, Gulf of Manaar, 11 fathoms. One specimen.

This Phyllodoceid worm is characterised by a relatively short and thick body and by the possession of broad closely imbricating scales or phyllodes (foliaceous dorsal cirri); the anterior phyllodes conceal the occipital region of the head, meeting across the middle line, the rest leave the mid-dorsum exposed. There are as many as ninety segments. The specimen measures about 20 millims. in length and 3 millims. in breadth.

The head is simple, with two large eyes in the posterior half, between which arises a brown-tinted tentaculum impar. The somewhat fusiform antennæ arise between the eye-region and the anterior border, and the fusiform palps, with rather long terminal flagellum, arise nearer the middle line from the under side of the frontal region. The left antenna was lost from the specimen. The four pairs of tentacular cirri are closely aggregated in the cephalic region, only two of them are seen from above, the second and fourth, the latter being the longest. The first cirrus is more massive than the others.

The great character of the species is given by the presence of three cirriform occipital or nuchal lappets, which hang backwards on each side from the back of the head (Plate III., fig. 61). This feature also occurs in *Phyllodoce multicirris*, Grube ('Ann. Semp.,' p. 100), which is clearly a closely allied species, differing in the structure of the head, especially in the decided possession of four eyes. The setæ and phyllodes also exhibit minor differences. Each occipital lappet has a pale border and a brown centre. The dorsal phyllodes have the same shape and arrangement as figured by Grube for *Ph. multicirris*, but they do not show the round surface markings of that species. The ventral phyllodes also have the same peculiar disposition, inserted high up near the extremity of the parapodium and lying outspread behind the pharetra setarum.

In the setæ the articular end of the shaft shows a character of its own. There are as many as 21 setæ in a ventral fascicle from the anterior region; most of them are broken. In optical section the ends of the shafts appear deeply excavate, the articular fossa bounded by stout refringent walls (Plate III., fig. 62). The dorsal ramus is represented by the lobe upon the summit of which the dorsal phyllode is inserted; it is penetrated by a single slender acicula. The appendices of the compound setæ are rather long and minutely serrulate.

Phyllodoce dissotyla, n. sp.—Plate III., figs. 63 to 66.

Station V., off Chilaw Paar, Gulf of Manaar, 11 fathoms. One specimen, 25 millims. long by 1 millim. broad; proboscis not extruded.

The head is longer than broad; the antennæ do not stretch back to the eyes; the eye shows a clear lens (Plate III., fig. 63). There are four pairs of long tentacular cirri of normal form. The dorsal phyllodes are rounded, not lanceolate, and strongly pedunculate. The setæ, 18 in a fascicle, are heterogomph, the articulation of the appendix distinct; the appendix with serrulate edge (Plate III., figs. 64 and 65).

The dominant specific character was ascertained by removing and opening the retracted proboscis, the adoral portion of which is beset with longitudinal rows of rounded normal papillæ; in two of the rows, probably median dorsal and median ventral (since they are separated from one another by normal rows), there are three large triangular papillæ placed one behind the other, with normal papillæ in front and behind in the same rows. These modified papillæ are denser than the rest and are noticeable under low magnification with a simple lens (Plate III., fig. 66). They are quite definite, two sets of three on opposite sides of the proboscis.

The phyllodes and setæ are also characteristic, but the determining character is given by the papillæ of the proboscis.

Phyllodoce foliosopapillata, Hornell—Plate III., figs. 67 to 69.

'Ceylon Pearl Oyster Report,' Part I., 1903, p. 16 and p. 28, "Yellowish green Phyllodocid."

Station XVII., outside Periya Paar, 11 fathoms.

The specimen, which is incomplete behind, has a length of 135 millims. (141 millims. with extruded proboscis); about 207 segments; ventral width between the parapodia 2 millims.; over the parapodia 5 millims. The proboscis is firm and sexangulate; towards the base it is traversed by transverse rugæ, and behind these, at the level of the head on each side, there are six rows of transversely elongate, foliate papillæ, 5 or 6 in the first row, 8 or 9 in the second, 10 in the third, and again decreasing below; at the free margin I counted 14 or 15 rounded papillæ (Plate III., fig. 67). The foliaceous dorsal cirri, which may be called phyllodes to distinguish them from the elytra of the Aphroditidæ, are borne upon broad peduncles to which they are strongly adherent. In this specimen the phyllophores are filled with ova (Plate III., fig. 68).

There are as many as 25 compound setæ in a parapodium. The long flexible spiniform appendices are serrulate along one border, but in some of them the serrulations are obscure or even obsolete. The setæ differ from those of other species in the presence of a long stout spur at the head of the shaft, which sometimes projects considerably beyond the neighbouring denticulations, even more so than in the example figured (Plate III., fig. 69).

Closely apposed to the sides of the prostomium is a pair of lateral nuchal organs (Plate III., fig. 67). The prostomium is broader than long, deeply emarginate behind, and in the notch there is an occipital papilla, such as occurs also in *Phyllodoce madeirensis* and other species.

The insertion of the four pairs of tentacular cirri is the same as in *Ph. madeirensis*, namely, on each side :—

Segment I., one tentacular cirrus ;
,, II., two tentacular cirri ;
,, III., one tentacular cirrus and a cirrus ventralis foliaceus.

The first appearance presented is that of two cirri in the first segment, but closer examination showed that this appearance is deceptive. The longest is the dorsal cirrus of the second segment, stretching back over eleven segments.

Phyllodoce macrolepidota, SCHMARDA—Plate III., figs. 70 and 71.

SCHMARDA, 'Neue Wirbellose Thiere,' ii., 1861, p. 83, Taf. xxix., fig. 229.
Phyllodoce tenuissima, GRUBE, 'Ann. Semp.,' 1878, p. 95.

Locality :—Galle Habour, on oyster cage. One specimen.

Body very long and slender, 200 millims., with a width of 3 millims. in front, over the setæ ; more than 350 segments. The proboscis is only half extruded, and this portion is inflated and soft ; it carries six longitudinal rows of broad, flattened, arcuate, dark-coloured papillæ on each side in front of the head-region, 8 to 10 papillæ in a row, and, in addition, a median dorsal row of six papillæ. The general arrangement of the papillæ and the presence of the median row are features which characterise *Ph. madeirensis*, LANGERHANS, of which this may be an Oriental representative, but it has nearly three times the length and about twice as many segments as in the type-species of LANGERHANS. There are 17 setæ in a parapodium (Plate III., fig. 70) ; they do not offer any striking character (Plate III., fig. 71). The head is about as long as it is broad, with rather large eyes in the centre of the posterior cephalic convexity on each side ; it is acutely notched behind, but the specimen does not show a nuchal papilla. There are two rather short, stout, subulate anal cirri.

Phyllodoce sancti-josephi, GRAVIER—Plate III., figs. 72 and 73.

GRAVIER, "Ann. Polychètes de la Mer Rouge," 'Arch. Mus. Paris (4 ser.), ii., 1900, p. 196.

Station V., off Chilaw Paar, Gulf of Manaar, 11 fathoms. Two specimens.

These worms differ from the type in the shape of the head and in the apparent absence of an occipital papilla. The widening of the head is correlated with the extrusion of the proboscis, and the occlusion of the papilla may be due to the same cause. One of the specimens has a length of 55 millims. and a total width in front of 2 millims.

The proboscis in its general consistency and in the presence of a posterior rugose portion resembles that of *Ph. foliosopapillata*, but the papillæ, of which there are six rows on each side, extend over the rugose region in front of the head (Plate III., fig. 72). In the second specimen the proboscis shows six prominent angulations in front of the rugose portion.

The head itself, under the condition of extruded proboscis, is about as broad as long and not deeply notched behind. On each side of the prostomium there is a prominent lateral nuchal papilla. The phyllodes resemble those of *Ph. macrolepidota* in shape and proportion, the dorsal phyllode being distinctly pedunculate and its axis occupied by a rete mirabile, from which radial vessels proceed to the margins. The parapodium carries twelve setæ of normal type (Plate III., fig. 73), though, as shown by M. GRAVIER, the number varies within narrow limits in different regions of the body. The number which I have given holds good for the mid-region. A foot from the posterior region has sixteen setæ.

Pterocirrus ceylonicus, MICHAELSEN.

This species is well characterised by the five long slender subequal prostomial appendages, longer than the prostomium. The remarkable winged ventral cirrus of the second segment which, seen from above along its thickened dorsal border, looks like an ordinary tentacular cirrus, is a generic feature of first importance. The dorsal phyllodes are more lanceolate than that shown in Dr. MICHAELSEN'S figure, "Polychäten von Ceylon," 'Jahrb. Hamburg. Wiss. Anstalt,' 1892, ix., 2, p. 103, otherwise I have nothing to add to his description. The colour of the preserved specimens is dark greenish-brown. Locality :—Ceylon Seas.

FAMILY: HESIONIDÆ.

Hesione ceylonica, GRUBE.

GRUBE, "Ann. Ceylon" (Holdsworth coll.) 'P. Zool. Soc. London,' 1874, p, 327.

Locality :—Numerous specimens from various stations.

This is probably a geographical form of *Hesione splendida*, SAVIGNY, which is characterised by the possession of one pair of frontal antennæ; eight pairs of tentacular cirri; sixteen pairs of uniramous parapodia; four distinct eyes; pigment disposed more or less in longitudinal bands or streaks. SAVIGNY was in error regarding the minute antennæ, and the illustrations do not correspond with the text in certain particulars, hence confusion has arisen.

The Ceylon specimens range in length of body from 9 millims. to 36 millims. ; in the latter case the ventral width between the parapodia is 4 millims., over the setæ 11 millims. In all cases the full number of setigerous segments, namely 16, is present. The extruded proboscis shows a median dorsal callosity or hard papilla (not seen in the smallest specimen) a short distance from the base, like that figured by AUDOUIN and MILNE-EDWARDS (1834) in *H. pantherina*. The compound falcigerous setæ have bidentate appendices with a spiniform guard arising below the denticulations. The guard may be worn away.

A specimen of 14 millims. length had a ventral width between the parapodia of 2 millims., over the setæ nearly 5 millims.

Hesione genetta, Grube. (See Grube, 'Ann. Semp.,' 1878, p. 104.)

One specimen from Chilaw Paar, Station LXIX.

This species is distinguished from the members of the *splendida* group by its very characteristic and enduring pigmentation. At the junction of the first and second setigerous segments there is a broad dark transverse band passing from one side to the other across the convex dorsum. Behind this band the segments are marked by transverse brown spots which are sometimes confluent. The cuticle is highly iridescent; the body flexed ventrally and the ventro-lateral borders elevated, leaving a median neural groove between them. The prostomium is quadratic; two frontal notches from which the minute antennæ arise; eyes barely visible. The body is shaped like that of *H. reticulata*, von Marenzeller (South Japan), and resembles the body of a caterpillar, as remarked by von Marenzeller. Length 13 millims., inclusive width 3 millims.

Irma limicola, n. sp.—Plate III., figs. 74 to 76.

This species is founded upon a single example which occurred in one of the mud-tubes of *Loimia montagui* from Palk Bay. It is not very well preserved in consequence of having been trapped in such a narrow recess. Its length is 20 millims., width 3 millims., with upwards of 50 segments.

The head is transverse, the eyes widely separated, the anterior and posterior eyes of each couple crescentic and closely approximated. From the frontal border of the prostomium on each side two equal cephalic appendages (antennæ and palps) curve backwards, lying over the eyes and sides of the prostomium. The biannulate proboscis is extruded. No tentaculum impar could be observed. Six tentacular cirri are present on each side of the buccal segment, placed in a dorsi-ventral manner, the upper and lower of the group being shorter than the intermediate.

The dorsal ramus of the parapodium is intimately connate with the cirrophore of the dorsal cirrus into which an acicula extends, and from a slight protuberance on the lower side of the cirrophore a bundle of very fine capillary setæ emerges (Plate III., fig. 74). The compound setæ of the ventral ramus are numerous, about fifty in each fascicle. They are falcigerous, carrying very long appendices curved at the tip and bidentate, the apical tooth frequently connected with the minor tooth by a limbus. The superior setæ of the ventral ramus have appendices about one-half shorter than the average; the inferior setæ, *i.e.*, the most ventrally placed setæ, carry quarter-sized appendices (Plate III., figs. 75 and 76). The relations of the dorsal and ventral cirri and the lip of the parapodium are shown in the figure (Plate III., fig. 74). Repeated examination failed to reveal any trace of a tentaculum impar in *Irma limicola*. In this respect it approaches the genus *Castalia*, Sav., as amended by M. Sars ('Christ. Vid. Selsk. Forh.,' 1861, p. 88), but there are no coronary papillæ on the proboscis and no jaws.

The definition of *Irma* should be modified as follows :—

Proboscis nuda; palpi biarticulati; antennæ 3 (interdum 2 observatæ); oculi 4; cirri tentaculares 12; pedes quasi biremes; ramus dorsalis vestigialis cum articulo basali cirri dorsalis connatus, setas dorsales capillares gerens aut nullus; setæ ventrales compositæ falcigeræ; aciculæ binæ.

The fact of an acicula passing into the cirrophore indicates the primitive biramous nature of the foot in those species where dorsal capillary setæ do not occur, exactly as in the analogous case of *Podarke*, EHLERS. The absence of a median antenna in *I. limicola* is puzzling, and will remain so until more material is obtained. The species described by me as *Oxydromus aucklandicus* ('"Southern Cross" Collections,' London, 1902, p. 281) should be transferred to the genus *Irma* as now defined.

FAMILY: SYLLIDÆ.

Typosyllis taprobanensis, n. sp.—Plate III., figs. 77 and 78.

Localities:—East side of Cheval Paar; and South-west Cheval Paar, Gulf of Manaar.

This is a variable species, one specimen seemed to resemble *T. variegata*, the next *T. krohni*, the differences being in part substantial, in part due to the fact that the pharynx of the one was on the point of being projected, that of the other was retracted completely.

Antennæ and cirri moniliform; in the first specimen (length 19 millims., width 1·5 millims.) the paired and unpaired antennæ were about equal in length to each other and to the palps, the paired rather slenderer than the impar, shorter than the dorsal cirri; the latter, not deciduous, longer alternating with shorter and slenderer; the first ventral tentacular cirrus slender, not much longer than the palps; head transverse, partially concealed below the buccal segment; pharynx, on the point of projection from the mouth, lined by thick dark-brown cuticle (showing dark purplish-black through the skin) carrying a subterminal dorsal tooth coloured the same as the chitinous intima; proventriculus, with about 37 rows, finely tessellated, glistening whitish with delicate flush.

In the second specimen the median antenna was long, showing 36 joints; most of the dorsal cirri were lost, that of the 5th setiger showed 42 joints, that of the 64th setiger upwards of 30 joints; the pharynx and proventriculus, seen by transparency, exactly resembled those of the first specimen and decided the specific identity, but were differently placed, being retracted; the pharynx extended from the 7th to the 15th setigerous segment, the proventriculus from the 15th to the 25th setigerous segment; colour of the first 24 setigerous segments:—two brown transverse bands in each segment; total number of segments 150; length 30 millims.

The setæ of both corresponded in general characters, differing in a manner shown in the figures (Plate III., figs. 77 and 78). In the anterior segments there are about

12 to 16 compound falcigerous bidentate setæ lying below 5 aciculæ; the aciculæ become reduced to 3 and posteriorly to 2; the setæ also undergo changes, the shaft becoming stouter and the appendix shorter; the shaft further assumes a characteristic dilatation of varying intensity below the joint (Plate III., figs. 77 and 78).

The anal cirri showed 24 joints; no median caudal process was observed. The head of the second specimen was normal, rounded, not transversely elongate, the latter condition apparently resulting from the commencing extrusion of the pharynx. The palps are quite separate, with distinct subfrontal insertions, a wide proximal half and a narrower distal halt.

In *Typosyllis variegata*, according to VON MARENZELLER,* the palps are fused together at the base. The Ceylon species would appear to be related to *T. krohni*, as described by LANGERHANS.† The difference noted above in respect of the shafts of the setæ may be correlated with the difference of age and size of the specimens of *T. taprobanensis*.

Haplosyllis spongicola (GRUBE)—Plate III., figs. 79 and 80.

GRUBE, 'Arch. Naturg.,' 1855, p. 104; MARION et BOBRETZKY, 1875, 'Ann. Marseilles,' p. 24.
Syllis hamata, CLAPARÈDE, 1868; LANGERHANS, Madeira, 1879, 'Z. f. w. Z.,' xxxii., p. 527; ST. JOSEPH, 'Dinard,' 1886, part i., p. 142; 1895, part iv., p. 185.
Syllis violaceo-flava, GRUBE, 'Ann. Semp.,' 1878, p. 115; see also LANGERHANS, Madeira, part iii., 'Z. f. w. Z.,' xxxiv., p. 128.

A small specimen, 4·5 millims. long, was taken from between the whorls of the operculum of a large Serpulid [*Pomatostegus actinoceros*], off Panadure, Station XLV., 25 fathoms.

Over 40 setigerous segments; setæ brittle, many of them with the tips broken off. The proventriculus is long, occupying segments 13–25, but the body is contracted. On examining the specimen *in toto*, it is common to see two hamate unguarded acicular setæ projecting from a parapodium, one of which is stronger than the other; both of these setæ have a bidenticulate apical tooth as figured by MARION and BOBRETZKY, and by LANGERHANS. (In *Haplosyllis djiboutiensis*,‡ GRAVIER found, in one individual, the apical tooth of the stronger seta simple.) The pharynx is armed in front with a single conical tooth surrounded by a crown of ten soft papillæ (Plate III., fig. 80). The head is shown in Plate III., fig. 79.

Syllis gracilis, GRUBE (1840).

(*Cf.* ST. JOSEPH, "Ann. de Dinard," part i., 'Ann. Sci. Nat.' (7) i., 1886, p. 158; part iv., t. xx., 1895, p. 190.)

Locality:—South-west Cheval Paar. Three specimens.

1. About 180 segments; length 45 millims.; body contorted; diameter uniform,

* 'Adriat. Ann.,' ii., 1875, p. 147.

† "Wurmfauna Madeira," i., 'Zeit. f. wiss. Zool.,' xxxii., 1879, p. 529.

‡ GRAVIER, "Ann. Mer Rouge," 1900, 'Arch. Mus. Paris' (4) ii., p. 147.

about 1 millim. without feet, 2 millims. inclusive. Anterior setæ compound, falcigerous, bidentate, in about 30 segments; thereafter simple furciform setæ; in the posterior segments some of the furciform setæ become quasi-compound. Dorsal cirri of about 40 anterior segments long, with a tendency to alternate longer and shorter; afterwards they become shorter, subfusiform, still alternating. Tentaculum impar with 27 joints; paired antennæ, about 16 joints; dorsal tentacular cirrus, 18–20 joints; first dorsal cirrus, 34 joints; posterior dorsal cirri, 8–12 joints. Pharynx black in segments 3–20; proventriculus in segments 20–28.

2. Length 15 millims., 83 segments followed by about a dozen regenerating segments showing small compound setæ of the usual type. Compound setæ in anterior 28 segments.

3. Length 22 millims.; segments 118; compound setæ in 28 anterior segments; in segments 29–90 simple furciform setæ; in segments 91–118 the falcigerous bidentate setæ re-appear. Pharynx brown in segments 1–13; proventriculus 14–20. Tentaculum impar moniliform, 18 joints; dorsal cirrus of first setiger longest, with 20 joints.

Autolytus orientalis, n. sp.—Plate IV., figs. 81 to 84.

Locality:—Found in plankton, 2nd and 3rd March, 1903, North-east Cheval. Several stoloniferous specimens; total length 10 to 20 millims.

In the example figured (Plate IV., fig. 81) there are 29 setigerous segments in the anterior or parent individual. The parapodia contain two aciculæ and numerous, upwards of 20, compound falcigerous setæ; the head of the shaft is laciniate and the appendix is minutely bidentate and minutely fringed (Plate IV., fig. 84). The dorsal cirri are rather short, lanceolate, petaloid, with strong basal articulation. The second dorsal cirrus, *i.e.*, the cirrus of the first setiger, is the longest. The rounded reduced palps, joined together in the middle line along their own length, are only visible from below (Plate IV., fig. 83). The pharynx is long and has a sigmoid flexure; it is armed in front with a circle of 44 denticles, larger and smaller irregularly alternating (Plate IV., fig. 82). The proventriculus shows 28 glandular rows.

Family: NEREIDÆ.

Nereis indica, Kinberg.

Kinberg, 'Annulata nova—Nereidum dispositio nova,' 'Öfv. Akad. Forh.,' 1865, p. 169.

Locality:—Galle, from buoy; one female containing ova.

Length 50 millims., inclusive width 4·5 millims. Tentacular cirri not long, reaching to third segment; antennæ $\frac{3}{4}$ length of prostomium; palps long with narrow terminal appendix; eyes large, equal, the posterior rather closer together. Body incomplete behind, 77 setigerous segments.

Feet subequal; dorsal cirri of anterior segments about twice as long as the blunt dorsal ligule; ventral cirrus not reaching the tip of the ventral ligule; in the middle segments the neuropodia and the bases of the cirri become membranous, the dorsal ligule becomes elongate and acuminate,* the dorsal cirrus exceeding it by about one-fifth only; in the posterior segments the dorsal cirri are upwards of four times the length of the dorsal ligule. Dorsal setæ homogomph spinigerous; superior ventral setæ homogomph spinigerous and heterogomph falcigerous; inferior ventral setæ heterogomph spinigerous and heterogomph falcigerous. The shafts of all the setæ are striated and all the appendices are strongly fringed (setulose); the falciform appendices are entire at the apex, not bidentate.

The proboscis was retracted and was dissected out:—I., 1; II., 12–12 (oblique acervi); III., 10 (triangular acervus); IV., 15–15 (three unequal rows); V., 0; VI., 6–6 (irregular); VII. and VIII., biserial, anterior row large alternating paragnaths; paragnaths of the posterior row half as large and one and a half times as numerous as those of the front row.

Nereis unifasciata, n. sp.—Plate IV., figs. 85 to 88.

Locality:—South-east Cheval Paar.

A small Nereid (length 11 millims., incomplete behind) characterised by the presence of a dark brown collar across the whole of the dorsum of the second setigerous segment. The buccal and the first setigerous segments are pale brownish at the sides, but there is no band across them. Commencing from the intersegmental groove between the fourth and fifth setigerous segments there are about twelve pairs of small intersegmental brown spots on the back. The feet are equal and resemble those of *Ceratonereis pectinifera* (p. 272) in the general proportions of parts (Plate IV., figs. 85 and 86). The two worms were collected at the same time and place.

The distribution of the setæ in the foot is as follows:—Dorsal, homogomph spinigers; superior ventral, homogomph spinigers and heterogomph falcigers; inferior ventral, heterogomph spinigers and falcigers. The heterogomph spinigers are not completely heterogomph, but, at least in the middle and posterior segments, present a condition which might be described as hemigomph (Plate IV., figs. 87 and 88). This small detail affords the only real distinction between the armature of the feet of this species and that of *Ceratonereis pectinifera*. The proboscis was not extruded, and, although as a rule I do not attempt the description of small Nereids unless the proboscis is extruded, I was anxious to test the specific value of the colour-markings and of the setæ. The dissected proboscis showed paragnaths in the adoral division, those of the order VI. in small acervi, of VII. and VIII. in a single row as in *Nereis trifasciata*, Grube. It is therefore not a *Ceratonereis*.

I cannot state any differences between the armature of the proboscis of this species and that of *Nereis trifasciata*.† The fact that such a minute detail as the presence

* The inferior lip of the notopodium is also produced as a ligule, the inferior dorsal ligule, resembling the superior ligule throughout, but rather shorter.

† Except that the maxillæ show seven teeth.

of hemigomph instead of homogomph spinigers in the inferior ventral fascicle is sufficient to indicate fundamental divergence is interesting. The third tentacular cirrus stretches back to the end of the seventh segment as in *N. trifasciata.*

Nereis ehlersiana, GRUBE. (GRUBE, 'Ann. Semp.,' 1878, p. 71.)

Locality :—Station LXIX., Chilaw Paar.

The anterior portion of the body comprises 15 segments (14 setigerous); the dorsal cirri of the first seven setigerous segments are modified, unequally elongate and foliaceous. A normal parapodium from the anterior region shows reduced rounded ligules, moderate dorsal cirrus much longer than its ligule, short ventral cirrus; dorsal setæ homogomph spinigerous; superior ventral homogomph spinigers and heterogomph falcigers; inferior ventral heterogomph falcigers.

Ceratonereis falcaria, n. sp.—Plate IV., fig. 89.

Locality :—South-west Cheval Paar, two specimens.

About 107 segments with an even diameter of 2·5 millims. up to the region of the 55th segment, then rapidly attenuating; length 27 millims. Frontal border notched so that the antennæ are borne upon ceratophores as in *C. tentaculata*, KBG., and *C. excisa*, GR. Eyes large, in a rectangle. Tentacular cirri moderately long; dorsal cirri more than twice as long as the dorsal ligules; ventral cirri of the two middle quarters of the body with basal lobules.

The distinctive character of the species is afforded by the setæ. In the first sixteen segments the setæ of the dorsal fascicle are homogomph spinigerous; of the superior ventral fascicle homogomph spinigerous and heterogomph falcigerous; in the inferior ventral fascicle heterogomph spinigerous and heterogomph falcigerous; the shafts are striated, the appendices fringed and the falciform appendices are simple, not bidentate. After this the dorsal setæ undergo a change, becoming homogomph falcigerous with a deeply set, strongly bidentate appendix without guard (Plate IV., fig. 89). Transitional forms between the two kinds of dorsal setæ are to be observed, namely, setæ in which the appendix is shorter and stouter than in the normal spinigerous setæ. Paragnaths :—I., 0; II., 5–5; III., 7 (in one row); IV., 10–10. Maxillæ with about six denticulations. In the character of the paragnaths this species approaches *C. vulgata*, KINBERG, from Honolulu. The change of dorsal setæ from spinigerous to falcigerous is remarkably diagnostic.

Ceratonereis pectinifera, GRUBE—Plate IV., figs. 90 and 91.

GRUBE, 'Ann. Semp.,' 1878, p. 66.

Locality :—South-east Cheval Paar.

A small Nereid, 17 millims. in length, almost the only one in the collection with the proboscis extruded. The systematic importance of the paragnaths of Nereidæ is well known, and a particular illustration of it is afforded by this species in comparison with *Nereis unifasciata* (q. v.). Antennæ shorter than proboscis, eyes in a wide trapezium or subrectangle; third tentacular cirrus reaches back to seventh segment. Posterior segments with brown glandular tracts on the dorsal sides of the segments and on the bases of the parapodia (Plate IV., fig. 91). Feet equal, dorsal cirrus longer than dorsal ligule; in the anterior feet there are prominent labia pharetrarum (Plate IV., fig. 90).

Dorsal setæ homogomph spinigerous; superior ventral setæ homogomph spinigerous and heterogomph falcigerous; inferior ventral setæ homogomph spinigerous and heterogomph falcigerous. The paragnaths do not quite agree with GRUBE'S formula, but I think nearly enough to determine the species:—I., 0, II., a double oblique row, 3 or 4 larger in the hinder row, 4 or 5 smaller in the front row; III., 1; IV., an acervus of 8, two very small in front, three rather larger in the middle and three still larger behind. The actual length of the third tentacular cirrus is about 2 millims.

The Ceylon specimen seems to agree with GRUBE'S *C. pectinifera* in all characters except the mouth-parts and with *C. lapinigensis* in respect of the mouth-parts. The maxillæ show 5 blunt teeth. Perhaps the two forms are co-specific. The arrangement of the setæ in the foot is not described by GRUBE in either of his species. The peculiarity here is the occurrence of homogomph spinigerous setæ as well as heterogomph falcigers in the inferior ventral group. In *Ceratonereis costæ*, according to EHLERS ('Borstenwürmer,' p. 525), there are only falcigerous setæ in the inferior ventral group. It is uncommon to find homogomph spinigers in the inferior ventral fascicle.

Platynereis bengalensis, KINBERG—Plate IV., figs. 92 to 94.

Muttuvaratu Paar, March 29. One specimen, incomplete behind, 45 setigerous segments, width over setæ 4 millims.

Description of a foot from anterior region (9th foot of right side):—Dorsal cirrus normal, $2\frac{1}{2}$ times the length of the dorsal ligule, which is short, rounded, and bulky; inferior dorsal ligule like the superior; ventral ligule like the dorsal ligules; ventral cirrus not reaching the end of the ventral ligule. Dorsal setæ homogomph spinigerous; superior ventral setæ homogomph spinigerous and heterogomph falcigerous (appendices simple, fringed, short); inferior ventral setæ heterogomph, spinigerous and falcigerous.

Description of the 44th foot of right side:—A large brown glandular tract divided into two portions at base of dorsal cirrus; ligules obtusely pointed, more than half the length of the dorsal cirrus (ventral ligule rather shorter than the two dorsal ligules and narrower at its base). Dorsal setæ homogomph spinigerous and falcigerous; superior ventral homogomph spinigerous and heterogomph falcigerous; inferior ventral heterogomph spinigerous and falcigerous. The appendix of a dorsal falciger is guarded and unfringed; its extremity is boldly hooked, and at the vertex of the hook there is a small tooth in front of which the guard makes another slight projection (Plate IV., fig. 92). The appendix of a superior ventral falciger in this foot is fringed along its lower portion, guarded along its upper half (Plate IV., fig. 93). The appendices of the other ventral falcigers of this foot and of the other feet, and also in many other species of Nereidæ, are minutely guarded quite at the apex beyond the fringe; a double contour at this point indicates a rudimentary guard, as may be realised by comparison with the structure of the superior ventral setæ here described (Plate IV., fig. 93).

The parapodium (44th) from the middle region of the body described above closely resembles that figured by GRAVIER for his *Platynereis insolita* ('Arch. Mus. Paris' (4), iii., 1901, p. 198), and, in fact, could not be distinguished from it. The only difference seems to lie in the structure of the appendices of the dorsal falcigerous setæ which have a smooth rounded vertex without any prominence in *P. insolita* (*loc. cit.*, p. 198, fig. 206). The same setæ with tooth on the vertex occur also, two in number, in the 19th foot of the Ceylon specimen.

The tentacular cirri are long, the third pair extending over 16 segments. The proboscis was retracted and had to be dissected out:—Paragnaths of the orders I., II., III., and V. absent; of the order IV. (Plate IV., fig. 94) in several more or less complete rows (as in the type). Antennæ as long as the palps, eyes in a trapezium.

FAMILY: ONUPHIDÆ.

Diopatra amboinensis, AUD. & M.-EDW.—Plate IV., figs. 95 to 97.

Station V., off Chilaw Paar, 11 fathoms.—One specimen with tube.

Another empty tube was taken from the Muttuvaratu Paar, 29th March, 1902.

The tube is characteristic, encrusted with unequal pieces of coarse broken shells which stand out at right angles to the wall of the tube, being attached thereto by one edge, giving the impression of pieces of shell threaded together; some of the fragments are nearly entire shells, as much as $\frac{3}{4}$ inch long, the majority are smaller; seaweed may grow on the shelly covering; the tube is from 3 to $3\frac{1}{2}$ inches long, and presents a tabulate appearance owing to the disposition described above.

The body of the specimen, which is incomplete behind, is flattened, 4 millims. wide. The dorsal side is brown coloured, with a dark hæmal line and a shining cuticle; the lateral parapodial tracts show up whitish in the preserved state; ventrally there is a pale neural tract flanked by two broad brown submedian bands, followed on the outside by the series of broad whitish ventro-lateral tori or cushions which resemble the uncinigerous tori of a Terebellid without the uncini, and doubtless serve to facilitate the passage of the worm up and down its tube. The first five setigers are much larger than the rest, with a ventral and porrect inclination, and carry ventral cirri instead of tori. The spiral penicillate branchiæ commence on the sixth segment (*i.e.*, fifth setigerous segment). Towards the fortieth segment they become reduced and finally cease in the region of the sixtieth; in the mid-region they are more than twice the length of the stout, subulate dorsal cirri.

The prostomial tentacles are somewhat pigmented, especially at the base, where the long flagelliform portion is inserted into the 10- or 12-ringed basal peduncle. The frontal antennæ have a stout pigmented basal portion, followed by a narrower apical portion, the whole as long as the peduncle of the lateral tentacle. The tentacular cirri arising from the border of the single apodous buccal segment are as long as the peduncles of the submedian tentacles, or slightly longer. The eye-tracts occur behind the submedian tentacles. The broad rounded palps have a teat-like apex. In the protruding jaws I counted 8 teeth on the right saw, 7 on the left, about 10 on the right arc, 8 or 9 on the left, and 5 teeth on the left impar. The lower jaw-plates or laminæ ventrales have thin white calcareous end-pieces with simple border and rounded divergent apices; the mandibles have the usual form (Plate IV., fig. 95).

This species is closely related to *Diopatra neapolitana*. Its differentiation from any other species of the genus will probably depend upon the character of the setæ in the anterior modified parapodia, about which our information is rather deficient, so far as I am able to judge from the literature of *Diopatra*. It is equally closely related to *Diopatra semperi*, Grube ('Ann. Semp.,' p. 282 = *D. luzonensis*, p. 138), but the latter has very short frontal antennæ and the calcareous caps of the lower jaw-plates are trilobate; the anterior setæ are not described. The identification of the present species cannot be considered final until fresh material for comparison is obtained from Amboina or adjacent parts. A preparation of the first left foot of *D. amboinensis* from Ceylon shows about 18 setæ projecting. There is a dorsal group of about six long, simple, curved acuminate, non-limbate capillary setæ; the rest have a bidentate apex beyond which the pointed guard projects (Plate IV., fig. 96-97). The anterior appendages possess other characteristic features besides the setæ which they carry. The lips of the orifice of the pharetra setarum are triangulate, an anterior short truncate border followed by a long stout cirriform posterior median lobe and a smaller ventral ligule; I do not know of any other species of *Diopatra* in which this third ligule has been described. Sometimes it is appressed against the median lobe and so concealed from view on the slide, but it can be found with a simple lens on the body of the worm. In Grube's description of *D. semperi* (= *D. luzonensis*) the diagnostic features of the anterior modified parapodia are not given. From the parapodia of the mid- and hind-body two aciculæ project with bifid apices as figured by Ehlers ('Borstenwürmer,' Taf. xii., fig. 15) for *D. neapolitana*. The scalprate setæ of the posterior segments have numerous fine denticulations (over 20), whereas according to Ehlers they are few (about 8) in *D. neapolitana*. The filaments of the branchiæ are long.

Onuphis basipicta, n. sp.—Plate IV., figs. 98 and 99.

Station XXXV., Galle, 7 fathoms. One specimen in company with *Glycera laneadivæ*. Length 23 millims., width 1 millim.

Patches of brown pigment on the bases (ceratophores) of the antennæ; submedian antennæ longer than the median (tentaculum impar); ceratophore of the median antenna normal, nearly one-third the total length of the antenna, less than one-half the length of the ceratophores of the submedian antennæ which are nearly one-half the total length of these appendages; ceratophores of the lateral antennæ about three-fourths the length of the submedian ceratophores, about two-thirds of the total length of the lateral antennæ.

The above proportions, the moderate length of the median and the considerable length of the submedian and lateral ceratophores are characteristic. The submedian antennæ stretch back over ten segments. The tentacular cirri were lost, one was observed detached. Setæ of the body-segments comprise 6 to 8 simple capillary with two bidentate guarded acicular setæ and three acuminate aciculæ; a small bundle of fine capillary setæ passes into the dorsal cirrus, sometimes extending far along the cirrus. Dorsal cirri normal, subulate. Branchiæ commence as a simple filament on the first setiger and remain simple for 7 or 8 anterior segments, then becoming pectinate with 5 or 6 processes.

The first setiger contains the dorsal bundle of setæ for the dorsal cirrus and a ventral fascicle comprising one simple capillary seta, six characteristic tridentate compound setæ and an acicula (Plate IV., figs. 98 and 99). The second setiger resembles the first, but contains in the ventral fascicle three simple setæ and five compound setæ of the same type as in the first. The posterior lingule of these anterior parapodia is long, acuminate, cirriform.

This species is determined by the combination of characters afforded by the ceratophores, setæ, and branchiæ. It occupies an intermediate position between *O. longissima*, Gr., and *O. teres* (Ehlers). The shape of the frontal antennæ is also important; these are broad, almost foliaceous, divergent, subtriangular appendages, neither filiform, fusiform, nor subulate. Their shape is liable to vary in different states of contraction and only the combination of characters can be relied upon. The setæ give the best indications, the peculiar setæ of the anterior parapodia and the simple setæ of the body-segments.

Onuphis conchylega, Sars (1835).

Localities:—South of Manaar, 8 to 9 fathoms; and from Station LII., Cheval Paar, 3 to 6 fathoms.

It is somewhat surprising to find this species which is common at Plymouth occurring also off the coast of Ceylon. Its flattened tube, covered with large horizontally placed shell fragments, is so characteristic that it is impossible to name it differently from the type. This species should be the type of the unfortunate genus *Northia*, of Johnston. I have carefully unravelled the confusion which this genus has caused, and the result is that I agree with the Baron de St. Joseph that it should be dropped. The species has wide distribution (see Ehlers, 'Florida-Anneliden,' 1887, p. 73) and is synonymous with *Diopatra eschrichti* (Œrst.).

The shelly tube is 40 millims. long by 10 millims. wide. The tentaculum impar stretches back over 12 segments; the prostomial tentacles are smooth, the basal joints short, subequal, pauci-annulate. The tentacular cirri are slender, elongated, acuminate, much longer than the narrow buccal segment, about as long as the prostomium. Branchiæ simple, commencing on the 8th setiger; stout, acuminate, appearing flattened towards the base. Anal cirri long, slender, filiform. First three setigers porrect, the first dorsal cirrus shorter than the following; the fourth setiger slightly porrect. Ventral cirri of first and second setigers subulate; of the third, shorter, obtuse, and fleshy; of the fourth reduced to a slight projection of the first torus ventralis.

A large female measures 30 millims. long by 3·25 millims. wide; a smaller specimen is 17 millims. in body-length (excluding the antennæ), and the branchiæ are flattened. The frontal antennæ are short, ovate. In the first foot there are no setæ associated with the dorsal cirrus; the setæ of this foot comprise two acuminate aciculæ, three bidentate acicular setæ which project, and one or two bidentate quasi-compound setæ. A gill-bearing foot carries six limbate capillary setæ, two aciculæ, and two bidentate acicular setæ, the prongs of which are gaping and subequal; there are no setæ passing to the dorsal cirrus.

Onuphis dibranchiata, n. sp.—Plate IV., fig. 100.

Locality:—Galle lagoon, low-tide, 3rd August, 1902. Several fragmentary specimens.

The annulate bases of the prostomial tentacles are well developed, nearly equal, the submedian slightly exceeding the others, and the median less than the rest; the submedian peduncles are less than one-third of the total length of the appendage; the median peduncle is barely one-fourth of the total length of the tentaculum impar, and the lateral peduncles are about two-thirds the total length of the lateral antennæ. The submedian peduncles show twelve annulations in addition to the distal collar-like portion into which the flagellum is inserted.

In the above proportions it will be noted that the lateral antennæ resemble those of *Onuphis basipicta*. The frontal antennæ are short and fusiform. The subulate tentacular cirri are inserted behind the submedian antennæ and slightly exceed the length of the buccal segment. The branchiæ commence as a simple filament on the first foot and continue simple on the first 17 parapodia, becoming bifid thereafter and considerably longer than the dorsal cirri. The first dorsal cirrus is tumid at the base, rather shorter than the first gill-filament, equal in size and shape to the posterior ligule of the first foot.

The setæ of the first foot do not afford such satisfactory distinction when compared with the corresponding setæ of *O. basipicta* as might have been hoped. There is a bundle of internal setæ associated with the dorsal cirrus; then three stout aciculæ ending in narrow flexible points; next several slender quasi-compound setæ like those of *O. basipicta*, but in some of them the third tooth is absent. Besides these setæ there are two stout setæ, tridentate (one damaged), which are not compound (Plate IV., fig. 100). These clearly represent the acicular setæ in the first foot. A parapodium from the anterior half of the body contains three aciculæ, a bundle of simple capillary setæ, two bidentate acicular setæ, and a small bundle of internal capillary setæ associated with the dorsal cirrus, passing nearly to the apex of the cirrus. The width of the worm is 3 millims.; the median antenna stretches back over 7 segments.

Onuphis holobranchiata, Marenzeller—Plate IV., fig. 101.

Station V., off Chilaw, Gulf of Manaar, 11 fathoms.

One specimen contained in a membranous tube coiled up between the valves of a Lamellibranch, adhering to one of the valves (Plate IV., fig. 101). The length of the coiled mass was 13 millims.; calcareous particles adhered to the borders of the tube; the whitish end of the tube projected beyond the posterior edge of the shell, like a siphon, to the length of 21 millims.; diameter 2·25 millims., a few shell-fragments and other calcareous débris attached. No part of the worm protruded from the mouth of the tube. After extraction of the anterior portion of the worm, which broke away from the rest of the body, it proved to be an Onuphid allied to *Onuphis holobranchiata*, Marenzeller.

The submedian ceratophores show about 10 annulations and a terminal collar; they are less than one-fifth the total length of the appendages; half as long again as the median ceratophore and equal to the lateral. The lateral ceratophores are half the total length of the appendages to which they belong. The median antenna stretches back over 21 segments, but the body has a dorsal flexure in the preserved state; the submedian antennæ are longer than the median. The frontal antennæ are obtusely subulate, coloured brown at the base. The tentacular cirri are shorter than the buccal segment, which is rather longer than the prostomium, and has a concave anterior dorsal border.

The first four parapodia are porrect, decreasing in size to the fourth, and occupying a ventral position. After the fourth, the line of parapodia bends up in a conspicuous arc to a more dorsal position. The first foot is not greatly enlarged, not longer than the buccal segment; the dorsal cirrus and posterior ligule are equal and similar and longer than the bulk of the foot. The unifilar branchiæ commence on the first foot. The first foot contains a small bundle of fine setæ passing to the dorsal cirrus, two aciculæ and four tridentate compound setæ. A parapodium from the region between the 40th and 50th segments contains, besides the internal setæ of the dorsal cirrus, four or five capillary setæ, three scalprate or comb setæ, four aciculæ, and two bidentate acicular setæ.

There are two discrepancies between the above description and that furnished by Marenzeller ('Südjapan. Ann.,' i., 1879, p. 24), and, in addition, the peculiar character of the habitaculum has not been described before. According to

Marenzeller, the buccal segment is three times as broad as long, and the tentacular cirri equal it in length. This feature may be attributed to the method of preservation. The second point relates to the lateral ceratophores which according to the author of the species are nearly twice as long as the submedian. This may be an individual variation, an abnormality, or the distinction of a local race. Unfortunately the length of the lateral ceratophore, in proportion to the total length of the antenna, is not stated. The calcareous ends of the laminæ ventrales of the jaws show an emarginate frontal border, agreeing closely with von Marenzeller's figure.

Hyalinœcia camiguina, Grube.

Grube, 'Ann. Semp.,' 1878, p. 142.
C. Crossland, "Maldive Polychæta," 'P. Zool. Soc. London,' 1904, p. 281.

Localities:—Several specimens, Station XXV., $\frac{3}{4}$ mile west-north-west of Foul Point, Trincomalee, 8 fathoms. Station XLIII., off Kalutara (Kaltura); one specimen in company with *Pectinaria* tubes. Station XLV., off Panadure; several specimens.

The tubes, 65 millims. to 70 millims., are faintly ringed at intervals of about 2 millims., and sometimes the annulation shows the double crescentic arrangement described by Grube. In the Ceylon specimens, the branchiæ commence almost constantly on the 22nd foot (23rd segment); once I found the first gill on the right side on the 21st foot. I only observed aciculæ with simple blunt rounded apices protruding from the first modified parapodium, but in the second foot may be found bidentate aciculæ and a compound seta as figured by Crossland, as well as acuminate forms. This species is closely allied to *H. tubicola*, of which it is clearly a local representative. A full account of the hyaline tube which is guarded internally by valves has been given by Mr. Arnold T. Watson ("On the habits of Onuphidæ," 'Trans. Liverpool Biol. Soc.,' vol xvii., 1903, p. 303).

Family: EUNICIDÆ.

Eunice afra, Peters (1855).

Crossland, "Polychæta of Zanzibar," 'P. Zool. Soc. London,' 1904, vol. i., p. 289.

(1.) Station V., off Chilaw, Gulf of Manaar, 11 fathoms. In this specimen branchiæ commence on the 19th foot, becoming successively 3-filar, 4-filar, and 6-filar, decreasing behind and leaving about 30 abranchiate posterior segments; they are inconspicuous, barely stretching halfway to the mid-dorsal line; body flattened and ribbon-like behind the anterior branchiferous region; length 75 millims., width 5·5 millims.

(2.) Galle, 14th February, 1902. Fragment of anterior region; gills begin as a bud on the 16th foot and rapidly attain the maximum of 5 filaments; calcareous caps of laminæ ventrales present; pale collar on the fourth setigerous segment; prostomial tentacles with violaceous annulations; body-colour of preserved specimen dark olive-green; width over the setæ, 5 millims.

Eunice antennata, Savigny.

Crossland, "Polychæta of Zanzibar," 'P. Zool. Soc. London,' 1904, vol. i., p. 312.

Locality :—South-east Cheval Paar, on pearl oysters, very numerous.

The pectinate branchiæ commence on segment VIII. (6th foot), the first gill is multifilar; they diminish towards the middle and then increase again both in size and number of filaments posteriorly. In some specimens small branchiæ commence on the 5th foot, in others on the 7th foot, very rarely on the 3rd and 4th foot. Antennæ and cirri moniliform. The acicular setæ show a third smaller tooth over the two main prongs; the compound setæ of the posterior feet are characterised by the presence of a third denticulation in a similar position to that in the acicular setæ.

Eunice coccinea, Grube.

Crossland, "Polychæta of Zanzibar," 'P. Zool. Soc. London,' 1904, vol. i., p. 297.

Station V., off Chilaw, Gulf of Manaar, 11 fathoms, two specimens.

The differentiation of this species from *E. afra* depends chiefly upon examination in the fresh condition. The colour is leucostict, but *E. leucosticta* is regarded as a synonym of *E. afra*. There is a pale collar on the 6th segment, so there is in *E. collaris*, which is another synonym of *E. afra*. Branchiæ commence on 13th foot, biramous on 15th, triramous and greatly exceeding the dorsal cirrus from 20th to 50th, long unifilar on 60th, decreasing and ceasing about the 90th, leaving upwards of 70 posterior segments without branchiæ and with rudimentary dorsal and ventral cirri. Another broken specimen had quadrifilar branchiæ. Complete specimen small, coiled, about 45 millims. long, width of anterior gill-bearing region 3 millims.; segments about 170; compound setæ normal; acicular setæ bidentate.

All characters are misleading except the shape of the body; the head is narrow, the body widening out markedly in the anterior region; the hind-body is rounded, not flattened; the intersegmental grooves are coloured brown. The general form of the body decides me to refer the present specimens to *E. coccinea*. *E. coccinea* apparently bears the same relation to *E. afra* that *E. murrayi* does to *E. antennata*.

Eunice indica, Kinberg.

Gravier, *op. cit.*, 1900, p. 242; Crossland, *op. cit.*, 'P. Zool. Soc. London,' 1904, p. 318.

Station V., off Chilaw, 11 fathoms, one small specimen, incomplete behind.

Prostomium seen from above with frontal border entire; tentacles smooth; compound setæ with projecting guards, best seen in the branchial segments; acicular setæ from the postbranchial segments with trifid tip, the apex equally bidentate, and a large subapical tooth.

Another specimen was associated in the trawl with *Phyllochætopterus ramosus* from Galle, Station XXXVIII., 17th February, 1902, depth 22 fathoms.

Eunice martensi, Grube—Plate IV., figs. 102 to 104.

Grube, "Mitth. über Euniceen," 'Schles. Ges.,' 1877; Breslau, 1878, p. 24.

Locality:—One specimen, labelled "Purple violet Eunice," taken from Buoy, Galle.

The dorsum of the 6th segment is pale; segments streaked longitudinally violaceous; antennæ and cirri banded violaceous and white. Segments 178, incomplete behind; length 100 millims.; width (ventral) over the feet 8 millims., over the setæ 10 millims. Antennæ nearly smooth, quasi-articulate, cirri smooth; tentaculum impar and submedian antennæ equal to seven segments, but the former ends bluntly and has probably been longer; dorsal cirri long throughout and smooth.

Branchiæ begin as a bud on the 7th segment (5th foot), plurifilar on the 8th, in subsequent segments acquiring 14 filaments; in the 17th segment the branchial stipe is shorter than dorsal cirrus, in the 28th it is equal to the cirrus, and in the 48th longer than the cirrus (Plate IV., fig. 102). The general distribution of the branchiæ and the number of filaments will be understood from the following enumerations, the Roman numerals giving the number of the segment:—

VII.,	VIII.,	XVII.,	XXVIII.,	XLVIII.,	LX.,	LXXI.,	CXIV.,	CXL.,	CLXX.
1.	4.	13.	13.	14.	14.	14.	12.	10.	5.

In the anterior segments there are 8 or 9 dorsal capillary setæ and about 20 compound falcigerous bidentate setæ in the ventral fascicle (Plate IV., fig. 103); the two-pronged ventral acicular setæ commence at the 35th foot (Plate IV., fig. 104); comb-setæ (scalprate setæ) more numerous posteriorly, with about 12 denticulations.

Jaws:—R. II.–6; L. II.–6; L. III. (the unpaired sinistral jaw-piece)–7; R. IV.–9; L. IV.–4.

This species belongs to that section of *Eunice* characterised by multifilar branchiæ and long dorsal cirri extending from end to end of the body. The type of this section may be taken to be *E. tentaculata*, Quatrefages (1865, i., p. 317), from South Australia (Bass Strait, Tasmania). Another example is the original *E. elseyi*, Baird (1870), from Queensland (not *E. elseyi*, McIntosh), which is synonymous with *E. aequabilis*, Grube, 'Schles. Ges.,' 1877, Breslau, 1878, p. 24, from Cape York.

Eunice murrayi, McIntosh.

Crossland, "Polychæta of Zanzibar," *op. cit.*, 1904, p. 310.

(1.) Station XLV., off Panadure (Pantura), depth 25 fathoms, inhabiting a tube on the under side of a *Spondylus* valve; a polynoid was in the same tube.

Prostomium wide, frontal border deeply emarginate; antennæ moniliform; the tentaculum impar longe-articulate, stretching back over 18 segments; gills with 12 pinnæ; guards of compound setæ slightly projecting; total width in anterior region, 4 millims. The tube which accompanies the specimen is encrusted with sand and Foraminifera.

(2.) South-east Cheval Paar; occurring with *Eunice antennata*.

Branchiæ commence unifilar on segment V. (3rd foot), trifilar on VI. and VII., sexfilar on VIII., then multifilar; they decrease rapidly after the 30th foot and cease after the 43rd. Antennæ submoniliform, impar stretching over 11 segments. Setæ normal; acicular setæ trifid, as many as four in the posterior segments.

Eunice siciliensis, GRUBE.

GRAVIER, "Ann. Mer Rouge," 'Arch. Mus. Paris' (4 ser.), ii., 1900, p. 261.
CROSSLAND, 'P. Zool. Soc. London,' 1904, p. 323. [= *Eunice valida*, GRAVIER.]

Station V., off Chilaw, Gulf of Manaar, 11 fathoms. Also from South-west Cheval Paar, 13th November, 1902.

Branchiæ commence on the 62nd setiger and remain simply filiform throughout. This well-known and widely distributed species can be recognised by the incurved rami of the lower jaw-plates.

Eunice tubifex, CROSSLAND.

Station LIX., Muttuvaratu Paar, without tube.

This is a worm of large size, one specimen measuring 120 millims. by 5 millims. It is distinguished by the occurrence of spinigerous setæ in the anterior segments and falcigerous setæ in the posterior region. I have nothing essential to add to the excellent description given by Mr. CROSSLAND ('P. Zool. Soc. Lond.,' 1904, p. 303).

The branchiæ commence as a small bud on the 20th segment and continue as a single filament, increasing in length to the 45th segment, after which a second filament appears. By the 100th segment there are still only three filaments; by the 200th there are four long filaments. Further back the number of branchial filaments increases to five, all arising from a very short axis; filaments subequal, much longer than dorsal cirrus; the latter increases somewhat posteriorly.

Some statements in a footnote on p. 308 of Mr. CROSSLAND's paper require to be modified. SCHMARDA's account of *Eunice depressa* from Auckland, New Zealand, which also possesses the two kinds of compound setæ, is fuller than many of his descriptions; this worm is, however, a *Marphysa*, since, as shown and stated by SCHMARDA, tentacular cirri are absent. GRUBE named two species of *Eunice* with spinigerous setæ from the Philippines, namely, *E. impexa* and *E. megalodus*, but records no distinction between the anterior and posterior setæ.

There is a headless fragment over 150 millims. long accompanying the specimen above described.

Marphysa chevalensis, n. sp.

Locality :—South-east Cheval Paar, Gulf of Manaar.

This species belongs to the same group as *Marphysa depressa* (SCHMARDA, 'Neue Wirbellose Thiere,' ii., 1861, p. 127, New Zealand) and *M. fallax*, MARION et BOBRETZKY

('Ann. Marseilles,' 1875, p. 13). Its interest lies in its occurrence here, not in its supposed differences from its two allied forms, since there are no differences which are figurable. The character of the group depends upon the presence of two kinds of compound setæ, spinigerous and falcigerous, in the parapodia. The special feature of the Ceylon representative depends upon the distribution of the branchiæ. Length 25 millims., width 2·75 millims.; 104 setigerous segments.

The frontal border of the prostomium is emarginate and the division is continued as a shallow median groove along the dorsal surface of the head. Branchiæ commence as a small filiform process on the 11th foot, uniramous from 11th to 19th foot, biramous from 20th to 25th, triramous from 26th to 68th, decreasing and ceasing at the 85th foot. Dorsal cirri fusiform, decreasing in size posteriorly. Anal cirri subulate, smooth, with ring of brown pigment at base; ventral anal styles minute filiform. Compound setæ, falcigerous and spinigerous, the spiniform appendices longer and shorter; both kinds of setæ occur together from the first parapodium, but in the specimen now being described only the spinigerous form was observed in the posterior segments.

In the anterior parapodia a dorsal fascicle of limbate capillary setæ, a central group of three aciculæ and the ventral fascicle of compound dimorphic setæ; in the posterior parapodia the dorsal fascicle contains limbate and scalprate setæ; there is a central group of two aciculæ, a ventral fascicle of compound setæ and a ventral bidentate acicular seta. A second specimen, darker coloured, anal cirri black, showed both kinds of setæ in the posterior feet; branchiæ from 10th to 55th foot; maximum number of three filaments observed on one foot only; length 9 millims.; width nearly 2 millims; segments about 73.

Paramarphysa orientalis, n. sp.—Plate IV., fig. 105.

Locality:—South-east Cheval Paar, Gulf of Manaar. Several specimens.

Length 21 millims., width 1 millim.; 91 setigerous segments.

Prostomium almost entire, a shallow groove only dividing the front; antennæ short, about the length of the prostomium, tentaculum impar somewhat longer. There is an eye-spot on each side of the head between the bases of the submedian and lateral antennæ. Bidentate ventral acicular setæ begin on the 26th foot; a segment or two behind this the main aciculæ become dark coloured; there may be two acicular setæ in the posterior parapodia. The superior fascicle of capillary setæ shows slight difference in anterior and posterior regions, the limbate tract being shorter and more convex behind; comb-setæ with long marginal laciniæ occur as far forwards as the 9th foot. The compound bidentate falcigerous setæ are normal, not markedly different in front and behind, distinguished by the slight inflated appearance of the end of the shaft (Plate IV., fig. 105).

Only one other species of *Paramarphysa* has been described to my knowledge, namely, *P. longula*, Ehlers ('Florida Ann.,' 1887, p. 99).

Lysidice collaris, Ehrenberg and Grube.

Grube, 'Ann. Semp.,' 1878, p. 166; Gravier, 'Arch. Mus. Paris' (4 ser.), ii., 1900, p. 272. Crossland, 'P. Zool. Soc., London,' 1904, p. 284.

Station V., off Chilaw, Gulf of Manaar, 11 fathoms. One specimen; length about 15 millims. Several other specimens in the collection.

Nematonereis unicornis, Schmarda.

Schmarda, 'Neue Wirbellose Thiere,' ii., 1861, p. 119. (Atlantic Ocean.)

Locality:—South-west Cheval Paar, Gulf of Manaar. Two specimens.

In the smaller specimen the head is entire and rounded; in the larger slightly emarginate; a pair of large eyes at the back of the head and between them a small occipital tentaculum impar about the same length as the prostomium. There are no tentacular cirri; no branchiæ; two achætous buccal segments. The larger specimen is a mature female.

In the parapodia the dorsal cirrus is short, subulate, about as long as the pharetra setarum; a central acicula separates the setæ into superior and inferior groups, the former consisting of simple capillary setæ, the latter of compound, bidentate, falcigerous setæ. In the posterior bundles there is also a guarded bidentate acicular seta, the subterminal tooth much larger than the apical tooth. The jaws are pale and normal:—II. 5–4, III. 4.

Family: LUMBRICONEREIDÆ.

Aglaurides fulgida (Sav.)—Plates IV. and V., figs. 106 and 107.

Gulf of Manaar. Several specimens.

The largest measured as much as 7 inches in length, a few segments missing behind; dorsum very convex; width 5 millims.; width including setæ nearly 9 millims.; segments narrow and very numerous; dorsal cirri large, foliaceous; head rounded to triangular in shape.

The characterisation of the cirrobranchiate Eunicea is at present somewhat obscure, and it is not rendered less so by the fact that the present species agrees identically with Schmarda's *Œnone diphyllidia* from Jamaica in respect of the size and shape of the dorsal cirri, the buccal and the parapodial armatures.* (Plate V., fig. 107.)

The buccal segment is of double nature, as in *Lumbriconereis*, the intersegmental groove being plainly visible at the sides and continued forwards to the edge of the mouth, so that the processus oralis of the second segment borders the mouth below. Dorsally the buccal segment lies over the back of the prostomium like a collar, the groove between the collar and the head deepening into a profound sinus, in which three minute papilliform occipital tentacles are occluded. In front of the tentacles there are four eyes, two large lateral eyes and two small submedian eyes, the latter

* *Cf.* Ehlers, 'Florida-Anneliden,' 1887, p. 109, Taf. 34.

sometimes simple, sometimes multiple (Plate IV., fig. 106). The arrangement of the eyes is the same as in *Œnone diphyllidia*, and they can easily be found by raising the margin of the collar. The presence of the antennæ or occipital tentacles is the one feature in which *Aglaurides* is believed to differ from *Œnone*, and in view of the absolute identity of the other parts this divergence appears remarkable.

In *Aglaurides*, especially if the material be well preserved, the mere pulling back of the collar will not always suffice to discover the prostomial tentacles. I have found it necessary to divide the collar by a longitudinal incision before the antennæ come into view. They are extremely fugitive structures, not too easily found even in half-macerated examples, so deep do they lie within the recesses of the nuchal sac. In *Aglaurides erythrœensis* recently described by GRAVIER ['Arch. Mus. Paris' (4th ser.), t. ii., 1900, p. 278] from the Red Sea the character of the jaw-pieces seems to differ from that of the corresponding parts in *A. fulgida*. The reader is left with the impression, that while "les pièces correspondantes sont plus développées à droite qu'à gauche," yet on the whole they are subequal, and only one half is figured on the plate. Otherwise the species is indistinguishable from *Aglaurides fulgida*, the shape of the head varying as mentioned above. The author does not mention the radices maxillarum, which in *A. fulgida* are very long, longer than the rest of the upper jaw, as in *Maclovia* and *Halla*, not short as they are in *Lumbriconereis* and *Lysarete*.

In addition to the characters presented by the antennæ and the details of the jaws as described and figured by EHLERS ('Borstenwürmer,' 1868, p. 408) the genus *Halla* (= *Cirrobranchia*, EHLERS) differs from *Aglaurides* in having two entire apodous segments behind the head, a peculiar processus oralis being furnished by the first segment. *A. fulgida* has been recorded from Ceylon by MICHAELSEN, 'Jahrb. Hamburg. Wiss. Anst.,' ix., 2, p. 99).

Aracoda obscura, n. sp.—Plate V., figs. 108 to 112.

Station XLIII., off Kaltura. A single specimen, incomplete behind, 16 millims. long, 1 millim. wide, in an empty *Pectinaria* tube.

Colour nearly black, with strongly iridescent tough cuticle. Prostomium pear-shaped or conical, nearly equal to the four next segments (Plate V., fig. 111); two distinct achætous segments in front, without processus oralis of the second segment. The usual long posterior ligule on the parapodia. There are six or seven simple curved limbate setæ in the parapodium; in some the limbus is nearly plain, in others denticulate as shown in Plate V., fig. 112. The dilated portion of the setæ is finely and obliquely striated.

The only way to identify the species of this and allied genera of *Lumbriconereidæ* is by the character of the jaws. These are black and overlap, consequently they are difficult to see in themselves and not easy to prepare from such a small specimen. The principal feature in this case is provided by the jaw-pieces of the first pair which are subequal and without a special terminal hamulus distinct from the dentate portion (Plate V., fig. 108). The jaw-pieces of the second pair are the most difficult to make out satisfactorily; one side, so far as I could ascertain, showed three large teeth, and a long edentulous shaft reaching back to the radices maxillarum (Plate V., fig. 110); on the other (probably the left) side the second jaw-piece, which was fractured near the apex, showed a strong apical tooth and a long posterior dentate portion (Plate V., fig. 109). There are, as usual, five pairs in all, the fifth being a simple hamulus. As stated above, the diagnostic character is the absence of a pronounced diastema between the apical tooth and the succeeding teeth of the first pair of jaws.

FAMILY: GLYCERIDÆ.

Glycera lancadivæ, SCHMARDA—Plate V., figs. 113 to 116.

SCHMARDA, *op. cit.*, 1861, p. 95; MICHAELSEN, 'Jahrb. Hamburg. Wiss. Anst.,' ix., p. 102.

Locality:—Galle, 14th February, 1902. Two specimens.

This species is a representative in these waters of the Atlantic *Glycera capitata*, and is characterised by the absence of branchiæ and by the biligulate anterior lip of the parapodium, the posterior lip being rounded and slightly emarginate. It appears to present a dimorphism analogous to that existing between *G. capitata* and the variety *G. setosa*. In the typical form the parapodia are longer than in the second form; we may refer to these as A and B respectively. In both, the body segments are biannulate, and there are two kinds of compound setæ differing in the structure of the articular end of the shaft; in one kind the transparent guard projects beyond the edges of the cup, in the other the guard is level with the cup and shows fine sulcations (Plate V., figs. 113 and 114). In form A, the ligules are fusiform and approximately equal in bulk, the ventral ligule rather longer (Plate V., fig. 115). In form B, the ligules are obtuse and the ventral ligule, besides being longer, has about twice the bulk of the dorsal ligule (Plate V., fig. 116). If these specimens had been taken at different times and places they would probably have been described as separate species. The extruded proboscis (form B) is covered with minute papillæ arranged irregularly, and of two kinds, acuminate and rounded, the former greatly predominating. Length of specimen of form A (incomplete behind), upwards of 60 millims.; form B, complete with subulate anal cirri, 45 millims. long, including the proboscis (7 millims.).

FAMILY: SPIONIDÆ. [See also p. 325.]

Polydora hornelli, n. sp.—Plate V., fig. 117.

From pearl oysters, Gulf of Manaar.

It is hard to say whether this species is really distinct from *Polydora ciliata;* the differences, so far as can be judged from preserved material and published records, are very slight, but such as they are, they seem to afford ground for separation when taken in conjunction with the geographical distribution and the character of the host.

The general appearance of the anterior end resembles that figured by CARAZZI* for *P. ciliata*. The ground colour is chocolate brown, and this pigment occurs upon the peristomium and upon the greater part of the caruncle; the latter projects beyond the front of the peristomium, terminating in two rounded lobes, divided from one another by a shallow notch. The proportions of the caruncle are characteristic; it is inserted over the length of the peristomium and over the first two segments of the trunk; in the region of the first setigerous segment there is a slightly dilated pale area causing an interruption of the brown pigment; there is a patch of pigment in the centre of this area which I shall call the ocular area, although I could not distinguish definite eye-spots; on each side of the ocular area on the dorsum of the first setigerous segment, midway between the caruncle and the margin of the body, there is a very small cirrus; at the outer margin of the same segment, on each side, there is another cirriform appendage, below which occurs a capillary fascicle; the latter appendage is shown in CARAZZI's figure, but not the former; the portion of the caruncle in front of the ocular area is longer than the portion behind it. The remaining segments of the body carry notopodial and neuropodial setæ, the 2nd, 3rd, 4th and 6th segments with capillary setæ only. The notopodial setæ of the 5th setigerous segment are modified, consisting of an oblique row of eight large brown acicular setæ with two not fully formed in reserve, each acicular seta being accompanied by a delicate colourless spatulate seta. The acicular setæ of the 5th segment differ from those figured by CARAZZI for *P. ciliata;* in *P. hornelli* these setæ are not toothed, but a convex limbus or vane occurs below the curved apex (Plate V., fig. 117). [See Mr. ARNOLD WATSON'S "NOTE" on p. 325—W. A. H.]

From the 7th segment the neuropodial series of capillary setæ are replaced by a single row of about a dozen bidentate guarded acicular setæ not differing in structure from those of *P. ciliata* as figured by Professor McINTOSH in 1868.† The branchiæ also commence on the 7th setigerous segment, but the material is so fragmentary that I cannot say where they end. The diameter of a large specimen is 1·5 millims. No other dorsal setæ beyond the modified setæ and their spatulate attendants were observed in the 5th segment, but a bundle of very delicate neuropodial setæ occurs at their base. The 5th segment is firm and the fore-body porrect. The 2nd, 3rd, 4th, and 6th setigerous segments carry a short cirriform notopodial ligule behind the dorsal fascicle. The long peristomial tentacles are lost from most of the specimens.

FAMILY: CAPITELLIDÆ.

Notomastus zeylanicus, n. sp.—Plate V., figs. 118 and 119.

Locality:—East Cheval Paar, 8 fathoms.

Anterior fragment of small individual. The first two segments are achætous; the

* D. CARAZZI, "Revisione del genere *Polydora*, BOSC, e cenni su due specie che vivone sulle ostriche," 'Mitth. Zool. Stat. Neapel,' xi., 1893, see Taf. ii., fig. 4.

† See also T. WHITELEGGE, "Report on the Worm Disease affecting the Oysters on the Coast of New South Wales," 'Rec. Austral. Mus. Sydney,' 1890, vol. i., No. 2.

eleven following segments are biannulate and carry dorsal and ventral fascicles of capillary setæ. The unciniform setæ commence on the 14th segment, the dorsal torus containing a single row of 19 setæ, the ventral torus a single row of 34 (Plate V., fig. 119). From the mouth projects a median tongue-like lobe. The head is half withdrawn into the buccal segment, but by pressing the latter backwards an acervus of eye-spots at the side of the head can be seen (Plate V., fig. 118).

Family: OPHELIIDÆ.

Armandia lanceolata, n. sp.—Plate V., fig. 120.

Locality:—South of Manaar Island, 8 to 9 fathoms.

One specimen about 17 millims. in length; 29 pairs of parapodia, the last three or four of which are very small; 22 pairs of cirriform branchiæ commencing on the 2nd setigerous segment; eleven pairs of lateral eyes situated in front of the parapodia from segments VII. to XVII. inclusive; no cephalic eyes observed. This is a slender worm 1 millim. in diameter; body pale.

Ophelioids of this group show a striking resemblance to *Amphioxus* in shape, size, habits, distribution, consistency, translucency, and movements. This has been remarked previously by Lo Bianco (1893) in the case of *Armandia polyophthalma* and by me (1896) in New Guinea waters.* Although infinitely removed from each other in morphology, *Armandia* and *Amphioxus* are closely approximated in bionomics. It is a case of true homoplasy; there is no question of affinity, nor of mimicry, nor of parallel evolution.

The ventral musculature in this species is so arranged as to cause two prominent longitudinal ventro-lateral ridges, like metapleural folds, extending uninterruptedly from the mouth to the base of the anal siphon, leaving a narrow deeply depressed median ventral tract, the neural groove, between them; and a lateral groove above on each side of the body in which the parapodia lie. The branchiæ can be kept lengthwise lodged within the lateral groove. The anal siphon is a narrow membranous tube terminating in a circular orifice fringed by not less than 12 subulate papillæ, subequal.

In *Armandia leptocirrus*, Grube ('Ann. Semp.,' p. 194) there are 33 pairs of gills,† a pair to each of 34 segments excepting the first; the lateral eyes are said to commence on the fifth setigerous segment and to occur on the ten following segments. Sometimes the eyes may be absent or lost from some of the ommatophorous segments. In this specimen of *A. lanceolata* they are complete on the right side, but on the left side missing from the 11th to 13th segments. The first eye occurs on the 7th setigerous (6th branchiferous) segment, the last on the 17th setigerous (16th branchiferous) segment. The anal siphon has a marked ventral flexure in the

* Cav. Lo Bianco, 'Atti Acc. Napoli,' v., 1893; A. Willey, 'Quart. Journ. Micro. Sc.,' vol. 39, August, 1896, p. 219.

† Given as 22 pairs by a misprint.

preserved specimen. The simple capillary setæ issue in two bundles, a dorsal bundle of five long setæ and a ventral bundle of about eight shorter setæ.

The anterior end of the body is produced as a transparent rostrum which terminates in a white appendix (Plate V., fig. 120). The mouth lies below on the level of the base of the rostrum, and the paired nuchal organs occur behind at a distance from the mouth, equal to the latter's distance from the frontal extremity. The long simple gills are traversed by blood-vessels.

Armandia leptocirris, Grube. ('Ann. Semp.,' 1878, p. 194.)

Locality:—Cheval Paar, Gulf of Manaar.

This species is twice as bulky as *A. lanceolata.* The essential differences are not easy to specify by the examination of preserved material only. Length 21·5 millims., diameter 2 millims.; 37 setigerous segments; 27 gills, commencing at the second setigerous segment; 20 marginal anal papillæ, larger and smaller intermixed; 14 lateral eyes, commencing in front of the 6th gill. Nuchal organs lie in front of the mouth; metapleural ridges commence at the sides of the mouth. The most striking feature of the specimen here described is the occurrence of several small cirriform papillæ protruding from the buccal orifice. Notopodia and neuropodia minute, contiguous.

Another example from Modragam Paar does not show the buccal papillæ protruding.

Polyophthalmus australis, Grube—Plate V., fig. 121.

Two specimens from east side of Cheval Paar, one measuring 15 millims. long by 1 millim. wide; the other 8 millims. by 0·5 millim.

The setæ are extremely delicate and not obvious at first examination. The head is rounded, the body with characteristic pigment markings figured by Grube ('Ann. Semp.,' p. 196), and the anus is surrounded by a circlet of papillæ. The body has the consistency of that of an *Ophelia.* When placed in fluid of different density from that in which it had been kept, it twitched convulsively like a Nematode.

In the smaller specimen there are 26 setigerous segments, capillary setæ in separate dorsal and ventral fascicles, the latter issuing from a convex crateriform elevation. The ciliated apparatus of the head, not figured by Grube, is shown on Plate V., fig. 121. The lateral eyes were not distinct.

Family: FLABELLIGERIDÆ.

Stylarioides parmatus, Grube—Plate VIII., fig. 5.

Stylarioides parmatus, Grube, 'Ann. Semp.,' 1878, p. 199.
Stylarioides iris, Michaelsen, 'Jahrb. Hamburg. Wiss. Anst.,' ix., p. 108.

Muttuvaratu Paar. Four specimens, one very small.

The distinction between *S. iris* and *S. parmatus* is based upon the number of long and gorgeously iridescent setæ of the second segment. These are disposed round the head in four bundles ; each bundle may contain up to 10 setæ. GRUBE found only six setæ in each bundle. The setæ of the third segment are much more slender and shorter than those of the second, but equally numerous, though the number of setæ in both these segments varies, probably in many cases through accidental loss. The caudal extremity of the body may be recurved as in *Pallasia*, as noted by Mr. WATSON, but, unlike *Pallasia*, the segments are all setigerous (Plate VIII., fig. 5).

FAMILY: MALDANIDÆ.

This family may be divided into three sub-families :—Clymeninæ, Rhodininæ, and Nicomachinæ. For the identification of the worms belonging here it is essential that the whole body should be preserved. There is a fragment of a Nicomachine Maldanid, of which only the six anterior setigerous segments have been preserved, obtained in 14 fathoms to the west of the northern end of the Periya Paar at Station LXI. In the absence of the anal segment it is unfortunately impossible to assign it to its proper genus with any certainty.

Nicomache truncata, n. sp.—Plate V., figs. 122 and 123.

Its head is extremely characteristic, the front vertical with a median crest widening out below into a transverse ridge which overhangs the mouth (Plate V., fig. 123). The peristome is indistinguishably fused with the prostomium, and the two together compose a remarkably short head. This is followed by a short first setigerous segment with the capillary fascicle in the centre ; next a slightly longer segment with the capillary fascicle nearer to the anterior than to the posterior border ; thereafter the segments become elongated, the setæ and tori occupying an anterior position in each segment. Below the first and third capillary fascicles there is a large acicular seta ; below the second there are three acicular setæ on the left side, one only on the right (Plate V., fig. 122).

FAMILY: AMMOCHARIDÆ.

Ammochares orientalis, GRUBE—Plate V., figs. 124 and 125.

GRUBE, 'Ann. Semp.,' 1878, p. 204.

Station LIV., south of Adam's Bridge, 4 to 40 fathoms. One specimen.

Total length 28 millims., width 1·5 millims., tapering to less than half this size behind. Length of the laciniate gills, 2 millims. ; length of first segment 2·5 millims., of second 3 millims., third 3·75 millims., fourth 3·25 millims., fifth 2·5 millims. Total number of setigers 22 pairs ; the last eight segments are quite short and were detached from the rest of the body. The first uncinigerous torus occurs below the fourth capillary fascicle. The œsophageal nerve-collar becomes confluent with the ventral nerve-cord in the region between the first and second fascicles (Plate V., fig. 124).

The first segment is a composite one, comprising three pairs of capillary fascicles unaccompanied by uncinigerous tori; of these the third pair has not been noticed by GRUBE (Plate V., fig. 125). On the dorsal side in the middle line, slightly in advance of the first pair of fascicles, there is a peculiar nuchal organ flush with the surface of the body (Plate V., fig. 125). The uncini are arranged in a polystichous manner in the tori; as many as 20 rows of peculiar minute uncini of a type best defined as ammocharine; when examined *in situ* they look like the separated teeth of multidentate uncini. The capillary setæ are linear, non-limbate, finely squamose towards the acute apex.

Tube tough, mucoid, encrusted with sand grains which are arranged with considerable regularity in an imbricating manner. Wider in front, tapering behind, the tube is much longer than the contained worm, being about 60 millims. The lips of the anterior and posterior orifices are approximated at their respective ends, so that the openings of the tube appear closed. The specimen was taken in company with *Panthalis nigromaculata*. The structure and habits of the Ammocharidæ form the subject of a paper by Mr. ARNOLD T. WATSON in 'Journ. Linn. Soc.,' Zoology, vol. xxviii., 1901, pp. 230–260, plates 23–25.

FAMILY: CHÆTOPTERIDÆ.

Chætopterus appendiculatus, GRUBE—Plate V., fig. 126.

GRUBE, "Ann. Ceylon" (Holdsworth coll.), 'P. Zool. Soc. London,' 1874, p. 328.
HERDMAN, 'Ceylon Pearl Oyster Report,' Part I., 1903, p. 80.

Locality:—Station LXII., near Periya Paar, 7 to 13 fathoms.

There are ten thoracic segments, the last two carrying uncinigerous tori and the last bearing a large aliform notopodium. The penultimate thoracic tori are separated by a deep median ventral notch; the last thoracic tori are confluent across the middle line. Uncini of the last thoracic torus mostly 6-dentate, some 5-dentate; uncini of a ventral abdominal torus 8-dentate.

In GRUBE'S original description, which was based upon a large specimen 124 millims. long, the tube measuring 364 millims. by 22 millims. in diameter, the uncini of the posterior ventral tori are said to have nearly 20 teeth. This is a large number for *Chætopterus*, twice the normal number,* and might conceivably be due to the uncini lying appressed, end to end, as they frequently do.

Of the thoracic parapodia the first, fourth, and ninth are the shortest in the specimen under examination. The fourth contains seven broad modified setæ of the type characteristic of the family. In this case these setæ show a finely crenulate or beaded distal border (Plate V., fig. 126). The fore-body of the specimen measures 5·25 millims. long by 3·5 millims. broad, hence much smaller than MARENZELLER'S *Ch. cautus* from Japan, where the corresponding measurements were 20 millims. by 10 millims., and there were 20 to 30 chætopterine setæ in the fourth parapodium.

* *Cf.* CROSSLAND, "Maldive Polychæta," 'P. Zool. Soc. London,' 1904, vol. i., p. 276.

The tube is pergamentaceous, finely fibrous, thinly encrusted with mud and calcareous minutiæ. The posterior notopodia adhered firmly to the inner wall of the tube and were greatly elongated.

Phyllochætopterus herdmani (Hornell)—Plate V., figs. 127 to 132.

Spiochætopterus herdmani, Hornell, 'Ceylon Pearl Oyster Report,' Part I., 1903, p. 16.

Locality :—Galle shore, under stones.

Narrow cylindrical tubes encrusted with relatively coarse sand-grains and hard fragments of all kinds, including Foraminifera. The worms outside their tubes are soft and convoluted, and the hinder portion of the body is very fragile. The three regions of the body behind the buccal region are the thoracic region, with ten (in one case nine) setigerous segments ; the branchial region, consisting of two segments ; finally the abdominal region with as many as 40 to 50 segments. The ventral wall of the thoracic segments is thickened to form a large glandular cushion, and the lateral wall of each abdominal segment is marked by a long narrow brown tract between the dorsal and ventral divisions of the parapodium on each side ; sometimes this pigment tract is very dark. Above its dorsal end occurs the clavate notopodium, and below its ventral end the neuropodium, subdivided into two narrow uncinigerous lobes. The head is surrounded by an incomplete collar, open dorsally (Plate V., fig. 127) ; above and behind the dorsal ends of the collar occurs the second pair of tentacles, supported by a bundle of three long delicate internal setæ. The long spirally coiled tentacles of the first pair are inserted immediately in front of the second pair, and are still retained in some of the specimens.

The first parapodium contains about twenty spatulate or vane-tipped setæ, arranged in general in a single row, forming a dorsiventral monostich. The length and width of the vane varies ; sometimes it terminates in a point, generally its border is broken up into shreds (Plate V., fig. 131). The second parapodium resembles the first, and so does the third as a rule, but in one specimen there are five modified setæ (resembling those which usually occur only in the fourth parapodium) intercalated between the normal spatulate setæ (Plate V., fig. 129). The fourth parapodium contains, in addition to the spatulate setæ, eight or nine modified flattened setæ (Plate V., fig. 128). The remaining thoracic parapodia contain the usual setæ. A notopodium from the second branchial segment contains 16 or 17 long internal setæ in the inner division of it. The plan of a branchial segment is shown on Plate V., fig. 130. The borders of the notopodium below the distal expanded bifid portion are densely ciliated. The dorsal body-wall of the branchial region appears to be glandular.

Next to the notopodium comes a gill, a thin membranous expansion folded upon itself in the preserved specimen ; this passes below into a wing-like dermal fold with free surfaces and a thickened outer border, which is the uncinigerous torus. The uncini in a neuropodium of a branchial segment have 9 to 11 denticulations ; when

9 or 10 occur they are distinct, when 11 are present the apical tooth is very small. The abdominal notopodia carry a bundle of four spatulate setæ. The abdominal uncini show 10 or 11, perhaps sometimes 12 denticulations. All the uncini show the peculiar ribbed structure noted by previous authors in other species (Plate V., fig. 132).

This species is closely related to *Phyllochætopterus aciculigerus*, described by Crossland from the Maldive Group (' P. Zool. Soc. Lond.,' 1904, p. 278). The aspect of the anterior region varies greatly according to the state of the preserved material; when well protracted and hardened, it resembles the condition figured by Crossland for *P. elioti* from Zanzibar (*cf.* Plate V., fig. 127), except for the absence of eyes in *P. herdmani*.

In nine specimens there are ten pairs of thoracic parapodia, in one specimen nine pairs, the latter being the number given for *P. aciculigerus*. The principal substantial difference appears to be due to the presence in the last-named species of a glandular cirrus of uncertain homologies arising from the centre of the neuropodial tori of the first branchial segment.

Phyllochætopterus ramosus, n. sp.—Plate V., figs. 133 to 136.

Locality:—A thick cluster of slender brown translucent ramifying tubes (Plate V., fig. 133), overgrown and welded together by foreign incrustations of other tubicolous and colonial organisms and vegetable growths, trawled off Galle, at Station XXXVIII.

A fairly complete worm measures 25 millims. in length, its tube twice this length, and 1·5 millims. in diameter. The first region of the body consists of 15 segments; the fourth parapodium contains one, sometimes two broad flattened modified setæ (Plate V., figs. 134 and 135). The second or branchial region comprises about 16 segments. As the worms were all preserved inside their closely investing tubes, the branchial region is not preserved sufficiently well to show details clearly. Practically it may be distinguished from the third or abdominal region by its long styliform notopodia, each supported by not more than four internal slender setæ. The abdominal notopodia are clavate papillæ, each supported by a single seta. The long tentacles are coloured with brown patches which give them a banded appearance; they are followed by the small second pair of tentacles. The prostomium carries a pair of elongated eye-spots.

This species represents *P. pictus*, Crossland (' P. Zool. Soc., London,' 1903, p. 174), from which it differs in the character of the modified setæ of the fourth parapodia, the number of branchial segments and the character of the tubes. In the anterior branchial region the uncinigerous tori encircle the sides of the body, appearing like silver bands by reflected light. The uncini are excessively numerous in these bands, and are disposed in a polystichous manner, nine or ten closely packed rows. Each uncinus shows about twenty minute teeth, the lower end terminating in a blunt, curved process (Plate V., fig. 136).

Family: CIRRATULIDÆ.

Cirratulus cylindricus, Schmarda—Plate VI., figs. 139 and 140.

Schmarda, 1861, 'Neue Wirbellose Thiere,' ii., p. 59.

Localities :—Galle, East Cheval Paar, &c. Associated with *Eupomatus heteroceros*, *Eunice antennata*, &c.

The paired dorsal acervi of tentacular cirri occur on the fifth setigerous segment, a double row on each side separated by an interval across the middle line. The body is short and thick, simply flexed, not twisted, and equal at both ends; length 16 millims., diameter upwards of 3 millims.; setigerous segments 130. The head is round and short, crescent-shaped, the mouth gaping below. Capillary setæ commence on the fourth segment, the ventral acicular setæ appear on the 19th setigerous segment, the dorsal acicular setæ on the 23rd; the capillary setæ are continued to the end of the body.

In *C. dasylophius*, Marenz., the tentacular acervi occur on the dorsum of the third and fourth setigerous segments; the ventral aciculæ begin on the 29th, the dorsal on the 43rd. In *C. comosus*, Marenz., the tentacular acervi occur on the seventh setigerous segment; the ventral aciculæ begin on the 42nd, the dorsal on the 85th. Both these species are from South Japan. The acicular setæ afford no diagnostic character in themselves.

Another, and perhaps more typical, individual of 30 millims. (from Galle, 4th August, 1902), which I assign to this species, shows the same form of head, but the dorsum of the anterior segments is elevated, and the tentacular acervi extend over more than one segment (Plate VI., fig. 139). The gill-filaments are inserted high up on the body, remote from the dorsal fascicles; the ventral acicular setæ commence on the 11th setiger, the dorsal about the 26th. The frontal border shows pigment specks (Plate VI., fig. 140).

In another specimen of 35 millims. from East Cheval Paar, 8th November, 1902, 8 fathoms, the ventral acicular setæ commence on the 9th setigerous segment, as many as six in one fascicle in the anterior segments, becoming less numerous and stouter behind; the dorsal acicular setæ are more slender than the ventral, and commence on the 25th setigerous segment. The first lateral branchial filament appears on the first setigerous segment, the transverse acervi occur in the region of the 7th and 8th body-segments (*i.e.*, 4th and 5th setigerous segments). Behind the acervus the segments carry one pair of branchiæ inserted at slightly different levels, lateral and more dorsal.

Cirratulus complanatus, n. sp.

Station XLV., off Panadure, 25 fathoms. Three specimens.

The length of the ribbon-shaped body is 33 millims., greatest width 5 millims. The body is much flattened, giving a flattened rectangle in section; the head pointed, elongate conical. The tentacular acervi occur on the dorsum of the second setigerous segment, *i.e.*, the fifth body-segment, the first three segments being as usual achætous. In one specimen a small gill occurs on the third achætous segment. Both dorsal and ventral acicular setæ are present in the 36th setigerous segment. Gill-filaments only occur in the anterior region of two complete individuals. The gill-filaments and tentacular filaments give the appearance of a dense tangle in front, the rest of the body being bare.

The species differs from *C. dasylophius*, Marenzeller, in the position of the tentacular cirri, the distribution of the gill-filaments and the shape of the body.

Heterocirrus typhlops, n. sp.—Plate V., fig. 138.

Locality :—South-west Cheval Paar, Gulf of Manaar.

A very small worm, total length 10·5 millims., diameter less than half a millimetre. Capillary non-limbate setæ in both fascicles; dorsal and ventral acicular setæ commence at the first setigerous segment; they resemble those of *Cirratulus;* the ventral acicular setæ are two in number, more curved and thicker than the dorsal. The disposition of such cirriform appendages as remain is shown on Plate V., fig. 138.

Family: AMPHICTENIDÆ.

Pectinaria panava, n. sp.—Plate V., fig. 137.

Locality :—Ceylon Seas.

The specific name is the vernacular word for comb, referring to the comb of paleæ. Nuchal disc subcircular, carrying a transverse series of twenty paleæ, divided by an interval into two linear groups of ten each; the paleæ terminate in curved setiform apical processes. At each ventro-lateral angle of the disc, at the outer ends of the paleal series, there is a tentacular cirrus; a similar pair of cirri occurs on the second segment. In front of and below the paleal crown there is a wide semilunar membrane carrying not less than 32 laciniæ frontales. Below the frontal membrane are the grooved tentacles surrounding the mouth. Third and fourth segments branchiferous; ventral portions of 3rd, 4th, 5th and 6th segments elevated, the crests traversed by transverse muscles; the crest of the 4th segment is produced on each side as a blunt lateral lobe below the gill; on the posterior surface of the lobe there is a pinhole aperture. Seventeen capillary fascicles commencing from the 5th segment; uncinigerous tori from the 8th; uncini with about eight teeth, reduced towards the base (Plate V., fig. 137). Scapha acetabuliform, with terminal supra-anal semilunar valve and two rows of dorsal paleæ at the base, 7 paleæ on each side.

This species is chiefly characterised by the number of paleæ, which however is likely to vary, and by the large number of the laciniæ frontales, which are filiform processes along the edge of the frontal membrane.

FAMILY: SABELLARIIDÆ.

Pallasia pennata (PETERS)—Plate VIII., figs. 1 and 2.

Sabellaria pennata, PETERS, "Ueber die Gattung *Bdella* SAV. und die in Mossambique beobachteten Anneliden," 'Arch. f. Naturg.,' xxi., 1855, p. 42; also 'Monatsber. Berlin. Akad.,' 1854, p. 613 (quoted from GRUBE, 'Ann. Semp.,' 1878, p. 220).

Hermella bicornis, SCHMARDA, 1861, 'Neue Wirbellose Thiere,' p. 24.

Locality:—This worm occurs off the west coast of Ceylon either singly or in large colonies, and builds a tube of coarse sand-grains cemented together, so as to form a sandstone of excessive hardness which is capable of withstanding the full force of the waves during the South-west Monsoon. It is evidently an important factor in the preservation of the coast line. Sometimes the tubes are still further protected by a Nullipore covering. The internal diameter of a large tube is about 6 millims.

The specific name given by SCHMARDA refers to the presence of a pair of large brown hooks bent towards the middle line, placed at the dorsal ends of the peristomial lobes which, with their armature, constitute the paleal crown. There is usually only one pair of hooks, but I have seen a specimen with three hooks (two on one side), and PETERS describes four hooks (two pairs) in the single specimen examined by him. Each peristomial lobe terminates anteriorly in a truncate dorso-ventral crescent-shaped area, from the inner and outer arcuate borders of which the modified bristles or paleæ arise. The number of paleæ in the inner row varies roughly between 20 and 30; the number in the outer row between 30 and 45. The paleæ of the outer row are long curved spines, slightly widened and strongly serrated along the distal three-fifths of their length; towards the apex of the palea the serrations are larger on the concave border than on the opposite border; all are directed towards the apex of the palea. The paleæ of the inner row are acuminate, smooth, and more slender than those of the outer row. In side view a series of 8 to 12 subulate papillæ occurs below the outer row of paleæ, the most dorsal papilla being placed behind the hook on each side, as shown in Mr. WATSON's drawing (Plate VIII., fig. 1).

Dorsally the peristomial lobes are confluent across the middle line up to the level of the hooks; ventrally they are separated down to the level of the mouth. The inner surface of each peristomial lobe is beset with numerous tentacular cirri arranged in rows, the columns being indicated externally by crenulations of the ventral border of the lobe (Plate VIII., fig. 2). On each side of the mouth occurs the neuropodial cirrus of the buccal segment, and at the base of this a bundle of capillary setæ. The second segment is distinct dorso-laterally, merging into the peristome below; it carries a bundle of neuropodial setæ, above and adjoining which there is a triangular lappet; farther up the side follows another triangular lappet and dorsally the first cirriform branchia (Plate VIII., fig. 1). The third, fourth, and fifth segments carry on each side a neuropodial fascicle of long, rather narrow spatulate setæ with laciniate tips ending in a point, and a laterally placed notopodial fascicle of similar setæ with a wider spatulate portion, disposed in a single series; in both fascicles the spatulate setæ are accompanied by more slender limbate setæ; dorsally these segments carry stout cirriform branchiæ. Next follow the uncinigerous segments, as many as 50 in number, after which the recurved achætous caudal extremity terminates the body.

The first 20 to 30 uncinigerous segments carry dorsal branchiæ; all carry ventral fascicles of fine capillary setæ, and the first three are provided with ventral ligules adjoining the capillary fascicles; the capillary setæ carry projecting laciniate scales or minute thecæ, overlapping like the cups of a Sertularian Hydroid. Adjoining the mouth, between the latter and the neuropodial cirri or ligules of the buccal segment, there is a pair of fleshy labial processes, which Mr. Watson identifies as tube-building organs (Plate VIII., fig. 2).*

It is possible that the Ceylon form may be varietally distinct from the Mozambique type, and should be known as *P. pennata*, var. *bicornis*.

Family: TEREBELLIDÆ.

Leprea inversa, n. sp.—Plate VI., figs. 141 and 142; Plate VII., fig. 197.

Station V., off Chilaw, Gulf of Manaar; 11 fathoms. One specimen.

The body-length, exclusive of tentacular cirri, is from 30 to 40 millims.; width in front 2·5 millims. The segments are numerous and the body much contorted. The anus is surrounded by a funnel-shaped pygidium. The branchiæ are inserted without reference to particular segments, the third gill occurring high up on the dorsal surface over the third or fourth setigerous lobe, the second over the first setiger and the first gill in front. Between the first and second gill there is a papilla. The first gill occupies the most ventral position and is the smallest in size, not more than one-third of the bulk of the second gill, the latter having about one-half to two-thirds the bulk of the third. There are eight ventral thoracic scutes behind the tumid labium; the first shield following after the labium is deeply grooved transversely; the scutes end sharply in the region of the 8th and 9th uncinigerous tori. The uncinigerous tori and the capillary fascicles are continued to the posterior extremity of the body; from the 7th torus (11th segment) backwards the uncini are biserially disposed. The tentacular cirri are not deciduous; no eyes were observed. The capillary setæ of the anterior segments are very narrowly limbate, with a slight twist towards the apex, but quite simple; those from the middle and posterior segments are geniculate (Plate VI., figs. 141 and 142).

In the anterior region, behind the ventral scutes, the median ventral tract is depressed between the tori. In the posterior abdominal segments the uncini (Plate VII., fig. 197) are still biserial. The proportions of the branchiæ, the difference between the anterior and posterior capillary setæ and the number of ventral

* A note upon the nature of the structures which, in the Sabellariidæ, surround the mouth, appeared in the 'Journal of the Marine Biological Association' (Plymouth), New Series, vol. vii. (1904), p. 301.

scutes are the principal features which differentiate this species from *Leprea ehrenbergi* (GRUBE), MARENZELLER ('Südjapan. Ann.,' part ii., 1884, p. 5 of reprint).

Polymnia labiata, n. sp.—Plate VI., figs. 143 to 145.

Locality:—One specimen from the pearl banks, Gulf of Manaar; another from Aripu Reef. The former inhabited a membranous tube encrusted with coarse unequal sand-grains and calcareous fragments (including an entire small Naticoid shell); the latter has a large test-like tube encrusted with foreign particles, mostly very small and chiefly calcareous. It appears that the incrustation of the tube of Terebellids affords no trustworthy evidence of specific identity except in particular instances. The tube in question is nearly six inches long, with a diameter of half an inch. The abdominal region of the contained worm had undergone fragmentation, but the other specimen from the pearl banks is complete; length about 115 millims., width of thorax 7 millims., segments upwards of 120. The transition from the torigerous to the pinnigerous region is not very abrupt, the diameter of the body gradually decreases and the anterior pairs of pinnæ may be rather wide and set low in the integument, resembling the tori. The well-marked scuta ventralia end between the ninth and tenth pairs of tori, leaving six clear pairs of tori behind the scutigerous region. When the ventral wall of the thorax is much contracted there is an appearance of ill-defined scuta being continued to the posterior end of the thoracic (torigerous) region. The tori of the right and left sides are always widely separated, not approximating in the mid-ventral line.

The diagnostic characters by which this species is to be distinguished from its congeners (in the absence of information concerning colour) are afforded by the structure and proportions of the uncini. The uncinus consists of three principal parts, the hook, the shaft or neck, and the manubrium; the relative dimensions of these parts appear to be constant for the species. The uncini of *P. labiata* are noticeable on account of the length and slenderness of the neck; the basal angle of the manubrium, which lies deepest in the integument, is produced into a short gubernaculum resembling the "Muskelfortsatz" of the uncinus of *Pista* (v. MARENZELLER, 'Adriat. Ann.'). The denticulations of the uncinus offer no tangible distinction and present considerable variety both in number and dimensions. Generally the main hook is surmounted by a pair of smaller hooks of the second order, followed by another row of three denticulations of the third order (the middle tooth usually much longer than the lateral) occupying the vertex of the uncinus. Occasionally accessory denticles may be observed on the brow of the uncinus (Plate VI., figs. 144 and 145).

No *Polymnia* was described by GRUBE from the Philippines. One species, *P. congruens*, v. MARENZ., is known from South Japan, differing clearly from *P. labiata* in the shape of the uncini, and in the number of scuta ventralia. GRUBE's *Terebella sarsii* from the Philippines ('Ann. Semp.,' p. 223) has three pairs of arborescent gills but no lateral lobes, conforming to *Nicolea* in the latter respect.

The description was based upon a single indifferently preserved specimen. If confirmed it will probably form the type of a new genus or sub-genus intermediate between *Polymnia* and *Nicolea*.

The labium and lateral lobes of the third segment are of the same nature as the corresponding processes in *Loimia* (Plate VI., fig. 143).

Polymnia socialis, n. sp.—Plate VI., figs. 146 to 148.

Locality:—Narrow sand-encrusted tubes of a small Terebellid were adhering to the tubarium of *Phyllochætopterus ramosus*, trawled off Galle at Station XXXIX., 16 to 30 fathoms. One of the larger tubes measured about 50 millims. in length, 2 millims. in diameter. Three pairs of arborescent gills, the first (longest) extending forwards beyond the upper lip. Seventeen pairs of capillary fascicles, sixteen pairs of thoracic tori, uncini uniserial in the first six tori, biserial and opposite in the rest, uniserial again in the abdominal pinnules, which are supported by fine sustentacular setæ. Capillary setæ simple, narrowly limbate. The band of scuta ventralia is well set off from the surrounding parts, rounded in front, attenuate behind, ending as a whitish streak in the region of the 13th–14th tori, but continued behind this point as a colourless median streak into the anterior abdominal region; behind the 9th torus the band of scuta becomes paler, whitish.

The dorsal surface of the worm is smooth and convex, not showing segmental divisions in the region of the thorax. The first segment which forms the lower lip is long below and deeply cleft, the right half slightly overlapping the left (Plate VI., fig. 146). The lateral lobe of the second segment, seen in side view, appears as a sub-elliptical or semilunar, symmetrical free dermal fold. The uncini are remarkable for the number of denticulations on the vertex, which exceed the narrow limits suggested by von Marenzeller for the genus. The vertex of the uncinus, when seen from above, shows a rosette of twelve denticulations, and attentive examination shows that these are arranged in arcs across the vertex. The general formula for an uncinus of this species, according to Marenzeller's system of notation ('Adriat. Ann.,' iii., 1884, p. 163, or p. 13 of reprint) would be as follows:—1, 22, 333, 4444, 55555. The rosette which appears in vertical view is formed by the teeth of third, fourth and fifth orders (Plate VI., figs. 147 and 148).

The limbus of the capillary setæ is, at least in some of them, wider over a sub-terminal tract than more distally, spreading like a pair of narrow fins on either side of the seta. The terminal portion presents a very narrow obscurely striated border. This is merely the continuation of the limbus, and is not like the laciniate plumose structure of the terminal filament in *Amphitrite*. In some setæ from one of the specimens the terminal portion is marked off by a shallow constriction from the bulk of the shaft. This is not a constant feature however, and the setæ of the larger individual end normally in a simple point.

Length of fore-body without the tentacular cirri (which are present knotted together and calling for no remark) 13 millims., width 2 millims., total length of body 20 millims.

Polymnia triplicata, n. sp.—Plate VI., figs. 149 to 152.

Locality :—Galle, 4th August, 1902. Several specimens.

This is another tribranchiate Terebellid of small size, with fragile body and highly deciduous tentacular cirri. Length of a specimen, incomplete behind, 35 millims. ; thorax barely wider than rest of body, 3 millims. in diameter, with 17 setigerous segments ; abdominal portion with 34 pinnigers. Another abdominal fragment had 80 segments.

The second, third, and fourth segments (the fourth being the first setigerous segment) carry lateral lobes of approximately equal size (Plate VI., fig. 149). The scuta ventralia are 14 in number, counting from the second segment ; they end sharply on the 13th setigerous segment, leaving four setigerous (thoracic) segments without ventral shields. The central portions of the scuta are slightly marked off from the anterior and posterior borders, but otherwise they are simple, not biannulate nor areolated.

The arrangement of the anterior thoracic segments seems to differ considerably from the condition observed in *P. labiata*. As shown on Plate VI., fig. 143, there is, in *P. labiata*, a large lower lip with free sinuous border, considered as belonging to the second segment (*i.e.*, the first branchiferous segment) and followed by another achætous segment (the second branchiferous segment) carrying prominent lateral lobes. In *P. triplicata* the lower lip is followed by two achætous segments carrying lateral lobes, and also bearing the first and second pairs of gills. It appears, therefore, that in *P. labiata* and in the species of *Loimia* the much larger lower lip is a product of the fused first and second segments, while in *P. triplicata* the first and second segments are distinct below, the former alone carrying the lower lip. In this and in other respects (number of scuta, &c.), the present form offers a striking analogy to *Lanice triloba* described by Fischli from Ternate,* and were it not for the existence of the generic distinction, which is not apparent at the surface, the two species would probably be ranged together.

The enumeration of the anterior segments and the nature of the prostomium of Terebellidæ are matters of some obscurity. On Plate VI., fig. 149, the thin half-collar which overhangs and protects the mouth like an epistome or upper lip is seen in side view ; at the back of it are the scars of insertion of the tentacular cirri, followed by a clear surface of a segment showing numerous eye-spots. Then follow the gills on the second, third, and fourth segments. The uncini are much smaller than in *P. labiata*, and usually only one denticulation of the third order is to be observed (Plate VI., figs. 151 and 152). The dorsal portion of the thoracic segments becomes biannular, commencing from the region of the eighth torus (Plate VI., fig. 149).

* H. Fischli, "Polychäten von Ternate," 'Abh. Senckenberg. Ges.,' xxv., 1900, p. 122.

The branchiæ (as in *Lanice triloba*, FISCHLI) show very clear-cut dichotomous ramifications, the main stem of each gill dividing near the base into two main branches. In the biserial tori the uncini of the two rows are alternate and opposite, (*i.e.*, base to base), those of the anterior row progressive, of the posterior row retrogressive. In *Lanice triloba*, the uncini of the biserial tori are inverted (*i.e.*, vertex to vertex), as in *Loimia*, though in structure they resemble the uncini of *Polymnia*.

Loimia annulifilis (GRUBE)—Plate VI., figs. 153 and 154.

Terebella annulifilis, GRUBE, 'Ann. Semp.,' 1878, p. 225.

Locality :—Galle shore, under stones. Eight specimens.

Tube encrusted with coarse, rather large shell and coralline fragments up to 8 millims. or 9 millims. in diameter. In most specimens the body-wall of the dorsal thoracic region has ruptured, and a coil of the gut is protruding. Diameter of thorax up to 9 millims. ; length of body about 150 millims. ; abdomen coiled ; more than 200 segments.

Uncini from the first torus, 5-dentate ; from the third torus, 5-dentate (Plate VI., fig. 153) ; from the sixth, 5-dentate, the fifth tooth becoming smaller and in some uncini obsolescent ; from the ninth torus, 4-dentate in both rows ; from the twelfth, 4-dentate ; from the sixteenth, 4-dentate ; from the twenty-seventh torus (which is borne upon the eleventh abdominal pinnule), 4-dentate. From these enumerations it follows that the uncini of the first six uniserial thoracic tori are 5-dentate, of the last ten biserial thoracic tori and of the uniserial abdominal pinnules 4-dentate. No such distinction is recorded by GRUBE among the five species of *Loimia* described by him from the Philippines. In some of the uncini from the anterior tori there seem to be indications of a sixth tooth, and in one uncinus from the first torus there are six distinct teeth.

The first pair of arborescent branchiæ greatly exceeds the second and third in size, quite overshadowing them. Seen with low magnification, they present a densely racemose or finely tufted appearance, due to the fact that the digitations arise in groups from the main stem and thicker branches, curving inwards like the half-closed fingers of a hand.

According to the accepted interpretation of the anterior complex of the Terebellidæ, the buccal segment is destitute of appendages and sense-organs (segmentum buccale nudum), but is produced ventrally into a large free labial fold, which closes the ventral opening of the horse-shoe-shaped collar or epistome formed by the prostomium surrounding the mouth above and in front. The hinder portion of the prostomium looks uncommonly like a cephalic segment and carries the tentacular cirri, which are ringed with purplish colour as in GRUBE'S *Loimia annulifilis*. The buccal segment is the first body-segment, and is here practically non-existent above, though represented below by the prominent labium. The second body-segment is the first branchiferous segment, well-marked dorsally, obsolete ventrally. The third body-segment or second branchiferous segment is evident above and below, and is produced outwardly into two ear-shaped lateral lobes, between which there is a narrow rim representing the ventral portion of the segment. Behind this follows ventrally the first ventral scute belonging to the fourth body-segment, which is at the same time the third gill-bearing segment and the first setigerous segment. The fifth body-segment is the first uncinigerous segment, and the uncini are arranged uniserially in the first six pairs of uncinigerous tori; the ten following tori carry uncini in two rows. The twentieth body-segment is the last thoracic segment. Then follows the abdominal region, which is destitute of capillary setæ, the uncini being borne in single file upon the abdominal pinnules. The first scutum differs from those which follow by its large size and corrugated surface. There succeed to this nine plain scuta ventralia, becoming narrower and longer behind. After this again the scuta become subdivided by transverse grooves, finally ceasing between the penultimate thoracic tori. The posterior subdivided scuta present a dark colour in the preserved material (Plate VI., fig. 154). There are 17 fascicles of capillary setæ, which have a fibrous internal structure, the fibres separating out when the seta is crushed or broken. Some of the setæ, however, which were presumably broken before death, show a clean fracture. It may be noted in conclusion, that in one specimen the scuta between the eighth and ninth uncinigerous tori are divided by a cross furrow.

Loimia crassifilis (Grube).

Locality :—East side of Cheval Paar.

One very small individual of 20 millims., including the tentacular cirri; the latter are banded as in *L. annulifilis*. There are ten clear scuta ventralia, after which these become quite obscure, but the tori remain separated by a wide decreasing median ventral tract to the end of the thorax. Uncini from the fourth torus 4-dentate, with an occasional rudimentary fifth tooth at the apex; from the biserial tori 4-dentate, the fourth tooth small; from the abdominal pinnules 5-dentate, namely, four clear teeth and a rudimentary apical tooth. The above corresponds with Grube's description ('Ann. Semp.,' p. 226), "uncini pectiniformes dentibus tororum 4," although his specimen was a very large one. The abdominal region is slender and even; the thoracic region tumid; about 67 segments.

Loimia medusa (Savigny)—Plate VI., figs. 155 to 159.

Savigny, 'Syst. des. Ann.,' p. 86 (quoted from Grube, 'Ann. Semp.,' p. 228).

(1.) Three specimens from Aripu Coral Reef, about 80 segments, width of thorax 10 millims.; total length nearly 90 millims., of which 30 millims. belong to the thorax; abdomen subcylindrical, varicose, simply flexed (not spirally coiled), narrower than thorax (Plate VI., fig. 155). Uncini from the first torus 6-dentate; from the third some 5-dentate, some 6-dentate; from the fifth 5-dentate; from the biserial tori and abdominal pinnules 4-dentate. There are five pairs of tori behind the scuta ventralia. The last plain scutum corresponds with the seventh pair of tori; the rest are subdivided, terminating after the eleventh tori. The subdivided scuta are dark-coloured. The three pairs of branchiæ are subequal.

(2.) Two more small worms which I assign to this species were taken from the South-west Cheval Paar. These also have five pairs of tori behind the scuta, but the junction of the undivided and subdivided (or anterior and posterior) scuta occurs at the level of the eighth tori, clearly so in one, approximately so in the other specimen. One has 52 segments with a length of 36 millims., the abdominal segments being closely compressed; the other has about 64 segments with a length of 45 millims. Uncini from the first torus 6-dentate, from the third also 6-dentate; from the fifth 5-dentate; from the biserial tori and abdominal pinnules 4-dentate. Part of a tube is encrusted with small shell-fragments of various sizes.

(3.) There are two other well-preserved worms taken from the Aripu Coral Reef, which afford the peculiarity of an accessory or eighteenth pair of capillary fascicles. The uncinigerous tori which accompany these fascicles are narrower than the preceding, thus affording a graduated transition from the tori to the pinnules. This is particularly so in one of the specimens where the accessory tori are much narrower than in the other. The tubes constructed by these worms are encrusted with coarse sand-grains with a scanty admixture of calcareous fragments.

The scuta ventralia are much narrower than in the first or typical variety, an appearance which may be partly due to the state of protraction of the body and the method of preservation (Plate VI., fig. 156). On account of this fact, together with the difference of the tubes and the presence of eighteen pairs of capillary fascicles, I will call this variety *angustescutata*, in order to facilitate future reference. The uncini from the first torus are mostly 6-dentate (Plate VI., fig. 157), the sixth tooth frequently reduced and sometimes obsolete; in the fourth torus the uncini are 5-dentate (Plate VI., fig. 158); from the biserial tori and abdominal pinnules, 4-dentate (Plate VI., fig. 159). The body of these worms resembles that of the typical form, though somewhat more slender; 83 segments, length about 100 millims., abdomen varicose, width of thorax 8·5 millims. The lateral lobes of the anterior segments resemble the corresponding structures in *L. annulifilis* (*q. v.*).

Loimia montagui (Grube)—Plate VI., figs. 160 to 163.

Terebella montagui, Grube, 'Ann. Semp.,' 1878, p. 224.
Loimia montagui, Marenzeller, 'Südjapan. Ann.,' ii., 1884, p. 205.
Not **Terebella montagui**, Quatrefages, 'Hist. Nat. Ann.,' ii., 1865, p. 361.

A large number of cylindrical worm tubes are labelled "No. 32, *Terebella*, Palk Bay." Many of the tubes are in short lengths, the more complete measure upwards of 100 millims. (4 inches) in length, with a diameter of 9 millims. They are coated with a thick dense layer of fine mud presenting a smooth surface, the lips of the terminal orifices approximated, so that no sign of the contained worm appears externally. I found two worms only belonging to the tubes.

The body is narrowed anteriorly (in the region of the scuta ventralia) and attenuated behind; in the middle region it is inflated and somewhat varicose; segments about 100, length about 85 millims., width of thorax in front 4 millims., behind the scuta 5 millims. (Plate VI., fig. 160). Counting the composite sternite of the 2nd, 3rd, and 4th segments as the first scutum, there are eight clear scuta followed by a rather ill-defined ninth. After this there is no trace of further scuta, the median ventral tract separating the tori uncinigeri is wide and smooth, and the length of body between the successive tori gives the worm a remarkable appearance. In the first torus the uncini are mostly 6-dentate, the sixth tooth sometimes large, sometimes rudimentary, and many uncini in the same torus are 5-dentate (Plate VI., figs. 161 and 162). In the fourth torus not one 6-dentate uncinus was observed, only 5-dentate uncini with a sprinkling (about 5 per cent.) of 4-dentate uncini. In the biserial tori only 6-dentate uncini were found in both rows (Plate VI., fig. 163). An abdominal pinnule contained 7-dentate uncini, the seventh tooth usually small and occasionally obsolescent, but clear enough to characterise the region.

In ventral view (Plate VI., fig. 160) this worm presents distinguishing features depending upon the size and limited number of the scuta ventralia, the absence of subdivided scuta behind the main series, and upon the divarication of the metathoracic tori. In the character of the uncini the species corresponds closely with *Loimia montagui*, Gr., as described by Marenzeller ('Südjapan. Ann.,' 1884, ii., p. 9, reprint), who, however, does not describe a definite succession of uncini such as I have noted above, namely, the 6-dentate uncini of the first torus, followed by a reduced denticulation in the succeeding uniserial tori, and this again by an increased denticulation in the biserial tori and a further increase in the abdominal pinnules. It agrees with *L. montagui* again in the triangular shape of the lateral lobes of the third segment and in the presence of a whitish glandular tract on each side of the dorsal surface over the capillary fascicles, extending from the gill-region to the eighth setigerous segment, where it ends in a point.

Although von Marenzeller records eleven scuta ventralia for *Loimia montagui* from Japan, and Grube ten for the example described by him from the Philippines; the former author specially notes that the most sharply circumscribed scutes are those from the second to the eighth inclusive, which accords with the variety from Palk Bay. Neither Grube nor von Marenzeller refers to the tube, which, in the case of Terebellidæ, may or may not be a matter of importance. Nor is any information given as to the nature of the locality. Both of these points, in the present instance, have a special interest, bearing upon the identification.

Loimia variegata (Grube).

Terebella variegata, Ehrb., 'Monatsber. Ak. Berlin,' June, 1869, p. 30 of reprint; Grube, 1878, 'Ann. Semp.,' p. 227.

One specimen in a thin membranous tube encrusted with shell-fragments and sand-grains was present in the same bottle with *Eupomatus heteroceros*, *Eunice antennata*, etc.; no locality being given: probably South-east Cheval Paar.

In the second of the above-quoted publications GRUBE makes the important correction that the uncini are not 4-dentate, as previously stated, but 5-dentate. This species resembles *L. medusa* in the number of scuta ventralia, and consequently in the occurrence of five pairs of tori behind the scuta. These posterior tori touch one another in the middle line in their respective segments.

The specimen in the preserved state has a nearly uniform pale flesh tint, only the branchiæ, which are matted together, showing up dark. There is no great contrast between the diameter of the thorax and that of the abdomen; the latter is sub-cylindrical, smooth, somewhat varicose. The total length is about 80 millims., and the number of segments about 60, the maximum width 7 millims., thus presenting a close numerical correspondence with GRUBE'S original type. The scuta ventralia are narrow as in the angustescutate variety of *L. medusa*. This species is said by GRUBE to differ in colour from *L. medusa*, but in the preserved state the chief characteristics are the nearly even diameter of the body, the uncini of the biserial tori and abdominal pinnules which are 5-dentate, to which may be added the pale flesh colour. The fifth denticulation at the vertex of the uncinus is small but distinct. The average width of the thorax (excluding the capillary fascicles) may be estimated at 6 millims., that of the abdomen at about 5 millims. At the same time, if it were not for the quinquedentate uncini, I should probably have placed the worm under *L. medusa*.

In the living condition more fundamental differences may come to light. The worm was closely invested by its tube. The preserved specimens of *L. medusa* have a dark neutral colour in marked contrast with the pale flesh colour of this worm. A second smaller specimen shows very clearly the quinquedentate uncini of the abdominal pinnules. In this case the abdominal region is more attenuated, and the scuta ventralia end rather sooner, so that there are six pairs of tori behind them.

Grymæa, MALMGREN, 1865.

Three pairs of acervi of filiform branchiæ.

Capillary fascicles commencing from the second segment (first branchiferous segment) and extending to the posterior abdominal region.

Tori uncinigeri commencing on the fourth (? or fifth) setigerous segment. Uncini avicular, uniserial.

MALMGREN says the tori commence on the fifth setigerous segment, but in a specimen of the type species, *Grymæa bairdi*, MALMGREN, collected off Norway by the Rev. Canon NORMAN, which I had the opportunity of examining at the British Museum some years ago, they commenced on the fourth setigerous segment.

Grymæa cespitosa, n. sp.—Plate VII., figs. 164 and 165.

One specimen, incomplete behind, was obtained, in 40 fathoms, south of Rameswaram Island, at Station LIV.

The fragment comprises twenty-two setigerous segments, total length about 30 millims.; width of thoracic region 3 to 4 millims.; thorax straight, porrect, abdominal region bent, with smooth, convex, turgid dorsum. The pharetræ setarum are high, upwards of 1 millim. in front, decreasing gradually backwards. The simple, narrowly limbate setæ issue in two principal bundles from between the oblique lips. The ventral portions of eleven segments from the second are flattened, forming broad ventral shields subdivided by transverse grooves. There are nine torigerous segments in the thoracic region, the posterior thoracic segments being nearly as long as broad. The thoracic tori graduate insensibly into the abdominal tori, which are sessile, not pinnuliform. The uncini have the form shown in Plate VII., fig. 165, and the general formula 1–22–3. In side view the three tiers of teeth show clearly.

The branchial filaments are numerous, forming dense coils. Those of the first acervus commence low down near the ventral surface. They break away easily from the body in groups. The tentacular cirri, plainly grooved on the lower side, are much stouter than the branchial filaments (Plate VII., fig. 164). The three branchiferous segments also carry capillary fascicles, the first uncinigerous torus occurring on the first post-branchial segment. The branchiæ arise from the anterior parts of the segments in front of the corresponding capillary fascicles.

Family: SABELLIDÆ.

Branchiomma acrophthalmos, Grube—Plate VII., figs. 166 and 167.

This is the oriental form of the well-known *B. vesiculosum.*

Locality:—East Cheval Paar, Gulf of Manaar.

Baron de St. Joseph has shown that the character of the limbate setæ of the European species varies at different ages, being spatulate in the young.

The Ceylon specimen is a fragment comprising 16 segments, 21 millims. long (including the gills), 3 millims. wide; 15 radioles* in each gill; gills banded about six times purple and whitish. Each radiole carries a subterminal eye, the two dorsal eyes being the largest. The definition of *Branchiomma* given by de St. Joseph (1894, 'Ann. Sci. Nat.,' xvii., p. 249) states "Soies dorsales d'une seule sorte au thorax." In the Ceylon specimen the dorsal fascicles of the thorax appear to contain, and in fact do contain, two distinct kinds of setæ, normal limbate to the number of eleven, and spatulate (Plate VII., fig. 166) to the number of nineteen. The thoracic tori are biserial, containing a row of avicular uncini and a row of cuspidate setæ.

Grube describes ('Ann. Semp.,' 1878, p. 258) the collar as trilobate, apparently overlooking the ventral incisure which divides the two acuminate ventral lobes. These are in close juxtaposition and give the appearance of the simple wide triangular lobe described by Grube. The dorsal portions of the collar show a characteristic form, the free border deeply emarginate externally and reflected round the base of the gill-supports (Plate VII., fig. 167). There are eight thoracic segments.

* See definition of this term on p. 308.

Branchiomma quadrioculatum, n. sp.—Plate VII., figs. 168 and 169.

Locality :—Aripu Coral Reef. One specimen, apparently incomplete behind, 48 segments.

Thorax 4·5 millims. long, 2 millims wide. Abdomen 13 millims. long. Eight thoracic segments. Gills 6 millims. long, banded with three or four purplish vittæ; 14 radioles in each. Collar with median incisura ventralis, a deep median dorsal notch and a still deeper submedian dorsal notch on each side. The four most dorsally placed gill-rays carry subterminal eyes, of which the dorsal pair are larger than the subdorsal pair (Plate VII., fig. 168). Seen from below, pressing the gills aside, laciniæ buccales are brought into view, including a flattened median tongue which rises up straight between and below the antennæ, and on either side of it an arcuate membranous fold. The buccal setæ are normal, capillary, limbate; thoracic setæ normal limbate and subspatulate; thoracic uncini biserial, an anterior row of cuspidate uncini * and a posterior row of avicular uncini (Plate VII., fig. 169). Abdominal setæ 15, limbate; abdominal uncini uniserial, avicular.

Hypsicomus phæotænia (Schmarda).

Sabella phæotænia, Schmarda, ii., 1861, p. 35.

Hypsicomus phæotænia, Marenzeller, 'Südjapan. Ann.,' ii., 1884, p. 16 of reprint, p. 212 of the 'Wiener Denkschr.'

Sabella pyrrhogaster, Grube, 'Ann. Semp.,' 1878, p. 250.

Localities :—Station V., off Chilaw, Gulf of Manaar, 11 fathoms, several specimens; and South-west Cheval Paar.

Marenzeller notes the resemblance between *Sabella pyrrhogaster* and *Hypsicomus phæotænia*, but adds that in the former only one kind of setæ was observed by Grube in the thoracic tori. According to Grube also the dorsal setigerous lobes of the thorax only contain paleæ, whereas in *phæotænia* there are a few lanceolate setæ in addition to the paleæ. The latter discrepancy is easily accounted for by the fact that the lanceolate setæ are frequently broken and hence cannot be observed. The former discrepancy with respect to the tori in which the armature is biserial and dimorphic in *phæotænia* and alleged to be uniserial and uniform in *pyrrhogaster*, is undoubtedly due to the circumstance that the row of cuspidate uncini was overlooked. Neither does Grube mention the branchial eyes, the pigment of which was perhaps dissolved out of his material. This species has also been described by Grube as *Sabella fuscotæniata* in 'P. Zool. Soc., London,' 1874, p. 328.

A small though complete specimen measures 25 millims. long without the branchiæ, which add another 8 millims. From the posterior end of the basal lamella to the anterior border of the interfilar membrane or web measures 3·5 millims. The eyes occur on each side of the distal portions of the gill-stems, 14 to 17 in number, not in pairs. The terminal filament of the gill-stem is long, somewhat flattened and tapering to a point.

* "Soies en pioche"; "Pickelborsten."

The macroscopic characters by which the species may be recognised are the occurrence of an arcuate oblique double row of modified setæ in the first segment and the rich dark-brown colour of the ventral shields of the abdominal region. The short collar still retains a band of violet below ; it is entire, its dorsal border being slightly concave, while its ventral border is produced forwards to a median point. The cuspidate uncini which accompany the avicular uncini are called "Pickelborsten" by von Marenzeller.

Accompanying the typical individuals described above there is another specimen in which the whole collar is violet except at the anterior border. It is in a state of protraction, and the modified setæ of the first segment are disposed in a slightly undulating longitudinal ridge which stands out pale upon the violet background. This specimen further shows violet vittæ and scattered spots on the gills, but no eyes are to be found; the terminal filaments into which the cartilaginoid axes extend are exceptionally long. The apparent absence of eyes is remarkable. The brown colour of the abdominal scutes is missing; only the anterior abdominal region is preserved.

Dasychone cingulata, Grube—Plate VII., figs. 170 to 173.

Two specimens in bottle with *Loimia variegata*, *Eupomatus*, &c. [? Cheval Paar].

Total length 26 millims., gills 9 millims. to 10 millims., thorax 4 millims., width 3 millims.; about 60 segments. Eight thoracic segments with eight fascicles and seven tori, the capillary limbate setæ of the first fascicle not different from the others. In each gill 19 to 21 radioles, each provided with about 14 pairs of dorsal stylodes and eyes; radioles subarticulate; terminal filaments of moderate length. In a thoracic fascicle there are 36 limbate setæ (Plate VII., fig. 170), and in an abdominal fascicle about half that number; the setæ issue in two bundles, upper and lower, those of the latter are shorter and (especially in the abdominal region) have a pronounced curvature, a broader limbus and a shorter flagellum (terminal filiform portion). It may be explained that the term "radiole," as applied to a single shaft or rhachis of the gills, is used here in the sense in which it has been employed by Professor McIntosh. It corresponds to Grube's filum branchiale. The actual branchial filaments which are borne upon a rhachis are the pinnæ, to which Grube applies the term radioli. Grube and McIntosh, therefore, use the term "radiole" in different senses. Grube ('Ann. Semp.,' 1878, p. 259) describes the radioles (*sensu* McIntosh) as longearticulate, which corresponds with the Ceylon specimen, and he remarks further that there are about ten pinnæ (branchial filaments) to each joint; this is also in accord with my observations (Plate VII., fig. 172). In the Ceylon specimen the articulation of the radioles is faintly indicated and best seen under low magnification.

Dasychone, like *Phyllodoce*, occurs singly in collections, and nearly every tropical specimen has proved to be a distinct species. Grube says that in *Dasychone decora*, Sars, the number of radioles in each gill varies from 20 to 36. The uncini of

Dasychone are striated parallel to the curvatures and are somewhat characteristic for the species. There are long-shafted and short-shafted forms and others, as in *D. bairdi*, McInt. ("Challenger") and *D. picta*, McInt., of special form. Examples of long-shafted uncini are those of *D. wyvillei*, McInt., and *D. orientalis*, McInt.; short-shafted uncini are in *D. cingulata*, Grube, *D. japonica*, McInt., *D. nigromaculata*, McInt., and *D. maculata*, Fischli ("Polychäten von Ternate," 'Abh. Senckenb. Ges.,' Band xxv., Frankfort, 1900, p. 125).

The radioles of the Ceylon specimen of *Dasychone cingulata* agree in arrangement and form of stylodes and eyes with the figures of *D. japonica*, McInt., and *D. maculata*, Fischli. The colour has vanished except for the minute dark pigment spots between the fascicles and the tori of the abdominal segments. The denticulations on the vertex of the uncinus occur in transverse rows (about three in a row) as in many of the Terebellacea; two appear above the main hook in side view (Plate VII., fig. 171).

Eurato porifera (Grube)—Plate VII., fig. 173.

Sabella porifera, Grube, 'Ann. Semp.,' 1878, p. 252.
Eurato, St. Joseph, 'Ann. Dinard,' part iii.; 'Ann. Sci. Nat.' (7 ser.), xvii., 1894, p. 249.

"Large Sabellid from centre of coral block, Muttuvaratu Paar; yellow-olive body, scarlet and yellow plumes." Total length about 90 millims., of which the gills occupy 30 millims. and the thorax 10 millims.; eight thoracic segments; width 8 millims.

The colour of the preserved specimen is sandy-yellow without any trace of pigment spots or markings. The only relief from the yellow ground colour is afforded by the characteristic spongy glandular tract which occurs on the anterior dorsal thoracic region. This has a brown colour and appears divided into right and left portions by the dorsal thoracic groove.

Limbate capillary setæ of different lengths throughout; uncini uniserial, avicular with multidenticulate (cross-hatched) vertex, not different from those figured by von Marenzeller for *Laonome japonica*.

Branchial stems in a single row, a few of them only occurring at a slightly deeper level than the rest, about 51 on each side. The length of the laciniæ tentaculares is about 7 millims.

The dorsal glandular tract by examination under a lens appears to consist of anterior and posterior portions, the former of a looser texture and thicker; but in the specimen under description both regions have the same brownish tint. Another smaller individual which accompanied the one described above shows the glandular area much more clearly. There is a posterior pale porous tract with a labyrinthine structure, the sulci running, in general, transversely; in front of this there are two dark-coloured convex porous cushions. In this specimen the general colour is duller and the gills rather olivaceous. In both cases the ventral fæcal groove bends up between the ninth and tenth ventral shields and passes round to the dorsum obliquely between the eighth and ninth capillary fascicles (Plate VII., fig. 173). The total length of the smaller worm is about 70 millims., of which nearly 7 millims. go to the thorax, 20 millims. to the gills.

Eurato notata (GRUBE)—Plate VII., figs. 174 to 176.

Sabella notata, GRUBE, 'Ann. Semp.,' 1878, p. 256.

A small worm in a finely encrusted closely investing tube was associated with *Phyllochætopterus ramosa* from Galle. The worm could only be removed from its tube with difficulty and not without damage, the gills adhering closely to it and to each other. The gills, with about 12 radioles in each, are banded with purplish colour, but the bands are all obscure in the preserved state with the exception of the basal band formed of a row of elongate dense purple spots, one on each radiole placed immediately in front of the level at which the radioles pass into the basal membrane which supports them. This is the first feature to meet the observer on removing the animal from its tube. The next distinction is afforded by the presence of a pair of subtriangular or pear-shaped pigment aggregates on the dorsal side of the first segment above the capillary fascicle, the apex directed forwards; this no doubt corresponds with the C-shaped mark which GRUBE noticed on his specimen. A pigment patch occurs on each side of the succeeding segments between the groups of setæ and the uncini, *i.e.*, between the fascicles and the tori.

In this specimen the thoracic segments were abnormal, fewer than normal and fewer on one side than on the other. Similar variations have been described in several Sabellidæ by the Baron DE ST. JOSEPH. On the left side there are three thoracic tori, on the right side four. In side view of the uncini three rows of teeth are to be seen on the vertex (Plate VII., fig. 174). The capillary setæ are all limbate, some long-limbate, others short-limbate and some rather wide-limbate (Plate VII., fig. 175). The limbus of these setæ is a kind of guard upon one surface embracing the setæ. From some points of view the seta appears bilimbate, but when the shaft is broken across, the limbus may be left projecting far beyond the broken edge (Plate VII., fig. 176).

The total length of the worm is about 12·5 millims., of which 2·5 millims. belong to the gills; width 1 millim., length of tube nearly 20 millims. The collar of this species is only conspicuous ventrally, where it is represented by a pair of ventro-lateral lobes, broad lappets subacute in front at the outer angles; these are what GRUBE called the laciniæ ventrales. GRUBE'S was a larger example and the proportion of the length of gills to body-length differs from that of the Ceylon representative. Another fragment of a larger individual was obtained on east side of Cheval Paar, and also showed clearly 4 thoracic tori on the right side, 3 on the left. The marks on the pronotum are C-shaped, with the concavity directed forwards and inwards.

Sabellastarte indica, Sav.—Plate VII., fig. 177a.

Cf. Quatrefages, 1865, 'Hist. nat. des. Ann.,' ii., p. 432.

A specimen from the pearl banks, upwards of 40 millims. long (without the gills) by 7 millims. wide, inhabited a tube nearly twice its own length encrusted with sand. The deciduous branchial crown together with the tentacular laciniæ was present, but thrown off. Projecting beyond the collar are two collapsible buccal lobes, evidently protruded by fluid pressure from within. At the ventral sides of the thoracic tori purple streaks occur, and similar streaks occur towards the dorsal border of the tori. In the abdominal region these streaks are replaced by minute spots. The gills are banded. The thorax is composed of eight segments with seven pairs of tori; the setæ, of all the fascicles alike, are limbate capillaries.

Another specimen labelled "No. 80, *Sabella fusca*, Grube, orange-bodied *Sabella*, on under side of boulder, Galle lagoon, off Breffit, 7th June, 1902," is larger and darker; 100 millims. long (without the gills), 10 millims. wide; body subcylindrical in front, more flattened behind. Gills very dark; inner surface of collar with black-purple band and a patch of the same colour on the outer surface of the dorsal portions of the collar.* In frontal view of the buccal crown the two buccal lobes described above are seen, though not protruding to the same extent (Plate VII., fig. 177*a*).

Sabellastarte indica, var. **quinquevalens**, nov.—Plate VII., fig. 177.

Another specimen, brought up by the divers from Muttuvaratu Paar, inhabited a membranous tube coated with fine mud. Total length 100 millims., of which 35 millims. belong to the branchiæ; more than 140 segments. The thorax is composed of six segments with five pairs of uncinigerous tori. The uncini are uniserial and show numerous denticles above the main tooth, presenting, in frontal view, a finely cross-hatched appearance, in side view a series of 8–10 minute rows on the vertex of the hook (Plate VII., fig. 177). Width of the thorax 8·5 millims., of the anterior abdominal region 7 millims. Branchiæ banded with purple, the radioles or stipes in two rows, but the bases of all show through the basal membrane. The radioles of the two rows are roughly alternate, though the outer row contains more than the inner. Terminal filaments of gill-stipes short; gill-filaments biserial. Collar with broad purple submarginal band on inner surface, as in the typical examples. It seems likely that *S. indica* is co-specific with Grube's *S. spectabilis* ('Ann. Semp.,' p. 253) and even with Marenzeller's *Laonome japonica* ('Südjapan. Ann.,' ii., 1884, p. 16). See also St. Joseph, "Ann. de Dinard," 'Ann. Sci. Nat.,' xvii., 1894, p. 249. The number of thoracic segments is known to be subject to individual variations. The collar is notched below by a median incisura ventralis.

* Similar colour-markings occur on the collar of the first example.

Jasmineira caducibranchiata, n. sp.—Plate VII., figs. 178 and 179.

Locality :—East side of Cheval Paar.

A small slender worm of nearly even diameter, gently tapering behind, 22 millims. long, 1·5 millims. wide; eight thoracic segments, 36 abdominal segments with anal groove passing obliquely across the first abdominal (9th body-segment) to the right side and on to the dorsal surface. The thoracic segments do not differ macroscopically from the anterior abdominal segments; there are 8 dorsal capillary fascicles, and 7 ventral tori carrying a single row of rostrate uncini with long manubrium (Plate VII., fig. 178). The abdominal uncini are avicular (Plate VII., fig. 179). The buccal segment carries the first capillary fascicle near its hinder border and towards the dorsal side; the collar is rounded and slightly projecting forwards below, with a median notch or incisura dividing the two low rounded lobes, and a shallow impression on each side of the notch. On the dorsal side the collar stands out at right angles to the body and is then inflected at an acute angle, to be inserted on either side of the anal groove in this region. The gill-radioles are lost, but their carriers are retained and show the scars of about a dozen radioles each. Inside the gill-crown there is a pair of broad, pinkish-white laciniæ, and below these there is a group of about six slender tentacular cirri attached to the lower ends of the gill-carriers.

FAMILY: SERPULIDÆ.

Eupomatus albiceps, EHRB., GRUBE—Plate VII., figs. 180, 180A, and 181.

GRUBE, 'Monatsber. Berlin. Akad.,' 1869, p. 520 (p. 40 of reprint).

One specimen inhabiting a quadrilateral tube winding round a tube of *Phyllochætopterus ramosus* from Galle.

The worm only measured 7 millims. in length including the branchiæ, and a fraction of a millimetre in diameter. GRUBE's example was rather larger. The operculum gives the character of the species. In this case there are eight nearly erect, slightly curved virgulæ and a laterally compressed ovate lamina dorsalis, the latter being a direct continuation of the columella and bearing a pair of broad dorso-lateral chitinous hamuli. The marginal teeth of the opercular disc are blunt. Thoracic uncini, as stated by GRUBE, show about nine teeth.

Another specimen, growing upon the tube of a larger species from South-east Cheval Paar, has length of about 20 millims. by width of 1·5 millims. There are seven virgulæ on the operculum, and the lamina dorsalis is quite flattened except at the back (Plate VII., figs. 180 and 180A). The uncini from the last thoracic torus show seven teeth. The bayonet setæ of the first thoracic fascicle show two clear spines at the base of the terminal process (Plate VII., fig. 181).

Eupomatus exaltatus, MARENZ.—Plate VII., fig. 182.

VON MARENZELLER, 'Südjap. Ann.,' ii., 1884, p. 217.

Station V., off Chilaw, Gulf of Manaar, 11 fathoms; one specimen without tube.

Differs from *E. heteroceros* in the structure of the operculum, other characters being approximately the same. The branchiæ are rather short, the stems stout and close together in a digitate manner, about 16 stems in each gill; terminal filaments slender, flagelliform. Thoracic uncini with six teeth, some with five only. The opercular style is stout, slightly flattened; the margin of the opercular cup carries 23 denticulations; from the centre of the cup a stout columella rises carrying a circle of eight large hooks, of which the dorsal one is larger than the rest and somewhat scythe-shaped, with a long hook directed ventrally and mesially; the seven smaller hooks have curved extremities directed outwards and are destitute of accessory processes (Plate VII., fig. 182). The operculum is associated with the right gill; no rudiment could be found on the left side. The first fascicle contains besides a few simple capillary setæ a bundle of strong unequally bifid setæ, the terminal process long and acuminate, the subterminal process very short and obtuse; these are called bayonet setæ (von Marenzeller).

The Ceylon specimen varies from the type, in which there is a crown of nine hooks instead of eight, and the thoracic uncini show seven or eight denticulations. In spite of these differences, which are not outside a possible range of variation,* the character of the crown of hooks is so distinctive as to leave no doubt as to the identification, notwithstanding the fact that von Marenzeller unfortunately omitted to state explicitly that the hooks of the crown, except the dorsal hook, are directed outwards; this is left to be inferred, and it is an important inference, since it decides the species.

Eupomatus heteroceros, Grube.

Grube, 'Verh. zool.-bot. Ges. Wien,' 1868, p. 639, Taf. 7, fig. 8.

Locality:—Several specimens from South-west Cheval and East Cheval, 8 fathoms.

Tube round, except flattened surface of attachment, doubled upon itself, U-shaped, or slightly convoluted and faintly ridged; it shows coarse growth rings and is overgrown with Bryozoa and pearl-oyster byssus. Thoracic uncini sexdentate. The opercular disc carries a crown of seven hooks turned inwards, of which one is larger and plain, the others equal among themselves and each provided with a pair of accessory lateral hamuli, and an inwardly directed basal process. The lateral hamuli are inserted lower down the shafts of the coronal hooks than in Grube's figures, and the basal hamules appear less upturned. The latter can hardly be seen without bisecting the operculum. The bayonet setæ of the first fascicle have bicuspidate processes as figured by Grube. The uniserial thoracic uncini, not observed by Grube, show five and six teeth, rarely seven. The marginal denticulations of the opercular disc end in rounded spatulate expansions.

The collection contains many examples of this species. In one series of seven individuals from the South-west Cheval, 13th November, 1902, one specimen has eight hamuliferous hooks on the operculum, in addition to the great hook instead of

* Compare *E. albiceps.*

the typical six. Two others have seven such hooks in addition to the simple hook. Meristic variations affecting a specialised organ composed of a limited number of parts are of considerable interest, especially in view of the analogy presented by *Eupomatus exaltatus* in this respect. Compare also the thoracic segments of *Sabellastarte indica.* Examples from East Cheval show six, seven and eight hamuliferous hooks respectively, in addition to the main hook.

The collar-margin is plain ventrally, not projecting forwards between the gills. The anterior free flap of the collar (seen from below) can be distinguished by a transverse groove from the posterior portion of the buccal segment, and at the sides of this groove there is a pair of thoracic organs analogous to those observed in *Pomatostegus actinoceros.* The orifice is guarded by a small triangular papilla which occurs at the level of the incisura lateralis of the collar.

Eupomatus minax (Grube).

Locality :—South-west Cheval Paar.

Small involved round tubes showing coarse growth-rings; pearl-oyster byssus sometimes attached to the tube. The marginal spines of the opercular disc vary between 19 and 21. The columellar spines are more erect than in Grube's figure ('Ann. Semp.,' 1878, p. 269); the large dorsal spine is vertical and has a strong recurved hook and two lateral accessory hooks.

Pomatostegus actinoceros, Morch—Plate VIII., figs. 3 and 4.

Morch, Otto A. L., 'Revisio critica Serpulidarum,' Copenhagen, 1863, p. 400, plate xi., fig. 16; Grube, 'Ann. Semp.,' 1878, p. 271.

This is an extremely variable species in regard to the structure of the operculum, and on the other hand it is the exact Indo-Pacific counterpart of the Antillean species *Pomatostegus stellatus*, Abildgaard (see Ehlers, 'Florida-Anneliden,' 1887, p. 296).

This species and *Eupomatus heterocerus* are the most abundant Serpulids in Professor Herdman's collection, and they must play an important part in consolidating the pearl banks as well as serving as a base for the attachment of the pearl oysters. This is proved by the byssi which still cling to many of the calcareous tubes secreted by these worms. The tube is massive, coarsely rounded or trigonal, rugged and overgrown. Sometimes the tube is provided with a high laciniate keel. The branchiæ are spirally rolled and banded. Their appearance varies according to the preservation. The transverse striation sometimes indicated is due to contraction, which causes wrinkling of the strong cuticle which covers the outer surface of the gills. The radioles have an internal septate structure, but the superficial wrinkles are not related to it, and the surface may be quite smooth. In one specimen from the Muttuvaratu Paar, brought up by the divers, I counted 36 radioles in one of the gills. The thoracic uncini showed as many as twelve teeth in addition to the basal, transversely expanded, scalprate process which VON MARENZELLER calls the "Meisselzahn." In the last thoracic torus the teeth of the uncini were not so numerous as in the preceding segments, not exceeding nine.

The collar is approximately as long as the rest of the thorax, entire below and at the sides, open above and continuous with the thoracic membrane on each side. The operculiferous style carries a broad wing-like membrane on each side which terminates above in a short free simple lobe. This membrane can embrace and protect the gills when retracted within the tube.

The disc of the operculum is covered with a chitinous cuticle and carries a long narrow columella arising excentrically near the dorsal side and furnished with circlets of spines at intervals (Plate VIII., fig. 4). The circlets of spines may be webbed or free. In the former case the chitinous membrane which they support projects beyond the spines and forms a stage or disc equal in diameter to the actual basal disc of the operculum. In the specimen before me the columella carries four stages above the opercular disc and two circlets of spines above the topmost stage. Another from the same locality shows two stages above the disc and three free circlets of spines above. A third has one stage above the disc and six circlets of free spines beyond. A fourth has three stages above the disc and two circlets beyond. A fifth has one stage above the disc, then two free circlets, then two more, narrower, stages followed by a terminal circlet. The abdominal setæ, as mentioned by GRUBE, have the apical portion slightly marked off. They closely resemble the abdominal setæ of *Omphalopoma langerhansii* figured by MARENZELLER ('Südjap. Ann.').

In another example taken from the Muttuvaratu Paar the opercular style retains a roseate flush in the preserved state. The tube has a low dorsal keel. The columella of the operculum carries two corneous stages over the disc, surmounted by five circlets of spines. The radioles of the gills are disposed in a simple spiral, about 27 in each gill; they are slender and the surface is smooth. Thoracic uncini from the sixth (last thoracic) torus show 7 to 9 teeth in addition to the scalprate process. A specimen from the South-west Cheval Paar shows three stages above the opercular disc followed by three circlets. Others were obtained from the East Cheval Paar in 8 fathoms.

The buccal setæ of this species are delicate, forming a small, frequently inconspicuous bundle of about a dozen setæ, among which may be found some slightly distinguished as bayonet setæ. On each side of the buccal segment, on its ventral aspect, there is a large orifice bounded by prominent lips (Plate VIII., fig. 3). The collar-margin projects forwards as a tongue between the gills ventrally as in *Spirobranchus cervicornis.*

An individual was taken off Panadure, Station XLV., 25 fathoms, measuring 20 millims. in side view from the free edge of the collar to the posterior extremity of the body; the collar and thorax 7 millims.; the operculum projects 7·5 millims. beyond the collar; width of thorax 4·5 millims. The brachysomatic condition of the abdomen may be due to regeneration. Between the whorls of the operculum a small Annelid was found by Mr. HORNELL (see *Haplosyllis spongicola*).

Protulopsis palliata, n. sp.—Plate VII., figs. 183 to 185.

Associated in the trawl with *Phyllochætopterus ramosus* from Galle, Station XXXIX., 16 to 30 fathoms.

A round, slightly curved calcareous tube, attenuated behind, widened in front. The body without the gills is 19 millims. long, 3 millims. maximum diameter. Gills with between 30 and 40 radioles on each side, rolled inwards in a single spiral turn; no operculum. Thorax consists of seven segments carrying seven pairs of capillary fascicles, but I do not find the uncini commencing before the fourth segment. The first fascicle contains numerous limbate capillary setæ of the usual form. In the fourth fascicle, in addition to the ordinary setæ, there is a group of salmacine setæ (Plate VII., fig. 183). There are about twelve of this kind of setæ in the fascicle, characterised by a short normally limbate tract followed by a clear striated border extending to the tip of the seta. The striated border is not limited by a refringent edge; the latter ceases suddenly at the upper end of the limbus. The uncini show about twenty equal denticulations; the last tooth at the base of the uncinus is followed by a long characteristic spur (Plate VII., fig. 184). The abdominal setæ occur to the number of five in a fascicle (Plate VII., fig. 185). The collar, in combination with the thoracic membrane, shows a remarkable development dorsally, where it is produced forwards on each side into a wide lappet, which is rolled upon itself and is probably able to follow the branchial spire to its termination; the ventral portion of the collar is marked off from the dorsal portion by an incisura lateralis, and its ventral border is slightly concave.

Serpula granulosa, MARENZ.—Plate VII., figs. 186 and 186A.

VON MARENZELLER, 'Südjapan. Ann.,' ii., 1884, p. 215 (p. 19 of reprint).

Locality: South-west Cheval Paar; several specimens.

Tube round, subcristate to cristate; fila branchialia (radioles) about 26 on each side*; operculum shallowly concave, with 46–52 rays which project as denticulations at the margin. The grooves which separate the rays do not all reach to the centre of the disc; they are the superficial indications of dissepiments which project vertically with a free inner border into the substance of the operculum (Plate VII., fig. 186A). Seven thoracic segments; modified setæ of the first segment unequally bifurcate; capillary setæ of the other thoracic segments simple, limbate; thoracic uncini 5-dentate. *Serpula granulosa* differs from *S. gervaisii*, QFG., by its cristate tube and the shallow cup of the operculum. The degree of concavity can be varied, sometimes the disc is nearly flat, sometimes slightly convex, but it does not seem likely that it could be deepened to the extent which characterises *S. gervaisii*.†

* VON MARENZELLER gives 35 for the type.

† *Cf.* GRUBE, 'Ann. Roth. Meer.' (Frauenfeld), 1868, p. 640.

In a typical example such as that figured on Plate VII., fig. 186, the total height of the tube in the region of the orifice is about 6 millims., of which the crest occupies 1 millim. The operculum is sometimes dextral. sometimes sinistral in position, and at the corresponding point on the other side, as noted by VON MARENZELLER, there is usually a rudimentary operculum. Minute tubercles are sparsely distributed on the concave opercular disc.

Serpula watsoni, n. sp.—Plate VII., fig. 187, and Plate VIII., fig. 6.

Locality :—Trincomalee, February, 1902.

I have much pleasure in dedicating this species to Mr. ARNOLD T. WATSON, whose drawing illustrates it (Plate VIII., fig. 6). It is characterised by the great length of the ampulla of the operculum, 3 millims., slightly exceeding the length of the style, the total length of the operculum being 5·5 millims. The ampulla is about twice the length of that portion of the style which rises above the collar. The disc of the ampulla is traversed by about 25 rays. There are about 30 radioles in each gill. The collar is entire below, divided on each side by an incisura lateralis. Uncini from the last thoracic torus with 5 and 6 teeth (Plate VII., fig. 187).

Spirobranchus cervicornis, n. sp.—Plate VII., figs. 188 to 192.

One specimen in bottle with *Loimia variegata*, *Dasychone cingulata*, &c. [? Cheval].

Total length 22 millims., made up as follows :—Gill-apparatus (including operculum) 7 millims., thorax 5 millims., abdomen 10 millims. Width of thorax 4·5 millims. The gills diverge outwards ; the gill-rays (radioles) are rolled inwards at the top and are disposed in a spiral of one turn and a half, about 30 in each gill. The thorax consists of seven setigerous segments with six pairs of uncinigerous tori. The first segment is produced into a capacious collar open above, its dorsal ends overlapping and covering the expanded style of the operculum, nearly reaching to the disc (Plate VII., fig. 188). Ventrally the collar-membrane is produced forwards as a tongue-like process between the gills (Plate VII., fig. 189). The buccal setæ (of the first fascicle) are of two kinds, long, slender, capillary setæ fringed with hair-like striæ though without a definite limbus ; towards the tips of the setæ the marginal hairs project ; secondly, stouter bayonet setæ with pilose extremities (Plate VII., fig. 191). The remaining thoracic setæ are of the common limbate type and call for no remark ; there are two groups of different sizes, more slender and stouter, in each fascicle. Thoracic uncini with fifteen teeth and a basal T-shaped mucro (Plate VII., fig. 192). The abdominal setæ are of the kind called "Dütenborsten" [geniculate setæ] by VON MARENZELLER ('Südjap. Ann.,' ii., Taf. iv., fig. 4*b*).

In *S. cervicornis* the horns of the operculum resemble a pair of antlers, of which the dorsal tine is half the length of the main tine (Plate VII., fig. 190). They only differ in proportion from the horns of *Spirobranchus giganteus* as figured by MORCH (1863) and EHLERS (1887).

It is not easy to define the limits of the genera *Pomatoceros*, PHILIPPI (1844) and *Spirobranchus*, BLAINVILLE (1818). GRUBE uses *Pomatoceros* in an extended sense and appears to disregard the prior claims of *Spirobranchus* ; the latter is retained by EHLERS (1887) and ST. JOSEPH (1894). The genus *Pomatoceros* s. str. comprises the species *crucigera*, GRUBE (Red Sea, 1869), *helicoides*, MARENZELLER (Japan, 1884), *triqueter*, L. (Europe, MORCH, 1863, ST. JOSEPH, 1894), and *bucephalus*, MORCH (Philippines, 1863). GRUBE'S *Serpula quadricornis* ('Ann. Semp.,' p. 275) appears to me to be probably co-specific with MORCH'S *Spirobranchus semperi* ('Revisio Serpulidarum,' 1863, p. 405). The species of *Pomatoceros* named above practically resolve themselves into two main groups represented respectively by the European *P. triqueter* and the Oriental *P. bucephalus.*

Spirobranchus semperi, MORCH.

MORCH, 'Revisio Serpulidarum,' Copenhagen, 1863, p. 405.
Serpula quadricornis, GRUBE, 'Ann. Semp.,' 1878, p. 275.

Opercular style with wing-like expansions as in the preceding species, opercular disc flat, carrying four distinct horns. Uncini from the last thoracic torus with 12 to 13 teeth.

Spirobranchus semperi, var. **acroceros**, nov.—Plate VII., fig. 193.

This variety is represented by several specimens apparently only differing from the typical form in the fact that the opercular disc is cone-shaped, carrying the horns at the top (Plate VII., fig. 193). Length 12·5 millims. (up to nearly 20 millims.) ; about 50 abdominal segments ; gill with 18 radioles.

Spirobranchus tricornigerus (GRUBE).

Serpula tricornigera, GRUBE, 'Ann. Semp.,' 1878, p. 273.

A small specimen from the pearl banks. The great feature of this species is the horizontal branching of the horns of the operculum, the main branches very slightly elevated and the ultimate ramifications lying approximately in one plane. The horns are very pale, calcareous, slightly chitinised. It is possible to distinguish three main branches proceeding from a common centre, but not so equilateral as in GRUBE'S figure. GRUBE assigns 20 teeth to the larger thoracic uncini. I only see the usual 12 teeth in the uncini of the last thoracic torus. The buccal setæ forming the first thoracic fascicle are of two kinds, simple capillary and bayonet setæ, both kinds with serrulate border. The gills are traversed by a strong, nearly black fascia a short distance in front of the basal membrane.

Vermilia pygidialis, n. sp.—Plate VII., figs. 194 to 196.

Locality :—South-west Cheval Paar.

Distinguished by the long, brown, horny, ringed, conoidal operculum, and by the obtuse posterior end of the body, which is furnished dorsally with an oval purplish-crimson cushion and long hair-like setæ (Plate VII., figs. 194 and 196). Ten radioles in the left gill; nine and the operculum in the right. Uncini from last thoracic torus with eleven teeth and a scalprate process (Plate VII., fig. 195). Capillary setæ of first thoracic segment not distinguished from the rest; simple limbate, accompanied by slender non-limbate setæ. Mid-abdominal region with dorsal uncini and ventral fascicles containing three geniculate setæ. Total length of operculum 5 millims., the style 2·5 millims., the ampulla and columella 2·5 millims. Length of gills 4 millims., of thorax 4 millims., of abdomen 11·5 millims. The terminal filaments of the gill-radioles are clubbed; in one specimen the clubs have a pinkish colour (Plate VII., fig. 194). The closeness of the intersegmental grooves gives the pygidium a foliate appearance. The tube is coiled horizontally upon itself, widens out in front, and presents 4 or 5 low longitudinal keels.

EXPLANATION OF THE PLATES.

PLATE I.

Fig. 1. *Chlœia flava.* Dorsal barbed bayonet seta. Zeiss 3 C.
,, 2. ,, Ventral furcate seta. Z. 3 C.
,, 3. *Hermione malleata.* Dorsal glochideal seta; the point is broken. Z. 3 C
,, 4. ,, Ventral furcate seta showing accessory tooth. Z. 3 C.
,, 5. *Pontogenia indica.* Anterior end.
,, 6. *Iphione muricata.* Anterior end.
,, 7. *Lepidonotus carinulatus.* Prostomium.
,, 8. ,, Carinulate papillæ of elytron arising from clear areoles.
,, 9. ,, Echinulate papilla.
,, 10. ,, Stellate papilla.
,, 11. ,, Ventral seta. Z. 3 C.
,, 12. *Halosydna zeylanica.* Parapodium.
,, 13. ,, Ventral seta. Z. 3 D.
,, 14. *Harmothoe dictyophora.* Elytron; the superficial filiform papillæ occurring on the larger shields are omitted.
,, 15. *Harmothoe dictyophora.* Head.
,, 16. ,, Ventral seta. Z. 3 C.
,, 17. *Hololepidella commensalis.* Dorsal seta. Z. 3 C.
,, 18. ,, Superior ventral seta. Z. 3 C.
,, 19. ,, Inferior ventral seta. Z. 3 C.
,, 20. ,, Head and proboscis.
,, 21. *Panthalis melanonotus.* Head and proboscis.
,, 22. ,, Fifty-fourth parapodium. *a*, geniculate appendix; *b*, dorsal cirrus; *c*, silken threads (tomentose setæ); *d*, notopodium; *e*, notopodial acicula; *f*, neuropodium; *g*, neuropodial acicula; *h*, ventral cirrus; *i*, coil of threads inside the body.

Fig. 23. *Panthalis melanonotus.* Lateral processes of four successive segments after the 28th, showing dorsal cirri with geniculate appendices, alternating with elytrophores and ovate processes; seen from above.
„ 24. *Panthalis melanonotus.* Superior ventral seta.
„ 25. „ Penicillate seta.
„ 26. „ Aristate seta.
„ 27. „ Inferior ventral seta.

,, 110. ,, Right set of jaw-pieces.
,, 111. ,, Anterior end.
,, 112. ,, Ventral seta. Z. 3 C.
,, 113. *Glycera lancadivæ.* Articular ends of shafts of compound setæ, of form A. Z. 3 D.
,, 114. ,, Portion of a seta of form B. Z. 3 D.
,, 115. ,, Parapodial ligules of form A. Z. 3 A.
,, 116. ,, Parapodial ligules of form B. Z. 3 A.
,, 117. *Polydora hornelli.* One of the modified acicular setæ of the fifth segment. Z. 3 D.
,, 118. *Notomastus zeylanicus.* Anterior end in left side view showing the half-retracted prostomium, the "tongue" below it, the first and second achætous segments, and the first setigerous segment.
,, 119. *Notomastus zeylanicus.* Unciniform or acicular seta. Z. 3 J. water imm.
,, 120. *Armandia lanceolata.* Anterior end from above; 1, tentaculum impar; 2, nuchal organ; 3, rostrum; 4, anterior portion of metapleural fold.
,, 121. *Polyophthalmus australis.* Anterior end from above showing pigment tracks and nuchal organs.
,, 122. *Nicomache truncata.* Anterior fragment from the left side. Actual length 47 millims.; width 5 millims.
,, 123. *Nicomache truncata.* Frontal view of head.
,, 124. *Ammochares orientalis.* Anterior end from below.
,, 125. ,, From above (dorso-lateral), showing three capillary fascicles in front of the first pair of tori.
,, 126. *Chætopterus appendiculatus.* Modified seta from 4th foot. Z. 3 C.
,, 127. *Phyllochætopterus herdmani.* Anterior end from above. First pair of spirally coiled tentacles are lost.
,, 128. *Phyllochætopterus herdmani.* Modified seta from 4th foot. Z. 3 C.
,, 129. ,, Modified seta from 3rd foot of an aberrant individual. Z. 3 C.
,, 130. ,, Plan of one of the branchial segments.
,, 131. ,, Spatulate seta from first parapodium. Z. 3 C.
,, 132. ,, Abdominal uncinus. Z. 3 D.
,, 133. *Phyllochætopterus ramosus.* Branching tube.
,, 134. ,, Modified seta from 4th foot in side view. Z. 3 A.
,, 135. ,, Modified seta from 4th foot of another specimen in back view. Z. 3 A.
,, 136. ,, Lower portion of an uncinus from a branchial segment.
,, 137. *Pectinaria panava.* Uncinus from a posterior torus.
,, 138. *Heterocirrus typhlops.* Anterior region from above.

PLATE VI.

Fig. 139. *Cirratulus cylindricus.* Anterior region from above.
,, 140. ,, Head and mouth from below.
,, 141. *Leprea inversa.* Capillary seta from second setiger.
,, 142. ,, Geniculate seta from 45th setiger.
,, 143. *Polymnia labiata.* Anterior end from below; the bases of the tentacular cirri are indicated in front of the labium (= 1st and 2nd segments); the lateral lobes of the 3rd segment project beyond.
,, 144. *Polymnia labiata.* Thoracic uncinus in front view. Z. 3 D.
,, 145. ,, Uncinus from 9th torus in side view. Z. 3 D.
,, 146. *Polymnia socialis.* Anterior region from below; the epistome projects in front; tentacles omitted.
,, 147. ,, Front view of a thoracic uncinus.
,, 148. ,, Side view of thoracic uncinus. Z. 3 D.
,, 149. *Polymnia triplicata.* Anterior region from the right side; *ep.*, epistome; *lab.*, labium.
,, 150. ,, Epistome (*ep.*), labium (*lab.*), and mouth in frontal view.
,, 151. ,, Uncinus in three-quarter view. Z. 3 D.
,, 152. ,, Uncinus in side view. Z. 3 D.
,, 153. *Loimia annulifilis.* Uncinus from third torus. Z. 3 D.
,, 154. ,, Anterior region from below, tentacles omitted; in front is the epistome, then the labium, then the lateral lobes.
,, 155. *Loimia medusa.* Anterior region from below.
,, 156. ,, var. *angustescutata*, showing additional tori and capillary fascicles.
,, 157. ,, Uncinus from first torus. Z. 3 D.
,, 158. ,, Uncinus from fourth torus. Z. 3 D.
,, 159. ,, Abdominal uncinus. Z. 3 D.
,, 160. *Loimia montagui.* Anterior region from below.
,, 161. ,, Quinquedentate uncinus from first torus. Z. 3 D.
,, 162. ,, Sexdentate uncinus from first torus. Z. 3 D.
,, 163. ,, Uncinus from 13th torus. Z. 3 D.

PLATE VII.

Fig. 164. *Grymæa cespitosa.* Anterior end from the right side. The small circles in the first branchial acervus are the scars of branchial filaments.
,, 165. *Grymæa cespitosa.* Uncinus. Z. 3 D.
,, 166. *Branchiomma acrophthalmos.* Spatulate seta from thorax.
,, 167. ,, Anterior end from above. In front the gill-bases are shown on each side, the radioles being omitted.
,, 168. *Branchiomma quadrioculatum.* Buccal segment and cephalic complex from below.
,, 169. ,, Uncinus. Z. 3 D.
,, 170. *Dasychone cingulata.* Average superior thoracic capillary seta. Z. 3 C.
,, 171. ,, Thoracic uncinus. Z. 3 D.
,, 172. ,, Portion of a gill-radiole showing stylodes and eyes and the bases of the gill-filaments.
,, 173. *Eurato porifera.* Anterior thoracic region from above.

Fig. 174. *Eurato notata.* Thoracic uncinus. Z. 3 D.
,, 175. ,, Thoracic capillary, broadly limbate seta. Z. 3 D.
,, 176. ,, Thoracic capillary seta with the shaft broken and the limbus projecting.
,, 177. *Sabellastarte indica.* Thoracic uncinus. Z. 3 C.
,, 177*a*. ,, Frontal view of cephalic crown; *d.*, dorsal side; *t.*, antenna or tentacular lacinia.
,, 178. *Jasmineira caducibranchiata.* Thoracic rostrate uncinus. Z. 3 C.
,, 179. ,, Abdominal uncinus. Z. 3 D.
,, 180. *Eupomatus albiceps.* Operculum in side view.
,, 180*a*. ,, Dorsal view of operculum.
,, 181. ,, Bayonet seta from first thoracic fascicle.
,, 182. *Eupomatus exaltatus.* Oblique lateral view of operculum.
,, 183. *Protulopsis palliata.* Salmacine seta from fourth thoracic fascicle.
,, 184. ,, Base of uncinus.
,, 185. ,, Abdominal seta.
,, 186. *Serpula granulosa.* View of orifice of tube with operculum *in situ*.
,, 186*a*. ,, Operculum bisected.
,, 187 *Serpula watsoni.* Uncinus from last thoracic torus. Z. 3 D.
,, 188. *Spirobranchus cervicornis.* Cephalic crown in dorsal view; *c.*, collar flap turned aside.
,, 189. ,, Cephalic crown obliquely from below.
,, 190. ,, One of the opercular horns in side view.
,, 191. ,, Bayonet seta from buccal segment.
,, 192. ,, Base of uncinus in side view and in frontal view.
,, 193. *Spirobranchus semperi*, var. *acroceros.* Operculum from below.
,, 194. *Vermilia pygidialis.* Anterior region from dorsal side.
,, 195. ,, Uncinus from last thoracic torus.
,, 196. ,, Posterior end.
,, 197. *Leprea inversa.* Posterior abdominal uncinus. Z. 3 J. water imm. From one of the last three or four segments.

PLATE VIII.

The figures on this plate were drawn by Mr. Arnold T. Watson, to whom the identification of the "building organs" of *Pallasia pennata* is due.

Fig. 1. *Pallasia pennata.* Side view of anterior region. *t.*, retracted tentacles; *b*, white portion of peristome; *c*, brown portion; *d*, brown with white zebra-like stripes. × 19. *a*, internal bristles crossing when head contracts.
,, 2. *Pallasia pennata.* Ventral view of anterior region; *b.o.*, building organ. × 19.
,, 3. *Pomatostegus actinoceros.* Ventral view; *op.c.*, opercular cavity; *x.*, thoracic orifice. × 16.
,, 4. ,, Dorsal view. × 16.
,, 5. *Stylarioides parmatus.* Showing recurved abdomen; the fore-body is seen from below. × 17. *a*, uncini.
,, 6. *Serpula watsoni.* Operculum. × 18.

NOTE ON POLYDORA ARMATA, Lnghs.*

BY

ARNOLD T. WATSON, F.L.S.

The specimens referred to in this note were found living commensally with a sponge, *Aulospongus tubulatus*, which is very common on the pearl banks, and is mentioned by Professor Dendy in his Report upon the Sponges in this series ('Ceylon Pearl Oyster Report,' Part III., p. 176).

A fuller description, with a figure showing the tubes piercing the sponge radially and the worms *in situ*, had previously been given by Dendy in his "Report on Sponges from the Gulf of Manaar" ('Ann. and Mag. Nat. Hist.' (6), iii., p. 73, 1889).

The general characteristics of the species are well described by Mesnil ('Bull. Sci. France et Belgique,' tome xxix., 1896, p. 203), and I have but few points of difference to note. Of these the most important, perhaps, relates to habitat.

The specimens described by Mesnil were obtained from *Lithothamnion*, through which they had pierced and in which they had formed tubes of calcareous sediment; while Carazzi and Lo Bianco report these worms as living in the shells of Venus and therein forming U-shaped tubes. A similar variation in habitat occurs in another closely allied species of this genus, *Polydora cæca*, which sometimes lives commensally with the sponge *Microciona plumosa*, as described by Hornell ('Nature,' vol. 47, 1892, p. 78).

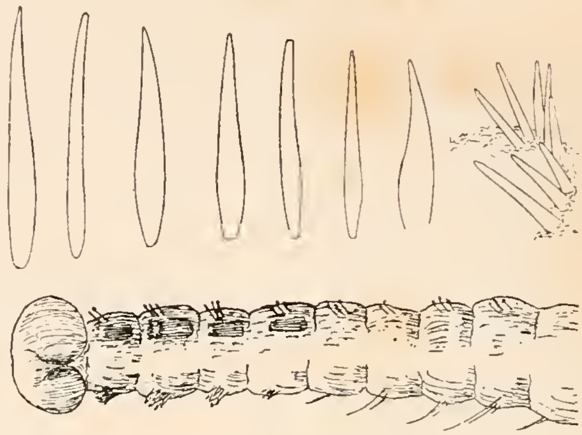
Owing to the difficulty of separating the worms uninjured from the sponge, it has only been possible to secure one or two fairly perfect specimens. The following notes, therefore, may be incomplete.

The Ceylon worm is apparently a smaller form of the species *Polydora armata*, Langerhans. The length varies from 2 to 3 millims. and the number of setigerous segments from 22 to 26. The branchiæ, of which I find four pairs, commence, as usual, on the 7th setigerous segment. They are comparatively broad and sometimes, but not always, of equal length. In one instance they gradually lengthen, the first being only half the length of the fourth. Eye-spots may or may not be present; most frequently they are invisible, but, after special treatment, in one case, I detected one pair. The tentacles are fairly long, reaching, in one specimen (though bent and twisted), to the 7th setigerous segment.

The setæ of the 5th segment, each with a characteristic hook, arising from an upright collar, which terminates on either side in a prominent pointed process projecting in the same direction as the hook (the whole having somewhat the appearance of an articulated seta), correspond well with Mesnil's figure. They number two, or sometimes three, in each parapodium.

* Langerhans, 'Zeitschr. f. Wiss. Zool.,' 34, 1880, p. 93.

Each parapodium of the 7th and following segments bears two or three hooded ventral uncinigerous setæ. The general outline of the worm is noticeable. The caruncle is slightly bilobed in front and extends backwards to about the 2nd setigerous segment; the anterior ten or eleven segments (except the 5th) are nearly equal to one another in length and breadth; they are followed by seven or eight segments, which are much larger, being nearly double the length and breadth of the former; in the hinder part of the worm the proportions of the segments become somewhat similar to those at the anterior end. The anal segment is broader than the preanal (see fig. in text). It is somewhat reniform in outline, the indent being dorsal. The segmental divisions in the anterior part, although fairly clear, are not deep, but commencing with about the 13th setigerous segment the separation becomes more and more distinct, until the last four or five preanal segments, in which it is very marked. This marked separation is further accentuated by the presence in the parapodia of these last segments of a fascicle of from 15 to 18 stout brown setæ, which vary greatly in form, size and proportion, a fact which was not shown by MESNIL. The forms comprised are acicular, lanceolate and scimitar-like (see fig. in text).



Polydora armata, LNGHS.—Posterior part in dorsal view, ×75; part of a dorsal posterior fascicle; and seven dorsal setæ from a posterior fascicle, ×375.

These setæ, which are more numerous than in MESNIL's examples, have usually their points drawn together in preserved specimens, forming a hollow, subspiral, truncate cone; but in several cases I have found the fascicle opened out, the points of the setæ being widely directed outwards, an arrangement extending over three parts of a circle, the central convexity of which is directed antero-laterally. By dissection the fascicle can be unrolled, when the setæ of which it is composed are seen to be arranged symmetrically side by side, the longest in the centre and the smallest at the outer edges. Probably in life the fascicle is expanded with a sweeping action. The forms of the setæ seem admirably adapted to the function described, the swollen parts, some distance from the base of the seta, doubtless acting as fulcra and rendering mutual support and aid in the action I have suggested.

The distribution of the species as noted by MESNIL is: Atlantic Ocean (Madeira), Mediterranean (Naples), British Channel (Manche: "Anse St. Martin"), to which we now add the Gulf of Manaar.

CONTENTS OF PART V.

PEARL OYSTER REPORT.

SUPPLEMENTARY REPORTS.

PREFACE.

This Report on the Pearl Fisheries and Marine Biology of Ceylon has required a much greater expenditure of time and labour, and has extended to a greater length, than was contemplated at the outset. In the winter of 1901, it was supposed that about one year must elapse, after my return from Ceylon, before the Report could be completed, but the necessary work has occupied all my leisure for over four years, and I am painfully conscious that it is still unfinished—there are several matters I should like to have included, or to have followed up further, had time for investigation and funds for publication been less limited.

But this must be the final volume, and I wish now, in bringing the work to an end, to make use of this opportunity mainly for the purpose (1) of reiterating my thanks to many friends who have kindly helped me, (2) of correcting such errors and omissions* in the former volumes as have come to my notice, and (3) of saying my final word as to the present position and future prospects of the pearl fisheries.

I have reluctantly come to the conclusion that an index to the five volumes is impracticable. If it contained all specific names it would be largely an unjustifiable repetition of our lists, and every Zoologist who consults the work will be readily able to find any desired species from the classifications given in the reports. It may, however, be some aid to the reader if I give here a scheme indicating in which Part each section of the subject and each special report will be found. The sections of the pearl-oyster report proper are arranged in chronological order, as that corresponds with the natural development of the subject, from preliminaries to final conclusions, and the special, or "supplementary," reports are placed in zoological order from the lowest groups to the highest, so that the position of each in the volumes can be ascertained from this list at a glance.

PEARL OYSTER REPORT.

* See p. 449.

SUPPLEMENTARY REPORTS.*

* If I may be allowed to offer the suggestion, I believe the most convenient form of reference to a species in one of these Supplementary Reports would be as follows:—*Sphæroma walkeri*, Stebbing, in Herdman, 'Ceylon Pearl Fisheries,' Part IV., p. 31, Suppl. Rep. XXIII., "Isopoda," 1905.

It has been my desire, so far as possible, to deposit the types of new species in the British Museum. In the case of some of the smaller forms the type specimens have become more or less used up in the process of examination, or exist only in the form of fragments on microscope slides or as sections. In other cases, the authors are still actively working at the groups in question, and it has been represented to me that the best interests of science would be served by allowing all the specimens to remain in their hands for the present. I have, however, already sent to the British Museum the types of new species, and, in some cases, representatives of additional species, in the following groups:—Echinodermata, Pantopoda, Hemiptera, Polyzoa, Cumacea, Amphipoda, Leptostraca, Schizopoda, Stomatopoda, and, in the case of other groups, the specimens are now in process of being picked out for packing and transmission.

I am very much indebted to my Zoological friends who have so ably helped me by taking charge of separate groups. The Supplementary Reports which they have contributed form a valuable body of information on the marine fauna of Ceylon which is indispensable in discussing any biological problems in that part of the Indian Ocean. A few corrections and additions kindly supplied by the authors will be found at the end of this volume.

I desire once more to acknowledge the very efficient help which I have received from Mr. James Hornell, F.L.S., both in the initial investigation and also during the production of this Report. Even after Mr. Hornell ceased to be formally my assistant in the matter, and was appointed to a responsible post under the Ceylon Government, he continued to spare no pains to keep me fully informed of the changes in the condition of the pearl banks and to obtain any specimens or evidence that might be required to clear up points in doubt.

Since the last volume of this Report was issued, another very successful pearl fishery has been held at Ceylon. Over 67 millions of oysters were fished, and the total proceeds amounted to 1,385,000 rupees. This does not, of course, rival the great fishery of 1905 (when over eighty-one and a half millions of oysters were fished and the revenue brought in was upwards of two and a half millions of rupees), but it comes second on the list of recorded fisheries, and makes the fourth in successive years of a remarkable series—the most profitable pearl fisheries that, so far as is known, have ever been held.

As to the future, it seems probable that the remaining oysters on the Muttuvaratu Paar, along with the patches which are known to be on the Karativo Paar, on the Mid-west Cheval and on a new ground inspected by Mr. HORNELL, lying three to four miles N.N.E. of the Muttuvaratu, will suffice for a fishery of moderate dimensions in 1907. Then, in 1908, there should be a good fishery on the Mid-east Cheval, where there is now a healthy bed of two-year-old oysters, which was reinforced with 1000 tons of cultch last spring. After 1908 the prospects depend upon further careful scientific inspecting, transplanting and cultching, upon the lines which have been laid down in successive sections of this report.

It can scarcely be doubted that the aquicultural operations which have been commenced under the auspices of the Ceylon Government will be carried on vigorously by the Pearl Fishing Company to which the fisheries have now been leased. It must be a matter of congratulation to all concerned—to the Colonial Government, to the Company, and to men of science—that, in the terms of the lease, the necessity for a scientific treatment of the pearl banks during the next twenty years has been duly recognised and provided for.

After such treatment the property ought to be returned to the hands of the Government at the end of the period in a still more valuable condition than it is at present, and even if that were to be the only economic result of the present Report, those who have spent thought, time, and money in the investigation and the publication will be able to feel that their labour has not been in vain.

I cannot conclude without expressing my appreciation of the honour done me by the Royal Society in undertaking the publication of this Report, and I desire especially to thank those I have had to consult with at the Colonial Office, as well as the Officers and Staff at the Royal Society, for much kindly interest and consideration, for advice given and trouble taken during the progress of the work.

REPORT ON THE PEARL OYSTER FISHERIES OF THE GULF OF MANAAR.—PART V.

PEARL PRODUCTION.

BY

W. A. HERDMAN, F.R.S.,
PROFESSOR OF ZOOLOGY IN THE UNIVERSITY OF LIVERPOOL,

AND

JAMES HORNELL, F.L.S.,
MARINE BIOLOGIST TO THE GOVERNMENT OF CEYLON AND INSPECTOR OF PEARL BANKS.

[WITH THREE PLATES AND SOME TEXT-FIGURES.]

THE investigation of a pearl fishery clearly falls into two parts—(1) the prosperity of the pearl-producing mollusc as part of the population of the pearl banks, and (2) the production of the pearls. It is the latter subject to which we now come. The preceding sections of this Report have dealt mainly with the pearl oyster as a healthy animal—with its distribution, structure and mode of life; while the Supplementary Reports have made known the many organisms which are associated with the pearl oyster on the banks, and which are inter-related with it in various ways and undoubtedly influence its life and prosperity.

The present section, on the other hand, treats of an abnormal process. Pearl-formation has often in the past been characterised, with substantial truth, as "a disease"; and whether the pearly material be deposited around a parasitic worm, or upon a particle of inorganic sand, or over an organically formed calculus, the resulting pearl is in each case a pathological product of the oyster's own tissues. It is always the shell-fish itself that makes the pearl. The pearl-inducing parasite does not produce the pearl any more than the grain of sand does, but either of them can apparently supply the stimulus which leads in the end to the formation of the gem. Many different kinds of shell-fish produce pearls, and these latter differ in quality in accordance with the animal that has deposited them rather than with the nucleus around which they have been formed. Still, even in the same shell-fish, pearls may differ much, and such differences are due to the nature of the nucleus, to the position in the body, and to the method of formation.

It is clear that pearls can be formed in several different ways, and recent discoveries show that some of the earlier suggestions are not altogether fanciful but contain an element of truth. The writings on pearl-production are numerous, and it is unnecessary to discuss all the views that have been held. But this report would have little claim to be regarded as even moderately complete if no mention were made of, at any rate, a few of the chief stages in the discovery of how pearls are formed.

HISTORICAL.

Our subject being the oriental pearl, it is only appropriate that we should mention first the early Hindu tradition, held even to the present day in the East, that at night or during heavy rain the pearl oyster ascends to the surface of the sea, opens its shell to the air and takes in drops of fresh water which become consolidated as pearls. PLINY and other classical writers record the similar belief that pearls are caused by drops of dew which enter the gaping shell at dawn and reflect the first rays of the sun, while still uncovered by the sea. Another poetical variant is that the pearls are due to the tears of the Nereids. These and other equally fanciful ideas are found scattered through the literature for centuries; and COLUMBUS, we are told, was convinced he had found the locality for orient pearls when he reached a spot, on the coast of Paria, in South America, where the trees grew down into the sea and had their roots covered with oysters gaping ready to receive the dewdrops from the leaves above.

As an example of an entirely different, but equally imaginative, idea, we have ÆLIAN'S statement that the pearls were formed by a lightning flash entering the opening shell. It must not, however, be supposed that all the views of the ancients on pearl-formation were wholly erroneous, for, as GIARD has recently pointed out, ATHENÆUS states that a certain ANDROSTHENES, who had travelled in the East, compared the developing pearls in the oyster to the Cestode larvæ in pork—a wonderfully close approximation to the truth.

Coming to more modern writers, we find many speculations as to more or less mysterious pathological effusions which may become solidified, as to displaced eggs which may form centres of deposition, as to possible similarity to calculi and to galls, and as to calcification of deposits formed around sand-grains, microscopic algæ, ova, embryos, and various kinds of minute parasites and other organic nuclei. We shall give here, in tabular form, some of the leading names (by no means a complete list) in the history of this inquiry, with, where known, the species of shell-fish on which the observations were made, and an indication of the view held, with more or less justification, as to the nature of the nucleus around which the pearl is formed.

Author.	Shell-fish investigated.	View as to origin of pearl or nature of nucleus.
Androsthenes	Oriental pearl oyster	(?) Cestodes.
Pliny	Oriental pearl oyster	Drops of dew.
Ælian	Oriental pearl oyster	Lightning-flash.
Rondeletius, 1554 . . .	. . . .	Parasites; also concretions.
Redi, 1671	. . . .	Grain of sand.
Réaumur, 1717	*Pinna, &c.*	Pathological effusion of shell-matter.
Bohadsch, 1761	*Aplysia*	Calculi.
Sir E. Home, 1826	*Anodonta*	Abortive ova.
Filippi, 1852–56	*Anodonta*	*Distomum* (Cercaria), &c.
Küchenmeister, 1856 . .	*Margaritana* and *Anodonta* . .	Mite (*Limnochares anodontæ*).
Von Hessling, 1856 . . .	*Margaritana* and *Anodonta* . .	Sand, algæ, ova, parasites.
Meckel, 1856	. . . .	Calculi.
Moebius, 1857	Both marine and fresh-water .	Entozoa.
Kelaart, 1857–59	Ceylon pearl oyster	Sand, diatoms, ova, parasites.
Pagenstecher, 1858 . . .	. . . .	Pathological concretions.
Garner, 1863, 1871 . . .	*Anodonta* and *Mytilus*	*Distomum.*
Harley, 1889	"British, Australian and Ceylonese" oysters	Calculi round inorganic or organic particles.
Comba, 1898	*Margaritifera vulgaris*	Parasites.
Diguet, 1899	*Meleagrina margaritifera* . . .	Pathological calcification of fluid formed around parasite.
Giard, 1897, 1901	*Donax, Tellina, &c.*	Distomids.
Dubois, 1901, 1903 . . .	*Mytilus* and *Margaritifera* . .	Distomid larvæ.
Jameson, 1902	*Mytilus edulis*	Distomid (Cercaria).
Herdman and Hornell, 1902, 1903, 1906	Ceylon pearl oyster (*Margaritifera vulgaris*)	Larval Cestodes.
Seurat and Giard, 1903, 1904, 1906	*Margaritifera margaritifera* . .	Larval Cestodes.
Shipley and Hornell, 1904	Ceylon pearl oyster	Larval Cestodes.
Crossland, 1905	Red Sea pearl oyster	Larval Cestodes.
Hornell, 1905	*Placuna placenta*	Larval Cestodes, rarely Distomids.

Omitting the more fanciful views, there are evidently three main methods which have been advanced as explaining the formation of pearls; and as is not infrequently the case when there are several competing theories, it cannot be said that one only is correct and of universal application and that the others are quite erroneous. The three methods referred to are:—(1) The grain-of-sand irritation; (2) the pathological secretion; and (3) the stimulation caused by the presence of a parasitic worm which acts as a nucleus, around which an epithelial sac deposits successive layers of pearly material. We shall briefly examine each of these views in turn.

Most of the attempts* at artificial "margarosis"—the production of pearls by stimulation of the Mollusc—have been based upon the belief that the nucleus of the

* There is, however, another artificial method which has been suggested—by infection with the parasites—which will be discussed below.

natural pearl is an inorganic particle. This "grain-of-sand" theory was supported by REDI and many other early and also more recent Naturalists, and it is the view which has been most generally adopted in the text books, and perhaps we may add in educated public opinion, as expressed, for example, in Sir EDWIN ARNOLD's lines :—

> "Know you, perchance, how that poor formless wretch—
> The Oyster—gems his shallow moon-lit chalice ?
> Where the shell irks him, or the sea-sand frets
> This lovely lustre on his grief."

Of late years, however, this view has been discredited by scientific investigators, and some recent writers seem to exclude altogether the grain of sand from participation in pearl causation. We cannot agree with that attitude. There is no doubt that occasionally a particle of sand or other inorganic material does form the nucleus of a free pearl. We have ourselves found three such, out of hundreds of pearls examined, in the course of our investigation. But, as a rule, any such foreign inorganic matter introduced between the mantle and the shell gives rise only to a pearly or nacreous excrescence, or blister, attached to the shell. Artificial pearls of an inferior sort are, however, sometimes produced in this way ; and the practice in China of forming rows of nacreous beads, or images of a Joss, or of Buddha, on the inner surface of the fresh-water mussel *Dipsas plicatus*, LEACH, depends simply upon the fact that foreign bodies placed outside the mantle will be cemented to the shell by a layer of nacre. The so-called "secret-process" of LINNÆUS, often referred to in the literature of pearl-formation, has been shown,* from manuscripts now in the library of the Linnean Society of London, to consist merely in piercing the shell and inserting a small fragment of calcareous matter kept in position by a piece of fine silver wire. LINNÆUS, on the evidence of contemporary manuscripts, seems to have obtained by the process certain pearls which the Swedish crown-jeweller declared to be in every way as good as those produced naturally. Probably they were compared not with the most precious pearls from the pearl oysters of Eastern seas, but with those of the Swedish fresh-water mussels (*Unio margaritifera*).

In 1898 BOUTAN experimented in artificial pearl-formation at Roscoff, and succeeded in obtaining pearls from the marine Gastropod *Haliotis;* and no doubt they might be obtained artificially from other shell-fish also.

The importance of all this, from our present point of view, is merely to show that the grain-of-sand method is occasionally found operative in the causation of true pearls, and it is possible that some of those that appear to have no nuclei may have been deposited around very minute inorganic particles.

The view that the pearl is produced as a calculus, or pathological deposit, was originated by RÉAUMUR in 1717, followed by BOHADSCH in 1761, was supported by MECKEL and by PAGENSTECHER nearly a century later, and again revived by

* 'Proc. Linn. Soc.,' 117th session, p. 18, 1905.

Dr. George Harley in 1889. Giard has recently pointed out that a considerable resemblance between the pearl and an animal calculus is compatible with the parasitic theory. Calculi commonly form around a nucleus, and many parasites are known to have calcified cysts deposited over them. Some pearls, as we shall show below, not of the finest quality, are probably formed as calculus-like growths independently of vermean parasites. Even when the parasite is present as a nucleus and causes the initial stimulation, it must be remembered that the pearl is produced by the molluscan host, not by the parasite, and so has been justly compared by more than one writer to an animal gall.

There are two papers by Harley in the 'Proceedings of the Royal Society.' The first (vol. 43, p. 461) dealt with the chemical composition of pearls, and the second (vol. 45, p. 612) with the structural arrangement of the mineral matters, and there Harley states two views, the one that they are "diseased concretions" comparable with "other morbid calculi," and the second that they are "misplaced pieces of organised shell." He recognises various kinds of nuclei, organic and inorganic, but also admits that pearls may sometimes begin "by the mere aggregation and coalescence of mineral molecules." (See our 'Calcospherules,' p. 27, below).

Composition of Pearl and Nacre.

In the paper on the "Composition of the Pearl and of Nacre," G. Harley and H. S. Harley ('Roy. Soc. Proc.,' 1888, p. 461) give the following as their analysis of "pure white pearls" (British, Australian and Ceylonese):—

Carbonate of lime	91·72
Organic matter (animal)	5·94
Water	2·23
Loss	0·11.

They also, for comparison, quote from Watts' 'Dictionary of Chemistry'* the following analysis of mother-of-pearl:—

Carbonate of lime	66·00
Water	31·50
Organic matter	2·50,

and express their surprise at the large amount of water found.

This difference between these two substances, produced in the same animal in a similar manner, and supposed to be so closely related to one another, is so very great that we felt that it was desirable to have another analysis made—especially since it is not stated in Watts' Dictionary who made the analysis quoted, nor what shell was

* Vol. iii., p. 1057, 1882.

used. A quantity of nacre was therefore detached from Ceylon pearl-oyster shells which had been lying dry in a box at the ordinary temperature of the Museum for about four years, and was handed to Dr. HERBERT E. ROAF, of the Bio-chemistry Department of the University of Liverpool, who has kindly supplied us with the following analysis :—

Calcium carbonate	88·79
,, sulphate	4·93
Organic matter	2·32
Water	2·28
Loss (no magnesium, no phosphates, faint trace of iron)	1·68.

From this it appears that the composition of the nacre is much more like that of the pearl than HARLEY supposed, and in fact the proportions of mineral matter and of water present in the two cases are practically the same if the "carbonate of lime" in the older analysis may be regarded as expressing the total salts of calcium present. The only notable difference remaining is the larger amount of organic matter in the free pearl than in nacre. In both, the calcareous part is in the form of aragonite.

The abnormal pearls which are formed not of nacre but of prismatic layers (calcite) or of horny material may very possibly have a composition widely different from that of the true orient or "cyst" pearl.

PEARLS AND PARASITES.

It is commonly thought that the Italian naturalist, PH. DE FILIPPI, originated in 1854 the view that the nucleus of the pearl is really organic, being an encapsuled parasite. But GIARD has recently reminded us that RONDELETIUS propounded the same view in 1558, and that ages before that ANDROSTHENES, who had travelled in the East, is reported by ATHENÆUS to have compared the developing pearls in the oyster to the Cestode larvæ in "measly" pork. This, in the absence of microscopic examination, can scarcely be regarded as a scientific demonstration ; but it was at least a very happy guess, for one of the first facts that we were able to determine in connection with the Ceylon pearl oyster, in the spring of 1902, was that the orient pearl in the Gulf of Manaar is deposited around the young larva of a Cestode.

Coming to actual identifications of the organic nucleus in comparatively recent times, we find that FILIPPI's pearl-parasite in *Anodonta cygnea* was the Trematode *Distomum duplicatum*, v. BAER ; ROBERT GARNER (in 1871) records "Distomes" from both fresh-water and marine mussels ; and GIARD attributes the origin of pearls in *Donax* and *Tellina* to a species of *Brachycœlium*—all these being cases of Trematoda. Other naturalists have since extended the discovery to other pearl-producing molluscs and to other worm parasites. To E. F. KELAART belongs the honour of having first connected the formation of pearls in the Ceylon oyster with the presence of vermean parasites. He and the Swiss zoologist, A. HUMBERT, who was with him at a pearl fishery off Aripu in 1857, found various parasitic worms infesting the viscera and other parts of the pearl oyster, and they agreed that these worms played an important part in the formation of pearls. KELAART moreover, in 1859, made the remarkable suggestion, in the case of the Ceylon pearl oyster, that it might be possible to increase the quantity of pearls by infecting the oysters in other beds with the larvæ of the pearl-producing parasites. This is exactly the idea that has lately been revived by DUBOIS in France.

OBSERVATIONS ON MYTILUS PEARLS.

Turning now to European shell-fish, we find that our countryman, ROBERT GARNER, in 1863 and again in 1871* associated the production of pearls in our common English mussel (*Mytilus edulis*), as well as in Anodon, with the presence of Distomid parasites.

Professor GIARD, in 1897, and other French biologists since, have made similar observations in the case of *Donax* and other Lamellibranchs—GIARD describing† the Distomid worm which he found as a species of *Brachycœlium* which he has identified since with *Distomum constrictum*, MEHLIS. LÉON DIGUET, in 1899, described the pearl-sac which secretes concentric layers of the nacreous deposit around the remains of parasites. We now come to quite recent years, during which there has been great activity. Professor RAPHAEL DUBOIS, in 1901, ascribed the production of pearls in mussels on the French coast to the presence of the larva of *Distomum margaritarum*. The next year (1902) Dr. H. L. JAMESON‡ followed with a more detailed account of the relations between the pearls in *Mytilus edulis* and the Distomid larvæ which he identified as belonging to *Distomum* (*Brachycœlium*) *somateriæ*§—the same sub-genus as GIARD had found some years previously in other Lamellibranchs. JAMESON's observations were made partly at Billiers (Morbihan), the same locality at which DUBOIS had also worked, and partly at the Lancashire Sea Fisheries Laboratory at Piel, in the Barrow Channel. DUBOIS published a further note‖ in January, 1903, in which he stated that JAMESON had come to Billiers after his departure and had confirmed the discovery made previously, first by GARNER and then by himself. But JAMESON had really done much more than that. He had shown that it is probable that the parasite causing the pearl formation in our

* 'British Association Report' for 1863, p. 114; and 'Journ. Linnean Soc., Zool.,' vol. xi., p. 426.

† 'Comptes Rendus Soc. Biol.,' November 13, 1897, p. 956.

‡ 'Proc. Zool. Soc. Lond.,' 1902, p. 140.

§ GIARD states ('Feuille des Jeunes Naturalistes,' January 1, 1904) that this species is the *Distomum constrictum* of MEHLIS, but there seems some reason to believe that JAMESON had more than one species under observation.

‖ 'Comptes Rendus Acad Sci.,' January 19, 1903.

common mussel (*Mytilus edulis**) is the larva of *Distomum somateriæ*, a Trematode worm, the adult of which† lives in the intestine of the eider duck and the scoter duck. He also stated that the larva inhabits Tapes or the cockle as a first host before getting into the mussel, and gave figures of the parasite in various conditions.

Two very important matters are, however, left in a somewhat unsatisfactory condition by JAMESON'S paper. The first of these is the mode of origin of the epithelial sac which encloses the larval parasite and which secretes from its cellular walls layer after layer of nacreous material so as to form a pearl. The presence of this sac was known before (VON HESSLING, 1858, and DIGUET, 1899), but no one had yet satisfactorily traced its origin. JAMESON several times compares it with the epithelium on the outer surface of the mantle, using such terms as "similar to" and "indistinguishable from," but he evidently considers that it has nothing to do with that epithelium, although it produces an identical pearly secretion. He describes the sac round the parasite as formed by the proliferation of a few cells which "are basally continuous with fibres of connective tissue." He also says of it, "This epithelium appears to arise quite independently of the outer epidermis." Now such a mode of origin as this is very unlikely, and from our own observations upon pearl-bearing mussels obtained from the same locality as JAMESON'S, we think there can be little or no doubt that the cells of the pearl sac are directly or indirectly, but at least genetically, connected with the exactly similiar cells on the outside of the mantle. It is very probable that the parasite in burrowing into the mantle carries in with it one or more epidermal cells which proliferate to form the sac. As the Distomid larvæ are found moving on the inner surface of the shell before coming to rest in the mantle, they must traverse the epidermis, and it is natural to suppose that in their migration they may push some epidermal cells in before them. Even in the absence of direct evidence of this, it will be admitted that it does not involve such a violent assumption as that the connective tissue in the centre of the mantle can produce an epithelial sac, the cells of which are indistinguishable both in structure and in function from the epidermis outside.

In giving a preliminary account of pearl-formation in the Ceylon pearl oyster to Section D of the British Association in September, 1903, we took up the position that the sacs enclosing the pearls were in all cases of ectodermal (epidermal) origin;

* JAMESON also states that he had found a Trematode in a sac in an example of the Ceylon pearl oyster ('Nature,' January 22, 1903, p. 281).

† ODHNER, however, has shown that JAMESON'S larval stages and his sexually mature form cannot belong to the same species, and that both belong to the genus *Gymnophallus*. The adult, according to ODHNER ('Fauna Arctica,' iv., 2, p. 291, 1905) is *Gymnophallus somateriæ* (LEVINSEN), and the larval form which causes the pearl-formation in *Mytilus* belongs to *Gymnophallus bursicola*, ODHNER. In a recent paper, "Über die Entstehung der Perlen," Dr. M. LÜHE also refers JAMESON'S stages to different species of *Gymnophallus*, and considers it probable that the parasite that causes pearl-formation in the mussel is a distinct species which must then be called *Gymnophallus margaritarum* (DUBOIS).

and it was gratifying to find that Professor A. GIARD in a note* on the subject shortly afterwards took the same view and considered that in the case of JAMESON'S mussel pearls there is a "passive immigration" of the epithelial cells caused by the migrating parasite.

Just as this section of the report was going to press I received a letter from Dr. JAMESON (now on the staff of the Transvaal Technical Institute, Johannesburg) in which he says: "I had never any doubt that it is a true epidermis, but I never got so far as to determine actually by observation whether it arose, as I think you have suggested, by the Trematode carrying in with it a fragment or pocket of epidermis; or, as I suspected, by means of epidermal or sub-epidermal replacement cells (Ersatzzellen)." From this it may be gathered that Dr. JAMESON would now agree with GIARD and BOUTAN and ourselves that the epithelium of the pearl-sac must be derived directly or indirectly from the epidermis of the mantle.

The second point in JAMESON'S account which, from the evidence presented, is not quite satisfactorily settled is the supposed infection of the mussel with parasites by other mollusca—*Tapes decussatus* in France and *Cardium edule* (the cockle) in the Barrow Channel. So far as regards this case, JAMESON'S conclusion is based upon the experiment of placing some mussels which he supposed to be free from parasites in a tank with French *Tapes* which were infected, and examining the mussels from time to time until he found they contained the parasites (Cercaria). Now in such an experiment it is necessary to be quite sure of the material used, to deal with sufficiently large numbers, and to have control experiments. JAMESON may have taken these precautions, but it does not appear from his paper. He says of the material: "These mussels, of which I examined a number, were practically without parasites. About one in every five of the largest examples contained a Cercaria, one had two Cercariæ, and one contained a small pearl." This can scarcely be described as free from parasites. He used 70 mussels, and if we take his own figures, one in five, as accurate, then about 14 of these specimens were infected at the beginning of the experiment. We find from his records that he only examined 13 of these mussels (2 after 11 days, 6 after 2 months, and 5 after $6\frac{1}{2}$ months), and found 12 of them infected. But it is obvious that that number may have been infected from the beginning, or may have become infected at any time from neighbouring mussels. The theory of transference of the parasite from one mollusc (such as cockle) to another (the mussel) may be true, but it is not proved by those experiments. It was not shown that the mussels were free from parasites at the start, the numbers in the recorded experiments are too small to yield definite conclusions, and the observations should clearly be repeated, using hundreds of cockles and of mussels with well-devised control experiments. In order to show the necessity for large numbers in this kind of work, it may be added that, Mr. ANDREW SCOTT having informed us of Dr. JAMESON'S observations at Piel, we had some samples of these same mussels and cockles sent to the Liverpool Laboratory,

* 'Comptes Rendus Soc. Biol. Paris,' December 19, 1903, lv., p. 1618.

where, with the assistance of Mr. WALTER TATTERSALL, B.Sc., and Mr. J. PEARSON, B.Sc. (in October, 1902), an independent examination of them was made, with results that do not altogether agree with Dr. JAMESON'S.

We may distinguish between four kinds of mussels examined by both of us, and described by JAMESON as follows:—

(A) From the beds opposite the Piel Hatchery—"where every specimen is abundantly infected . . . . and almost every specimen contains pearls."
(B) From the piles of the old pier at Piel—"practically without parasites."
(C) From Roosebeck Scar, outside Barrow Channel—"not infected."
(D) Roosebeck Scar mussels transplanted to foreshore at Piel two years ago—"all were infested" . . . . "each contained several small pearls."

Of (A) we examined a sample of 25 mussels which contained in all 151 pearls and 11 parasites, but 4 of the specimens had neither pearls nor parasites and no less than 18 out of 25 had no parasites. We cannot therefore agree that "every specimen is abundantly infected."

Of (B) we examined also 25 mussels, which showed in all 21 pearls and 22 parasites, 7 had neither pearls nor parasites, and 13 had no parasites. These, then, showed far fewer pearls than (A), but twice as many parasites, and fewer of them were free from infection. They can scarcely be called "practically without parasites."

Of (C) we examined 28 mussels, which contained 73 pearls and 37 parasites, 4 had neither pearls nor parasites and only 9 (out of 28) had no parasites. These, then, are evidently just as much infected as the mussels on the Piel foreshore (A).

Of (D) we examined 24 mussels, and they contained 65 pearls and 26 parasites, 3 had neither pearls nor parasites and 12 out of 24 had no parasites. So in place of these transplanted "Roosebecks" having become more infected on the Piel shore, they on the whole showed rather less infection than the mussels taken direct from the parent bed.

Finally, we examined a sample of 25 cockles from Piel, and found in them 8 pearls, but no parasites at all of the right kind. This does not support the view that the cockle contains the earlier stage of the parasite and passes it on to the mussel.

At the end of October, 1902, Mr. ANDREW SCOTT, A.L.S., and Mr. JAMES JOHNSTONE, B.Sc., examined some further samples at Piel with the following results:—

(A)	Examined	61,	got	390	pearls and	191	parasites.
(B)	,,	103,	,,	100	,,	61	,, *
(D)	,,	53,	,,	161	,,	66	,,

(Roosebeck Scar mussels could not be got at the time.)

* Mr. JOHNSTONE, however, informed me that before he made this examination a gale had washed away some of the piles of the old pier, and that, consequently, his sample of (B) was obtained from rather a lower level than JAMESON'S and so may have contained more parasites.

The most noteworthy difference between these results and those given above are in the case of the parasites in (A), where Mr. Scott found about 7 times as many as we did. The sample of (B) in this case also, it will be noticed, is by no means free from infection. Since that time Mr. Scott has examined a few more samples from these same beds with slightly different results, and also a number of batches of mussels from other parts of the coast of the Irish Sea. As these may be interesting for comparison with other localities and other molluscs, we give Mr. Scott's notes, with which he has kindly supplied us, in summarised form, as follows :—

Beds on the estuary of the Wyre :—			
"Wardleys"	72 mussels had	30 pearls	and 3 parasites.
"Hambleton"	11 ,,	1 pearl	,, 0 ,,
"Skear"	12 ,,	1 ,,	,, 0 ,,
"Knott End"	10 ,,	0 pearls	,, 3 ,,
"Fleetwood Lighthouse" .	13 ,,	23 ,,	,, 6 ,,
On the Lune :—			
"Crook Skear"	10 ,,	2 ,,	,, 1 parasite.
"Abbey Skear"	10 ,,	0 ,,	,, 0 parasites.
On the Ribble :—			
"St. Anne's"	9 ,,	2 ,,	,, 0 ,,
"North Training Wall" .	27 ,,	1 pearl	,, 0 ,,
At Morecambe :—			
"Ringhole"	42 ,,	27 pearls	,, 27 ,,
"Knott End"	32 ,,	0 ,,	,, 5 ,,
"Bailing Knott"	34 ,,	3 ,,	,, 12 ,,
"Reap Skear"	5 ,,	0 ,,	,, 0 ,,
Cheshire :—			
"Wallasey"	68 ,,	0 ,,	,, 0 ,,
North Wales :—			
"Conway"	12 ,,	33 ,,	,, 8 ,,
"Ogwen River"	15 ,,	77 ,,	,, 14 ,,
"Llanfairfechan"	20 ,,	18 ,,	,, 1 parasite.
"Carnarvon"	18 ,,	9 ,,	,, 8 parasites.
"Aberdovey"	21 ,,	2 ,,	,, 0 ,,
"Barmouth"	26 ,,	6 ,,	,, 4 ,,
Barrow Channel :—			
"Roa Island"	53 ,,	231 ,,	,, 77 ,,
	520	466	244

The totals show nearly as many pearls as mussels, and nearly twice as many pearls* as parasites, but that must not be considered as a conclusion that can be generally applied. The last item on the list shows how much more abundant the pearls and parasites may be in one locality than in others.† In fact, we do not wish to attach much weight to any of these figures given above. The point we desire to make is rather that in working with these comparatively small samples each fresh examination gives a somewhat different result, and that, consequently, it is necessary that some one living on the spot, with abundance of material at hand and with tanks for experiments under constant observation, should make a comprehensive investigation of some hundreds or thousands of each kind of mussel and cockle in order to clear up the distribution of pearls and parasites, and settle this question of infection.

It must not be supposed that we are disputing Dr. LYSTER JAMESON's theory of pearl-formation. We recognise the excellence of his work and appreciate the energy he displayed in prosecuting the research, both at Billiers and at Piel. His paper marks a distinct advance in our knowledge of the subject. But there remain the two points on which it seems to us the evidence in JAMESON's paper is not completely satisfying. These are (1) the origin of the epithelial sac that secretes the pearl, and (2) the infection of the mussel from a previous molluscan host, the *Tapes* or the cockle. There may be such a host, but JAMESON's observations and our own later ones leave the matter still doubtful.

Finally we desire to emphasise the point that JAMESON's observations and conclusions refer to pearl-formation in the common marine mussel of North-west Europe, *Mytilus edulis*, and cannot, without further evidence, be extended to other pearl-bearing molluscs. It is becoming clear that several parasitic worms and several distinct processes are at work in bringing about the production of pearls in shell-fish.

ARTIFICIAL INFECTION.

To continue our historical survey, Professor M'INTOSH‡ has described the examination of 700 mussels from near St. Andrews, where he found that 300 in all, or nearly 43 per cent., were pearl-bearers—a small proportion, however, com-

* In comparing these statistics with those of the Ceylon pearl oyster, one is struck by the wholly different ratio borne by pearls to parasites in the two cases. In the mussels, pearls are far more numerous than the living parasites. In our Ceylon oyster, parasites may be exceedingly abundant; while pearls (cyst-pearls) are relatively very rare, probably not more than one to a hundred parasites.

† Mussels that grow rapidly and regularly have few pearls. It is the old "blue-nebs" of uncertain age and battered appearance that have the most pearls. We may add that the same general principle holds good in the case of the Ceylon pearl oyster. The most prolific pearl-bearers are those of stunted appearance and somewhat rounded form the "Koddapakku" or Areca-nut oysters, as the divers call them.

‡ 'Ann. Mag. Nat. Hist.,' June, 1903, p. 549. W. NICOLL has a recent note ('Ann. and Mag.,' January, 1906) on Trematode parasites in the cockle and mussel at St. Andrews. He finds the adult in the oyster-catcher, but it is evidently not the form described by JAMESON, since NICOLL refers to it as probably a new species of *Echinostomum*.

pared with our results from Piel. He associates the occurrence of pearl-bearing mussels in St. Andrews Bay with the presence of large numbers of parasites in the wild ducks that feed upon these mussels; and suggests that possibly other birds, such as the oyster-catcher, may be found to harbour the same parasites.

Professor R. DUBOIS, whose former observations had been made in Morbihan, has since turned his attention to the Mediterranean coast. He found that the southern French mussel (*Mytilus gallo-provincialis*) forms pearls caused by another Distomid, distinct from that of Brittany. He then worked at the acclimatisation of a true oriental pearl oyster ("pintadine") in French waters and the artificial production of pearls.* He brought the pearl oysters from the Gulf of Gabes, in South Tunis, to the marine laboratory at Sfax, and caused them to multiply and increase in size. The pearls produced in Tunis are small and very rare—it is necessary to open 1,200 to 1,500 oysters to find one pearl; but DUBOIS tells us† that by placing them on ground where *Mytilus gallo-provincialis* becomes infested with pearls and parasites, he very easily provoked the production of fine pearls in the "pintadine" to such an extent that three successive individuals opened contained each two little pearls. This, if corroborated, is a remarkable circumstance from several points of view. First, it will, if it proves a success, be a striking verification of what KELAART in Ceylon, fifty years ago, declared might be done. Secondly, if the "pintadine" in question is really the same species as the Ceylon pearl oyster (GIARD considers that it is not), it is curious that a Distomid parasite should prove to be so efficacious in setting up pearl-formation, since we have found that in the Gulf of Manaar the pearl-parasite is a Cestode larva. Thirdly, it is remarkable that the parasite of the *Mytilus* should transfer itself so readily to a new host belonging to a distinct family.

It is this last paper by DUBOIS that has given rise to various more or less exaggerated or even erroneous statements in the public Press, such as that the pearl-oyster must be infected with a microscopic germ in order to render it pearl-producing; or even that inoculation with a serum causes the oyster to produce artificial pearls. The parasite that causes the irritation is, as has been known for many years, not a "germ," and still less a "serum," but a worm which is visible to the eye—a worm which in *Mytilus* seems to be usually a Trematode, and in the Ceylon pearl oyster (*Margaritifera vulgaris*), according to our observations, is certainly a Cestode.

According to an interesting note by Professor GIARD,‡ the discovery of Cestode larvæ as nuclei of pearls, which we had made upon the Ceylon pearl oyster in 1902, was shortly afterwards corroborated by Dr. L. G. SEURAT, working independently in his laboratory at Rikitea in the Island of Mangareva (Gambier Archipelago). The oyster on which SEURAT worked was *Margaritifera margaritifera*, var. *cumingi*,

* COMBA had, however, in 1899, introduced the same mollusc on the South Coast of Italy, and experimented there in artificial pearl-formation.

† 'Comptes Rendus Acad. Sci.,' October 19, 1903, p. 611.

‡ 'Comptes Rendus Soc. Biol. Paris,' November 6, 1903, lv., p. 1222.

REEVE, and the Cestode parasite found, is, according to GIARD, an *Acrobothrium* (= *Cyathocephalus*) or some allied form. Some of our Ceylon pearl-oyster parasites very closely resemble the figures given by GIARD, and possibly may also belong to the genus *Cyathocephalus*, although most of them are certainly Tetrarhynchids.

GIARD, in a further note in the same Journal (p. 1225), discusses the statements that have been made in regard to "margarose artificielle," and evidently considers that DUBOIS' claim to have established the artificial production of pearls is not yet justified by the facts. About the same time, M. L. BOUTAN* wrote showing that "fine pearls" do not really differ from "nacre-pearls," since both are secreted from open or closed epithelial sacs derived from the epidermis; and GIARD very properly replied, a few days later,† that this fact is quite in accord with general principles, and was previously known. M. BOUTAN then published a more detailed account‡ giving figures illustrating his point that in all cases the pearl-sac is formed by an invagination of the surface of the mantle, and that it is of ectodermal origin, not mesodermal as he supposed JAMESON to have indicated. Finally, in a letter (January 20, 1904) to one of us, he states that he is on the point of departure for the East in order to investigate the matter further. The results have not yet appeared.

CEYLON PEARLS AND PARASITES.

Turning now to the investigations on the Ceylon pearl oyster in the Gulf of Manaar, let us first recall the work of our predecessor, Dr. E. F. KELAART, in the same field and on the same animal nearly half a century ago. KELAART, in 1857, in his "Introductory Report on the Natural History of the Pearl Oyster of Ceylon," after describing the secretion of nacre by the mantle, said:—"It will be thus clearly understood, that when a grain of sand or the larva of an insect is introduced between the mantle and shell, it will become covered over with the pearly secretion; which, always going on, is augmented at the part where the foreign matter lies. This phenomenon I have detected with the aid of the microscope, in its very earliest stage." The probability is that by "larva of an insect" in this passage KELAART meant such an organism as the Cestode larva which we now find is the determining cause of such pearl-formation.

In another passage, in his "Report on the Pearl Banks of Arripo for Season 1858," he says:—"The presence of a worm (a species of *Filaria*) found in the oysters has, I am positive, much to do with the formation of pearls. I would rather reserve this part of my investigation for longer experience. But this much I can say at present, with perfect safety: that whenever I found good pearls in a batch of oysters, I found this worm and its eggs in large numbers in the liver, ovary, mantle, and other parts

* 'Comptes Rendus Acad. Sci.,' December 14, 1903, p. 1073.

† 'Comptes Rendus Soc. Biol. Paris,' December 19, 1903, p. 1618.

‡ "Les Perles Fines: leur Origine réelle," 'Arch. Zool. Expér.,' sér. 4, t. ii., p. 47, 1904.

of the oyster." This "Filaria" may possibly be either the *Ascaris* or the *Cheiracanthus* which we have found, and which are described as new species by SHIPLEY and HORNELL; or it may possibly be the elongated, later stage of the *Tetrarhynchus* larva which also occurs.

Finally, at the end of KELAART's last Report (1859) occurs the remarkable passage where, in speaking of the corroborative observations of Mons. A. HUMBERT, he said :—"We both agree that these worms play an important part in the formation of pearls; and it may yet be found possible to infect oysters in other beds with these worms, and thus increase the quantity of these gems." As we stated in the Introduction to this work (Part I., p. 7, 1903), "Dr. KELAART's short reports show that he was tackling the problems in a scientific manner, and his researches were incomplete at the time of his sudden death."* We may take these observations as our point of departure. THURSTON, in 1894, however, confirmed KELAART, finding in the tissues and also in the alimentary canal of the oyster "larvæ of some platyhelminthian (flat worm)"; but he was able to add little beyond figuring ("Madras Museum Bulletin," I., Plate ii., fig. 1) a section showing two of the parasites encysted between the alimentary canal and the gonads. Here the matter practically rested so far as actual investigation of the Ceylon pearl oyster was concerned, until we found the Cestode larvæ in association with pearls in the tissues during our cruises in the "Lady Havelock" in the Gulf of Manaar, in February and March, 1902. It was about March 6th (see "Narrative," p. 70, in Part I.), when cutting up oysters from the western part of the Cheval Paar, that we first became convinced that the opaque white globular larvæ we were finding encysted in the liver belonged to Cestode worms. Subsequent work showed us that some of them at least were referable to the genus *Tetrarhynchus*, and the various stages that we were able to find up to the spring of 1904 were described by SHIPLEY and HORNELL in Part II., p. 79.

Since then large numbers of pearl oysters from various paars in the Gulf of Manaar have been examined by us in the field and in the laboratory, and although many small pearls and many parasites have been found, it is apparently very difficult indeed to hit upon a stage showing the commencement of the pearl-formation, or any evidence bearing on the entrance of the parasite into the mollusc.

The youngest stages in the life-history of *Tetrarhynchus* are still unknown, and it is still uncertain whether the free-swimming larvæ found on Muttuvaratu Paar really belong to this life-history. They have calcareous corpuscles and an indication of an invaginated head, and are almost certainly young Cestodes. We reproduce here (fig. 1) four of the figures of this presumed youngest stage, given by SHIPLEY and HORNELL, and are unable to add anything to their statement (*loc. cit.*, p. 86) :—"On the whole we think it probable that this larva is the first stage in the life-history of the pearl-forming organism," &c.

* When in medical attendance on General LOCKYER. Both the General and the Doctor died in the Red Sea, in 1859.

Many of the pearl oysters which we examined in the Gulf of Manaar in February and March, 1902, and also those we have examined since, both in Liverpool and at Ceylon, show numerous encysted parasites in various parts of the body. We have

Fig. 1. Free-swimming larvæ caught in the tow-net on Muttuvaratu Paar.

found these cysts on the branchiæ, in the mantle, in the liver and gonads, and elsewhere amongst the viscera. Fig. 2, giving a transverse section (A) and a lateral view (B) of a pearl oyster, shows a number of pearls and a few encysted parasites in the positions where we most commonly find them.

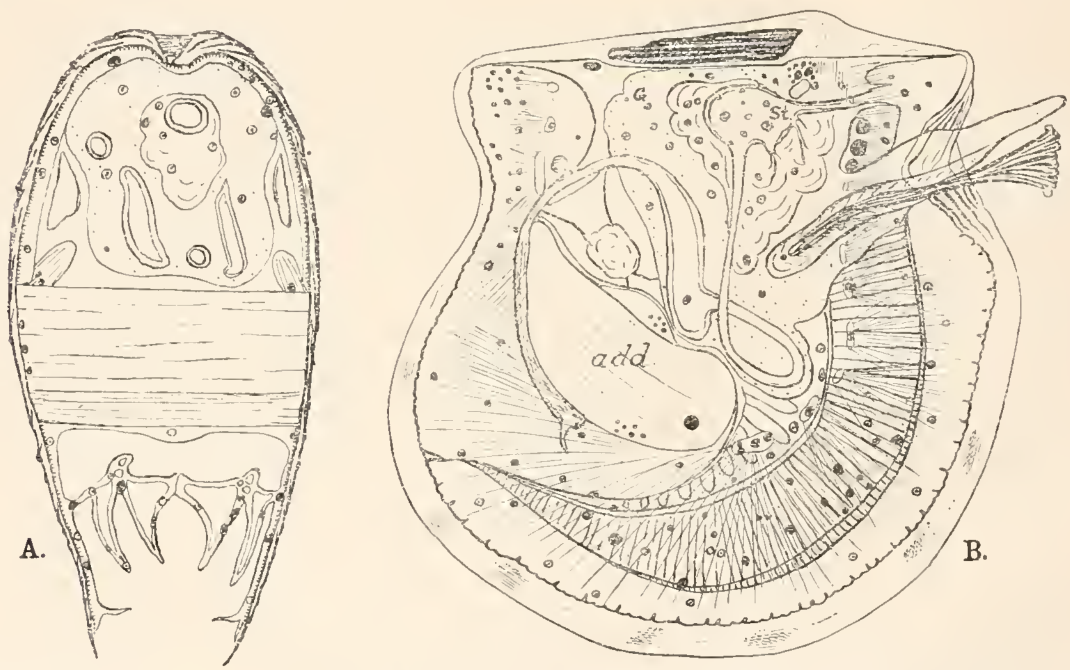

Fig. 2. **A**, transverse section of *Margaritifera vulgaris*, and **B**, dissection from the right side, to show the usual positions occupied by pearls and parasites.

These cysts, though small, are usually visible to the eye, and measure from 0·13 millim. to 1·3 millims. in diameter. The contained parasite is not always in the same stage of development, but is always, so far as our observations go, a young Cestode worm. It is possible, however, that more than one species of Cestode is represented—one is certainly a species of *Tetrarhynchus* (*Rhynchobothrius*), and another is probably the same genus or may possibly belong to *Cyathocephalus*, Kessler (= *Acrobothrium*, Olsson), characterised by the unarmed head and the terminal circular bothrium.

Seurat, writing in 1906,* states that in the case of the pearl oysters (*Margaritifera margaritifera*, var. *cumingi*, Reeve) of the Gambier Archipelago the numerous encysted parasites scattered through various parts of the body—branchiæ, mantle, heart, liver, &c.—are the scolices of Cestodes "appartenant aux genres *Cyathophyllus* [*Cyathocephalus*†] ou *Acrobothrium*."

In a letter received on February 28th, M. Seurat gives as his latest opinion "L'adulte du Cestode qui produit les perles à Mangareva vit dans la raie-aigle ; je me propose de l'appeler *Aphanobothrium*, n.g., *margaritiferæ*, genre voisin des *Cyathocephalus*, Kessler." Finally, in a further letter (March 8th), he says :—"Je crois pouvoir ranger le Cestode margaritifera dans le genre *Tylocephalum*, Linton, et ne pas avoir à créer de nouveau genre. Ce sera donc le *Tylocephalum margaritiferæ*. Hab. scolex—*Margaritifera cumingi*, Reeve. Hab. adulte—Intestin spiral de *Ætobatis narinari*, Euphr."‡

We agree at least with Seurat that the parasites are Cestodes, and that is clearly the first point to establish.

In order to be able to co-relate our work with that of Dr. Jameson and make a comparison between the Ceylon specimens and those from European seas where the parasite is a Trematode, we obtained material from the pearl-bearing mussels (*Mytilus edulis*) at Piel,§ on the Lancashire coast, the same locality where Dr. Jameson worked. Figs. 1 to 12 on Plate I. show the condition of affairs in this material ; and the chief points of contrast with the Ceylon pearls are :—

(1) The distinctness of the pearl-sac (figs. 8, 10, 11).
(2) The large size of the nucleus in the pearl (where a nucleus is present) and its characters, which are quite different from those of the encysted parasites in the Ceylon pearl oyster.

We agree entirely with Jameson, of course, that the organism in the *Mytilus* pearls is a Distomid, and the marked difference that we find in our own preparations of the two cases (*Mytilus* and *Margaritifera*) confirms us in our belief that the Ceylon parasite cannot be a Trematode.

* "La Nacre et les Perles en Océanie Française," par M. L. G. Seurat, Chargé de mission à Tahiti, in 'Compte Rendu des Trav. Première réunion internat. d'Agronomie Coloniale' : Alcan, Paris, p. 308.

† Seurat writes "*Cyathophyllus*," but surely that must be intended for *Cyathocephalus*.

‡ Since published in 'C.R. Acad. des Sci.,' 26 Mars, 1906, p. 801.

§ We are indebted to our friend Mr. Andrew Scott, A.L.S., Resident Naturalist at the Piel Marine Laboratory, for the help he has kindly given us in this matter ; and to Mr. T. Southwell, in the Liverpool Laboratory, for assistance in the preparation of many specimens.

Before leaving the *Mytilus* material, we may add two further points of interest. The first is that some pearls have no trace of a nucleus. Plate I., fig. 5, shows a case where a careful search through all the sections (serial) showed no internal cavity and no imbedded foreign structures We have similar cases also in our Ceylon material. The second point is that in some places the pearl sac shows a mass of enlarged and proliferating epithelial cells which are generally adherent to the pearl at points where there is a depression and a marked irregularity in the deposition of the layers (Plate I., figs. 10 and 11). Some of the *Mytilus* pearls are exceedingly irregular in form, projections being given off which appear like separate pearls in some of the sections (fig. 11). In addition to such cases, there are sometimes two or more pearls in the same sac (fig. 2), and in figs. 6 and 7 we find a pearl and a parasite enclosed together by the one layer of epithelium. In some places small blood sinuses adjoin the pearl-sac for portions of its extent, but these are not larger than those seen elsewhere in the mantle of *Mytilus*. We do not find that the pearl-sac is surrounded by a blood sinus, as BOUTAN states is the case.

ENCYSTED CESTODES.

The smallest and simplest cysts we have seen in the Ceylon pearl oyster are in the mantle (Plate II., fig. 1). They have no pearl and no pearl-secreting epithelial sac, and the connective-tissue cyst contains an embryo which shows only an outer wall and some irregularly scattered internal cells. It is presumably an onchosphere or pro-scolex stage in which the hooks have been lost and invagination to form the scolex has not yet taken place.

Similar early stages are found also in the gills, either in the principal gill filaments (see Plate II., fig. 3), or, more usually, alongside the great blood-vessels in the axis of the gills where they adjoin the body.

The majority of the cysts, however, contain later stages (text-fig. 3) where more or less invagination to produce the scolex has taken place. These measure from 0·07 millim. to 0·16 millim. in longest diameter, most of them are about 0·14 millim. A number may be present in the same host; we have frequently seen two close together in the same section, under the microscope. Figs. 17 to 22 on Plate II. show several of these stages, from the liver, the gonads, and the mantle. One end of the globular or ovate parasite forms a cup-like invagination with a central boss or papilla rising from the bottom of the cup. In some cases the margin of the cup is turned in so as almost to close the aperture. Round the outside of the invagination there may be more or less of a projecting pad in the form of a collar or annular thickening. This form (seen typically in Plate II., fig. 17) agrees very closely with the figures given by SEURAT for the pearl-causing Cestode parasite of the Gambier Islands,* and with the figures given by SHIPLEY and HORNELL of the nuclei of pearls in Part II. of this Report

* See GIARD, "L'Origine Parasitaire des Perles," 'Comptes Rendus Soc. Biol.,' lv., p. 1222.

(p. 79, 1904). Although most of those which we have examined are not surrounded by any pearl, there can be no reasonable doubt that these are the parasites that form the nuclei of the orient pearls. When we compare SHIPLEY and HORNELL'S figures

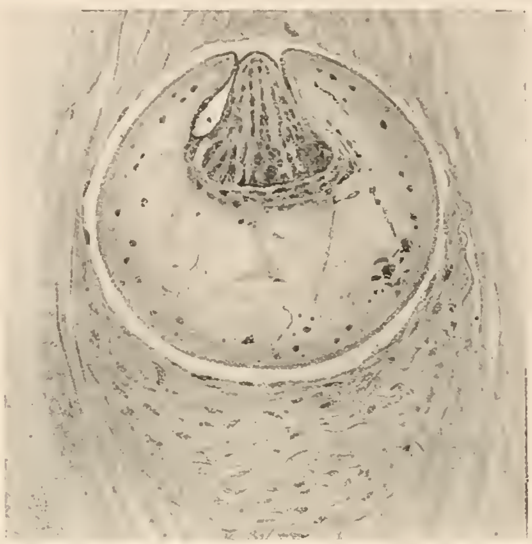

Fig. 3. Young larval Cestode (*Tetrarhynchus*, sp.) encysted in connective tissue of pearl oyster.

(Part II., Parasites, Plate I., figs. 4 to 6 and 13) with SEURAT'S figures (GIARD, *loc. cit.*, figs. 1, 2 and 3) and our present figures (Plate II., figs. 17 to 22 and Plate III., figs. 1 to 8) there can be little or no doubt that these all represent similar stages in the same kind of organism. We do not mean that our larvæ necessarily belong to the same species as SEURAT'S. In fact, differences in size and details of structure convince us that they are not identical, but the resemblance is sufficiently close to indicate that they all belong to allied organisms.

Moreover, it is clear that these are all larval Cestodes in the blastocyst condition containing young scolices. It was the possession of calcareous corpuscles noticed in the fresh condition in 1902 in the Gulf of Manaar that caused us first to identify these larvæ as Cestodes. We now enumerate as Cestode characters :—

1. The invagination to form the head of the adult worm ;
2. The hooks upon portions of the invaginated surface ;
3. The calcareous corpuscles in the walls of the vesicle ;
4. The division of the (? muscular) tissue on the floor of the invagination into several masses (probably four, as either two or three can usually be seen in different views).

The invagination (Plate II., figs. 17, 20) agrees very closely with the "figures idéales" of early stages of the genus *Tetrarhynchus* given by P. J. VAN BENEDEN ("Vers Cestoïdes," pl. xxiii.), and with the sections of the larvæ of *Rhynchobothrius adenoplusius*. PINT., from *Lophius*, showing receptaculum and developing scolex, published in the third part of his 'Studien über Tetrarhynchen' (Taf. ii., fig. 11), by PINTNER, in 1903, and is quite consistent with the section of a Cysticercus of *Tetrarhynchus* given by MONIEZ in his 'Essai Monographique sur les Cysticerques,' at plate iii., fig. 1, and with PINTNER's figure of *Tetrarhynchus smaridum* ('Sitzb. Akad. Wiss., Wien.,' Jahrg. 1893, Abth. I.).

The hooks (Plate III, figs. 2 and 9) are similar to those shown by various authors as belonging to different larval Cestodes. The spines upon the projecting annular pad or collar are, for example, rather like those of *Tænia* (*Devainea*) *frontina*, DUJARDIN; and PINTNER shows a very similar arrangement to what we figure, in his 'Studien über Tetrarhynchen,' III., Taf. i., fig. 6.

The calcareous corpuscles are not seen so well in the preserved specimens from which the sections have been made in Liverpool as they were in the fresh material we examined in Ceylon, but there can be little doubt that it is the remains of these bodies that we show along with the loose network of connective tissue in the vesicle behind the invagination in figs. 6, 7 and 8 on Plate III.

The division of the more opaque (? muscular) tissue in the scolex at the bottom of the cup cannot be seen distinctly in all specimens, but the appearance shown in Plate II., figs. 19 and 20, can scarcely be interpreted otherwise than as the beginning of the segregation to form four discs (or bothridia) with their proboscides.

The possession of all these characters together, in our opinion, definitely stamps the organisms as larval Cestodes. It is no easy matter, however, to refer these larvæ to their proper genus. We find later stages in the tissues of the pearl oyster which clearly belong to *Tetrarhynchus*, in a wide sense, but it is difficult to find conclusive evidence that these younger larvæ belong to the same organism as the later forms with four proboscides. GIARD is of opinion that SEURAT's similar figures represent a member of the group Monobothria in the order Pseudophyllidea. SEURAT gives as his later opinion, as we have shown above, that they belong to a new species of LINTON's genus *Tylocephalum*. In either case the terminal invagination would represent a sucker with a papilla on its floor. We are inclined to regard it rather as the opening in a hood or depression formed by the sinking of the scolex into the front of its vesicle. The changes of shape which we observed in this larva in the living state, the protrusion and retraction of the papilla-like part which we regard as the anterior end of the scolex, agree with this interpretation. Consequently, we are of opinion that this larval Cestode is not one of the Monobothria—that it belongs to neither the Pseudophyllidea nor the Tetraphyllidea, but is a young Tetrarhynchid belonging to the Trypanorhyncha, and we give here (fig. 4) a series of diagrams in order to show the positions that we suppose our stages to occupy in the development of such a form.

In regard to the life-history of the pearl-inducing parasite, we have little to add to what has already been published in the preceding parts of this Report. In the Introduction (Part I., p. 12) an outline of the history was sketched which still holds true in the main. SHIPLEY and HORNELL in Part II. (p. 77) described and figured various stages of the Cestode larvæ both from the centre of decalcified pearls and also free in the tissues of the pearl oyster, but left it an open question whether the subglobular younger larvæ belong to the same life-history as the elongated older forms

A. B. C. D. E. F.

Fig. 4. Series illustrating the connection between the Cestode larvæ found in the pearl oyster. A, B, C, and D represent stages that commonly occur, E is the hypothetical connecting link, and F is a young *Tetrarhynchus*, copied from fig. 31, of Plate II., in the "Report on the Parasites of the Pearl Oyster" (Part II.). Since this figure was made, a still younger *Tetrarhynchus*, very slightly more advanced than is shown in E here, has been found in the liver of the pearl oyster (see text, p. 22, and Plate III., fig. 10).

which are young Tetrarhynchids. If our arrangement of the stages observed in the tissues of the pearl oyster is correct, and if all these larvæ belong to the same species, then the interpretation we have given above brings us to the conclusion that the larger of our two globular larvæ belongs to the worm which Shipley and Hornell described as *Tetrarhynchus unionifactor* in 1904. Figs. 1 to 8 on Plate III. show most of the common stages we have found, and in regard to which there can scarcely be any doubt (1) that they all belong to the same life-history, and (2) that they are young Tetrarhynchids leading on to the stages shown in figs. 10 and 11.

If we distinguish the genus *Rhynchobothrius* from *Tetrarhynchus* by the possession of only two bothridia, then the correct name of the species becomes *Rhynchobothrius unionifactor* (Shipley and Hornell). The adult condition of this species is found in the large ray *Rhinoptera javanica*, M. and H. (see this vol., p. 65). In addition to these larger larvæ there is, however, a smaller form of globular larva (Plate II., fig. 19, &c.) which we meet with in the tissues of the pearl oyster, and which probably belongs to a distinct species of Cestode. The two forms of larvæ are seen side by side in fig. 17 on Plate II., and, as shown there, the larger (B) is about six times the diameter of the other (A). The two are, however, closely related forms and in similar stages. In both there is the same anterior invagination with the central papilla—various stages in the formation of which are shown in figs. 20, 21, 22 on Plate II. and figs. 1, 2, 6 and 8 on Plate III. There are the same cuticular spines round the margin of the invagination in both, and the same histological structure in the body wall of the vesicle and the future scolex. In size, Seurat's larvæ approach more nearly to our smaller form; but differ from both in proportions and details of structure.

Although we have examined sections of several hundred of these parasites from various parts of the pearl oyster, we have been unable to find any stage intermediate between that shown in figs. 6 and 8, on Plate III., and the young *Tetrarhynchus* with four proboscides. It is probably therefore a rare occurence for the larva to advance further in its development in this molluscan host; but that it does occasionally happen is shown by our finding a few young Tetrarhynchids in cysts on the wall of the pearl oyster's intestine (see Plate III., fig. 11, for a section of this stage, and fig. 16 on Plate II. for the general appearance of what is probably the same species). We have found, in all, about six such Tetrarhynchids in company with over 200 of the globular parasites. If the parasite normally does not go beyond the globular stage in the body of the pearl oyster, but only occasionally advances a stage further and acquires the four proboscides, and then again remains quiescent in a cyst, it follows that the transition form which we have looked for in vain may be passed over very rapidly. In that case we should find the greater number of the parasites in the younger globular stage, a very few in the more advanced Tetrarhynchid condition, and practically none in an intermediate state.

Since the above was printed, and the diagrams shown in text-fig. 4 (p. 21) were drawn, we have found, encysted in the liver of the pearl oyster, a very young Tetrarhynchid larva which possesses the characteristic four proboscides, but has not yet become elongated. It is of ovate form (Plate III., fig. 10) and measures 0·53 millim. in length. It shows at the anterior end the lateral projections bounding the central depression just as in earlier stages (see fig. 6), but the central papilla is traversed by several openings which are clearly the tubular proboscides (fig. 10). In fact it agrees so well in all other respects except the proboscides with the larger form of globular larva that we can scarcely fail to recognise it as the later stage of the same animal—*Rhynchobothrius unionifactor* (SHIPLEY and HORNELL).

SHIPLEY and HORNELL have described (this vol., p. 43, *et seq.*) several other species of *Tetrarhynchus* from Ceylon, but none of them from the pearl oyster; so we are as yet unable to refer to its species the smaller globular larvæ which we find commonly encysted, and which may occasionally form the nuclei of pearls.

Both our larval Tetrarhynchids we believe to be pearl-inducing parasites in the Ceylon pearl oyster. The figures on Plate II. show for the most part the appearances presented by the smaller globular parasite in our specimens. Though small, they are visible to the eye (figs. 1 and 2). Fig. 17 shows the relation in size between the two kinds of larvæ—the larger (0·9 millim. in length) being about six times the size of the smaller (0·14 millim. in length). SEURAT'S larvæ are 0·25 millim.

We give on Plate II. (figs. 3 to 16) some of the drawings made by one of us (J. H.) in Ceylon, and which were used in SHIPLEY and HORNELL'S article upon the parasites of the pearl oyster (this work, Part II, 1904). They show mode of occurrence in the tissues (figs. 1, 2, 3, 17, 18, 19), relation to pearls (figs. 4, 5, 6, 7), stages in the structure of the larva (figs. 8, 9, 10, 17, 20, 21, 22), differences in the amount of the connective-tissue cyst (figs. 17, 18, 19, 21, 22), and finally some later stages of

Tetrarhynchids which we have met with either in the pearl oyster or in fishes which we know to feed upon that mollusc (figs. 11, 12, 13, 14, 15, and 16).

It is quite evident from the examination of a large series of sections, such as we have worked through, that the majority of these encysted parasites do not become encased in pearls. Probably none of those in thick connective-tissue cysts are destined to form nuclei. They are awaiting their legitimate further development in the next host, after their sheltering mollusc has been devoured by a fish. In such cysts and around such parasites we find no epithelial sac, and as a consequence there can be no pearl. Whether or not it is the case that only dead parasites supply the stimulus necessary to induce pearl-formation, and whether, as GIARD has suggested, the parasites may be infested and killed by a species of *Glugea*, so that that Sporozoon comes to be eventually responsible for the pearl, we are not prepared to say—we have found no fresh evidence in the Ceylon material bearing upon that point. It seems clear to us, however, that the epithelium is always associated with pearl-formation, and that in the absence of the epithelium only a thick-walled connective-tissue cyst is produced. If we adopt the view (see below) that this epithelium is genetically related to the ectoderm, then a possible explanation of the difference in behaviour in the encysted condition would be that those larvæ that carried in ectodermal cells became covered (when dead or while still alive) by a pearl sac and embedded in a pearl, while those that were free from ectoderm become surrounded by the connective-tissue cyst.

The larger globular larva (*Tetrarhynchus unionifactor*) is illustrated in Plate III. Figs. 5 and 6 show common stages; fig. 8 is more highly magnified, giving histological details, and the spines at the anterior end are shown enlarged in fig. 9. The sections represented by figs. 3 and 4 are probably oblique. Fig. 11 shows a section of a young *Tetrarhynchus*, such as we find in the wall of the intestine and occasionally elsewhere in the tissues of the pearl oyster; and after the finding of the intermediate form shown in fig. 10, it can scarcely be doubted that these Tetrarhynchids are a later stage of the pearl-inducing globular larvæ.

In our first account of these parasites we suggested that the next stage after that found in the pearl oyster, occurred in a species of *Balistes*, which we showed was sometimes found feeding on oysters, and that the adult worm inhabited one of the large Elasmobranch fishes (Rays), which in their turn devour the *Balistes*. SHIPLEY and HORNELL have now identified as the adult *Tetrarhynchus unionifactor* a parasite that we found in *Rhinoptera javanica*,* the "Walwadi tirikkai" of

* SEURAT considers that the sting-ray *Aetobatis narinari*, EUPHRASEN, is the host of the pearl-inducing Cestode which he investigated in the Pacific. He does not state what evidence he has of this, but it is quite probable. We find the same species in Ceylon, where it is known as "Kuruvi tirikkai" by the natives, and it has an evil reputation on the pearl banks and many Entozoa in its interior. Its main food in Ceylon, as shown by the stomach contents, consists of sand-living Lamellibranchs, such as species of *Cardium* and *Venus*.

the Tamils (see this vol., p. 60, and Part III., Preface, p. viii). No fresh light has been thrown upon the possible occurrence of an immature stage in *Balistes* (which is eaten by the large rays), and although that intermediate host may not be necessary to the life-history, since the rays also feed upon pearl oysters, still there is nothing in the observed facts to forbid the existence of such a stage, and it is not unusual in Tetrarhynchids to have two fish-hosts, an intermediate Teleostean which is devoured by a final Elasmobranch.

Cyst and Pearl-Sac.

We now turn from the larvæ to the cysts which enclose them. In the youngest stages of both species these are merely thickenings of the connective tissue of the mantle (Plate II., figs. 17 and 18), or the mesoderm around the tubules of the liver, gonads, and other viscera. The thickening is laminated (Plate II., fig. 21), and the fibres, when fibres are visible in the lamellæ, run concentrically around the more or less spherical body of the larva. In the thicker cysts the outer layers may contain many blood spaces (lacunæ), and sometimes the thickening becomes quite spongy or œdematous (fig. 19). In some cases a considerable increase in the number of connective-tissue corpuscles or leucocytes is evident, and in later stages (Plate III., figs. 7 and 10) cells are sometimes seen to accumulate, and probably proliferate, along the inner surface of the fibrous cyst. It is just remotely possible that it is in this way that the pearl-producing epithelial sac is formed, from apparent mesoblast cells, inside the connective-tissue cyst. The other and more probable view that may be held is that these cells proliferating on the inner surface of the connective-tissue cyst are ectodermal in origin, and produce the pearl-sac.

As our specimens do not give conclusive evidence as to the stages in the formation of the epithelial sac, and as previous observers seem to have left this matter in some doubt, we think it advisable to state here fully the two possible alternative views that have been and may be held.

The first of these views is that the epithelial sac which surrounds the parasite and secretes the pearl is derived directly or indirectly from the ectoderm on the outer surface of the mantle—the layer which normally secretes the nacreous layer of the shell. By "directly" we mean where the sac as a continuous layer is formed by a pouching inwards of the ectoderm, the pouch being then cut off from the surface to form a closed sac. We should call "indirect" such cases as those where isolated ectoderm cells wandered into the mesoderm or were carried in by a moving parasite (the "processus cœnogénétique" of Giard); these ectoderm cells proliferating, it may be supposed, around the parasite to form the sac which then secretes the pearl.

In favour of this ectodermal origin may be stated :—

1. The very close resemblance between the epithelium of the pearl-sac and that of the outer surface of the mantle, amounting to identity in staining reaction.

Figs. 8 and 10, on Plate I., show examples of this from *Mytilus edulis*, where the sections were stained with eosine and methyl blue, and in both ectoderm and pearl-sac the cells and nuclei are of the same size and shape, and the nuclei are stained red with eosine and the cytoplasm blue to the same extent, so as to have a precisely similar appearance. In looking at a small part of the section under a high power, one receives the impression that the two adjacent epithelia are folds of the same layer (see Plate I., fig. 12). We show the same point in the case of the Ceylon pearl in fig. 16. Here the section is stained with gentian violet and light green, and in both ectoderm and pearl-sac the nuclei have taken up the violet, and the cytoplasm the green, to a quite similar degree.

2. The fact that pearls formed in different parts of the mantle have the character of the layers of the shell formed by the ectoderm in their neighbourhood—"horny" pearls, resembling the periostracum, have been found at the mantle edge; in the zone above that, pearls have been found having the characters of the prismatic layer of the shell; and finally, the great majority of pearls, both in the mantle and in the deeper tissues, show the structure of nacre, the layer produced by the greater part ot the surface of the ectoderm on the mantle. It is difficult to account for these facts if the epithelium of the pearl-sac has no genetic connection with the layer of ectoderm lying outside it. The ordinary nacreous pearl is clearly produced in a similar manner to the inner part of the shell. The nacre is formed from epithelium on the outer surface of the mantle; the pearl from epithelium lining a closed sac. The most natural working hypothesis to hold until it is disproved, is that the epithelium of the closed sac is derived in some manner from the outer surface of the mantle.

Against this view, however, there is the notable fact that most recent investigators* have been unable to find any evidence of the pushing in of the ectoderm to form the pearl-sac. We may feel fairly certain, then, that the majority of pearls are not formed in actual pouches of ectoderm closed off from the mantle, as, if such structures were formed in any numbers, we could scarcely fail to obtain some evidence of their presence.

* The one definite exception to this statement is the case of M. L. BOUTAN, who, in his paper in 1904 ("Les Perles fines: leur origine réelle," 'Arch. Zool. Expér.,' 4 sér., tome ii., p. 47), describes and figures the actual pouching in of the ectoderm around the Distomid parasite to form cyst pearls in the case of *Mytilus edulis*. In this paper BOUTAN criticises adversely GIARD'S comments on our short note read at the Southport Meeting of the British Association in 1903; but our intention in that paper certainly was to express our belief in the ectodermal origin of the cyst pearls. When we stated "In all cases, whatever its nucleus may be, the pearl, like the nacre, is deposited by an epithelial layer," we intended to imply the ectoderm; and where, further on, we speak of "closed sacs," we meant to indicate that the ectodermal pouches alluded to in the previous sentence have become closed off. Professor GIARD interpreted our words correctly; and although in the present report we have discussed both possible views, still we have from the time of our first observations in Ceylon believed, as BOUTAN does, in the ectodermal origin of the cyst or "fine" pearls.

There still remains, however, the indirect connection, the possibility that, as the result of stimulation, cells from the outside of the mantle have migrated inwards to surround the parasite, or that the larva destined to form the nucleus of a pearl has in its wanderings carried in a few ectoderm cells which have eventually proliferated around it to form the pearl-sac. These would naturally be very difficult matters to prove, and the fact that no undoubted evidence of the migration, active or passive, of ectoderm cells in the case of the Ceylon pearl oyster has yet been found is not sufficient to disprove the possibility that the process takes place.

As a matter of fact there are some appearances in our sections that might be interpreted as indicating a migration of ectoderm cells (Plate I., figs. 18, 19, 20). When the pearl is in the mantle there is no great thickness of connective tissue between the ectoderm cells and the very similar epithelium forming the pearl-sac, and in some cases we have observed cells giving the same appearance and staining reactions in intermediate positions, and a few of these sub-epithelial cells are undoubtedly undergoing division (fig. 18). These may be regarded as wandering and proliferating ectoderm cells; we think they can scarcely be interpreted in terms of the other alternative—to which we now pass.

The second view that may be held is that the epithelium of the pearl-sac is formed from the neighbouring mesodermal connective-tissue cells modified *in situ* in response to the stimulation caused by the parasite. In favour of this view there is the absence of any direct evidence of the derivation of the cells from elsewhere, so that, so far as appearances go, the cells, although so very similar to those of the ectoderm, seem to arise from the tissue in which the parasite and pearl are placed—and in the present state of opinion amongst pathologists no one is likely to deny that indifferent mesodermal cells might become aggregated around a foreign body to produce an epithelial sac. Whether, however, we should be justified in imagining that such an epithelium might, under the stimulation of the parasite, produce layers of pearly material similar to the ectodermal nacre of the shell, is not so clear.

It is a distinct difficulty in the acceptance of this view that so many parasites in all parts of the body are merely surrounded by connective-tissue cysts, have no epithelial sac, and are apparently not being encased in pearls. If the pearl-producing epithelium can be formed *in situ* from connective-tissue elements, one would expect that every quiescent parasite which was becoming encysted would eventually be the centre of a pearl; but that does not appear to be the case. For one cyst pearl in our Ceylon material we find something like 100 encysted parasites, and these are surrounded by laminated connective tissue which may extend for several times the diameter of the parasite (Plate II., fig. 19).

Another strong reason against accepting this view is the point mentioned above, that pearls in different parts of the mantle present the characters of the ectodermal exoskeleton of their own neighbourhood. It would be difficult to understand that indifferent mesodermal cells could simulate specialised ectodermal cells to that extent.

In conclusion, then, we still adhere to the view we expressed in 1903, that in cyst pearls containing an organic nucleus the pearl-secreting epithelium is of ectodermal origin.

Muscle Pearls.

There are some pearls, however, that show no nucleus whatever, either organic or inorganic, and it seems probable that these have been formed by the deposition of calcareous matter around a minute calculus in the tissues. These are the pearls that we have distinguished ('Brit. Assoc. Report, Southport,' p. 695) as "Muscle pearls," since we find them most abundantly in the muscular tissue near the insertions of the levator and pallial muscles. Figs. 5A and 5B, illustrate the distribution of cyst pearls

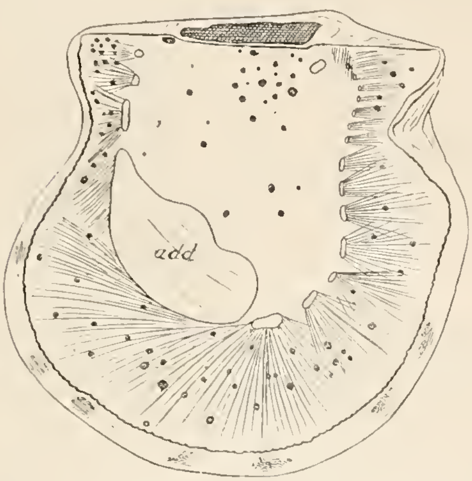

Fig. 5A. Diagram showing the comparative frequency of position of cyst pearls in the various parts of the mantle.

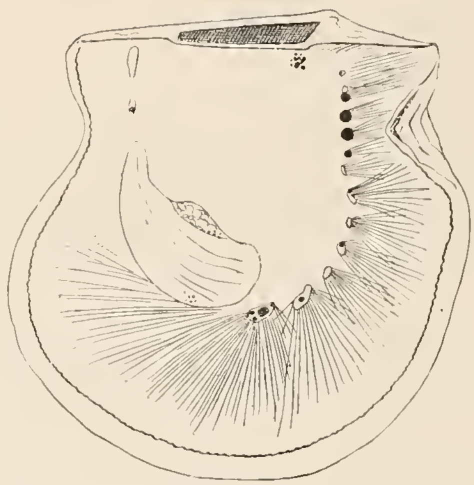

Fig. 5B. Diagram showing the positions most frequently occupied by muscle pearls.

and muscle pearls respectively, the localities most commonly occupied by the pearls being indicated by spots. Figs. 13 and 14 on Plate III. show also the mode of occurrence of the muscle pearls near the insertion scars.

The muscle pearls when present are usually abundant,* and when examining under the microscope a young pearl of this kind, *in situ*, it is common to find a large number of minute calcareous depositions, or calcospherules (Plate III., fig. 12), scattered in the neighbouring tissue. It is probable that the muscle pearls are formed around these microscopic calcospherules as centres of irritation, and as these positions are invariably in our experience close to the surface of the muscle or the mantle, there is no difficulty in understanding that there, if anywhere, ectoderm cells might migrate to the source of irritation and thus be responsible for the deposition of a pearl.

* At the insertion of one levator muscle, 23 small pearls were counted with the eye, while under the microscope 170 additional tiny spherules were found to be present.

CONCLUSIONS ON PEARL-FORMATION.

We may now sum up our views as to pearl-formation in the Ceylon pearl oyster as follows (using with but slight changes and additions the wording of our 1903 note* on the subject) :—

1. The majority of pearly excrescences on the interior of the shell are due to the irritation caused by *Clione*, *Leucodore*, and other boring animals. In exceptional cases a free pearl may be formed in this way.

2. Minute grains of sand and other inorganic particles only form the nuclei of pearls under exceptional circumstances. Probably it is only when the shell is injured, *e.g.*, by the breaking of the "ears," thus enabling sand to get into the interior, that such particles supply the irritation that gives rise to pearl-formation. The ectoderm, in such cases, would probably also be damaged, and cells may be carried in with the inorganic particles.

3. Many pearls are found in the muscles close to the surface, especially at the levator and pallial insertions, and these are formed around minute calcareous concretions, the "calcospherules," which are produced in the tissues and form centres of irritation. These are, in all cases, close to the surface of the mantle, or even in contact with the ectoderm.

4. Most of the fine pearls found free in the body of the Ceylon oyster contain the remains of Cestode parasites, so that the stimulation which leads to the formation of an "orient" pearl is, as has been suggested by various writers in the past, due to the presence of a minute parasitic worm. Probably in all cases, whatever its nucleus may be, the pearl, like the nacre, is deposited by an epithelial layer derived from the ectoderm.

These four categories are separated according to the cause of the stimulation. The first set, however, can scarcely be considered as "pearls," and the others may be conveniently classified under the following three names :—

I. *Ampullar-pearls*, where the nucleus and resulting pearl lie between the shell and the body, or in a pouch (the ampulla) of the ectoderm projecting into the mantle. The others lie in closed (ectodermal) sacs.

II. *Muscle pearls*, formed around calcospherules near the insertions of muscles.

III. *Cyst pearls*, formed around encysted parasites. The parasite in the case of the majority of the cyst pearls of Ceylon is the larva of one or more species of Cestodes, belonging to the genus *Tetrarhynchus*.

It seems possible that in *Placuna placenta*, the "vitre chinoise" or window oyster of Tampalakam Lake near Trincomalee, a Distomid parasite which we find in the tissues both free and encysted, may also occasionally be a cause of pearl-formation.

* 'British Association Report, Southport,' p. 695.

The encysted Cestode larvæ found in the pearl-oyster are, however, also present in *Placuna*—sometimes in great numbers, so as to be densely crowded together in the superficial layer of the mantle, as shown in fig. 6. Compound cysts, where one larva occurs within the vesicle of another, are sometimes seen. Similar larvæ, both alive and as nuclei of pearls, are also found in specimens of *Placuna placenta* from the Gulf of Kutch.* In fact, a fuller experience is causing us to incline to the view that various parasites may act as pearl nuclei even in the same mollusc. Some pearls are certainly formed round intrusive Nematodes. We have a complete cyst pearl, free and unattached, of which the nucleus is a coiled *Cheiracanthus uncinatus*, on which the pearl deposit is not sufficiently thick and opaque to obscure the coils so as to render identification difficult.

Fig. 6. Aggregation of encysted Cestode larvæ in the mantle of *Placuna placenta*; magnified.

But although Kelaart's statement, half a century old, that various kinds of worms are concerned in pearl-formation may be correct, still we hold that our investigation has shown that in *Margaritifera vulgaris*, at Ceylon, the production of the orient pearl is dependent upon Cestode infection and that the species mainly concerned is *Tetrarhynchus unionifactor*.

The next question that naturally arises is—Can we profitably follow up Kelaart's suggestion that it might be possible to increase the number of pearls by infecting the molluscs with the appropriate parasites? This "margarose artificielle" has been tried, as we have shown above, by Dubois in a case where the parasite was supposed to migrate from one mollusc (a *Mytilus*) to another of a different genus (*Margaritifera*). Giard and others have pointed out the difficulties in the way of accepting this case, and the doubts that naturally arise; and we are probably correct in concluding that the method has not as yet resulted in a marked success on the southern coast of France; although it is quite possible that similar methods with other shell-fish elsewhere may give good results.

On the Ceylon pearl banks, however, it is probably quite unnecessary to take any steps to ensure infection with the appropriate parasite. Oysters, wherever they appear, when they are old enough contain pearls, and encysted parasites are even more abundant. Even when new beds are formed artificially by transplanting to unoccupied ground, as we do not doubt will be the case in the future, that operation may be carried out with perfect confidence that when the four-year-old oyster is fished it will contain the normal† supply of pearls. The parasites are probably so widely spread that every pearl oyster in the Gulf of Manaar, or, for that matter, around the coast of Ceylon, runs a fair chance of becoming infected. Cyst pearls are found in the

* See Hornell's Reports from the Ceylon Marine Biological Laboratory, Part II., 1906.

† Of course some beds are richer in pearls than others and some years are better than others.

oysters at Trincomalee; the fishes that are, in all probability, the hosts of the parasite in its more advanced stages abound at various points. It is the molluscan host and not the parasite that stands in need of artificial aid in Ceylon. If we can increase the number of beds, and can prevent catastrophes from devastating the oyster populations, so that the divers can collect them annually in their tens of millions, we need not fear any scarcity of pearls.

As BOUTAN, who thinks favourably of artificial methods, points out*:—" Mais il ne faut pas oublier que l'infection d'un animal par un parasite ne favorise pas précisément le développement normal du sujet infesté." He advocates as an alternative method experimental trepanning of the shell, but that or any other mode of individual treatment is clearly impracticable in dealing with the millions of the Ceylon pearl banks. Our own opinion is that, although all pearl-production is a departure from the normal, the pearl-inducing parasites are not sufficiently abundant to affect seriously the health of the oyster; and that, to reverse the popular saying, if we attend to the prosperity of the bed as a whole, the individual oysters may be left to take care of themselves, both in regard to health and pearl-production.

DISTRIBUTION OF PEARLS.

Figs. 5A and 5B, on p. 27 show the usual distribution of cyst and muscle pearls respectively in the Ceylon pearl oyster. The following table will show the numerical proportion between the two kinds in various parts of the body. It is the summary of a number of observations made by us in 1902 and 1903:—

Locality.	Number of oysters dissected.	Cyst pearls—		Muscle pearls at insertion of —				Total pearls.
		In mantle lobe outside the pallial line.	Within the pallial line.	Levator muscles.	Palpar pallial muscles.	Other pallial muscles.	Adductor and retractor.	
South-east Cheval . .	378	7	10	48	9	4	6	84
Mid-east Cheval . .	450	19	10	13	4	1	—	47
North-east Cheval . .	266	7	2	11	3	—	—	23
Periya Paar Karai .	168	6	3	10	1	1	—	21
West Cheval . . .	83	2	1	—	1	—	—	4
Dutch Modragam . .	17	—	—	—	—	—	—	0
Muttuvaratu . . .	38	2	—	—	—	—	—	2
Totals	1400	43	26	82	18	6	6	181

* 'Arch. de Zool. expér.,' 1904, p. 89.

As these two classes of pearl differ not only in value but in mode of occurrence, it is worth while to contrast their distribution more definitely. If we unite the subdivisions of the pearl-classes, we find the proportions to be :—

Locality.	Number of oysters dissected.	Number of cyst pearl-bearers.	Number of muscle pearl-bearers.	Total number of pearl-bearers.	Percentage of cyst pearls.	Percentage of pearl-bearers of both classes.
South-east Cheval . .	378	17	67	84	4·5	22·2
Mid-east Cheval . . .	450	29	18	47	6·4	10·4
North-east Cheval . .	266	9	14	23	3·4	8·6
Periya Paar Karai . .	168	9	12	21	5·4	12·5
Western Cheval . . .	83	3	1	4	3·6	4·8
Dutch Modragam . .	17	—	—	—	—	0·0
Muttuvaratu	38	2	—	2	5·3	5·3
Total	1,400	69	112	181	—	—

From this it is seen that of the 1,400 oysters, aged from 3 to $3\frac{3}{4}$ years, which were individually dissected with the greatest care, only 181 proved to be pearl-bearers, equal to a percentage of 13.

A remarkable feature of these and other observations we have on record is the relatively great abundance of individuals upon the South-east Cheval containing muscle pearls. On the other hand, as the value of the oysters is chiefly dependent upon the proportion of cyst pearls present, these oysters appeared to be commercially inferior to those of the Mid-east Cheval—a conclusion subsequently proved correct by the actual returns obtained from these two banks during the course of the Fishery of 1903. The proportion of muscle pearls for the South-east Cheval at that fishery was over 90 per cent. Of 94 pearls dissected out, only 9 were cyst pearls.

Whatever may be the cause of certain pearl oysters containing exceptionally large numbers of muscle pearls, it is worthy of note that the vigorous and healthy oysters of the Eastern Cheval and Periya Paar Karai produced practically all the examples of this class of pearls, there being 111 muscle pearl-bearers from these banks out of 1,262 oysters, whereas the 138 oysters from the beds characterised by stunted growth—the Western Cheval, Dutch Modragam, and Muttuvaratu paars—gave but a solitary instance of this class.

The variation in the number of cyst pearls is due, ultimately, to the relative abundance of the pearl oysters on different grounds and of the *Tetrarhynchus* larvæ that cause pearl-production, and that ratio must be affected amongst other factors by the abundance of the fish-host of the sexually mature Cestode.

We give now another tabular statement obtained more recently :—

Pearl-yield of Representative Samples of Oysters (over $3\frac{1}{2}$ Years Old) Examined in November, 1905.

Name of bank.	Number of oysters examined.	Cyst pearls.			Muscle pearls.			Pearl bearers, both cyst and muscle.	Percentage of total pearl-bearers to total examined.
		Number of cyst pearls.	Individuals containing cyst pearls.	Percentage of cyst pearl-bearers.	Muscle pearls found.	Individuals containing muscle pearls.	Percentage of muscle pearl-bearers.

NATIVE CLASSIFICATION OF PEARLS.

It may be useful if we place on record here the native system of classification of pearls, which is supposed to be of extreme antiquity and is still made use of in Government reports, at the fisheries and by the pearl merchants.

We may conveniently give the procedure of the native in classifying his pearls in the words of CORDINER*—one of the earliest English writers on the subject, as his observations were made on the fisheries which took place at the beginning of last century, under the Government of Lord GUILDFORD.

"After the pearls are separated from the sand, washed with salt water, dried, and rendered perfectly clean, they are sorted into classes according to their sizes, by being passed through ten brass sieves or saucers full of round holes. The saucers are apparently all of one size, but made so as to go in within one another. They are distinguished into numbers, 20, 30, 50, 80, 100, 200, 400, 600, 800, and 1000. This is a kind of ratio to estimate the value of the different sizes of pearls; and probably the distinguishing numbers, in some measure, correspond with the quantity of holes in each basin. These completely occupy the bottom of the vessel; and as they increase in number, necessarily decrease in size. The pearls are thrown in a promiscuous heap into the uppermost sieve, which being raised a little and shaken, the greater part of them pass through into the second sieve, and only those remain which exceed a large pea in size. The second sieve is shaken in the same manner; the pearls that remain in it are of the size of a small pea, or grain of black pepper. The quantity of pearls gradually increases as the size diminishes. Those which fall through the tenth saucer (No. 1000) belong to the class of Tool, or seed pearls, so called from the smallness of their size.

"I saw this operation of sorting the pearls performed with the produce of seventeen thousand oysters, which only weighed three-quarters of a pound, and was contained in a vessel smaller than a common soup-plate. Out of that quantity there were not found two perfect pearls, either of the first or second order. About twenty or thirty pearls remained in these saucers, but almost all of them were slightly deformed, rugged, and uneven. Of the smaller sizes many were round and perfect.

"The pearls contained in the sieves from No. 20 to 80, inclusive, are distinguished by the general name of Mell, or the first order. Those of the sieves from No. 100 to 1000 are denominated Vadivoo, or the second order. Both these orders are divided into various sorts, according to their shape, lustre, and other qualities; amongst which are Annees, Annadaree, Kayerel, Samadiem, Kallipoo, Koorwel, Pesul, and Tool. The Annees are the first sort, perfectly round, and of the most brilliant lustre. Annadaree is a sub-division of them, possessing the same qualities in an inferior degree. Kayerel is the next in beauty, but not so completely round, and of a duller

* 'Description of Ceylon,' London, 1807, vol. ii., p. 62.

colour. To this class belongs the Samadiem, which is nearly of the form of a pear, and the Kallipoo, which has flat sides. The Koorwel, or third class, is a double pearl, ill-shaped, and of a dull water; to it may be added the Pesul, the most deformed of all the pearls; and the Tool, the most diminutive."

From the above it will be seen that CORDINER could get no definite information as to the numbering of the ten sieves, viz., 20, 30, 50, 80, 100, 200, 400, 600, 800, and 1000. Sir WILLIAM TWYNAM informs us that these numbers indicate that so many pearls from such sieves stand to a "Kalanchu." We show here in fig. 7, A and B, the impression, natural size, of the bottoms of the two extreme sieves of the series, 20 and 1000, kindly supplied to us by Sir W. TWYNAM.

As regards sieve No. 1 (the 20 sieve, fig. 7, A), it is, of course, only the pearls which just escape going through the sieve that can be taken into account in making the estimate. Large pearls of more than ordinary value are regarded as exceptional, and are not taken into account in valuing samples. It is said that the native merchants judge the value of samples chiefly by what remains in the No. 4 (80 sieve).

This account of the methods in use a hundred years ago applies perfectly at the present day (as may be seen from the modern valuation form we print below, p. 38) except for some slight changes in the spelling of the names. We give now a list of the classes of pearls distinguished by the native valuers and merchants, with some indication of the meaning of the name and any other information* we have as to the kind of pearl. The list begins with the finest class of pearls and ends with the poorest. In each case we give first the Tamil name written in English, according to the Government spelling, then the literal meaning of the word, to which may be added the more extended meanings in present usage, the size, shape and other characters, followed by any peculiarity in use or native estimation. It will be noticed that some of the terms, such as "Mel" and "Tul," indicate relative size, while others, such as "Ani," apply to quality, or, such as "Kuruval" and "Kodai," to shape and colour.

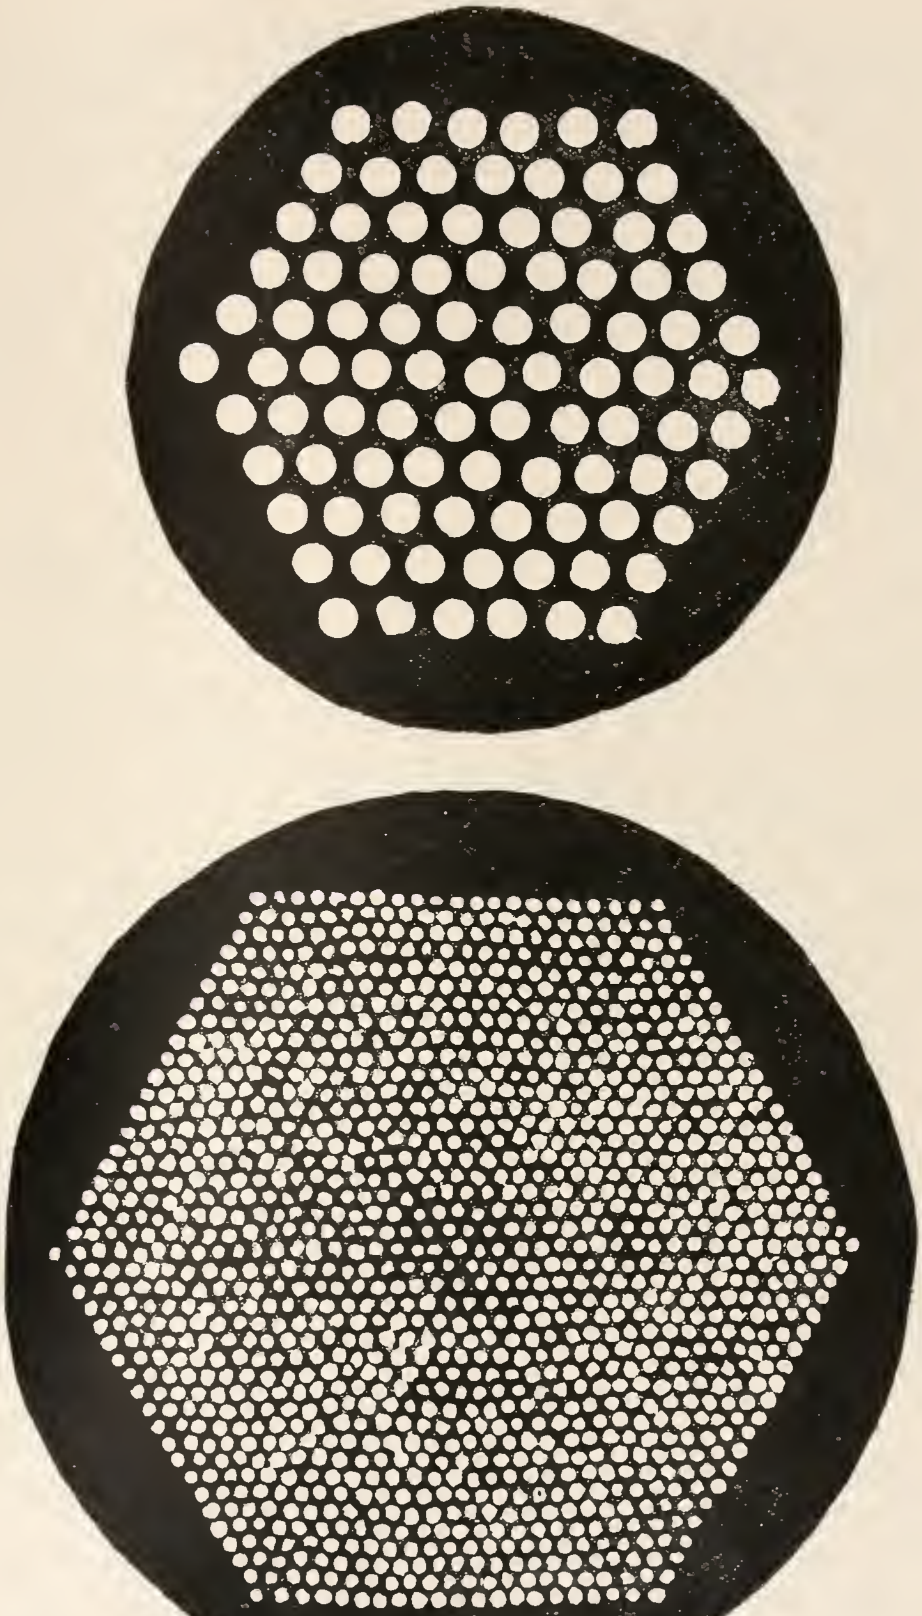
"MEL" or "MEL-MUTTU," meaning "upper," or superior pearl. This is a term of size, not of quality, and applies to pearls retained in the 20 to 80 sieves.

"ANI," meaning "best"; excellent—a fine, superior pearl both as regards quality and perfectly spherical shape, of the best lustre and colour, the true "orient" pearl.

"ANATARI," meaning "follower" or "second"; a pearl closely approximating to the Ani, but with some slight departure from perfection, such as a speck or a flattening on one side.

"KALIPPU," meaning "rejected," or inferior to Anatari; a good pearl, more or less symmetric, may be lens-shaped or oblong, usually flattened.

* We are indebted for some of this information to Sir WILLIAM TWYNAM, of Jaffna, who has been most kind in supplying us with details as to former fisheries and native methods, both during our expedition in 1902 and also on occasions since.



A.

B.

Fig. 7. Impressions of the largest and the smallest of the pearl merchants' ten sieves. **A**, the 20 sieve or basket ; **B**, the 1000 sieve or basket.

"KURUVAL," meaning "short"; deformed and double pearls, but not necessarily inferior in quality, may be of excellent lustre but of irregular form. "Ani-Kuruval" is where two Ani are partially fused together, whether the pearls be of equal size or not; but each must be so formed that if not fused it would be spherical. "Pisal-Kuruval" is where several pearls of good lustre and colour are partially and irregularly fused together. "Pampara-Kuruval" is a pearl grooved regularly, like a top.

"KAYARAL," meaning "the clasp of a necklace"; a dark-coloured treble pearl, not completely round, and of a dull colour.

"SAMADIAM," a pearl with a reddish tint, pear-shaped, but of a dull colour.

"NIMELAI," a nose-pearl, a perfect-skinned, pear or egg-shaped pearl.

"SIRIPPU," a pearl grooved with irregular wrinkle-like furrows.

"MASAKU," badly coloured pearls; usually grey, but symmetrical and with lustre.

"PISAL," meaning "torn"; a deformed pearl or cluster of small misshapen pearls of little or no value, of bad colour, usually slag-like in appearance.

"KODAI," meaning "brown"; like a nut, with no nacreous lustre, formed of prismatic shell, may be large and is usually spherical and includes pearls of different colours, and those white ones that have black or brown marks. "Van-Kodai" is a Kodai pearl with one side nacreous. "Karunk-Kodai," a black or blue-black slag-like pearl.

"VADIVU," meaning "beauty"; also "decreasing"; that which is strained or sifted, an intermediate pearl, found in the 100, 200 and 400 sieves. These small pearls of regular form, good colour, and lustre, are what are held in most general esteem in the East.

"MADANKU," meaning "folded or bent"; all pearls of Vadivu size that are imperfect in form or colour.

"TUL," meaning "powder"; the seed-pearls, smallest size, those that are retained by the 600, 800 and 1000 sieves.

"MASI-TUL," meaning "ink-dust" or chalk powder; smaller than the 1000 sieve. These are generally used for medicinal purposes or burnt and used as chunam to be eaten with areca nut and betel by the natives.

"ODDU" or "OTTUMUTTU," meaning "shell-pearl"; an attached pearl or nacreous excrescence on the inside of the shell.

If we consider only the size of the pearls as separated out by the sieves, we find :—

"Mel-muttu" in the 20 to 80 sieves;

"Vadivu" and "Madanku" in the 100, 200 and 400 sieves;

"Tul" in the 600, 800 and 1000 sieves; while

"Masi-Tul" are those that pass through the finest sieve.

Considered from the point of view of perfection in lustre and quality generally, the "Mel-muttu" or large pearls are grouped as "Ani," "Anatari," "Kalippu," "Kuruval," &c.; while some of the remaining terms refer to special abnormalities or unusual shapes and colours.

As may be seen from the valuation form printed below, "Kalippu," "Kuruval," "Pisal," "Kodai" and other inferior classes may be of large size and so occur along with "Ani" and "Anatari" amongst the "Mel" in the 20, 30, 50 and 80 sieves.

As showing the relative abundance of the three grades of good pearls comprised under the head of "Vadivu," those obtained from the washing of 11,000 four-and-a-half year old oysters from the South-east Cheval Paar in November, 1905, were found to be as follows:—

	108	pearls of the	100	basket size	(weight	$11\frac{8}{32}$ Manchadi)
	154	,,	200	,,	(,,	$9\frac{11}{32}$,,)
	253	,,	400	,,	(,,	$9\frac{10}{32}$,,)
Total	515					

Finally we print here a sample of the official valuation given in the 'Ceylon Government Gazette,' previous to a fishery, as the result of the examination (by the Inspector, the local Adigar, and three native pearl merchants) of the samples of oysters lifted from the banks during an inspection (see p. 38).

Kalanchu (corruptly Kalangi) and Manchadi are weights, there being 20 Manchadi (originally the scarlet seed of a plant) of 0·546 gramme each in the Kalanchu, which thus weighs 10·920 grammes. Now the Manchadi has been standardised and is a tabular brass weight of square form. The fractions and multiples represented by the little brass weights commonly employed by the Tamil pearl merchants range from the $\frac{1}{32}$ of a Manchadi to 10 Kalanchu.

The Chevoe, used in the valuation of the finest pearls, is an imaginary criterion depending partly upon weight and partly upon quality, and the valuers have to estimate how many such chevoe there are in each of the Ani and Anatari grades of pearl in the sample.

Bombay and Surat merchants as a rule do not employ the brass weights favoured by the Tamil merchants. They prefer beautifully modelled, pear-shaped weights of agate—sometimes red, sometimes greyish-white in colour. A rupee weighs approximately $1\frac{1}{16}$ Kalanchu.

The monetary basis employed in the calculation of values is the Star pagoda, a small plano-convex gold coin that was the standard gold currency in South India less than one hundred years ago. Its nominal value in the calculations made is Rs. $3\frac{1}{2}$. So if Masi-tul be valued at two star pagodas a Kalanchu, this indicates the market value to be Rs. 7 per Kalanchu. It should be noted that although the nominal value of the star pagoda is taken for the purpose of calculation at but Rs. $3\frac{1}{2}$, its intrinsic value as a gold coin at the present rate of exchange is considerably greater, being worth fully Rs. 6 as gold.

STATEMENT of the Valuation and Produce of 12,000 Oysters taken from the South-west Cheval Paar in February, 1904.

Description.	Size in basket.	Number.	Quantity in Chevoe.	Kalanchu.	Manchadi.	Total. Kalanchu.	Total. Manchadi.	Value.	Total value.	Per Chevoe.	Per Kalanchu.

.................., Valuer.
.................., Valuer.
.................., Valuer.

Marichchikaddi,
March 9, 1904.

South Indian pearl merchants make constant use, in working out their valuations, of a useful Pearl Merchants' "Ready Reckoner," published in 1890 at Tondimundalam, Madras, under the name of "Pearl-calculating Tables." It is printed wholly in Tamil, and gives the number of chevoe for a certain weight in Kalanchu and Manchadi of special classes of pearl. That obtained, the valuers fix the estimate according to what they agree shall be considered the market price of the day per chevoe of this quality. It may be accepted that this figure given in the official valuation is always considerably under the true ruling price of the day, and at the auctions during the fishery that follows, the oysters always sell at far above the estimate given in this valuation.

It is possible that with the advent of the London syndicate, to which the Ceylon pearl fisheries have been leased for the next twenty years, these picturesque old-time native methods, which have survived through the Portuguese, Dutch and British administrations, may now give place to more exact modern financial requirements. We are glad to have had this opportunity of putting on record a system which, existing, it is said, at the time of the "Periplus of the Erythræan Sea," has come down to our own day, practically unaffected by European civilisation, and may before long be doomed to disappear.

Pearl merchants.—From a photograph by J. Hornell.

EXPLANATION OF THE PLATES.

PLATE I.

Fig. 1. Part of a gill lamella of *Mytilus edulis*, showing a larger pearl occupying the whole thickness of the lamella and a smaller one in an enlarged gill filament. × 40.

,, 2. Group of four pearls in the mantle of *Mytilus edulis*—two of the pearls being in one sac. × 40.

,, 3. Pearl from the mantle of *Mytilus edulis*, showing a small, but quite simple nucleus, evidently, from its staining, an organic particle, but having no visible structure. × 40.

,, 4. Pearl from the mantle of *Mytilus edulis*, showing a relatively very large, deeply stained, but disorganised nucleus. × 40.

,, 5. Pearl from the mantle of *Mytilus edulis*, showing no nucleus, no cavities, and no foreign structure. × 100.

,, 6. Pearl and Trematode lying together in the mantle of *Mytilus edulis*. × 40.

,, 7. Pearl (with several centres) and Trematode lying together, enclosed in the same sac, in the mantle of *Mytilus edulis*. × 40.

,, 8. Pearl in a gill lamella of *Mytilus edulis*, showing a very large, disorganised nucleus, and a distinct sac, with epithelium closely resembling that of the adjacent ectoderm. × 300.

,, 9. Pearl from *Mytilus edulis*, decalcified to show the layers of conchiolin. × 40.

,, 10. Portion of a pearl and its sac (*p.s.*) from the mantle of *Mytilus edulis*, to show the similarity between the epithelium and the ectoderm (*Ect.*). × 300.

,, 11. Another portion of a pearl and its epithelial sac from the mantle of *Mytilus edulis*, to show irregularly projecting parts of the pearl cut separately. × 300.

,, 12. Adjacent portions of pearl sac and ectoderm from fig. 10, to show similarity. × 1000.

,, 13. Section through a Ceylon pearl in the natural condition. × 40.

,, 14. A partially decalcified pearl in the mantle of the Ceylon pearl oyster. × 100.

,, 15. Section through a partially decalcified Ceylon pearl. × 100.

,, 16. Portion of pearl sac and adjacent ectoderm of Ceylon pearl, to show similarity. × 1000.

,, 17. Portion of a Ceylon pearl and its epithelial sac. × 200.

,, 18 Portion of Ceylon pearl and its epithelial sac and mantle, to show large clear cells. × 900.

,, 19. Ceylon pearl and mantle, to show the large clear cells in the ectoderm (B) and in the pearl sac (A). × 900.

,, 20. Mantle of Ceylon pearl oyster over a pearl, to show the distribution of the large clear cells. × 900.

PLATE II.

Fig. 1. Margin of mantle of a highly infected Ceylon pearl oyster from Muttuvaratu Paar, showing nine encysted Cestode larvæ. Natural size.

,, 2. Transverse section through viscera of Ceylon pearl oyster, showing four Cestode cysts in the liver. Slightly enlarged.

,, 3. Gill filaments of Ceylon pearl oyster, showing encysted Cestode larva. × 12.

,, 4. A. Outline of a cyst pearl for comparison with B. Outline of the Cestode larva that forms the pearl-nucleus. × 20.

Fig. 5. Nucleus of a decalcified cyst pearl from the posterior ear-region of a Cheval Paar oyster, showing the characters of the Cestode larva. × 20.

,, 6. Partially calcified cyst around a dead Cestode larva, from the mantle of a 3-year-old Muttuvaratu Paar oyster. × 20.

,, 7. Nucleus of a decalcified cyst pearl from the mantle of a Cheval Paar oyster, showing a Cestode larva with a spherical calcification in its interior. × 20.

,, 8. Young Cestode larva (*Tetrarhynchus unionifactor*), extracted from thick-walled cyst in mantle of pearl oyster. × 40.

,, 9. Young *Tetrarhynchus* larva, extracted from a cyst in the mantle, showing the spines upon the "collar." × 40.

,, 10. The same, seen after slight pressure has caused the evagination of the "head." × 40.

,, 11. Another slightly later stage, seen under slight pressure. × 60.

,, 12. Rather later stage of the larva, showing elongation of body; from a cyst in viscero-pedal part of pearl oyster. × 30.

,, 13. Encysted later larva of *Tetrarhynchus pinnæ*. × 10.

,, 14. Later larva of *Tetrarhynchus pinnæ*, freed from the cyst-membrane. × 10.

,, 15. Late larva of *Tetrarhynchus balistidis*, from the liver of the File-fish, which eats pearl oysters. Natural size, and "head" × 16.

,, 16. The latest larval stage of *Tetrarhynchus unionifactor* met with in the pearl oyster. × 30.

,, 17. Part of the liver of the pearl oyster, showing one of the smaller (A) and one of the larger (B) Cestode larvæ encysted in the connective tissue. × 50.

,, 18. Globular larval Cestode encysted in the connective tissue of the liver. × 300.

,, 19. One of the smaller larvæ (*Tetrarhynchus* sp.) surrounded by a very thick connective-tissue cyst, showing a laminated structure. × 50.

,, 20. Larva in the same stage, showing the division of the muscle masses into incipient bothridia, or proboscides. × 300.

,, 21. Another larval stage, surrounded by a dense connective-tissue cyst. × 300.

,, 22. Another similar larva, slightly younger, showing a very slight cyst. × 450.

PLATE III.

Fig. 1. Section of larva of *Tetrarhynchus unionifactor*, showing an unusually depressed head. × 300.

,, 2. Section of another larva, showing the usual protruding papilla. × 960.

,, 3. An oblique section, × 40—showing the developing muscular tissue at *a* enlarged.

,, 4. Another oblique section, showing lateral muscular thickenings. × 40.

,, 5. Section through a larva, showing infoldings on the head. × 40.

,, 6. Section of the usual form, with large muscular protruding head. × 40.

,, 7. Posterior end of the last section, showing details. × 300.

,, 7A. Details of the fibres and spines on the cuticle of the last, more highly magnified.

,, 8. Typical longitudinal section through the larva of *T. unionifactor* as seen commonly encysted in the pearl oyster. × 960.

,, 9. Group of hooks *in situ* from the cuticle on the anterior invagination of the larger Cestode larva (*T. unionifactor*); with enlarged outlines of two isolated hooks. × 1000.

,, 10. Section through a very young *Tetrarhynchus*, with the four proboscides; from cyst between stomach and liver in pearl oyster. × 50.

,, 11. Section through more elongated *Tetrarhynchus*, also from a cyst *in situ* in the viscera of the pearl oyster. × 50.

Fig. 12. Three calcospherules from the insertion of anterior levator muscle; a, simple; b, compound; c, optical section showing pearl layers (*a*) being deposited round calcospherule.

„ 13. Diagram showing position of two irregular compound muscle pearls in 2nd and 3rd pallial muscle insertions; *a* and *b* show the two pearls, slightly enlarged.

„ 14. Diagram showing two rows of muscle-scars, the outer being the present functional ones; *a* marks the position of a muscle-pearl on the site of a former muscle-insertion (palpar region).

„ 15. Six cyst pearls in the mantle of the posterior ear, left side; four others lay in a corresponding position on right side.

„ 16. Two cyst pearls in mantle, posterior to dorsal end of adductor muscle.

„ 17. Six cyst pearls, misshapen through mutual pressure, in the mantle of the posterior ear.

Figs. 13 to 17 are about natural size.

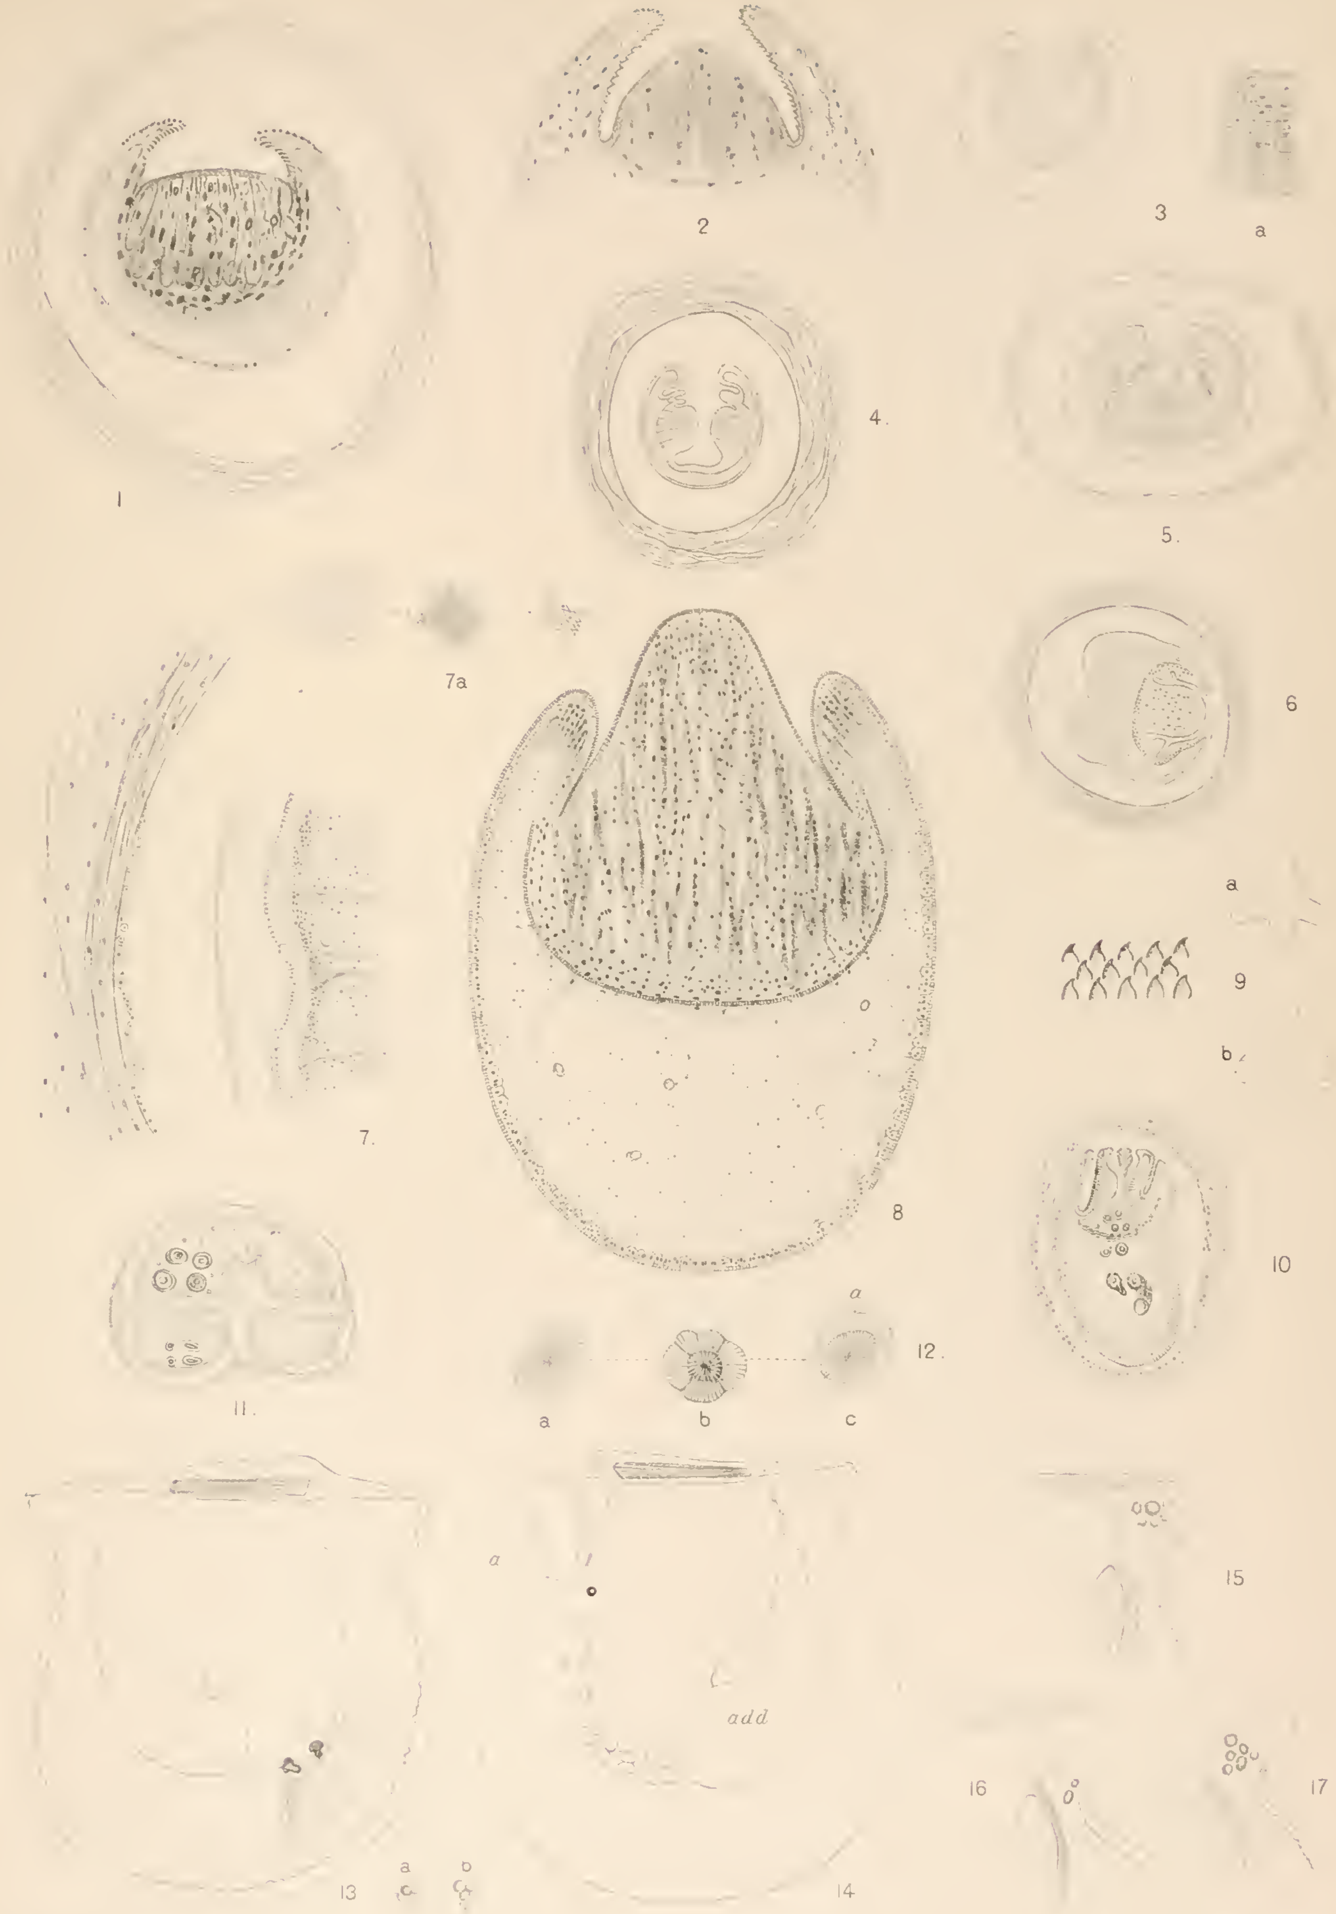
PEARLS AND PEARL CYSTS

CESTODE LARVÆ



CESTODE LARVÆ AND PEARLS

REPORT

ON THE

CESTODE AND NEMATODE PARASITES

FROM THE

MARINE FISHES OF CEYLON.

BY

ARTHUR E. SHIPLEY, M.A., Hon. D.Sc. (Princetown), F.R.S.,
FELLOW AND TUTOR OF CHRIST'S COLLEGE, CAMBRIDGE,

AND

JAMES HORNELL, F.L.S.,
MARINE BIOLOGIST TO THE CEYLON GOVERNMENT AND INSPECTOR OF PEARL BANKS.

[With SIX PLATES.]

In this Report the Cestodes and Nematodes collected from fishes taken off the Coast of Ceylon, and especially in the Gulf of Manaar, mainly in the first half of 1905, are described alphabetically under their several hosts, which in their turn again are arranged alphabetically. The Trematodes follow in a separate article which Dr. Lühe, of the University of Königsberg, has been good enough to write.

Owing to the necessity of bringing to a conclusion this "Report to the Government of Ceylon," the time allowed for the investigation of the large number of Cestodes in the collection was very limited, and it has not, except in very few cases, been found possible to "sectionize" the tape-worms. The following descriptions are based on observations made on the living animals and on those that had been killed, stained, and mounted. Many genera and species were represented by but two or three specimens, and in some cases even one was all that was available for study. We are greatly indebted to Mr. E. Wilson, of Mill Lane, Cambridge, for the care he has taken in drawing many of the figures which illustrate this Paper.

I. CESTODA.

We shall print the names of the fish-hosts in small capitals in the centre of the line, the names of the Cestode parasites will be in Clarendon type, the genera in the centre of the line, and the species at the left-hand margin.

AETOBATIS NARINARI (EUPHRASEN).

The Tamil name is "Pua tirikkai." Occasionally it is also termed "Kuruvi tirikkai," the "bird-ray"; but this latter is a somewhat general term applied to several of the bird-like rays and analogous to our use of the term "eagle-ray." *Pua tirikkai* is the true distinctive Tamil term. In Sinhalese it is "Pulli-maduwa." Very characteristic features of this fish are the *blue-black* tint of the flesh, and the manner in which the inner surface of the stomach is raised into a multitude of stout fleshy papillæ.

The specimens dissected were :—

A. A small individual from Puttalam Lake, opposite Kalpitiya. Width of disc, $14\frac{1}{2}$ inches; $6\frac{3}{4}$ inches between mouth and anus; length of tail, 32 inches. December 30, 1904.

B. A larger one from the open sea off Dutch Bay Spit. January 2, 1905.

C. A third individual from same locality as B. January 6, 1905. Dimensions :—Width of disc, $27\frac{1}{2}$ inches; length of disc, 27 inches; length of tail, 34 inches. From the root of the tail to the root of the tail spine was 11 inches.

Food :—Specimen A. The stomach contents consisted entirely of the remains of Lamellibranch shells and visceral masses. There were fully two hundred recognizable pedal fragments, belonging apparently to a small *Mactra* and allied forms.

B had been feeding principally upon the feet and siphons of Gastropods. A single small Hermit-crab (*Eupagurus* sp.) was also present. The stomach of C was empty.

Cephalobothrium, n. gen.

A large, median, circular sucker takes up most of the head; it is controlled by longitudinal muscles. Four small spherical suckers are placed equidistant from each other in the rim of the circular sucker. The proglottides are wider than broad, with the exception of the last six or seven. The reproductive pores are lateral and very irregularly alternate.

Cephalobothrium aetobatidis, n. sp.—Plate I., figs. 1, 2, 3 and 4.

This curious Cestode was drawn from life by Mr. HORNELL in Ceylon, the enormous terminal sucker being, in that state, much more conspicuous than in the preserved material. This sucker is round, with thickened edges, and from its underside run longitudinal bands of muscles which apparently control it.

The whole head is rounded, shaped like a turban, and bears four minute spherical suckers on the edge of the great median terminal sucker. There is no neck. The proglottides begin immediately after the sucker.

The whole length of the single worm we had at our disposal is 10 millims., but the posterior proglottides seemed ripe; the breadth of the head and of the posterior proglottides is 0·5 millim., the rest of the body is very fine and slender. The proglottides remain broader than they are long until within the last six; here they become square, and the last of all is almost twice as long as it is broad. The posterior angles of each proglottis overlap the anterior rim of the succeeding one, but not to a very pronounced degree. The reproductive openings are very irregularly alternate and lateral.

Habitat:—The spiral valve of *Aetobatis narinari*, taken off Dutch Bay, Ceylon. The specimens came from the fish described above as B.

Hornellobothrium, n. gen.

Very minute, 2 millims. in length. Head with rostellum and four suckers. No neck, but the body behind the head expands into a flattened region, something like the hood of a cobra; some twenty segments make this; the breadth then contracts and the proglottides become cylindrical. Cuticle finely striated. Reproductive pores alternate, slightly irregular.

Hornellobothrium cobraformis, n. sp.—Plate I., figs. 5 to 10.

Great numbers of this curious and very minute species were found in the spiral intestine of *Aetobatis narinari*; five of these were sent to England. They are so small as not to be much more than visible to the naked eye, for although they are—or at any rate the two larger are—2 millims. in length, they are of an extreme tenuity in breadth, looking like little bits of very fine white silk.

When alive, these Cestodes have a head with knob-like rostellum, on a constricted stalk; this emerges from a broader squarish base, whose angles bear four deep suckers. The whole is capable of considerable expansion and contraction; and constitutes the head. There is no neck, the proglottides beginning immediately after the head. The first twenty proglottides widen out to form a broad flattened part of the body, in outline like the inflated hood of a cobra. These proglottides are all many times as broad as they are long, and the ratio of these diameters is greatest about the tenth or eleventh segment. About the twenty-first or twenty-second segment the proglottides become, perhaps, twice as broad as long and by the twenty-fourth they are square; the remaining four or five proglottides are longer than broad, but the longest is never more than twice as long as broad. The posterior edges of the proglottides overhang the succeeding segments, but the extent to which this is done varies with the state of the contraction or expansion of the body. The cuticle is finely striated. The reproductive pores are alternate, but rather irregularly so, two consecutively left or right sometimes appearing.

Habitat :—*Aetobatis narinari*, in the spiral intestine.

Kystocephalus, n. gen.

Head bladder-like, with four small suckers and a myzorhynchus which is partially covered by a membrane. Proglottides with very salient posterior borders, most of them much broader than long. Lips of reproductive pores, which are irregularly alternate, very prominent.

Kystocephalus translucens, n. sp.—Plate I., figs. 11 and 12.

The two specimens of this worm at our disposal measured, respectively, 10 millims. and 35 millims., yet each appeared to end in ripe proglottides.

The head and the thicker part of the body measured 0·4 millim. in breadth. The head is a curiously bladder-like concern, which takes little stain and bears four very small spherical suckers. There seems to be a myzorhynchus, surrounded and half enclosed in a circular membrane. The membrane, however, has a central circular aperture through which the myzorhynchus protrudes. Immediately behind the head the proglottides appear, and for about one half the body-length they are considerably broader than long; they then become square, and the last five or six are longer than broad. The posterior end of each proglottis widens out like the walls of a funnel and overlaps the anterior end of the succeeding proglottis to a much greater extent than is usual, so as to sometimes cover a third of the hinder proglottis. At least this is the case in one of our specimens; in the other this salient edge was curled back like the brim of a top-hat. The genital orifices are lateral and in the posterior proglottides have very prominent lips; they are irregularly alternate, usually two or three on one side and then three or four on the other.

This form seems to be not far removed from the genera *Tylocephalum* and *Cephalobothrium*, but it is marked off by quite definite features.

Habitat :—*Aetobatis narinari*, in the intestine.

Myzocephalus, n. gen.

"Head" with four slipper-shaped bothridia each divided by a horizontal partition into two areolas. "Head" surrounded and smothered in four most voluminous and crumpled folds like the bothridia of *Anthobothrium*. Proglottides barrel-shaped. Reproductive pores irregularly alternate. Cuticle finely ringed.

Myzocephalus narinari, n. sp.—Plate I., figs. 13, 13*a*, 14, 15, 16*a*, *b*, *c*.

This remarkable form reminds one of an *Anthobothrium* which has enormously developed and crumpled up its bothridia, as in *Phyllobothrium*, and which retains a myzorhynchus or "head." The largest of our specimens measured 25 millims. in length. The head with its ruff-like bothridia measures 2 millims. across and the posterior ripe proglottides measure 1 millim. transversely. The anterior end consists of a head which bears four slipper-shaped bothridia each divided by a horizontal ridge into two areolas. They are very mobile. In life the head is very contractile and readily alters its shape (figs. 16*a*, *b*, *c*). Its anterior end is rounded. The water vascular canals penetrate the head and anastomose there, branches are also given off into the "ruff." During life the puckered bothridia were continually undergoing changes of form and the whole mass was in constant motion and transformation. The ruff is formed of four immensely crumpled lateral extensions which branch all together and completely hide the head and give the anterior end of the body the appearance of a cauliflower. These four extensions are borne on four stalks which are equally immersed in their voluminous folds. It needs but an extension of the so-called bothridia of *Anthobothrium* to produce this ruff, but if the extensions are morphologically bothridia, then in this worm we have a double set of bothridia, one in the head, the other forming the ruff. The excretory tubes on each side extend to the end of the myzorhynchus, and then double back.

There is no neck, the transverse divisions beginning immediately after the insertions of the ruff. The line between the proglottides is straight, and except faintly at the anterior end of the body there is no trace of overlapping. The cuticle is finely ringed. The proglottides are barrel-shaped, arching out at each side. The first differentiation which arises in the growing proglottides is the appearance of the scattered testes, and almost at the same time the primordium of the uterus and genital ducts arise. The uterus even in our ripest specimens remains unbranched. The complex of the ovary and shell gland lies posteriorly. The openings of the genital duct are irregularly alternate, perhaps 4 on the right side, 1 on the left; 5 on the right, 3 on the left, and so on.

Habitat:—The spiral intestine of *Aetobatis narinari* taken off Dutch Bay, Ceylon. These Cestodes came from the specimen B mentioned on page 44.

Myzophyllobothrium, n. gen.

Long worms, some 80 millims. in extent. Head with myzorhynchus with four suckers, four bothridia, sessile, with smooth edges and a thickening (? small sucker) at the apex. No neck. Proglottides never overhanging, with anteriorly straight sides. Red pigment at base of head apparently associated with water vascular system.

Myzophyllobothrium rubrum, n. sp.—Plate I., figs. 17 and 18, and Plate II., figs. 19 to 21.

This curious worm, taken from the intestine of *Aetobatis narinari*, belongs to the order Tetraphyllidea,* Carus, and to the family Phyllobothriidæ, but it seems to us to

* Bronn's 'Thierreich.' "Cestoda," by M. Braun.

form a new genus which we have called *Myzophyllobothrium*. This form obviously comes near *Phyllobothrium*, but there is no neck and there is a distinct "myzorhynchus." It is a much larger form than *Hornellobothrium cobraformis* found in the same specimen.

The worm is a long one for a Selachian parasite, measuring some 8 centims. in our longest specimen, and about 0·4 millim. broad. The head is 1 millim. across. It consists of a terminal myzorhynchus which bears four almost terminal suckers; the whole is very delicate, transparent, mobile and capable when alive of great extension. The myzorhynchus is flanked by four bothria or sessile, leaf-like extensions; these also bear at their apex a small thickening which may represent a sucker. The edges are not crumpled and wrinkled as in *Ph. lactuca*, but are smooth and entire.

There is practically no neck. The proglottides are cut off from one another by perfectly flat partitions at right angles to the surface. The two sides of each proglottis in the anterior half of the body are flat and, as nearly as possible, parallel; behind this the sides become somewhat bowed outward, and thus there is a constriction at the "joint." There is no trace of overlapping of the posterior end of a proglottis over the anterior end of the next succeeding. The centre of the body consists of proglottides, which are about square; the most posterior proglottides may reach a length of three times the breadth.

The testes appear early, and are always accompanied by an L-shaped structure (Plate I., fig. 17*a*), which has a limb passing from the genital aperture to the centre of the proglottis and then another limb running straight back; this probably represents the vas deferens and vagina. The posterior proglottides nearly always have their penes protruding.

When alive, the posterior proglottides readily detached themselves from the worm, and then showed very active movements, crawling about rapidly.

There is a deposit of granular red pigment just behind the head which seems to accompany the excretory canals; at any rate, it runs back along the main longitudinal ducts. It contrasts strongly with the general milk-white colour of the worm.

Habitat:—In the spiral intestine of *Aetobatis narinari*, the individual A from Puttalam Lake.

Tylocephalum trygonis (SHIPLEY and HORNELL).*

Tetragonocephalum trygonis, SHIPL. and HORN.

This species, which has hitherto been recorded only from the intestine of *Trygon walga*, was found associated with *Tetragonocephalum aetobatidis* and with *Myzocephalus narinari* in the intestine of *Aetobatis narinari*.

* This Report, Part III., p. 51. Since writing this article we have come to the conclusion that the genus we described as *Tetragonocephalum* is identical with LINTON'S *Tylocephalum*, 'U.S. Commission of Fish and Fisheries,' Commissioner's Report for 1887, Part xv., 1891, p. 805.

Tetrarhynchus aetobatidis, n. sp.—Plate II., figs. 22 to 24.

This species, of which we had but two specimens, measures 12 millims. in length. The head is squarish, with two well-marked suckers on each side and the proboscides emerging at the four angles of the anterior surface. These proboscides are perhaps a little stouter and thicker than usual. They bear the hooks in oblique rows. The hooks at the anterior end of the extended proboscides are strongly curved backward and have a very characteristic haft. There is a prominent projection anteriorly, just where the hook is inserted into the skin. Posteriorly the hooks become more sabre-like.

One characteristic feature of this species is the swelling which takes place at the posterior half of the head, caused by the presence of the stout muscular bulbs of the proboscis. Just before the junction of the proboscis tubes with the proboscis bulbs are two aggregations of red pigment spots. This region is at least twice the diameter of the succeeding body. There is a short neck, or, at least, a region where no divisions are visible. The number of the proglottides in our two specimens hardly surpassed thirty-five, but the posterior ones were not mature. The proglottides are barrel-shaped. The reproductive pores are irregularly alternate, but, as a rule, there are not more than two consecutively on the same side. The cuticle is roughly ringed.

The diagnosis of *Tetrarhynchus aetobatidis* is as follows :—

Head squarish ; proboscides rather stout ; hooks with tubercle at their base, the anterior strongly recurved, the posterior more sabre-like. The part of the head in which the proboscis bulbs lie is much thicker than the body. Short neck. Proglottides barrel-shaped. Reproductive pores irregularly alternate. Red pigment at posterior end of proboscis tubes.

Habitat :—The intestinal spiral valve of *Aetobatis narinari*. It is also said to occur in *Trygon walga*, and to be common in both Elasmobranchs in Dutch Bay and on the pearl banks.

BALISTES MITIS, Bennett.

The Tamil for this File- or Trigger-fish is "Kilati."

These fishes were abundant on the South-west Cheval Paar pearl banks, Ceylon, on February 5, 1905 ; eight specimens were caught within a short time. The stomach contents were worms, small Crustaceans, small Lamellibranchs, but no pearl oysters in these particular individuals, due to the absence from this locality of any young pearl oysters at the date in question.

Free in the abdominal cavity of one was a strangely coloured Trematode, $\frac{1}{4}$ inch long. It was light brownish-yellow in ground tint, blotched prettily with chestnut-brown splashes.

From the same individual several encapsuled larvæ of Tetrarhynchids were obtained belonging to several species. Two species are quite distinct from either of the two described in our first report. The teeth in both more or less graded from large to small in each row, and are not all similar as in those already described.

Tetrarhynchus sp.—Larvæ.

At least two young forms were taken together with some Trematodes from *Balistes mitis*. Some of these belonged to the species *T. balistidis*,* others were in the form of cysts with the head protruded, others again had their heads enveloped in a bladder. A fourth form is shown in Plate II., fig. 25. It is like *T. balistidis*, and consists of a head which has not yet begun to bud off proglottides. The anterior part of the head bearing the lappets is just about as long as the part bearing the proboscis sacs, whilst the median portion traversed by the proboscis sheaths is two to three times as long as either. The proboscis teeth are graded in each row from long narrow, sabre-like outlines to short beaked forms (Plate II., fig. 26). From the account drawn up at the time of capture from the living material this form had evidently only just escaped from a cyst of the *T. erinaceus* type.

A very different form of *Tetrarhynchus* larva was also taken from the tissues of *Balistes mitis*, and is shown in fig. 27. Here there is no enveloping bladder, but the Tetrarhynchid head is attached and protrudes from a vesicle which shows signs of an excretory pore posteriorly. This larva is evidently one of VAULLEGEARD'S first division, of which *T. lingualis* is the type. The larva differs from the form we described, under the name of *Tetrarhynchus balistidis*, in Part II. of these reports inasmuch as there is the large vesicle present. The whole length of the larva and head is just under a millimetre. The teeth, as drawn from living specimens, are shown in Plate II., fig. 27*a*. The wall of the vesicle, seen under a high power, seems to contain a large number of globules, possibly calcareous bodies.

CARCHARIAS GANGETICUS, MÜLL. and HENLE.

A specimen, measuring 5 feet 6 inches in length and 32 inches in breadth behind the pectoral fins, was taken on January 3, 1905, in Dutch Bay, Ceylon. The contents of its stomach were many fish-bones, but in the small intestine a number of Tetrarhynchids which fall into two species were found. No Entozoa were found in the spiral valve, usually a favourite haunt of parasites.

Tetrarhynchus gangeticus, n. sp.—Plate II., figs. 28 and 28*a*.

Two forms of *Tetrarhynchus*† were taken in the intestine of *Carcharias gangeticus*, one with a stout smooth head, which we have named *T. gangeticus*, and the other smaller with a rumpled head. The former was found in very few numbers, and the three specimens sent to England were short, 10 millims. long, but at least 2 millims.

* See this work, Part II., p. 89.

† Neither agree in many particulars with the *T. carchariæ rondeletii* of WAGENER, *v.* 'Acta Ac. German.,' xxiv., supplement, 1854.

broad, and the head is 3 millims. at least in width. *T. gangeticus* has a smooth, white head, two very clearly defined and large lappets, somewhat heart-shaped, the apex pointing forward and the four proboscides issuing near the two apices, two on each side (Plate II., fig. 28). The proboscides are stout and bear teeth of many sizes. On the concave side of the extruded proboscis are large, strongly recurved teeth ; these are flanked by teeth of lesser size, and they gradually diminish until upon the convex side there are a multitude of fine toothlets. Although it is rather masked, these teeth are really arranged in very obliquely placed rings.

The edges of the lappets are outstanding and sharply separated from the head, and they have clear-cut edges.

The proboscis-tubes leading to the proboscis-bulbs are not spirally twisted so much as bent in and out. The head narrows posteriorly, anteriorly it is 2 millims. in width, and the whole is 3 millims. in length.

There is no neck, the proglottides appear immediately after the head. As there were but three specimens, one only was mounted, and this, which is drawn on Plate II., fig. 28, shows only just the anterior five or so proglottides.

The diagnosis of *Tetrarhynchus gangeticus* is as follows :—

Short (10 millims.), stout (2 millims., and head 3 millims. in breadth) forms. Head with two very clearly cut lappets standing out from general surface. Proboscides stout, with large hooks on one side, diminishing regularly to small hooks on the other. Hooks arranged in oblique rings. Proboscis-tubes bent in and out.

Habitat :—Small intestine of *Carcharias gangeticus*.

Tetrarhynchus perideræus, n. sp.—Plate II., figs. 29, 30, 30*a*, 31*a*, *b*, *c*.

This species was present in large numbers in the small intestine of *Carcharias gangeticus*. The head, and a peculiar extension of the head in this species, is a well-marked shade of dark grey, which contrasts vividly with the matt-white of the rest of the body. Even in the stained and mounted specimens, peculiar coloured granules can be recognized, which doubtless give rise to this colour in the live animals.

This is a big species, some specimens attaining a length of 70 millims., possibly more, as the bottle in which they travelled was full of fragments. The width varies, but is never great, and even the head never exceeds about 1·3 millims. The head bears two lappets, but they are so divided in the centre as to appear like four. They are very compressed into the head and do not stand out. They appear rather puckered at their edges. The proboscides are slender, and bear oblique rows of very minute teeth, all of uniform size (Plate II., fig. 30*a*). The proboscis-tubes and proboscis-sheath are alike short. The head is produced backwards into a very characteristic collar which overhangs and embraces the anterior part of the body. This is a very marked feature (Plate II., fig. 30).

There is a fairly long neck, the first trace of segmentation occurring some way behind the posterior limit of the collar. The proglottides have straight sides, and except at the posterior end there is no sign of the cuticle being indented between them. One peculiarity is that the body, usually about the middle of its length, is thrown into coils and twists of a very characteristic form. In the anterior proglottides one sees a central stained part, possibly the uterus; posteriorly, however, the scattered testes are visible, and the vas deferens and penis, represented sometimes by a clear area, runs from about the centre of the anterior border of each proglottis to the middle of either side, right or left, irregularly alternating.

The diagnosis of *Tetrarhynchus perideræus* may run :—

Head with well-marked backwardly directed collar which, together with the head, is dark grey; the body is white. Some 70 millims. long. The two lappets are almost split into four and lie adpressed and crumpled in the head. Teeth all of the same size. Neck rather long. No constrictions between the proglottides except posteriorly. Penis runs from centre of anterior edge of proglottis to the centre of either side.

Habitat :—The small intestine of *Carcharias gangeticus.*

CARCHARIAS MELANOPTERUS, Quoy and Gaimard.

This fish is in Sinhalese called "Kunda mora." The specimen we examined contained in its stomach a large specimen of the genus *Caranx.* It was caught at Dutch Bay Spit on January 5, 1905, and contained in its intestine the three species of Cestodes described immediately below.

Phyllobothrium minutum, n. sp.—Plate III., figs. 32 and 33.

One or two examples of two forms of *Phyllobothrium* were found in the intestine of *Carcharias melanopterus.* They are a great deal smaller than, for instance, *Phyllobothrium thridax* described by Zschokke, but their head and general structure coincides with that of the genus.

Phyllobothrium minutum measures 8 millims. in length and at the widest 0·3 millim. in width. The neck is very fine and whip-like; it terminates in a small head. The head bears four bothridia with on each an accessory sucker or areola (Plate III., fig. 33). The edges of the bothridia are crumpled, at least slightly so. The round areola was near the centre of each bothridium. The neck is long .and very transparent. The number of proglottides some 80 to 100; each slightly overlaps the one behind it. The central proglottides are still a little broader than they are long, but the posterior are at least one and a half times longer than broad (Plate III., fig. 32).

The reproductive pores are lateral and all on the same side.

The diagnosis of *Phyllobothrium minutum* may run :—

Length 8 millims., greatest breadth 0·03 millim. Head with four sessile bothridia, each bearing a single, large, round areola near the centre. Proglottides 80 to 100, neck fine and transparent.

Habitat :—*Carcharias melanopterus*, in the intestine.

Phyllobothrium pammicrum, n. sp.—Plate III., figs. 34 and 35.

This is the second small *Phyllobothrium* found in the intestine of *Carcharias melanopterus.*

Two specimens which were mounted measured 13 millims. and 11 millims. respectively. The greatest width was 0·5 millim. The head and neck are very transparent. The head carries four sessile, rather crumpled bothridia, in which there are no areolas. The edges of the bothridia are decidedly crumpled. Many muscles run down from the head through the neck, which is long (Plate III., fig. 35).

The strobilization is peculiar. There is no sign of the gradual differentiation of the proglottis first as a narrow band, which broadens as it passes backward, but the most anterior segment is almost as large as those which succeed it—perhaps one ought to say, those which precede it (Plate III., fig. 34). The proglottides have straight parallel sides and straight parallel ends, and their hinder edges do not overhang the front edges of the next behind. The reproductive pores are lateral and confined to one side. The posterior segments are three times as long as they are broad, sometimes even a little longer.

The diagnosis of *Phyllobothrium pammicrum* may run :—

Length 11 millims. to 13 millims. Greatest breadth 0·5 millim. Head with four sessile bothridia crumpled, with no areola. Neck long. Proglottides when they first appear are almost of full size, with straight sides and ends, and no overlapping. Reproductive pores lateral and on one side only.

Habitat :—In the intestine of *Carcharias melanopterus.*

Tetrarhynchus carcharidis, n. sp.—Plate III., figs. 36 and 37.

A minute form of *Tetrarhynchus* was found in the intestine of a *Carcharias melanopterus* taken in Dutch Bay on January 5, 1905. The length usually 9 millims. The anterior end of the body is extremely thin and whip-like; the body, however, thickens posteriorly until the two last proglottides are 0·5 millim. in thickness. These proglottides are very long, 1·5 millims. and 2 millims. respectively.

The head is minute, and in stained specimens takes little stain. The two lappets are smooth at their edges, not wrinkled, and with no indentation or sign of division into two. The proboscides are very fine, and bear a number of spines, not hooks. These spines are thicker at the base than at their free end; they all point backwards. They are very minute, and seem to be arranged in slightly oblique rings. The proboscis-tubes are very closely coiled, and end in the four muscular bulbs, which hardly occupy one fifth of the total head length. The whole head seems to be dusted through with granules (Plate III., fig. 37).

There is no neck. The narrow, band-like proglottides appear immediately behind the head, and they and even the hinder proglottides are separated by quite clear transparent divisions. There are only some eighteen or nineteen proglottides, and we were unable to make out the anatomy of these, as it seemed the material was not very well preserved.

The diagnosis of *Tetrarhynchus carcharidis* is as follows :—

Minute, some 9 millims. Anterior end of body very fine and whip-like. Head small, proboscides very fine, with backwardly directed spines, not hooks; lappets with simple edges, not wrinkled; proboscis-tubes very coiled, proboscis-bulb one-fifth the length of head. Eighteen or nineteen proglottides, separated by clear, transparent partitions, at first very narrow from front to back. The last two attain a length of 1·5 millims. and of 2 millims., and a width of 0·5 millim.

Habitat :—*Carcharias melanopterus*, in the intestine.

CHILOSCYLLIUM INDICUM (GMEL.).

This fish is termed "Kurakan sūra" in Tamil.

A female, sexually mature, and having an egg capsule in each uterus, was caught on the North Modragam Paar, Ceylon pearl banks, on February 3, 1905. The stomach contents consisted of small fishes.

Carpobothrium, n. gen.

A minute form, belonging to the Phyllobothriidæ. The head consists of four stalked bothridia, each ending in a circular, flat area, from which project two processes, which are opposed to one another. One of these is obcordate in outline. The body is coiled, with little or no neck, the cuticle very crinkled.

Carpobothrium chiloscyllii, n. sp.—Plate III., figs. 38 and 39.

These peculiar and minute little tape-worms were taken from the intestine of a *Chiloscyllium indicum*, the common "dog-fish" of the Indian Ocean, on the North Modragam Paar, Ceylon. They are short and in all cases coiled forms, the whole animal being twisted up into a bunch not more than 1 millim. by 0·5 millim.

The head is remarkable for four long arms which end in four remarkable suckers. The arms stand out at right angles to one another and to the neck; they consist of a stalk terminating in a very peculiar bothrium. The stalk is capable of considerable extension. In a sketch made from a living specimen each of the four stalks are extended till they attain a length of about one-sixth the total body length and have parallel sides. In the preserved specimens the stalk is contracted and conical. Each stalk ends in a circular, slightly concave area, from the centre of which emerge two processes, slightly flattened and opposed to one another. The process which is nearer to the centre of the head is obcordate like a violet leaf, the second process is rounded. Around the base of these is a ring of muscle fibres, which is, however, broken into two halves, as is shown in Plate III., fig. 39. The bothridia are very mobile, and take up different outlines in different specimens.

There is practically no neck; the sharp, unstained clear lines which represent the division between one proglottis and the next begin close behind the head. At first the proglottides are much broader than long, but they very soon become square and then much longer than broad, till at the hind end the length is six or seven times the breadth. There are only seventeen or eighteen proglottides in all. Unfortunately the details of the inner anatomy refused to reveal themselves by staining. Two peculiarities of the body are the way it is coiled up, as is characteristically shown in Plate III., fig. 38, and the rapid rate at which the proboscides lengthen.

Habitat:—The intestine of *Chiloscyllium indicum.*

CHIROCENTRUS DORAB (Forsk.).

This fish, the only representative of the family to which it belongs, inhabits the Indian Ocean and the seas of China and Japan. It is known as "Vālai" or "Wālai" in Tamil, and as "Katuwalla," Sinhalese, literally a "bunch of thorns," a reference to the multitude of needle-like bones that are present in this fish. Our specimen was caught at Kalpitiya, Ceylon, on December 29, 1904, and contained Trematodes in the anterior end of the intestine and Tetrarhynchid cysts.

Tetrarhynchus, sp.—Cysts (α).—Plate III., figs. 40, 40*a* and 41.

A number of small cysts containing *Tetrarhynchus* heads were found in the body of *Chirocentrus dorab*, taken at Kalpitiya. They were all taken from the peritoneum.

The cysts are 8 to 12 millims. long, and consist of an oval head 0·7 millim. in breadth and 1 millim. in length, and a long flaccid tail about 0·3 millim. to 0·4 millim. in width. The larval *Tetrarhynchus* lies entirely in the head (Plate III., figs. 40 and 41). It consists of a head and a small unsegmented body piece. The head shows well the four proboscides with their teeth, the proboscis-tubes and the proboscis-bulbs.

The whole cyst is contained in an outer sheath, which is probably a portion of the host. The Cestode part resembles a cysticercus which has been drawn out into a long tail. The head of the *Tetrarhynchus* is invaginated into the sac, but the outer wall of the invaginated portion seems to fuse with the inner wall (which is, of course, the actual outer wall of the *Tetrarhynchus* head) near, but not quite at the posterior end.

The whole cavity of the cyst, into which the end of the larva sticks, is full of cells sparsely distributed with apparently many vacuoles containing fluid between the cells. The nuclei are large. The same tissue occupies the lumen of the tail.

Judging from the number collected, these cysts must have been common in the fish. Unfortunately, it was impossible to make out any detail of the teeth in the retracted proboscis, and as the head alone was present, all characteristics of the proglottides were equally hidden. Hence nothing could be done to determine the species.

Tetrarhynchus, sp.—Cysts (β).

Two different kinds of cysts were found in a second specimen of *Chirocentrus dorab* taken at Marichchukaddi. One closely resembled *T. balistidis*, the other was enclosed in a cyst of peculiar form. The head of the animal lay in a little golden cyst, 2 millims. long by 1 millim. broad, which is continued posteriorly into a long, thin tail some 8 millims. or 9 millims. long.

CYBIUM GUTTATUM, Cuv. and Val.

This fish, one of the "Mackerels" or Scombridæ, harboured two kinds of Tetrarhynchid cysts. The "Seer," as it is called, is one of the most esteemed food-fishes of the Europeans in Ceylon.

Tetrarhynchus, sp.—Cysts.—Plate III., figs. 42 and 43.

A number of Tetrarhynchid larvæ were taken from the peritoneum of a *Cybium guttatum* captured off Trincomalee. Like those described in Part II. of this work as *T. balistidis*, they exist in two stages, one in a cyst, the other without a cyst. Whether one of these is, as we assumed in our description of *T. balistidis*, an older form of the other, or whether they represent separate species, is uncertain. That they are both larval is shown by the entire absence of any proglottides. The form without the cyst is somewhat egg-shaped, 4 millims. long and at its widest 2 millims. broad (Plate III., fig. 42). The most interesting feature in it is that the tail or posterior end is ensheathed in a circular fold like a petticoat, and from it runs up a number of ribs or ridges which fade out in the head. The teeth on the proboscides are large and stout and comparatively sparse (Plate III., fig. 42).

The other larvæ, which on the whole we are inclined to regard as a different species, are enclosed in a voluminous cyst which may attain a length of some 14 millims. and a breadth of 2·5 millims. They were dissected out from the peritoneum of *C. guttatum*. The larval head is very much smaller than that just described; it is invaginated, and the walls of the cavity in which it lies meet and all but fuse (Plate III., fig. 43). They are then continued backward as the wall of the cyst, which is constricted here and there. Posteriorly the exit of the excretory system is visible. The cyst is enclosed in a secondary cyst pathologically formed from the tissues of the host in which it lives. They evidently belong to the second group into which VAULLEGEARD divides the Tetrarhynchidæ, the type of which is *T. erinaceus*.

In another specimen of *Cybium guttatum*, taken at Marichchukaddi, there were several cysts very like those described above, and two very different species of Trematode.

DIAGRAMMA, sp.

Tetrarhynchus, sp.—Cysts.—Plate III., fig. 44.

A number of Tetrarhynchid cysts were taken from an undetermined species of *Diagramma*, a sea-perch common in the hotter parts of the Indian and the Pacific

Oceans. They belonged to the form enclosed in a bladder, *e.g.*, *T. erinaceus*. They are small, measuring 2 millims. by 1 millim., and the head is extremely minute and rather coiled. We figure the cyst on Plate III., fig. 44.

LUTJANUS ANNULARIS, Bloch and Schn.

Tetrarhynchus, sp.—Cysts.

A few small cysts of *Tetrarhynchus* were found in the tissues of this fish, one of the Serranidæ, but little could be made out of them. The same tissue contains a number of oval, brown, glistening, granular-looking bodies, which may have been a species of *Sarcocystis*.

MYLIOBATIS MACULATA, Gray and Hardw.

This common Eagle-ray is known in Tamil as "Panjadi" or "Panchadi tirikkai," also "Neduvali tirrikai," or the long-tailed Ray, and in Sinhalese as "Panjadiya maduwa."

The food of this fish consists of Crustaceans (hermit crabs) and the feet of Molluscs, chiefly *Turbinella* and *Murex*, also *Strombus*, whose opercula were found in the stomach.

Anthobothrium crispum, n. sp.—Plate III., figs. 45 and 46.

A few specimens of this species were taken from the intestine of *Myliobatis maculata*. For Elasmobranch Cestodes they are large tapeworms, reaching a length of 8 centims. or 9 centims. The head is 3·5 millims. in diameter. It is produced into bothridia whose edges are much crumpled, frilled, fringed and subdivided. In some cases the subdivision extends a good way towards the pedicel, and gives the head the appearance of consisting of six or eight bothridia. The pedicels are very short and the bothridia seem to be almost sessile. No myzorhynchus was visible.

The neck is very long, and even quite posteriorly the proglottides show very little demarcation. There is no indentation of any sort. The line which separates one proglottis from its neighbour is usually clear and sharp in the centre, but it hardly reaches the sides of the tapeworm. These latter are quite smooth, and, except that the body slightly increases in thickness, they would be quite parallel. The neck is about 0·7 millim. in width, the posterior part of the body 1 millim. in width.

The specimens did not stain well, and all that could be made out was an L-shaped structure, of which one arm represents the reproductive ducts running to the pore and the other arm the uterus. The reproductive pores are irregularly alternate.

This form is much more slender than the *A. rugosum* of *Trygon walga* and the bothridia are less stalked.

The diagnosis of *Anthobothrium crispum* is as follows:—

Length, 8 or 9 centims. Head with four fringed bothridia, somewhat sub-divided and with practically no pedicels. Neck long. Division between proglottides feebly marked, no constriction or overlapping, and the dividing line does not reach the edges. Sides smooth and almost parallel. Reproductive pores irregularly alternate.

Habitat :—Intestine of *Myliobatis maculata.*

Diagonobothrium, n. gen.

Head 2·3 millims. in length, about 1 millim. in breadth. There is a large terminal muscular sucker and two ear-like bothridia which run down right and left of the head. One edge of each of these bothridia runs forward obliquely, and loses itself in the crinkled membrane which surrounds the terminal sucker. There is only one edge on each side thus prolonged, and the two prolongations cross one another at about a right angle. The head is thus asymmetrical. The neck is long and shows hardly any structure.

Diagonobothrium asymmetrum, n. sp.—Plate III., fig. 47.

A single specimen of a curious tapeworm was found, with *Anthobothrium crispum,* in the intestine of *Myliobatis maculata* taken in Dutch Bay. Unfortunately the head and neck, which showed no strobilization and no structure, were alone taken. The head consists of a very large and muscular sucker, centrally placed and terminal. The sucker is surrounded by a rather wrinkled membrane. The head is 2·3 millims. long and anteriorly 1·2 millims. wider ; its average width is about 1 millim.

Each side of the head are two somewhat ear-shaped lateral, hollow bothridia, and the peculiar feature of the head is that one edge of the bothridia is continued up on to the membrane which surrounds the terminal sucker in an oblique manner (Plate III., fig. 47). The other edge of each bothridia is not so prolonged. Thus it comes about that these prolonged edges cross one another, one being on one side, and the other being on the other side of the head. Hence the head is not symmetrical about any plane, and it would be impossible to cut it into two symmetrical " looking-glass " halves. This feature is very unusual in a Cestode, and one could not put from one's mind that it might be an abnormality, especially as only one specimen was taken, and that without any proglottides.

The neck was long and showed little structure, and it was broken across before it began to segment.

Habitat :—The intestine of *Myliobatis maculata.*

Rhoptrobothrium, n. gen.

Minute forms. Head with four bothridia surrounding a myzorhynchus which carries four suckers. Bothridia stalked and leaf-like, with the terminal end cut off and forming an areola. Head extends behind the insertions of the stalk of the bothridia and is followed by a neck,

Rhoptrobothrium myliobatidis, n. sp —Plate III., fig. 48.

Of this minute Cestode, one only was available, and that included little more than the head, and was in a poor state of preservation, showing very little histological detail. The length of the worm, which was obviously imperfect, was 1·8 millims., and the arms of the head when stretched measured 1 millim. from tip to tip.

The head somewhat resembles the head of *Anthobothrium* or *Echeneibothrium*, that is to say there are four arm-like bothridia, but in *Rhoptrobothrium* the bothridia surround a myzorhynchus which projects forward from their common base. Anteriorly, this ends in a bluntly-pointed knob. It bears at equal distances four rather leaf-like suckers whose edges are curled inwards, and bear half-way along their edge a pair of inwardly directed projections.

The bothridia are stalked and in general outline much resemble an ovate leaf. The stalk arises not opposite the suckers in the myzorhynchus, but opposite the space between each pair of neighbouring suckers. The tip or terminal fifth of each bothridium is cut off from the rest by a ridge, and forms a shallow sucker or areola. The edges of the remaining four-fifths are incurved.

Behind the insertion of these bothridia there is a region which may be called the head; this does not stain deeply. It contracts and is succeeded by a neck which stains well. In the single specimen from which this description is taken the rest of the body was absent.

Habitat :—*Myliobatis maculata*, in the spiral intestine.

Tylocephalum dierama, n. sp.—Plate III., figs. 49 and 50.

Along with *Rhoptrobothrium myliobatidis*, a specimen or two of what we take to belong to LINTON's genus *Tylocephalum** were found.

The worms measured between 20 millims. and 35 millims. They were very slender anteriorly, but the posterior proglottides attain a width of 0·5 millim., and the head is about 0·6 millim. in breadth, and is rather longer than broad.

The head consists of an anterior cushion, called a myzorhynchus by LINTON; it is obviously to some extent retractile, and in one of our specimens was slightly "pulled in" in the middle, so that the whole head resembled a cottage loaf. This myzorhynchus is separated from the second part of the head or "bothrial disk," as LINTON has it, by a narrow band, not only by a constriction, but by a band. The "bothrial disk" is spherical and bears four equidistant, simple suckers. There is a short neck. The proglottides are, at the posterior end, not more than twice as long as they are broad. They are flattened. Anteriorly they have salient posterior borders, and these, as they approach the hinder end, become much more conspicuous and overhang an eighth or a sixth of the length of the succeeding proglottis. These funnel-like extensions are very characteristic of this species; they are much less marked in

* 'U.S. Commission of Fish and Fisheries,' Commissioner's Report for 1887, Part xv., 1891, p. 805.

LINTON's species, *T. pingue*. The last proglottides were equally rounded, and contained a uterus full of ova.

The diagnosis of *Tylocephalum dierama* is as follows :—

Length between 20 millims. and 30 millims. Proglottides with very overhanging posterior borders. The body is flattened.

Habitat :—*Myliobatis maculata*, in the intestine.

RHINOPTERA JAVANICA (MÜLLER and HENLE).

"Of the two species of *Rhinoptera* recorded from Indian waters, *R. javanica* is the fish known as 'Valvadi tirikkai' to Tamil fishermen. From the accounts received of a very closely allied but much larger species which goes by the name of 'Mundeikanni tirikkai,' and which I have not yet seen, I have no doubt that it is the second Indian species of *Rhinoptera*, *R. adspersa* (MÜLLER and HENLE).

"Prior to the present, 'Valvadi tirikkai' has been wrongly identified with *Trygon uarnak*. Mr. H. SULLIVAN THOMAS ("Report on Pearl Fisheries and Chank Fisheries, 1884," Madras, 1884, p. 17) was the first in this error, and until the present his identification has been followed. During my recent stay of several weeks' duration at the fishing station of Dutch Bay I had exceptional opportunity to examine large numbers of Rays, and to learn the native names. Before I had seen any specimen of 'Valvadi,' by enquiry from many different sources I learned that its characteristics were entirely those of a *Rhinoptera*. All the men I cross-examined concerning 'Valvadi' laid stress on the snout being truncate; the skin smooth, without tubercles; and the teeth 'stony.' I showed them sketches of Rays, and in each case they recognised a woodcut of the dental armature of *R. javanica* as identical with that of their 'Valvadi.' They all agreed that this is an oyster-eating species, and SULLIVAN THOMAS' statement that the 'Valvadi' devours pearl oysters is correct, but not his linking of it with the name *Trygon uarnak*.

"Later I had the opportunity to dissect both *R. javanica* and *T. uarnak*. The former agreed in every particular with the description of the oyster-eating 'Valvadi,' whereas the latter had the median region of the dorsum tuberculated, a pointed snout, and a dental apparatus wholly unfitted for devouring oysters of large size. The teeth were comparatively weak and closely approximated in form and arrangement with those of the Crustacean-eating *Trygon walga*. The stomach contents in *T. uarnak* were also Crustaceans, consisting of some scores of the young of a small swimming crab. It goes by the distinctive Tamil name of 'Pullian tirikkai,' *i.e.*, 'spotted Ray.' *T. uarnak* is thus the 'Pullian tirikkai' of the natives.

"Reverting to *R. javanica*, the dissection of three specimens showed the food, as evidenced by the stomach contents, to be exclusively molluscan. They consisted almost wholly of Lamellibranch fragments.*

* The shells from the stomach of this specimen were kindly examined by Mr. E. A. SMITH and Mr. B. B. WOODWARD, of the British Museum, but the fragments were too small to be identified.

"The first individual came from Puttalam Lake, opposite to Kalpitiya.

"Samples from the stomach of the second specimen, taken from the open sea off Dutch Bay, contained nothing but the broken shells and visceral masses of a small thin-shelled *Mactra*, rayed with brown.

"These fishes appear to be gregarious, going about in shoals of great numbers. A reliable fish-curer has informed me that during the Pearl Fishery of 1889 a single net, operated on the adjacent coast, took in a single haul 7,000 individuals. My informant was certain as regards the number stated, as it was he himself who purchased the entire catch. His men, even with additional help, took eight days to complete the cutting up. To keep the fish till ready to cut up, the whole lot was buried in trenches in the sand after being roughly eviscerated. Afterwards the men started at one end and worked methodically through the trenches, one after the other. The same year cholera broke out in the Pearl Fishery Camp in the vicinity (Dutch Bay), and many of the ignorant natives traced the source of the epidemic to this vast heap of fish, which no doubt gave off a strong fishy odour during curing operations."*

Echeneibothrium javanicum, n. sp.—Plate IV., figs. 51, 52, 53, 54, 55, 56.

A collection of seven or eight of these Cestodes was taken from the spiral intestine of a *Rhinoptera javanica* captured off Dutch Bay on January 21, 1905.

The specimens are from 9 millims. to 12 millims. in length and about 0·5 millim. in breadth at the broadest part, but the head, when the bothridia are bent out, is at least 1 millim. across.

The head is followed by a long neck which occupies from about one-third to near one-half of the whole body length. It is in this particular alone that our specimens depart from the diagnosis of the genus given by Braun in Bronn's 'Thierreich.' His description includes the words "Hals kurz oder fehlend." In our specimens the neck is very long, very thin, and most clearly marked off both from the head and from the body (Plate IV., fig. 52).

The head consists of four pedunculated pad-like bothridia, somewhat triangular in shape. Each is traversed by two longitudinal and a number of transverse ridges, separating the surface into a number of areolas (Plate IV., fig. 54). One of these is apical. At the base of each bothridium there are seven areolas, and these are followed by three rows of seven, the central row being ended by the apical areola (Plate IV., fig. 54); the disposition of the areolas is easily understood by a reference to the figures. The bases of the four bothridia fuse together and so form the head, but there is no extension forward of any central portion. There is no myzorhynchus, and the bothridia can be widely divaricated, as fig. 52, drawn from the life, shows. Internally the head contains the nervous system, which consists of a transverse ganglion, runs at each side into the lateral nerve-cord, a plexus of water vascular

* This quotation is from Mr. Hornell's notes.

canals which unravel themselves into two dorsal and two ventral canals which run down the neck (Plate IV., figs. 55 and 56), and a series of muscle-fibres which pass to the base of the bothridia. These muscle-fibres gather themselves up into stout strands which run down the neck, and these, together with the nerve-cords and the lateral pairs of water vascular canals, make up all there is in the neck. The neck and the proglottides are alike striated, the cuticle being very clearly ridged. The striation of the neck is more apparent than that of the body, possibly because the proglottides to some extent break it up. The longitudinal muscles can be seen running down the neck. The proglottides begin at the base of the neck, and their appearance can be judged by Plate IV., fig. 51. In the ripe proglottides the central uterus and the lateral yolk-glands take the form of a coil with three limbs. The coil starts from a point in the posterior middle line, passes forward and turns either to the right or left and returns again posteriorly, then passes across the proglottis and runs forward again. One curious feature is that the turning to the right or left goes in pairs. A pair of proglottides with the turning to the left is followed by a pair with the turning to the right, and so on. These markings, which somewhat resemble the Greek key pattern, give a characteristic appearance to the proglottides. The transverse bar which seems to connect the uterus with either the right or left row of vitellaria is formed of the genital duct and penis. The genital pores are lateral and alternate in pairs, first a pair on the left side, then a pair on the right. The penis is covered with minute spines.

The diagnosis of *Echeneibothrium javanicum* is as follows :—

Length from 9 millims. to 12 millims. Head with no myzorhynchus; the four bothria divided by two longitudinal ridges into three rows of areolas, one of these being terminal; then come three longitudinal rows of seven areolas, and at the base is a transverse row of seven large areolas. A long narrow neck occupies one-third to one-half the body-length. Cuticle very definitely striated.

Habitat :—*Rhinoptera javanica*, in the intestine.

Echinobothrium rhinoptera, n. sp.—Plate IV., figs. 57, 58 and 59.

Along with the *Eniochobothrium gracile* a few specimens of a curious Cestode which we place with the genus *Echinobothrium* were found. The specimens measured about 3 millims. in length, the head slightly over 0·2 millim. As a rule in the genus *Echinobothrium* the head is succeeded by a portion called the "Kopfstiel" by German writers. This bears eight rows of very characteristically shaped spines. In our specimen, however, the head is borne by a long "neck," devoid of spines. This "neck" is 0·3 millim. in length, and in the fresh condition it seemed strobilized, but in the stained and mounted preparations this seems not to be so much a real strobilization as a more or less regular wrinkling of the cuticle. Unfortunately, the number of specimens was so small that we could not settle this point by an appeal to the knife.

The "neck" is followed by an armed region 0·2 millim. long. This has eight longitudinal rows of characteristic *Echinobothrium* teeth, with their basal process, their long fine point and the two side rods at right angles to the rest. The number of teeth in each row was either twelve or thirteen. The armed region was greater in circumference than the neck. Behind it the body soon broke up into proglottides, and of these seven or eight could be recognized as distinct. They increase very rapidly in size, and in our mounted specimen the seventh proglottis is 0·75 millim. in length and 0·2 in breadth, and occupies a bulk of about one half to one third the rest of the body. The only internal organs visible are the testes, arranged much as those of *E. musteli*, as figured by PINTNER,* the cirrus bulb and the cirrus. When the latter was exserted, it was seen to bear very numerous minute recurved hooks (fig. 57). The two points in which this Cestode differs from the other members of the genus, *e.g.*, *E. affine*, *E. typus*, *E. brachysoma* and *E. musteli* are the complete absence of any spines on the head,† and the presence of the naked region or "neck" between the head and the armed region of the body. On the other hand, the shape of the head with its four projecting lappets and its intervening two spoon-like depressions, the armed region, the shape of the teeth, the number of the rows of teeth, the number of the proglottides, the arrangement of the testes, all resemble what we know of the genus, and justify us in including this amongst the species of *Echinobothrium*.

The diagnosis of *Echinobothrium rhinoptera* is as follows:—

No spines on the head. An unarmed region, the "neck," separates the head from the toothed region. Teeth in eight longitudinal rows, about twelve to thirteen in each row.

Habitat:—The intestine of *Rhinoptera javanica*, MÜLL. and HENLE, taken in Dutch Bay, Ceylon, on January 10, 1905.

Eniochobothrium, n. gen.

Small Cestode, ranging from 6 millims. to 12 millims. in length. Head unarmed, with four suckers, rostellum conspicuous. Body divided into several regions, first a narrow neck of three or four segments; secondly, an oval region of eighteen segments, which get broader until about the tenth proglottis and then narrow again —the segments of this region overlap like a many-caped cloak; thirdly, a second very narrow region of eighteen segments, all about the same size; fourthly, the reproductively ripe region of six to eight segments rapidly maturing and becoming very large, the last, and in some cases the last two, being as large as the rest of the body. The reproductive pores are lateral and alternating; the cirrus bulb and cirrus are very large, and the latter has a broad band of chitinous spicules.

* 'Arb. Inst. Wien,' viii., 1888.

† These may have fallen off, but no trace of them was observed in the fresh state.

Eniochobothrium gracile, n. sp.—Plate IV., figs. 60 to 62.

Along with certain specimens of *E. javanicum* from the intestine of the *Rhinoptera javanica* captured off Dutch Bay on January 10, 1905, were some small but very remarkable Cestodes which we have named *Eniochobothrium gracile.* Unfortunately but few specimens of each were taken.

Eniochobothrium gracile measures, according to Mr. Hornell's drawing, natural size, 12 millims., but in the few specimens put into spirit none surpassed 5 millims., and the only one mounted attained a length of 3·5 millims. These specimens, it is true, had all lost their heads, but, as the sketches show, this takes up but a small proportion of the total body length. Possibly they may have shrunk in spirit.

The head is pyramidal in form, the apex pointing forward (Plate IV., fig. 62). This part, which represents the rostrum, is circular in outline, but at the base of the pyramid the circumference becomes quadrangular and bears at each angle a small but conspicuous sucker ; behind these the head rapidly narrows towards its insertion into the neck. The rostrum is unarmed.

The drawings made from the fresh specimens show behind the head a short neck of three segments. This is followed by a remarkably expanded portion of the body forming an oval somewhat pointed at both ends (Plate IV., figs. 60 and 62). This expansion consists of some eighteen segments which, beginning behind the neck, gradually increase in width until the ninth or tenth segment and then diminish again until they reach their narrowest at about the eighteenth segment. The posterior edges of these segments are very salient and overlap the succeeding segments, except in the middle line, where there is a break just as there is in front between the right and left sides of an Inverness cape. In fact this portion of the body looks somewhat like the elderly coachmen who figured in the early half and middle of the nineteeth century, encased as they were in innumerable capes, each a little longer than the other, as one penetrated inwards from without.

Behind this oval portion comes another isthmus, consisting again of about eighteen segments, very much narrower than any in the expanded oval region and very much shorter from before backwards. They are perhaps a little wider than the segments of the neck, but they are very small.

We can easily imagine how segments can become larger as they are pushed backward by the intercalation of new segments behind the head, but it is not so easy to see how they shrink. The wide large tenth segment of the oval expanded area must gradually dwindle as it becomes in turn the eleventh, twelfth, thirteenth, and finally the eighteenth. There must be an almost sudden shrinkage as the eighteenth passes into the nineteenth segment, and then the bulk of the segments remain about constant and very minute until the thirty-sixth segment is reached (Plate IV., figs. 60 and 61). After this come some six or eight segments which very rapidly increase in size ; so quickly do they grow that each of the last two may equal or even surpass the whole of the rest of the tape-worm

The most conspicuous feature of these large proglottides is the cirrus bulb and the cirrus. The former is conspicuous and median, the latter is in all cases we have examined protruded in the last two proglottides, but most fully in the last. The cirrus is a pleurecbolic introvert, and for one portion, and one portion only, it is covered by a broad band of bristles or minute chitinous teeth or rods. Traces of vitellaria and testes can also be made out. The genital openings are lateral and alternating.

Unfortunately we had only two or three specimens at our disposal, and it was not advisable to cut any of them into sections, so that our knowledge of the minute anatomy is still to seek.

The peculiarities of this Cestode are so marked that it deserves to be recognised as at least a new genus, if not as a representative of a new family. Until we know more of its anatomy it is probably wiser to confine ourselves to the establishment of a new genus, and we suggest the name *Eniochobothrium*, in view of the Cestode's many-caped-coachman-like appearance.

Habitat:—From the intestine of a *Rhinoptera javanica*, Müller and Henle, taken off Dutch Bay, Ceylon, on January 10, 1905.

Tetrarhynchus unionifactor, Shipley and Hornell.—Plate IV., figs. 63 and 64.

These specimens were taken from the intestine of *Rhinoptera javanica*, Müll. and Henle, captured in Dutch Bay. They are described as existing in swarms in the stomach, especially at the pyloric end. Very few were found in the spiral intestine. They occurred in all the specimens of *Rhinoptera javanica* captured. The longest was 3 centims., the other two were about half that length; but Mr. Hornell states that when alive they can extend themselves to 4 or 5 inches. The head and body are stout, averaging a little under a millimetre in diameter; the proboscides are very small and fine, and are invisible to the naked eye. They arise apically, close together at the anterior surface of the head, and are supported by two shallow cephalic suckers or bothridia on each side which meet anteriorly. The neck extends for 1·5 millims. to 2 millims., and contains the four clearly-marked proboscis sheaths and four tubules proceeding from them enclosing the retractor muscles of the proboscides; these are very convoluted. The proglottides are at first broad and shallow, but they soon lengthen, and in the middle of the body they are cylindrical, three times as long as broad and circular in transverse section; their posterior border just overlaps the succeeding segments, but only just. Posteriorly the proglottides lose their shape, become baggy, and develop a purplish-brown colour, and here they are 2 millims. in length and rather over 1 millim. in breadth.

The genital openings are irregularly alternate, there being perhaps two pores on the right side, succeeded by two on the left, then one on the right, and so on.

The anterior proglottides are very shallow, and lie one upon another like a series of saucers or a pile of developing ephyræ; when they deepen a little, they have one, rarely two, transverse creases in their cuticle, but as they get to be as deep as they are broad, the number of these creases has very much increased, and the posterior end of the body is quite crinkled.

The proboscides are armed with hooks which are spirally arranged; the hooks are not very hooked, and the angle is slight; further, the hooks are all shaped alike and are all about the same size. They are very small.

The two bothridia are comparatively shallow, but during life their edges are obviously very mobile, and they may deepen or become shallower as occasion arises. Their outline is roughly triangular, one angle being anterior. The angles are very rounded, and the deepest part of the bothridium lies in the posterior angles.

We have in these forms, undoubtedly, the mature generation of the larval form we described and named *T. unionifactor* in the tissues of the pearl-forming oyster, *Margaritifera vulgaris*, SCHUM. In the structure of the head, the lappets with bothridia, the arrangement, shape and size of the hooks on the young and the old animals closely resemble one another. There is no doubt that the immature *T. unionifactor* is swallowed by *Rhinoptera javanica* when it eats the oysters, as it undoubtedly does, and that the tapeworm becomes mature in the intestine of the fish, that it lays eggs, and that these, somehow or other, make their way into the pearl oyster. Whether some of these become the little Cestode larvæ around which the pearls are deposited is still largely a matter of conjecture; if they do, they perish in a costly coffin. It is certain, however, that many of the young of *T. unionifactor* escape entombment and grow into the larval forms described in Part II. of these Reports. If we could find quite young larval forms of this *T. unionifactor*, and if on comparison with the forms which make the pearl they appeared to us to be identical, we should have solved the problem of pearl-formation, at any rate in the Ceylon seas. It seems increasingly probable that the pearl-forming Cestode is a *T. unionifactor*, but this has not yet been *proved*.

We described the species from the larva as we had no adults at our disposal; we now add a few more features taken from the adult.

The diagnosis of *Tetrarhynchus unionifactor* is:—

Head and proboscides as in the larva (see Part II. of these Reports, p. 88). Length, 1·5 millims. to 3 millims. Head and body stout. Neck containing the much-coiled proboscis sheaths, and the proboscis bulbs 1·5 millims. to 2 millims. in length. Genital pores irregularly right and left. Anterior proglottides shallow and saucer-like, with projecting edges, but about the middle of the body the proglottides hardly overlap at all, and the right and left sides form a straight line. There is, however, especially anteriorly, a tendency to be crinkled.

The larval form is found in the tissues of the pearl oyster, *Margaritifera vulgaris*, SCHUM., and possibly encysted in the pearls. The adult lives in the stomach of *Rhinoptera javanica*, MÜLLER and HENLE, a great Ray which feeds on oysters.

Tiarabothrium, n. gen.

About 11 millims. to 12 millims. long. Head with four sessile bothridia, each divided into twelve transverse areolas; the bothridia can be raised off the head anteriorly. Two stout muscles enter the head laterally and split up into four muscles on each side, two of which are inserted into each bothridium. Definite neck present, provided with an extensile collar. Proglottides with slightly concave sides, divided from each other by perfectly flat partitions. Genital pores alternate. Penis with numerous spines.

Tiarabothrium javanicum, n. sp.—Plate IV., figs. 65, 66, 67 and 68.

Length of the worm 11 millims. to 12 millims. Breadth of head 1 millim., average breadth of body 0·5 millim.

The head bears four bothridia, each divided by transverse ridges into twelve areolas, which, since each bothridium is oval in shape and rather pointed at each end, are very diverse in size, the anterior and posterior areolas being much smaller than the median. The bothridia are sessile upon the head, and judging from the preserved specimens were closely attached to the head by their whole inner surface. However, the drawing made by one of us of a living specimen shows that they are capable of standing out from the head anteriorly for about one-quarter to one-third of their length. The remainder of the bothridium remains, however, always in continuity with the head, and there is never any question of a stalk. The presence of the bothridia with the areolas gives the head something the appearance of a spherical Chinese lantern (Plate IV., figs. 66 and 67).

Longitudinal sections show that the head is a rather more flattened globe than is our earth. The interior of this globe consists of dense connective tissue, but between this and the inner faces of the bothridia is a layer of very loose tissue, and it is by the play this loose tissue allows that the bothridia can be in the anterior half raised a little away from the surface of the head (Plate IV., figs. 67 and 68).

Two very stout lateral muscles enter the head from the neck. They soon split up into eight separate muscles, of which two are dorsal, two are ventral, and two are right and two are left laterals. There is a lateral and a dorsal behind each of the dorsal bothria, and a lateral and a ventral behind each ventral bothria. As these muscles pass forward the laterals die out, but the two dorsals and the two ventrals are continued forward and break up into a number of small strands, which ultimately disappear in the connective-tissue mass which occupies the centre of the head. The water vascular system lies laterally, but there are at one or two levels cross communications between the right and left vessels, and the vessels on each side are very convoluted and coiled; as they pass down the neck they take up the position of dorsal and ventral vessels on each side of each segment.

The head is followed by a definite neck, and this is clothed by a very turn-down collar, such as a lower-form Eton boy wears. The free edge of this collar projects backwards for a variable distance. In the living form drawn by one of us the collar is far more extensive than it appears to be in the preserved specimens; it may have shrunk in the preserving fluids. In the one which was cut longitudinally there is evidence of such shrinking, especially at the base of the head.

The proglottides are at first extremely narrow, but lengthen out until about the centre of the body they are as long as they are broad. Posteriorly they may be three times as long as they are broad, and here they have the somewhat melon-seed outline of the *D. cucumerina*. In front of the last three or four proglottides, each has slightly convex sides, and the posterior edge is slightly broader than the anterior, so that the posterior edge of each proglottis extends a little beyond the anterior edge of the next behind it, but it does not overlap. The junction of two proglottides is always in one plane. The transverse section is almost circular, the dorso-ventral axis being but little shorter than the ventral.

The genital pore is lateral. The penis is armed with innumerable minute recurved spines. The yolk glands are very definitely arranged in a layer external to the other reproductive organs. As they stain deeply they form a conspicuous ring just inside the muscular layer, which is thin. Posteriorly they converge to a spot near which the ovary probably lies. The uterus is thick walled. The testes occupy a large part of the body within the vitellaria, and there is a conspicuous vesicula seminalis, crowded with spermatozoa. There were only two specimens available for study; one of these was mounted whole, the other was partially sectionized, but in none of the proglottides cut were there eggs in the uterus.

Other specimens of the species *Tiarabothrium javanicum* came from the intestine of the *Trygon walga*. The bothridia were not very distinct, and the number of areolas could not be made out. In one specimen, which was mounted, the breaking up of the longitudinal muscles as they entered the head was very clearly shown. The proglottides are broadest in the middle and narrow towards each end, and the posterior end is no wider than, and does not overlap, the anterior end of the next succeeding proglottis. There is no unsegmented neck, the first proglottis coming immediately behind the head, and the anterior half of the body is broadest at about the region between the eighth and the sixteenth proglottis. The cirrus is armed with spines. The collar is small.

Habitat :—Intestine of *Rhinoptera javanica*.

RHYNCHOBATUS DJEDDENSIS, Forsk.

A ray common throughout the Indian Ocean, from the Red Sea to Sumatra.

Tetrarhynchus rhynchobatidis, n. sp.—Plate IV., figs. 69, 70, and 71.

The Tamil name for *R. djeddensis* is "Pal-ulluvi," the Sinhalese "Kiri-uluwa," or "Uluwa mora." Both "pal" and "kiri" signify milk and refer to the milk-white spots on the body of the species. Two individuals were dissected; in one the remains of a number of fish, including a young *Pristis* sp., were found, in the other only crustacean fragments. The parasites were few in number and all belonged to one species of *Tetrarhynchus*.

The largest specimen of this *Tetrarhynchus* attained a length of 5 centims.—but since some loose proglottides measured 4 millims. each, probably the full length is greater—and its posterior end a width of 1 millim. The length of the head is 4 millims. The lappets are short and widely separated; anteriorly they occupy 1 millim., and the remaining 4 millims. are equally divided between the part of the head which contains the proboscis tubes and the part which contains the proboscis bulbs. The part of the head which bears the lappets is 1·2 millims. broad, but behind this the head tapers. The colour of the living specimens is an opaque milk-white.

The hooks in the proboscides are arranged in longitudinal rows and also in rings; the latter are almost horizontal, there being only a very slight trace of obliquity as they surround the stem. One peculiarity which we have not noticed in other species is that on each proboscis there is a longitudinal row of hooks, whose points are reversed and look towards the tip of the proboscis and not to the base, as do all the others. The shape of the hooks is shown in fig. 71; some of them are not nearly so hooked as others and pass into sabre-like forms.

Another peculiarity is that the outer muscles of the proboscis bulb are very oblique, very clear, and cross one another at right angles, giving a "Malvolio, cross-gartered" appearance to these structures.

There is a short neck, and then a number of proglottides, five or six times as broad as long, separated one from another by perfectly straight lines and with at first parallel straight sides. They soon, however, begin to lengthen, and at the end of the first quarter they are square. The sides also begin to bow outwards, but the ends are always flat, and there is absolutely no overlapping.

The reproductive pores are lateral and at the juncture of the anterior two-thirds with the posterior third. Their circular lips are prominent and everted. The pores are irregularly alternate; for instance, starting at the last of one specimen, they run as follows:—1 right, 3 left, 2 right, 1 left, 1 right, 2 left, and so on.

The diagnosis of *Tetrarhynchus rhynchobatidis* is:—

Five centims. long, posteriorly 1 millim. broad. Head with small lappets. Milk-white when alive. Proboscides with longitudinal rows of hooks, one row being turned the wrong way, hooks also arranged in nearly horizontal rings. Proboscis bulb chequered by external, obliquely-placed muscles, crossing each other at right angles. Proglottides not overlapping. Genital pores with everted lips, lateral, irregularly alternate, situated at anterior border of last third of the proglottis.

Habitat:—Intestine of *Rhynchobatus djeddensis*.

In another specimen of *Rhynchobatus djeddensis* were a couple of single proglottides

15 millims. in length by about 0·5 millim. in breadth, but in the absence of the head they could not be identified. Specimens of *T. herdmani* described under *Trygon walga* were also taken from this fish.

SPHYRÆNA COMMERSONI, Cuv. and Val.

This is the sole genus in the family Sphyrænidæ. The species are often called "Barracudas"; they are large voracious fishes living in the tropical and sub-tropical seas.

Tetrarhynchus, sp.—Cysts :—

A considerable number of large Tetrarhynchid cysts were taken from the abdominal cavity of a *Sphyræna commersoni.*

The cysts are large forms varying in length between 8 millims. and 30 millims., with a breadth of about 3 millims. They belong to Vaullegeard's *T. erinaceus* series, being enclosed in a vesicle as well as in a cyst, which latter is apparently formed by the tissues of the host. The teeth were very crowded, and the excretory opening was visible, but little else could be made out.

TRYGON KUHLI, Müller and Henle.

This large ray is called in Tamil, "*Kătti tirikkai.*"

Two individuals were dissected ; the first captured off Dutch Bay, the second caught on the pearl bank known as South Modragam Paar.

From the stomach contents of these two it would appear that the food consists almost exclusively of small annelids and small crustaceans. In the first named the stomach was distended with a large mass of *Lumbriconereids*, mingled with which were a few thin-shelled small crustaceans. In the second specimen the material was wholly annelidan—*Terebella*, *Lumbriconereis*, *Eunice*, &c.

Phyllobothrium blakei,* n. sp.—Plate V., figs. 72 and 73.

Some half a dozen specimens of this minute worm were taken from a *Trygon kuhli* captured in the pearl banks. Half of these were without heads. They are very delicate, thin, fragile creatures, measuring 10 millims. in length of the body, and at their greatest width some 0·25 millim. to 0·33 millim.

The head measures something over 0·5 millim. It consists of four crumpled bothridia with thickened edges, which are so twisted that they show numerous little bays and rounded recesses which at first sight might easily be taken for small circular suckers. These bothridia spring with practically no stalk from the edge of a hollow which shows some circular markings as if there were here two rings of circular muscles. There is no kind of armature.

The proglottides immediately following the head are broader than the subsequent

* Named in honour of H.E. Sir Henry Blake, K.C.M.G., the present Governor of Ceylon.

ones; they soon, however, narrow, and only very slowly widen again. The sides of the proglottides are straight and almost parallel, and although they project very slightly at their hinder end they do not overlap the succeeding segment. The posterior proglottides are almost three times as long as they are broad, and instead of having square ends they have rounded ones and are swollen in the middle. Their contents seems to be a roomy uterus with numerous large ova. In the stained specimens the central region of each proglottis stains deeply, making a deep line along the centre of the body. The reproductive pores are alternate.

The diagnosis of *Phyllobothrium blakei* is :—

Small delicate forms, 1 centim. long. Head with four frilled bothridia, practically sessile. No neck; the proglottides which come after the head are broader than those that follow. No overlapping at the posterior end of each proglottis. Ends of posterior proglottides rounded. Genital pores alternate.

Habitat :—Intestine of *Trygon kuhli*.

Rhinebothrium ceylonicum, n. sp.—Plate V., figs. 74 and 75.

Although the stalks or pedicels of the bothridia (if indeed they exist at all) must be very short, the specimens about to be described seem to us to belong to LINTON's genus *Rhinebothrium*.* The head bears four fleshy bothridia at the four angles, back to back. Each bothridium is divided into two halves, as in *Rh. flexile*, LINTON, by a longitudinal groove, and each half bears a number of horizontal slit-like areolas placed transversely. The number of these areolas was not exactly made out, but it is somewhere about twenty. The whole recalls a rasp (ῥίνη), after which the creature takes its name. In the preserved specimens, of which only two were taken, the head was rather broader than it was long, its greatest breadth being 4 millims. Judging from the figure taken of the head whilst alive, the length about equalled the breadth. In the living form also the bothridia seem more clearly distinct from one another and from the head; in the preserved form they have all shrunk together.

The length of the body of our longer preserved specimen is 5 centims., but, as in both, the tail is curved up in the lateral plane, and perhaps, if uncoiled, the length would be 5·8 centims. or 6 centims. When alive, it measured 9 inches. The body is stout and wide. Our second specimen—also giving off mature proglottides—was a little more than half this size. In the middle, which is the widest portion, it is 3 millims. broad, and it tapers away slightly both in front and behind. It is 2 millims. thick and is very stiff and firm in the preserved condition.

The neck is short, and the proglottides are at first very narrow from front to back. There seems to be a curious false strobilization whereby five or six segments are grouped together, but this may have been an individual character. The posterior angle of each proglottis was salient and projected slightly over the

* 'United States Commission of Fish and Fisheries,' Report of the Commissioner for 1887, part xv.; p. 768. Washington, 1891.

succeeding proglottis. Only at the hinder end are the proglottides as long as they are broad, and only the last three or four are longer than they are broad. The incurved tail seemed characteristic, at any rate it occurred in both our specimens.

The body was too thick and too opaque for us to make out any details of the internal anatomy.

The diagnosis of *Rhinebothrium ceylonicum* is as follows :—

Head with sessile or almost sessile bothridia, each with two rows of some twenty transverse areolas. Body very stout, 3 millims. in its widest part ; very thick, 2 millims. ; and varying from 3 centims. to about 5·8 centims. in length. Proglottides with salient posterior edges, mostly much broader than long, but the last few longer than broad and a few squarish. Tail incurved.

Habitat :—*Trygon kuhli*, spiral intestine. According to the collector, the same species occurs both in *Myliobatis maculata* and in *Trygon walga*.

In the same bottle with these two worms was another of a different kind, but whose head was so damaged that it is impossible to accurately diagnose it.

Tylocephalum kuhli, n. sp.—Plate V., figs. 76 and 77.

A single specimen was taken from the intestine of *Trygon kuhli*. It measured 12 millims. in length, and its greatest width, which lies a little before the posterior end, is 0·6 millim. The head consists of two portions, something like a cottage loaf, and in general resembling those of *T. uarnak* and *T. trygonis*. The anterior part or myzorhynchus is, however, somewhat smaller than in those species. The larger and posterior part bears four small spherical suckers. The muscles which enter the head from the body spread out in this portion in a button-like manner. Immediately behind the head is a constriction, and then the proglottides begin.

At first the proglottides are very shallow, with projecting rims like a pile of saucers upside down, then about half-way along the body each proglottis is seen to have a groove in it dividing it into approximately equal halves. If we trace the proglottides still further back, we see that these two halves have very different fates ; the anterior becomes the proglottis full of reproductive organs, etc. (Plate V., fig. 76), the posterior becomes the pronounced, everted, and almost recurved, salient edge.

The hindermost proglottis is square, and in no case is the longitudinal diameter greater than the transverse. The last two or three proglottides had the penis protruded, and these were all on the same side.

The diagnosis of *Tylocephalum kuhli* is as follows :—

This form measured 12 millims. in length by 0·6 millim. in width at the widest point. Head separated from body by a sharp constriction. Proglottides at first very shallow, and never longer than broad. About the middle of the body each proglottis is divided into two halves, the posterior does not develop so quickly as the anterior and forms the very marked, recurved, salient, posterior angle.

Habitat :—Intestine of *Trygon kuhli*.

TRYGON SEPHEN (Forsk.).

This fish is known as "Ada tirikkai" in Tamil, and as "Polkolla maduwa" in Sinhalese. A large individual of this species was obtained from the fishermen on Dutch Bay Spit, on January 3, 1905. The breadth of the disc was 47½ inches, and the length from the snout to the butt of the tail was 34 inches.

The stomach itself was empty, but the large intestine was choked with sand, intermixed with which were a large number of partially digested skins of worms, apparently Gephyreans. A few limbs of crabs were also present. It would seem that this *Trygon* feeds principally upon worms, with such small crustaceans as may be associated with them in sand.

Anthemobothrium, n. gen.

Fourteen millims. long when preserved. Head about 1 millim. in diameter, almost spherical, with four small suckers in the hinder half, and fourteen feathered bothridia radiating over the anterior half. Neck narrow and short. Proglottides slightly overlapping their successors. The skin is faintly striped. The uterus in the posterior proglottides occupies almost all the space and is crowded with ova.

Anthemobothrium pulchrum, n. sp.—Plate V., figs. 78, 78*a*, 78*b* and 79.

A single example of this beautiful and remarkable Cestode was found amongst the crowd of *Tetrarhynchus leucomelanus* and *Prosthecobothrium walga* taken from the intestine of a *Trygon sephen* captured in Dutch Bay.

It measures 14 millims. in length when preserved in formaline, and as the posterior segments are crowded with eggs, it is apparently a full grown worm. The head, which is almost spherical and as broad as it is long, measures just under 1 millim. across (Plate V., fig. 79). The neck is very slender and short, and the body gradually, but slowly, broadens until the last segments are about 0·6 millim. broad by 0·9 millim. or 1 millim. long.

The head consists of a basal hemisphere bearing four equidistant, small, rounded suckers. From the distal end of this basal part emerge fourteen radiating bothridia, which are flattened down and look like so many neatly arranged ostrich feathers or frilled petals of a flower.

The neck is narrow and short. The proglottides soon appear, at first much wider than long, but by the middle of the body they are square, and behind are twice as long as they are broad. The genital pore is not clearly visible, but some proglottides seemed to show an aperture on the flat surface near the anterior end. The uterus arises also at this end and is soon evident as a clear coiled tube. The divisions between neighbouring coils soon break down, and in the last proglottis the uterus, crammed with eggs, occupies almost all the space in the segment.

Each segment has a very short lip posteriorly, which slightly overlaps the succeeding one. There is also a curious arrangement, probably of glands, in the skin, which gives the Cestode a longitudinally striped appearance, darker bands where the glands are present alternating with lighter areas where they are not.

Habitat :—Intestine of *Trygon sephen.*

Prosthecobothrium trygonis, n. sp.—Plate V., figs. 80, 81, 82 (*a* and *b*).

One specimen of this Cestode was taken from the intestine of *Trygon walga* and three from *Trygon sephen.* The longest measured when preserved 120 millims. in length. The worm is very slender and soft and anteriorly very narrow, 0·5 millim. only in breadth, though posteriorly it broadens out to a couple of millimetres.

The head is 1 millim. in width. It is square, something like a cushion which is indented in the centre and along the lateral and dorso-ventral axes. The head is thus divided into four squares of equal area, and each of these squares bears at its external angle anteriorly a large hollow or bothridium, on the anterior edge of which lie the hooks mentioned below. Behind each is a single, round, rather small but quite conspicuous sucker. This sucker is a simple sucker and has no sub-divivions or areolas. On its surface each of the four squares bears two hooks more or less connected at their base ; each hook is forked and consists of two unequal-sized prongs ; of these, that which is next the diagonal lines or lines joining the bases of the suckers is the larger and bears a tubercle at its base. The hooks are dark brown, chitinous-looking structures.

The neck is very long, 2 centims. or 3 centims. at least. It is smooth and traversed by a number of longitudinal muscle bands which are conspicuous through the epidermis. They split up in a symmetrical way in the head.

The proglottides are extremely numerous, they have salient posterior angles. They always remain somewhat broader than they are long, even at the posterior end, except perhaps the very last. This species obviously differs considerably from that described by VAN BENEDEN in his "Recherches sur les Vers Cestoïdes"* under the name *Acanthobothrium dujardini*, especially in the relative proportions of the head ; in our worm this is broader than long, in VAN BENEDEN'S it is longer than broad.

The diagnosis of *Prosthecobothrium trygonis* is :—

Slender Cestode some 12 centims. in length. Head square and divided by depressions into four equal squares. Each of these bears a sucker at its free corner and on the surface a pair of unequally two-pronged hooks. Neck very long. Proglottides very numerous, with very salient edges, never longer than broad, except perhaps the last.

Habitat :—*Trygon walga*, MÜLL. and HENLE, and *Trygon sephen* (FORSK.), in the spiral intestine.

Tetrarhynchus leucomelanus, n. sp.—Plate V., figs. 83, 83*a* and 84.

This large species of *Tetrarhynchus* was found in the intestine of *Trygon sephen.*

* 'Mem. Ac. Belgique,' xxv., 1850, p. 133.

Many specimens were taken which measured in length 5 centims. to 8 centims. The anterior end of the body is slender, scarcely 1 millim. broad, though the lappets are quite that. The body, however, slowly widens, and the posterior third is about 3 millims. wide, and here the proglottides are almost square and in the centre 1·5 millims. thick, though they thin off towards all four edges.

One of the most characteristic features of this species is that, when preserved, it is half white and half black. This is perhaps not strictly accurate, it is about the posterior third that is black, and there is no sharp transition, the pigment appearing about, or soon after, the middle and gradually deepening until it reaches a deep slatey black. The living specimens are described as milky white with a rosy pink smudge, fading away behind, at the base of the proboscis sheaths.

The head is 7 millims. long, at the level of the lappets it is 2 millims. broad, behind this 1·5 millims. and it narrows down to less than 1 millim. at the posterior end. The lappets are but very slightly hollowed, their length is about one fifth the length of the head and they are very symmetrically placed (Plate V., fig. 84). The four proboscides are covered with an immense number of very minute hooks; these are regularly arranged in rings and in numerous longitudinal rows, though the arrangement may be upset near the tip, owing to a bit on one side being more evaginated than on the other. The hooks are all the same size. The proboscis tubules are short and coiled, the arrangement is very symmetrical, the two tubes on each side being coiled parallel to one another. The proboscis sheaths are very long and occupy seven-tenths of the total length. There seemed a certain difficulty in withdrawing the proboscides, at any rate they are seldom completely withdrawn. They are fine and narrow and converge near the posterior end. There is a short neck, and at first the segments are six or seven times as broad as they are long; by the middle of the body they are almost square and the last two or three are longer than broad. A row of well separated but clearly marked longitudinal muscles is conspicuous, especially in the larger segments. The posterior edge of each proglottis is salient and at first a little overlapping, in the posterior proglottides it sticks out like a frill, and forms a quite distinct rim round the posterior end of the proglottis. The generative pores are alternate and rather irregular.

The diagnosis of *Tetrarhynchus leucomelanus* is as follows :—

Five centims. to eight centims. long, with posteriorly thick, stout proglottides, 3 millims. broad. Anterior half or two-thirds of the preserved body white, the remainder slaty black, deepening into a dense black. When alive, milky white, with a pink patch behind the proboscis sheath. Head with two shallow lappets, well defined. Proboscides with an enormous number of very minute teeth, all uniform in size and shape, arranged in rings and longitudinal rows. The proboscis sacs are very long, occupying seven-tenths of the length of the head. There is a short neck, the posterior edge of each proglottis is salient. Generative pores irregularly alternate.

Habitat :—Intestine of *Trygon sephen.*

TRYGON UARNAK (Forsk.).

This fish is called "Pullian tirikkai" in Tamil, which signifies "spotted ray," and well describes its appearance.

One specimen was obtained at Dutch Bay on January 6, 1905. The length of the disc was 28 inches, the breadth 33 inches, and the tail was 56 inches long.

Food.—The stomach contents consisted exclusively of some score of small, swimming crabs.

Tylocephalum uarnak, n. sp.—Plate V., figs. 85 and 86.

A few examples were taken from the intestine of *Trygon uarnak.* The longest measured some 35 millims. The number of segments is, however, small, varying from 30 to 40. The head, which is a little exaggerated in our figure (Plate V., fig. 86), stands out like a button or knob at the end of the fine neck. The body is thickest in the middle, some 0·7 millim. in breadth, the posterior extremely elongated proglottides have a somewhat attenuated look.

The head consists of an anterior lobe, resting on a squarish cushion; the anterior lobe or myzorhynchus seems to be fixed on to an extension borne by the cushion as though on to a peg. This extension seems to be a thickened tissue, into which the longitudinal muscles are inserted. The cushion is square, with suckers at each angle; the anterior lobe is separated from it by a simple contraction, not by a band as in *Tylocephalum pingue.* There is a short neck. The proglottides show very early traces of reproductive organs. The excretory pore is immense, a great round opening, more or less median; posteriorly it loses its firm outline, becomes crinkled, and is pushed a little aside by the development of the uterus. The testes are scattered mostly at the anterior end of each proglottis, and as the uterus develops the testes are pushed towards the periphery and tend to disappear. The uterus is a long sac, constricted in the middle by the reproductive pore like an old-fashioned "ring" purse. The posterior proglottides are extremely long, at least 5 millims. in length, some ten times as long as they are broad. None of the proglottides overlap. Their ends are flat and their sides very nearly straight, or at most slightly bowed.

The diagnosis of *Tylocephalum uarnak* is as follows:—

Length some 35 millims. Greatest breadth in middle region of body. Genital pore very large, round and median. Testes scattered in anterior end of proglottis, pressed outward by the growing uterus. The latter forms an anterior and posterior swollen part united by a thinner portion. Number of segments 30 to 40.

Habitat:—The intestine of *Trygon uarnak.* This species also occurs in *T. walga.*

Tetrarhynchus macroporus, n. sp.—Plate V., figs. 87, 87*a* and 87*b*.

These are fair-sized Tetrarhynchids, averaging about 25 millims. in length and 1 millim. in breadth.

The lateral lappets are small, each divided into two, each half corresponding with one of the four hooked proboscides. The head is 6 millims. long, and swells out a little behind where the muscular sheaths of the proboscides lie. When alive, there is a patch of pink anterior to these sheaths. Each proboscis bears on its concave side when unrolled a number of strongly recurved teeth, which gradually pass into a much straighter, sabre-like tooth on the convex side (Plate V., fig. 87*b*). The recurved teeth have a marked anterior process something like a sword-guard, where the tooth passes into the haft, which is embedded in the tissue. This is absent in the more sabre-like teeth. The teeth are in rings, which are not obliquely placed.

There is practically no neck, and the number of the proglottides is small, some 30 to 35. Until the last three or four, the sides of the proglottides are parallel, straight at their ends, and with no sign of overlapping. The whole body is marked by a curious longitudinal striation, which is due to the presence of minute pigment spots, and to the fact that these little brownish particles are arranged along certain longitudinal lines; also these pigment spots seem broken up into other areas, which give a mottled appearance to the skin.

The last four or five proglottides are remarkable for the enormous development of the genital pore, which sometimes occupies one quarter to one third of the length of the proglottis. From this gaping cavity a minute penis protrudes. These same four or five proglottides lose their uniform shape, and become very irregular in outline. The pores are in all cases lateral and irregularly alternate.

The diagnosis of *Tetrarhynchus macroporus* is :—

These Cestodes are about 25 millims. in length and 1 millim. in breadth. They have small lappets, turned forward, hooks recurved sabre-like, in straight lines; no oblique rows. Proglottides number about thirty, and the last four or five are distorted by the enormous development of the genital pore.

Habitat :—The intestine of *Trygon uarnak*.

Thysanobothrium, n. gen.

Length 7 centims. ; posterior proglottides being 1·5 millims. to 2 millims. long. Head squarish, with a sheath bearing four minute suckers at the angles ; within the sheath a rounded knob, and between the sheath and the knob a ring of some twenty finger-like tentacles stretched forward. Neck long. Genital pores very irregularly alternate.

Thysanobothrium uarnakense, n. sp.—Plate V., figs. 88 to 91.

This remarkable form attains, for a tapeworm parasitic in Elasmobranchs, considerable proportions. Our largest specimen measured 7 centims., and in this animal the posterior proglottides reached a length of 1·5 millims. to 2 millims., and a breadth of 1 millim. The anterior end of the body is, however, very slender, 0·3 millim. to 0·25 millim. in width, but the head, though small, is somewhat wider than this, and attains a breadth of at least 0·5 millim.

The head is squarish, and yet sub-globular, with four minute suckers equidistant from one another at the angles. The suckers are borne on a kind of cup-like external bowl, which surrounds a central portion, and between this cup-like shield and the central portion a number of simple tentacles protrude.

These tentacles are very curious, and, as far as we know, are unique amongst the Cestoda. They are finger-like processes, with no branching, and they hang over the central portion of the head. They seem to be about sixteen to twenty in number, but in the preserved specimens it was impossible to count them accurately.

In the living specimens a number of concretions, apparently of a calcareous nature, occurred at the base of the head, just where it joins the neck. The neck is long, no trace of strobilization appearing for at least a distance of half a centimetre behind the head. The proglottides, when they do appear, are shown by lines in the centre of the body, which do not at first reach the side, so that for a time the sides of the worm are unindented, straight, and almost parallel; then the dividing lines reach the edge and the sides of each proglottis bow out, and by the time the proglottides are about as long as they are broad the body has a somewhat moniliform appearance. The proglottis is symmetrical about a line which passes across it midway between its anterior and posterior edge; there is no overlapping and no trace of it. The posterior proglottides are flask-shaped, and seem to be little more than bags of eggs. The reproductive pores are very irregularly alternate, some six or seven being to the right, then one or two to the left, then seven or eight to the right, and so on. The penis was often protruded.

Habitat:—The intestine of *Trygon uarnak*.

TRYGON WALGA, Müller and Henle.

The Tamil name is "Manal tirikkai," signifying "Sand Ray." This species is perhaps the commonest Ray taken by fishermen in the neighbourhood of the pearl banks. A considerable number were examined, as follows:—

A. Caught on the N.W. Cheval Paar, April 4, 1904.

B, C, D, E, and F. Caught in fishermen's nets in the open sea, January, 1905, off Dutch Bay Spit, N.W. Province, Ceylon.

G. Taken on a line on the North Modragam Paar pearl banks, February 2, 1905.

Food.—As shown by stomach contents, this Ray lives chiefly upon small crustaceans, supplemented frequently by octopods, gephyreans, polychætes, and occasionally thin-shelled small molluscs.

Anthobothrium rugosum, n. sp.—Plate V., fig. 92.

Two specimens of the worm were taken from the intestine of a *Trygon walga*. One measured 65 millims. when preserved, but it had stretched to 12 inches when alive, the other 20 millims. in length. The greatest breadth of the body is about 2 millims.

The head consists of four bothridia, each borne on a short stout stalk. Each bothridium consists of a simple bag-like sucker or depression, the walls of which are rather crinkled and marked with lines, and the edges which surround the opening of the depression are distinctly puckered. All these four bothridia are in both our specimens very much flattened, and all lie in the same flat plain; the head, in fact, looks like a pressed flower. As far as we know, the animals had never been compressed in any way, and this flatness may be natural to the species. Each sucker measures 3 millims. across at its broadest, and the whole head measures 6 millims. from side to side.

It is followed by a neck which extends some 5 millims. or 6 millims., and then the body becomes segmented. The proglottides are always broader than long, and the body is broad throughout, differing in that respect from *A. cornucopia*, VAN BEN.,* whose body "est extraordinairement fin et effilé en avant." Anteriorly there is a curious wrinkling at the edges, and the exact correspondence of this with the limits of the proglottides was not made out. The strands of muscles which run down the body in this region are also very conspicuous and easy to see.

Diagnosis of *Anthobothrium rugosum*:—

This species is distinguished from the *A. cornucopia*, VAN BEN., and the *A. musteli*, VAN BEN., by the wrinkling of the bothridium and the shape of the body, and from the *A. elegantissimum* of LÖNNBERG,† by the absence of a myzorhynchus. Its most striking characteristics are the crumpled suckers, the stout neck, and the longitudinal muscles. Length, when alive, 1 foot.

Habitat:—The intestine of *Trygon walga*.

Echeneibothrium minimum, VAN BENEDEN.‡—Plate V., figs. 93 and 94.

This species is in all probability the *Echeneibothrium minimum* of VAN BENEDEN, although instead of the bothridia fading at their lower end into a stalk like the leaflet of a rose, they are borne on the stalk in a peltate manner. As in *E. variabile*, and unlike *E. gracile*, where there is a terminal areola at each end of the bothridia, the areolas in this species are paired throughout. There is no myzorhynchus. There are thirteen pairs of areolas in each sucker. The bothridium is fringed by a transparent, extensible membranous edge. An excretory tubule runs underneath it. The stalks are very muscular and very mobile.

The worms are slender but long, larger than those which as a rule live in Elasmobranchs, and are intermediate in length between *E. variabile*, with its 100 millims., and *E. minimum*, with its 15 millims. to 17 millims. Our species ranged from about 60 millims. to 30 millims. It attains at the maximum a breadth of 1 millim., and this maximum is not necessarily at the posterior end of the animal.

* 'Mem. Ac. Belgique,' xxv., 1850.

† 'Bih. Svenska Ak.,' xiv., 1888–9.

‡ 'Mem. Soc. Belgique,' xxv., 1850, p. 114.

The body has, in fact, a somewhat lumpy, untidy appearance, and is thrown in irregular wrinkles and sometimes knots. There is no neck, as in *E. gracile*.* The posterior segments are not very long, at most twice or three times as long as wide. The genital pore is lateral.

This species came from the intestine of *Trygon walga*, the same specimen which contained *T. herdmani*.

Echeneibothrium simplex, n. sp.—Plate VI., figs. 95, 96 and 97.

The species is one of the simplest of the genus to which it belongs. Its head consists of four stalked bothridia, each shaped like a violet leaf. The edge of each is divided by horizontal ridges into areolas, some twenty-two in number. It was difficult to make out the exact number. There is no myzorhynchus. The body measured 2 centims. in length. There is also no neck, the transverse divisions beginning immediately behind the head. The number of segments is about 100. They are nearly all broader than long, except the last six or seven; the anterior three of these are about square, the others are longer than broad, the last being perhaps twice as long as broad. The reproductive pores are lateral and alternate; there are often two on the same side, followed by two on the other.

The diagnosis of *Echeneibothrium simplex* is :—

Very simple leaf-like bothridia, with areolas, some twenty-two stretching right round the edge of each bothridium. No neck. Genital pores rather irregularly alternate.

Habitat :—Intestine of *Trygon walga*.

Echeneibothrium trifidum, n. sp.—Plate VI., figs. 98 and 99.

This beautiful little Cestode was taken from the spiral intestine of *Trygon walga*, where it lived with a *Tylocephalum uarnak*. There were only three examples, which differed a little in length, but averaged 6 millims. or 7 millims. The head bears four leaf-like bothridia, stalked and very mobile. The basal or posterior half of each bothridium is single, and carries nine transversely elongated areolas. The proximal end of each bothridium is, however, split into two halves, and each half bears nine areolas, of a somewhat rounded form. There are thus altogether twenty-seven areolas, nine large and eighteen small, in each bothridium. A fine, delicate, extensile membrane edges the bothridium. These bothridia are borne on stalks which can be readily elongated and contracted, as the sketch indicates. The unsplit part is usually curled with the split part into a C. There is no myzorhynchus. The proglottides at an early stage show traces of the testes, but only the posterior half show any genital pores. These are lateral, and very irregularly alternate.

Diagnosis of *Echeneibothrium trifidum* :—

This species is characterised by its trifid bothridia with twenty-seven areolas.

Habitat :—The intestine of *Trygon walga*.

* ZSCHOKKE, 'Mem. Instit. Nat. Genev.,' xvii., 1889.

Echeneibothrium trygonis, n. sp.—Plate VI., fig. 100.

This species is much more delicate and slender than *E. minimum*. It measures from 8 millims. to 15 millims., and its greatest breadth is about 0·3 millim., if we leave out of account the head, which, when the bothridia are turned out, may attain the width of nearly 1 millim.

The head does not bear the bothridia on stalks, but the neck passes into the head like the stem of a goblet into the bowl. The head is, in fact, rather like the seat of those three-legged camp-stools upon which artists sometimes sit, only there are four instead of three legs. The bothridia face inwards, are deeply hollowed, and acting together must form a very effective sucker.

On the inner face of each bothridium are seven or eight areolas which stretch across the bothridium, and thus there is no median longitudinal line.

The head is carried on a stout unsegmented neck, which is a good deal broader than the succeeding segmented part. The proglottides, in fact, do not become thicker as they become posterior; the anterior and posterior edges of each proglottis are of the same width, and the ripe posterior proglottides are loosely attached to one another, like so many sausages, the medium which keeps them together being apparently the cuticle. In this region they are some five times as long as they are broad. The stained specimens showed no detail of structure and the specimens were too few to cut into sections.

Diagnosis of *Echeneibothrium trygonis* :—

Delicate slender form. The four bothridia spring from the neck with no stalk, and bear a single row of seven or eight transverse areolas. The posterior proglottides get thinner as they get older.

Habitat :—The intestine of *Trygon walga.*

Echeneibothrium walga, n. sp.—Plate VI., fig. 101.

This very delicate little tapeworm was found amongst a collection of *Tylocephalum trygonis* and *Echeneibothrium minimum*. Unfortunately but one specimen was taken. This measures 7 millims. in length and about 0·2 millim. in breadth. The posterior proglottides are ripe and the animal is probably full grown.

The head breaks up into four long stalks, each bearing two bothridia or rather two halves of a bothridium. The stalks appear to be permanently about 1 millim. long, though doubtless they may expand and contract within narrow limits. Each of the half bothridia faces the other and they somewhat resemble the clasping appearance of a Gecko's toes. They each contain a double row of some twelve areolas which are not rounded off towards the longitudinal median partition. Numerous muscle strands pass into each stalk after they have made a cruciform plexus in the head.

There is scarcely any neck, the narrow, straight-sided proglottides appear close behind the head. About half way along the body the proglottides are square, whilst the mature ones at the posterior end are perhaps twice as long as broad. Here the remains of the penis are visible, and it seems to bear spicules. In the few proglottides where it is visible, the reproductive pores appear to be regularly alternate. In appearance this somewhat resembles VAN BENEDEN'S figure of one phase of *E. minimum*.* It is however, we believe, a distinct species.

The diagnosis of *Echeneibothrium walga* is as follows :—

Head provided with four long stalks, each bearing a pair of opposed half bothridia, each composed of twenty-four areolas. Body minute, neck hardly present, reproductive pores regularly alternate.

Habitat :—Intestine of *Trygon walga.*

Echeneibothrium ceylonicum, n. sp.—Plate VI., figs. 102 and 103.

Four specimens varying in length from 8 millims. to 25 millims. were taken from the intestine of *Trygon walga.* The head is comparatively small and resembles in general architecture the head of *Echeneibothrium trygonis,* but it differs considerably in details. The head itself is longer and takes up a greater proportion of the whole body. It splits into four short arms, and each of these bears a bothridium. The bothridia are built up of fourteen areolas, of which one is terminal at each end and twelve are paired, as in the figure (Plate VI., fig. 103). Special muscles run from each arm down the neck, and the several arms are very mobile and contractile and take on different shapes in different states of contraction.

The body is stouter than in the case of *Echeneibothrium trygonis* ; the neck is of fair length ; the proglottides bulge out a good deal at the sides, so that the outline is like a thread of beads. The reproductive pore is median. The mature proglottides are never more than twice as long as they are broad, and their sides are curved, not straight and parallel. Mixed with the adults were a number of young forms, with tapering bodies, but not yet divided into proglottides.

The diagnosis of *Echeneibothrium ceylonicum* may run :—

Length up to 25 millims. Head with four inwardly directed bothridia, bearing fourteen areolas ; of these, two are terminal and twelve are paired. Proglottides rounded at the side, the oldest, ready to break off, never more than twice the length of the breadth. Reproductive pore median.

Habitat :—Intestine of *Trygon walga.*

Phyllobothrium lactuca, VAN BENEDEN.—Plate VI., figs. 104 (*a* and *b*) and 105.

This is by far the longest Cestode found in *Trygon walga.* It attained in one preserved specimen the length of 33 centims. In this particular specimen the width hardly exceeded 2 millims., and the texture was flimsy and soft, but in another specimen, which was in pieces, the consistency of the worm is stiff and almost brittle, and the width had swollen out to 4·5 millims. and, although broken up, its length could have

* 'Mem. Ac. Belgique,' xxv., 1850, Plate ii., fig. 3.

exceeded 150 millims. The width gradually increased as we passed backwards until the last half dozen proglottides, which narrowed a little (Plate VI., fig. 104). When alive the worm was in all probability much longer; they contract when being killed.

The head resembles the figs. 2 and 3 of VAN BENEDEN's pl. iv. of his "Recherches sur les vers cestoïdes,"* which represent *Phyllobothrium lactuca*, but the bothria are more definitely arranged in four, and the edge, which is crinkled and ruched, has not such a square section (Plate VI., fig. 105). The neck is very long. The proglottides all through the body are broader than they are long, except the posterior six or seven, which are slightly longer than they are broad. Each proglottis overhangs the ones which follow it, and thus its posterior border is wider than its anterior. The sides are oblique and, as the figures show, slightly wrinkled.

Habitat:—Intestine of *Trygon walga.*

Tylocephalum trygonis (SHIPLEY and HORNELL).

Tetragonocephalum trygonis, SHIPLEY and HORNELL.

Several specimens of this species were found in the intestine of *Trygon walga.* They permitted one to observe what was not recorded in the original description,† that the genital pores are very irregularly alternate. Thus in one specimen, using R for right and L for left, the genital pores were arranged as follows:—R 6, L 2, R 1, L 2, R 1, L 1, R 1, L 1, R 3, L 1, R 2, L 2, R 3, L 2, and so on. In the posterior segments the pore is very large and stands out from the proglottis just as the portion which bears the leaf stands out from a bare twig of a chestnut tree in winter.

Tetrarhynchus equidentatus, n. sp.—Plate VI., figs. 106 and 107.

This is, I think, the largest *Tetrarhynchus* I have seen, and it is certainly very large to come from the alimentary canal of an Elasmobranch. Unfortunately but one specimen was taken, and this measured 4·7 centims. in length, not a very great length; but it is the breadth which gives the magnitude to this animal. It is almost uniformly 3 millims. broad from one end to the other, though it increases very slightly as we pass backward, but the last proglottis is narrowed. It is perhaps 0·3 millim. thick.

Compared with the size of the body, the head is very small, and the muscular sheaths come right up to the anterior end of it, and thus there are no more or less coiled tubes between them and the base of the exserted proboscides. The proboscides bear spiral or rather obliquely placed rings of hooks; the hooks are all of precisely equal size and most regularly arranged. They are 0·049 millim. in length. The head bears laterally well-marked lappets or bothridia. It is succeeded by an unsegmented region

* 'Mem. Ac. Belgique,' xxv., 1850.

† This Report, Part III., p. 51.

which is about 2 to 2·5 times the length of the head. This region terminates, as in *Tetrarhynchus herdmani*, in a well-marked collar with somewhat scalloped edge. The collar hangs back and overlaps the body region.

The divisions between the proglottides are anteriorly very insignificant, but they soon become distinct and the proglottides become a little longer. The total number is between one and two hundred. But they are never very long, never even square. The posterior proglottides are always some six or seven times as long as they are broad, and the anterior perhaps twice as much again. Their edges are rounded, there is no trace of overlapping, and in the latter half of the body the reproductive organs cause an opaque patch in each segment.

The diagnosis of *Tetrarhynchus equidentatus* is :—

Very small head, muscular proboscis sheaths reach anterior end of head ; unsegmented region, terminating in a well-marked collar, follows head ; proglottides, 100 to 200 in number, always much broader than long, rounded edges, no overlapping. Proboscis hooks same size throughout, arranged in regular obliquely placed rows.

Habitat :—Intestine of *Trygon walga*, MÜLL. and HENLE.

Tetrarhynchus herdmani, n. sp.—Plate VI., figs. 108 and 109.

The second species to *Tetrarhynchus*, found in the alimentary canal of *Trygon walga*, and later in the same position in *Rhynchobatus djeddensis*, is a long and comparatively slender one. We had only three or four specimens, which averaged about 30 millims. in length. The head is small, about 1 millim. in length. It has two well-developed lappets which, as usual, are very contractile and extensile. The four proboscides emerge from very short muscular sheaths, which lie near the posterior limit of the head. Instead of being half as long as the head, as is often the case in the Tetrarhynchidæ, they are perhaps one-twelfth to one-tenth the head length. The proboscides which emerge from them are slender and covered with minute teeth, all of the same size, arranged in spiral rows. The teeth are about 0·01 millim. in length.

The most characteristic feature of this Cestode, but one which it shares with *T. equidentatus*, to be described is a peculiar fold or collar which hangs back from the head and covers the anterior part of the neck. This collar seems to be very extensile. In the figure drawn from the live specimen, its border of free edge is scalloped, but in the specimens in spirit the collar seems more retracted and the free edge is smooth and undivided.

The neck is very short. Almost immediately after the head the proglottides are indicated by sharp lines. There are some 80 to 100 proglottides present, all separated from one another by clear, horizontal, and in no case concave, lines. Till the proglottides become packed with eggs, the lateral contours are also straight and parallel ; there is no overlapping. Thus the Cestode does not increase in width until we get to the posterior proglottides, and in these the presence of the eggs entails a slight lateral swelling, so that this end is almost moniliform. The eggs are about 0·07 millim. in length.

In the centre of each of the last half dozen proglottides is a large clear place. This may possibly be the remains of the genital atrium, and if it is so, this is median.

Tetrarhynchus herdmani is characterised by having a small head with well-developed bothridia, short muscular proboscis sheaths, one-tenth to one-twelfth the length of head, teeth on proboscis, uniform in spiral lines, 0·01 millim. in length, well-developed collar, 60 to 100 proglottides, most with parallel sides.

Habitat :—Stomach of *Trygon walga* and *Rhynchobatus djeddensis,* MÜLL. and HENLE.

Tetrarhynchus macrocephalus, n. sp.—Plate VI., figs. 110, 111 and 112.

At least six different species of *Tetrarhynchus* are found in the intestine of *Trygon walga.* This species is a short, stout, thick-set form, with large bothridia or lappets, which, however, when the proboscides are extended, are far less conspicuous than when they are retracted (Plate VI., fig. 110).

The total body length averages 7 millims. or 8 millims., and the body is stiff and straight. The relative length of the different parts of the body in one specimen, whose total length was 8 millims., was 3 millims. for the part of the head traversed by the coiling ducts of the proboscis sheath, 3 millims. for the part of the head which contains the muscular proboscis sheath, and 2 millims. for the rest of the body. The second portion, that which contains the muscular sheath, is the thickest, and its walls are smooth ; the anterior half of the head is wrinkled.

The four proboscides were in some specimens extended, but not fully ; they attained a length of some 2 millims. Each bears a longitudinal double row of minute, almost straight spines, diverging from one another (Plate VI., fig. 111), the whole producing the effect of a stitch known, I believe, to housewives as "herring-boning." This lies the whole length of the proboscis. There are also very numerous sharply hooked spines, which lie in transverse rows some hundred or more in number. Each of these rows consists of some ten or twelve hooks, grading in size from the largest, which is just opposite the "herring-boning," to the smallest, which flank the "herring-boning."

When the whole is retracted it passes first into the very coiled ducts of the muscular sheaths, which are very apparent in the specimen.

The strobila is smaller than either half of the head ; the piece immediately succeeding the head is anteriorly concave, and receives into its concavity the convex end of the head (Plate VI., fig. 110). It soon begins to "segment," and the proglottides grow rapidly. They are few in number, and the most posterior, which is about the tenth or twelfth, is almost as large as all the others put together. It shows clearly the exit of the water vascular system. The specimens were probably young ones.

Diagnosis of *Tetrarhynchus macrocephalus* :—

The characteristic features of this species are the relatively enormous head, the few —some ten or twelve—proglottides, the "herring-bone" spicules on the proboscides, and the arrangement and grading of the hooks on the same.

Habitat :—The stomach and intestine of *Trygon walga*.

Tetrarhynchus platycephalus, n. sp.—Plate VI., figs. 113 and 114.

This is a moderate-sized form, measuring 10 millims. or 12 millims. in length. The head and neck occupy about one-sixth of the whole body length. The head is compressed from front to back and spreads out laterally, having something the appearance of a Toreador's hat. The four-hooked proboscides bend out towards the edge of the hat, and finally emerge at the angles (Plate VI., fig. 114). The hooks are large, sabre-like, and of uniform size.

The body consists of ten or eleven segments, the last two of which are as big as the rest of the body altogether. The proglottides are at first some six times as broad as they are long, but the fourth or fifth proglottis is already square, and the last is perhaps four or five times as long as broad. They are rounded and plump, stouter half way along than at either end, and stouter in front than behind. The most characteristic feature is the genital pore. This is a great cleft which runs almost half across the proglottis and seems to half cut it in two. This appears already in the fourth or fifth proglottis, and gives the appearance of an irregular and abnormal segmentation. The pores are lateral and alternate as a rule, though now and then two will consecutively follow each other on the same side.

The diagnosis of *Tetrarhynchus platycephalus* is as follows :—

Head much flattened, proboscides coming out of the edges of the flattened head. Hooks uniform in size, sabre-like. Proglottides ten or eleven in number, broader in the middle than at either end. Reproductive pore resembles a huge cleft, which seems to half cut the proglottis in two; alternate, but slightly irregular.

Habitat :—The intestine of *Trygon walga*.

Tetrarhynchus rubromaculatus (Diesing).—Plate VI., figs. 115 and 115*a*.

This is by far the smallest of the Tetrarhynchids found in *Trygon walga*. Only two specimens were taken, one measuring 4 millims., the other 7 millims. in length. The head occupies nearly half this length, and the proboscis sheaths, which vary a little in the two specimens, are nearly half the length of the head (Plate VI., fig. 115).

The bothridia are distinct even when the proboscides are protracted. The latter are four in number and bear sickle-shaped spines, not arranged in very definite rows; between some of them are short rows of minute straight spines.

Behind the head the body consists of six or seven proglottides: the first two of these are band-like, the third longer, the fourth about square, the fifth twice as long as broad, the sixth and seventh four to five times as long as broad. In one specimen the posterior proglottis bore a lateral eminence, presumably the genital pore, which much resembled the similar process figured by WAGENER* in a *Tetrarhynchus* taken from a *Trygon pastinaca.*

In some notes which Mr. HORNELL sent with the material, he states that in the bottle which contained the *E. trygonis* were two species of Tetrarhynchid, one with collar and the other with red pigment anterior to the muscle sacs. Now, as a matter of fact, there were four species of Tetrarhynchids in the bottle, and two of these were collared forms. Thus there is a reasonable degree of probability that the species we are describing, although colourless in spirit specimens, had a reddish patch in front of the muscular proboscis sheaths. In his figure of the *Tetrarhynchus* taken from a *Trygon pastinaca,* WAGENER paints a bright red splash just in this place. Neither WAGENER'S figure nor DIESING'S† diagnosis, given under the name *Rhynchobothrium rubromaculatum,* descend into any details, which might not apply to many Tetrarhynchids, yet there is nothing in the figure or in the diagnosis which differs materially from what we find in our specimens, and on the whole we seem justified in regarding these as belonging to the species *T. rubromaculatus* (DIESING).

Habitat :—The intestine of *Trygon walga.*

Tetrarhynchus ruficollis (EYSENH.)—Plate VI., figs. 116, 117.

Several specimens of this worm were taken from the intestine of *Trygon walga.* They measure 40 millims. to 50 millims. and had the characteristic criss-crossing of the proboscis sheaths. The teeth are not quite so regular as in VAN BENEDEN'S specimens, and he does not figure any of the posterior proglottides; these are cylindrical and smooth, the same diameter throughout and eight to ten times as long as they are broad. They are so cylindrical that it is impossible to say if the genital pore is on the edge or median. There are besides the larger teeth, arranged in more or less oblique rows, two longitudinal chains of very minute tubercles.

VAN BENEDEN'S specimens came from *Mustelus vulgaris,* MÜLL. and HENLE, ours came from the intestine of *Trygon walga,* MÜLL. and HENLE.

MARGARITIFERA VULGARIS, SCHUM.

Finally, we insert the pearl oyster as a host to complete the series.

Tetrarhynchus unionifactor, SHIPLEY and HORNELL—Plate VI., fig. 118.

A few specimens in the same stage as those described and figured in Part II. of this work, p. 88 and Plate II. But what is of greater interest was the discovery of a number of still younger forms of the same species in the stomach and alimentary canal of the oyster. These are quite small forms 1 millim. in length; and they

* 'Acta Ac. German,' xxiv., 'Supl. Taf.,' xxi., 253.

† 'S.B. Ak. Wien.,' xlviii., 1863, 1st Abth., p. 292.

consist of hardly anything more than the head, but the little piece of body shows some slight traces of the markings at the hinder end of the large larval form (see Part II., Plate II., fig. 20). The arrangement of the lappets, the proboscides, the proboscis sheath and the proboscis tubes are similar to those of the older larvæ, and so, as far as it could be made out, and that was by no means completely, was the shape and arrangement of the teeth in the proboscides.

Assuming—for we have as yet no absolute proof—that the youngest form of *T. unionifactor* forms the nucleus around which the pearls are deposited, we have in this lately found larval form an explanation of how the species is preserved. Of the given number of larvæ which enter at a very early stage into the body of the Oyster a certain number arrive in the mantle and other tissues, acquire an ectodermic sac and there encyst, and find a costly grave in the developing pearl. The remainder, however, reach the alimentary canal and grow and flourish there. When they attain the dimensions of the stages described in Part II., they leave the alimentary canal and encyst usually upon the outer surface of the intestine. Now they are too big for enclosure in a pearl, and they can wait without anxiety for the advent of their second host (*Rhinoptera javanica*) within whose intestine they rapidly become sexually mature. It is not entirely impossible that these Tetrarhynchids are different species, though at present the evidence is in favour of the two being different stages of the same species. If they are different species, the smaller probably corresponds with the smaller pearl-forming larvæ described in the previous paper (this vol., p. 22).

Further specimens of the Trematode *Aspidogaster margaritiferæ* were also collected.

II. NEMATODA.

Professor M. Stossich, of Trieste, whose untimely death has deprived us of a most helpful friend, has supplied us with the names and in some cases with short descriptions of the few Nematodes collected on this occasion.

AETOBATIS NARINARI (Euphrasen).

Spiropterina scillicola, v. Ben.

Aetobatis narinari is a new host for this species.

CARCHARIAS MÜLLERI, Müll. and Henle.

Ascaris, sp.

An embryonic form too young to be identified.

MARGARITIFERA VULGARIS AND PLATAX TEIRA.

Ascaris meleagrinæ, Linstow.

Part II. of this work, p. 99.

Platax teira is a new host for this species. The stomach of *Platax teira*, one of the "sea-bats," contained numbers of Octopuses entangled with Lumbriconereids and Eunicidæ. This Nematode also lives in *Balistes mitis* and *B. stellatus*.

Echinocephalus gracilis, n. sp.

The following account of this new species is due to the late Professor M. Stossich: "In the pearl oyster, *Margaritifera vulgaris*, there lives the larva of a Nematode, which Linstow recently ascribed to the species, *Echinocephalus uncinatus*, a species created by Molin for the form living in the Adriatic *Trygon*, but in comparing these with some of the examples of *E. uncinatus* from the Adriatic, it is evident that they are entirely different, and neither belong to the species of Linstow or of Molin. I therefore create a new species, *Echinocephalus gracilis*, with the following diagnosis :—

"Body about 12 millims. long, caudal end hooked and twisted; the head is surrounded with a spherical swelling of the cutis, covered with six transverse rings of hooks, each containing some 40 to 50 hooks; these hooks resemble closely those of certain *Echinorhynchus*, and consist of a large half imbedded in the skin and of a free blade; they gradually increase in size from the first to the sixth row. The mouth is surrounded by six lips, the dorsal and ventral are the largest and are truncated at their outer end, the four lateral have their free end distinctly crenated.

"Habitat :—*Margaritifera vulgaris*, in the adductor muscle."

STEGOSTOMA TIGRINUM, Günther.

The stomach of this fish contained the feet of Gastropods and remains of Pleurobranchi.

Acanthocheilus nidifex, Linton.

Allied species occur in *Mustelus vulgaris*, *M. laevis*, *Scyllium catulus*, *S. stellare*, *S. canicula*, and other Elasmobranchs.

INDEX TO PARASITES AND HOSTS IN THIS AND THE TWO PREVIOUS REPORTS (PART II., p. 77, AND PART III., p. 49).

NATIVE NAMES OF ELASMOBRANCH FISHES.

We add a list of such native names of Elasmobranchs in use in the North of Ceylon as we have so far been able to ascertain, together with the scientific designation. Where possible the signification of the native names is given.

We are well aware that the list is far from complete. It is offered in lieu of anything fuller being in existence, and in the hope that it may prove of assistance to anyone who may pursue investigation in Ceylon touching the Elasmobranchs.

Preliminary List of the Native Names of Elasmobranchs in Use in the North of Ceylon.

Species.	Native name.	Signification.
Aetobatis narinari (Euphrasen)	Pua tirikkai, Tamil. Pulli-maduwa, Sinhalese.	Spotted Ray.
Carcharias melanopterus, Quoy and Gaim.	Kunda mōra, Sinh.	
Chiloscyllium indicum (Gmel.)	Kurakan sura, Tam.	Kurakan-shark (Kurukan = *Eleusine coracana*).
Chirocentrus dorab (Forsk.)	Valai or Walai, Tam. Katuwalla, Sinh.	Bunch of thorns.
Dicerobatis eregoodoo (Russell)	Koppu tirikkai, Tam. Kombu tirikkai, Tam. Añga maduwa, Sinh.	Horned Ray.
Mustelus manazo, Bleeker	Pāl sura, Tam.	Milk-shark.
Myliobatis maculata, Gray and Hardw.	Panjadi tirikkai, Tam. Panjadiya maduwa, Sinh.	
Narcine timlei (Bl. Schn.)	Hiri maduwa, Sinh. Timilī, Tam.	Numbing ray-fish. Numbing fish.
Pristis cuspidatus, Latham	Vēlā-mīn, Tam. Dētī m̆ōra, Sinh.	Sawfish. Saw-shark.
Pristis zyson, Bleeker	Illīpā, Tam.	
Pteroplatea micrura (Bl. Schn.)	Attavănnai tirikkai, Tam.	
Rhinobatus sp.	Gāl uluwa, Sinh. Kāl uluvi, Tam.	Rock uluwa. Rock plough-fish.
Rhinoptera adspersa, Müll. and Henle	Sankkudi tirikkai, Tam. Mundeikanni tirikkăi, Tam.	Chank-eating Ray (Madura coast). Goggle-eyed Ray (North of Ceylon).
Rhinoptera javanica, Müll. and Henle	Valvadi tirikkai	Gregarious Ray.*
Rhynchobatus djeddensis (Forsk.)	Kiri-uluwa, Sinh. Uluwa mōra, Sinh. Pāl-ūlŭvĭ. Tam.	Milk-uluwa. Uluwa-shark. Milk plough-fish.
Stegostoma tigrinum (Gmel.)	Komorin sura, Tam. and Pullian sura, Tam.	Comorin-shark. Spotted-shark.
Trygon kuhli, Müller and Henle	Kāttī tirikkai, Tam.	Ray with boils.†
Trygon sephen (Forsk.)	Adā tirikkai, Tam. Polkolla maduwa, Sinh.	Coconut-leaflet Ray.‡
Trygon narnak (Forsk.)	Pullian tirikkai, Tam.	Spotted Ray.
Trygon walga, Müll. and Henle	Mānāl tirikkai, Tam.	Sand Ray.
Urogymnus asperrimus (Bl. Schn.)	Kālli tirikkai, Tam. Erabadu maduwa, Sinh.	Prickly-pear Ray. Erabadu§ Ray.
Zygæna blochi, Cuvier	Udalŭ mōra, Sinh. Komban sūra, Tam.	Pickaxe-shark. Horned-shark.

* From its habit of going about in great shoals.

† A reference to the boil-like appearance of the large blue spots upon the disc.

‡ This name has reference to the resemblance borne to the pinna of a coconut leaf by the tail and its cutaneous fold.

§ Erabadu, the tree *Erythrina indica*, L., which has the trunk and branches studded with strong prickles.

EXPLANATION OF THE PLATES.

PLATE I.

Fig. 1. *Cephalobothrium aetobatidis.* × 10. Entire worm, drawn from preserved specimen.
,, 2. The head of the same. × about 35.
,, 3. The head of the same, drawn from life. × about 40.
,, 4. The head of the same, drawn from life. × about 40.
,, 5. Anterior end of *Hornellobothrium cobraformis*, with the suckers expanded. × about 100.
,, 6. The same, with suckers retracted. × about 100.
,, 7. Outline of edge of body in anterior broad region.
,, 8. The same, in the narrower posterior region.
,, 9. Body of *H. cobraformis*, × 45, drawn from stained specimen.
,, 10. Enlarged view of head, × about 450, showing button-like myzorhynchus and the extended suckers.
,, 11. *Kystocephalus translucens.* × 16. The head in this specimen is rather diagrammatic.
,, 12. Head of *Kystocephalus translucens*, × about 50, showing the terminal myzorhynchus.
,, 13. *Myzocephalus narinari.* × 10.
,, 13*a*. Posterior proglottis. × about 40.
,, 14. Head of *Myzocephalus narinari.* × about 40.
,, 15. The same simplified and opened out to show myzorhynchus. × about 40. Semi-diagrammatic.
,, 16. *a*, *b*, *c*. Bothridia on myzorhynchus, showing outline of shapes assumed.
,, 17. *Myzophyllobothrium rubrum.* × 6. (17.)
,, 17*a*. ,, proglottis from the middle of the body. × 25.
,, 17*b*. ,, last proglottis. × 25.
,, 18. ,, head. × 25.

PLATE II.

Figs. 19, 20, 21. *Myzophyllobothrium rubrum*, drawn from living specimens, showing various views of the head. The red pigment spots are represented by black dots.
Fig. 22. *Tetrarhynchus aetobatidis.* × 12.
,, 23. ,, extremity of a proboscis. × about 100.
,, 24. ,, showing the more sabre-like teeth at the base of the proboscis, and the position of the red granules.
,, 25. *Tetrarhynchus*, sp. Young form with no proglottides formed. × 40.
,, 25*a*. ,, Tip of proboscis. × about 150.
,, 26. A series of teeth of the above, showing the gradations of a single ring.
,, 27. *Tetrarhynchus*, sp. Young form with cyst still present. × about 75.
,, 27*a*. Proboscis and teeth of the same.
,, 28. *Tetrarhynchus gangeticus*, head. × 20.
,, 28*a*. ,, Still further enlarged view of proboscis.
,, 29. *Tetrarhynchus perideraeus.* × 12. Showing the coiled portion of the body.
,, 30. ,, the head. × 36.
,, 30*a*. More highly magnified view of the proboscis of the same.
Figs. 31*a*, *b*, *c*. Three views of proglottides of *T. perideraeus*, showing the modification in the pattern as one passes backward.

PLATE III.

Fig. 32. *Phyllobothrium minutum.* × 20.
„ 33. „ head. × 80.
„ 34. *Phyllobothrium pammicrum.* × 10.
„ 35. „ head. × 70.
„ 36. *Tetrarhynchus carcharidis.* × 20.
„ 37. „ head. × about 40.
„ 38. *Carpobothrium chiloscyllii.* × 100.
„ 39. „ single bothridium. × 150.
„ 40. Anterior end of a *Tetrarhynchus* cyst from *Chirocentrus dorab*, enclosed in a secondary cyst formed from the tissues of the host. × 20.
„ 40*a*. The whole cyst. × 2.
„ 41. View of the *Tetrarhynchus* when the cyst has been ruptured.
„ 42. Very young *Tetrarhynchus* from *Cybium guttatum*, × 25, showing also shape and arrangement of teeth.
„ 43. Cyst of *Tetrarhynchus* from *Cybium guttatum*, highly magnified.
„ 44. Tetrarhynchid cyst, × 30, from *Diagramma*, sp.
„ 45. Head of *Anthobothrium crispum.* × 10.
„ 46. A few segments of *Anthobothrium crispum*, × about 12, showing the characteristic L markings.
„ 47. Head of *Diagonobothrium asymmetrum.* × about 30.
„ 48. Head of *Rhoptrobothrium myliobatidis.* × about 66.
„ 49. *Tylocephalum dierama*, the entire animal × 6, and two more highly magnified sketches of proglottides to show the extent of the overlap.
„ 50. Head of *Tylocephalum dierama.* × about 60.

PLATE IV.

Fig. 51. *Echeneibothrium javanicum.* × 22. An enlarged view of the striated cuticle is shown to the left.
„ 52. A sketch of the same from life, showing the bothridia divaricated.
„ 53. Another sketch from life, showing the bothridia concentrated.
„ 54. A single bothridium, showing the areolas.
„ 55. A transverse section through the neck of the same, showing the fine excretory canal, the two nerve-cords, and bundles of muscles.
„ 56. A transverse section through the head, showing the hollows of the four bothridia and their areolas.
„ 57. *Echinobothrium rhinoptera*, magnified. *p.* penis; *p.h.*, enlarged view, the hooks of the penis; *s.r.*, spinous region.
„ 58. Head of the same, more highly magnified.
„ 59. Spine from the spinous region, very highly magnified.
„ 60. *Eniochobothrium gracile.* × 30. Rather diagrammatic sketch from life.
„ 61. The body of the same. × 30. Drawn from a preserved specimen.
„ 62. More highly magnified view of head and anterior end of body of *Eniochocephalum gracile.*
„ 63. *Tetrarhynchus unionifactor.* × 8. *a.*, enlarged view of a proboscis, showing arrangement of teeth; *b.*, a tooth still more enlarged.
„ 64. The same, drawn when alive, showing the anterior meeting of the two bothridia and the apical emergence of the proboscides.
„ 65. *Tiarabothrium javanicum.* × 16. Drawn from a spirit specimen.

Fig. 66. Head of the same, × about 50, drawn from life. *c.*, collar. *w.v.*, excretory canals.
,, 67. Longitudinal median section through the head of *Tiarabothrium javanicum*. *a.*, areola of bothridium. *c.*, collar contracted.
,, 68. Transverse section through the collar region of the same. *c.*, collar. *n.*, neck.
,, 69. *Tetrarhynchus rhynchobatidis.* × 4.
,, 70. The head of the same. × about 18.
,, 71. End of a proboscis of the same, × about 100, showing the curiously reversed teeth.

PLATE V.

Fig. 72. *Phyllobothrium blakei.* × 20
,, 73. The head of the same. × about 50.
,, 74. *Rhinebothrium ceylonicum.* × 2, drawn from the contracted preserved specimen.
,, 75. Head of the same, × about 5, drawn from the living specimen.
,, 76. *Tylocephalum kuhli.* × 20.
,, 77. The head of the same. × 60.
,, 78. *Anthemobothrium pulchrum.* × 8. *a.*, proglottis from middle; *b.*, from end of body.
,, 79. Head of the same. × 40.
,, 80. *Prosthecobothrium trygonis.* × 1·5.
,, 81. Head of the same. × 36.
Figs. 82*a* and *b*. Hooks from the head of *Prosthecobothrium trygonis*, highly magnified.
Fig. 83. *Tetrarhynchus leucomelanus.* × 2.
,, 83*a*. Proglottis from middle of the body, showing longitudinal striations.
,, 84. Head of the same, × about 30, with tip of proboscis highly magnified.
,, 85. *Tylocephalum uarnak.* × 10.
,, 86. Head of the same. × 40.
,, 87. *Tetrarhynchus macroporus.* × 10. *a.*, posterior segment, × about 30; *b.*, portion of the proboscis highly magnified.
,, 88. *Thysanobothrium uarnakense.* × 2.
,, 89. Head of the same. × about 20.
,, 90. Posterior view of head of the same. × about 20.
,, 91. Another view of head of the same. × about 20.
,, 92. *Anthobothrium rugosum.* × 7.
,, 93. *Echeneibothrium minimum*, highly magnified, with the bothridia expanded.
,, 94. The same, less highly magnified, with the bothridia contracted.

PLATE VI.

Fig. 95. *Echeneibothrium simplex.* × 6.
,, 96 Head of the same, from a spirit specimen. × 35.
,, 97. The same, from life. × 35.
,, 98. *Echeneibothrium trifidum*, magnified.
,, 99. Head of the same, more highly magnified.
,, 100. *Echeneibothrium trygonis.* × 20.
,, 101. *Echeneibothrium walga.* × 26.
,, 102. Anterior end of *Echeneibothrium ceylonicum*, magnified.
,, 103. Head of the same, more highly magnified.

Fig. 104. *Phyllobothrium lactuca*, VAN BEN. × 2. *a.*, outline of proglottides about middle of body; *b.*, the same from posterior part of body.
,, 105. Head of *Phyllobothrium lactuca*. × 6.
,, 106. *Tetrarhynchus equidentatus*. × 4.
,, 107. Proboscis of the same. × 50.
,, 108. *Tetrarhynchus herdmani*. × 6.
,, 109. The head of the same. × 60.
,, 110. *Tetrarhynchus macrocephalus*. × 10.
,, 111. View of the concave side of a proboscis of the same.
,, 112. View of the convex side of a proboscis of the same.
,, 113. *Tetrarhynchus platycephalus*. × 10.
,, 114. Head of the same. × 45.
,, 115. *Tetrarhynchus rubromaculatus* (DIESING). × 40. *a.*, a further enlarged view of the end of a proboscis.
,, 116. *Tetrarhynchus ruficollis* (EYSENH.). × 6.
,, 117. Head of the same. × 12. *a.*, further enlarged view of the end of a proboscis.
,, 118. *Tetrarhynchus unionifactor*, × about 100, from alimentary canal of pearl oyster.

PARASITES

REPORT

ON THE

TREMATODE PARASITES

FROM THE

MARINE FISHES OF CEYLON.

BY

MAX LÜHE, Ph.D.,

KÖNIGSBERG IN PREUSSEN.

[With TWO PLATES.]

By the kindness of Mr. A. E. Shipley,* to whom I wish to express here my warmest thanks, I have had the opportunity of studying a very interesting collection of Trematodes, mostly parasites of fishes, obtained from Ceylon by Professor Herdman and Mr. Hornell. The collection contained seven different species, all of which are new to science. They are described below.

One of the seven species belongs to the ectoparasitic Trematoda or Heterocotylea. Two are larval forms of Distomids, one of which, however, is a well-distinguished species of the genus *Stephanochasmus*, Looss, the systematic position of the other larva being still doubtful. Of the four adult Distomids contained in the collection, three belong to new genera.

Epibdella (Benedenia) macrocolpa, n. sp.—Plate I., figs. 1 to 3.

From the skin of *Rhinoptera javanica*, Müll. and Henle.

1. Kalpitiya.—Three specimens in bottle No. 36 (the type specimens).
2. Dutch Bay.—Two specimens in bottle No. 2.

Body oval, flattened; length 9 millims. to 10 millims., breadth 5 millims. to 7 millims. The two anterior suckers well developed, circular, with a diameter of about 1 millim., connected together by a thin membranous continuation of the

* These Trematodes were sent to Mr. Shipley with the other parasites (see preceding Report) and were by him sent on to Dr. Lühe for description.—W. A. Herdman.

anterior end of the body. Posterior sucker oval, with a longitudinal diameter of 2·3 millims. to 2·6 millims. and a broadest transverse diameter (a little before the middle of the sucker) of 2·1 millims. to 2·4 millims., with three pairs of hooks very similar in form and arrangement to those of *Benedenia hendorffi* (v. LINST.), and with four pairs of notches on the hinder half of its margin, due to the insertion of muscular fibres, the third of these notches just behind the third pair of hooks.

Mouth behind the plane of the hinder margin of the anterior suckers; œsophagus wanting. On the cerebral ganglion are two pairs of eyes; the posterior eyes a little larger than the anterior ones and directed forwards and outwards, the anterior eyes directed backwards and inwards.

Genital openings on the left lateral edge of the body, near the anterior end, by the side of the anterior sucker; the opening of the vagina just behind the common genital pore. Testes large, two in number, paired, irregularly round. Ovary large, elliptical, with its longer axis at a right angle to the longer axis of the body, situated in the median line, just in front of the testes and midway between the anterior end of the body and the centre of the posterior sucker. Vitellarium extending from the anterior end of the body, between the two suckers, to about the front end of the posterior sucker, that of the two sides intermingling with each other both in front of the cerebral ganglion and behind the testes. Paired yolk ducts directed transversely to the long axis of the body, uniting together near the median line just in front of the ovary. Unpaired yolk duct dilated to form a capacious yolk reservoir, situated in front of the left half of the ovary. The thinner end of the unpaired yolk duct unites soon with the oviduct, which arises from the middle of the anterior border of the ovary and proceeds forward. The canal arising from the united oviduct and yolk duct runs from about the median line to the left, undergoing several convolutions and opening into the ootype, which lies in the same line with the left border of the ovary. It has a characteristic rhomboid shape and is continued into the short uterus. The vagina is exceedingly long (hence the specific name *macrocolpa*); it arises from the yolk reservoir at its left border, and running on the left side of the body, outside the ovary and the testes, turns in a varying level between the hinder border of the testes and the front margin of the posterior sucker lateral and oral, and then proceeds orally, almost in a straight line, to reach the left margin of the body, at about the level of the hinder margin of the anterior suckers. Vasa efferentia relatively long, uniting with each other on the left side of the ovary; the vas deferens runs in an almost regularly curved line round the left side of the ovary and yolk-reservoir, and forms a large, close pack of numerous complicated convolutions between the ootype and the yolk-reservoir, then turning tailwards in a curved line and entering the penis in about the median line, a little in front of the ovary. Penis long, running in a curved line round the shell glands, ventral from the curved end of the vas deferens, and oral from the right half of the ovary, and entering into the very long genital atrium, which reaches the median line just before the ootype.

Stephanochasmus ceylonicus, n. sp.—Plate I., figs. 4 to 6.

From the subcutaneous tissue of *Narcine timlei*, Henle, taken off Dutch Bay, Ceylon. Several specimens.

Of this species only the encysted larval form was found, but there can be no doubt that the species is a new one, although closely allied to *Stephanochasmus pristis* (Deslongch.).

The specimens are about 2·0 millims. to 2·6 millims. in length, and 0·25 millim. broad. Margins of oral sucker projecting laterally over the thinner neck. Diameter of oral sucker 0·18 millim. to 0·2 millim., of ventral sucker 0·18 millim. Distance between the two suckers 0·6 millim. Length of præpharynx 0·4 millim. Pharynx 0·126 millim. in length, and 0·056 millim. broad. Round the mouth a double wreath of 36 large spines, which is not interrupted ventrally, as it is in *Stephanochasmus cesticillus* (Molin). The larger spines of the first row are 0·059 millim. and the somewhat smaller spines of the second row are 0·056 millim. in length. The small spines of the general body surface are best developed close behind the oral sucker, and become gradually smaller posteriorly, though more numerous. Behind the level of the ventral sucker the skin acquires the finely spinous structure described by Looss for *Hæmatolœchus asper*, Lss., and the posterior half of the body is smooth. Of the genital organs only the two testes, situated near the posterior end, are visible. The excretory vesicle is Y-shaped, with a short but ample median trunk, and two long branches reaching almost to the oral sucker.

The worms were encysted in round cysts, with a diameter of the outer wall of about 0·5 millim. to 0·8 millim., and of the inner wall of about 0·36 millim. to 0·47 millim. According to Mr. James Hornell, who collected the worms and has made drawings from the living objects, the fluid filling the space in the cyst around the larva was granular. In an uninjured cyst which I examined this fluid seemed quite clear.

Sub-family: ACANTHOCOLPINÆ, nov.

Provisional diagnosis.—Distomids with a very elongate and but slightly muscular body, whose cross-section is round or oval. Ventral sucker near the anterior end of the body. Oral sucker terminal or subterminal, but always cup-shaped, never funnel-shaped, followed mostly by a very distinct tubular præpharynx. Pharynx well developed, œsophagus short, intestinal cœca long, reaching almost to the posterior end of the body.

The two testes situated in the posterior part of the body, one behind the other, their axial diameter longer, more or less, than their transverse diameters. Cirrus-pouch long and slender, cirrus with spines. Ovary in front of the testes, median or sub-median. Vitellarium formed by numerous little follicles, situated on the sides of the body and behind the testes (in *Stephanochasmus* and *Acanthocolpus*) or only on the sides of the body (in *Deropristis* and in *Distomum semiarmatum*). Uterus running directly oral (in *Stephanochasmus* and *Acanthocolpus*), or at first tailwards and then turning in front of the testes (in *Deropristis*), or reaching the posterior end of the body (in *Distomum semiarmatum*). Vagina always very distinct and provided with similar spines to the cirrus. Genital atrium tubular, almost without spines, but sometimes (in *Acanthocolpus*) in its posterior part with similar spines to the vagina and cirrus. Genital opening in front of the ventral sucker in the median line.

From the generic differences mentioned in this diagnosis it results that *Acanthocolpus* is much more closely related to *Stephanochasmus* than to *Deropristis* and to *Distomum semiarmatum*.

Acanthocolpus, n. gen.

Provisional Generic Diagnosis :—Distomids of small size, with a thin, slender, very elongated body, round or oval in cross-section, without spines in the skin and around the mouth, with a transverse section of oval shape, rounded behind, somewhat pointed in front. Neck not enlarged Ventral sucker near the anterior end of the body somewhat pediculated. Oral sucker subterminal, followed by a very distinct præpharynx. Pharynx well developed, not far in front of the ventral sucker. Œsophagus short. Intestinal cœca long, ending not very far in front of the posterior end of the body.

Genital opening just before the short stalk of the ventral sucker in the median line. The two testes are oval shaped, with the longest diameter in about the long axis of the body, situated near the posterior end of the body in the median line, just behind each other. Ovary just in front of the testes. Very numerous follicles of yolk glands on the sides of the body and behind the testes, reaching the posterior end of the body.

Uterus developed in the same manner as in *Stephanochasmus*, opening into a very distinct long vagina, which bears on its inner side numerous spines ; cirrus-pouch very long, vesicula seminalis and pars prostatica lying on the dorsal side of the uterus ; cirrus of about the same length and with similar spines to the vagina. Cirrus and vagina opening into a long, tubular, genital atrium, the posterior half of which bears likewise similar spines to the cirrus and vagina. The spines are of a very characteristic shape, much broadened, and excavated at their bases. Eggs yellow-tinted.

This new genus, the type, and till now only species, of which is *Acanthocolpus liodorus*, is allied to the genera *Stephanochasmus*, Lss., and *Deropristis*, Odhn., and to another genus hitherto still unnamed, the type species of which is *Distomum semiarmatum*, Mol., a parasite of the sturgeon, found by me several years ago at Trieste, but the description of which I have not yet published, since another helminthologist, to whom I have sent my drawings, intended to write a special report upon the Trematode parasites of the sturgeon.

The above-named genera form together a separate sub-family, which I have named Acanthocolpinæ, the spines in the vagina being one of the striking characters.

Acanthocolpus liodorus, n. sp.—Plate I., figs. 7 and 8.

Specific diagnosis.—Length 2 millims. to 4 millims., breadth 0·36 millim. to 0·6 millim. Diameter of the oral sucker 0·12 millim. to 0·16 millim. Ventral sucker oval, with the largest diameter transverse to the long axis of the body; length 0·18 millim. to 0·24 millim. and breadth 0·24 millim. to 0·3 millim. Distance between the two suckers 0·24 millim. to 0·36 millim.

Præpharynx 0·21 millim. to 0·24 millim. long. Pharynx 0·13 millim. to 0·17 millim. long, 0·08 millim. to 0·10 millim. broad. Genital atrium 0·4 millim. to 0·7 millim. long, dividing behind the ventral sucker. Vagina about 0·25 millim. to 0·5 millim. long. Cirrus-pouch about 0·5 millim. to 1·05 millims. long, 0·07 millim. to 0·10 millim. broad. The long axis of the testes not quite in the long axis of the body, but somewhat oblique, the posterior end directed ventrally and the anterior end directed dorsally, and the two testes overlapping each other a little in this way. Ovary near the ventral surface of the body, partially still ventral from the anterior end of the anterior testes. The testes 0·35 millim. to 0·60 millim. long, 0·20 millim. to 0·24 millim. broad. Diameter of the ovary 0·14 millim. to 0·22 millim. Eggs 0·075 millim. long, 0·045 millim. broad.

From the intestine of *Chirocentrus dorab*, Cuv.; from Kalpitiya. About two dozen specimens.

Schistorchis, n. gen.

Provisional generic diagnosis.—Distomids of large size, with a very muscular, thick and wrinkled body, without spines. Shape almost rectangular, with rounded anterior and posterior ends. Mouth terminal, small, opening into the globular oral sucker. Pharynx well developed; præpharynx as well as œsophagus wanting; intestinal cœca long. Excretory vesicle **Y**-shaped, with long median trunk and long paired branches, crossing the intestinal cœca ventrally and finishing near the anterior end of body by the sides of the oral sucker.

Genital opening just in front of the ventral sucker. Cirrus-pouch well developed.

Testes in about the middle of the body, divided into several small separated pieces (in the same manner as in *Gorgodera*), five on the one side, and six on the other, lying for the most part behind each other in two lateral folds, which are separated from each other by the anterior end of the median trunk of the excretory vesicle. As in *Gorgodera*, the greater number of testes is on the ovarian side.

Ovary just in front of the testes and between the paired branches of the excretory vesicle, near the median line. Seminal receptacle present. Very numerous follicles of yolk glands on the sides of the body and behind the testes. Uterus very small, corkscrew-like, almost only by the side of the ventral sucker. Eggs clear yellow-tinted.

Type, and so far the only species of the genus: *Schistorchis carneus*, n. sp.

Schistorchis carneus, n. sp.—Plates I. and II., figs. 9 to 12.

Specific diagnosis.—Blood red tinted during lifetime, about 10 millims. to 15 millims. long, and about 4 millims. to 6 millims broad. Diameter of the oral sucker about 2 millims. to 2·5 millims., of the ventral sucker about 0·8 millim. to 1·0 millim. The oral sucker, in all the specimens examined, somewhat retracted, not reaching the outer surface of the body. Distance between the two suckers at the most 0·9 millim.

Pharynx much broader than long, 0·8 millim. by 0·3 millim. in the largest specimen, 0·6 millim. by 0·3 millim. in a smaller one. The intestinal cœca run in the beginning transversely outwards, then, after turning in almost a right angle, slightly convergent to the posterior end of the body. In several specimens they are filled with a dark matter. The paired branches of the excretory vesicle cross the transversely running beginnings of the intestinal cœca, and finish at the level of the greatest diameter of the oral sucker.

Diameter of the single testes reach 0·6 millim. to 1·0 millim. in the largest specimen. Cirrus-pouch with a large vesicula seminalis, which lies in the median line just behind the ventral sucker and opens in the pars-prostatica, turning round the left side of the sucker. Ovary near the median line, just behind the cirrus-pouch, and of about the same size as the single testes. Receptaculum seminis behind the ovary or at the left of it. Both ovary and receptaculum seminis in the triangle between the paired branches of the excretory vesicle, which unite just behind them. Vitellarium beginning at the level of the ovarium or of the vesicula seminis.

From the stomach of *Tetrodon stellatus*, Günther; from South Modragam Paar, Ceylon Pearl Banks. Eleven specimens.

General Remarks on Distomids with Numerous Testes.

Already several genera of Distomids with an increased number of testes are known. With some of these, *Syncœlium*, Lss., *Otiotrema*, Setti, *Hapalotrema*, Lss., this new genus has no affinity at all. Also with the above-named *Gorgodera*, Lss., it has no close resemblance beyond the number and arrangement of the testes. However, the resemblance is far greater with the genus *Pleorchis*, Raill., the anatomy of which, it is true, is but little known as yet; but the general arrangement of the genital organs is the same in *Pleorchis* as in *Sinistorchis*. The two species of *Pleorchis* also being intestinal parasites of marine fishes, it seems quite possible that the new genus is allied to *Pleorchis*, which differs, however, from it in several important points, justifying the creation of a new genus for the Ceylonese species described above. For *Pleorchis* is provided with spines in the cuticula, with a greater number of testes (24 to 30), with a long præpharynx, and with anterior branches of the intestinal cœca, similar to, though smaller than, the anterior branches of the H-shaped intestine of *Accacœlium*.

Referring to the species of *Pleorchis*, I must justify the mention of two species, although only one is quoted in the literature since the establishment of the genus *Gorgodera* for *Distomum cygnoides*, ZED. = *Pleorchis cygnoides*, STOSS. This only species is *Pleorchis polyorchis* (STOSS.), an intestinal parasite of the Mediterranean *Corvina nigra*. To the same species LINTON has referred an intestinal parasite of the North-American *Cynoscion regalis*, which I regard as a different species and which I will name *Pleorchis americanus*, n. sp. Besides the different habitat, the two species differ from each other in several important points of their anatomy; a distinct œsophagus is wanting in *Pl. polyorchis*, but present in *Pl. americanus*, and the anterior branches of the intestine are short and run parallel to the main branches in *Pl. polyorchis*, but are somewhat longer and form an angle with the larger intestinal cœca in *Pl. americanus*. In the latter species, moreover, the size of the two suckers seems to be smaller than in *Pl. polyorchis* (according to the figures given by STOSSICH and LINTON), and the number of testes somewhat larger than in *Pl. polyorchis*, which, according to STOSSICH, is provided constantly with 24 testes, whilst LINTON has counted 26 to 30 in *Pleorchis americanus*. It is of interest, that in this species also, as in *Gorgodera* and in *Sinistorchis*, the number of the testes is different on the two sides. In one specimen only LINTON found 15 testes on each side, and in another 15 on the right and 12 on the left, while of nine specimens with 14 testes on the right, two were provided with 16, three with 15, two with 13, and two with 12 testes on the left.

Gastris, n. gen.

Provisional generic diagnosis.—Distomids of large size, with a very muscular body, without spines. Anterior part of the body, between the two suckers, ventrally excavated; posterior part of the body, behind the ventral sucker, broadened, oval-shaped.

Oral sucker subterminal; pharynx well developed; œsophagus short; intestinal cœca long, and finishing not very far in front of the posterior end of the body.

Excretory system U-shaped, with long branches, situated between the intestinal cœca. Genital opening about midway between the two suckers, in the median line. Cirrus-pouch large, oval-shaped, situated in the angle between the two intestinal cœca.

The two testes globular, situated nearly symmetrically side by side, touching laterally the intestinal cœca and separated from each other by the uterus. Ovary in front of the testes near the median line. Yolk glands in the posterior half of the body, laterally to the intestinal cœca, arranged in several (6 to 7) groups, which lie behind each other and are separated from each other by a small interspace, in the same manner as in the genus *Opisthorchis*, R. BL. Uterus running at first to a little extent forwards, but turning very soon, proceeding then posteriorly and reaching the level of the blind ends of the intestinal cœca, not extending laterally beyond the branches of the excretory vesicle, but filling the whole space between these branches and behind the testes in numerous loops very densely pressed together. Eggs very dark, almost black.

At first view the arrangement of the genital organs of specimens somewhat compressed exhibits a superficial resemblance with *Dicrocœlium*, but closer examination exhibits no intimate affinity between this and the new genus.

Gastris consors, n. sp.—Plate II., figs. 13–16.

Specific diagnosis.—Length up to 16 millims.; just behind the ventral sucker 1·5 millims. to 1·7 millims. broad; greatest breadth about midway between the ventral sucker and the posterior end of the body up to 5½ millims.

Oral sucker circular, with a diameter of 1·0 millim. to 1·1 millims. Ventral sucker oval, with a greater diameter transverse to the long axis of the body of 2·6 millims. to 2·8 millims., and a smaller diameter parallel to the long axis of the body of 2·0 millims. to 2·2 millims. The opening of the ventral sucker is a transverse slit. Distance between the two suckers 1·6 millims.

Pharynx 0·6 millim. long, 0·84 millim. broad. Intestinal cœca end 1·8 millims. in front of the posterior end of the body, in several specimens filled with a dark matter.

Cirrus-pouch about 0·8 millim. long, about 0·5 millim. broad. Testes in about the middle of the body; vitellarium beginning at the level just behind the testes and not reaching the level of the blind ends of the intestinal cœca.

From *Tetrodon stellatus*, GÜNTHER.—Four specimens along with *Schistorchis carneus*, found apparently also on South Modragam Paar and also in the stomach of the host.

Anaporrhutum largum, n. sp.—Plate II., fig. 17.

From the body cavity of *Rhinoptera javanica*; Kalpitiya. A single specimen.

Body very flat, membranous, smooth, oval, 9 millims. long, 8 millims. broad; the greatest breadth just behind the ventral sucker.

Oral sucker subterminal, oval, with a longitudinal diameter of 0·65 millim. and a transverse diameter of 0·8 millim. Ventral sucker very large, but little excavated, slightly oval, with a longitudinal diameter of 2 millims., and a transverse diameter of 2·2 millims. Distance of the two suckers from each other 1·5 millims. Distance of the posterior margin of the ventral sucker from the posterior end of the body 4·8 millims.

Pharynx 0·42 millim. long and 0·48 millim. broad, not projecting into the oral sucker (as it does in *A. albidum*, OFENH.). Œsophagus short, about 0·6 millim. long. Intestinal cœca large and long, end about 1 millim. in front of the posterior end of the body, embracing a space smaller than that between their outer edge and the lateral margins of body. This broadening of the parts outside the intestinal cœca, together with the excessive diameter of the ventral sucker and the extreme thinness of the whole body, gives to the species a characteristic appearance, different from that of the other Anaporrhutinæ.

Excretory vesicle Y-shaped, with long median trunk, dividing a little behind the level of the posterior end of the yolk glands, and with shorter paired branches not crossing the intestinal cœca, but ending at the sides of the posterior edge of the ventral sucker.

Genital openings ventral from pharynx, somewhat at the right of the median line. Cirrus-pouch wanting.

Testes outside the intestinal cœca, but still within a distance of almost 2 millims. from the lateral margins of the body, extending from 0·5 millim. behind the posterior margin of the ventral sucker to 1·8 millim. behind the same. Their number is 14 at the right side of the body and 17 at the left side, pressed closely together in two rows which unite behind; the inner edge of these rows has but about half the length of the outer. Each testis is mulberry-shaped. The vasa efferentia from the single testes arise between the two rows and unite soon to form the vas deferens of each side. The two vasa deferentia do not anastomose with each other, as they are said to do in *A. albidum*, but only unite at about the level of the division of the intestinal cœca to form a very convoluted vesicula seminalis.

Ovary globular, with a diameter of 0·4 millim. It is situated just behind the ventral sucker, at the right side of the body. Receptaculum seminis of about the same size, situated at the side of the ovary in the median line. Yolk glands between the intestinal cœca and the paired branches of the excretory vesicle, the left just behind the ovary, and the right symmetrically on the other side of the body, each of them consisting of several tubules, which do not anastomose with each other, as they are said to do in *Anaporrhutum albidum*, Ofenh., and *Probolitrema capense*, Looss.*

Uterus similar to that of *Probolitrema richiardi* (Lop.) Lss., but ending about 0·7 millim. in front of the blind end of the intestinal cœca, and passing at the right side of the ventral sucker.

The new species *Anaporrhutum largum* differs from both *Anaporrhutum albidum*, Ofenh., and the two species of the genus *Probolitrema*, Lss. (*P. richiardi* and *P. capense*), in several points of its anatomy, especially in the position of the testes and the yolk glands, to which Looss has ascribed generic value. Accepting *Probolitrema* as a separate genus, it would be necessary therefore to create a third genus for the new species. But doubtless all these Anaporrhutinæ living in the body cavity of Selachians are more closely related to each other than to *Plesiochorus cymbiformis* (Rud.), placed by Looss in the same sub-family. It seems to me, therefore, that *Probolitrema* is to be regarded only as a sub-genus of *Anaporrhutum*, or

* In addition to *Anaporrhutum largum* I have also examined a species of *Probolitrema* very similar to *P. richiardi* (Lopez), if not identical with this, which is found in an undetermined shark from the Ulle Sea (Dutch India), and belongs to the Natural History Museum of Hamburg (No. 17705). In this species also the tubules of the yolk glands do not anastomose with each other.

that *Plesiochorus* is to be regarded not as a member of the Anaporrhutinæ themselves, but as the representative of a separate sub-family of the Gorgoderidæ allied to the Anaporrhutinæ.

Distomum, sp. (larva).—Plate II., fig. 18.

From *Pinna*, sp. One specimen.

A small larva of a Distomid, about 1 millim. long, and about 0·36 millim. broad, without spines. Ventral sucker very large, projecting, situated in the posterior half of the body, its distance from the posterior end of the body 0·20 millim., its diameter 0·33 millim. Diameter of the oral sucker 0·18 millim., of the pharynx 0·12 millim. Œsophagus wanting. Intestinal cœca ending at about the middle of the body. Excretory vesicle V-shaped, ending at about the same level as the posterior end of the intestinal cœca.

From the genus *Gymnophallus*, larval forms of which are found in some marine Lamellibranchs (*Mytilus edulis*, *Saxicava rugosa*), this parasite of *Pinna* differs in the absence of spines in the skin, of a distinct œsophagus, of an unpaired median trunk of the excretory vesicle, and by the smaller length of the excretory vesicle.

GENERAL SUMMARY AND RECOMMENDATIONS.

As the results of this investigation, which has extended over four years and a half, are scattered through a number of articles in the five volumes of this Report, it seems desirable, now that the practical work is concluded, that I should give a summary account of the conclusions arrived at, and should bring together and revise the various recommendations made to the Ceylon Government from time to time. In doing so I shall omit all consideration of purely speciographic and faunistic results, as these matters will be dealt with in a separate article on Geographical Distribution at the end of the Supplementary Reports in this volume. I am here only concerned with those biological results which have a bearing upon the life-processes of the pearl oyster, the nature and characteristics of the "paars" and the prosperity of the Ceylon fisheries.

The observations upon which these conclusions are based were made :—

1. During the two cruises of the "Lady Havelock" in the Gulf of Manaar, and around Ceylon, during the spring of 1902.

2. During our subsequent work with the divers on the inspection ship "Rangasami-Poravi."

3. By Mr. Hornell at the Marine Biological Station, Galle, after I had left Ceylon.

4. During Mr. Hornell's various inspections, and the fisheries that have been held since 1902.

5. All of which observations have been corrected when necessary, and correlated where possible by the laboratory work in Liverpool upon the material sent home for investigation. In this laboratory work I have had the advantage of frequent help on special points from scientific friends in other Universities, and from some of my assistants in the Zoological Department of the University of Liverpool.

The factors which determine the problems of the life-history, prosperity and pearl-production of the Ceylon pearl oyster are so inter-related, that it is scarcely possible to make a consistent classification into mutually independent sections; still, I think it may conduce to clearness and help the reader, by providing landmarks, if I group the results under a few main headings. It will be readily seen that these overlap in places, that the groups are not all of the same value, and that it has not been possible to keep the "Summary of Conclusions" and the "Recommendations" strictly separated.

A.—SUMMARY OF CONCLUSIONS.

I. The Pearl Banks—the Physical Surroundings of the Pearl Oyster.

The pearl oyster, or rather "mussel" (*Margaritifera vulgaris*, Schum.) of the Ceylon fisheries lives in very pure and clean sea-water in the Gulf of Manaar on certain patches of hard ground known as "paars" (see charts and maps in Part I.). There is no strict line of demarcation between the paars and the neighbouring sea-bottom. We have evidence to show that the outlines, and the extent of the paars, may be altered from time to time by the weather. What is a hard patch one season may be covered by an overwash of sand in the next, and then again be swept clear by an exceptional storm or current. These changes, although they may occasionally cause damage to an oyster bed, are not wholly detrimental; they sometimes uncover fresh ground upon which young oysters may settle, and they cause us to recognise that the whole of the wide shelf within the 10-fathom line in the northern part of the Gulf of Manaar is potential paar-ground, and is susceptible of artificial improvement for purposes of cultivation.

The paars are, for the most part, at depths of 6 to 9 fathoms, and those that are best known as fishing grounds lie at a considerable distance from land, the Cheval Paar 9 to 14 miles, the Periya Paar Karai 12 miles, and the Modragams about 8 miles from the nearest coast.

The Muttuvaratu Paar, at about 4 miles off Karativu Island, is the only one where important fisheries have been held that is near the shore. In no cases have the pearl oysters been found between tide-marks, or contiguous to the beach, in the Gulf of Manaar, although it has been shown that they can live in such a position in the sheltered waters of Trincomalee. For further details as to the positions, depths, extent and other characters of the paars, see the sections on "Description of the Pearl Banks" in Part I., and on the "History of the Principal Pearl Banks" in Part II. of this Report.

The hard bottom of the paars is to some extent formed of corals and shells, but to a much larger extent by a modern rock now forming *in situ*. This has been called a "calcrete" (see "Report on the Sea-bottoms," by Mr. Lomas, in Part I., p. 147), as it is composed of the sand and neighbouring organic remains cemented into a continuous hard mass by carbonate of lime.

It has been shown in this Report that the cementing, although no doubt in part a chemical process, is in places a biological result, since it is largely due to the growth of living Nullipores and Polyzoa—especially the latter (see fig. 1).

When the bottom on the pearl banks is not calcrete, it is formed of a coarse sand, in some places almost wholly inorganic, containing large quartz grains, and derived from the waste of the granulitic rocks of Central Ceylon brought down by the rivers:

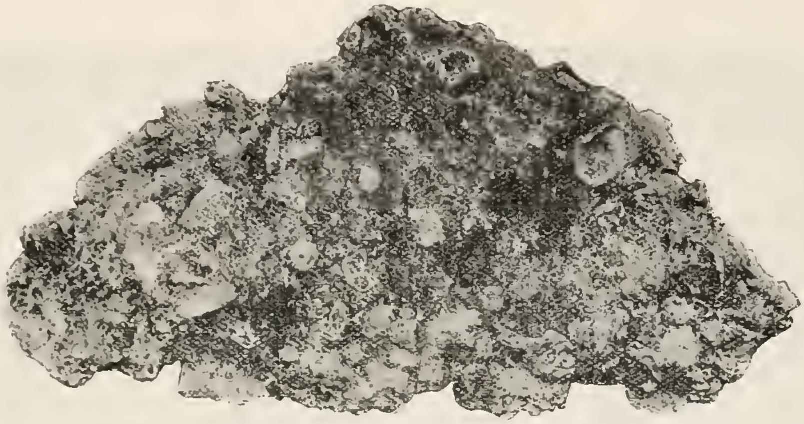

Fig. 1. Lump of calcrete showing large quartz grains and felspars with fragments of coral, shells and worm tubes, along with many Polyzoa colonies. From Jokkenpiddi Paar.

Elsewhere the sand is of organic origin, and is formed chiefly of the shells of large bottom-living Foraminifera, such as *Amphistegina lessonii*, *Alveolina melo*, *Heterostegina depressa* and *Orbitolites marginalis*, mixed with the calcareous remains of many other kinds of animals (see Report upon the Foraminifera in this volume). The divers distinguish between a hard bottom (the "paar") suitable for pearl oysters, and a sandy one which is more or less useless. The sand, however, in the neighbour-

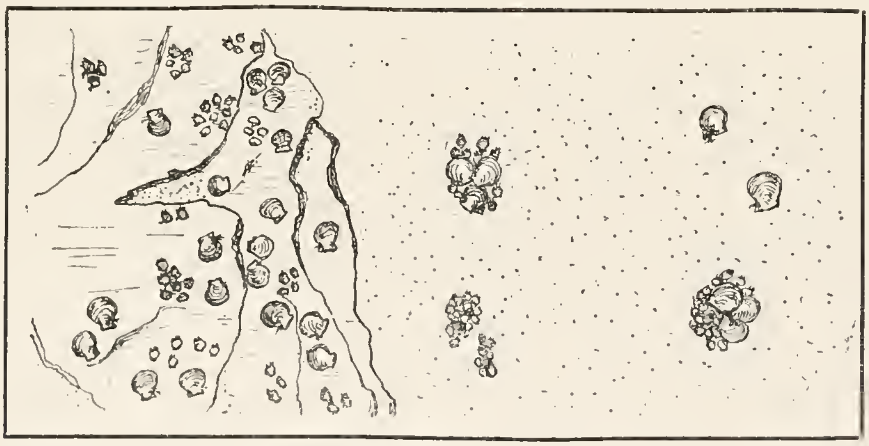

Fig. 2. Diagram showing the arrangement of pearl oysters (large and small) in clumps on the sand and singly attached to flat ledges of rock.

hood of paars often bears considerable numbers of oysters in clumps (fig. 2) adhering to fragments of dead coral, to old molluscan shells, or more frequently to nullipore nodules (*Lithothamnion fruticulosum*), see fig. 3.

Such pieces of natural cultch are of enormous importance to the prosperity of the fisheries, and the area covered by these fragments and so made available for the attachment of pearl oysters, might be largely extended by artificial "cultching." Large areas of the important Cheval Paar, for example, would be improved by further cultching.

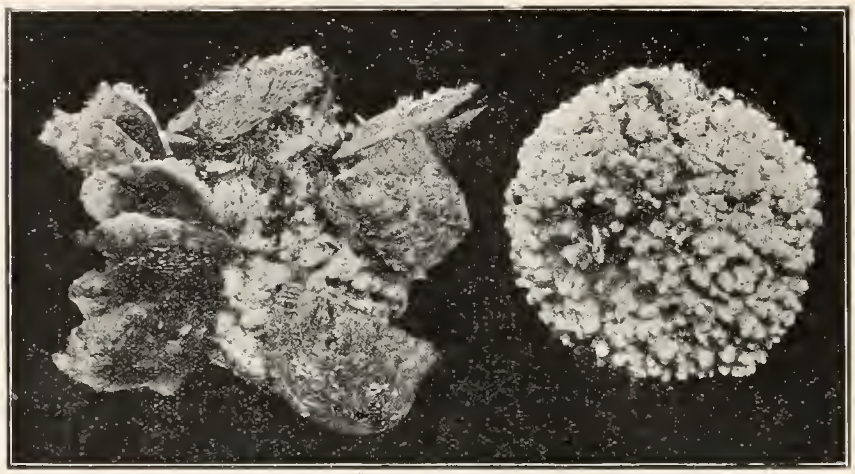

Fig. 3. Nullipore ball (*Lithothamnion fruticulosum*) with tags of byssus where pearl oysters have been attached (to the right), and a similar ball still covered with young pearl oysters (to the left); natural size.

The temperature of the sea-water in which the pearl oysters live in the Gulf of Manaar is high. In our experience in 1902 it ranged from about 77° F. in January to close on 90° F. in April. In February, 1904, the range was from 80° to 84°, in March from 81° to 86°, and in April from 84° to 88° F. In all cases the temperature was taken at a depth of 2 feet below the surface of the sea, at 7.30 A.M., noon, and 5.30 P.M. each day. Probably the normal range during the greater part of the year is from 82° F. to 86° F.

The specific gravity we found to be fairly constant at 1·023 on the pearl banks; at Galle it was slightly lower, averaging 1·022 ; at Trincomalee in the inner bay, and especially in Tampalakam, it was distinctly lower (1·015 to 1·019). At exceptional spots and seasons in the Gulf of Manaar we have found the specific gravity lower than the normal. Off Chilaw, in November, 1902, it was slightly above 1·019, and on the Muttuvaratu Paar in the same month it averaged about 1·020. No doubt on occasions of great floods on the land it may be lower still on those paars that are near the mouths of the rivers. There is no reason to think (as has sometimes been stated) that some admixture of fresh water is necessary for the prosperity of the oyster or for pearl-formation. On the contrary, exceptional floods are probably harmful to any paars they may reach. On the other hand, it is possible that the outflow from the great land-locked lagoons (*e.g.*, Portugai Bay and Dutch Bay) influence the sweep of the coastal currents and help to determine spat-falls on the neighbouring banks. The great tidal outflow from Dutch Bay probably influences deposition on the Muttuvaratu Paar by breaking up the north or south current into local eddies. Similarly the South-east Cheval and Modragam Paars are within the influence of the outflow from Portugai Bay.

There is a general drift of the water over the banks from south to north between April and September, and from north to south during the height of the north-east monsoon, with intermediate periods of calms and variable winds from February to April, and usually again in November. But we are still in want of more definite information (such as can only be obtained by some years of observation and experiment with "drifters") in regard to the usual surface drift during the periods of variable winds between the monsoons, before we can be certain of the source of "spat" supply to particular banks, or of the destiny of larvæ produced from our adult oysters. "Drift-bottle" experiments, such as have been recently made for fisheries purposes in several European seas, should be instituted in the Gulf of Manaar. It is only after such work has been carried on systematically for two or three years at least that it will be possible to determine the course taken by the larval pearl oysters between the time of hatching and the deposition of spat, and again between the attachment to floating Algæ and the appearance of young oysters on a paar. These are details which it was impossible for us to determine in the time at our disposal in 1902, but which could be readily settled by the Marine Biologist if he were given the necessary facilities. Such information will obviously be of value whenever it becomes necessary to decide upon the best section of a bed of oysters to be reserved as a breeding stock.

II. Fauna and Flora—the Biological Surroundings of the Pearl Oyster.

The Fauna and Flora of the Gulf of Manaar, comprising the whole assemblage of plants and the other animals, large and small, which surround the pearl oyster, have a profound effect upon the well-being of the stock upon the beds, and hence upon the prosperity of the fisheries. We have taken every opportunity of investigating this fauna and flora; and the results of our collecting are reported upon in detail by specialists, in the series of Supplementary Reports given in these volumes. It will suffice to point out here, that the microscopic forms floating in the water and captured by our fine silk tow-nets included (1) the pearl oyster itself in its youngest free-swimming stages, (2) its food, not merely when young, but throughout life, and (3) young stages of the parasitic worms which infest the oysters and some of which induce pearl-formation; and that the larger animals on the sea-bottom—sponges, corals, starfish, molluscs, crustaceans, and fishes—are the all-important enemies or fellow-competitors of the oyster (for food and attachment areas and growing room), which may ruin a promising bed either by their direct aggressive action or indirectly in the struggle for existence.

It is impossible, until a careful study has been made of each case, to say which members of the fauna and flora of an oyster bed are of most importance to its prosperity—probably none are wholly without influence for good or evil, so closely interwoven in past history and present function is the web of living nature.

III. Reproduction and Life-History of the Pearl Oyster.

We find that the Ceylon pearl oyster is diœcious, or has the sexes separate, not only at any one period, but throughout the life of the animal. Our observations on innumerable microscopic sections of preserved material, and Mr. Hornell's experiments at Galle (see Part I., p. 125), have shown that quite definitely; and there are no traces of hermaphroditism. Emission of the generative products takes place directly into the surrounding water, where the ova are fertilised, and consequently there is no retention of eggs or embryos within the body of the female. The male is stimulated to emit spermatozoa by the presence of ova in the surrounding water, and as the animals are gregarious, and males and females are found mature together, it becomes practically certain that all eggs will be fertilised under normal conditions.

There is no marked disproportion in numbers between the sexes; out of a couple of hundred collected together at random and examined in 1902, 87 were males, 71 females, and the remainder immature or indeterminate. Similar observations made on several occasions since have given us much the same results.

Reproduction appears to take place to some extent throughout the year, and stray individuals may be found to be sexually ripe in any month; but there are two maxima when the majority of the pearl oysters in the Gulf of Manaar become mature and shed their reproductive elements, viz., in mid-summer from May to July and in mid-winter from November to January. It must be remembered that the temperature and other conditions in these two periods of the year do not differ very greatly. The one period is during the prevalence of the south-west monsoon and the other during the north-east. Hence the importance of ascertaining precisely the resulting currents that would carry floating embryos as the result of the prevailing winds at each such period is obvious. It will be noted that these statements are only made in regard to the pearl oyster in the Gulf of Manaar. It may well be that even the same species in other localities, such as the Persian Gulf or the Red Sea, has other breeding habits.

Larval development takes place in the surface waters of the sea, and from our observations we draw the conclusion that the young animal may settle down as "spat" within 5 days of the fertilisation of the egg. At the same time, from the size of some of the larvæ we have found, we consider it probable that the free-swimming period may on occasions be considerably prolonged. We were able to rear young larval stages in the Galle Marine Biological Station, and we caught the later ones in the tow-nets on the pearl banks. We found the youngest fixed spat on Zoophytes and Algæ early in November and early in March. All fixed stages, from one similar to the latest of the free stages up to young oysters having the adult characteristics of shell, were found during March and April, 1902, attached to both rooted and floating Algæ in various parts of the Gulf of Manaar. The so-called "false-spat" (other smaller allied shell-fish, such as species of *Avicula*) also occurs on Zoophytes and Algæ; but during the time of our investigations there was undoubtedly abundance of the true pearl-oyster spat both on filamentous green and red Algæ from the bottom (Plate, figs. 32, 33), and also on floating *Sargassum* weed (fig. 4). The importance of these Algæ in thus affording attachment to the youngest stage of the spat, and in afterwards distributing it widely, can scarcely be over-estimated (for the names of the species of Algæ involved, see 'Report on the Algæ,' Part I., p. 163).

Fig. 4. Sketch of young pearl-oyster spat attached to *Sargassum*.

Mr. HORNELL has been unable, since he became Inspector of the Pearl Banks, to obtain, during the anxious and busy periods of successive inspections and fisheries, the amount of free time necessary in order to make detailed observations on the embryonic development; but we give here a brief outline, illustrated by a series of figures (see Plate), most of which he made in the summer of 1902 from embryos reared at the Galle Biological Station. Figs. 1 and 2 show the living egg on extrusion to be provided at one end with a micropyle through which fertilisation takes place, and which may be prolonged (fig. 1) as a slender tube. Figs. 3 and 4 represent the mature ovarian egg, fixed and stained as we now find it in our sections, and showing a well-marked nucleolus lying in a clear vacuole. The egg shown in fig. 4 measured about 0·05 millim. along its greater axis. Fig. 5 gives the outline of the spermatozoon much more highly magnified than the ova.

The segmentation is complete, but unequal, and the stages seen in figs. 6, 7, and 8 agree with those we are familiar with in some other allied molluscs. The enclosure of the larger macromeres by the smaller micromeres, seen in progress in figs. 7 and 8, is shown far advanced in 9 and completed in 11. The single macromere of fig. 8 has divided into two in 9 (see optical section 10) and into four in 11 (see optical section 12). Fig. 11 shows the flattening of the lower, posterior, end and the first appearance of a zonal (præ-oral) band of cilia round the widest part of the body. This is a young trochophore stage, and completed trochophores are seen in figs. 13 (22 hours), 14 and 15 (26 hours), and 16 (30 hours after fertilisation). These stages show an enteron opening to the exterior near the posterior end, a posterior patch of cilia, a long anterior tuft on the prostomium, and an equatorial præ-oral circlet of cilia (see fig. 15).

After this stage our series is not so complete, but we give such stages as we have of later larvæ, as they may be useful to future observers for comparison with forms captured in the tow-net. Fig. 17 shows a couple of unfertilised eggs, not yet beginning to decay or disintegrate, at three days after extrusion from the parent. Fig. 18 shows the first appearance of the larval shell, three days after fertilisation; and figs. 19, 20, and 21 show three pelagic (also shown in text-fig. 5), but shelled, forms. The ciliated velum (a), the adductor muscles, the mobile foot, the otocyst, a pigmented eye-spot, the developing gill filaments, &c., are readily seen.

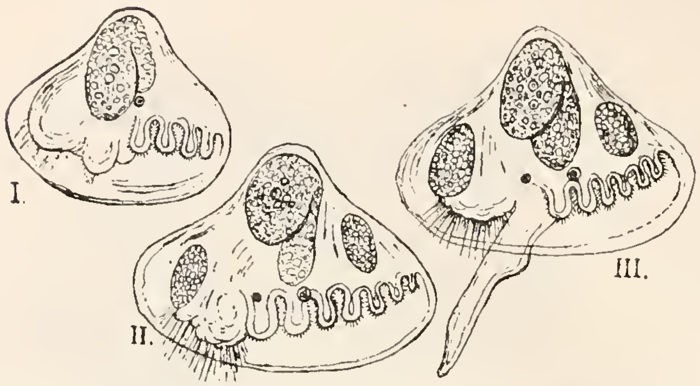

Fig. 5. Free-swimming larval stages of pearl oyster caught in the tow-net. I. has the ciliated velum retracted. II. and III. show the stage at which the larva becomes attached to Algæ. III. has the mobile foot extended.

The larva is now at a stage when it is ready to affix itself to some foreign body (Plate, fig. 32), such as the filamentous green Algæ. Figs. 22 to 27 (and also text-fig. 6) show young stages of growth of the shell after fixation. Fig. 22, the youngest fixed form we have found adhering to Algæ, measures 0·4 millim. in greatest extent, and is identical with fig. 21, the latest free-swimming stage we have found. Fig. 23 shows that the new growth added to the shell ("prodissoconch") of the "spat" after fixation is formed of prismatic substance, and is entirely different in appearance from the structureless embryonic shell marked only by concentric lines of growth. Fig. 31 shows the junction of these two layers of the shell, and also the free margin, magnified, at this stage. Further additions of prismatic substance which is gradually surrounding the embryonic shell are shown in figs. 24 and 25. The byssal sinus, indicating the anterior end of the shell, appears in these stages. In the next (fig. 26) it has worked its way further dorsally. Developing gill filaments are present in all these stages, seen through the thin shell of the "spat." In fig. 26 the filaments have become long and slender, and are about 10 in number. The spat is now 1 millim.

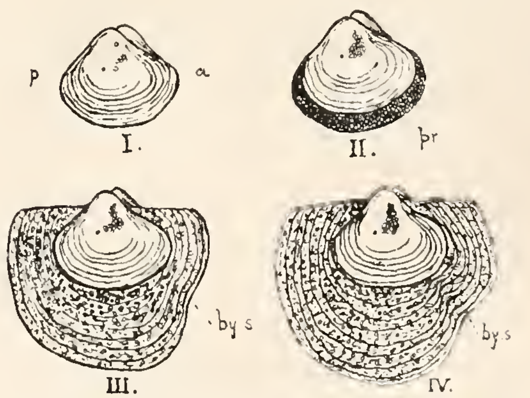

Fig. 6. Stages in the growth of the shell after the attachment of the larva. I. is identical with the latest free-swimming stage; a, anterior, p, posterior end. II. shows the first formation of prismatic shell (*pr.*). III. and IV. show the change in shape and the byssal sinus (*by.s.*).

across, and three regions are distinctly visible in the shell, the structureless, clear, embryonic shell or prodissoconch marked by very regular and delicate lines of growth, and forming the hinge (with 5 anterior and 5 posterior teeth, separated by a slight median interspace, figs. 28, 29, on each valve) and the umbo; the now very extensive prismatic part extending to the free margin all round and having very much the shape of the adult; and finally an intermediate region which in addition to the prismatic part has a lining of nacre. These three regions of the shell are still seen in fig. 27, but the prodissoconch is now becoming imbedded in the later formed shell and so loses its distinctness; its umbo, however, is still prominent. This specimen, which measures 1·5 millims. in diameter, is seen from the left side; the preceding figures were seen from the right. In fig. 27 pigment has commenced to form in the prismatic layer, producing 4 to 6 yellow or ruddy-brown radial bands, most marked at the periphery and dying away internally. These and still larger young oysters are shown in fig. 33, natural size, attached to an Alga; while a sample of "false spat" is shown in fig. 34, and enlarged in fig. 30 (*Avicula vexillum*, Reeve).

The spat in all these stages of growth is very actively locomotive. Although it can fix itself by the byssus threads, it does not usually remain fixed for long. When moving, it pulls itself along by means of the large mobile foot (see fig. 7). We have many observations showing the rapidity with which it can detach and re-attach itself, and the rate at which it can travel (see Part I., p. 68). There is no doubt, then, that in this young stage the pearl oyster can leave the weed to which it first becomes fixed and transfer its attachment to a coral or nullipore fragment on the paar, or can move from an unsuitable spot in search of a better. Its tendency to climb upwards whenever shaken on to the floor of an aquarium (see "Narrative," Part I., p. 69) is probably an indication of an instinct to ascend any solid objects on the sea-bottom, which must often save it from being smothered in the loose sand.

Fig. 7.

Our experiments on the pearl banks in 1902, and at the Galle laboratory, have shown that not only the young but also the adult pearl oyster is able to cast off its old attachment, move to a new place, and there spin a new byssus, and this not once or twice, but repeatedly, up to eight times in fourteen days, as our records show (see fig. 8).

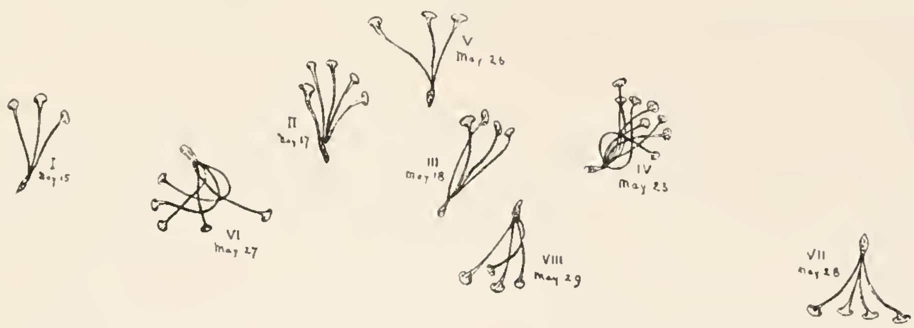

Fig. 8. Diagram showing the eight successive positions in which a pearl oyster formed new byssus strands in a fortnight. One half natural size.

We do not mean to assert that the oysters have a power of locomotion that would enable them to migrate to any great distance; but our observations have convinced us that they have powers of freeing themselves from sand, of moving to a better position, of re-attaching themselves when torn off from their moorings, and of repairing injuries to shell and mantle (for details see section 'Observations and Experiments,' &c., Part I., p. 125), with which they are not usually credited.* All these field and laboratory observations, it is scarcely necessary to point out, have an important bearing upon some of the practical recommendations that follow (p. 133).

IV. Practical Considerations.

Many of our observations and experiments were made with the view of gaining information as to the practicability of transplanting the pearl oysters from one locality to another. We have shown that the transportation of oysters, both old and young, even for considerable distances—such as from the head of the Gulf of Manaar to Galle, a matter of four or five days—at the hottest season of the year, is comparatively easy if ordinary precautions be taken to keep the water in the vessels as cool as possible and to prevent any decomposition taking place. Transplanted specimens, moreover, flourished in our hands. Both at Galle and in the Gulf of Manaar (where some batches were moved from the Muttuvaratu Paar to the Cheval) the oysters improved in health and grew rapidly in size when moved to a new locality. We have given the details of growth for both old and young oysters in preceding sections of this Report (see Part I., p. 136). These and other experiments were all undertaken because of their bearing upon that transplantation, in quantity, from overcrowded and unreliable paars to more suitable ground, which we have advocated throughout this Report.

Some of our experiments gave us a clear indication, which, however, we also obtained from observations on the pearl banks, of the kinds of foreign objects best suited for young pearl oysters to settle down upon, and also of the objects, such as living coral, to which they cannot become attached. This, then, led us to recognise the value of natural "cultch," or suitable hard objects, such as dead coral fragments, old shells and nullipores, upon the bottom, and the importance of increasing the area available for beds by the artificial "cultching" of the more sandy parts of the paar-ground.

We must not try to be too precise in regard to the positions, sizes and outlines of the paars. Our work in the "Lady Havelock" showed us that some spots around and between them are more or less hard-bottomed, and even, in some cases, bear oysters, and are evidently capable of becoming fishable paars. On the other hand, it is clear from the record of the inspections that many parts of the known paars may be

* Although Kelaart observed certain powers of locomotion and of byssus regeneration nearly fifty years ago; and more recently H. Sullivan Thomas (1884) made similar observations.

temporarily, and possibly some parts even permanently, unsuitable for the attachment and rearing of oysters.

We may consider, then, the whole pearl-bank plateau of the Gulf of Manaar as potentially paar-ground, some parts of it better suited for one purpose and some for another, some parts more constantly covered by the shifting sands, others more regularly bare and hard. It is this condition that gives man his opportunity and renders possible the farming operations, such as cultching and transplanting, which we urge in our Recommendations.

The history of the pearl fisheries in the past, especially during the nineteenth century (see Part II., p. 1), has shown that :—

1st. A number of the smaller paars, which are hard patches of limited extent largely covered with living corals, are practically worthless from an economic point of view.

2nd. Some parts, such as the Periya Paar, might be used as most valuable sources of supply of young brood oysters for transplantation, but cannot be relied upon to produce an adult stock suitable for fishing.

3rd. Others again, such as the great Cheval Paar with its various subdivisions, and the North and South Modragams, the Periya Paar Karai, and the Muttuvaratu Paar, are very valuable and fairly reliable grounds, upon which most of the successful fisheries of the past century have taken place. Others, such as Chilaw, Dutch Modragam, Alantura and Karativu, are less reliable, but may be valuable on occasions, and are also of importance as sources of spat-production available for transplantation.

It became clear to us during our work on the "Lady Havelock" in 1902—when we understood why it is that the Periya Paar is unreliable and the Cheval Paar so much more satisfactory—that the main hope of introducing some constancy of result and a more regular succession of fisheries must rest upon a system of transplanting young "strikes" or broods of oysters, whenever they make their appearance upon useless or unreliable paars, to wherever there is room for them at the time upon ground that is more certain to give them a better chance of living and growing to maturity.

Speaking generally, the Cheval appears to be the most reliable of these areas, and more especially its south, south-east, and mid-east sections. Whenever possible, the brood oysters, to replenish the Cheval Paar, should be brought from the Periya Paar, which is most suitable by reason of its proximity, the frequent spat falls thereon, and the impossibility of such spat growing to maturity on its own area. Next to the Periya Paar the most suitable grounds from which to obtain spat are the many small paars off Chilaw. Like the Periya Paar, these paars seldom bring their oysters to a fishable age, and when they do, the numbers and value are comparatively insignificant. But in the economy of the banks they have importance as sources whence the Cheval may be replenished. They should be utilised whenever the Periya Paar is not available; and even when brood oysters on the latter are to be had, it may be preferable to go to the Chilaw banks for the supply if the oysters thereon are older. If year-old oysters can be had on the Chilaw beds in quantity, while those on the Periya Paar are only three months old, then it is best to move the older, Chilaw, oysters first, since they have already survived the critical first year of life, and are probably worth three times their number of the younger brood.

The transplantation system can be extended also to older oysters. We have shown that even adults can throw off the old byssus and form a new attachment-cable whenever necessary. Consequently, overcrowding or any other source of danger should now be mitigated whenever possible by transplanting to unoccupied ground on the more favourable paars.

V. Causes of Disaster.

The above-mentioned points raise the whole question of the causes of death in the pearl oyster, the reasons of the intermittence in the history of the fisheries, and the conditions which render some paars more reliable than others. These matters have been discussed in various preceding sections of this Report (see especially Part I., p. 120, Part II., p. 35, and Part III., p. 25)

The following gives a summary of our results :—

(I.) The most important agent in causing wide-spread death of pearl oysters—both young and old—in the Gulf of Manaar is the shifting of sand due to the strong currents prevalent during the south-west monsoon, and no doubt occasionally (but rarely) to exceptional storms. We obtained a good deal of evidence as to the manner in which the sand is carried about and piled up by the currents, and is churned up in places by the swell of a strong south-west monsoon, and we made observations as to the effect of burying oysters of different sizes in various amounts of sand. The successive broods of young oysters which have appeared, and as regularly disappeared, upon the Periya Paar during the last quarter century have, there can be no doubt, been overwhelmed by the bottom currents caused by the south-west monsoon upon that bank which lies furthest from land and faces the deep water of the Indian Ocean. The destruction from this cause is enormous. In March, 1902, we ran a line of observations along more than six miles of the length of the Periya Paar, and estimated that the bank bore at that time not less than about a hundred thousand millions of young oysters. When Mr. Hornell returned the following November, he searched the ground from end to end and found only a few dead shells. In November, 1904, this paar was again found to be covered with millions of young oysters, but a year later not a single survivor was left. On the Periya Paar this colossal destruction is probably an annual occurrence. On certain other less exposed paars it happens occasionally, and loss to a minor extent from overwashes of sand may occur almost anywhere under exceptional circumstances. For example, the disappearance, from the Muttuvaratu Paar, of 72 million oysters, one year old in 1897, before 1899 was probably due to this cause; and also the sweeping away, by an exceptionally strong current, of the oysters on the north end of the East Cheval Paar between November, 1887, and February, 1888.

(II.) Next in importance come, we consider, the ravages of natural enemies, the most noteworthy of which are:—

(*a*) Voracious fishes, chiefly rays (*Rhinoptera javanica* and other allied species) and file-fishes (*Balistes mitis*, *B. stellatus*, &c.).

(*b*) Boring Gastropod Mollusca, chiefly *Sistrum spectrum* and *Pinaxia coronata*, along with species of *Nassa*, *Murex*, *Purpura*, and *Turbinella*.

(*c*) Boring Sponges (*Cliona margaritiferæ*).

(*d*) Boring worms (*Polydora hornelli*).

(*e*) Starfishes, chiefly *Pentaceros lincki*, *P. nodosus*, and *Luidea maculata*.

(*f*) Smothering Lamellibranch Mollusca, such as *Modiola barbata*, the "Suran," which weaves nests and other entanglements around masses of young oysters, and may, when present in quantity, cause serious mortality.

(*g*) Crabs and cuttle fishes, and possibly other animals also, which can tear off the byssus and crush the shell.

(*h*) Associated animals, such as Corals, Barnacles, and Sponges, adhering to the shell, which, mechanically or by competition for food, cause injury and even death.

A few of these natural enemies call for some further remarks.

The file-fishes (several species of *Balistes*) and also the "Vellamin" (*Lethrinus*, spp.) feed upon immature oysters. We have found the broken shells in the stomach; but although these fish frequently snip pieces out of the margins of quite large shells, they probably do not destroy adult thick-shelled oysters. Shells which are rendered rotten by the borings of the sponge *Cliona* fall an easier prey to all oyster-eating fish.

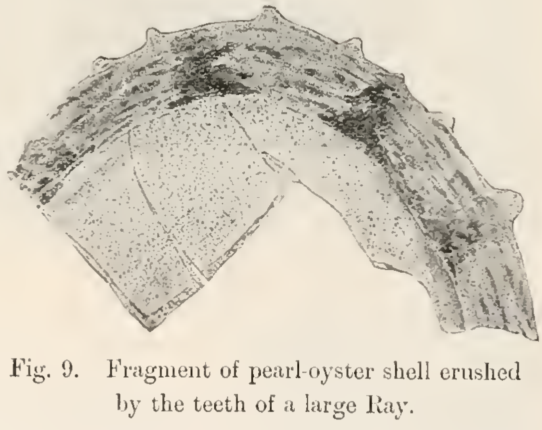

Fig. 9. Fragment of pearl-oyster shell crushed by the teeth of a large Ray.

The larger Elasmobranchs, such as the Eagle-Rays, and allied forms, may cause very serious reduction in a bed of mature oysters. In 1903 Mr. HORNELL found large rays feeding on the Periya Paar Karai, and, on exploring the bottom in a diver's dress, obtained abundance of the crushed shells left by the rays. Shells broken up by these fish have a peculiarly cracked and splintered appearance, which is characteristic (see fig. 9), the fragments of the brittle nacre being held together by the tougher prismatic margin.

In regard to these various fish enemies of the oyster it is necessary to bear in mind that, from the pearl-fisheries point of view, their influence is not wholly evil, as their ravages are closely associated with pearl-production. Although these fishes doubtless devour many of the oysters, at the same time they receive and pass on the parasite which leads to the production of pearls in others. One of the largest and most voracious of rays, *Rhinoptera javanica*, the "Valvadi tirikkai" or gregarious ray of the divers, we have found to be the host of the adult *Tetrarhynchus unionifactor*, which in its larval stages causes pearl-production in the oyster. The loss of some individuals from a bed is in that case a toll that we may willingly pay, and no one could advocate the extermination of that particular enemy, although we may desire to restrain his ravages within limits. During the fishery of 1889, the gregarious ray was present in such abundance that about 7,000 were caught in a single haul of a net, near Dutch Bay (see this vol., p. 61).

The Mollusca, which bore into shells by means of their radula, a toothed band lying in the floor of the mouth, are for the most part small Gastropods, and they are collectively known as "uri" by the divers. Fig. 10 shows a group of "uri" such as we have frequently caught in the act of penetrating the valve of a pearl oyster. It is chiefly young shells that are attacked, and amongst a large number of dead valves, about an inch in diameter, examined on one occasion, we found 60 per cent. were perforated by the neat circular hole which clearly indicated the cause of death. Probably adult pearl oysters are rarely killed by these small enemies.

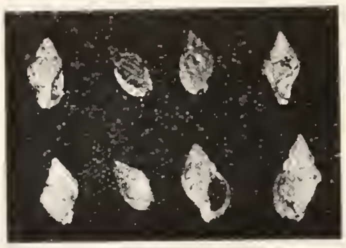

Fig. 10. "Uri," small Gastropods that destroy young pearl oysters by boring through the shells and sucking out the soft body.

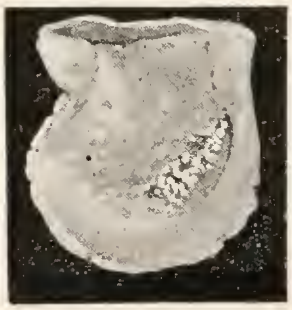

Fig. 11. Inside of pearl-oyster shell, showing adductor impression affected by *Cliona* borings on the outside. $\times \frac{1}{2}$.

During our work on the pearl banks we have not found a single full-grown shell perforated by a Gastropod. If such do occur, the enemy cannot be the small "uri" figured above, but must be more powerful animals, such as the larger species of *Murex* and the Chanks *Turbinella pyrum* and *Fasciolaria trapezoides*.

The boring Sponge, *Cliona margaritifera*, Dendy (see Part III., p. 128), may be considered damaging from two points of view—first, as causing thickened deposits of nacre and other irregularities, and hence disturbance of function, at the attachment of the great adductor muscle (see fig. 11); and secondly, as honeycombing the shell in all directions, rendering it so rotten that it can no longer hold together, and so falls an easy prey to any assailant. Many pearl oysters have their valves penetrated by *Cliona* to some extent, and in some beds a considerable proportion are as much affected as the example shown in fig. 12. This is a disease of adult life. Young shells never contain *Cliona*, and the older the affected oyster is the worse does it get. It will be noticed that the ravages of this sponge have a bearing on pearl formation. The more friable shells are eaten more readily by the voracious fishes, and consequently *Cliona margaritiferæ* may be regarded as facilitating the transference of the pearl-inducing parasite from the oyster to its ultimate host.

Fig. 12. Pearl-oyster shell honeycombed by *Cliona margaritiferæ*, DENDY.

Another boring enemy is the small Polychæte worm *Polydora* (or *Leucodore*) *hornelli*. It is questionable, however, whether this really does serious harm, except indirectly, in the case of the Ceylon pearl oyster. It no doubt, by its burrows between the layers of the shell, helps in disintegration; it lets in mud and sand-grains, and it is sometimes the cause of nacreous thickenings or blisters in the interior. It is not, however, of anything like the same importance as *Cliona* and the Gastropods, and cannot, taken by itself, be considered a cause of death. A few other organisms, lamellibranchs, worms, algæ, &c., bore in the pearl oyster's shell—which is sometimes a veritable microcosm containing representatives of nearly every group of the Invertebrata—but none of them do serious harm, and they need not be considered further.

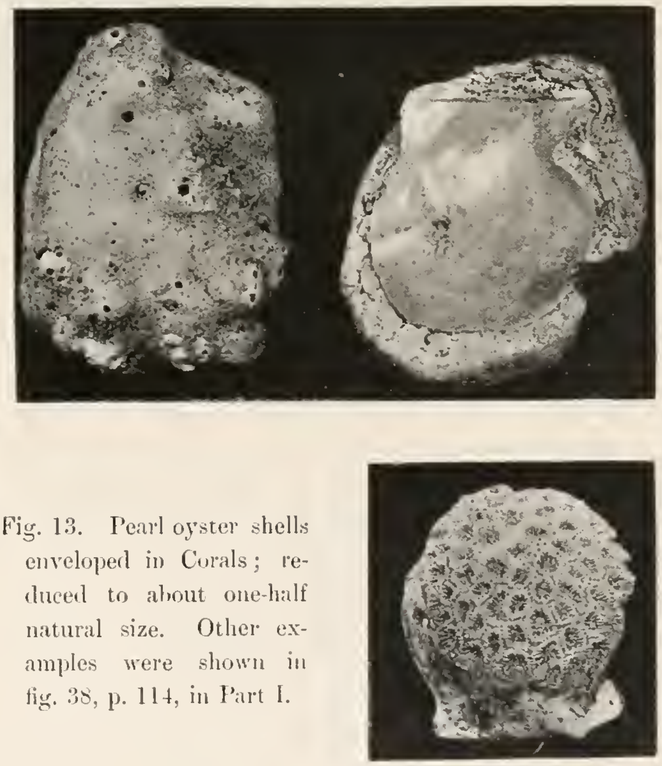

Fig. 13. Pearl oyster shells enveloped in Corals; reduced to about one-half natural size. Other examples were shown in fig. 38, p. 114, in Part I.

Similarly, the associated animals on the outside of the shell in most cases cause inconvenience rather than real injury. There are only two classes of cases where the matter may become more serious, (1) where rapidly growing corals and sponges of large size settle on the shell and practically envelop it (figs. 13 and 14) or overweight it to such an extent as to interfere with the movements and nutrition of the oyster; and (2) where the acorn-barnacles (*Balanus amphitrite*, and other species) spread, as they sometimes do, all over the shells, and are so large and active as to compete successfully for the microscopic food in the water and so lead to enfeeblement and, it may be, diseased conditions in the pearl oysters. Young barnacles in the Ceylon seas appear to settle down in April or May, and then grow with astounding rapidity, so that in a few weeks, rocks, shells, boats, stakes, ropes and any other objects in the water become covered with an almost continuous layer. The living corals on the surface of the shells may also act by depriving their host of food, and we certainly find that the Ceylon pearl oyster cannot exist on the living coral reefs or where there is much live coral scattered over the bottom.

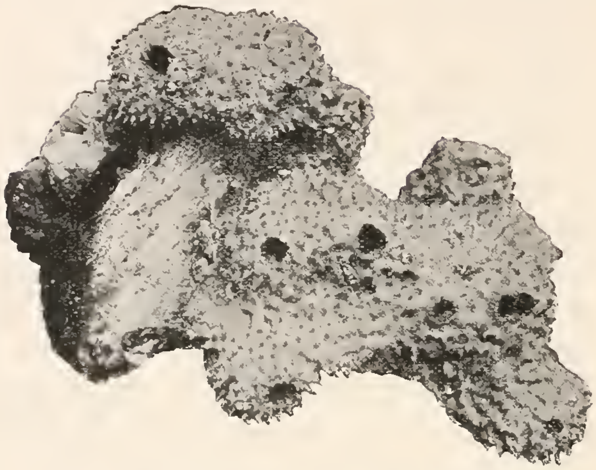

Fig. 14. Pearl oyster enveloped in a Sponge (*Pachychalina spinilamella*, DENDY).

The action of the little "smothering" mussel (fig. 15) called "Suran" by the divers is also, probably, partly mechanical and partly of the nature of competition for food. It weaves its tough byssal threads round neighbouring stones and dead and living oyster shells, entangling all in a matted mass in which it alone appears to flourish. It is, however, small and can have no effect upon adult oysters. It can only, then, do harm when it gets in large quantities amongst a bed of young oysters of its own size, and forms a blanket over and around them, interfering with respiration and nutrition. But it is very rarely sufficiently abundant, in Ceylon waters, to cause serious injury.

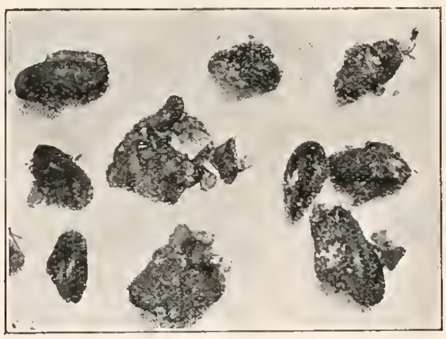

Fig. 15. "Suran," the small mussel (*Modiola barbata*) that entangles stones and small pearl oysters in its byssus; natural size.

Octopod cuttle fishes (such as *Polypus herdmani*) are abundant on some parts of the banks and are well known to subsist on oysters and mussels. Crabs are also numerous and no doubt cause some destruction; and there may be other members of the associated fauna that play their part in decimating the oyster beds.

Lastly, starfishes are probably the most serious of all invertebrate enemies. They are present in very large numbers on some parts of the pearl banks. We have a record that during the 1905 fishery, when the s.s. "Violet" was dredging for oysters on the South Modragam Paar, between 200 and 300 specimens of *Pentaceros lincki* and *P. nodosus* were brought up and destroyed each day.

Further, we know these starfishes to be exceedingly voracious, tenacious of life, active and fatal in their attacks on shell-fish. They seem to migrate from place to place in search of food, and are found to congregate round the rich feeding ground presented by a new oyster bed. One of the commonest kinds of the larger starfishes is *Pentaceros lincki* (fig. 16), known locally as the "Kondatchi Star," from its

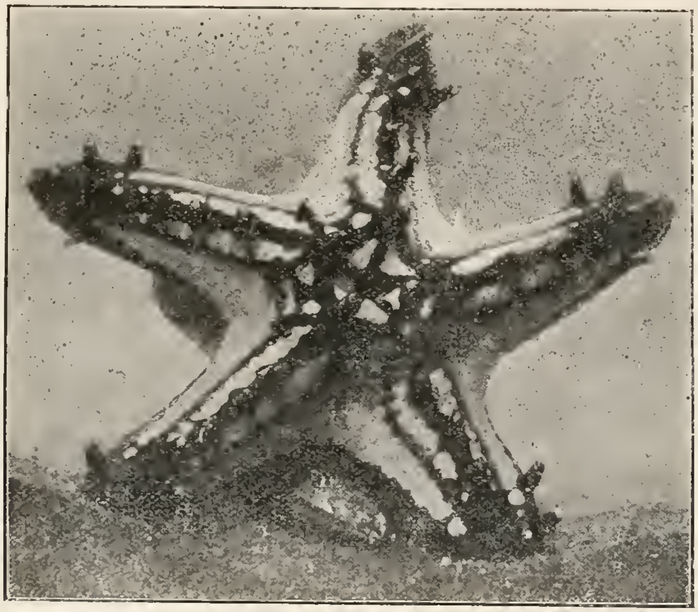

Fig. 16. *Pentaceros lincki*, DE BL., lying on a large pearl oyster, half natural size.

abundance on that paar. When we examined this bank in March, 1902, it had a bed of pearl oysters estimated at $5\frac{3}{4}$ millions. These had all gone by March, 1903, and it is probable that their disappearance may be accounted for by the very large number of starfishes present at that time.

(III.) There are still three other causes of death in pearl oysters that require mention, and may on occasion be serious, perhaps disastrous, *viz.* :—

(*a*) *Overcrowding.*—The older oysters are sometimes buried in masses of younger ones. The young are often piled together in such profusion as to interfere with each other's nutrition and growth. Thinning out must—and does—take place. If we don't do it, Nature does it for us. If it were done artificially, by transplanting some, all or nearly all might be preserved ; if we leave it to be effected naturally by survival of the fittest, the survivors may be very few indeed.

(*b*) *Disease*, due to the invasion of parasites, either (1) worm parasites which are moderately large and usually not very numerous, and which, unless abnormally abundant, probably do little or no harm; or (2) the more minute and more deadly protozoon parasites, such as sporozoa, which may on occasion be present in enormous quantities, and probably cause epidemic diseases. We have in various cases found sporozoa in the tissues of the pearl oyster. We also know that a bed of adult oysters may get into bad condition, the individuals becoming thin, discoloured and feeble; and under such circumstances rapid decimation takes place, and the bed, although not yet arrived at old age, may be practically wiped out by what is clearly a parasitic disease. It is highly probable that such diseased conditions are, if not the result of, at least generally concomitant with, overcrowding. For example, the Muttuvaratu Paar seems especially liable to dense deposits of spat, leading to overcrowding; and in our experience the oysters are more diseased and stunted and feeble on that paar than anywhere else.

(c) *Over-fishing.*—This is the exhaustion of the breeding stock of the district at a time when no further supplies of young in the larval stages are being brought by currents from neighbouring grounds. That, however, will comparatively rarely happen, and is only likely to be serious during the last year of a series of fisheries. So long as there are oysters in their second or third years on adjoining paars, which will be fished in the two succeeding years, it is safe—so far as the reproduction of the race is concerned—to take every older oyster that can be got from the ground, as those coming on, although not yet ready to be fished, are sexually mature, and may be relied upon to supply spat. But in the final year of a series of fisheries, when no further mature oysters remain for the following years, it is important to leave sufficient stock for breeding purposes. The complete clearing of the ground, which has sometimes been put forward as the ideal to aim at in a fishery, may be a short-sighted and disastrous policy.

In the future, however, if transplanting on an adequate scale is adopted, it may be expected that such a state of affairs as the last fishery of a series with no younger oysters growing up in the neighbourhood will be very unlikely to occur. Each individual case must, however, be considered on its merits, and the Marine Biologist, after an inspection of the banks, should be able to advise how the maintenance of adequate breeding reserves of adult oysters may best be secured.

VI. The Production of Pearls.

As pearl-formation is discussed very fully in another section of the present volume, it is unnecessary here to do more than add a very few sentences for the sake of completing this summary of results. In the Ceylon oyster there are several distinct causes which lead to this unhealthy or abnormal process, the production of pearls. Some pearls or pearly excrescences on the interior of the shell are due to the irritation caused by boring sponges and burrowing worms. Minute grains of sand and other foreign particles gaining access to the body inside the shell, which are popularly supposed to form the nuclei of pearls, only do so, in our experience, under exceptional circumstances. In the whole of our observations we have only records of three cases in which a grain of sand undoubtedly formed the nucleus of a pearl.

Pearls of another class are found in the muscular tissue of the animal, most frequently in the levators, in the palpar region, and in the pallial insertions. These muscle pearls have no visible foreign bodies as nuclei. They form around minute calcareous concretions—the calcospherules—which are sometimes very abundant in the tissues. Yet the pearls are very irregularly distributed. Single oysters have been known to contain from one to two hundred pearls, and, on the other hand, a hundred oysters may be opened without finding a single pearl.

The best pearls, however, the " fine " or " orient " pearls, lie in the pallial connective tissue at the sides of the body or in the tissues around the liver and kidney, or, when large, they may be free in any cavity of the body. The majority of these fine pearls contain as their nuclei the more or less easily recognisable remains of certain Platyhelminthian parasites, which we identify as the larval condition of Cestodes belonging to the genus *Tetrarhynchus*. The evidence for this will be found in the section dealing with pearl-formation (this vol., p. 19), and a description of the probable species of *Tetrarhynchus* in question will be found in SHIPLEY and HORNELL'S report on the parasites (p. 87). We have traced most stages in the life-history of this pearl-producing *Tetrarhynchus*, and find that it passes, in the adult condition, into the body of one of the larger carnivorous fishes—*Rhinoptera javanica*, a Ray. The adult parasitic worm in its last host must then set free its numerous young embryos, which pass into the sea and so gain access to the gills, liver, and mantle of the pearl oyster. But it is not sufficient for the oyster to be infected by the *Tetrarhynchus* larva. It must also live, retaining its parasite until such time as it can produce sufficient deposit of the calcareous secretion to entomb the living source of irritation, which thus becomes the nucleus of a pearl. This history is discussed more fully in another section of this volume (p. 14).

The Cysticercoid cysts of the *Tetrarhynchus* larvæ are frequently very abundant in the liver of the pearl oyster. In the case of some paars, the Muttuvaratu especially, scarcely any of the individuals examined are free ; we have counted eleven encysted larvæ in a single liver. In the gill filaments and in their membranous bases also they are common, while in many cases the mantle is infested. The gonads, the foot and the palps all occasionally harbour the parasite. The muscles are the only large organs where the cysts are rarely found. In one individual oyster Mr. HORNELL made out a total of 45 cysts for all the tissues. It may be well to repeat here that the Cestode parasites are not only common, but are also apparently very wide spread and generally distributed, and that the fish-host with its parasite occurs also generally in the seas around the Island, as well as in the Gulf of Manaar ; and that, in short, there can be no doubt as to the probable infection of pearl oysters grown at any other suitable localities around Ceylon

Pearl production in the Ceylon oyster does not commence actively until the third year of life, and progresses most rapidly after the fourth year. An example or two taken from the history of beds of known age will show how important it is to let the oysters have any time that is possible after the fourth year in which to increase, not in size, and certainly not in numbers, but in value. The successive valuations of the bed ot oysters now being fished on the Muttuvaratu Paar was as follows :—

In November, 1903, at the average age of $2\frac{1}{2}$ years, 1·50 rupees per thousand.
,, 1904, ,, ,, $3\frac{1}{2}$,, 3·15 ,, ,,
,, 1905, ,, ,, $4\frac{1}{2}$,, 22·69 ,, ,,

Finally, these oysters have sold (March, 1906) at prices frequently exceeding 30 rupees per thousand, and on one day even exceeding 40 rupees.

A striking example of increased pearl-production, and enhanced market value, is seen in the case of the remainder of a large bed of oysters on the South-east Cheval, most of which was prematurely fished along with the South Cheval in 1905.

In November, 1904, it was valued at 10·76 rupees per thousand.
,, 1905, ,, ,, 52 to 58 ,, ,,

In March, 1906, the oysters when fished sold, after the first week, at rates ranging from 112 to 282 rupees per thousand.

These oysters were, on the average, 3 years old in November, 1904, and were therefore fished in 1905 when under 4 years. At the present time those that remain are in their fifth year; and if the whole of this bed, with the neighbouring South Cheval of the same age, had been held over for the present fishery (1906), there can be no doubt that, although the number of oysters might have been somewhat reduced, the increase in pearls and in value would have been great.*

VII. Dredging.

The results of our cruises in the "Lady Havelock," detailed in the "Narrative," showed clearly the advantages of dredging both as a method of exploring and surveying the banks, and also for the purpose of raising considerable quantities of oysters from the bottom in a short time. Worked from a handy, seaworthy vessel, of the type of a large tug, or a modern steam trawler, with a steam winch near the stern, the dredge becomes in practised hands an instrument of precision, and will bring up a fair sample of everything on the ground, including the bottom deposit.

* A letter just received from the pearl-fishery camp at Marichchukaddi states that "the merchants are very pleased with the oysters of the South-east Cheval." . . . . "They say there never has been anything like it as to results, and large profits have been made by several."

Moreover, the operation is a speedy one. A line of soundings and dredgings can be run over a very considerable area in one day's work, and a much larger and more continuous, and therefore more representative, sample obtained than would be possible by diving. From such a steamer, on the occasion of a fishery, six dredges at least could be worked simultaneously, and mechanical contrivances might be devised for increasing the number still further. There need be no fear that dredging operations will be destructive to any young oysters that may be mixed with the old, or will in any way damage the ground as an oyster paar. Dredging is the usual practice on oyster beds in Europe and America, and it is well known that a certain amount of dredging improves the condition of a bed.

Our results on the "Lady Havelock" showed that neither young nor old oysters brought up by the dredge are injured, and it would be a simple matter on the steamer to separate the young and return them to the water or transport them to other ground; while it would be very difficult, if not impossible, to get this done in the divers' boats under present conditions.

On several occasions, as shown in the "Narrative," we discovered, by dredging, considerable numbers of pearl oysters on spots not recognised as known "paars." I feel confident, from the nature of the ground and our knowledge of other conditions (such as depths, currents, and the free-swimming stages of the young pearl oyster), that new deposits of spat must make their appearance from time to time at new localities, and may appear any time on some grounds outside the recognised paars—and all such new beds will probably remain unknown unless discovered by dredging traverses across the whole oyster-bearing plateau of the Gulf of Manaar. At several localities we examined the ground outside the known paars down to the 100-fathom line, with the view of ascertaining whether there is any evidence in support of statements which have sometimes been made to the effect that there were probably unknown beds of pearl oysters further out and in deeper water, from which spat was produced for the supply of the in-shore paars. No such evidence was obtained. All fresh spat which has appeared in the past after grounds have been cleared by fishing must, then, have come from other beds of adult oysters upon the plateau within the 10-fathom line—beds which have remained unknown and unfished. Kutiramalai Paar, fished in 1905, is an instance of a great bed of oysters growing to maturity outside the limits of the recognised paars. At the inspection which followed the fishery in the present year, Mr. Hornell found mature oysters in quantity to the north-north-east of the Muttuvaratu on ground that is not recognised as a paar and has never been inspected.

In addition to beds of adult oysters which may in this way be found by dredging traverses, it must be remembered that newly-established deposits of young oysters upon unsuitable ground where they cannot mature will be certainly made known from time to time, and this will give the material for re-planting paars recently cleared by a fishery. Our experiments showed that young oysters are more easily transported than older ones, and more readily re-establish themselves on new ground.

The thinning out of overcrowded beds, sometimes a very necessary operation, can be carried on concurrently with transplantation to a depleted area. For example, in November, 1905, the dredging carried on amongst the overcrowded young oysters of the Mid-east Cheval relieved pressure on that bed and at the same time provided a stock for replenishing the denuded South Cheval Paar.

As I have pointed out in a previous volume of this Report, it must be remembered that the utility of dredging is by no means confined to the finding and fishing of adult oysters, but is really manifold, and consists in the following, at least :—

(*a*) In exploring the ground ;
(*b*) In fishing oysters ;
(*c*) In cleaning the ground and removing starfishes and other enemies ;
(*d*) In thinning out overcrowded beds ;
(*e*) In oyster transplantation.

The value of dredging is not properly assessed if account be taken of only one of these, such as fishing, or even of fishing and transplanting alone. Finally, it is important to bear in mind that several of these useful operations can usually be carried on simultaneously in the same series of dredgings.

VIII.—Other Marine Economic Work.

In regard to the fish-trawling operations, I have to report that the greater part of Palk Bay presents a large open expanse with a uniform soft bottom suitable for trawling. Our hauls in both the northern and the southern parts of the area showed that there are plenty of fish, and apparently this shallow sea serves as a very valuable nursery for young sea-fish. We also found off Galle, to the east of the Gallehogalle Bank, at a depth of 25 to 30 fathoms, an area which may be regarded as a fish-nursery. Here it is evident that the young of both flat and round fish, belonging to about ten species and including such valuable forms as may be called "Soles," "Turbot," and "Plaice" (although not the same species as those in home seas), congregate in large numbers.

Fig. 17. The commercial sponge (*Euspongia officinalis*, var. *ceylonica*) from Trincomalee, as seen when alive ; reduced in size.

It will naturally be part of the duty of the Marine Biologist to the Colony to make himself acquainted with the conditions of the native fisheries, and be prepared to advise as to whether facilities should be given for introducing trawling in suitable localities, or whether any regulations are required for the protection of the fish-nurseries.

As an example of an additional investigation such as will naturally be undertaken by the Marine Biologist, I may note that during our visit in February, 1902, to Trincomalee, we found the commercial sponge living in the harbour (fig. 17). I asked Mr. HORNELL to return later in the year and look into the matter. He did so in October, and was very successful in determining the localities and mode of growth of the sponge—which is a variety of the true *Euspongia officinalis*, and is very similar to the Mediterranean form. Professor DENDY, the sponge specialist, who has examined samples for me, thinks well of the quality, and says, "the possibility of establishing a sponge-fishery is worth consideration" (see also Part III., p. 211).

Fig. 18. The edible rock oyster of Ceylon (*Ostrea cucullata*).

An edible oyster (*Ostrea cucullata*, see fig. 18) is abundant on some parts of the Coast of Ceylon. The "trepang" and other marine industries are also worthy of attention.

IX. THE MARINE BIOLOGICAL STATION.

For the proper carrying out of our work in Ceylon it was found necessary to fit up the scientific man's workshop—a small laboratory on the edge of the sea, with experimental tanks, a circulation of sea-water and facilities for microscopic and other work. For several reasons, which were given fully in the "Narrative" (Part I., p. 87), we chose Galle at the southern end of Ceylon, and we had, at first, every reason to be satisfied with the choice. With its large bay, its rich fauna and the sheltered collecting ground of the lagoon within the coral reef, it is probably one of the best possible spots for marine biological work in Eastern tropical seas. But as time went on it became clear to Mr. HORNELL that, for experimental work with the pearl oyster, such as he required to undertake in the course of his investigations, a larger area than could be obtained in artificial tanks, and a more sheltered one than the bay at Galle during the south-west monsoon, was essential. Fortunately, some very suitable buildings, in the best possible place, then passed into the hands of the Colonial Government through the abandonment of Trincomalee as a Naval Dockyard Station; and on being consulted last year by Sir HENRY BLAKE and the Colonial Office, I was able to concur with Mr. HORNELL and recommend strongly that the Marine Biological Station be transferred from Galle, in the south of the island, to the former Naval Hospital at Trincomalee, on the north-east coast. That transference has now been effected, and the magnificent almost land-locked inner bay at Trincomalee, in which pearl oysters naturally live in shallow water, is now available for experimental scientific work at all times of the year.

It is clear to me, in concluding this Summary of Results obtained so far, (1) that there is still a great deal of biological work that must be done in connection with all the Ceylon marine fishing industries; and (2) that the Marine Laboratory now at Trincomalee, enlarged if necessary and more fully equipped, is the best place in which to carry on all such investigations, and ought in the future to play an important part in the scientific work of the colony.

B.—RECOMMENDATIONS.*

The following Recommendations are based upon the conclusions briefly given in the preceding pages and also upon the detailed evidence in the "Narrative" and other sections in the preceding volumes of this Report.

1. That dredging be employed extensively to supplement diving operations, either wholly or in part, both on the inspections and also, where possible and when desirable, at the fisheries.

* These Recommendations, sent to the Governor of Ceylon in September, 1903, as a private document accompanying an "advance" printed copy of the first volume of this Report, are subordinate to my primary proposition, which was that the Colonial Government should appoint a Marine Biologist to carry on the investigations I had started. This proposition and my further recommendation that Mr. JAMES HORNELL, F.L.S., should be appointed to the post, were adopted, and Mr. HORNELL commenced his work as Marine Biologist to the Government on January 1st, 1904. A few weeks later, on the retirement of the Master Attendant of Colombo from the office of Inspector of Pearl Banks, the duties of the latter post were, temporarily, added to those of the Marine Biologist, and since that date Mr. HORNELL has acted in the dual capacity, and has thus discharged both advisory (biological) and executive (inspectional) functions in connection with the pearl banks during the last two years. The record fisheries of 1904 and 1905 have taken place under the new auspices, and of the latter (the great fishery of 1905 which brought in over £150,000 profit to the Government) it is gratifying to find that His Excellency Sir HENRY BLAKE has placed on record in his despatch of June 14th, 1905, to the Secretary of State that "This result is due to the careful and methodical examination of the banks by Mr. HORNELL."

2. That a steamer be provided, of the type of a modern steam-trawler, from which a number of dredges could be worked simultaneously; and be fitted with tanks or "fish-wells" in which large numbers of pearl oysters could be transported.

3. That attention be paid to inspecting not merely the known paars, but also to traversing with the dredge at least once a year certain lines across the pearl bank plateau, in order to search for new deposits of oysters.

4. That whenever young oysters are found in quantity on the Periya Paar or other localities where there is very little prospect of their ever arriving at maturity, as many as possible should at once be dredged up and transplanted to more favourable grounds, to be determined by careful examination of the bottom conditions and the stock of oysters already present.

Such transplantation, in order to be successful, must be conducted on a large scale. There can be no doubt that even healthy beds of oysters on favourable ground tend to diminish as they grow older, and may sometimes from the action of their natural enemies become greatly reduced in numbers before arriving at fishable age. The bed of $1\frac{1}{2}$-year-old oysters on the Muttuvaratu Paar, which was estimated in March, 1902, as 277 millions, was found in November, 1904, to be reduced to about 20 millions. Again, the bed of 3-year-old oysters on the West Cheval Paar, estimated at 123 millions in February, 1902, was found two years later to be reduced to 35 millions. No doubt these are exceptional cases, but the conclusion to be drawn is that in transplanting young oysters it is necessary to deal with large numbers, so as to allow for the natural decrease which will inevitably take place.

5. That during an inspection, or a fishery, when large quantities of young pearl oysters are found associated with older ones, or when an immature bed is obviously overcrowded, as many as possible of the young should be removed, by dredging and sorting, and be saved by transplanting to other paars unoccupied at the time. Dredging can also be made use of to remove great numbers of sponges, crabs, star-fish, and other enemies of the pearl oyster from the productive paars.

6. That if dredging cannot be wholly substituted for diving at the fisheries, at least the dredges should be kept in readiness, so that in the event of the divers failing to obtain sufficient oysters in the limited time, or in case the fishery should be unfortunately stopped prematurely by an epidemic or other unforeseen occurrence, the remaining mature oysters on the bottom may not all be lost, but may, by means of the dredges, be brought to the surface speedily in bulk.*

7. In order to increase the area available for the attachment and growth of young pearl oysters, large areas of the sandy bottom adjoining the more important paars, especially the Cheval Paar, should undergo artificial "cultching," that is, should have broken material, such as fragments of dead coral, lumps of rock and other rubble, scattered over the bottom. Such material can be obtained in quantity close to hand

* On February 4th, 1902, on the Periya Paar, in 15 minutes, one dredge brought up 14,912 young pearl oysters,

on the shores and reefs of the Gulf of Manaar, and the transport and distribution could be effected easily by means of the steamer.

8. In order to facilitate the search for new deposits of young oysters, "drift-bottle" experiments should be made, so as to determine the prevalent currents in the Gulf of Manaar, at the breeding times of the oysters.

9. Very young "spat," such as is sometimes found in great abundance attached to floating weeds, should be saved from being carried away by the currents, and may be deposited on the bottom along with suitable cultch, to which it can adhere.

10. That, in order to determine when and how the dredges should be used; where from and where to, and in what quantities, the transplantations of young oysters should be made; which mature oysters, if any, should be retained as a breeding reserve: where and how the "cultching" should be carried out, and similar matters, a Marine Biologist should be appointed as a permanent official to take part in all inspections and fisheries, to advise as to the farming operations, and carry out the work when sanctioned, and generally to supervise the pearl-oyster banks and assist in regulating the fisheries.

11. That the Marine Biologist be charged, as his first duty, with the farming of the pearl-oyster banks in such a manner as to aim at ensuring a more constant supply of mature oysters. He should search at each inspection, and where possible during a fishery, for new spat and for fresh beds of young oysters, should locate the oysters of different ages, transplant them when necessary, thin them out when overcrowded, remove young which would necessarily be killed during the fishing of the old, or would prevent their neighbours' growth; and thus he should endeavour to have all the more reliable paars occupied by stocks, some in one and some in another stage of growth, and to bring on a succession of adults ready for fishing. He should also see to the cleaning of the banks by dredging and the removal of enemies of the pearl oyster, should improve the bottom by laying down artificial cultch, and should maintain adequate breeding reserves of adult oysters. He should advise in all cases that the order of fishing of the beds be determined by practical biological considerations, affecting not merely the interests of a particular fishery, but the future prosperity of the industry.

12. That during the time of the monsoons, when it would be impossible to work in the Gulf of Manaar, the Marine Biologist should carry on his investigations at the marine laboratory. There will be plenty to do in connection with the life and growth of the pearl oyster, and the formation and abundance of pearls, to occupy his attention even if he had no other work.

But as secondary duties, when not fully occupied with pearl-oyster questions, I would recommend that the Marine Biologist should be instructed to investigate the "window-shell" oyster fishery at Tampalakam, the pearl oyster at Trincomalee and elsewhere on the East Coast, the edible oyster at various localities, the trepang fishery, chank diving, the possibility of establishing a commercial sponge fishery at

Trincomalee, and the native fish-trawling industries. With these and other practical applications of science which he would discover and make known, the time and energies of the Marine Biologist would be more than fully occupied throughout the year in useful work for the Colony.

13. If these recommendations are adopted and a Marine Biologist is permanently charged with the work of conserving and promoting the pearl-oyster and other fisheries, he must be given the means of carrying on his work satisfactorily. For inspecting, dredging, cultching, and transplanting, a steamer is necessary. It need not be large nor swift, but it must be fit for the work and specially fitted with the tanks, winch, dredges, &c., which will be necessary. He will also require laboratory equipment on shore, and the usual mechanical and clerical assistance; but it is not obvious that any useful purpose can be served, under the circumstances, by establishing a small laboratory at Aripu or elsewhere in the Gulf of Manaar (as had been suggested). It must be clear to any scientific man who knows the locality that any biological work on the pearl banks must be done at sea, from a ship, during the inspections and fisheries, and cannot be done at all during the monsoons because of the heavy sea and useless exposed shore. At these latter times the necessary laboratory work, supplementing the previous observations at sea, could be done much better at Colombo, at Galle, or at Trincomalee, than at Aripu or Manaar.

14. Consequently I recommend that the Marine Biological Laboratory, now at Trincomalee, be regarded as the headquarters of the Government Marine Biologist's work; and that, in the interests both of the various fishing industries and also of scientific investigation in general, the institution be established at once on a permanent basis, with suitable assistance and equipment. The building ought, moreover, to be of sufficient size to accommodate two or three additional zoologists, such as members of the Staff of the Museum and of the Medical College at Colombo, or scientific visitors from Europe. The work of such men would help in the investigation of the marine fauna and in the elucidation of practical problems, and the laboratory would soon become a credit and an attraction to the Colony. Such an institution would be known throughout the scientific world, and would be visited by students of science from other countries, and it might reasonably be hoped that in time it would perform for the marine biology and the fishing industries of Ceylon very much the same important practical functions as those fulfilled by the celebrated Gardens and Laboratory at Peradeniya for the botany and associated economic problems of the land.

W. A. Herdman.

EXPLANATION OF PLATE.

LIFE-HISTORY OF PEARL OYSTER.

REPORT

ON THE

CIRRIPEDIA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

N. ANNANDALE, D.Sc., C.M.Z.S.,
DEPUTY SUPERINTENDENT OF THE INDIAN MUSEUM, CALCUTTA.

[WITH NINE TEXT ILLUSTRATIONS.]

INTRODUCTORY.

I HAVE to thank Professor HERDMAN for sending his Ceylonese Barnacles to me for description. The collection is small, including examples of only eleven species; but some of these species are of considerable interest. Indeed, so little is known of the Indian Cirripedes that any specimens with accurate localities are of value. Professor HERDMAN has asked me to add to my report a list of the species known from Ceylon and the Gulf of Manaar. I have interpreted the request freely, adding notes as well as names in the case of forms of which I have examined specimens, even if they are not represented in the collection under review.

Every addition to our knowledge of the Barnacles tends to prove the wide distribution, not only of genera, but even of species and varieties. It is, therefore, impossible to draw precise geographical conclusions from the presence of any form in a local fauna, while its absence often means no more than that it has not been observed. The following list, in which the species obtained by Professor HERDMAN are indicated by a star, gives the names and known distribution of those recorded hitherto or for the first time in the present Report. There can be no doubt that further research will greatly increase the number found both in the Gulf of Manaar and in the Bay of Bengal.

Professor HERDMAN informs me that some species of *Balanus* are of real economic importance in competing for food with the pearl oyster in the Gulf of Manaar.

BARNACLES KNOWN FROM CEYLON.

LEPADIDÆ.	DISTRIBUTION.
1. *Lepas anserifera*, L.	Cosmopolitan.
*2. ,, *anatifera*, L.	,,
3. ,, *tenuivalvata* (ANNAND.)	Ceylon.
4. *Dichelaspis equina*, LANCH.	East coast of India, Maldives, Ceylon, Burma, Malaya.
5. ,, *pellucida*, DARW.	East coast of India, Ceylon, Burma.
6. *Pœcilasma kæmpferi*, DARW.	Gulf of Manaar, Malaysia, Japan, Madeira.
7. *Scalpellum gruvelii*, ANNAND.	Gulf of Manaar, Laccadives, Andaman Sea (859 to 1022 fathoms.)
8. ,, *alcockianum*, ANNAND.	Gulf of Manaar, Andaman Sea (859 to 960 fathoms).
9. ,, *japonicum*, HOEK	Gulf of Manaar (595 to 556 fathoms); Japan (565 fathoms).
10. ,, *squamuliferum*, WELT.	Deeper Indian seas (112 to 1840 fathoms); Japan.
? ,, *truncatum*, HOEK	Between New Guinea and Australia (1400 fathoms); (?) Gulf of Manaar (590 fathoms).
11. ,, *tenue*, HOEK	South of Indian Ocean (1375 fathoms); Gulf of Manaar (595 to 556 fathoms); Bay of Bengal (199 fathoms).
12. ,, *subflavum*, ANNAND.	Gulf of Manaar, Gulf of Oman, Andaman Sea, west coast of India (130 to 700 fathoms).
BALANIDÆ.	
13. *Chelonobia testudinaria* (L.)	Gulf of Manaar, warm and temperate seas.
14. *Creusia spinulosa*, LEACH	Ceylon, Indian Ocean and Central Pacific, West Indies
*15. *Pyrgoma conjugatum*, DARW.	Red Sea, Ceylon, Mergui.
*16. *Tetraclita serrata*, DARW.	South Africa, Ceylon.
*17. *Acasta cyathus*, DARW.	Ceylon, South America, Australia, Madeira.
*18. ,, *funiculorum*, n. sp.	Ceylon.
*19. *Balanus tintinnabulum* (L.).	Cosmopolitan.
*20. ,, *amphitrite*, DARW.	Warm and temperate seas.
*21. ,, *amaryllis*, DARW.	Indian Ocean and Central Pacific.
*22. ,, *allium*, DARW.	Red Sea, Ceylon, Western Australia.
*23. ,, *terebratus*, DARW.	Maldives, Ceylon.
*24. ,, *æneas*, LANCH.	Malaya,† Ceylon.
*25. ,, *maldivensis*, BORR.	Maldives, Ceylon.
‡26. *Chthamalus stellatus* (POLI)	Warm and temperate seas.

† It is convenient to confine the term "Malaya" to the Malay Peninsula, south of the Isthmus of Kra, and the small adjacent islands, such as Singapore and Penang, giving "Malaysia" a wider significance, to include the great archipelago.

‡ In addition to the above-mentioned species, I have lately examined specimens of a variety of *Conchoderma hunteri*, OWEN, taken by Mr. E. E. GREEN on a sea-snake (*Hydrus platurus*) from Ceylonese waters. Their valves are of typical form, but very small and feebly calcified. The relative length of the peduncle varies considerably. The integument is transparent and almost colourless; but faint vertical bars can be detected on it in certain lights.—*April* 30, 1906.

DESCRIPTION OF THE SPECIES.

LEPADIDÆ.

***Lepas anatifera**, L.

Localities:—Galle (on a buoy rope) and Cheval Paar, Gulf of Manaar.

Several of the specimens from the Cheval Paar belong to Darwin's var. A.

It is often almost impossible to distinguish tropical examples of this species from *L. anserifera* by mere examination of the shell. The pale colour of the upper part of the peduncle is a good diagnostic character of the latter, but one which cannot always be detected in faded or shrunken specimens. The only safe method of distinguishing the two species is to examine the filamentous appendages.

L. anserifera appears to be more abundant in the Bay of Bengal than *L. anatifera*. So far as my experience goes, examples of both species from the Indian region are generally small; indeed, it seems probable that they do not reach the same dimensions, except very occasionally, as those attained by individuals reared in higher latitudes. Their stalk, especially, is frequently stunted.

Lepas tenuivalvata (Annandale) (**14**).

In my account of this species (as *Dichelaspis tenuivalvata*) I did not describe the penis or the anal appendages. Having now been able to dissect a specimen in detail, I am in a position to give an account of these organs. The penis is long, slender, tapering, with a few scattered hairs on its surface. The anal appendages are uniarticulate, claw-shaped, and naked. Taking these characters into account, the species should probably be placed in the genus *Lepas*. In placing it in *Dichelaspis*, I relied chiefly on the shape of the carina. The specimens are probably immature, but the shape of this valve distinguishes it from any other representative of the former genus.

Dichelaspis equina, Lanchester (**8**).

Some doubt as to the difference between this species and Gray's *Octolasmis warwickii* is hinted at by Gruvel (**10**). The most constant external character of the former is the division of the carina into two parts by a horizontal cleft near the base of the capitulum. I have now examined a large number of specimens, which vary greatly as regards the shape of the terga and the transparency of the membrane, and all agree in this respect. It seems to be a good specific character; but two distinct forms have probably been confused, if Darwin's figure (**1**) is correct, under the name *D. warwickii* (see figs. 2 and 3).

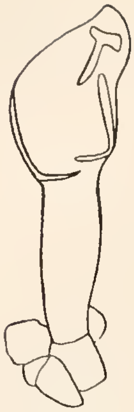

Fig. 1A.

Fig. 1.

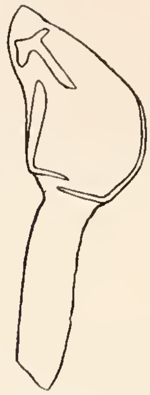

Fig. 1B.

Fig. 2.

Fig. 3.

Figs. 1, 1A, 1B. *Dichelaspis pellucida*, DARWIN. Fig. 2. *Dichelaspis equina*, LANCHESTER.
Fig. 3. *Dichelaspis warwickii* (GRAY)—After DARWIN.

D. equina is the commonest member of its family found attached to crabs from shallow water off Ceylon and the east coast of India.* It occurs both on species which swim near the surface and on those which crawl on the bottom, and is occasionally taken on sea-snakes, though less frequently than *D. pellucida*. On the crabs it does not confine itself to any particular part of the body. The following is a list of the Crustaceans on which I have found it :—*Neptunus gladiator*, *N. pelagicus*, *Scylla serrata*, *Doclea ovis*, *Egeria sp.*, *Areania septemspinosa*, and *Dorippe dorsipes*.

Dichelaspis pellucida, DARWIN (**1**).

I have recently examined a considerable number of specimens of this species from the coasts of Burma and Ceylon. They vary considerably not only in size and in the shape of the valves, but also as regards the degree of calcification of these structures and of transparency of the membrane, as well as the form and the relative proportions of the peduncle and capitulum. Figs. 1, 1A, and 1B show the outline of some specimens in the Indian Museum. Transparency, outline and proportions probably alter considerably if specimens are not carefully preserved. It seems not improbable that DARWIN'S *D. grayii* and *D. pellucida* are identical, in which case the former name would have precedence, as the description is printed before that of *D. pellucida*. I have no doubt that GRUVEL'S *D. lepadiformis* also belongs to the same species, although I separated it in my recent list of the Indian Lepadidæ (**13**). His account of the penis (**12**), which is the most striking feature of the form, does not differ very materially from HOEK'S description of that of *D. pellucida* (**4**), to which description no reference is given in GRUVEL'S monograph. Judging from specimens I have examined, the exact outline of the penis in the more

* Since this was written specimens have been received at the Indian Museum from the Persian Gulf.—*April* 30, 1906.

delicate species—and *D. pellucida* is one of the most delicate—depends to some extent on the state of preservation of the specimen examined.

D. pellucida has only been found on sea-snakes. It occurs most commonly, in Indian seas, on *Hydrus platurus;* but I have seen it on more than one species of *Distira.*

Pœcilasma kæmpferi, DARWIN **(1).**

The Ceylonese specimens (from 430 fathoms in the Gulf of Manaar) I have examined belong to the typical form of the species, which is probably circumtropical. It is found attached to various prawns.

Scalpellum gruvelii, ANNANDALE **(15).**

I give an outline of the valves of this species (fig. 4). It is one of the larger members of the section of its genus with imperfectly calcified valves, the figure being twice natural size. In the variety *quadratum*, also from the Gulf of Manaar, the carina is much more strongly bowed, and in the typical form the preumbinal portion of the carina is often relatively more extensive. The section to which this species belongs merges gradually into that with fully calcified valves, but the division is convenient for the sake of reference. In *S. gruvelii*, as in *S. alcockianum*, *S. laccadivicum*, and *S. japonicum*, the plates are actually imbedded in membrane, and traces of the imperfectly calcified parts which are not fully formed can be detected. In *S. inerme** from near Java, on the other hand, not only are the valves very much stouter, despite the shape of the tergum, but they are lightly attached to the inner surface of the membrane and their outlines are quite sharp.

Fig. 4. *Scalpellum gruvelii*, ANNANDALE. × 2.

S. gruvelii is only found at great depths, at which it is not uncommon in the Indian seas.

Scalpellum japonicum, HOEK **(3).**

Locality :—Gulf of Manaar, 595 to 556 fathoms (R.I.M.S. Ship "Investigator").

Col. ALCOCK has recently called my attention to certain Barnacles attached to living shells of *Turbo indicus* from the above locality. Two of them agree with HOEK'S description and figures of *S. japonicum* from Japanese seas. *S. laccadivicum*, which will also be found (in all probability) in the Gulf of Manaar, is related to this form, but has the valves less imperfectly calcified, especially in the variety *investigatoris.*

* I understand that HOEK regards this form as a variety of *S. stearnsii*, PILSBURY ; but his paper, read before the Royal Academy of Sciences of Amsterdam in January, has not yet reached Calcutta.—*April* 30, 1906.

Scalpellum squamuliferum, WELTNER (6).

The adult of this Barnacle is characterised by the possession of two well developed ovigerous lamellæ, which are absent from young specimens. They take the form of stout filamentous outgrowths of the integument of the body wall, rounded posteriorly and grooved on their anterior surface. The tip is generally pointed, but may be bifid, and the lamella is often more or less distinctly jointed. The lamellæ may be compared as regards relative position and extent with those of *Cryptophialus*, being situated, one behind the other, on the dorsal aspect of the thorax; the eggs form a two-layered, coherent mass surrounding the back and sides of the body, and the lamellæ are imbedded in them. These structures will be figured in the next number of the "Illustrations of the Natural History of the R.I.M.S. Ship 'Investigator,'" 1906.

I include this species among the forms recorded from the Gulf of Manaar because it is the most abundant deep-sea Lepadid in the Bay of Bengal, and has been taken just outside the Gulf to the north-west.

? Scalpellum truncatum, HOEK.

Locality:—Gulf of Manaar, 590 fathoms (R.I.M.S. Ship "Investigator").

There is a specimen in the "Investigator" collection from the Gulf of Manaar which probably belongs to this species. It differs from HOEK's figure, however, in the following particulars:—(1) The carina is relatively longer, and (2) the valves are not so closely knit together. As I have only examined one specimen, and as HOEK has only described the external characters of his single example, I do not feel quite certain of my identification; but several deep-sea species vary as regards the characters indicated.

S. truncatum was described from a depth of 1400 fathoms; but several of the Indian members of the genus have a greater range in depth than the identification of the "Investigator" specimen with HOEK's species would imply. It is noteworthy that in the Indian seas the genus is only found at a considerable depth, probably always below 100 fathoms, although in more temperate latitudes it occurs in 15 fathoms and downwards. It is probably unable to endure warm water, although it is found in every sea.

Scalpellum tenue, HOEK.

Locality:—Gulf of Manaar, 595 to 556 fathoms (R.I.M.S. Ship "Investigator").

Four specimens, together with those of *S. japonicum* recorded above, from the shell of *Turbo indicus*. My *S. subflavum* is very near this species, from which it is most readily distinguished by its smoother shell.

S. tenue was described from the south of the Indian Ocean. The only other specimen in the Indian Museum is from a depth of 1997 fathoms, in the Bay of Bengal.

Scalpellum subflavum, ANNANDALE (15).

This species belongs to the section of its genus with perfectly calcified valves and a simply bowed carina, as do all the species which have the first of these characters that have been recorded from the immediate neighbourhood of India.

It is almost as commonly found in the deeper parts of the Bay of Bengal (especially in the Andaman Sea) as is *S. squamuliferum*, but is rarer because less gregarious. More than two individuals are seldom found together. I have examined several specimens from the Gulf of Manaar.

BALANIDÆ.

Chelonobia testudinaria (L.).

THURSTON (7) records this species from Rámésvaram Island, and there are specimens (on the carapace of *Chelone imbricata*), which are probably from the Gulf of Manaar, in the Indian Museum.

Ch. testudinaria appears to be found most frequently on turtles, in all warm and temperate seas, but not to be confined to any one species; indeed, it has been observed on the shells of molluscs. GRUVEL (11) has recently described a species of the same genus from the skin of *Manatus senegalensis* under the name *Ch. manati*. I could obtain no evidence during a recent visit to the Gulf of Manaar that Barnacles are ever found on *Halicore* there.*

Creusia spinulosa, LEACH.

This species is recorded from Ceylon by WELTNER (5). I have examined specimens from Mergui on the lower surface of *Turbinaria crater*. They are of considerable size and have their shell covered by a thin layer of coral. In some specimens not only does the opening remain patent, but the junction between the basis and the shell, and even the divisions between the compartments, are visible on the surface, the former as a clear-cut line, not merely as a rounded furrow. The coral appears to have grown over the base and then to have commenced to climb the shell at one point, as much as possible avoiding narrowly all the depressions upon it, thus protecting the Barnacle without injuring it. Nevertheless, some examples of the Barnacle have been completely engulfed by the coral and so have perished, or else, having perished, have been engulfed.

***Pyrgoma conjugatum**, DARWIN.

Localities :—Coral reefs off Ceylon.

There are numerous specimens on fragments of *Turbinaria* evidently collected in a living state. Even when completely imbedded they can be recognised by the form

* They occur, however, on the Dugong in Australian waters (see DEXLER and FREUNDE, 'Amer. Nat.,' xl., 469, p. 69, 1906).

of the opening, which is a regular oval, while that of BORRADAILE'S (9) *P. madreporæ* from the Maldives, the shell of which is very similar, is rhomboidal.

WELTNER (5) has already recorded this species from Ceylon (on *Prionastræa acuticollis*). It was originally described from the Red Sea, and is abundant on specimens of *Turbinaria* and *Porites* collected by the late Dr. J. ANDERSON in Mergui.

Professor HERDMAN'S specimens occur on both the upper and the lower surface of the *Turbinaria*, but chiefly on the latter. In either case they have been covered by the living tissues of the organism while still small. In younger individuals the basis is almost flat as a whole, but deeply sulcated and with an oval depression, corresponding to the opening of the shell above, in the centre. The shell is conical. As the calcareous substance of the coral is deposited round them, the shell becomes relatively flatter and the base deeply concave from within. The whole animal is finally buried. An opening is retained for a time by the action of the cirri and possibly of the opercular plates; but in some examples examined even this has been closed over and the Barnacle has perished, its presence being indicated by a smooth, rounded mound on the surface of the coral. The division between shell and basis can usually be detected, however, on the surface of the coral. A cyst in which the opening still remains open measures 9 millims. in depth, 14 millims. in length, and 10 millims. in breadth, all the measurements being taken externally. The shell is about 1 millim. thick above, but slightly thicker at the point where the valves meet the basis. The internal depth is a little over 8 millims., of which the basal portion occupies 5 millims. The basis is barely distinguishable from the substance of the coral. In some Mergui specimens the cyst is twice as deep and far more protuberant on the surface of the coral, but the opening of the shell is still patent.

*Tetraclita serrata, DARWIN.

Locality:—On a dead *Heteropsammia* off Ceylon.

The presence of the operculum enables me to identify the single specimen obtained by Professor HERDMAN, which is small (antero-posterior diameter of base = 5 millims.). The species does not appear to have been recorded hitherto from the eastern part of the Indian Ocean.

*Acasta cyathus, DARWIN (2).

Locality:—South end of Cheval Paar, Gulf of Manaar.

The specimen is longer and less spheroidal than the one figured by DARWIN, but otherwise agrees closely with his figure. The shell is white instead of pink; but this may be due to the action of spirit. The basis, while nearly flat as a whole, bears a circular depression in its centre, if the shell be viewed from below. This is probably due to the presence of a minute Polychæte, which is coiled up, inside a transparent tube, within the depression.

The penis is extremely long and fine and bears a few scattered hairs. Although the remainder of the body is almost colourless, this organ is of a deep horn-colour, minutely ringed with purplish brown. The latter tint evidently represents a pigment common in Barnacles, but more usually associated with the mouth parts. In *Scalpellum alcockianum* it colours the limbs almost black, while in *Balanus æneas* it tinges the softer structures connected with the mouth. Many other examples of its occurrence might also be noted in both sections of the non-parasitic Cirripedes, both in shallow and in deep water.

A. cyathus has not previously been recorded from the Indian region, and is probably a scarce form where it occurs; but its distribution is evidently circumtropical.

*__Acasta funiculorum,__ n. sp.—Figs. 5–9.

Locality:—Gulf of Manaar.

Diagnosis.—Rostrum and laterals greatly enlarged; carino-laterals much reduced, generally shorter than the rostrum by about two-thirds. Radii of rostrum very

Fig. 5.

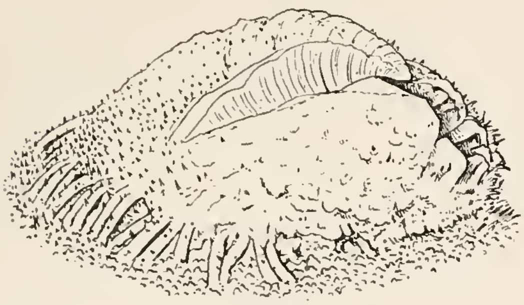

Fig. 6.

Fig. 9.

Fig. 8.

Fig. 7.

Fig. 5. *Acasta funiculorum*, n. sp., lateral view. ×10.
„ 6. „ „ view from above. ×10.
„ 7. „ „ tergum, external view. ×16.
„ 8. „ „ scutum, „ „ ×16.
„ 9. „ „ rostrum, internal view. ×10 (smaller specimen).

broad, longitudinally ridged, oblique. External surface of parietes and radii rough and irregularly spiny, with spiny, cylindrical processes connecting the basal part of the rostrum and the laterals with the coral to which the Barnacle is attached. Internal surface of parietes strongly sulcated longitudinally above and vertically below. Shell fragile, mound-shaped, generally narrower in front than behind, basis flat. Opening more or less vertical, irregularly oval, strongly denticulate. Colour, dirty white; where covered with epidermis, yellowish; tinged, more or less deeply, with steel-blue above. Scutum triangular, with muscular depressions feebly developed; tergum pointed above, much wider than high, with a broad, bluntly rounded spur.

Several dried specimens on the lower surface of *Turbinaria*.

I have been in much doubt as to the proper generic position of this form. As the basis is absolutely flat it can hardly be put in DARWIN'S Section B of *Balanus*, with which its true affinities may lie. On the other hand, its more or less globular outline, its fragile shell, and the shape of its compartments certainly ally it to *Acasta*, if this group can be given generic rank. The periphery of the basis is pierced by small irregular holes as in some species of *Acasta*. It is almost impossible to lay down an exact line between *Acasta* and Section B of *Balanus;* but in most cases there is no difficulty in seeing a difference as regards species.

No species of *Acasta* has hitherto been recorded from a Madreporarian coral. The present form occurs with *Balanus allium*, *B. terebratus*, and *Pyrgoma conjugatum*, and it is interesting to note the different ways in which the four species have been adapted for the same mode of life. With *P. conjugatum* I have already dealt. *B. terebratus* anchors itself among the living tissues of the coral by means of prolongations of the outstanding vertical ridges on its shell. These tissues do not grow over it as they do over the *Pyrgoma*, at least, in the specimens examined. By deepening its base, it can compensate to some extent for the growth of the calcareous part of the coral; but it appears to be continually thrust outwards on to the surface, and none of the specimens show any signs of being engulfed. *B. allium*, as far as one can see, is more frequently destroyed, several specimens having been completely buried. Possibly the peculiar smooth, glistening surface of their shell may be, however, in some way a protection to them, although the smoothness is of texture rather than actual surface. *A. funiculorum* is a more highly specialized form than either of the preceding two. Its cables, so to speak, are not prolongations of such ridges as occur on other species, but seem to be special structures, allied to the spines which occur on the shell of *A. cyathus*, but very much more highly developed; their closest homologues being the processes on the shell of *Balanus tintinnabulum*, var. *spinosus*. By means of them the Barnacle anchors itself to the slippery surface of the coral. If the coral commences to grow round it, it can save itself for a period by elongating the posterior part of its shell, so that the opening may approach the horizontal more closely than it usually does; but individuals are frequently buried and perish. It may be noted that while the *Pyrgoma*, which can be surrounded by calcareous substance without immediate danger to itself, is scattered all over the pieces of *Turbinaria* examined, the other forms occurring with it are almost entirely confined to the inner parts of the colony (where growth is less vigorous, the maximum thickness having been almost reached), or to parts where the living tissues have been killed or weakened by boring organisms.

***Balanus tintinnabulum** (L.).

Locality :—Cheval Paar, Gulf of Manaar.

The only specimen which I can refer with certainty to this extremely variable species belongs to the variety *communis*, which I have taken also on the Pamban Channel, between the Gulf of Manaar and Palk Bay. The shell of Professor HERDMAN's specimen is partly covered by an incrusting Alcyonarian.

***Balanus amphitrite**, DARWIN.

Localities :—Galle ; Gulf of Manaar.

Numerous specimens on shells, ropes, and submerged baskets. All but one belong to the variety *venustus*, which I have taken on an *Avicula* attached to a Gorgoniid at Kílakarai, on the Indian shore of the Gulf of Manaar. The one exception represents the variety *communis*. Both these varieties have an extremely wide distribution, and Professor HERDMAN's specimens are quite typical.

The most interesting are those on the submerged baskets, as their approximate age is known. The baskets were put into the sea on April 17 and were drawn out on May 9. The Barnacles which had formed on them during this period measure from 3 millims. to 8 millims. in their antero-posterior diameter, while the largest individuals obtained from the same seas measure about 14 millims. It is clear, therefore, that individuals of this species take, at this season, not more than three weeks to attain more than half their adult size. I have recently recorded a case in which a specimen of *B. tintinnabulum* (12) was known to have reached a great size (diameter of base, which was approximately circular, 60 millims ; height of shell, 65 millims.) in about a year at Pamban, on Rámésvaram Island.

Professor HERDMAN tells me that *B. amphitrite* and possibly other species grow on the shells of living pearl oysters in the Gulf of Manaar. They appear in April or May, and spread with great rapidity. Such forms may be classed as enemies of the pearl oyster.

***Balanus amaryllis**, DARWIN.

Localities :—Palk Bay and Gulf of Manaar.

The majority of these specimens belong to DARWIN's variety B, but a few are obscurely striped with dull pink. The opercular plates resemble those of the typical form, rather than of that noted by WELTNER (5), and later described by LANCHESTER (8) as sub-species *dissimilis*. The specimens are all small.

***Balanus allium**, Darwin.

Locality :—Coral reefs off Ceylon.

Several small specimens on *Turbinaria*, together with *B. terebratus*, *Acasta funiculorum* and *Pyrgoma conjugatum*. Probably they are immature, as the base is nearly flat, although the shell and operculum agree with Darwin's description and figures.

This Barnacle has been recorded from the Red Sea and from Australia as well as from Ceylon. It is probably another circumtropical species, its small size and inconspicuous appearance having caused it to be neglected by collectors.

***Balanus terebratus**, Darwin.

Locality :—Coral reefs off Ceylon.

Several specimens, with those of the preceding species. They agree closely with Borradaile's description (9) as regards the structure of the operculum. Darwin (2), who had examined a single specimen, said regarding it, "the interspaces between the ridges (on the basis) are penetrated by small rounded apertures, of irregular shape and unequal sizes." Borradaile was unable to see these apertures, and they are absent in some examples I have examined. In one individual, however, there appear to be indications that they have been present, but have been almost obliterated during growth. The specimens are small, the antero-posterior diameter of the largest being 7 millims., and are apparently more steeply conical than the type.

***Balanus æneas**, Lanchester (8).

Locality :—Pearl Banks, Gulf of Manaar.

Numerous small individuals, measuring about 3 millims. in antero-posterior diameter, on a piece of sodden palm fibre, on a shell, and on dead *Heteropsammia*.

In spite of their small size these individuals contain eggs inside the shell. The eggs are of a broad ovoid outline, measure 0·333 millim. in length and 0·2 millim. in maximum breadth, and are comparatively few in number. The maxillæ have in one specimen only six teeth, the third being represented merely by a short bristle; while in the other individuals there are seven.

Loose in the shell of one specimen I found a peculiar little Nematode, the affinities of which I do not venture to decide.

***Balanus maldivensis**, Borradaile (9).

Locality :—Gulf of Manaar.

Five specimens on a piece of dead coral. Possibly some other very much worn examples, fixed to a dead *Heteropsammia*, may also belong to this species. The shells are white with vertical stripes of rose-pink. Their coloration gives them a general resemblance to some specimens of *B. amphitrite*, var. *venustus*.

Borradaile's section H of the genus *Balanus*, created for this form in 1903, is not the same as Gruvel's section H, which was published for *B. dybowskii* in the same year. The definition of the former is "All parts of shell present, heavy, and without pores"; of the latter, "Basis calcareous; no radii; basis and parietes porous."

Borradaile's section approaches *Acasta* technically, although the form and character of the shell are different. It is convenient, therefore, to call it section I, retaining Gruvel's designation for *his* section H.

Chthamalus stellatus (Poli).

A common Indian species with a wide distribution. I have lately taken specimens in the estuary of the Matla River, Lower Bengal, at a place where the water was decidedly brackish. They were attached to the trunks of mangrove trees, and could only have been covered by the tide during a very small part of each day.

On the whole, the Barnacles of Ceylon, in so far as they are known, bear out the remark made in the Introductory note to this paper, that every addition to our knowledge of the distribution of the group tends to prove the wide dispersal of the species and varieties. Of the 26 species recorded above, 3 occur in all seas, their migrations being assisted by human agency; at least 6 will probably be found in every sea which is not too cold; 4 are widely spread in the Indian Ocean and the warmer parts of the Pacific, while 12 are only known from the Indian Ocean. Of the last, however, 4 come from great depths, which have been little explored, while the remaining 8 are small, inconspicuous forms. Except *Tetraclita serrata*, which is probably found at the extreme south of the West African coast, none of the 26 species are known only from the Atlantic and Pacific Oceans. It seems possible that the continent of Africa has proved a barrier in some cases as regards the migration westwards of Oriental species.

REPORT

ON THE

MARINE HEMIPTERA (HALOBATES)

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

GEO. H. CARPENTER, B.Sc., M.R.I.A.,
PROFESSOR OF ZOOLOGY IN THE ROYAL COLLEGE OF SCIENCE, DUBLIN.

[WITH ONE PLATE.]

DURING his researches in the Gulf of Manaar, Professor HERDMAN collected many specimens of *Halobates*, that interesting pelagic genus of bugs, familiar to all students of insects since the publication of BUCHANAN WHITE'S classical memoir in the 'Challenger Reports.'* These insects are allied to our common "pond-skaters," and skim over the surface of the ocean in warm latitudes, as those do over the water of ponds and streams. WALKER, who has given much attention to the habits of *Halobates* in recent voyages, states† that they dive below whenever the surface is ruffled by a breeze.

All the specimens in the present collection are referable to a new species, and as the material is abundant, the opportunity has been taken to investigate some details of the external anatomy, and in particular the structure of the ovipositor.

FAMILY: HYDROMETRIDÆ.

GENUS: **Halobates,** ESCHSCHOLTZ.

Halobates herdmani, n. sp.—Plate, figs. 1 to 19.

Length of male 5·2 millims., of female 5·7 millims. Feeler with 4th segment half as long again as 3rd, slightly shorter than 2nd (figs. 3, 4). Fore foot with the two tarsal segments sub-equal (figs. 5, 6, 9). Intermediate foot with the proximal tarsal

* 'Challenger,' Zoology, vol. vii., 1883, part xix.

† 'Ent. Monthly Mag.,' vol. xxix., 1893, pp. 227–232.

segment two and a half times as long as the distal (figs. 1, 11). Abdomen of male with the 8th segment slightly asymmetrical (figs. 13, 14, 15), the "horns" being both inclined towards the left, so that while the right horn is closely applied to the 9th segment, the left is somewhat divergent from the axis of the body; both horns are falcate at the tip.

Habitat:—Coasts of Ceylon. Old Dutch Modragam Paar, numerous males and females; Galle Bay, two males and one female; off Mutwal Island, Gulf of Manaar, two females; off Manaar Island, several young specimens.

This species is most nearly allied to *H. flaviventris*, Eschs., of all members of the genus hitherto described. It differs from that species principally in the shape and in the slight asymmetry of the "horns" of the 8th abdominal segment of the male. The form of this segment in the present insect shows an interesting stage of transition between the symmetrical condition found in the great majority of the species of *Halobates* and the excessive irregularity of *H. micans*, Eschs. (*H. wüllerstorfii*, Frauenf.), in which the left horn of the segment projects almost at right angles to the axis of the body.

In colour *H. herdmani* resembles the other species of the genus. The dorsal and lateral surfaces appear deep blue-black when wet, and ashy grey (owing to the dense pubescence) when dry. On the head are the usual pair of orange triangular marks, while the feelers and legs are black. The thoracic sternum is dark centrally, showing only two pale elongate patches towards the lateral sutures (fig. 14) close to the bases of the hind legs. The abdominal sterna are mostly pale, but they appear dark laterally and along their hinder borders; the 1st abdominal segment, on which is the opening of the repugnatorial glands, is deep brown.

The sutures, partially marking the junctions of the anterior abdominal terga, can be unusually well seen in this species (figs. 1, 2), and the male has a median longitudinal suture extending from the front of the mesothorax to the hinder edge of the 2nd abdominal segment. The recognition of the transverse dorsal sutures reminds us that though the abdomen is indeed much reduced in this genus, as compared with most of its fresh-water allies, yet the peculiar modification of the body is principally due to the abnormal extension of the mesothorax, and to the backward growth of that segment and of the metathorax on either side of the anterior abdominal segments.

Fore Legs.—The fore legs of the various species of *Halobates* have been frequently described and figured, affording as they do excellent diagnostic characters. A few details are, however, worthy of especial notice. The tarsal segments in the present species are longer and more slender in the female (fig. 9) than in the male (figs. 5, 6). The whole of the limb is covered with a fine pubescence, but on the upper surface a number of short, stout spines are interspersed among the delicate hairs (fig. 5), these spines being especially strong in the male and being absent from the under surface of the foot in both sexes (figs. 6, 9). At the end of the shin, however, on this surface are a number of long, stiff bristles lying in the shallow groove close to the joint with the proximal tarsal segment. BUCHANAN WHITE drew attention to the curious row of stout, blunt hairs or spines on the edge of the inner apical prominence of the shin. In the present species there are more than twenty of these on the male's leg (figs. 5*a*, 7), and five on the female's (figs. 9*a*, 10). The arrangement of these structures is highly suggestive of a stridulating organ, and it is probable that they form an instrument for rasping along a "comb" formed by a row of sharp, strong spines (figs. 5*b*, 6*b*, 8, 9*b*), about ten in number, and increasing in length as the tip of the shin is approached. This "comb" is situated on the upper face of the apex of the shin. The "file" of each foot must of course play on the "comb" of the other—quite a possible arrangement when we remember that the fore legs in these insects are very mobile, and that the feet can be crossed over each other in front of the head. Similar structures occur towards the distal end of the shin in the allied reef-haunting genus *Hermatobates* (CARPENTER).*

Male Abdominal Segments.—As mentioned above, the present species is characterised by a comparatively slight asymmetry in the "horns" of the 8th segment in the male's abdomen (figs. 13, 14, 15); while the right horn is closely applied to the globose 9th (genital) segment, the left horn is directed laterally outwards at a slight angle. Each horn is expanded at the tip into a falcate process with a few stout black spines (fig. 15). In the allied *H. flaviventris*, ESCHS., the horns are symmetrical,† and each has a somewhat pointed process on the outer margin about the middle of its length, tapering at the tip. It is of interest to remember that *H. flaviventris*, to which the present species is most nearly allied, has been recorded from the Indian Ocean near Ceylon, while *H. micans*, the species with the very divergent "horn," inhabits all the warmer oceans. It is exceedingly likely that with these insects, as with others, our specific distinctions will become less definite as our knowledge of the possible variations in structure increases.

Female Abdominal Segments and Ovipositor.—It is rather remarkable that while the hindmost segments of the male *Halobates* have attracted much attention from entomologists, the corresponding region in the female has been neglected. This is probably because, in preserved specimens, the lateral sclerites of the 8th segment (figs. 16, 17, 18, *a*) are usually in close contact ventrally, and

* 'Sci. Proc. R. Dublin Soc.' vol. vii., 1891 (plate xii., fig. 6). For descriptions of other stridulating organs in the *Hemiptera* see HANDLIRSCH, 'Ann. Naturhist. Hofmus. Wien,' vol. xv., 1900, pp. 127–141; KIRKALDY, 'Journ. Quekett Micros. Club' (2), vol. viii., 1901, pp. 33–46; and BERGROTH, 'Proc. Zool. Soc.,' vol. ii., 1905, pp. 146–154.

† BUCHANAN WHITE states (*loc. cit.*, p. 33) that "in all the other species examined [except *H. wullerstorffi = micans*] both horns are symmetrical," though his figure of *H. flaviventris* from the dorsal aspect (plate ii., fig. 2*g*) shows the left horn only visible, and slightly divergent as in the present species. NASONOV, however, in his figure of *H. flaviventris*, var. *kudrini* ('Entomological Researches,' 1893—in Russian—Warsaw, 1897, fig. 14), shows the genital segments of the male from beneath, and the two horns appear perfectly symmetrical.

the ovipositor retracted beneath them. BUCHANAN WHITE remarks that "the ovipositor appears to consist of four valves," and NASONOV in his figures* shows only two pairs of processes (gonapophyses). Several of the females in the present collection have, fortunately, the ovipositor well extended, and it is not difficult to see that the three pairs of processes usual in the insectan ovipositor are present.

In a specimen with the ovipositor thus extended the two lateral sclerites of the 8th segment (figs. 16, 17, 18, *a*) are widely separated, and a transversely striated, flexible cuticle (figs. 17, 18, *b*) is seen to occupy the ventral region of the abdomen behind the 7th sternite. As this cuticle must be folded between the sclerites of the 7th and 8th segments when the ovipositor is retracted, and as it lies in front of the genital opening (figs. 17, 18, *c*), it is to be regarded as an intersegmental membrane, while the small sclerites that are visible behind it—a triangular pair (fig. 19, *d*) supporting the bases of the anterior processes of the ovipositor, and a very slender pair (figs. 17, 18, d^1) continuous with the chitinous rim that lies posterior to the genital aperture, must represent the 8th sternite. In front of the genital aperture the intersegmental membrane projects in the form of a hood (figs. 17, 18, c^1) with a pointed and forwardly-directed process.

The anterior pair of gonapophyses (figs. 17, 18, 19, *e*) are attached to the reduced 8th abdominal sternite, as previously mentioned. Each of these processes is broad at the base, which is pale and feebly chitinized except at the outer margin, where a firm dark ridge is developed. Distally the process becomes tapering in form, brown in colour, firm and well chitinized in texture, and beset with rows of prominent bristles. In addition to this main axis of the process there is a small delicate internal limb (figs. 17, 18, e^1) which lies close to the genital opening.

Beneath the lateral sclerites of the 8th segment there lies on each side an elongate sclerite (figs. 17, 19, *f*), whose shape and relations become evident only when the overlying 8th segment has been removed. Then it is clear that these sclerites (*f*) belong to the 9th segment. At its dorsal extremity each is produced into a dark, prominent knob, which lies just anterior to the small "tail-segment" (figs. 16, 17, 19, *j*), while at its ventral end each supports the two posterior gonapophyses. The outer pair of these processes (figs. 16, 17, 18, 19, *g*) are strong and flexible at the base, while distally each is produced into a straight, firm "guide" on which the inner process slides to and fro. When the ovipositor is extended, the tips of these hinder outer processes do not reach quite as far as the tips of the anterior processes. The inner posterior processes (figs. 16, 17, 18, 19, *h*) are very long, slender, and flexible at the base, but distally they become somewhat broad and flat, and terminate in a hook-like tip beset with fine hairs. The gonapophyses of the 9th segment remain free from one another, except for an extensive pale membrane (figs. 16, 17, 18, *i*) which is stretched between them when the ovipositor is extended. This membrane terminates in a pair of short pointed prominences.

* *Loc. cit.*, figs. 11, 12.

When the ovipositor is retracted, the slender basal portions of the hinder gonapophyses, especially of the inner pair, become bent almost in a semicircle (fig. 19), while the tips of the processes are withdrawn dorsalwards and fit just in front of the anal segment, so that they can be covered by the lateral sclerites of the 8th segment, meeting in the mid-ventral line.

It has been shown by HEYMONS* that in *Naucoris* and other Hemiptera the ovipositor is composed of the three pairs of gonapophyses usual in insects, not, as supposed by VERHOEFF,† of two pairs only. *Halobates* has therefore an ovipositor in which can be recognised all the parts typical of its order and class. But the processes of the 8th segment in *Halobates* recall by their appearance the outer pair of the 9th segment in *Naucoris* and in many other insects; while the latter pair, instead of being as is usual blunt and hairy, form in *Halobates* stiff, rod-like "guides" for the inner pair of the 9th segment. These last-named processes, which in most hemipteran and hymenopteran ovipositors are closely approximated or even fused together, remain apart in *Halobates*. Thus the ovipositor has here a somewhat primitive arrangement, intermediate between the simple condition found in the Orthoptera and the specialised form to be observed in such Hemiptera as the Cicadidæ.

The egg of *Halobates*, which is of large size, must be held between the processes of the 8th segment and the inner processes of the 9th segment. These are the processes that hold the eggs in insectan ovipositors generally.

If the narrow sclerites above-mentioned (figs. 17, 19, *f*) represent the skeleton of the 9th abdominal segment, then the "tail-segment" (figs. 16, 17, 19, *j*) (with which the large dorsal anchor-shaped sclerite in the male presumably corresponds) belongs to the 10th segment, and the small sclerite below it bounding the anal opening (figs. 16, 17, 19, *k*) represents the 11th segment. And thus all the segments of the typical insectan abdomen can be recognised in these remarkable marine bugs, in spite of the many special adaptations that they have undergone in correspondence with their wonderful manner of life.

* 'Nova Acta Acad. Leopold Carol.,' lxxiv., 1899, No. 3.

Halobates herdmani, n. sp.

[CEYLON PEARL OYSTER FISHERIES—1906—SUPPLEMENTARY REPORTS, No. XXXIII.]

REPORT

ON THE

LEPTOSTRACA, SCHIZOPODA AND STOMATOPODA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

WALTER M. TATTERSALL, B.Sc.
ASSISTANT NATURALIST (FISHERIES BRANCH) DEPARTMENT OF AGRICULTURE AND TECHNICAL INSTRUCTION FOR IRELAND.

[WITH THREE PLATES.]

THE collections of these three groups of Crustacea Malacostraca, made by Professor HERDMAN and Mr. HORNELL in Ceylon, and kindly entrusted to me for examination, are small both in number of species and, with one or two exceptions, in individuals as well. Nor is the number of new forms by any means remarkable or at all out of proportion to the total number of species, only two hitherto undescribed forms, both in the Stomatopoda, having been met with in the collection. Still, the material is not without interest, at least six very rare species being comprised therein; this afforded an opportunity for completing or adding to the published descriptions, or of increasing materially the known geographical range.

The LEPTOSTRACA are represented by a single species, which differs so slightly from the well-known and widely distributed northern form, *Nebalia bipes*, that I cannot consider it as a distinct species or even variety.

The SCHIZOPODA are on the whole distinctly disappointing. Five species are represented in the collection; but as three of these occurred only in tow-net gatherings taken on the outward journey to Ceylon, only two can therefore be regarded as belonging to the Ceylon fauna. One of these, *Euphausia latifrons*, appears to be an abundant form, but of the other, a Mysid, *Siriella paulsoni*, only a single specimen is present.

So little is known of tropical Mysidæ, that one had hoped that the collections made by Professor HERDMAN in Ceylon would have added considerably to our knowledge, especially as the material of the other groups of Crustacea, more notably the AMPHIPODA, ISOPODA, and CUMACEA, has been found to be so rich in the number of species, both described and new. Still, as, so far as I am aware, no SCHIZOPODA have previously been recorded from Ceylon waters, the present collection, though small, provides a first contribution to our knowledge in this respect.

To judge from the contents of the stomach of a ray, *Dicerobatis ergoodoo*, which contained several hundred specimens of *Euphausia latifrons*, the Euphausians in the tropics, equally with those of more temperate climes, are economically of primary importance as fish-food, an importance which can scarcely be over-estimated.

With the STOMATOPODA, Professor HERDMAN was distinctly more successful, ten species of adult and ten types of larvæ being present in the collection. Remembering the difficulty which always attends the capture of adult Stomatopoda of any kind, the results obtained must be regarded as highly satisfactory considering the limited time at Professor HERDMAN'S disposal. Five species are added to the fauna of Ceylon, two of which, *Gonodactylus herdmani* and *G. acanthurus*, are new to science, both possessing features of great interest.

Species of adult STOMATOPODA have been recorded from Ceylon by HELLER (1868), MIERS (1881), MÜLLER (1887), and HENDERSON (1890 and 1893). The full list is as follows, with the names of the recorders :—

Squilla nepa [HELLER, HENDERSON, 1890].
S. oratoria [HELLER].
S. scorpio [HENDERSON, 1890].
Lysiosquilla maculata [HENDERSON, 1890].
L. saracinorum [MÜLLER].
Pseudosquilla ciliata [MÜLLER, HENDERSON, 1890].
Gonodactylus chiragra [MÜLLER, HENDERSON, 1893].
G. glabrous [HENDERSON, 1893].
G. graphurus [MÜLLER, MIERS, HENDERSON, 1890].
G. demani [HENDERSON, 1893].
Odontodactylus scyllarus [MÜLLER].
Protosquilla trispinosa [HENDERSON, 1893].
P. trispinosa, var. *pulchella* [HENDERSON, 1890, MIERS].
P. stoliura [MÜLLER].
P. ectypa [MÜLLER].

Of this list, *Squilla oratoria*, as recorded by HELLER, is regarded by MIERS as synonymous with *S. nepa*. This leaves a total of thirteen species and one variety of Stomatopods already known from Ceylon. To these must now be added the following five species :—

Squilla raphidea, FABRICIUS.
Odontodactylus brevirostris (MIERS).
Gonodactylus herdmani, n. sp.
G. acanthurus, n. sp.
Protosquilla spinosissima (PFEFFER).

The larvæ in this collection which could be referred to already described forms are recorded below under the names given to them by their describers. Those which do not appear to have hitherto been met with, or at least not named, are not given new specific designations, as I am of the opinion that such a proceeding in connection with larval forms is not desirable. They are, however, described and figured in the hope that they may be recognised in future collections, and their life-history more fully traced.

In the preparation of this paper I have been kindly aided by Dr. NOBILI, of Turin, and Professor PFEFFER, of Hamburg, with information on various species, and to these gentlemen I desire to express my grateful thanks. I am especially indebted to Dr. W. T. CALMAN for his kindness and help while at the British Museum, and for very valuable assistance with the literature of the subject.

I.—LEPTOSTRACA.

FAMILY: NEBALIIDÆ.

Nebalia bipes (FABRICIUS).

Localities:—

Cheval Paar, February, 1902, 5 to 8 fathoms. Five.

Washings from pearl oysters, Ceylon. Thirteen.

Periya Paar, February 5, 1902, tow-net at night, surface. Few.

The specimens of *Nebalia* obtained by Professor HERDMAN in Ceylon may all, I think, with certainty be referred to the type species, though differing from northern examples of that species in one or two minor points. They do not fall into any of the numerous varieties of *N. bipes* recently indicated by THIELE (1904), but I do not propose to designate them by a separate varietal name, because the differences are too slight to deserve such an honour. Insignificant as these differences are, they serve to bring still closer together the two supposedly distinct species of this genus, *N. bipes* and *N. longicornis*. The characters which serve to distinguish the two latter species from each other have recently been defined by THIELE (1904). Briefly, *N. bipes* may be distinguished from *N. longicornis* (1) by the size of the rostrum, which in the former is much longer proportionately to the breadth than in the latter; taking the breadth of the rostrum as unity, its length in *N. bipes* is 2·62, and in *N. longicornis* 1·75;* (2) by the armature of the fourth joint of the peduncle of the first antenna. This joint in *N. bipes* is armed on its outer edge with at least three (sometimes as many as eight, *cf. N. bipes*, var. *valida*) spines and five or six setæ, whereas in *N. longicornis* there is only one spine and seven or eight setæ.

In *N. bipes* from Ceylon the rostrum is in all the specimens about two and a third times as long as broad, and shaped on the whole as in THIELE's fig. 70. The fourth joint of the peduncle of the first antenna bears on its outer edge two spines (without exception in all of the eighteen specimens) and four or five setæ. The characters, therefore, of Ceylon *N. bipes* are exactly intermediate between those of *N. bipes typica* and *N. longicornis*.

The specific differences between the two latter species as given by THIELE are very

* These figures are taken from THIELE's drawings, 1904, plate iv., figs. 66 and 70.

slight in themselves, and in the light of Ceylon specimens of the former species would appear to almost reach vanishing point.

The eye in the Ceylon examples has the sensory papilla well developed, while the fourth pair of pleopods does not appear to differ from those of typical specimens of *N. bipes*. *N. bipes* in one or other of its varieties is a very widely distributed form in the northern hemisphere. Since the examples noted by STEBBING from Sandal Bay, Lifu, and New Britain are more properly, according to THIELE, referable to *N. longicornis*, Ceylon is the southernmost point from which *N. bipes* has as yet been recorded.

II.—SCHIZOPODA.

FAMILY: EUPHAUSIIDÆ.

Euphausia mutica, HANSEN (1905).

E. pellucida (*pars*), SARS (1885).

Localities:—

Indian Ocean, south of Sokotra, surface tow-net. Three specimens of 10 millims.; and five, 6 millims and under.

Indian Ocean, between Sokotra and the Laccadives, surface tow-net. Forty, 5 to 15 millims.

Indian Ocean, between the Laccadives and Ceylon, surface tow-net. Two, 11 millims.

This species was not actually met with in Ceylon waters, but was captured on the outward journey there by means of tow-nets. All the specimens were taken at the surface in crossing the Indian Ocean from Sokotra to Ceylon.

This species has only recently been founded by HANSEN for specimens formerly referred by SARS to *E. pellucida*, DANA, in which he also included *E. mülleri*, CLAUS, and *E. bidentata* (M. SARS), as synonyms. HANSEN (1905), however, rejects *E. pellucida*, DANA, as unrecognisable from DANA's descriptions and figures, and makes *E. mülleri* the type of the genus, with *E. bidentata* as a synonym. From *E. mülleri*, *E. mutica* is chiefly distinguished by having the leaflet on the basal joint of the antennular peduncle bidigitate instead of multidigitate. This latter character is also shared by *E. recurva*, HANSEN, and *E. brevis*, HANSEN. *E. mutica*, *E. recurva*, and *E. brevis*, which all have two lateral denticles on the carapace, are separated from each other, by HANSEN, on the characters of the armature of the second joint of the antennular peduncle and the shape and direction of the antennular leaflet.

Small examples of *E. mutica* in this collection, 5 millims. in length, while in other respects agreeing fairly well with larger examples, only possessed a single lateral denticle on the carapace. This is quite in accordance with the fact that the second denticle is of late appearance, and SARS (1885), moreover, describes and figures a young Euphausian, 7 millims. long, which he refers to *E. pellucida*, and which has the second denticle on the carapace still undeveloped.

Euphausia mutica is, according to HANSEN, known from the tropical and southern Atlantic, Red Sea, Indian Ocean, and various parts of the North Pacific.

Euphausia latifrons, G. O. SARS.—Plate I., figs. 1 and 2.

Localities :—

South end of Red Sea, surface tow-net. Three, 3 to 5 millims.

Indian Ocean, between Sokotra and the Laccadive Islands, surface tow-net. One, 8 millims.

Off Kalpentyn Island, Ceylon, February 3, 1902, surface tow-net all night and early morning. Fourteen, 8 to 10 millims.

Watering Point, Galle, February 15, 1902, surface tow-net. One, 7·5 millims.

Off Mutwal Island, Ceylon, March 19, 1902, surface tow-net. One, 8 millims., and two larvæ.

North-east of Chilaw Paar, Ceylon, March 20, 1902, surface tow-net. Two, 4 and 6 millim.

Periya Paar, November 13, 1902, from stomach of a ray, *Dicerobatis ergoodoo.* Several hundreds, 8 to 10 millims.

The *carapace* is about half as long as the pleon, and has a single lateral denticle placed near the posterior end of its inferior margin just in front of the luminous organs of the penultimate thoracic limbs. It is produced in front into a squarely truncate or slightly emarginate rostral projection, the lateral angles of which are somewhat acutely pointed. The antero-lateral corners are pointed, and there is no very prominent dorsal keel.

The *segments of the pleon* decrease in depth posteriorly. The first five are subequal in length, while the sixth is about one and a half times as long as the preceding segment and has its posterior median dorsal border very slightly acuminate. The preanal spine is well developed, curved and simple. The epimera of the first five segments are rounded, those of the last segment slightly acuminate.

The *eyes* are rather small with the pigment black.

The *antennular peduncle* (figs. 1 and 2) is rather stout, with the basal joint slightly longer than the terminal two combined. The outer distal corner of the basal joint is produced into a short spine, while its inner distal margin bears about six long plumose setæ which interlock with those of the other peduncle. On the dorsal surface there is a leaflet running obliquely across the distal end of the basal joint. The leaflet is strongly curved, and the external half of its margin is divided up into eleven acutely pointed lappets. The external part of the leaflet overhangs the spine on the outer distal corner of the basal joint. The second joint of the peduncle is longer than the third.

The *antennal peduncle* is about as long as the scale, and has the terminal joint almost as long as the basal two combined.

The *antennal scale* extends to the distal end of the second joint of the antennular peduncle. It is about four times as long as broad, with its outer margin slightly curved and terminating in a distinct though feeble spine. The apex of the scale is broadly rounded, while its basal spine is short and smooth.

The *mouth parts and thoracic limbs* offer no points of special interest.

The *telson*, including the subapical spines, is about as long as the last two segments of the pleon combined. It is narrowly lanceolate in shape, with the portion beyond the insertion of the subapical spines suddenly constricted and acutely pointed. Its dorsal surface bears five pairs of dorsal denticles on its distal half. The subapical spines have rather broad insertions and their inner distal edge bears five small denticles.

The *uropods* have the plates subequal in length and very slightly shorter than the telson. The inner plate is much narrower than the outer, which terminates in a minute spine on its outer edge.

Length of the largest specimen 12 millims.

The numerous specimens in this collection which I refer to this species differ from the descriptions and figures of SARS in four points, (1) in the presence of a lateral denticle on the carapace, (2) in the very much more digitate form of the membranous leaflet of the antennules, (3) in the presence of five instead of three pairs of denticles on the telson, (4) in the greater relative development of the uropods. The last three points of difference may be accounted for by the difference in size and age of SARS' specimens and my own. SARS' descriptions and figures were taken from a specimen 7·5 millims. long, while the above description is of a specimen 12 millims. long. The first of the above-mentioned differences is due to an error on SARS' part.

The examination of the type of *E. latifrons*, for which I am greatly indebted to Dr. W. T. CALMAN, reveals the presence of a small but quite distinct spine on the lateral margin of the carapace just in front of the luminous organ of the penultimate thoracic limb. The type specimen, according to information kindly given to me by Dr. CALMAN, is one of those from Port Jackson, Australia, mentioned by SARS in his 'Challenger Report,' p. 96, as having come to hand late. It is, therefore, not the specimen figured or described. It is not quite as large as some of the Ceylon specimens, but considerably more developed than the one SARS figured. The leaflet on the basal joint of the antennular peduncle of this specimen is divided up distally into nine rather short lappets, being thus intermediate in development between SARS' figure and my own.

STEBBING (1905), in recording this species from S. Africa, notes the presence of a lateral denticle on his specimens, and is of opinion that it probably becomes obsolete in quite adult examples.

Euphausia latifrons is the smallest known species of the genus, and is at once distinguished from all other described species by the peculiar form of the rostral projection.

Distribution: -Australian seas and East Pacific near the Phillipine Islands ('Challenger'); South Africa (Stebbing).

Its occurrence at Ceylon thus fills up a gap in the distribution of the species in the Pacific. Round Ceylon it would appear to be a very abundant species, judging from the contents of the stomach of a ray, *Dicerobatis ergoodoo*, which contained several hundred specimens. All the other specimens were taken at the surface of the sea, though its occurrence in the stomach of a bottom-living fish like a ray would seem to indicate that the species does not always adopt an entirely pelagic habitat. The depth over which the species was captured by tow-nets in no case exceeded 20 fathoms.

Nematoscelis microps, G. O. Sars (1885).

N. rostrata, G. O. Sars (1885). **N. mantis**, Chun (1896). **N. microps**, Hansen (1905).

Locality:—Off Mutwal Island, Ceylon, March 19, 1902, surface tow-net. Two, 3·5 millims.

Hansen (1905) has recently demonstrated that *Nematoscelis rostrata* is in reality only the young of *N. microps*, and I here adopt his view of the matter.

The two small Ceylon specimens agree very well with the description and figures given by Sars of the Cyrtopia larva of *N. rostrata*. The rostrum is large and well developed, and the lateral spine on the carapace very prominent. Though the specimens measure only 3·5 millims. in length, the long leg is already well developed and measures about 2 millims. in length. It is too stoutly built to admit of referring the specimens to *N. tenella*. In other points, such as the general proportions of the body, the Ceylon specimens are in harmony with Sars' figures.

N. microps was taken by the "Challenger" at several stations in the tropical and subtropical Atlantic Ocean and in the Pacific to the north of New Guinea. It has since been recorded from the Mediterranean by Chun, and from the tropical Atlantic Ocean off America and Africa by Ortmann and Hansen respectively.

Family: MYSIDÆ.

Siriella paulsoni, Kossmann.—Plate I., figs. 3 to 7.

S. jaltensis, Paulson (1875), *nec*, Czerniavsky. **Siriellides paulsoni**, Czerniavsky (1880).

Locality:—Pearl Banks, Cheval Paar, March, 1902, 8 fathoms. One female, 12 millims.

The general form of the body is robust and rather stoutly built.

The *carapace* is shorter than the pleon and of equal breadth throughout. It is produced in front into a short acutely pointed rostrum.

The *pleon* has the first segment slightly longer than the next four, which are subequal in length. The sixth segment is about one and a half times as long as the fifth.

The *eyes* are large and globose, not quite reaching the distal end of the basal joint of the antennular peduncle. The pigment is black.

The *antennular peduncle* (fig. 4) is rather long and stoutly built. The basal joint is longer than the remaining two combined. The second joint is quite short and has its outer edge armed with short plumose setæ. The third joint is longer than the second. All three joints have a plumose seta on their inner distal corners.

The *antennal peduncle* is rather long and slender, with the penultimate joint about three times as long as the terminal one.

The *antennal scale* (fig. 4) extends almost to the distal end of the antennular peduncle and is about three times as long as broad. Its outer margin is entire and terminates in a strong spine, beyond which the evenly rounded apex of the scale projects for a little distance.

The *mouth parts*, in so far as they could be studied in the single available specimen, agreed well with KOSSMANN's figures.

The *first thoracic limbs* (maxillipedes) (fig. 5) are rather short when compared with the same appendage in *S. thompsoni*. The merus is longer than the carpus, the propodus is small and the nail distinct and longer than the propodus. The whole limb is moderately well armed on its inner edge with short plumose setæ.

The *second thoracic limbs* are missing in the specimen.

The *remaining thoracic limbs* (fig. 6) are somewhat slender and elongate. The tarsus is about as long as the merus and distinctly two-jointed, the first joint shorter than the second one. The nail is distinct and long, and the whole limb well armed with simple setæ, with a bunch of plumose setæ at the basal part of the nail.

The *exopods* of all the thoracic limbs are well developed, and have the outer distal corner of the expanded basal joint slightly acuminate. The flagelliform part is composed of ten joints.

The *pleopods* are of the usual type found in the females of this genus.

The *telson* (fig. 7) is about one and a half times as long as the last segment of the pleon. It is narrowly linguiform and tapering in shape with a prominent constriction at about one third of its length from the base. The apex is armed with a pair of long spines, between which are a pair of median setæ and three small equal-sized spinules. The sides below the constriction are armed with about 28 spines arranged in series of five distally, and three and four proximally. The proximal spine of each series is the shortest, the succeeding spines gradually increasing in length. Above the constriction the lateral margins are armed with three stout spines, longer than the spines arming the distal part of the margins.

The *inner uropod* is about one and a sixth times as long as the telson, narrow and having about 45 spines on its inner margin, the spines commencing at the inner posterior corner of the otocyst and extending to the tip. The spines are arranged in series of sometimes two and sometimes three, the most posterior spine nearly as long as the terminal spines of the telson. The otocyst is well developed.

The *outer uropod* is a little longer than the inner and much broader, the terminal joint being about one quarter of the length of the proximal one, the latter armed on the distal two thirds of its outer margin with 15 strong spines increasing in length posteriorly.

Length of an ovigerous female 12 millims.

The above description is based on the single Ceylon specimen in this collection, which I refer to this species. The male is as yet unknown. Professor PAULSON (1875) first described this species, though he referred his specimens at the time to *S. jaltensis*, CZERNIAVSKY. KOSSMANN (1880), who had a much larger specimen of what he believed to be PAULSON's species at his disposal, recognised that it differed rather markedly from *S. jaltensis*, and, therefore, re-described it, with figures, under the name *S. paulsoni*. CZERNIAVSKY (1880) likewise came to the conclusion that *S. jaltensis*, PAULSON, was not the same as his species, and, apparently unacquainted with KOSSMANN's earlier paper, fortunately also re-named it *S. paulsoni*. He had, however, no specimens, and drew up his diagnosis entirely from PAULSON's work.

Though both CZERNIAVSKY's and KOSSMANN's descriptions are imperfect in many points, they only differ in one important detail from the Ceylon example, namely, in the number of spines on the outer margin of the first joint of the outer uropod. CZERNIAVSKY gives the number as seven, KOSSMANN figures eight, while the Ceylon specimen has fifteen. This great difference may, I think, be explained by the difference in size of the individuals from which the various descriptions were drawn up. CZERNIAVSKY's description was based on PAULSON's specimen, 4 millims. in length; KOSSMANN's example was 8·5 millims., while the Ceylon one is 12 millims. The spinulation of the telson and uropods is known in other species of the group to vary with the size of specimens. In all other respects the present example agrees in the main with KOSSMANN's figures. *S. paulsoni* approaches nearest to *S. denticulata*, G. M. THOMPSON, among all the species of *Siriella* which have been described, but differs from the latter (1) in the length and proportion of the joints of the antennal peduncle; (2) in the deviating form of the antennal scale; (3) in the presence of spines on the lateral margins of the telson above the constriction; (4) in the much larger number of spines on the inner uropod. From the three Pacific species of the genus—*S. gracilis*, *S. thompsoni* and *S. indica*—*S. paulsoni* may be at once distinguished by having the outer uropod longer than the inner, and in having many more spines on the outer edge of the former. Previous to Professor HERDMAN's capture of this species in Ceylon it was only known from the Red Sea. Its geographical distribution has thus been considerably extended. As far as I am aware, it is the first Mysid ever recorded from Ceylon.

Haplostylus erythræus, KOSSMANN (?).

Locality :—South end of Red Sea, surface tow-net. One female, 5 millims.

In consequence of its small size and damaged condition the absolute identity of this specimen is a matter of some doubt. A description of the specimen is therefore given.

The *carapace* has the rostral projection short and bluntly rounded. It is without any trace of dorsal lobes on its hinder margin, which is slightly emarginate.

The *pleon* has the sixth segment about one and a half times as long as the preceding one, which shows no trace of a median posterior dorsal spine.

The *antennular peduncle*, which is only slightly longer than that of the antenna, has two small spines on the outer margin of the second joint.

The *antennal scale* is very short, scarcely reaching beyond the distal end of the basal joint of the antennular peduncle. Its outer margin is entire and terminates in a very strong spine. The apex of the scale does not project beyond the tip of the spine.

The *telson* is as long as the last segment of the pleon and cleft at its apex, the cleft, as usual in this sub-family, being serrated. The lateral margins bear six long and stout spines.

The *uropods* are both slightly longer than the telson, the inner a very little longer than the outer. The outer uropod has eleven strong spines on the outer margin, while the inner bears five spines on its internal margin.

Length, 5 millims.

It is probable that the above specimen belongs to *H. erythræus*. As just described, it differs from *H. normani* in the antennal scale, which has a stronger terminal spine and the apex not produced beyond the spine, and also in having a much blunter rostral projection. The males further differ from those of *H. normani* in having the inner branch of the third pleopod in the male quite absent.

H. erythræus is only known from the Red Sea, where both KOSSMANN'S types and the above specimen were obtained.

III.—STOMATOPODA.

FAMILY: SQUILLIDÆ.

Squilla raphidea, FABRICIUS.

Locality:—South-west part of Palk Bay, off Adam's Bridge and Rámésvaram Island, 7 to 9 fathoms. One male, 125 millims.

This specimen differed from large examples of this species which I examined in the British Museum in having the lateral processes of the fifth thoracic somite obtuse instead of acutely spinous.

Distribution:—*S. raphidea* has a general Indo-Pacific distribution, though not previously recorded from the coast of Ceylon.

Squilla nepa, LATREILLE.

Locality:—South-west of Palk Bay, off Adam's Bridge and Rámésvaram Island, 7 to 9 fathoms. One male, 42 millims.

Distribution :—*S. nepa* has already been recorded from Ceylon by HELLER (1868). Its distribution is general over the whole of the Pacific and Indian Oceans.

Pseudosquilla ciliata (FABRICIUS), MIERS.

Locality :—Talaivillu Paar, off south end of Mutwal Island, 10 to 14 fathoms. One male, 33 millims.

It is interesting to note that this specimen agrees with BROOKS' West Indian examples in those points in which the latter differ from the Pacific ones. I have confirmed this by an examination of BROOKS' "Challenger" specimens. BORRADAILE (1900) has proposed the varietal name *occidentalis* for this form.

Distribution :—*P. ciliata* has been recorded from Ceylon once previously by F. MÜLLER (1887). It is another widely distributed Indo-Pacific form.

Gonodactylus chiragra (FABR.), var. *smithii*, POCOCK (1893).

Locality :—Muttuvaratu Paar, 45 to 50 fathoms, in cavities of coral. One female, 12 millims.

This specimen agrees very well with LANCHESTER'S var. *smithii* (A) (LANCHESTER, 1902), except that the spine on the median carina is perhaps not so well developed.

Distribution :—China seas (POCOCK, 1893) ; Funafuti and the Loyalty Islands (BORRADAILE, 1898) ; Malay Peninsula and the Maldives (LANCHESTER, 1902).

Gonodactylus chiragra (FABR.), var *incipiens*, LANCHESTER (1902).

Locality :—Trincomalee. One male, 18 millims.

The single specimen which I refer to this variety of the type species agrees with LANCHESTER'S var. *incipiens* (A) (1902, plate xxiii., fig. 10).

Distribution :—Funafuti (LANCHESTER).

Gonodactylus glabrous, BROOKS (1885).

Localities :—

Cheval Paar, 6 to 8 fathoms. One female, 46 millims. ; one male, 16 millims.

Coral Reefs, Gulf of Manaar. Three females, 40, 30 and 15 millims. ; one male, 34 millims.

Pearl Banks, Gulf of Manaar. Two males, 18 and 20 millims.

Entrance to Galle Harbour, 4 to 7 fathoms. One male, 18 millims.

South end of Periya Paar, 8½ to 13 fathoms. One female, 22 millims. ; three males, 22, 20 and 17 millims.

South of Adam's Bridge, 4 to 40 fathoms. One male, 25 millims.

West and south-west of Periya Paar, 11 to 24 fathoms. One male, 20 millims.

West of Periya Paar, 17 to 24 fathoms. One female, 16 millims.

On weed-bearing oyster spat, south-east of Modragam, 4½ to 5½ fathoms. One male, 27 millims.

Aripu Reefs. Six males, 29, 26, 24, 20, 18 and 17 millims.; four females, 16, 15, 15 and 13 millims.

Galle Lagoon. Two females, 32 and 29 millims.

Galle, from cavity beneath Polyzoan crust. One female, 33 millims.

Off Mutwal Island, 10 to 14 fathoms. One female, 38 millims.; two males, 34 and 27 millims.

From the above list of captures it will be seen that this species is a very common one in Ceylon. In all, 33 specimens were captured, 19 of which were males ranging from 16 millims. to 34 millims. in length, and 13 females of from 13 millims. to 46 millims. in length. In no case did the depth of water over the ground on which they were taken exceed 24 fathoms. LANCHESTER (1902) in a survey of *G. chiragra* and the allied forms *G. glabrous* and *G. graphurus* expresses the opinion that the two latter species are in reality only varieties of the type species of the genus, and figures a series of telsons in support of this view, at the same time defining under separate varietal denominations a series of types leading from *G. chiragra* through *G. glabrous* to *G. graphurus*. The material in the present collection is by no means sufficient to attempt a discussion on the point raised by LANCHESTER, but its very uniformity has led me, at least for the present, to regard *G. glabrous* as a species distinct from *G. chiragra*, and constantly distinguished from the latter by the presence of two extra carinæ on the telson.

In only one specimen (not included in the above list of records, but referred to below) was any striking divergence in the form of the telson from that of the type to be noticed, and although it falls within one of the new varieties proposed by LANCHESTER, I regard it not as a definite varietal form, but as an individual abnormality.

It is true that the 33 specimens recorded above vary slightly among themselves in the relative tumidity of the carinæ of the telson, and in the absence from one or other of them of the terminal spines. But the difference between the extremes is at most slight, and the variation in any single instance (not even including the abnormality noted below) is not at all such as to cause any doubt for a single moment as to the validity of the specific separation of *G. glabrous* from *G. chiragra*.

LANCHESTER (1902) also notes on the telson of *G. glabrous* and *G. graphurus* the presence of two tubercles just beyond the distal end of the median carina. These two tubercles are present in all the Ceylon specimens, and also in BROOKS' type which I have examined at the British Museum.

A note on the colour of the Ceylon examples may be of interest. Several of the labels in the bottles had notes to the effect that the specimens contained therein were a vivid green colour when alive, and, indeed, a general bright green coloration seems to be the prevailing one in most of the specimens in the collection, many of which after three years' preservation still show strong evidence of this fact. All the specimens which appear to have been a uniform green when alive have four sharply defined though quite small dark green pigment spots, two on the sixth abdominal segment and two on the telson. Those on the sixth abdominal segment are always placed between the intermediate and lateral carinæ, and those on the telson occupy a corresponding situation. The constancy of the association of these pigment spots with a uniform green colour in the specimens of *G. glabrous* in this collection was, indeed, striking. One or two specimens, however, appear to have been a more mottled colour, with a distribution of dark pigment corresponding more or less with that noted by BROOKS for his single type specimen. In these examples the four prominent pigment spots noted above were not present.

The single abnormal specimen to which reference has already been made was a female, 24 millims. long, taken at Trincomalee. It agreed almost exactly with LANCHESTER'S var. *segregatus* (B) = var. *affinis*, DE MAN. I prefer, however, to regard it as an abnormal *G. glabrous*, having the anterior portion of the intermediate carinæ obsolete.

Distribution :—This species has a generally wide distribution throughout the Indian and Pacific Oceans.

Gonodactylus, sp.

Localities :—

10 miles north of Cheval Paar, $7\frac{1}{2}$ to 9 fathoms. One, 11 millims.

Mudalaikuli Paar. One, 8 millims.

These two specimens, apparently belonging to the same species, are still post-larval in development. They probably belong to either *Gonodactylus glabrous* or *G. chiragra*. The telson agrees fairly well with that figured by BROOKS (1886, plate xvi., fig. 5) from a specimen which he attributes to some species of *Gonodactylus*. The dactylus of the raptorial claw in both specimens has a notch on the external margin near to the proximal end.

Gonodactylus herdmani, n. sp.—Plate I., figs. 8 to 10.

Locality :—Coral Reefs, Gulf of Manaar. Two females, 28 and 26 millims.

The *rostrum* (fig. 8) is of the *Protosquilla* type, with acutely produced median and antero-lateral spines. The median spine extends for rather more than half way along the eye. The antero-lateral spines are not so much produced.

The *carapace* is rectangular in shape, and of about equal width throughout. Its antero-lateral and postero-lateral angles are both evenly and broadly rounded.

The *last three thoracic segments* have their lateral parts rounded.

The first five abdominal segments are quite smooth all over, without carinæ or furrows of any kind, and with their postero-lateral angles rounded.

The *sixth abdominal segment* (fig. 9) bears on its dorsal surface four equidistant, perfectly smooth, narrowly oval, blunt carinæ. The central two of these carinæ are slightly posterior to the lateral ones. None of the carinæ end in spines. There is also a prominent, rather sharp carina on each side of this segment, quite near to the lateral margins and running into the postero-lateral angles.

The *telson* (fig. 9) has the six marginal spines well developed, unusually stout and blunt. In the largest specimen the lateral spines are almost obsolete. The submedian spines have a small movable spinule at their tips. There are *no* submedian, intermediate, or lateral denticles whatever. The dorsal surface of the telson bears a median, broadly oval carina, and a narrower and rather sharper carina on each side of it. There is also a prominent carina running down into the submedian and intermediate spines of the telson. The median carina bears at its posterior end a prominent blunt spine, with two small blunt tubercles on each side of it. The lateral carinæ and those which run into the intermediate and submedian spines of the telson are broken up into irregular tubercles. The lateral carinæ and those of the intermediate spines are composed of three of the tubercles, those of the submedian spines of four, which are moreover rounder and more regular in shape.

The *uropods* (fig. 10) are very powerfully built. The basal joint bears a very prominent dorsal ridge, which is continued down both joints of the exopod. These joints are therefore triangular in cross section. The first joint of the exopod bears eleven stout spines on its outer edge. Both paddles are unusually tough and chitinous, and quite unlike the flat, thin, membranaceous, lamella-like paddle usually met with in Stomatopods. Both have prominent dorsal ridges, and the inner one is of a most unusual scythe shape (fig. 10). De Man figures a similar paddle to the inner uropod of *G. drepanephorus*. The setæ are mostly broken off.

Length of the largest specimen 28 millims.

The *colour* of the preserved specimens is generally pale, but there is a distribution of black pigment, which is the same for both specimens. There are three prominent black pigment spots on the posterior part of the carapace, surrounded by numerous pigment flecks. Anterior to these, on each side, on the suture separating the median from the lateral parts of the carapace, is a small, narrowly oval, pigmented area. There is a prominent median black pigment spot surrounded by numerous pigment flecks in the ante-penultimate thoracic and first, third, fourth and fifth abdominal segments, while scattered pigment flecks are to be seen on the lateral parts of all the abdominal segments.

Four species of *Gonodactylus* have been described with a *Protosquilla*-like rostrum, viz., *G. acutirostris*, de Man, *G. drepanephorus*, de Man, *G. festæ*, Nobili, and *G. demani*, Henderson. From all these *G. herdmani* is at once distinguished by the unusual bluntness and stoutness of the marginal spines of the telson, the presence of a movable spinule at the tip of the submedian spines, and the *complete absence* of submedian, intermediate, or lateral denticles on the telson. Its nearest relative is *G. drepanephorus*, which has the same peculiar paddle to the endopodite of the uropods, but the spines on the telson of the latter are much sharper and more numerous than in *G. herdmani*, while the tubercles on the sixth segment end in spines, whereas in the present species these tubercles are quite smooth.

I have named the species in honour of its discoverer.

Gonodactylus acanthurus, n. sp.—Plate I., figs. 11 to 15.

Locality:—Muttuvaratu Paar, 45 to 50 fathoms. One female, 10 millims.; one male, 8 millims.

The *rostrum* (fig. 11) is of the usual *Gonodactylus* type, with a long acute median spine reaching very nearly to the cornea of the eye, and slightly produced, bluntly rounded antero-lateral angles.

The *carapace* is rectangular in shape, of about equal width throughout. Its antero-lateral and postero-lateral angles are rounded.

The *last three thoracic segments* have their lateral parts rounded.

The *first five abdominal segments* are quite smooth all over, without carinæ or furrows of any kind. The postero-lateral angles of the first four segments are broadly rounded, those of the fifth segment produced somewhat, but rounded at the tip.

The *sixth abdominal segment* has the postero-lateral angles ending in prominent spines. On its dorsal surface are six carinæ, the submedian and intermediate of which are narrowly oval, smooth, and blunt, the lateral ones being somewhat sharper and running into the spines of the postero-lateral angles. The submedian and intermediate carinæ do not terminate in spines.

The *telson* (fig. 14) has the six marginal spines well developed, long, acute, the laterals slightly curved. There are about nine submedian, two intermediate, and a single lateral, rather long and acute denticles on each side. The dorsal surface of the telson bears three very blunt carinæ, the central one broadly oval and larger than the rather narrowly oval lateral ones. The posterior half of the telson, beyond the carinæ, is armed with long, powerful, acute spines arranged approximately in two transverse rows, five spines in a row. The first row is placed just posterior to the carinæ, and consists of a long median spine immediately below the base of the median carinæ, a long intermediate spine immediately behind the lateral carina on each side, and a rather short lateral spine. The second row, which is posterior to the first, consists of five long spines, the median one immediately below that of the first row, the intermediate and lateral ones alternating with those of the first row. There is a moderately long spine on each side of the posterior end of the median carina, and two small median spines. Each lateral carina bears two small spinules at its posterior end and immediately external to the posterior end of these lateral carinæ is a small spine.

The basal joint of the *uropods* (fig. 15) bears a strong posterior dorsal tooth. The paddle of the endopodite has its inner margin drawn out into six acute spines, its outer margin as usual fringed with setæ. The external margin of the basal joint of the exopodite bears eight strong spines. The terminal joint or paddle is small, its inner margin drawn out into three acute spines, its outer margin setose.

The *raptorial claw* (fig. 12) is of the usual type, without a notch on the external margin of the dactylus, and the internal margin of the propodus minutely serrated.

A figure of the endopodite of the first abdominal appendage of the male (fig. 13) is given for comparison with other species.

Length of the type male 8 millims., of the type female 10 millims.

The *colour* of the preserved specimens is uniformly pale, with rather a characteristic group of chromatophores on the first abdominal segment, and a less distinct group on the ante-penultimate thoracic segment.

This species of *Gonodactylus* is abundantly distinguished from all known species of the genus by the spinous inner margin of both paddles of the uropods, as well as by the rather distinctive armature of the telson.

Odontodactylus brevirostris (Miers, 1884).—Plate II., figs. 16 to 18.

Locality :—Pearl Banks, Gulf of Manaar. One female, 16 millims.

I have thought it advisable to give a brief description of the single Ceylon example.

The *rostrum* (fig. 16) is rather more than twice as wide as long, quite smooth, not sinuate but transverse, and evenly rounded in outline. The centre of the anterior margin is, however, slightly depressed, so that the rostrum, *in situ*, appears to be slightly emarginate (fig. 17).

The *carapace* is rectangular in outline, of about equal width throughout and having its antero-lateral and postero-lateral angles rounded.

The lateral parts of the last three thoracic segments are rounded.

The *abdomen* is of about equal width throughout. The postero-lateral angles of the first three segments are rounded, those of the fourth and fifth produced into short acute spines. The first five segments are quite smooth and devoid of all carinæ and ridges. The sixth segment bears six rather sharp carinæ, all of which end posteriorly in acute spines. There is also a small tubercle on each side of the sixth segment between the intermediate and lateral carinæ.

There is no spine at the articulation of the uropods.

The *telson* has the six marginal spines well developed, long and acute, the submedian ones with a movable spinule at their tips. There are sixteen submedian two intermediate, and a single lateral denticle on each side. The dorsal surface bears a median crest and four other rather sharp carinæ. The dorsal crest is interrupted slightly at its anterior end, and posteriorly it ends in a prominent spine. The carina on each side of the crest is very low and does not end posteriorly in a spine. The lateral carinæ are more elevated than the intermediate ones and not spinous posteriorly. There is also a prominent carina running into the submedian spines.

The *uropods* have the outer spine of the basal prolongation longer than the inner and reaching to the level of the tips of the submedian spines of the telson. The basal joint of the exopod bears ten strong movable spines on its outer edge.

The *raptorial claw* (fig. 18) has the dactylus very little ventricose at its base and provided with seven spines on its internal margin in addition to the terminal one.

Length 16 millims.

The *colour* of the specimen, as preserved, was dark mottled brown with traces of purple on the uropods. The second to the sixth abdominal segments have four small equidistant dark eye-spots.

The above specimen differs from the type in having only seven teeth instead of eight on the internal margin of the dactylus of the raptorial claw, but its close agreement with it in other characters leaves little doubt that it belongs to the same species.

O. brevirostris appears to be very closely allied to *O. havanensis*, BIGELOW, 1894. The latter has the rostrum more semicircular than *O. brevirostris*, and the dactylus of the raptorial claw is more dilated at the base and bears only six teeth on its internal margin.

The type, and only previously known specimen, of *O. brevirostris*, was taken in 19 fathoms off Providence Island, Indian Ocean. It is thus an addition to the Stomatopod fauna of Ceylon.

Protosquilla trispinosa (DANA), var. *pulchella*, MIERS (1880).

Localities :—

Pearl Banks, Gulf of Manaar, February, 1902, 6 to 11 fathoms. Two females, 44 and 15 millims.

South-west of Palk Bay, off Adam's Bridge and Rámeswaram Island, 7 to 9 fathoms. One female, 38 millims.

Coral Reefs, Gulf of Manaar. One female, 17 millims.

This variety differs from the type species mainly in the absence of corrugations on the median portion of the fifth abdominal somite

An examination of WHITE's type of *Protosquilla trispinosa* reveals the presence of a few scattered corrugations on the fourth segment of the abdomen. They are not present in MIERS' type of var. *pulchella*, nor in any of the Ceylon specimens.

The two large females in this collection appear to differ from the smaller ones and from MIERS' type in having the tubercles on the sixth abdominal segment much more swollen and without spines. It is possible that the spines on the tubercles are hidden by the general spinulose armature, or they may become obsolete in large examples. The small specimens had the tubercles of the telson very much less densely spinulose than the large ones.

Distribution :—*P. trispinosa*, var. *pulchella* is only known from Ceylon (MIERS) and the Indian Archipelago (DE MAN). The type form has also been recorded from Trincomalee, Ceylon, by HENDERSON, and seems to have a wide Indo-Pacific range.

Protosquilla spinosissima (PFEFFER).—Plate II., fig. 19.

Gonodactylus spinosissimus, PFEFFER, 1889.

Localities :—

Coral Reefs, Gulf of Manaar. Six females, 31, 29, 28, 28, 26 and 25 millims.; five males, 23, 23, 22, 21 and 20 millims.

Muttuvaratu Paar, 45 to 50 fathoms, from the cavities of Coral. Eight females, 28, 27, 27, 25, 24, 24, 23 and 19 millims.; eight males, 27, 25, 23, 21, 21, 21, 20 and 13 millims.

Pearl Banks, Cheval Paar. One male, 24 millims.

Talaivillu Paar. One male, 10 millims.

Through the kindness of Professor PFEFFER I have been permitted to examine the type of this species, with which I find the Ceylon specimens in perfect agreement. LENZ (1905) has recently pointed out that this species is a true *Protosquilla*, combining, as it does, a tridentate rostrum with the complete fusion of the sixth abdominal segment with the telson. It has thus no connection with *Gonodactylus spinosus*, with which BIGELOW, when describing the latter, compared it. A brief description of the species is appended, and a figure of the endopodite of the first abdominal appendage of the male given for comparison with that of other species (fig. 19).

The *rostrum* has the median spine very long and acute, extending to the corneal part of the eye. The lateral spines are acute, but not as much produced as the median one, and extend along the outer edge of the eye not quite as far as the corneal part.

The *carapace* is of about equal width throughout and oblong in shape. The antero-lateral angles are acutely rounded, while the postero-lateral angles are more broadly rounded.

The lateral parts of the last three thoracic segments are rounded.

The *abdomen* increases in width slightly from the front backwards. The postero-lateral angles of the first three segments are rounded, while those of the fourth and fifth segments are acutely produced. The first four segments have well-marked marginal carinæ, but are otherwise quite smooth. On the lateral parts of the fifth segment there are two or three sharp carinæ separated by slight furrows. The central part is almost smooth, except near the posterior margin, where a few short, scattered, transverse furrows may be noticed. The sixth segment is fused completely with the telson, though the suture is still distinctly visible. On its dorsal surface there are four rounded tubercles, the median two of which are smaller than the lateral ones, placed near to one another and separated from the lateral tubercles by a furrow. The tubercles and lateral parts of the segment are thickly beset with numerous, long, acute, upright spines.

The *telson* is longer than broad, with its lateral edges slightly curved. The posterior margin is cleft in the centre by a triangular fissure into two somewhat diverging lappets. Each of the latter is again divided by a very much shorter slit into two spines, which correspond with the submedian and lateral spines of the telson, the intermediates being suppressed. The dorsal surface bears three very prominent rounded tubercles, the median one placed anterior to the cleft, the lateral ones being placed entirely posterior to the median, one on each apical lappet. The median tubercle is bounded laterally and posteriorly by a deep furrow. The whole surface of the telson is thickly beset with spines similar to those on the sixth abdominal segment. The spines on the lateral portions of the telson external to the tubercles are arranged in three rows.

The *uropods* have the outer spine of the basal prolongation much broader and longer than the inner, and reaching to the top of the telson. The basal joint of the exopodite bears nine or ten stout spines on its outer edge. Its paddle is rather small.

Length of the largest male 27 millims., of the largest female 31 millims.

The *colour* of preserved specimens is generally dark, with various mottlings, the tubercles of the sixth abdominal segment and the telson tinged distinctly red.

This *Protosquilla* approaches most nearly to *P. brooksii*, DE MAN, and *P. hystrix*, NOBILI. The former may be distinguished from *P. spinosissima* (1) by having the four tubercles on the sixth abdominal segment quite smooth; (2) by the much fewer and much shorter spines on the telson and the sixth abdominal segment; (3) by the cleft in the lateral apical portions of the telson being nearly obsolete.

P. hystrix differs from the present species (1) in the absence of tubercles from the sixth abdominal segment; (2) in the form of the spines arming the sixth abdominal segment and the telson, which are shorter and stouter than in *P. spinosissima*, and hooked at the tip instead of simple.

Distribution:—The type and only previously known specimen of *P. spinosissima* was taken at Zanzibar, West Coast of Africa. The species would appear to be by no means rare in Ceylon.

STOMATOPOD LARVÆ.

BELONGING TO THE GENUS **Squilla**, FABRICIUS.

Alima *α*.—Plate II., figs. 20 to 25.

Localities:—

South end of Red Sea, surface tow-net. Thirteen, 11 to 23 millims.

Off Ráméswaram Island, surface tow-net. Seven, 4·5 to 7 millims.

Palk Bay, trawl. Eighteen, 12 to 27 millims.

Off Mutwal Island, surface tow-net. One, 27 millims.

All the above *Alimæ* appear to belong to one species. It will be most convenient to describe the largest specimen first, and then add a note on the small specimens.

Larva 27 millims.

Body generally greatly elongate and narrow; *rostrum* fairly short, about one-third of the length from the antero-laterals to the posterior margin of the carapace; *antero-laterals* short, not extending to the eye-stalk; *postero-laterals* rather long, reaching to the junction of the second and third abdominal segment, a single secondary spine near to its base; *postero-median dorsal spine* short; about sixteen small denticles on the lower (ventral) in-turned edge of the carapace; the latter with a very well-marked carina running down the whole of its median dorsal length and terminating in the postero-dorsal spine. Last three thoracic segments exposed behind the carapace; all the abdominal segments with their postero-lateral angles very acutely drawn out into spinous processes; sixth abdominal segment with a pair of median dorsal spines on its posterior border.

Telson (fig. 23) quite flat, without carinæ of any sort, but a series of well-marked concentric pits present, about one and a fifth times longer than broad, six marginal spines, well developed, acute, and slightly curved; margin between the submedian spines deeply emarginate, with a slight notch in the centre, and bearing seventeen denticles on each side; eleven intermediate and a single lateral denticle present on each side.

Uropods (fig. 24) barely reaching the level of the lateral spines of the telson; traces of six spines on the external edge of the outer branch; inner spine of the basal prolongation slightly longer than the outer, but not yet reaching the tip of the outer uropod.

Eyes somewhat large, placed on slender stalks.

Raptorial claw (fig. 25) with no signs of teeth as yet on the dactylus, two prominent teeth at the proximal end of the propodus, the inner margin of which is spinulose.

Last three thoracic appendages present and biramous, but still very small.

Abdominal appendages well developed, with gills just showing.

The smallest larva belonging to this species in the collection measures 4·5 millims. in length (fig. 20). It has the carapace rather wider, proportionally, than older larvæ, but the median dorsal carina is already very well marked. There are three spines on the ventro-lateral edge of the carapace between the antero- and postero-lateral spines, and a single secondary spine on the latter. The telson (fig. 21) is of somewhat different shape to the older larvæ, being much more quadrangular, with the marginal spines much shorter. The margin between the submedian spines is relatively much wider and more shallowly emarginate, without a trace of median notch. The telson bears seven submedian, five intermediate, and a single lateral denticle on each side.

The next stage, 7 millims. long, has a carapace much as in the last. The telson, however, has assumed a much more octagonal shape (fig. 22), and the margin between the submedian spines is relatively much narrower and more deeply emarginate than in the larva of 4·5 millims. The marginal spines are much more prominent, and there are fourteen submedian, ten intermediate, and a single lateral denticle on each side.

After 7 millims. the larva assumes practically the same shape as described above for a 27 millims. larva, and a slight notch appears in the margin of the telson between the submedian spines. The marginal spines likewise become longer and more acute.

This *Alima* is most closely allied to *Alima bidens*, Claus. The latter is the only *Alima*, as far as I am aware, which has a well-marked median carina on the carapace, but the present *Alima* differs from *A. bidens* in having a well-marked postero-median dorsal spine on the carapace.

Three *Alimæ*, captured in a trawl off Galle, do not seem to differ materially from the above except in size. They measure 19 millims. in length, but are more advanced in their development than the larva of 27 millims. described above. The uropods extend very nearly to the intermediate spines of the telson and have traces of seven spines on the outer edge of the external branch. The telson is about as long as broad, and bears twelve submedian, ten intermediate, and a single lateral denticle on its margins. Its shape is in substantial agreement with the 27-millims. larva described above.

Alimerichthus unidens, LANCHESTER, 1902.—Plate II., fig. 26.

Locality:—East of the Gallehogalle Bank, 16 to 30 fathoms, fine sand. Two specimens, 12 millims. and 9 millims. long, from the eye to the telson.

The largest of the Ceylon larvæ is practically the same size as LANCHESTER's type, and appears to be at the same stage of development. I am able to confirm the fact, established by LANCHESTER, that in some *Alimerichthii* at least the postero-lateral angles of the abdominal segments end in acute spines, because both in the specimens here referred to *A. unidens*, and also in another species described below, such spines are distinctly present and well developed. As points not noticed by LANCHESTER, it may be mentioned that the telson in both specimens has forty-four submedian spinules and eight intermediate ones. There are eight spines on the outer uropod of the large specimen, but only two on that of the smaller, a difference quite in accordance with the difference in size. The dactylus of the raptorial claw (fig. 26) has in both specimens one fully developed spine in addition to the terminal one and traces of two others beneath the skin. A figure of the raptorial claw is given for comparison with the other *Alimerichthus* described below.

Distribution:—Maldive and Laccadive Islands (LANCHESTER). This is the only previous record for the species, the distribution of which is now extended to Ceylon.

Alimerichthus α.—Plate II., figs. 27 to 29.

Locality:—Cheval Paar, 7 fathoms. Two specimens, 9 millims. and 10 millims. long from eye to telson.

This larva differs chiefly from *A. pyramidalis*, LANCHESTER, and *A. unidens*, LANCHESTER, the only two described species of this type of larva, in size, being only 9 millims. long, but at a stage in its development rather later than either *A. pyramidalis* at 16 millims. or *A. unidens* at 12 millims. It evidently belongs to a smaller species of adult than either of the above two. A brief description may enable the species to be recognised in any future collections.

Carapace (figs. 27 and 28) rather wide, leaving only one thoracic segment exposed, exhibiting in lateral view the same pyramidal form already noticed by LANCHESTER for the other species of the type; rostrum slightly shorter than the length of the carapace extending to about the same level as the flagella of the antennules, two ventral spinules at about the level of the eye; posterior median dorsal spine well developed, arising from the pyramidal base noted above, much shorter than the postero-lateral spines, a prominent carina running from the rostrum along the middle of the carapace, terminating in the postero-dorsal median spine; antero-lateral spines rather short, with a prominent spine of equal length arising from their bases and projecting ventrally; postero-lateral spines well developed, extending backward to the level of the boundary between the second and third segment of the abdomen, with a secondary spinule on each near the base; no prominent ventro-lateral spine on the carapace midway between the antero- and postero-lateral spines, as seen in *A. pyramidalis* and *A. unidens*; two small spinules on the ventro-lateral margin very near to the point of origin of the postero-lateral spines.

Abdomen with all its segments well developed, each having their postero-lateral corners very acutely drawn out into spines, rather more so than in *A. unidens;* sixth segment with a pair of rather long and acute spines on the median posterior border.

Telson about as long as broad, six marginal spines well developed and acute; between the submedian spines there are 32 denticles, that is, 16 on each side of the centre; between the submedian and intermediate spines on each side there are 7 intermediate denticles, and between the intermediate and lateral spines on each side there is a single lateral denticle situated at the base of the lateral spine.

Appendages of abdomen all well developed, each with a rudiment of the future gills already present.

Uropods fairly well developed, reaching slightly beyond the lateral spines of the telson; basal prolongation with the inner spine much longer than the outer, and exhibiting a very slight swelling near the origin of the latter; external edge of the outer branch showing traces of six spines.

Raptorial claws (fig. 29) having the dactylus with two developed spines in addition to the terminal one, and showing traces of two more below the integument.

Length 9 millims.

The second specimen, which measures 10 millims., agrees perfectly with the above description except that the telson only has 26 denticles between the submedian spines and six denticles between the submedian and intermediate spines on each side. The distinguishing features of this larva are:—

(1) Its small size taken with its advanced state of development;
(2) Absence of a prominent ventro-lateral spine on the carapace;
(3) The spines arming the dactylus of the raptorial claw;
(4) The spinulation of the telson.

This *Alimerichthus* at 9 millims. long is at exactly the same stage of development as CLAUS' *Alimerichthus* at 18 millims. long (CLAUS, 1871, fig. 30).

Belonging to the genus Lysiosquilla, Dana.

Lysioerichthus duvaucellii (Guérin).

Locality :—East of Gallehogalle Bank, 16 to 30 fathoms, fine sand. One specimen, 22 millims. long, excluding rostrum.

The single example which I refer to this distinct and rather remarkable species agrees in all particulars save two with Claus' figures (Claus, 1871, fig. 16). The first point of difference lies in the complete absence from the present specimen of a dorsal spine. In Claus' figure the latter is represented by a slight acumination only.

The Ceylon specimen has two very small spinules between the submedian and intermediate spines of the telson and a very small one at the base of the lateral spines. These spinules are not represented in Claus' figures, but are so small as to be easily overlooked. The raptorial claw shows indications of seven teeth below the skin, and the outer uropod is armed with five not fully developed spines.

From a comparison of the Ceylon specimen with the figures of *L. duvaucellii* given by Claus (1871), Brooks (1886), and Jurich (1904), it seems at least doubtful that all three writers were dealing with the same species.

It is unfortunate for an absolute settlement of this point that Claus omitted to mention the length of his specimen. The Ceylon example, which seems almost certainly to belong to the same species as Claus', measures 22 millims. without the rostrum, but is considerably more developed than Brooks' largest specimen (which is stated to be over an inch, *i.e.*, 25 millims. in length), in having more segments of the abdomen exposed below the carapace, in the limbs of these segments being much more advanced in development as shown by the appearance of gills and in having more spines on the outer uropod, and differs in the absence of the dorsal spine of the carapace. Jurich's largest specimen, which measures 20·5 millims. without the rostrum, agrees with Brooks' figures in all essential particulars, and the differences between them, namely, the less developed abdomen and the absence of indications of teeth beneath the skin of the raptorial claw in Jurich's specimen, are only those of age. From these considerations it seems improbable that Brooks' and Jurich's specimens belong to the same species as Claus', though certainly very nearly allied. Brooks mentions that some of his larvæ were without the dorsal spine on the carapace, but, if this latter gradually becomes obsolete as larval development proceeds, we should naturally expect that it would be his largest larvæ which would be without the spine. This is not so, as is apparent from the text. It is more probable that he had two species of larvæ under consideration. As already noted, a definite conclusion on this point is precluded by a want of knowledge of the size of Claus' larva, but the possibility of two closely allied species of larvæ having been confounded under the one specific denomination, *L. duvaucellii*, seems worthy of notice.

Distribution :—Bay of Bengal (Guérin); Indian Ocean (Claus); West Pacific ("Challenger"); Indian North Equatorial Current (Jurich).

Lysioerichthus α.—Plate II., figs. 30 to 34.

Localities :—

Off Kalpentyn Island, surface tow-net, all night. One, 8 millims.

Cheval Paar, surface tow-net. One, 8 millims.

Off Mutwal Island, surface tow-net. One, 7 millims.

This species is very closely allied to *L. ophthalmicus*, Hansen, from which it chiefly differs in having a pair of spines on the postero-median border of the sixth abdominal segment.

Carapace (fig. 30) rather small and compact ; rostrum short, about one-half of the total length of the carapace, no ventral teeth ; antero-lateral spines very small indeed ; postero-lateral spines rather short, not reaching to the posterior end of the first abdominal segment, without secondary spinules ; postero-median dorsal spine and lateral spinules of any kind absent.

Abdomen with all the segments developed, and having their postero-lateral corners acutely angulated ; pleopods all well developed, but no rudiments of gills present ; sixth abdominal segment with a pair of median dorsal spines on its posterior border.

Telson about as long as broad, six marginal spines present ; margin between the submedian spines almost straight, without trace of median cleft, and bearing twenty-four submedian denticles ; one intermediate denticle present between the submedian and intermediate spines of each side ; no lateral denticles.

Uropods (fig. 31) fairly well developed, extending as far as the level of the lateral spines of the telson ; traces of four spines on the external margin of the outer branch ; outer spine of the basal prolongation very much longer than the inner one.

Second to fourth thoracic appendages (figs. 32 to 34) agree in essential details with those figured by Hansen for *L. ophthalmicus*.

Last three thoracic appendages, though still very imperfectly developed, are, however, already biramous.

Length 8 millims.

The specimen, 7 millims. long, agrees well with the above description, but is generally less developed, having only three spines on the outer uropods, and the last three thoracic appendages are mere buds. It has also only twenty-two submedian denticles on the telson.

Among all described *Lysioerichthii* the present species comes nearest to *L. ophthalmicus*, Hansen (1895), from which it differs (1) in having a pair of submedian spines on the posterior border of the sixth abdominal segment, and (2) in the relatively smaller size of the inner spine of the basal prolongation of the uropods.

Lysioerichthus β.—Plate III., figs. 35 to 40.

Localities :—Muttuvaratu Paar, surface tow-net. Two hundred and seventy-five specimens, from 2 millims. to 6 millims. in length.

South end of Cheval Paar, surface tow-net. One specimen. 5 millims.

East Cheval Paar, surface tow-net. Two specimens. 5·5 millims. and 7 millims.

South end of Mutwal Island, surface tow-net. Seven specimens, 6·5 millims. to 8·5 millims.

North end of Chilaw Paar, surface tow-net. Three specimens, 4 millims.

Description of largest specimen:—

The length of the largest specimen of this larva was 8·5 millims. from the eye to the telson, or 11 millims. from the tip of the rostrum to the telson.

Carapace with the rostrum very long and acute, its length measured from the antero-lateral spine to its tip greater than the length from the antero-lateral spines to the posterior border of the carapace; six small spinules on the ventral edge of the rostrum; antero-lateral spines quite small; postero-lateral spines long, extending half-way along the telson, with a prominent spine at its base projecting ventrally; postero-median dorsal spine quite short; dimensions of carapace, length from antero-laterals to the posterior border, 3·5 millims.; antero-laterals to tip of rostrum, 4 millims.; postero-lateral spines, 3 millims.

Abdomen, with all the segments and their appendages developed; first segment hidden by the carapace; postero-lateral angles of all the segments rounded; sixth segment without a pair of median dorsal spines; appendages all well developed, and setose, with the gills just appearing.

Telson (fig. 41) about one-third as broad again as long; six marginal spines well developed; the margin between the submedians with two very prominent spines dividing this part of the margin of the telson into three parts, each part deeply emarginate, the central part slightly smaller than the lateral portions and each portion bearing seven spinules with very minute comb-like spinules in between; two intermediate and one lateral spinule present on each side.

Uropods short, only as yet reaching to the lateral spines of the telson; outer edge of external branch with two spines; ventral prolongation of the uropods with the two spines subequal in length.

Raptorial claw (fig. 40) still without any signs of teeth below the integument; last three thoracic appendages present and biramous, but very small.

The large number of larvæ of this type present in the collection has enabled me to trace, in a fairly complete manner, its life-history from the earliest stage, the *Erichthoidina*, to the stage described above. The most important and interesting changes are undergone by the carapace, and a study of these changes has led me to differ from Brooks in one or two points. A very brief description of larvæ at various stages may first, with convenience, be given.

Larva 2 millims. (tip of rostrum to telson). This is the smallest larva of the series, and represents the *Erichthoidina* stage. The carapace is without any trace of antero-laterals and there is no spine at the base of the postero-laterals. The rostrum is quite short and without ventral spinules. The postero-laterals are also very short (fig. 35). A larva of 3 millims. is in substantial agreement with the one at 2 millims. except that the rostrum is relatively a little longer.

Larva 4 millims. This stage (fig. 36) is distinguished by the appearance of a small spine at the base of the postero-lateral spines of the carapace. The rostrum is relatively longer than in the 3-millims. stage, and now bears a single ventral spinule. A single thoracic segment is exposed posterior to the carapace.

Larva 5 millims. This larva agrees very well with the one at 4 millims., but the rostrum is a little longer and bears two ventral teeth (fig. 37). Two thoracic segments are now exposed behind the carapace.

Larva 6 millims.—At this stage the antero-lateral spines of the carapace make their first appearance. The rostrum continues to increase proportionally in size and now bears four ventral spinules. The postero-lateral spines are likewise relatively longer and the uropods are just discernible as buds.

Larva 7 millims.—The carapace (fig. 38) is now fully formed with antero-laterals, postero-laterals, and the spine at the base of the latter, all well developed. The rostrum is as long as the remainder of the carapace from the antero-laterals to the postero-median dorsal spine, and bears fine ventral spinules. The uropods show one spine on the outer edge of the external ramus.

Later stages only differ from the 7-millim. larva in the continued relative increase in length of the rostrum and postero-lateral spines, to the proportions shown in the larva 9 millims. (fig. 39), which agrees with the still larger larva, 11 millims. long, described above.

During development the telson gradually becomes broader in proportion to its length (see figs. 36, 39 and 41), but the number of spines varies very little from the numbers given in the description of the large larva above.

A comparison of the figures here given to illustrate this *Lysioerichthus* larva with figs. 1, 2A, 2B, 4 and 5 of CLAUS' memoir (1871) will show that the species dealt with here is very closely allied to, if not identical with, the one CLAUS had under observation, and that the three supposed species of *Erichthoidina* described by the latter author under the names *E. gracilis*, *E. armata* and *E. brevispinosa* in all probability represent developmental stages in the life-history of one species only, the development of which, as gleaned from CLAUS' figures, follows very closely the lines indicated in the Ceylon larvæ. The latter are also in all probability identical with the *Erichthoidina* figured by BROOKS in his "Challenger" Monograph, plate xii., figs. 1 and 2. BROOKS has expressed the opinion that CLAUS' *E. brevispinosa* is a young stage of *Gonodactylus*, and bases his view on the presence in the latter of a spine at the base of the postero-lateral spine of the carapace which he regards as characteristic of *Gonerichthii*. The Ceylon series clearly shows that this spine, though not present in the earliest *Erichthoidina*, is a later development, and thus its presence cannot be regarded as diagnostic of *Gonerichthii*, but may be present in some *Lysioerichthii* as well (see also HANSEN, 1895, plate vii., figs. 4A and 5A, where such a spine is represented on the carapace of two species of *Lysioerichthii*). For this reason I venture to differ from BROOKS, in regarding CLAUS' *Erichthoidina brevispinosa* as a *Lysioerichthus* rather than as a *Gonerichthus*.

BELONGING TO THE GENUS **Pseudosquilla** (GUÉRIN) DANA.

Pseuderichthus communis, HANSEN (1895).

Locality :—South end of the Red Sea, surface tow-net. One specimen, 15 millims.

HERDMAN'S example is smaller than either CLAUS', HANSEN'S or JURICH'S larvæ, but agrees well with all three in its chief points. At this stage, however, only three spines are to be noted on the outer uropod. The tooth on the ventral edge of the rostrum just in front of the eye is very prominent.

Distribution :—General throughout the tropical Atlantic and Indian Oceans (CLAUS, HANSEN and JURICH).

BELONGING TO THE GENUS **Gonodactylus**, LATREILLE.

Gonerichthus *α*.—Plate III., fig. 42.

Locality :—Cheval Paar, surface tow-net. One specimen, 11 millims. long from eye to telson.

Carapace (fig. 42) with rostrum fairly long, equal in length to the rest of the carapace from the eye to posterior dorsal spine; about eight small denticles on the ventral edge of the rostrum; antero-lateral spines short; postero-lateral spines long, extending to the junction of the third and fourth segments of the abdomen; a small postero-ventral spine at the base of the postero-laterals; postero-median dorsal spine very small.

Abdomen with all the segments developed, and having their postero-lateral corners acutely angulated; sixth segment with a pair of small median dorsal spines on its posterior border; appendages all well developed, biramous and setose; gills well developed and already digitate.

Telson about as long as broad, six marginal spines well developed and somewhat acute; margin between the submedian spines somewhat deeply emarginate and distinctly notched, bearing thirty submedian denticles; two intermediate and a single lateral denticle present on each side.

Uropods very well developed and almost as long as the telson; external margin of the outer branch with only two distinct spines; inner spine of the basal prolongation much longer than the outer, which is quite small.

Raptorial claw without any signs of spines on the dactylus; last three thoracic appendages well developed and biramous.

Length 11 millims. from the eye to the telson.

This larva is distinguished among *Gonerichthii* by the somewhat unusual character of having the inner spine of the basal prolongation of the uropod much longer than the outer. In no *Gonerichthus* yet described is such a character found. In other respects the larva is a perfectly typical *Gonerichthus*, especially in the characters of the third and fourth thoracic limbs, which have not the swollen propodus characteristic of *Lysioerichthii*. The larva is very far advanced in development, but the raptorial claw shows no signs of spines on the dactylus. It must be concluded therefore that the larva belongs to the genus *Gonodactylus*.

Gonerichthus β.—Plate III, figs. 43 to 45.

Locality :—Off Kalpentyn Island, surface tow-net, all night. Forty-two specimens, from 4 to 7 millims. in length from eye to telson.

Carapace (figs. 44 and 45) with rostrum very long, the length from the antero-lateral spines to the tip of the rostrum exceeding the length from the antero-laterals to the posterior median dorsal spine ; eight small teeth on the ventral edge of the rostrum ; antero-lateral spines very small ; postero-lateral spines very long, extending to the junction of the sixth abdominal segment with the telson, a small spine at its base projecting ventrally ; postero-median dorsal spine very short.

Abdomen with all the segments well developed, and having their postero-lateral angles slightly angulated ; sixth segment with a pair of median dorsal spines on its posterior border ; abdominal appendages very well developed, with digitate gills already present.

Telson rather longer than broad ; six marginal spines present ; margin between the submedian spines emarginate, with a slight notch in the centre, and bearing twenty-four submedian denticles ; two intermediate denticles present on each side, but no lateral denticle could be discerned.

Uropods well developed, extending to the level of the intermediate spines of the telson ; traces of ten spines on the external margin of the outer branch ; outer spine of the basal prolongation extending nearly to the level of the submedian spines of the telson, much longer than the inner spine.

Raptorial claw without traces of spines on the dactylus ; third and fourth thoracic appendages of the usual *Gonerichthus* type, and not exhibiting the swollen propodus of the *Lysioerichthus* ; last three thoracic appendages fairly well advanced and already biramous.

Length 7 millims. from the eye to the tip of the telson.

The smaller larvæ referable to this type differ chiefly in the proportional length of the rostrum and postero-lateral spines, both of which increase in comparative length as the larva advances (see fig. 43).

This type evidently belongs to quite a small species of adult. At 7 millims. length it is as far advanced as type α at 11 millims., and is evidently not far from maturity. It is one of the most abundant *Erichthus* larvæ in the collection.

Gonerichthus γ.—Plate III., figs. 46 to 47.

Localities:

Off Kalpentyn Island, surface tow-nets all night. Twelve specimens, from 4 to 7 millims. in length from the eye to the telson.

Cheval Paar, surface tow-net. Three specimens, 5 to 6 millims. long.

This *Gonerichthus* is very closely allied indeed to the last, and the description there given will answer for this species, save in the following particulars:—

Rostrum (figs. 46 and 47) comparatively much shorter, the length from the antero-lateral spine to its tip being much shorter than the length from the antero-laterals to the postero-median dorsal spine; only three or four teeth on its ventral edge.

Antero-lateral spines of the carapace, though still small, are more developed than in type β.

Postero-lateral spines relatively much shorter, and only extend about half way down the second abdominal segment.

Telson, while agreeing in general shape and armature, is comparatively a little broader.

The above comparison between the types β and γ is drawn up from specimens of the same size, 7 millims., and at the same stage of development. Figs. 46 and 47 show the carapace of the type γ in dorsal and lateral view respectively, and the differences between types β and γ are readily seen in comparison with figs. 44 and 45, in which the carapace of type β is shown. Type β at 4 millims. has a carapace of about the same proportions as type γ at 7 millims. (see fig. 43). It seems clear from this that the larvæ β and γ are distinct and belong to separate though closely allied adults.

REPORT

ON SOME

PARASITIC COPEPODA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

CHARLES BRANCH WILSON, M.A.,
DEPARTMENT OF BIOLOGY, STATE NORMAL SCHOOL, WESTFIELD, MASS.

[WITH FIVE PLATES.]

OF this small collection of Parasitic Copepods* obtained by Professor HERDMAN and Mr. HORNELL at Ceylon it can be said with even greater emphasis than was declared by Rev. T. R. R. STEBBING of the Isopods from the same locality: "The interest of the present collection is not to be measured by the number of species, or the number of specimens, still less by the size of the animals."†

There were only five vials of the Parasitic Copepods, and yet from these were obtained four new species, two of which were the types of new genera. There were also two other species which had been previously described, but both of which were founded on a single sex and on a very limited number of specimens. Neither of these had been seen since originally described forty years ago. Of one of them the male sex is here added for the first time, while of the other many supplementary details of structure are given.

There was thus not a single species in the small collection which did not present something new and interesting—a truly remarkable record.

* The main report on the large collection of free and a few parasitic Copepoda, by the late Mr. I. C. THOMPSON and Mr. ANDREW SCOTT, will be found in Part I. of this work (1903) at p. 227.

† Part IV. of this Report, Supplementary Report XXIII., "On the Isopoda," 1905.

DESCRIPTION OF THE SPECIES.

Family: CALIGIDÆ.

Sub-family: CALIGINÆ.

Lepeophtheirus brachyurus, Heller—Plate I., figs. 1 to 10.

This species was briefly described by Heller in the 'Reise der Novara,' 1865, and has not been seen by any other investigator since. Heller's specimens were obtained near Java upon the gills of the same host as the present Ceylon specimens.

The following description, and the figures given on Plate I., supplement as well as corroborate Heller's original diagnosis :—

Female.—Carapace ovate, considerably narrowed and rounded anteriorly, widened and emarginate posteriorly. The length of the carapace is more than twice that of the rest of the body, but is a little less than its width. The grooves on the dorsal surface are distinct, with the cross-bar of the H about in the centre of the carapace, while the anterior and posterior halves of the lateral grooves are inclined like the sides of an hour-glass. The frontal plates are narrow, scarcely more than one-third the width of the carapace, with a deep but narrow central incision. The eyes are moderately large and placed far forward, about one-fifth the length of the carapace from its anterior margin. The thoracic area is large and wedge-shaped, three-quarters of the width of the carapace and slightly concave at its posterior margin, less than half the width and slightly convex at the anterior margin.

The fourth or free thorax segment is very short and concealed in dorsal view by the overlapping carapace. The genital segment is transversely elliptical, one-third wider than long, with evenly rounded sides and a nearly straight posterior margin. The fifth legs are visible at the posterior corners.

The abdomen is short and narrow, one-fourth the length and one-fifth the width of the genital segment, one-jointed, with the posterior margin wedge-shaped. The anal laminæ are minute, fastened to the sides of the wedge, and each armed with three plumose setæ and a small spine.

The egg-cases are about the same length as the entire body and as wide as the abdomen. The eggs are of medium thickness, about 70 in each string.

Of the appendages, the first antennæ are short and unusually wide, a considerable portion of the basal joint being concealed beneath the edge of the carapace. The terminal joint is only about half the length of the basal and carries a tuft of spines at its tip. The second antennæ are stout and of the usual form, with a long terminal claw bent abruptly near the tip (fig. 2).

The first maxillæ are very small and rudimentary ; the basal portion is swollen and circular, while the terminal part is slender and curved. The second maxillæ are short and simple, broadly triangular, with a narrow, pointed, and more or less curved tip. The rudimentary exopod appears as a large papilla upon the basal portion of the appendage, which is fused with the ventral surface of the carapace. These appendages are quite small, less than half the length of the mouth-tube, and are attached at some little distance to the right and left of the base of the latter. The mouth-tube itself is short and wide, somewhat triangular, with a broadly rounded tip; the mouth opening is terminal with a scanty fringe of hair (fig. 3).

First maxillipeds of the usual pattern; second pair enlarged and stout, the terminal claw strongly curved and less than half the length of the basal joint, with an accessory spine on its ventral surface near the base. Basal joint much swollen and furnished at the centre of its anterior margin with a large and stout process projecting diagonally outwards. The under surface of this process is grooved, and into this groove fits the tip of the terminal claw (fig. 4).

The furca is slender, the basal portion longer and wider than the terminal and with a large elliptical lumen, the branches slender and divergent with rounded points.

The swimming legs are of the usual pattern, but the basal joint of the second pair is very narrow. The basal apron of the third legs is also short and narrow, but it is attached so far back and the free segment is so short that it overlaps a little the genital segment. Another feature not noted by HELLER is the fact that the dorsal surface of the apron of these third legs projects backward between their rami as a rounded knob, as long as the rami themselves. These latter are small, well separated, and each is two-jointed (figs. 6 to 9).

The fourth legs are small and rudimentary, and are entirely concealed beneath the apron of the third legs, another fact not noted by HELLER. They contain only two joints of about the same length, the terminal one carrying three spines, of which the inner one is twice as long as the others.

The ovaries are rather small and triangular and are situated just behind the eyes at some distance from each other. The oviduct is coiled very regularly in the sides of the genital segment, as can be seen in fig. 10. The cement glands are comparatively wide and reach forward nearly to the anterior margin of the segment. Their anterior half is curved in toward the mid-line and is occupied by about eighteen large cells, the last two or three of which at either end diminish abruptly in size. The posterior half is even a little wider than the anterior and is filled with a homogeneous mass, in which there is no distinction of cells or ducts. The semen receptacle is bent in a half circle, the convex side forward, and is about the same diameter throughout. The vulvæ open near together on either side of the median line.

The colour of the preserved specimens is a uniform light yellowish gray, without pigment spots or lines.

Total length 4·5 millims., length of carapace 3 millims., width of same 3·35 millims., length of genital segment 1 millim., length of abdomen 0·5 millim., length of egg-sacs 4·4 millims.

There were two specimens of this species, both females, obtained from the gills of a puffer, *Tetrodon stellatus*. They may be easily distinguished from other species of the genus by the relatively large size of the carapace compared with the rest of the body, by the correspondingly diminutive size of the fourth segment and the abdomen, and by the rudimentary fourth legs, which are entirely concealed in both dorsal and ventral view. The large rounded spine which projects between the rami of the third legs is also peculiar to this species.

Lepeophtheirus æsopus,* n. sp.—Plate I., figs. 11 to 19.

Female.—Carapace ovate, considerably narrowed anteriorly, and a little more than two-fifths the entire length. Frontal plates prominent, but less than half the width of the carapace. Eyes large and placed well forward. Thoracic area exceptionally small, one-third the length and three-fifths the width of the carapace, its anterior and lateral margins forming nearly a perfect half circle, its posterior margin slightly re-entrant. Lateral lobes broad, blunt and short, leaving a wide sinus between the carapace and the genital segment, which is entirely filled by the large basal joints of the third and fourth pairs of swimming legs.

The fourth or free thoracic segment is transversely elliptical and widened considerably through the bases of the fourth legs. The genital segment is quadrate, two-thirds the size of the carapace, and a little wider anteriorly than posteriorly, with evenly rounded corners.

The abdomen is narrow, only one-sixth the width of the genital segment and less than half its length. It is indistinctly three-jointed, the middle joint larger than the other two, which are about the same size. The groove separating the terminal joints is distinct and can be traced the entire width of the abdomen, but the basal groove can be seen only at the margins, and it is not certain that the abdomen is really jointed there. The anal laminæ are narrow, three times as long as wide and pointed at the tips where each is armed with four small setæ. The egg-strings are wider than the abdomen and three-quarters of the entire length; the eggs are large, 50 or 60 in each string.

Of the appendages, the second antennæ have a large basal joint and a very slender terminal claw, which is bent sharply at right angles near its tip. The basal joint is re-enforced by a stout spine, pointing backward (fig. 12).

The first maxillæ are small and well curved, the basal half fused to the ventral surface of the carapace and only the tip free. As an offset to this, the second pair are exceptionally large and stout, with a broad, triangular base and a long, straight, and pointed tip which reaches far beyond the end of the mouth-tube. Each maxilla

* *Æsopus*, different footed, each pair of legs differing considerably from the ordinary type in this genus.

is two-jointed and is actually longer and wider than the mouth-tube. Upon the basal joint, which is fused to the carapace, appears the rudimentary exopod in the form of a small papilla bearing two setæ. It is situated near the centre of the basal joint and close to the endopod. The endopod itself is simple as in the genus *Caligus*, and not bifurcate as in many species of *Lepeophtheirus* (fig. 13).

The first maxillipeds are of the usual pattern, but the outer terminal claw is lengthened so that the two cross each other from opposite sides of the body when the appendages are at rest. The second maxillipeds are small and weak, the terminal claw only half the length of the basal joint, and slender (fig. 14). No trace of any furca could be found.

The first swimming legs are small and weak; the three terminal claws are of nearly the same length, as is also the seta at the inner corner. The basal joint of the second legs is exceptionally narrow, being but little wider than the connecting piece across the centre of the body; the rami are of the usual pattern. The rami of the third legs are so close together as to be in actual contact at their bases, but the exopod stands out at right angles to the basal apron, while the endopod is closely appressed to the margin of the latter. The exopod is three-jointed, the joints of about the same size; this gives it considerable length, which, together with its position, makes it unusually prominent. The basal joint also bears on its inner margin a wide circular lamina, which extends outward to the tip of the terminal joint and inward to overlap the endopod; this latter is of the usual form (figs. 15 to 18).

The fourth legs are also exceptional in having a stout and swollen basal joint and three small and weak terminal joints. The second joint also, instead of being cut off diagonally at the distal end as in other species, is cut squarely across.

The second and third joints each carry a single spine at the outer distal corner, while the last joint is terminated by a row of three spines; the five are approximately of the same size.

No fifth legs are visible, but the genital segment bears upon its margin at each posterior corner three small spines which probably represent the rudiments of these legs.

The oviducts are not much coiled in the genital segment; the cement glands are narrow and nearly straight, situated on either side of the mid-line and close to it. In the specimen observed the spermatophores were long and narrow, and turned forward along the ventral surface of the genital segment. Each was curved away from its fellow like a pair of parentheses marks; the anterior ends almost touched each other, but the posterior ends, entering the vulvæ, were about the diameter of the abdomen apart (fig. 19).

Colour of the preserved specimen a uniform yellowish white, without pigment spots or lines.

Total length 5·75 millims., length of carapace 2·4 millims., width of same

2·4 millims., length of genital segment 1·95 millims., length of abdomen 0·92 millim., length of egg-sacs 4·2 millims.

SUB-FAMILY: TREBINÆ.

Trebius exilis,* n. sp.—Plate II., figs. 20 to 33.

Female.—Carapace ovate, one-seventh longer than wide, contracted anteriorly, and well arched. Transverse grooves separating the cephalic and thoracic portions of the lateral areas situated far forward, leaving the thoracic portion much the longer of the two. Eyes small, purplish red, and some little distance from the anterior margin. Frontal plates better developed than either *T. caudatus* or *T. tenuifurcatus*, but still less than half the width of the carapace.

Third thorax segment only a trifle wider than the fourth and considerably shorter. It projects backward, however, nearly its whole length beyond the lateral lobes of the carapace, just as the thoracic area does in some of the Caliginæ (*Caligus rapax*, *C. rufimaculatus*, &c.). Fourth segment considerably longer than the third, and widened through the bases of the fourth legs more than in either of the other two species, giving it a spindle shape.

Genital segment almost a perfect ellipse, the only deviation being anteriorly, where it is contracted into a short and narrow neck before joining the fourth segment. It is more than three-fifths the size of the carapace and shows no spines or processes at the posterior corners. The egg-strings are about the same width as the abdomen, but are from two and a half to three times its length, thus contrasting sharply with those of *T. caudatus* which are but a trifle longer than the abdomen. The eggs are of medium thickness, 40 to 50 in each string.

The abdomen, even including the anal laminæ, is one-half shorter than the genital segment instead of one-half longer as in *T. caudatus*. It is also made up of a single joint and is of the same diameter throughout. The anal laminæ are elongate, more than twice as long as wide, well separated at the base, but convergent toward the tips, where each carries four good-sized plumose setæ. As in *T. caudatus*, the outer seta is the shortest, the inner one next in length, while the two middle ones are considerably longer.

Of the appendages the first antennæ are relatively much longer than in *T. caudatus*, the basal joint is stouter and more heavily armed with plumose setæ, while the terminal joint is slender, not enlarged at the tip, and stands out prominently. The second antennæ are large and stout; the terminal claw is wider at the base than in *T. caudatus* and is relatively as long. But the abrupt bend is at the centre instead of near the tip, and this makes the claw appear shorter. There is also a long and slender hair on the inner margin of the claw near its base (fig. 22).

* *Exilis*, slender, beautiful.

The first maxillæ are straight, small, and weak, and they are fused to the ventral surface of the carapace throughout their entire length, not even the tips being free.

The second maxillæ are also very different from those of *T. caudatus.* They are two-jointed, the basal joint being fused to the ventral surface of the carapace, and carrying at its centre the rudimentary exopod. This is in the form of a good-sized papilla armed with two setæ of about the same length, and less than one-third the length of the endopod. The latter is elongate-triangular, extends for half its length beyond the tip of the mouth-tube, and is bluntly pointed at the end, without any trace of bifurcation.

The mouth-tube is not as long as in *T. caudatus,* but is jointed similarly at the centre of the upper lip, with deep lateral incisions. The bony framework shows some similarity to that of both *Lepeophtheirus hippoglossi* and *Caligus rapax.* There are in it two sets of rods hinged together at the centre just above the joint (fig. 23). In the basal half the rods are four in number arranged in the form of the letter M. The two outside ones (*a*) start from just behind the bases of the mandibles and run diagonally forward and inward until they nearly meet at the mid-line. These must be regarded as belonging to the framework of the lower lip, although they are buried in the tissues of the ventral surface of the carapace. From their inner ends two other rods (*b*) start and run parallel with each other on either side of the mid-line outward nearly to the jointing at the centre of the mouth-tube. These evidently belong to the framework of the upper lip. From the outer ends of the first pair, just behind the bases of the mandibles, a stout rod (*c*) runs along either side of the under lip, the two curving around and meeting on the mid-line at the tip of the lip. Near the joint in the mouth-tube each of these rods divides and sends a branch rod up to the upper lip, the branch ending in the lateral incision on either side. Articulating with the end of the branch at this incision is a long bone (*d*), shaped like the human femur, which sweeps inwards and forwards until it meets its fellow from the opposite side near the centre of the tip of the upper lip.

The upper lip is thus jointed near its centre, while the lower lip articulates directly with the ventral surface of the carapace. As the mouth-tube naturally points backward the upper lip is longer than the lower lip, and this jointing at its centre greatly facilitates the freedom of motion. The mouth-opening is a terminal transverse slit, heavily fringed with hairs. The mandibles are slightly curved towards their tips, where they are toothed on the inner margin. They pass out through the sides of the mouth-tube at the lateral incisions and articulate with the ventral surface of the carapace just in front of the bony framework.

The first maxillipeds are comparatively large and stout as in *T. caudatus,* but the basal joint is not as much enlarged, being a trifle smaller than that of the second pair. The two terminal claws are about the same diameter, but the inner one is almost twice the length of the outer. The second maxillipeds are much reduced in size as compared with those in the Caliginæ; the basal joint is stouter than in

T. caudatus, but the terminal claw is as short and weak as in the latter species. No spine could be seen on its inner margin in any of the specimens examined (fig. 25).

The furca is small, the length four times the width, the branches short, simple, divergent, and pointed, leaving a V-shaped sinus, only one-fourth or one-fifth the entire length.

The first swimming legs have a broad and well-rounded basal joint, carrying a small seta on its posterior margin. Both rami are two-jointed, the exopod nearly twice the length of the endopod. The basal joint of the exopod is considerably wider than the terminal, and somewhat swollen; the terminal joint is only half the length of the basal, is not bent at a right angle as in *T. caudatus*, and is armed with three short and stout spines on its distal end, and three plumose setæ, as long as the entire ramus, on its posterior margin. The basal joint of the endopod is also twice the length of the terminal, and somewhat swollen; the terminal joint is bent at a right angle and tipped with three stout plumose setæ.

Second swimming legs similar to those of *Lepeophtheirus* in the shape and arrangement of the joints and in the number and distribution of the spines and setæ.

The third swimming legs are like the second, but differ in a few particulars. The exopod carries three spines on the outer margin of the terminal joint; the basal and second joints of the endopod are much enlarged, while the terminal joint is reduced in size and carries only four plumose setæ.

The fourth swimming legs are very different from those of *T. caudatus*. The basal joint is larger than that of the second legs, and almost circular. The exopod is three-jointed and more than twice the length of the endopod; the three joints are about the same length, the two basal ones with a stout spine at the outer distal corner, and a single plumose seta on the inner margin. The terminal joint has three spines on its outer margin, the last one more than twice the length of the other two, and four spines on the inner margin. The endopod has only two joints of about the same size, the basal one carrying a single plumose seta on its inner margin, the terminal one tipped with three such setæ.

The fifth legs are small and close to the lateral margin on the ventral surface of the genital segment, a little in front of the posterior corners.

The cement glands are comparatively wide and reach forward almost to the anterior end of the segment; their component cells are narrow and fill the entire lumen of the glands. The sperm receptacle is a nearly straight tube of uniform width, reaching across from one oviduct to the other. The spermatophores are elongate-ellipsoidal, and are fastened close together on either side of the mid-line, their long diameters parallel with the body axis (fig. 31).

Total length 5·75 millims., length of carapace (including third thorax joint) 2·5 millims., width of same 2·1 millims., length of genital segment 1·57 millims., length of abdomen 1·1 millims., length of egg-strings 3·1 millims.

Colour of preserved material a uniform yellowish white without pigment spots or lines.

Male.—Carapace ovate and narrowed anteriorly, with grooves and markings on the dorsal surface like those of the female, but it is relatively larger, being more than half the entire length, and nearly as wide as long. The eyes are distinct and small, about one-third the distance from the anterior margin.

The second and third thorax segments are wider than in the female; the fourth segment is the same width as the genital segment and only a trifle longer than the second and third segments. The genital segment is elliptical-oblong, one-fourth longer than wide, and not quite one-fifth of the entire length. Both the fifth and the sixth legs are visible dorsally, the former on the lateral margins at about the centre of the segment, the latter at the posterior corners.

The abdomen is two-jointed and at least one-half shorter than the genital segment; the two joints are equal in size. The anal laminæ are narrow, but nearly as long as the entire abdomen, each tipped with four very long plumose setæ.

Appendages and colour as in the female.

Total length 2·75 millims., length of carapace (including third thorax segment) 1·4 millims., width of same 1·3 millims., length of genital segment 0·5 millim., length of abdomen (including anal laminæ) 0·6 millim.

Developmental stages.—Young females were obtained in two stages of development respectively 2·5 millims. and 3·5 millims. long.

In the former, the second thorax segment is not yet fused with the carapace, but is semilunar in shape, with the convex side projecting a little way into the posterior portion of the carapace. The lateral processes on this segment are nearly as large as the posterior lobes of the carapace (fig. 32).

The third segment is much narrower than the second, but is still wider than it is long. The fourth segment is considerably longer than wide and has a broad spindle shape. In the genital segment each of the posterior angles projects strongly sidewise, is well rounded, and armed with two stout spines. This makes the segment twice as wide across the posterior margin as across the anterior. The abdomen is also slightly wider at its posterior end.

The first antennæ are short and thick and are appressed closely to the margin of the carapace. The other appendages are similar to those of the adult except the swimming legs, in which the rami have but two joints instead of three.

In the later developmental stage the carapace has enlarged considerably, and the second thorax segment has widened with it (fig. 33). The longitudinal and transverse grooves on the dorsal surface of the carapace are now fully formed, so that the same areas are seen as in the adult. The third and fourth thorax segments are about the same as in the previous stage, but the genital segment has changed radically. It has widened into a broad acorn shape, as wide anteriorly as posteriorly, with the posterior corners projecting slightly backwards and showing the fifth legs plainly at their tips. The abdomen has elongated and its sides are now parallel.

The appendages have assumed their final form, and the rami of the swimming legs have all become clearly three-jointed.

About ten specimens of this species were obtained from *Rhinoptera javanica*, including the two stages of early development. The species is of peculiar interest, because it is the only one besides Kröyer's original type (*T. caudatus*) of which a full description of even one sex could be obtained.

It confirms Kröyer's genus diagnosis in all but two particulars. The second maxillæ are not forked at the tip like those of *Lepeophtheirus*, but are simple and pointed like those of *Caligus*. Furthermore the endopod of the fourth legs, instead of being as large as the exopod, is reduced so much as to be rudimentary and contains only two joints. These two particulars furnished data which will at once distinguish the species from *T. caudatus*.

Sub-family: EURYPHORINÆ.

Dissonus,* n. gen.

First thorax segment fused with the head to form the carapace, which is semilunar in shape and about twice as wide as long.

Second, third, and fourth thorax segments free, each considerably wider than long, the second one only provided with lateral plates. Genital segment not much enlarged, without plates or processes, but with the entire ventral surface covered with stout spines. In the male the fifth legs are seen on the posterior lateral margins and the sixth pair at the posterior corners. Abdomen small, one-jointed in both sexes ; anal laminæ of medium size and armed with large plumose setæ.

Egg-strings four-fifths of the entire length and not quite as wide as the abdomen. Eggs large, about forty in each string.

Antennæ and mouth-parts like those in the Caliginæ. Second maxillæ longer than the mouth-tube and bifurcate at the tip. First maxillæ and furca wanting. Mouth-tube short and triangular in shape with a rounded tip, jointed transversely near the centre. The four pairs of swimming legs biramose ; rami of the first pair two-jointed, of the other pairs three-jointed ; spines and setæ almost exactly like those in *Trebius*.

Dissonus spinifer,† n. sp.—Plate III., figs. 34 to 47.

Female.—Carapace transversely semilunar, twice as wide as long ; the ventral surface around and outside of the second antennæ is raised somewhat, and beneath it

* *Dissonus*, disagreeing or different, *i.e*, not agreeing with any of the established genera.

† *Spinifer*, bearing spines (on the ventral surface of the genital segment).

can be seen the powerful muscles which move those appendages, and which radiate outward from the basal joint of the antennæ to the lateral margin of the carapace.

The dorsal surface has but a single pair of grooves, one on either side separating the lateral areas from the central cephalic area. Eyes moderately large, situated close to the anterior margin and in contact with each other on the mid-line, but not fused. In front of the eyes and on the very margin is a pair of elliptical spots, a little larger than the eyes and raised above the surrounding surface like a pair of lenses. These correspond exactly with the so-called "conspicilla" found by DANA in his *Specilligus curticaudis*, and which occur also in the males of other species belonging to the Pandarinæ. They have also been noted by KRÖYER in the male of *Trebius caudatus*, but are not found in the male of the new species of *Trebius* just described. In the present genus they are much farther forward and nearer together, being just in front of the supra-œsophageal ganglion.

The second, third, and fourth thorax segments are free and diminish regularly in size. The second segment is the same width as the body of the carapace and its lateral plates are as wide as the lateral lobes of the carapace. The third and fourth segments are considerably narrowed, but even the fourth is more than twice as wide as long, and the basal joints of the legs attached to both these segments closely resemble in dorsal view the lateral lobes of the carapace and the lateral plates on the second segment.

The genital segment is quadrangular, a little wider than long, and a little narrower than the fourth segment. The processes at the posterior corners are very small, and the fifth legs are almost invisible dorsally. The entire ventral surface of the genital segment is covered with stout scattered spines which point diagonally backward. These are thickest along the sides and must furnish a very effective preventative against slipping, as in the genus *Argulus*.

The abdomen is three-eighths the length of the genital segment, one-fourth wider than long, and one-jointed, with a shallow anal fissure. The anal laminæ are quadrangular-oblong, of medium size, each armed with four large plumose setæ. Three of these are terminal, while the other comes out of the lateral margin near the anterior end.

Of the appendages, the anterior antennæ are large and prominent, two-jointed, with the joints about the same length, but the basal one considerably thickened. Each antenna is one-fourth longer than the frontal plate from whence it comes. The setæ and spines are similar to those in the Caliginæ. The second antennæ are stout and of the same pattern as in *Caligus*. The terminal claw fits into a small pocket made for its reception in the ventral surface of the carapace near the margin (fig. 37).

The first maxillæ and furca are entirely lacking. The mandibles are slender, three-jointed, and armed with hook-like teeth along the inner margin of the slightly curved terminal joint. The mouth-tube is triangular, with a narrow and well-rounded tip; the mouth-opening is terminal and quadrilateral, with a heavy fringe of hairs.

The bony framework is peculiar in its structure, although in some particulars it shows a resemblance to *Caligus rapax* and other Caliginæ. There is in the lower lip a rod (*a*, fig. 38) along either edge, the two meeting in the centre at the distal end. The bases of these rods articulate on the ventral surface of the carapace together with the mandibles. From these articulations a short rod (*b*) extends forward and inward on either side along the ventral surface of the carapace.

From the inner ends of these rods another pair extend upward and inward along the upper lip to the lateral incision opposite the joint (*c*). From these incisions radiate four pairs of rods, three of which (*d*) are in the upper lip, while the fourth pair (*e*) extend downwards on either side to the rod that runs along the edge of the lower lip. Of the three pairs in the upper lip two extend inward side by side, one above and one below the joint, and meet on the mid-line. The lateral incisions at the joint are deeper than in any of the Caliginæ or in *Trebius*, and the mouth-tube must be very flexible.

The second maxillæ are large and powerful; although attached opposite the base of the mouth-tube they reach well beyond its tip. The basal portion of each maxilla is enlarged and flattened, and is about one-third of the entire length. The terminal portion is narrowed abruptly and then tapers gradually to a blunt point, being curved first inward toward the mouth-tube and then outward away from it. At the tip each maxilla is divided into two branches, of which the outer one is the longer and the larger. At the end of the basal portion, where it is abruptly narrowed, there is on the ventral surface a large papilla, from whose summit arise three spines, the outer one twice the length of the other two. These represent the rudiments of the exopod of the maxilla (fig. 39).

The first maxillipeds are of the pattern common to the Caliginæ, the terminal joint two-thirds the length of the basal joint and tipped with two claws, the outer of which is three times as long as the inner.

The second maxillipeds are greatly enlarged, the basal joint stout and swollen and nearly twice the length of the strongly curved terminal claw. On the proximal half of the ventral surface of the basal joint the integument forms a sort of pad with raised edges and a more or less corrugated surface. The distal edge of this pad is raised into a stout knob, down behind which the tip of the terminal claw shuts when closed.

All four pairs of legs are biramose, the rami of the first pair two-jointed, of the other pairs three-jointed. In the first pair the exopod is a little more than twice the length of the endopod. Its basal joint is three times as long as the terminal one, is heavily fringed with hairs along its posterior margin, and ends in a stout spine. The terminal joint is nearly spherical and is attached at right angles to the basal joint, not at the tip, but some distance back on the posterior border. It is armed, as in the Caliginæ, with three terminal spines, three rowing setæ, and a smaller seta at the inner distal corner. The endopod joints are about the same size, the terminal one armed with four spines on the outer margin and three rowing setæ on the inner.

The second, third and fourth swimming legs are as in other Euryphorinæ and the Trebinæ, particularly in the form of the second joint of the endopod and in the number and arrangement of the spines and setæ. The following table represents the arrangement of spines and setæ on each joint:—

Second legs,	exopod	2–1,	1–1,	1–5.
,,	endopod	0–1,	0–2,	0–6.
Third legs,	exopod	1–1,	1–1,	3–5.
,,	endopod	0–1,	0–2,	1–4.
Fourth legs,	exopod	1–1,	1–1,	3–5.
,,	endopod	0–1,	0–2,	1–3.

The fifth legs appear as small papillæ at the posterior corners of the genital segment, each armed with three setæ.

Of the reproductive organs the cement glands are rather small, broadly club-shaped, and they reach but little in front of the centre of the genital segment. The component cells are of medium size and there are about twelve in each gland. The semen receptacle is very close to the posterior margin; it is considerably curved, with the concave side directed forwards. The ends are slightly enlarged and from each a duct runs forward and empties into the oviduct anterior to the opening of the cement gland.

Colour of preserved specimens a uniform yellowish white without pigment spots or lines.

Total length 3 millims., length of carapace 0·85 millim., width of same 1·75 millims., length of free thorax 1·1 millims., length of genital segment 0·71 millim., of abdomen 0·34 millim., of egg-strings 2·35 millims.

Male.—Similar to the female in general appearance and in most of the details of structure. Carapace transversely semilunar, a little more than twice as wide as long. Second, third and fourth thorax segments diminishing slightly in width, but increasing in length, the fourth segment nearly one-half longer than the second. Second segment the only one furnished with lateral plates, but the large basal joints of the third and fourth legs have all the appearance of lateral plates in dorsal view, as in the female.

Genital segment elongate-spindle-shaped, one-third longer than wide, with evenly rounded sides; the anterior margin re-entrant, the posterior one nearly squarely truncated. Two pairs of rudimentary legs are visible, one pair on the lateral margin about one-fourth the distance from the posterior end, and the other pair at the posterior corners.

Abdomen not as wide as in the female, the anal laminæ a little smaller, but the plumose setæ considerably larger.

Of the appendages, the second antennæ are especially large and stout; their terminal claw is bent abruptly at a right angle one-third its length from the tip, and is armed on the inner margin of the basal third with a long curved and sharp spine, a short and blunt one, and a long slender hair (fig. 36). The second maxillæ are similar to those of the female but larger and more powerful. The outer branch at the tip is nearly twice as long as the inner, while the three spines which make up the rudimentary exopod are much larger and stouter. The maxillipeds and legs are the same as in the female. The ventral surface of the genital segment is also covered with spines, larger and rather more numerous than in the female (fig. 47).

Total length 3 millims., length of carapace 0·8 millim., width of same 1·9 millims., length of free segments 1·08 millims., of genital segment 0·8 millim.

This new genus is very interesting since it stands as a connecting link between the Euryphorinæ and the Pandarinæ. At first sight it would be taken for a *Nogagus* species, showing that which was so long sought after, a mature female with her egg-strings. But the description just given excludes it from that genus. The dorsal aspect, to be sure, is very similar to that of a typical *Nogagus*; the carapace is perhaps a little too short, but the free segments, the genital segment, and the abdomen are almost identical with those in some species of *Nogagus*. When we examine the ventral surface and the appendages, however, we find radical differences.

First there are no traces of sucking disks which are found in all the species of *Nogagus*. The mouth-tube, mandibles and second maxillæ are like those found in the Euryphorinæ and quite different from the typical form of the Pandarinæ.

The mouth-tube is short and broadly rounded at the tip instead of being narrow and pointed. The mandibles are curved at the tip, toothed on the concave border, and come together end to end, instead of being straight, with the toothed margins interlocked for their entire length. The second maxillæ are very long, pointed, and bifurcate at the tip, with a well defined exopod, instead of being short, triangular or broadly laminate, and without any trace of a second ramus.

The second maxillipeds have a simple swollen basal joint and an ordinary terminal claw unlike the distorted form in *Nogagus* with its swellings and knobs.

The swimming legs have three-jointed rami, except those of the first pair; a typical *Nogagus* has no ramus with more than two joints. We have here then a genus whose body-form is almost exactly like that of *Nogagus*, while its appendages are all modified and approach much nearer to those found on *Euryphorus*, *Alebion*, and *Dysgamus*. And since in any systematization, but more especially here among the Parasitic Copepods, the appendages are of more value than the body form in determining relationship, this genus must be placed with the Euryphorinæ.

It will be the only genus in the sub-family possessing three free thorax segments, but as it is an intermediate form, any close conformity to the characteristics of a single family could not be reasonably expected.

Family: DICHELESTIIDÆ.

Cætrodes,* n. gen.

Body regions distinct. Head covered with a dorsal carapace which is obovate in shape, strongly arched and considerably widened anteriorly, narrower and rounded posteriorly. This posterior portion is flattened and projects far back over the thorax segments, but is not attached to them. Frontal margin turned under the carapace a little, carrying the base of the anterior antennæ back with it on the ventral surface.

At least four (probably five) free thorax segments, indistinctly separated and diminishing in width posteriorly, the fifth one sending back a wide lobe on either side of the genital segment. Genital segment small, transversely oblong, enclosed on three sides by the fifth segment.

Abdomen small, hemispherical, one-jointed. Anal papillæ longer than the abdomen, narrow, cylindrical, and terminating in a spine and a claw.

First antennæ five-jointed, slender, with very few setæ except on the terminal joint. Second pair stout, ending in a prehensile claw. Mouth-tube short and wide; mouth-opening terminal.

First maxillipeds rudimentary, attached close beside the second maxillæ and of about the same size. Second pair slender, two-jointed. Two pairs of biramose swimming legs, close together and just behind the second maxillipeds; rami linear and two-jointed. Egg-tubes longer than the body; eggs large and uniseriate.

Cætrodes pholas,† n. sp.—Plate IV., figs. 48 to 57.

Female.—Head wider than the rest of the body and two-fifths of the entire length; covered dorsally with a strongly arched carapace which is divided into right and left halves by a prominent ridge or rib at the centre. The posterior margin of this carapace is prolonged backward in the form of a thin flattened plate which covers the anterior half of the thorax segments.

With the point of a needle, or by sharply flexing the body, this plate may be lifted away from the thorax segments, and this shows that it is not attached to them in any way. There is no trace of the median rib in this posterior part of the carapace. The passage from the arched to the flattened portion of the carapace is very irregular and forms a broken line over the posterior margin of the head. At the centre there is a wide triangular sinus extending forward, with its point on the median line. On either side of this is a blunt, rounded projection extending backward, outside of which is a wavy line curving forward as it runs toward the margin. There are no traces of frontal plates or of eyes.

The thorax is composed of at least four (probably five) free segments, which are imperfectly separated from one another.

* *Cætrodes*, like a small round shield.

† *Pholas*, lurking in a hole or burrow.

The first two of these are very short and considerably narrower than the head; the third and fourth (fused) are longer and wider, and together are about three-fifths the size of the carapace shield. The fifth segment is shorter and narrower than the fourth. It is divided transversely into thirds, the two outer divisions extending backwards in the form of wide rounded lobes on either side of the genital segment and abdomen, the median division forming a shallow rounded sinus for the attachment of the genital segment.

The genital segment and abdomen together form a hemisphere about the size of one of the posterior lobes of the fifth segment. The abdomen is one-jointed and bears on its ventral surface, at the posterior margin, two large cylindrical anal papillæ. These are longer than the abdomen itself, and each is tipped with a claw and a spine. The claw, which is on the inside, is nearly as long as the papilla, stout, and abruptly curved near the tip, exactly like the prehensile claws on the second antennæ of the Caligidæ. The spine is only one-fourth as long as the claw, and straight (fig. 57).

Egg-tubes wider than the genital segment and one-third longer than the entire body; eggs large, about 30 in each tube.

The first antennæ are five-jointed, the joints diminishing in diameter towards the tip; the setæ are very scattered except on the third and last joints. The second antennæ have a stout and conical basal joint, and a slender, strongly-curved terminal claw.

The mouth-tube is short and wide, with a rather blunt tip, enclosing the slender mandibles which are toothed on their inner margins. The second maxillæ and first maxillipeds are about the same size and close together at the sides of the mouth-tube. Each is two-jointed, and is made up of a short and plump basal joint and a slender terminal spine. The maxillipeds, of course, are rudimentary when reduced to this size, and are similar to those found in *Pseudoclavella*, *Cycnus*, *Cybicola*, and other Dichelestiids (fig. 52).

The second maxillipeds are fairly developed and much resemble the first pair in the Caligidæ. They are two-jointed, the joints about the same length, the terminal one tipped with a short and straight claw.

There are only two pairs of swimming legs, both biramose, with the rami linear and two-jointed. In each pair the exopod joints are about the same length, while the basal joint of the endopod is much shorter than the terminal.

Owing to the habit which the species has of lying in a burrow, the oviducts open on the dorsal surface, on either side of, and quite near to, the mid-line. The ovaries and the internal portions of the oviducts fill the entire thorax and even project forward into the head. The external portions (egg-tubes) start out at right angles to the dorsal surface, and are thus lifted well above the edge of the burrow. They then curve over and lie in close contact with the surface of the fish's gill outside the burrow (fig. 48).

Colour of the entire animal, a deep reddish yellow, like that of the gill on which it lives. The two arched halves of the anterior portion of the carapace are almost white, and the uneven line, where the arched portion passes into the flattened plate, stands out prominently in consequence of the meeting of this white colour with the deep yellow.

Total length 1·15 millims.; length of carapace 0·9 millim.; length of head 0·5 millim., width of same 0·9 millim.; length of thorax 0·65 millim.; length of egg-strings 1·8 millims.

This Dichelestiid is particularly interesting on account of its peculiar burrowing habit. About fifteen specimens, all females, were obtained from the gill filaments of *Tetrodon stellatus*. After fastening themselves to the surface of the filament by the prehensile second antennæ, and, we strongly suspect, by the terminal hooks on the anal laminæ, these parasites in some way irritate the epithelium until it is raised into a broad fold or flap, entirely surrounding the Copepod's body and overlapping its margin on all sides. A small convex mound is thus formed, beneath the open centre of which lies the body of the parasite, its egg-tubes projecting freely and lying along the surface of the gill filament. The anterior margin of the head and the posterior extremity of the body, including the abdomen and anal laminæ, are burrowed under the edge of the epithelium fold and fastened by their prehensile hooks.

Apparently, therefore, the parasite can have no freedom of motion, but is fastened immovably in place. No similar case of burrowing is known to the author; there are, of course, many genera among the Chondracanthidæ and Lernæidæ which bury the head and neck in the flesh of their host. There are also genera of the Dichelestiidæ, such as *Anthosoma*, *Eudactylina*, and the like, whose prehensile claws irritate the epithelium of the host until it grows up in a fold over the claws themselves.

But so far as is known, this is the only case where the epithelium folds entirely surround the body, so that the latter is securely held in place by them. The result is that the body of the parasite lies in the bottom of a hole or burrow, with only a portion of its dorsal surface visible.

Hatschekia, ? n. sp.—Plate V., figs. 58 to 60.

A single specimen of a species belonging to this genus was obtained from the stomach of *Carcharias mülleri*. It was a young female without egg-strings but with spermatophores, and was only a trifle over 1 millim. in length.

While it seems to be a new species unlike any thus far described, yet its small size, its poor condition, and the manifest fact that it is not a fully developed adult furnish sufficient reasons to prevent its establishment as a new species. The following description and the figures which accompany it must await future confirmation, therefore, before being finally established.

Female.—Head transversely elliptical, one-half wider than long, one-fifth the entire length. Thorax composed of two free joints and the genital segment. First free joint a little narrower than the head, second joint and genital segment considerably wider. The latter sends out a blunt rounded process on either side of, and nearly as large as, the abdomen. No appendages are visible on these processes or elsewhere on the genital segment. Abdomen very small and nearly spherical, with a pair of minute anal papillæ, each of which ends in three small setæ. First antennæ slender and apparently six-jointed; second pair large and terminated by a stout prehensile claw. Mouth-tube short and narrow and bluntly rounded at the tip; second maxillæ and first maxillipeds in the form of two small papillæ on each side of the mouth-tube, each tipped with a single seta. Second maxillipeds slender, the terminal joint shorter than the basal. Two pairs of biramose legs placed close behind the second maxillipeds; basal joints rounded and flattened laminæ, rami linear and cylindrical; exopods two-jointed, endopods one-jointed. Spermatophores comparatively very large and attached by long delivery ducts.

Colour a pale yellow, the ovaries and internal oviducts showing a dark brown through the transparent integument.

Total length 1·07 millims.; length of free thorax 0·35 millim.; length of genital segment 0·5 millim., width of same 0·48 millim.

Family: LERNÆIDÆ.

Peniculus, Nordmann.

Head oval or elliptical, elongate, without horn-like processes, connected with the body by a short and narrow neck, which is made up of two distinct thorax segments. Body a fusion of several thorax segments, elongate, wider than the head, and sometimes prolonged posteriorly into two elongate flattened processes.

Abdomen small, consisting of a single joint and carrying minute anal papillæ, which are tipped with non-plumose setæ. Egg-strings filiform; eggs large and uniseriate.

First antennæ reduced to mere knobs; second pair large and chelate, projecting in front of the head and forming the chief organs of prehension. Mouth a simple tube projecting from the ventral surface of the head; mouth-parts entirely wanting, except a single pair of very rudimentary maxillipeds beside the mouth tube. Four pairs of rudimentary swimming legs; first two pairs placed close behind the head, third and fourth pairs some distance from them and from each other.

Male smaller than the female and with a shorter thorax; posterior processes also shorter than those of the female, but wider and truncate at the tip.

Peniculus furcatus, Kröyer—Plate V., figs. 61 to 66.

Female.—Head elliptical, slightly widened posteriorly, about twice as long as wide, with evenly curved sides. Posteriorly the head passes into a neck of about half its width, made up of three thorax segments which are distinctly separated on both the ventral and dorsal surfaces. The fourth and genital segments are fused, with no line of demarkation except the position of the fourth legs on the ventral surface. This fused portion constitutes the body of the Copepod, which is nearly twice the width of the head, and twice as long as wide, with parallel sides.

The body widens sharply from the neck, its anterior corners well rounded, while its posterior corners are produced into a pair of wide, flattened processes, nearly as long as the rest of the animal, and either straight or slightly divergent, Along the sides, toward the centre, these processes often show incisions and grooves, very irregularly placed in different specimens and suggesting imperfect segmentation.

Between the bases of these processes lies the small abdomen, a little wider than the processes, and also a little wider than long. Its posterior corners are produced into short and rounded processes, similar to those on the genital segment but much smaller. Between these processes on the posterior margin are the tiny anal papillæ, each of which terminates in three non-plumose setæ. Of these latter, the inner and outer ones are considerably longer than the middle one (fig. 66).

The first antennæ are reduced to mere knobs, so rudimentary as to be invisible unless seen in profile and under the best conditions. The second pair are much enlarged and extend forward diagonally in front of the head. They are the organs of prehension and consist of an enlarged basal joint filled with strong muscles, and a stout terminal claw which is buried in the flesh of the host. The basal joints are united throughout their entire length, and are enlarged at the end into a double disc, from the edge of which on either side project the terminal claws. The mouth-tube is a simple hollow cone projecting but little from the ventral surface; the mouth-parts have all been aborted, with the exception of the second maxillipeds. These appear as tiny two-jointed appendages on either side of the base of the mouth-tube (fig. 64).

There are four pairs of rudimentary legs, the first three of which are close together on the thorax segments which form the neck, while the fourth pair are some distance farther back on the ventral surface. We may presume that the line of junction of the fourth and genital segments is just behind the bases of these legs. Each leg consists of a triangular basal lamina tipped with two minute, one-jointed rami scarcely larger than spines, and naked.

Colour a dark grey by reflected light, a greyish yellow by transmitted light. Under the latter conditions spots of dark pigment are seen along the sides of the head and neck, at the posterior end of the genital segment, and along the centre of the posterior processes. The two oviducts also show through the dorsal surface of the genital segment as two broad lines of dark brown, broken up into separate spherical eggs.

Total length 2·35 millims., length of head 0·35 millim., length of genital segment 0·79 millim., length of posterior processes 1 millim., length of egg-strings 0·6 millim., width of genital segment 0·4 millim.

Male.—Similar to the female, but with certain marked differences in the body proportions. The head and free thorax segments are about the same, but the genital segment is relatively longer and narrower, being nearly half the entire length.

The posterior processes are only one-third as long as in the female, and are spathulate, being somewhat enlarged and strongly flattened at the tips. Their width at the tip is three-fifths of their length, while in the female it is less than one-seventh. The abdomen lacks the posterior processes, and is nearly hemispherical in shape; the anal papillæ are relatively larger, and their setæ, also non-plumose, a trifle longer.

Colour the same, except that there are no pigment spots on the posterior processes, and there are two narrow lines of pigment parallel to the sides of the genital segment in place of the wide broken lines of eggs seen in the female.

Total length 1·6 millims., length of head 0·35 millim., length of genital segment 0·71 millim., length of posterior processes 0·35 millim., width of genital segment 0·3 millim.

This species was founded by Kröyer upon a single female obtained by exchange from the Vienna Museum. And Kröyer himself states that this specimen was imperfect, so that the description given was necessarily incomplete. This original type specimen was obtained from a species of *Holacanthus* (*Tetrodon*) taken in the Indian Ocean.

The present lot of material is from the same region and was found on the same genus of fish (*Tetrodon*)—whether upon the same species or not, is impossible to tell, since Kröyer does not name the species. The specimens include some twenty females and two males, nearly all of which are in excellent condition. We are thus justified in supplementing Kröyer's description, and in presenting a complete account of both sexes with accurate figures. A genus diagnosis is also here given for the first time (p. 206).

EXPLANATION OF THE PLATES.

PLATE I.—*Lepeophtheirus brachyurus*, Heller, and *Lepeophtheirus æsopus*, n. sp.

REPORT

ON THE

ANOMURA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

T. SOUTHWELL, A.R.C.Sc.,
ASSISTANT IN ZOOLOGICAL DEPARTMENT, UNIVERSITY OF LIVERPOOL.

[WITH TEXT-FIGURES.]

THIS collection of Anomura, entrusted to me for description by Professor HERDMAN—whose kind help in many ways I desire to acknowledge here—comprises 48 species, distributed amongst 22 genera. Two of these species, viz., *Munida alcocki* and *Porcellana hornelli*, are new to science, and a number of others are new to the marine fauna of Ceylon, and add considerably to our knowledge of the geographical distribution of the group.

The Anomuran fauna of this region of the world has been made known chiefly through the descriptions (1) by HENDERSON of the material collected in the Gulf of Manaar by THURSTON, and (2) by ALCOCK of the collections made during the cruises of the "Investigator," and contained in the Indian Museum. In all, about 52 species have now been recorded from the seas around Ceylon, and the present collection adds 23 more species to that list, in addition to the two new species cited above. The species collected by the "Investigator" and described by ALCOCK are, in many cases, deep-water forms, while the following is a list of the collection made by THURSTON, and described by HENDERSON (8), from shallow water in the northern part of the Gulf of Manaar, the exact locality where the bulk of the present collection was obtained. It will be of interest for comparison with the list in the pages that follow :—

Dromidia unidentata (RÜPP).
,, *australiensis*, HASWELL.
Cryptodromia pentagonalis, HILG.
Pseudodromia integrifrons, HEND.
Raninoides serratifrons, HEND.
Hippa asiatica, MILNE-EDW.
Albunea symnista (LINN.).
* ,, *thurstoni*, HEND.
**Coenobita rugosa*, MILNE-EDW.
**Diogenes diogenes* (HERBST).
* ,, *merguiensis*, DE MAN.
* ,, *miles* (HERBST).
,, *custos* (FABR.).
,, *planimanus*, HEND.
,, *avarus*, HELLER.
* ,, *costatus*, HEND.
**Pagurus punctulatus* (OLIV.).
,, *deformis*, MILNE-EDW.
Pagurus varipes, HELLER.
* ,, *setifer*, MILNE-EDW.
**Troglopagurus manaarensis*, HEND.
**Aniculus aniculus* (FABR.).
* ,, *strigatus* (HERBST).
**Clibanarius padavensis*, DE MAN.
,, *arethusa*, DE MAN.
**Eupagurus zebra*, HEND.
Petrolisthes dentatus (MILNE-EDW.).
,, *boscii* (AUD.).
* ,, *militaris* (HELLER).
Porcellanella triloba, WHITE.
**Polyonyx obesulus*, MIERS.
,, *tuberculosis*, DE MAN.
**Galathea elegans*, WHITE.
,, *spinosirostris*, DANA.
Munida spinulifera, MIERS.

Of the above 35 species, Professor HERDMAN found the 16 marked with a star, and also 32 additional species which were not obtained by THURSTON.

ANOMURA.

HIPPIDEA.

FAMILY: HIPPIDÆ.

Remipes testudinarius, LATREILLE. (See MIERS, 10.)†

Galle, Station XXXVII., depth 7 fathoms; one specimen measuring 5·5 centims. in extreme length, and six smaller ones of 2 centims. Not previously recorded from Ceylon.

Mastigochirus gracilis (STIMPSON). (See MIERS, 10.)

Galle, Station XL., depth 34 fathoms. Three small male specimens. Not previously recorded from the Indian Ocean.

FAMILY: ALBUNEIDÆ.

Albunea thurstoni, HENDERSON (8).

Localities:—(1) Galle, Station XL., 34 fathoms; (2) off Mutwal Island, Station LXVI., 10 to 35 fathoms; (3) west of Periya Paar, Station LV., 24 fathoms; (4) on Aripu coral reef, shallow water. One specimen from each locality. The carapace of the largest specimen measures 1·6 centims.

† These numbers refer to the literature cited at the end.

PAGURIDEA.

Family: COENOBITIDÆ.

Coenobita clypeatus, Latreille. (See Alcock, 1.)

On Watering Point, Galle, Station XXXVII. One large male, carapace measuring 4·5 centims. This is a common form in the Indian Ocean, but apparently has not been previously recorded from Ceylon.

Coenobita rugosus, Milne-Edw. (See Alcock, 1.)

Localities:—(1) Foul Point, Trincomalee, Station XXV.; (2) on Watering Point, Galle, Station XXXVII.; (3) Kattanattu Point, on shore; (4) Welligam Bay, Station XXXIV., on shore.

The collection contains a large series of this common species, many of which are females bearing eggs. The average length of the carapace is 3 centims. The specimens from Watering Point at Galle, Kattanattu Point in the Gulf of Manaar, and near Mirissa in Welligam Bay, were collected in rough ground at the top of the beach. Professor Herdman's notes contain the following sentences in regard to Welligam:—" Pagurids of several species, some inhabiting the shells of Helix and other land Molluscs, were very common on the upper part of the beach and in the cocoa-nut plantations beyond. A crowd of several dozen were found congregated upon a small heap of dung, evidently feeding. Others were sheltering in numbers about the roots of the trees."

All the specimens, however, belong to *C. rugosus*, and the shells they inhabit have been identified by Mr. R. Standen, as follows:—*Ranella bufonia*, *Ranella granifera*, *Littorina scabra*, *Nassa* sp., *Sistrum spectrum*, *Sistrum* sp., *Turbo argyrostoma*, *Purpura persica*, *Nerita* sp., *Trochus* sp., *Cantharus* sp., *Rapana bulbosa*, *Murex trilobus*, *Pyrula vespertilio*, *Natica* sp., *Natica monile*, *Ampularia* sp., *Helix hæmastoma*, *Cyclophorus menkianus*, *Tritonidia nodosa*.

Family: PAGURIDÆ.

Diogenes investigatoris, Alcock (1).

Localities:—(1) Gulf of Manaar, under 10 fathoms; (2) Palk Bay, Station XVIII., 7 to 8 fathoms. Several small specimens. Carapace measuring about 5 millims. Found inhabiting shells of *Minolia* sp., *Ranella argo*, and *Buccinum pusilla*. This is a new record for Ceylon.

Diogenes rectimanus, Miers (12).

Localities:—(1) On coral reefs and pearl banks in Gulf of Manaar; (2) off Foul Point, Trincomalee, Station XXV., 8 fathoms. Six specimens found inhabiting shells of *Minolia terebra*, *Minolia* sp., *Terebra duplicata*, *Sistrum spectrum*, *Eburna caniculata*, and *Cancellaria antiquata*. This is a new record for Ceylon.

Diogenes costatus, HENDERSON (8).

Localities :—(1) Pearl banks, Gulf of Manaar, under 10 fathoms ; (2) off Foul Point, Trincomalee, Station XXV., 8 fathoms. Eight specimens ; carapace of largest measuring 7 millims. ; found inhabiting shells of *Conus generalis* and *Olivella* sp. This species was found by THURSTON at Rameswaram.

Diogenes miles (HERBST). (See ALCOCK, 1.)

Locality :—Welligam Bay, Station XXXIV., 2 to 7 fathoms. Two males, in shells of *Nassa* sp. ; length of carapace, 6 millims.

Diogenes diogenes (HERBST). (See ALCOCK, 1.)

Locality :—Stat. XV., Periya Paar, Gulf of Manaar, 9 fathoms. Thirteen specimens, in shells of *Strombus marginatus*, *Latirus* sp., *Natica melanostoma*, and *N.* sp., *Ranella bufonia*, *Oliva* sp. and *Tudicla spirillis*. Length of carapace of largest, 1·3 centims.

Diogenes merguiensis, DE MAN. (See ALCOCK, 1.)

Locality :—Pearl banks, Gulf of Manaar, under 10 fathoms. Five specimens ; carapace measuring 2 centims. ; in shells of *Cassis glauca*, *Natica* sp., *Triton* sp.

Pagurus setifer, MILNE-EDW. (See ALCOCK, 1.)

Localities :—(1) East Cheval Paar, and other pearl banks in Gulf of Manaar, under 10 fathoms ; (2) south of Adam's Bridge, Station LIV., 4 to 40 fathoms ; (3) Welligam Bay, Station XXXIV., 2 to 7 fathoms ; (4) off Mutwal Island, Station LXVIII., 10 to 14 fathoms ; (5) Trincomalee, Station XXI., 8 to 12 fathoms ; (6) Aripu coral reef, shallow water ; (7) outside pearl banks, Gulf of Manaar, Station LXIII., 50 fathoms ; (8) Chilaw Paar, Station V., 9 to 11 fathoms. This is evidently a common species, as it occurred in abundance at various parts of the Coast of Ceylon, including Welligam and Trincomalee as well as the Gulf of Manaar. Amongst the specimens were several females bearing eggs. The carapace of the largest specimen measured 3 centims., that of the smallest, 7 millims.

These specimens were found inhabiting shells of *Turbinella* sp., *Delphinium* sp., *Murex haustellum*, *Murex* sp., *Murex rota*, *Murex trispinosum*, *Natica monile*, *Trochus* sp., *Solarium* sp., *Dolium* sp., *Dolium marginalis*, *Terebra duplicata*, *Cerithium* sp., *Strombus succinctus*, *Strombus elegans*, *Strombus marginatus*, *Strombus gibberulus*, *Pinaria coronata*, *Xenophora conica*, *Xenophora* sp., *Ranella bufonia*, *Ranella* sp., *Ranella granifera*, *Nassa glans*, *Turritella* sp., *Harpa ventricosa*, *Ancilla ampla*, *Ancilla* sp., *Pyrula reticulata*, *Bulla ampulla*, *Tudicla spirillis*, *Oliva* sp., *Terebra* sp., *Cassis vibex*, *Mitra crebrilyrata*.

Pagurus asper, DE HAAN. (See ALCOCK, 1.)

Localities :—(1) Pearl banks off Aripu and elsewhere in Gulf of Manaar, under

10 fathoms; (2) west of Periya Paar, Station LXI., 12 fathoms; (3) Periya Paar Karia, Station LXII., 7 to 13 fathoms. This species, like the preceding one, was fairly abundant. The carapace of the largest measured 3 centims. The specimens were found inhabiting shells of *Dolium marginalis*, *Natica melanostoma*, *Natica* sp., *Ranella bufonia*, *Ranella crumera*, *Cerithium columba*, *Triton angulatus*, *Sistrum spectrum*.

Pagurus punctulatus, Olivier. (See Alcock, 1.)

Two male specimens, one from Station XXXIX., off Galle, depth 16 to 30 fathoms, and the other from the coral lagoon at Galle. Carapace measured 3·2 centims.; eye stalks of a maroon-red colour; chelipeds, legs, and carapace red, the latter with numerous whitish ocelli.

Clibanarius padavensis, de Man (9).

One female with eggs, from Lake Tampalakam, carapace measuring 2 centims.; also two male specimens having carapace measuring 2·2 centims., from Gulf of Manaar, in shells of *Purpura coronata* and *Natica* sp.

Clibanarius æquabilis, var. **merguiensis**, de Man (9).

Localities:—(1) Galle coral lagoon, shallow water; two males, carapace measuring 1·6 centims.; (2) Trincomalee, Station XXIII., 4 to 8 fathoms; one specimen in shell of *Cerithium maurus*.

Calcinus elegans (Milne-Edw.). (See Alcock, 1.)

Locality:—Off Galle, Station XXXVII., 7 fathoms; and also on the shore at Galle. One female and two male specimens, in shells of *Purpura persica* and *Ricinula horrida*. This is a new record from Ceylon.

Calcinus gaimardi (Milne-Edw.). (See Alcock, 1.)

Locality:—Gulf of Manaar, under 10 fathoms. Four male specimens; carapace measuring 9 millims.; in shells of *Latirus nodosus* and *Cerithium* sp. This is a new record for Ceylon.

Aniculus aniculus (Fabr.). (See Alcock, 1.)

Locality:—Lake Tampalakam, Trincomalee, shallow water. Two specimens; carapace measuring $5\frac{1}{2}$ centims.

Aniculus strigatus (Herbst). (See Alcock, 1.)

Localities:—(1) Pearl banks and coral reefs in Gulf of Manaar, under 10 fathoms; (2) Palk Bay, Station XIX., 4 to 8 fathoms; (3) Aripu coral reef, shallow water. In all about 13 specimens, including three females with eggs; carapace of largest measured 2 centims.; found inhabiting shells of *Strombus succinctus*, *Strombus auris-*

dianæ, *Strombus* sp., *Conus tesselatus*, *Conus augur*, *Conus generalis*, *Cyprea ocellata*, and *Oliva* sp. One specimen was found in association with an anemone, containing only the apex of a molluscan shell.

Eupagurus zebra, Henderson (8).

Localities:—(1) Coral reefs, Gulf of Manaar, shallow water; (2) off Mutwal Island, Station LXVI., 10 to 35 fathoms; (3) south of Galle, Station XXXIX., 16 to 30 fathoms. The largest specimen measured 1 centim. along the carapace; a few were found in association with anemones, the rest in shells of *Tritonidea nodosa*, *Latirus turritus*, *Pleurotoma tigrina*, *Nassa granifera*, *Triton* sp., and *Fusus* sp.

Eupagurus carpoforaminatus, Alcock (1).

Locality:—Station XLIII., off Kaltura, 22 fathoms. Two males, carapace measuring 1·5 centims., with the pin-hole foramen on the under surface of the carpus very distinct.

Spiropagurus spiriger (de Haan). (See Alcock, 1.)

Localities:—(1) Off Galle, Station XXXIX., 16 to 30 fathoms; (2) off Foul Point, Trincomalee, Station XXV., 8 fathoms; (3) Station XLIII., off Kaltura, 22 fathoms. Six males, and one female with eggs; carapace of largest measured 2·2 centims.; found inhabiting shells of *Pyrula reticulata*, *Natica monile*, *Natica* sp., *Natica melania*, *Latrunculus zeylanica*, *Harpa minor*.

Catapagurus ensifer, Henderson (8).

Localities:—Gulf of Manaar, under 10 fathoms; (2) west of Dutch Modragam Paar, Station LVI., 8 to 9 fathoms. Five specimens; the carapace of the largest measured 1 centim.; found inhabiting shells of *Natica*, 2 spp., carrying anemones. This is a new record for Ceylon.

Paguristes hians, Henderson (7).

Locality:—Coral reefs and pearl banks, Gulf of Manaar, shallow water. Three specimens; carapace measuring 1 centim.; in shells of *Ranella bufonia*, *Murex* sp., and *Strombus marginalis*. This is a new record for Ceylon.

Paguristes incomitatus, Alcock (1).

Locality:—Pearl banks and coral reefs, Gulf of Manaar, shallow water. Eight specimens, including two females with eggs; carapace measuring 1·1 centims.; in shells of *Tritonidia nodosa*, *Latirus turritus*, *Ranella* sp., and *Cerithium* sp. This is a new record for Ceylon.

Paguristes pusillus, Henderson. (See Alcock, 1.)

Localities:—(1) Coral reefs and pearl banks, Gulf of Manaar, shallow water; (2) Station XLIII., off Kaltura, 22 fathoms; (3) off Mutwal Island, Station XLVII., 10 to 14 fathoms. Fifteen specimens in all; two of the specimens were females bearing eggs; carapace of largest measured 2 centims; found inhabiting shells of *Cerithium citrinum*, *Ranella granifera*, *Cancellaria* sp., *Turbo* sp., *Cerithium*, 2 spp., *Seraphs terebellum*, *Pleurotoma* sp., *Triton* sp., *Strombus elegans*.

Cancellus investigatoris, ALCOCK (1).

Locality:—Gulf of Manaar, shallow water. One specimen; carapace measuring 1·5 centims.

Nematopagurus muricatus, HENDERSON. (See ALCOCK, 1.)

Localities:—(1) Gulf of Manaar, shallow water; (2) near Chilaw Paar, Station IV., 9 fathoms. One male from each; carapace measuring 5 millims.

Nematopagurus sp.

Locality:—Gulf of Manaar, shallow water. A damaged male specimen, without chelipeds and legs; carapace measuring 6 millims; cornea but little dilated; antennal acicle curved and setose, and as long as the eye peduncles; ophthalmic scales well separated; rostrum small, obtuse, and rounded, projecting but little; the ophthalmic peduncles reach the middle of the terminal joint of the antennular peduncles; vas deferens protruding on both sides, the right one being much the longer.

The character of the vas deferens shows that this form belongs to the genus *Nematopagurus*, but, in the absence of all the appendages, I cannot venture to identify it further.

Troglopagurus manaarensis, HENDERSON (8).

Locality:—Coral reefs, Gulf of Manaar, shallow water. Two specimens; carapace measuring 1 centim.

Troglopagurus jousseaumii, BOUVIER. (See ALCOCK, 1.)

Locality:—Pearl banks, Gulf of Manaar, shallow water. Five specimens; carapace measuring 7 millims. This is a new record for Ceylon.

GALATHEIDEA.

FAMILY: PORCELLANIDÆ.

Petrolisthes militaris (HELLER). (See HENDERSON, 8.)

Localities:—(1) Cheval Paar and other pearl banks, Gulf of Manaar, shallow water; (2) off Galle, Station XXXVIII., 9 to 22 fathoms; (3) Palk Bay, Station XVIII., 7 to 8 fathoms; (4) Periya Paar, Station LV., 1 1 to 24 fathoms; (5) Muttuvaratu Paar, Station VI., 6 to 9 fathoms; (6) Chilaw Paar, Station III., 9 to 14 fathoms. This species was fairly abundant, the collection comprising about 25 specimens; carapace of largest measured 1·1 centims.

Petrolisthes (?) armatus (Gibbes). (See Henderson, 7.)

One damaged specimen, from Galle lagoon, is doubtfully referred to this species.

Length of carapace, 4 millims.; the carpus of both chelipeds is armed with 3 spines; ambulatory legs missing. *P. armatus* is a West Indian species, and so would be a new record for Ceylon.

Petrolisthes serratus, Henderson (7).

Locality:—Coral reef, Galle; one female bearing eggs. Length of carapace 2 centims. This is a new record for Ceylon.

Porcellana serratifrons, Stimpson. (See Henderson, 7.)

Localities:—(1) Pearl banks, Gulf of Manaar, shallow water, five young specimens; (2) south end of Cheval Paar, Station XLIX., 9 to 13 fathoms, one specimen; (3) south of Galle, deep water, Station XLI., 100 fathoms, two specimens; (4) Galle coral lagoon, shallow water, one specimen. Carapace of largest measured 8 millims. This is a new record for Ceylon.

Porcellana quadrilobata, Miers (12).

Localities:—(1) Welligam Bay, Station XXXIV., 2 to 7 fathoms, one specimen; (2) Gulf of Manaar, outside pearl banks, Station LXIII., about 40 fathoms, one specimen; (3) off Mount Lavinia, Station XLVI., 25 to 30 fathoms, two specimens; the carapace of largest measured 5 millims. This is a new record for the Indian Ocean, as the species has only been found on the coast of Queensland.

Porcellana hornelli, n. sp.—Text-fig. 1.

Carapace oval in outline, naked, very convex, a little longer than broad,* and obscurely lineolate; front fairly prominent and four-lobed. The two median lobes—one on each side of the centre—have rounded apices which are minutely notched and are slightly longer and much broader than the two lateral lobes, each of which is triangular, curved, and terminates in a spine.

Eyes small and protruding but little.

Lateral margin of carapace armed with a series of spines. There is a large spine behind the orbit; and very near to it, but still nearer to the eye, is a much smaller one. A little further back are two additional spines, and between them is a rounded lobe bearing a few minute spines.

The external maxillipeds have the ischium a little shorter and broader than the merus. Both these joints are flattened from above, and each has its internal face produced into a rounded lobe.

Chelipeds smooth, obscurely lineolate, and a little longer than the carapace. The merus has its inner border produced into a rounded crest obscurely toothed. Carpus

* In the figure (p. 219) the carapace is shown rather too narrow.

a little longer than broad, also crested internally, the crest being entire. Palm longer than the fingers. Fingers curved, slightly gaping, crossing at their tips and minutely notched on their opposing surfaces (see figure).

Walking legs short and slender, their last two joints bearing a few setæ.

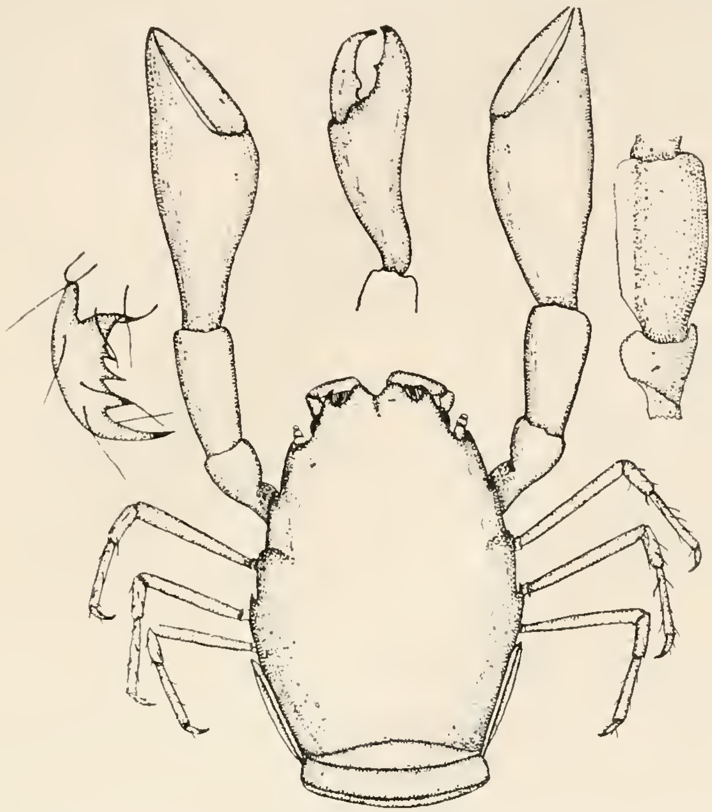

Fig. 1. *Porcellana hornelli*, n. sp., × 7; showing also right cheliped, × 6; merus and carpus of right cheliped, × 8; and dactylus of third left leg, × 30.

Localities:—(1) Aripu reef and other coral banks, Gulf of Manaar, shallow water; (2) Dutch Modragam Paar, Station LVII., 12 to 36 fathoms. Six specimens; length of carapace, 7 millims.; breadth, 6 millims.

This species is named in honour of Mr. James Hornell, F.L.S., who took an active part in making this collection.

Polyonyx biunguiculatus (Dana, 4).

Localities:—(1) Off Mutwal Island, Station LXVII., 10 to 14 fathoms; (2) coral banks, Gulf of Manaar, shallow water. Six males, and one female bearing eggs; length of carapace, 5 millims.

Dana figures the left cheliped of this species a little larger than the right one. Only one of the Ceylon specimens has both chelipeds intact, but in this case the right is very slightly larger than the left. Otherwise the specimens answer to

DANA's description and figure, and the tarsus of the walking legs is very noticeably two-clawed. This is a new record for Ceylon.

Polyonyx obesulus (WHITE). (See MIERS, 12.)

Locality:—Cheval Paar, Gulf of Manaar, shallow water. One specimen; carapace measuring 1 centim. This is a new record for Ceylon.

This and the last species seem so closely related that it is difficult to believe that they are distinct. Some of our Ceylon specimens seem intermediate in their characters.

Pachycheles pulchellus (HASWELL). (See MIERS, 12.)

Localities:—(1) Cheval Paar and other pearl banks, Gulf of Manaar, shallow water, nine specimens; (2) South of Modragam Paar, Station LXIV., 4 to 5 fathoms, one specimen.

Carapace of largest measured 9 millims. In these specimens the penultimate joints of the walking legs bear a few hairs on their external surface, and there is a little variation in the size of the crest on the carpus of the chelipedes.

This is a new record for the Indian Ocean, having only been found previously off the coasts of Australia.

FAMILY: GALATHEIDÆ.

Galathea elegans, WHITE. (See HASWELL, 6.)

Locality:—Chilaw Paar, 8 miles from shore, Station V., 9 to 11 fathoms. One specimen; extreme length 1·9 centims.

Galathea longirostris, DANA (4).

Localities:—(1) North of Cheval, Station LIII., 7 to 9 fathoms; (2) Gulf of Manaar, shallow water. Three specimens; extreme length 2 centims. Colour markings well defined. Brought up adhering to specimens of *Antedon bella*. This is a new record for the Indian Ocean.

Galathea corallicola, HASWELL (6).

Localities:—(1) South of Galle, Station XLI., 100 fathoms; (2) off Kaltura, Station XLIII., 22 fathoms; (3) coral reefs, Gulf of Manaar, shallow water. Six specimens in all; carapace of largest measuring 9 millims. This is a new record for the Indian Ocean.

Galathea australiensis, STIMPSON. (See HASWELL, 6.)

Localities:—(1) South of Galle, Station XLI., 100 fathoms; (2) off Kaltura, Station XLIII., 22 fathoms; (3) Gulf of Manaar, shallow water. In all, five males and two females bearing eggs; carapace of largest measured 1 centim.

In one of the specimens the rostrum was armed with only three teeth on the left side, the right side having four—the normal number. In STIMPSON's original description of this species, from a female, it is stated that the fingers of the chelipeds did not gape. MIERS, describing a male of the same species (see **12**), specially noticed that the fingers in his specimen "had an hiatus between them when closed." In all the Ceylon specimens the fingers are gaping, some more than others; from which one may conclude that this character is of comparatively little importance. This is a new record for Ceylon. I am inclined to agree with MIERS that this and the last species might well be joined as one.

Galathea (?) grandirostris, STIMPSON. (See HENDERSON, **7**.)

Locality:—Dutch Modragam Paar, Station LVII., 12 to 36 fathoms. A damaged specimen, without chelipeds and legs, is doubtfully referred here. Rostrum long, deflexed, triangular, with a broad base, and armed laterally with small teeth; gastric region unarmed; striæ on the carapace numerous and ciliated; length of carapace, 1·6 centims. This is a new record for Ceylon.

Munida japonica, STIMPSON (**18**).

Localities:—(1) Trincomalee, Station XX., 11 to 13 fathoms; (2) south of Galle, Station XL., 34 fathoms; (3) off Kaltura, Station XLIII., 22 fathoms; (4) outside banks in Gulf of Manaar, Station LXIII., about 40 fathoms; (5) Aripu reef, shallow water. Thirteen specimens, including some females bearing eggs; the carapace of the largest measured 1·5 centims.

ORTMANN ('Zool. Jahr.,' Band 6, Abth. f. Syst., 1891–2, p. 254), in giving a detailed description of this species, pointed out that the abdomen was unarmed, and assumed that this was the case in STIMPSON's original specimens, although STIMPSON himself did not describe the abdomen. ORTMANN also noticed that his types differed from those described by STIMPSON in having a large spine at the antero-lateral angle of the carapace.

The Ceylon specimens agree with ORTMANN's description except in the following points:—

(1) The supra-ocular spines are as long as the eye.

(2) The setæ fringing the cornea are short.

(3) The spines in the transverse row on the anterior gastral region vary a little in number. Usually there are 13, consisting of 6 pairs and a median one. In one of the Ceylon specimens there are only 11 spines, the outer pair—normally situated near the edge of the carapace—being absent. In another specimen the median spine is short, blunt and rounded, with another spine behind it in the middle line.

(4) The lateral margin of the carapace is armed with 7 or 8 spines.

(5) The chelipeds vary enormously in length. In the female the fingers of the chelipeds are as long as the palm and scarcely gaping, whilst in the male the fingers

are shorter than the palm and the gape may be very pronounced, or scarcely noticeable.

(6) A few long iridescent hairs occur on the carapace and abdomen.

It might be thought that a variety could be established on these characters, but I prefer to regard them as individual variations. This species is new to the Indian Ocean, being only previously known from Japan.

Munida alcocki, n. sp.—Text-fig. 2.

The rostrum is about one-third the length of the carapace, and has about three regular and minute notches towards the apex. It is slightly sigmoid. The supra-orbital spines are as long as the eye and half the length of the rostrum. A few setæ

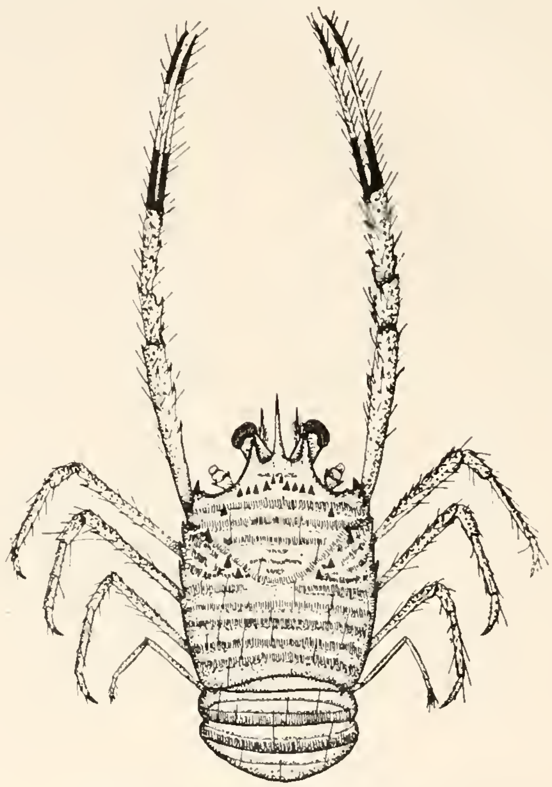

Fig. 2. *Munida alcocki*, n. sp., × 4.

overlap the cornea. The striæ on the surface of the carapace are numerous and pubescent. A few long iridescent hairs arise from the ridges of the thorax and abdomen. There is a transverse row of ten spines at the base of the rostrum. The median pair are situated a little in front of the rest, the second and fourth pairs being a little longer than the third and fifth. Separated from these by the first ciliated line is another pair of spines, situated laterally. Three additional pairs of lateral spines are situated a little behind the cervical groove, making eighteen spines in all. The lateral margin of the carapace is armed with seven spines.

The merus of the third maxilliped bears two large spines at the distal extremity.

The chelipeds are spinose and slender, nearly twice the length of the carapace, and bearing a few hairs. The spines on the merus increase in size distally. The fingers of the chelipeds are cylindrical, acute, slightly incurved, and in spirit specimens are marked with two red bands, one proximal, the other distal.

The walking legs bear a few hairs, and the tips of the anterior pair reach the base of the fingers of the chelipeds.

Localities:—(1) Dutch Modragam Paar, Station LVII., 12 to 36 fathoms; (2) Aripu Reef and elsewhere in Gulf of Manaar, shallow water; 23 specimens. The carapace of the largest individual measured 1·7 centims.

This species bears a general resemblance to *Munida honshuensis*, BENEDICT, in the disposition of the spines on the carapace, but differs from it in having (1) the abdomen unarmed; (2) the carapace a little broader; (3) the possession of long iridescent hairs; (4) the rostrum shorter; and (5) two additional spines on the carapace.

This species is named in honour of Col. ALCOCK, F.R.S., who has done so much to elucidate the Crustacean fauna of the Indian Ocean.

REPORT

ON THE

FORAMINIFERA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

W. J. DAKIN, B.Sc.,

ZOOLOGICAL DEPARTMENT, UNIVERSITY OF LIVERPOOL.

[WITH ONE PLATE AND TEXT-FIGURES.]

THE collection of deposits from the various places where dredgings were taken during the Ceylon expedition has revealed, in most cases, a great abundance of Foraminifera, and this is especially true with regard to a few species which in some cases make up the greater part of the deposit. The material which I have worked through for the purpose of this report had been taken mainly from (1) several stations in the Gulf of Manaar, (2) Palk Bay (north of Adam's Bridge), (3) off Trincomalee, and (4) off Galle, to the south of the island. The material from the different dredgings in the Gulf of Manaar has yielded the greatest abundance of species, and that from Galle and the south of the island generally the most interesting forms, especially where, from the 100-fathom line, about 12 miles off the land, the bottom was composed of a unique marine foraminiferal deposit, composed solely of a new species of the genus *Ramulina*. In the shallower waters off Galle, however, foraminifera were much less abundant than at corresponding depths in the Gulf of Manaar.

The deposits examined were mostly from depths of less than 40 fathoms, and the collection consists, therefore, mainly of shallow-water species, and there is but little difference between the various samples, except as regards the numerical proportions in which certain forms occur. One of the most interesting points is the great abundance of *Heterostegina depressa*, which makes up as much as 40 per cent. of one deposit, and often attains a size of 18·5 millims., and *Amphistegina lessonii* is not far behind this in point of numbers. A considerable range of individual variation was noticed, especially as regards the surface markings in such a case as *Amphistegina lessonii*, and this has occasionally given rise to some difficulty in the determination of species.

The total number of species and varieties recorded is 131, belonging to 51 genera, and of these 49 species are recorded for the first time from the seas around India and Ceylon, most of the previous records being from the reports by Murray and Chapman on the deposits obtained by H.M.S. "Investigator" in the Bay of Bengal and the Arabian Sea. Only 15 species have actually been recorded previously from Ceylon, consequently nearly all those mentioned in this report are additions to the fauna of that colony.

In conclusion, I have to thank Professor Herdman for the opportunity given me to examine this interesting collection, and also for his very valuable advice throughout the work.

Note on a New Ramulina Deposit.

Along the 100-fathom line, about 12 miles south of Galle, the dredge brought up quantities of a remarkable and unique foraminiferal deposit, consisting of masses varying in size from a hazel nut to a small apple 5 centims. in diameter, and formed of many stout calcareous tubules. At first sight it would hardly oe taken to be of Protozoan origin ; and, as a matter of fact, a few other animals occur with it. Worm tubes extend into the crevices and wind about the tubules : masses of *Polytrema* and colonies of Polyzoa use the foraminifer as a support, and corals are embedded by its vigorous growth. The result is a substantial marine deposit, which cannot be of small importance in the building up of the ocean floor, and is still another, and probably the most important case in the district, of the part played by foraminifera in contributing to the form of the earth's surface, and in affecting the metabolism of the ocean. This organism has been identified as a very luxuriant and complex growth of a new species of *Ramulina*, which I desire to name after Professor Herdman, by whom it was found and first identified as a *Ramulina* (see "Narrative," this Report, Part I., 1903, p. 51).

The genus *Ramulina* of Rupert Jones, 1875, is defined by Brady in the '"Challenger" Report' as follows:—"Test free, branching ; consisting of a calcareous tube, swollen at intervals so as to form more or less definite, often irregular segments, from which lateral stolons or branches are given off. Texture hyaline." Some alteration will, however, have to be made in this definition of the genus, since this new species is certainly not hyaline. The species described by Brady is *R. globulifera*, and from the description it appears that the swellings referred to in the definition of the genus arise only at intervals, and are connected by tubular portions. In our

Ceylon species, on the other hand, there may be a whole series of globular segments opening directly one into the other.

The generic name was first applied in the 'Report and Proc. Belfast Nat. Field Club,' 1873, by JOSEPH WRIGHT, to two fragmentary specimens, and no definitions were then given. Later, the name was definitely given to the genus by RUPERT JONES, in 1875. BRADY, in 1884, named and described the species *R. globulifera*, and WRIGHT, also in 1884, figured another species, *Ramulina aculeata*, from specimens found in the cretaceous rocks of Kerry, Ireland. Mr. WRIGHT, who was consulted by Professor HERDMAN, at first recognised the resemblance of this species from Ceylon to his *R. aculeata*; but further investigation suggested that it is a new species, and with that opinion Mr. WRIGHT now concurs.

The differences leading to this conclusion are that (1) the spinous processes are not developed to such an extent on the Ceylon species as on *R. aculeata*, and (2) the cretaceous species only occurs in small fragments and does not show the complex and extensive mode of growth seen in this specimen from the Indian Ocean.

This foraminifer consists of a mass of anastomosing calcareous tubes, inextricably commingled, and assuming two principal forms of growth. Many specimens show a long series of globular segments, arranged irregularly, and opening directly into one another by large openings. These globular chambers at intervals give off numerous radiating straight tubes, varying in length from quite small outgrowths to 1·25 centims., with a diameter of 1·5 millims. to 2 millims. These straight portions may run in the same direction, separating but little, and becoming more compact (see text-fig., C), or they may at once diverge and radiate from a common centre.

A. B. C.

Three masses of *Ramulina herdmani*. Natural size.

Eventually they reach either the globular chambers or other straight tubules with which they fuse, the cavities becoming continuous (see also Plate, figs. 1–6).

The radiating straight tubes I shall term the *pipes*, and the globular chambers *ampullæ.* These masses of *Ramulina herdmani* may be in places predominantly ampullate in their mode of growth, as in text-fig. C, which shows an irregular mass of ampullæ opening into one another at different angles, and not lying simply in one and the same plane. In fig. A, on the other hand, the ampullæ are arranged in definite planes (not parallel to one another), and between these planes pass the pipes opening into the ampullæ at either end. The larger piece, shown in fig. B, is almost wholly composed of pipes, with only a suggestion of ampullæ, or perhaps two or three where several pipes open near each other.

The walls of the pipes and ampullæ are strong, calcareous, but not hyaline, and in some places as much as 0·065 millim. in thickness; but about 0·05 millim. is the average. All these walls are uniformly perforate, but the external surface differs in appearance in places, being sometimes quite smooth and elsewhere bearing minute denticles, either sparsely or more closely set. There also seem to be definite larger openings to the exterior, or *mouths* (see Plate, fig. 5). These are quite large openings, about 2·5 millims. across, and are situated where one or two ampullæ meet. They do not occur very frequently.

At such mouths the walls of the ampullæ are prolonged to form 4 to 6 protuberances of unequal size which surround the orifice.

In accordance with this description of the new species, the definition of the genus requires to be somewhat modified—which, however, was necessary before, since the original definition will not include WRIGHT'S *Ramulina aculeata.*

The definition of the genus given by BRADY was quoted above. I should suggest that this be now modified so as to read:—Test free, *or adherent,* branching and *anastomosing;* consisting of a calcareous tube, swollen at intervals to form more or less definite, often irregular segments (*ampullæ*), *opening into one another and being contiguous, or separated and connected by tubules. From these segments straight tubes (pipes) are given off.* Texture hyaline *or opaque.*

The alterations or additions are printed in italics. The definition of the new species will be given at its systematic position in the catalogue that follows.

LIST OF SPECIES.

FAMILY: MILIOLIDÆ.

Biloculina ringens (LAMARCK).

This form occurs rarely in the deposit from Stat.* LXVIII. It has been recorded (2),† (4) from the Indian seas.

Biloculina ringens, var. **striolata**, BRADY.

Of very rare occurrence in material from Stat. LXIV., south of Modragam Paar, depth 5 fathoms. This variety has also been recorded from the Indian seas (2).

* For particulars as to the Stations see "Narrative," this Report, Part I., 1903, p. 17.

† These numbers refer to the bibliography at the end.

Biloculina ringens, var. **denticulata**, Brady.

Of very rare occurrence in material from Stat. LVIII., Gulf of Manaar—a new record for Indian seas.

Biloculina lævis (Defr.).

Of rare occurrence in the Gulf of Manaar. This is a new record for Indian seas.

Miliolina cultrata, Brady.

Occurs frequently at Stats. LVI. to LVIII., near Karativo Paar, 8 to 26 fathoms. Previously recorded by Brady (1) from Ceylon.

Miliolina seminulum (Linn.).

This is common at the same stations as the last, and also off Trincomalee—a new record for Indian seas.

Miliolina scrobiculata, Brady.

This form appears rarely in the sample from Stat. LVII. It is a new record for Indian seas.

Miliolina tricarinata (d'Orb.).

Occurs very rarely at Stats. LVI., LVII. and LXVIII. It has been recorded (2) from Indian seas.

Miliolina auberiana (d'Orb.).

Found in samples from Stats. LVI., LVII. and LVIII., and also from Welligam Bay—previously recorded (2) from Indian seas.

Miliolina insignis, Brady.

This form occurs in material from Stats. LVII. and LXIV.—previously recorded from Ceylon (1) and Indian seas (2).

Miliolina valvularis (Reuss).

Occurs in material from Stat. LVIII., outside Karativo Paar, depth about 20 fathoms. This is a new record for Indian seas.

Miliolina ferussacii (d'Orb.).

Occurs very rarely in the same sample as the last, and is also a new record for Indian seas.

Miliolina circularis, Bornemann.

This form was also present in the material from Stat. LVIII.—recorded previously from Indian seas (2).

Miliolina fichteliana (D'ORB).

Present sparingly at Stat. LVIII., and also at Stat. LVI., off Kodramallai Point, depth 8 or 9 fathoms—a new record for Indian seas.

Miliolina parkeri, BRADY.

Found at Stat. LVIII. This form is usually found associated with coral banks—recorded previously from Indian seas (2).

Miliolina rupertiana, BRADY.

Occurs frequently in material from Stat. LVI.—previously recorded for Ceylon (1).

Miliolina oblonga (MONTAGU).

This form occurs rarely in two samples from the Gulf of Manaar, Stats. LXIV. and LXVIII., both under 20 fathoms; and also at Welligam Bay—previously recorded from Ceylon (1).

Miliolina agglutinans (D'ORB.).

Very rare, and occurs only at Stat. LXIV. This is a new record for Indian seas.

Miliolina reticulata (D'ORB.).

Occurs sparingly between E. and W. Cheval paars at about 6 to 7 fathoms—previously recorded from Indian seas (2).

Miliolina terquemiana, BRADY—Plate, figs. 9 and 10.

This species, described by BRADY for the first time in the '"Challenger" Report' (1), is noted as being exceedingly rare, and known only from Calpentyn, Ceylon, and the East Coast of Madagascar. It has been recorded so far from no other place in the Indian Ocean. One specimen only was present in our collection, and it was found in a deposit from the southern part of the Gulf of Manaar, only a few miles to the north of Calpentyn, where it was originally found. It is in excellent preservation and is rather larger than BRADY's specimen, the length being 0·76 millim. This rare Ceylon specimen is shown in figs. 9 and 10 on the Plate.

Spiroloculina grata, TERQUEM.

This is common in deposits from Stats. LVI and LXIV. It is a coral bank species, and has been previously recorded from Indian seas (2).

Spiroloculina limbata, D'ORB.

Frequent in deposits from Stats. LVIII. and LVI.—previously recorded from Indian seas (2).

Spiroloculina fragilissima, BRADY.

One specimen in material from Stat. LVIII.—a new record for Indian seas.

Spiroloculina arenaria, Brady.

This species occurs in material from Stat. LVIII.—previously recorded from Indian seas (2).

Spiroloculina crenata, Karrer.

Of very rare occurrence in the deposit from Stat. LVI.—a new record for Indian seas.

Hauerina ornatissima, Karrer.

Very rare in material from Stat. LXIV., S. of Kodramallai. This is a new record for Indian seas.

Hauerina complanata, n. sp.—Plate, fig. 7.

This species has the characteristic planospiral porcellaneous test, milioline only in the very early convolutions. It is very thin, with practically circular convolutions. Four of these, with indications of a fifth, are present; the outer, or last, consisting of four chambers. Diameter of specimen, 0·62 millim. This species differs from *H. compressa* in being more regular and even more compressed; the number of convolutions also appears to be greater and a larger number of chambers is present. Several specimens occur in deposits from Stat. LVIII., Gulf of Manaar.

Articulina sagra, d'Orb.

Occurs frequently in deposits from Stats. LXVIII., LXIV. and LVII. This is a new record for Indian seas.

Vertebralina striata, d'Orb.

Occurs rarely in the Gulf of Manaar—a new record for Indian seas.

Peneroplis pertusus, var. **arietinus**, Batsch.

This occurs very commonly in the deposit from Stat. LVII., and less frequently at Stat. LVI.

Peneroplis pertusus, var. **planatus** (Fichtel and Moll).

This variety is much less common than the above, and occurs rarely at Stat. LVII. These are both new records for Indian seas.

Orbiculina adunca (Fichtel and Moll).

This species is of somewhat rare occurrence in the Gulf of Manaar—previously recorded for the Indian Ocean (1).

Orbitolites marginalis (Lamk.).

One of the most common of foraminifera in the shallower deposits, but less frequent in the deeper ones. It is common, however, in all. Previously recorded from the Indian Ocean (2).

Orbitolites duplex, Carpenter.

Occurs rarely at Stat. LVII—a new record for Indian seas.

Alveolina melo (Fichtel and Moll).

This is exceptionally common in the shallow-water deposits, and makes up a large percentage of the material. In most cases also the size is above the average, the length reached being 22·5 millims. It occurs at Stats. LXIV., LVI., LVIII.; off Trincomalee and Chilaw; but is especially common in the deposit from Stat. LXVIII.

Alveolina boscii (Defr.).

This is frequent in the same deposits as the species *A. melo*. Both have been previously recorded from the Indian Ocean (2).

Family: ASTRORHIZIDÆ.

Technitella legumen, Norman.

Of very rare occurrence from the Gulf of Manaar—a new record for the Indian seas.

Saccammina spherica, Sars.

Of rare occurrence at Stats. LVI. and LVIII.—previously recorded from Indian seas (2).

Rhizammina, sp.?

One specimen from Gulf of Manaar. The species *R. indivisa* has been previously recorded from Indian seas (2).

Sagenella frondescens, Brady.

Of rare occurrence in deposits off Chilaw. This is a new record for Indian seas.

Family: LITUOLIDÆ.

Reophax difflugiformis, Brady.

Occurs somewhat frequently in Gulf of Manaar—previously recorded from Indian seas (2).

Haplophragmium canariense (d'Orb.).

Only one specimen in material from Stat. LVIII.—previously recorded from Indian seas (2).

Carterina spiculotesta (Carter).

One specimen was found in the deposit from Stat. LXIV. in Gulf of Manaar. This is of interest since the specimens described by Carter came from the same place (1).

Family: TEXTULARIIDÆ.

Textularia gramen, d'Orb.

Occurs in deposits from Stats. LVIII., LVII., LXIV., and LXVIII.—previously recorded from Indian seas (2).

Textularia agglutinans, d'Orb.

Of frequent occurrence at Stats. LVIII., LVII., and LVI.—previously recorded from Indian seas (2).

Textularia transversaria, Brady.

Occurs rarely at Stat. LVIII. A new record for Indian seas.

Textularia quadrilatera, Schwager.

Occurs rarely at Stat. LVII. This also is a new record for Indian seas.

Textularia sagittula, Defrance.

Occurs rarely in the Gulf of Manaar, at Stat. LVI.—previously recorded from Indian seas (2).

Textularia sagittula, var. **fistulosa**, Brady.

This variety is of more frequent occurrence than the above, and is probably a tropical variation of it. It was found in the Gulf of Manaar—previously recorded from Indian seas (2).

Verneuilina spinulosa, Reuss.

Occurs rarely at Stats. LVII. and LVI. in Gulf of Manaar—previously recorded from Ceylon (1).

Chrysalidina dimorpha, Brady.

Found sparingly at Stat. LVIII.—recorded previously from Ceylon (1).

Clavulina communis, d'Orb.

Very rare at Stat. LVIII. Has been previously recorded from Indian seas (2).

Gaudryina subrotundata, Schwager.

This is of moderate frequency in several deposits in the Gulf of Manaar—previously recorded from Indian seas (2).

Bulimina elegantissima, var. **seminuda,** Terquem.

This form is of rare occurrence at Stat. LVIII.—has been previously recorded from Ceylon (1).

Bolivina punctata, d'Orb.

This is of fairly frequent occurrence at Stats. LVI. and LXIV. It has been already recorded from Indian seas (1), (2).

Bolivina textularioides, Reuss.

Of rare occurrence in the Gulf of Manaar—previously recorded from Indian seas (2).

Bolivina limbata, Brady.

Of rare occurrence in the deposit from Trincomalee, W.N.W. of Foul Point, 8 fathoms—previously recorded from Indian seas (2).

Family: LAGENIDÆ.

Lagena sulcata (Walker and Jacob).

Of very rare occurrence at Stat. LVI.—recorded previously from Indian seas (2).

Lagena globosa (Montagu).

Rare in deposit from Stat. LVI.—recorded previously from Indian seas (2).

Lagena lævis (Montagu).

Of very rare occurrence in deposit from Stat. LXIV., and also from Welligam—recorded previously from Indian seas (2).

Lagena lagenoides (Williamson).

This is of very rare occurrence in the deposit from Stat. LXVIII.—recorded previously from Indian seas (2).

Lagena castrensis, Schwager.

This form is very rare in the deposit from Stat. LVIII., and also from Welligam Bay—recorded previously from Indian seas (2).

Lagena orbignyana (Seguenza).

This form is also very rare in the Gulf of Manaar.

Lagena staphyllearia (Schwager).

Of very rare occurrence in the Gulf of Manaar.

Lagena marginata, var. **semimarginata,** Reuss.

Of very rare occurrence in the Gulf of Manaar deposits. The last three species of *Lagena* have all been previously recorded from the Indian seas (2).

Lagena elcockiana, MILLET (3).

Only one specimen found in a deposit from the Gulf of Manaar. This is a new record for Indian seas. Previous occurrence in the Malay Archipelago (3).

Nodosaria obliqua (LINN.).

This species occurs sparingly at Stat. LVIII., but is more frequent at Stat. LVI., both in the Gulf of Manaar. Recorded previously from Indian seas (2).

Nodosaria cylindracea, n. sp.—Plate, fig. 8.

The test of this species is elongate, and cylindrical, 0·85 millim. in length, and terminates in a rounded apex. Chambers, about nine in number, arranged in a straight line, and separated by unconstricted sutures, which have the appearance of a series of depressions. Surface with fine longitudinal ribs, about eighteen in number, and marked with minute striæ between them. Aperture, a round opening with a slight lip in the centre of the last segment.

It is possible that this is a new species of the genus *Sagrina*, in which the early spiral arrangement has been lost, but no trace of this is seen in the specimen.

Of very rare occurrence in the Gulf of Manaar.

Nodosaria raphanus (LINN.).

This form occurs somewhat frequently in the Gulf of Manaar. Recorded previously for Indian seas (2).

Nodosaria intercellularis, BRADY.

Occurs sparingly at Stats. LVIII., LVII., and LVI. This is also previously recorded from Indian seas (2).

Nodosaria perversa, SCHWAGER.

Of rare occurrence in the Gulf of Manaar—a new record for Indian seas.

Nodosaria simplex, SILV.

Of very rare occurrence in Gulf of Manaar at Stat. LXIV.—a new record for Indian seas.

Nodosaria hispida, D'ORB.

This species is of rare occurrence in the Gulf of Manaar. This is also a new record for Indian seas.

Nodosaria scalaris, var. **separans**, BRADY.

Rare in the deposit from Stat. LXIV. This has been recorded from the Indian seas already (2).

Cristellaria tricarinella, Reuss.

Of very rare occurrence in the deposit from Stats. LVIII. and LVI. This is a new record for the Indian seas.

Cristellaria rotulata (Lamk.).

This is of rare occurrence in the Gulf of Manaar—previously recorded from Indian seas (2).

Cristellaria orbicularis (d'Orb.).

Occurs very rarely in the samples from Stat. LVI.—previously recorded from Indian seas (2).

Cristellaria vortex (Fichtel and Moll).

This is of rare occurrence in the deposit at Stat. LXIV. This is a new record for Indian seas.

Polymorphina regina, Brady, Parker and Jones.

Occurs very rarely in material from Stat. LXIV.—a new record for Indian seas.

Uvigerina aculeata, d'Orb.

This is of frequent occurrence at Stat. LXIV. in some hauls—previously recorded from Indian seas (2).

Uvigerina asperula, Czjzek.

Of rare occurrence at Stat. LVIII. This species is previously recorded from Indian seas (2).

Uvigerina pygmæa, d'Orb.

Found sparingly at Stat. LVII., and also at Welligam Bay. Also recorded before from Indian seas (2).

Sagrina raphanus, Parker and Jones—Plate, fig. 11.

Found sparingly at Stat. LVI., and also off Trincomalee—previously recorded for Ceylon (1). The specimen figured differs from the normal type by having the test bent almost at right angles in the fifth chamber from the terminal one. This appears due to greater growth having taken place on one side than on the other during the formation of this chamber.

Sagrina striata, Schwager.

Of rare occurrence in the Gulf of Manaar—a new record for Indian seas.

Ramulina herdmani, n. sp.—Plate, figs. 1–6, and also text-figs., p. 227.

Tubules anastomosing so as to form a large adherent mass. Chambers or ampullæ numerous, connected by tubules or contiguous and aggregated. Walls strong, calcareous, not hyaline, and only slightly spinose on the surface. Length of an average pipe 1 centim., diameter of an average ampulla 1·8 millims., masses up to 9 centims. in length. (See also p. 226.)

Family: GLOBIGERINIDÆ.

Globigerina bulloides, d'Orb.

This is a common form in all the deposits examined—previously recorded from Indian seas (2) (4).

Globigerina sacculifera, Brady.

Of very rare occurrence at Stat. LVI.—previously recorded from Indian seas (2) (4).

Globigerina cretacea, d'Orb.

Of very rare occurrence at Stats. LXVIII. and LVI.—previously recorded from Indian seas (2).

Orbulina universa, d'Orb.

Rare, found in material from Stat. LVI.

Hastigerina pelagica, d'Orb.

Of very rare occurrence at Stat. LVII. Both the two last named have been previously recorded from Indian seas (2) and (4).

Family: ROTALIIDÆ.

Spirillina limbata, Brady.

Common in deposits from Stat. LVII.—a new record for Indian seas.

Spirillina obconica, Brady.

Of rare occurrence from Galle and Station LXIV.—a new record for Indian seas.

Spirillina inæqualis, Brady.

Of rare occurrence at Galle and Stat. LVI.

Spirillina vivipara, Ehrenberg.

This occurs rarely in deposits from Stats. LVIII. and LVII.—previously recorded from Indian seas (1).

Spirillina decorata, Brady.

Of very rare occurrence at Stat. LVI. With the exception of *S. vivipara*, these are all new to Indian seas. They have all been recorded by Egger (5) from Mauritius.

Cymbalopora poeyi (D'ORB.).

Occurs rarely at Stat. LVI., and also off Trincomalee—previously recorded from Indian seas (2).

Discorbina rosacea (D'ORB.).

Occurs frequently at Stats. LVIII. and LXIV. This has been recorded from Indian seas (2).

Discorbina orbicularis (TERQUEM).

Of common occurrence at Stats. LVII., LXIV., and LXVIII., in the Gulf of Manaar. This is a new record for Indian seas.

Discorbina bertheloti, var. **baconica**, HANTK.

Found sparingly in deposits from Stats. LVII. and LVI., and, like the last, is a new record for Indian seas.

Discorbina patelliformis, BRADY.

Found rarely in the Gulf of Manaar. It has been already recorded from Ceylon (1).

Discorbina saulcii (D'ORB.).

Occurs rarely in the Gulf of Manaar—a new record for Indian seas.

Discorbina vilardeboana (D'ORB.).

This occurs very rarely in the Gulf of Manaar, and is probably a variety of *D. rosacea*. It is a new record for Indian seas.

Truncatulina ungeriana (D'ORB.).

Of rare occurrence in the deposits from the Gulf of Manaar—previously recorded from Indian seas (2).

Truncatulina rostrata, BRADY.

Occurs rarely in deposits from Stat. LVIII. in the Gulf of Manaar—a new record for Indian seas.

Truncatulina lobatula (WALTER and JACOB).

This species is very rare in the deposit from Stat. LXVIII.—already recorded from the Indian seas (2).

Truncatulina tenera, BRADY.

This species occurs somewhat frequently in the Gulf of Manaar. It is also a new record for Indian seas.

Anomalina ammonoides (Reuss).

Occurs frequently in deposits from Stats. LVII. and LVIII.—previously recorded from Bombay (1).

Anomalina gosserugosa (Gümbel).

This species is much more rare than *A. ammonoides*, but occurs in the same deposits—previously recorded from Indian seas (2).

Anomalina ariminensis (d'Orb.).

Of very rare occurrence at Stat. LVI.—a new record for Indian seas.

Pulvinulina menardii (d'Orb.).

Very common at Stats. LVI., LVII., LVIII., LXIV. and LXVIII.—previously recorded from Indian seas (2), (4).

Pulvinulina brongniarti (d'Orb.) (4).

This species occurs rarely in the deposit from Stat. LVII.—previously recorded from Mauritius (5) and Malay Archipelago (3)—a new record for Indian seas.

Pulvinulina umbonata, Reuss.

Occurs rarely in material from Stat. LVIII. This is a new record for Indian seas—previously recorded from Mauritius (5).

Pulvinulina oblonga (Williamson).

Of rare occurrence at Stats. LXVIII. and LVI.—previously recorded from Indian seas (2).

Rotalia calcar, d'Orb.

This species is of very common occurrence at Stats. LVI., LVII., LVIII., and also from Welligam Bay and Galle—recorded already from Ceylon (1) and Indian seas (2).

Calcarina hispida, Brady.

Of very common occurrence in all samples examined from Stats. LVIII., LVII., LVI., LXIV., and LXVIII., also off Galle and Trincomalee—previously recorded from Indian seas (2).

Calcarina defrancii, d'Orb.

This occurs somewhat sparingly at Stats. LVI. and LVIII.—a new record for Indian seas.

Calcarina spengleri, Linn.

Of rare occurrence at Stat. LVIII. This is also a new record for Indian seas, but has been recorded from Mauritius (5).

Planorbulina larvata, PARKER and JONES.

Occurs sparingly at Stats. LXIV. and LVII. It has been recorded from Indian seas previously (2).

Planorbulina mediterranensis, D'ORB.

This is of rare occurrence at Stats. LXVIII. and LVIII.—a new record for Indian seas; recorded previously from Mauritius (5).

Gypsina inhaerens (SCHULTZE).

Occurs rarely at Stat. LVII. This is a new record for Indian seas; recorded from islands south of New Guinea and from the European coast (1).

Carpenteria utricularis, CARTER.

Occurs on calcareous Algæ from the Gulf of Manaar and also off Galle. Recorded previously from the Gulf of Manaar (7).

Polytrema miniaceum, LINN.—Plate, fig. 12.

Of very frequent occurrence, and forming at Stat. LXVIII. quite a large proportion of the foraminifera. Also found at Stats. LVI., LVII., LVIII., and LXIV. A fine specimen is figured. Recorded previously from Ceylon (CARTER, 7).

Polytrema miniaceum, var. **alba**, CARTER.

Of rare occurrence in deposits from Stat. LVIII.—recorded previously from Gulf of Manaar by CARTER.

FAMILY: NUMMULINIDÆ.

Nonionina boueana, D'ORB.

Of very rare occurrence, from stations in the Gulf of Manaar. This is the first record for Indian seas; previously recorded from the Red Sea (1) and Mauritius (5).

Polystomella crispa (LINN.).

Very common in all the deposits examined from Stats. LVIII., LVI., LVII., LXIV. and LXVIII., also from Trincomalee, Welligam Bay and Galle—previously recorded from Indian seas (2).

Polystomella craticulata (FICHTEL and MOLL).

Of very rare occurrence at Stat. LVII. This is the first record for Indian seas; recorded already from Mauritius (5) and Red Sea (1).

Amphistegina lessonii, D'ORB.—Plate, fig. 13.

This is extremely abundant in all the deposits, and forms about 25 per cent. by weight and volume of the deposit from a haul at Stat. LXIV. Its surface markings are extremely variable ; one of the varieties is figured and this specimen was not in any way water worn. Noted from Stats. LVI., LVII., LVIII., LXVIII., and other hauls at Stat. LXIV., also off Galle, Trincomalee and Chilaw. Recorded from the Indian seas previously (2).

Amphistegina radiata (Fichtel and Moll).

Rather rare, from Gulf of Manaar. Recorded by Chapman (2) from Arabian seas.

Heterostegina depressa, d'Orb.—Plate, fig. 14.

This is the most abundant foraminifer at practically all the stations. Its size is on the whole above the average, often attaining a diameter of 18·5 millims., and it gives therefore the chief character to the deposit. On these grounds a figure is given here (fig. 14) from one of the most perfect specimens. Occurs at Stats. LVI., LVII., LVIII., LXIV., LXVIII., and off Galle, Trincomalee and Chilaw. Previously recorded from Ceylon (1) and Indian seas (2).

Operculina complanata (Defr.).

Occurs sparingly at Stats. LVII. and LXIV.—previously recorded from Indian seas (2).

Operculina complanata, var. **granulosa**, Leymerie.

This variety occurs somewhat frequently in the Gulf of Manaar. Like the previous species, it has been already recorded from Indian seas (2).

REPORT

ON

JOUSSEAUMIA

A NEW GENUS OF EULAMELLIBRANCHS COMMENSAL WITH THE CORALS HETEROCYATHUS AND HETEROPSAMMIA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

GILBERT C. BOURNE, M.A., D.Sc., F.L.S.,

FELLOW OF MERTON COLLEGE, OXFORD, LINACRE PROFESSOR OF COMPARATIVE ANATOMY.

[WITH THREE PLATES.]

IN a very interesting paper describing the true nature of the commensalism between corals of the genera *Heteropsammia* and *Heterocyathus* and a Sipunculid belonging to the genus *Aspidosiphon*, E. L. BOUVIER (4) pointed out that there is a third partner in the commensalism in the form of a minute Lamellibranch which he figured and named *Kellia deshayesi*, without, however, giving any diagnosis of the species. As I shall point out in the course of this report, BOUVIER'S figure, though it gives a correct enough representation of the external form of the Mollusc, as seen lying in the left valve of its shell, is incorrect in the representation of the hinge teeth, and the Lamellibranch in question certainly does not belong to the genus *Kellia*, differing from it not only in the hinge teeth, but also in the sutural unions of the mantle edges and in other important particulars. Though BOUVIER announced that his colleague M. JOUSSEAUME intended to make a study of this commensal Lamellibranch, it does not appear to have been described or to have attracted any further notice until Dr. A. E. SHIPLEY in his report on the Gephyrea collected by Professor HERDMAN in Ceylon (13) mentioned its occurrence along with *Aspidosiphon* in the basal chambers of *Heteropsammia* and *Heterocyathus*, and states that it was referred by Mr. E. A. SMITH to ANGAS' genus *Mysella*.

Among the solitary corals from Ceylon sent me by Professor HERDMAN were numerous spirit-preserved specimens of *Heteropsammia michelini* and *Heterocyathus æquicostatus*, and on opening the *Aspidosiphon* chamber in one of these I was at once struck by the presence of the numerous small Lamellibranchs, many of them imbedded in the skin of the posterior part of the body of the Sipunculid, as described by BOUVIER; others lying free in the innermost coils of the chamber, especially in its terminal part.

Having many specimens of the corals at my disposal, I examined a large number of them and invariably found a number of the Lamellibranchs inhabiting the *Aspidosiphon* chamber. In some of the larger specimens of *Heteropsammia* I found as many as 30 or 35 specimens of different ages, in some of the smaller specimens of *Heterocyathus* not more than a dozen or fifteen.

BOUVIER left it an open question whether the commensal Mollusc was an adult form or not. My observations quickly showed me that a proportion of the specimens inhabiting each coral were adult, and that along with them were numerous young forms in all stages of growth. With the abundant material at my disposal I proceeded to make a careful study of the anatomy, and, as far as the circumstances allowed, the development of this hitherto undescribed species, and although but few out of the many specimens were sufficiently well preserved to admit of satisfactory microscopical examination, I found a sufficient number in good enough condition to enable me to work out the structure in some detail.

DESCRIPTION OF THE GENUS AND SPECIES.

The description of the genus *Mysella* given by ANGAS (1) is based on the characters of the shell only, and his figure of the hinge apparatus is so small that it is difficult to make out the characters of the hinge teeth clearly, but it is evident that the species commensal in the two corals cannot be referred to his genus.

The specimen on which the genus *Mysella* was founded was 7·5 millims. in length, and was found in black mud near Port Jackson. The shell is inequilateral, the anterior side being the shorter and subtruncate; judging by the figure, the umbones are prosogyrous. The ligament is internal, and there is a single small diverging subcircular flattened cardinal tooth in one valve, and two short thin horizontal lateral processes in the other valve.

My specimens agree with *Mysella* in having an internal ligament, and in having a single cardinal tooth in the right valve and two teeth in the left valve; but there are in addition well-developed lateral teeth, and the shape of the shell is quite different. Moreover, the largest of my specimens does not exceed 1·5 millims. in length and the average length of the adult forms is 1·0 millim.

It is extremely difficult to get a clear view of the hinge teeth in very small bivalve shells. BERNARD (3) has remarked on the unsatisfactory results obtained from dry specimens mounted on black paper and recommends fixing them direct on a glass slide and varying the sub-stage illumination. I found that much the most satisfactory results were obtained by thoroughly cleaning the shells in potash or Eau de Javelle and then mounting them under a coverslip in glycerine jelly. By altering the sub-stage illumination and rotating the stage one can get very clear pictures of the minutest details.

After a careful examination of the shells and of the anatomy of my specimens, I satisfied myself that they belonged to two species of a new genus, which I propose to call *Jousseaumia*, in honour of the French naturalist who first discovered this Mollusc in the *Aspidosiphon* chamber of the two above-named corals. This new genus and the two species may be defined as follows :—

Jousseaumia, n. gen.

Shell small, thin, triangular, equivalve, inequilateral, the anterior side the longer, with numerous fine concentric ridges or striations; umbones small, slightly opisthogyrous. Hinge heterodont, with a somewhat elongately oval internal ligament; a single styliform more or less obtusely pointed cardinal tooth in the right valve and two curved lamellate cardinal teeth in the left valve. Lateral teeth somewhat distant, elongate, in the form of two ridges in the left valve fitting into corresponding depressions in the right valve. Adductor impressions subequal, the anterior impression somewhat elongated; pallial line entire. Mantle largely open, with a single pallial suture; no pallial tentacles and no distinct siphons. The foot elongate, linguiform, geniculate, with a byssus consisting of a few long adhesive threads; a byssal groove on the posterior edge of the foot. Gills astartiform, homorhabdic, non-plicate, with three or at most four rows of simple interfilamentar junctions. Interlamellar junctions few, irregular; the external demibranch wanting; the reflected lamellæ of the inner demibranch more or less developed, generally at the anterior end of the gill only and attached to the sides of the foot. Hermaphrodite and protandric.

Jousseaumia heterocyathi, n. sp.

The single cardinal tooth of the right valve bluntly rounded at its extremity, with a narrower pedicle of attachment. The anterior cardinal tooth of the left valve well developed, lamella curved posteriorly; the posterior cardinal tooth a short, ill-defined diverging ridge. Found only in *Heterocyathus*.

Jousseaumia heteropsammiæ, n. sp.

The single cardinal tooth of the right valve styliform, with a bluntly pointed extremity and a broad base of attachment. The posterior cardinal tooth of the left valve well developed, longer than the anterior tooth, diverging posteriorly, its upper margin excavated to form the ligamentar fossa. Found only in *Heteropsammia.*

The differences in the cardinal teeth between the specimens found in *Heterocyathus* and those found in *Heteropsammia* appear to be constant, and are sufficient to justify my ranking them as distinct species. In addition, the mature individuals of *J. heterocyathi* seem to be rather smaller, the concentric ridges seem to be more prominent and the posterior and ventral margins of the valves appear to be more rounded than in *J. heteropsammiæ.*

As may be seen from an inspection of figs. 2 and 3, the ligament is distinctly dorsal and exterior to the posterior cardinal tooth of the left valve, and is contained in a fossa lying just behind the umbones. The hinge, therefore, is not that of a *Mactra*, to which it has a superficial resemblance from the characters of the lateral teeth, nor yet that of a *Scrobicularia* or *Syndosmya.* It may rather be compared with the hinge of a *Lucina* or *Diplodonta* in which the ligament has become very much shortened and enclosed by the overgrowth of the valve margins dorsally and posteriorly. On the other hand, the excavation of the posterior cardinal tooth suggests a first step in the evolution of the spoon-shaped ligamentar tooth of the Myidæ and many of the Anatinacea (*Thracia, Anatina*), and, as will be seen, the anatomy of *Jousseaumia* suggests some affinities with the Anatinacea.

ANATOMY AND HISTOLOGY.

As *Jousseaumia heterocyathi* and *J. heteropsammiæ* do not differ from one another in any important anatomical feature, the following account will apply to both species. A general view of the anatomy of *J. heterocyathi*, as seen in optical section, is given in fig. 1.

The mantle edge is thickened and muscular, but there are no pallial tentacles, no eyes or pigment spots. There is a single pallial suture (figs. 16, 17, 18, *p.s.*) separating a rather elongate anal or exhalant orifice from the large pedo-branchial orifice, the latter extending as far forward as the anterior adductor muscle. The mantle edges are somewhat prominent and the radiating muscle fibres are rather better developed in the region of the anal orifice than elsewhere, but there is no true anal siphon.

The foot is large, more or less linguiform, and geniculate like that of *Cardium.* There is a specially strong muscular band running down the posterior margin of the foot, below the byssus groove, and the sudden contraction of these fibres would have the effect of straightening the foot and enabling the animal to spring like a *Trigonia* or a cockle. It is difficult to conjecture of what use the geniculate and muscular foot can be to an animal leading a sedentary existence embedded in the skin of the *Aspidosiphon* with which it is commensalistic; but as I find it very well developed in the youngest forms, I suspect that these may escape from the *Aspidosiphon* chamber and use the foot for progression and for springing on and attaching themselves to an *Aspidosiphon* when projected from the basal aperture of another coral. At all events, there must be some means by which *Jousseaumia* can be transferred from coral to coral, and the highly developed musculature of the geniculate foot suggests that the transference is effected in this manner. The anterior and posterior retractors of the foot are well developed and together form an elongated muscular band, by which the foot appears to be slung up in the mantle cavity. Practically the whole of the viscera are dorsal to this band. The protractor muscle of the foot is also well developed and has a separate muscular slip ventral to the anterior adductor muscle, and it is evident that, in spite of its sedentary habit, *Jousseaumia* shows no degeneration in the organs of progression.

The attachment of the young forms to an *Aspidosiphon* inhabiting another coral would be effected by means of the byssus, which has the form of a moderately stout thread, branching and ending distally in adhesive enlargements. The posterior edge of the foot is furrowed by a well-marked byssus groove leading into a byssus cavity at the hinder end of the foot. As the structure of the byssus gland and the mode of formation of the byssus has been a subject of dispute, and as some of my specimens were sufficiently well preserved to enable me to make tolerably accurate observations, I shall describe the histology of this organ in some detail. The whole of the centre of the foot is occupied by a core of more or less polygonal relatively large glandular cells which appear pale in sections stained with borax-carmine and picro-indigo-carmine, but stain deeply in hæmatoxylin or safranin. With the last-named dye the gland cells stain brilliant scarlet, and the stain is shown by high powers of the microscope to be confined to minute granules with which the cells are stuffed. The behaviour of these cells and granules will be described later. The byssus groove begins as a very shallow furrow near the pointed extremity of the foot, and gradually deepens as it passes dorsally along the posterior edge of the foot, eventually ending in a duct which enlarges to form a considerable byssus cavity contained in the upper part of that organ. Fig. 4 is a section taken through the open part of the groove near the middle of the foot. It shows the structure described by CARRIÈRE (5) and HORST (8), namely, a furrow of irregular shape opening to the exterior, and in the depth of the furrow a crescentic gutter or demi-canal ("halbmondförmige Rinne") bounded on either side by a projecting fold. Contrary to the statements of previous authors, I find in *Jousseaumia* that the furrow is lined by a low, non-ciliated epithelium continuous with that of the external surface of the foot. This epithelium has a distinct cuticle, staining blue in picro-nigrosin or picro-indigo-carmine, and though I am unwilling to make a positive assertion in consequence of the indifferent state of preservation of my specimens, I can say that I was unable to find any trace of cilia either in the furrow or on the external surface of the foot. The crescentic demi-canal, on the other hand, is lined by larger cubical or short columnar cells, with clear cell contents and rounded nuclei, and these cells are very distinctly ciliated. Fig. 5 represents a section taken through the duct of the byssus cavity, shortly above the point where the lips of the furrow have united to enclose a canal. It can easily be seen that the duct consists of two portions, (*a*) a lower portion whose epithelium is continuous with that of the open furrow and, like it, is non-ciliated and provided with a cuticle; the walls of this region are thrown into a number of folds; (*b*) an upper portion continuous with the crescentic demi-canal, and lined by the same clear ciliated cubical or columnar cells. Fig. 6 represents a section through the middle of the byssus cavity. At the upper (really the anterior) end of the cavity is the crescentic demi-canal lined by the same clear ciliated cells as before. The remainder of the cavity is broken up by septa, of which two thick folds on either side of the demi-canal, a central partition springing from the lower (posterior) end of the cavity, and two minor lateral folds may be particularly noticed. These septa are covered by a ciliated epithelium, evidently of the same nature as that lining the demi-canal, but the cells are very much elongated and enlarged at their outer extremities. Those on the thick lateral folds are especially long, and diverge in a fan-shaped manner from the band of connective tissue and muscle fibre which forms the centre of the fold. This figure agrees in most respects with CARRIÈRES' drawing of the byssus cavity of *Cyprina islandica* (**5**, fig. 12, B). In a section taken through the deeper end of the byssus cavity, the characters of the epithelium are the same as those of the preceding section, but the cavity has been divided into two by the forward extension of the median septum, the crescentic demi-canal has disappeared, and the lateral septa are smaller. These two anterior prolongations of the byssus cavity end blindly close beneath the pedal ganglia. These three figures are drawn from horizontal sections of the whole animal, and are therefore nearly transverse sections of the foot. Fig. 7 is a highly magnified drawing (ZEISS' $\frac{1}{12}$ immersion) of a transverse section of the whole animal, which therefore cuts the foot and byssus cavity obliquely. It corresponds to the top part of a section rather anterior to that shown in fig. 6. The section was stained with safranin and licht-grün, and does not show the cell contours very clearly, but the granules of byssogen, stained bright scarlet, are very clearly seen. At *by.gl.* are seen the large polygonal glandular cells occupying the central part of the foot. On either side these cells may be seen to be breaking up and their granules are streaming outwards along definite lines to pass either into the central tongue-shaped projection (which is a part of the here incomplete median septum) or into the lateral swellings projecting into the byssus cavity. As they pass outwards, the granules form little pyriform or club-shaped masses, whose swollen ends are directed towards the lumen of the byssus cavity, and it is evident that they are travelling, probably by intercellular paths, to be discharged into the lumen, and there converted into the material of the byssus. The granules themselves are clearly not byssus substance, but "byssogen," as the lumen of the cavity is filled with a granular material (not shown in the figure) which is not stained either by safranin or hæmatoxylin, and the byssus itself is similarly unaffected. The interest of this observation consists in the demonstration that the byssus gland-cells, like those of sebaceous follicles, are broken up to form the secretion, and that the secretum travels in and among the epithelial cells for relatively long distances until it reaches the lumen into which it is finally discharged. Thus the existence of a great mass of gland cells, forming a central core to the foot, and apparently distant from the byssus cavity and groove, is satisfactorily explained. The secretion is not confined to the byssus cavity, but throughout my sections I find the same indications of granules streaming between the ciliated cells of the crescentic demi-canal, but not between the non-ciliated epithelial cells of the furrow. In spite of some differences in detail, which can be accounted for by the widely different genera examined by us, my observations agree in all fundamental particulars with those of Horst (8). The byssus, as he maintained, is undoubtedly a secretion product and not a cuticular structure. Comparing Horst's figures of *Dreissensia polymorpha* (*loc. cit.*, plate xi., figs. 2, 3, and 4) with mine, it will be seen that in the latter species the byssogenous glands are concentrated in the region of the demi-canal, and that there are numerous mucus glands, of which I could find no trace in *Jousseaumia*. And whereas he shows numerous branching and anastomosing canals passing from the cells of the byssus gland between the epithelial cells of the demi-canal, these canals becoming narrower in diameter as they approach the lumen of the byssus cavity, and gives no indication of the breaking up of the cells themselves to form the secretum, I find that the cells are broken up and the secretion travels (probably) between the epithelial cells in the form of streams or strings whose ends nearest the lumen are swollen. It appears that in both cases the secretum follows intercellular paths, and that in both cases it has the form of granules which are converted in the lumen of the byssus cavity, probably by the action of a ferment, into the material of the byssus.

The Alimentary Canal.—The labial palps are relatively large, and the upper and lower palps pass respectively into the upper and lower lips. Posteriorly the labial palps are continuous with the anterior ends of the gill plates. The palps are richly ciliated, the cilia being borne by large cubical epithelial cells with a very distinct limiting membrane, but the surfaces of the palps appear to be smooth, and not thrown into ridges as is usually the case in Lamellibranchia. The mouth leads into a buccal cavity lined by somewhat elongated columnar epithelial cells continuous with those covering the labial palps, and provided, like the latter, with a very distinct limiting membrane or cuticle, through which the cilia project. The pharyngeal cavity is wide and strongly compressed dorso-ventrally. As it passes back into the œsophagus, the shape of the lumen, as seen in transverse section, alters. There is a diamond-shaped central lumen (fig. 8), the lateral angles of which are produced into lateral diverticula, suggestive of a comparison with the œsophageal pouches of Gastropoda. Such pouches are only known in the Protobranchia among the Lamellibranchia, and in them, *e.g.*, in *Leda pella*, as figured by Pelseneer (11), they are much more highly developed than in *Jousseaumia*, but there is a correspondence between the thinner epithelium lining the lateral pouches in his figure and in mine which leads me to believe that we have here an indication, though in a very much reduced form, of these ancestral structures.

The œsophagus is triangular in section and lined by a richly ciliated columnar epithelium. It passes insensibly into the capacious stomach, whose anterior walls are richly ciliated (fig. 13, *st.*), but posteriorly the lining epithelium changes in character. Laterally and ventrally the cells retain their columnar epithelial character, but dorsally (figs. 14 and 15, *gl.c.*) they lose their cilia and become glandular. The cells throughout this region are rather long and columnar, and are full of green refringent granules. It is in this region that the thick cuticular lining of the stomach begins, and I have little doubt that these glandular cells of the dorsal wall secrete the cuticle, and give rise to the crystalline style with which the cuticle is continuous. The liver lobes are four in number, a right and left dorsal and a right and left ventral. They open into the stomach near its posterior end, just in front of the commencement of the intestine and cæcum, by wide ducts on either side, the ducts of the dorsal and ventral lobes of each side uniting just before they open into the stomach. The liver cells were too much macerated to enable me to say anything definite about their histological characters. The left upper end of the stomach is prolonged into a large conical cæcum (figs. 1, 16, and 17, *cæ.*), which projects backwards into the posterior part of the visceral mass and is a conspicuous object in specimens mounted whole. The cæcum is lined throughout by a very definite cubical epithelium, whose cells bear short, stiff, bristle-like cilia, as is the case in the cæca of other Lamellibranchia. In the anterior part of the cæcum the cells of its dorsal wall are transitional between the ordinary cæcal cells and those of the dorsal wall of the stomach, for they are filled with the green refringent granules, while retaining their cubical character and their stiff brush-like cilia. The cæcum is separated from the stomach by a constriction, and at the constriction the epithelial cells are elongated and their ends are produced into rather long irregular processes, apparently formed of fused cilia. These processes seem to form a straining apparatus, preventing particles of any size from entering the cæcum, for while the stomach, intestine, and rectum are full of the skeletons of diatoms, the cæcum is always devoid of such contents. The crystalline style is very large in some specimens, but small, or even wholly absent, in others. It projects some way forward into the stomach and some way back into the cæcum, but seldom extends to the posterior end of the latter.

The intestine leaves the stomach on the right lower side, close to the opening of the cæcum. It runs backwards as a widish, thin-walled ciliated tube as far as the posterior end of the cæcum, where it turns upwards and forwards to reach the dorsal surface of the visceral mass; there its diameter narrows to form the rectum, and it bends sharply backwards, running parallel with the posterior margin of the shell over the posterior adductor muscle to end in the anus. The rectum traverses the pericardium, and is wrapped round by the ventricle.

THE CIRCULATORY SYSTEM is of the typical lamellibranchiate character, and requires no special description. The ventricle, as has been mentioned above, is traversed by the rectum. The auricles are excessively thin and can only be distinguished with difficulty in sections. Owing to the minute size of the animal the relations of the principal blood sinuses could not be determined with certainty, but I was able to distinguish a large ventral sinus above the muscular band formed by the anterior and posterior retractor muscles of the foot, and there are the usual afferent and efferent branchial sinuses at the bases of the gills.

THE GILLS, as may be seen by an inspection of fig. 1, are of a very simple type. The outer demibranch is wanting, a feature which *Jousseaumia* shares with the Lucinidæ, *Corbis*, *Scioberetia* and the Teredinidæ. The direct lamella of the inner demibranch is always well developed, and may be described as consisting of about 18 filaments, united at regular intervals by three, or in large specimens by four, rows of non-vascular interfilamentar junctions. The reflected lamella is present in many adult individuals, but is either absent or very feebly developed in others, and it is always absent in young and immature specimens. When present, it is confined to the anterior region of the demibranch, and the upper edge of the reflected lamella is fused to the body wall along the line of junction of the foot and the visceral mass. Posterior to the foot, where the reflected lamella is absent, the lower edge of the direct lamella of one side is, in all but very young individuals, fused with the lower edge of the corresponding lamella of the other side. If the reflected lamella is absent in the region of the foot, its place is taken by a continuous sheet of membranous tissue, which is attached to the sides of the upper part of the foot. Below and behind the posterior adductor muscle the upper edges of the direct lamellæ are connected with the mantle (figs. 18 and 19), and the result of this arrangement is that the gills divide the pallial cavity into an inter-lamellar or supra-branchial chamber, opening behind by the anal pallial aperture, and a large infra-branchial chamber.

Though I have spoken of filaments, the gills are not developed as separate filamentar outgrowths which subsequently form the above described unions with one another and the body wall and mantle, but by the fenestration of a pair of lateral folds of the body wall, as has been described by other authors for *Cyclas* (STEPANOFF, **14**), *Teredo* (HATSCHEK, **7**), and *Scioberetia* (BERNARD, **2**). Although I have not been successful in finding the earliest stages of gill development, I have a complete series of post-larval stages showing that the fenestration proceeds from before backwards, and that new fenestræ are added at the posterior ends of the two gill membranes until the adult stage is reached. Fig. 27 represents a young *J. heterocyathi* in which there are five fully formed fenestrations and the commencement of a sixth posteriorly. Fig. 28 is a drawing of a somewhat older individual with seven fenestrations. In the youngest form of which I have cut sections the fenestrated gill lamellæ are not reflected, and at the sides of the foot the lamellæ of opposite sides are quite free from one another and from the body wall and foot. Behind the foot the lower edges of the lamellæ of opposite sides are united by a band of connective tissue, and still further back the organic connection between the lower ends is more complete ; a vascular connection is established, and at the extreme hinder end of the gill, where fenestration is still in progress, the gill lamellæ of the two sides are blended in a mass of embryonic connective tissue channelled by numerous irregular blood sinuses. It follows from the above description that, if we speak of the bars between the fenestræ as gill filaments, they are at all stages of growth organically united in longitudinal series at their lower ends, and as the filaments assume their complete histological structure, the chitinoid-supporting skeleton of the filaments forms a dorsal and a ventral arcade, the upper end of each hollow chitinoid gill bar curving forward to unite with the bar in front of it, and a similar connection is eventually established at its lower end. In young specimens, however, the skeletal bars pass below into a mass of undifferentiated connective tissue. As growth proceeds, this undifferentiated tissue at the lower edge of the anterior part of the gill lamella grows out in the form of a membrane, and as it grows the membrane is reflected along the sides of the foot and grows upwards, becoming fenestrated as it grows, and eventually the upper edge of what we now recognise as the reflected lamella becomes attached to the body wall along the line of union of the foot and visceral mass, thus completing the separation between the supra-branchial and infra-branchial chambers. It would, perhaps, be more correct to say that, as the reflected lamella grows upwards, the fenestræ of the direct lamellæ extend into it. When the adult relations are established, the chitinoid skeletal bars of the filaments form an arcade along the upper edge of the reflected lamella where it is attached to the body wall. In those adult individuals in which the reflected lamella is imperfectly developed or absent (and such individuals are not uncommon in both the species under consideration), it would appear that there is an arrest of development, and that the larval condition of the gill becomes permanent in the adult. This arrest of development suggests that the gills of *Jousseaumia* are degenerating. As may be expected from the order of formation of the gill fenestræ, the anterior gill filaments are the longest, and they decrease progressively in length from before backwards.

In the youngest specimens there are no interfilamentar junctions, but these are added in the course of growth, and, as can readily be understood from a consideration of the manner in which the gills are formed, the posterior filaments have fewer junctions than the anterior, as has been described by Bernard for *Scioberetia*.

A few irregularly scattered interlamellar junctions are formed soon after or during the growth of the reflected lamella. These interlamellar junctions are vascular, whereas the interfilamentar junctions are non-vascular.

Owing to the very small size of *Jousseaumia* and the minuteness of the elements composing the gill filaments, I had some difficulty in making out the details of the gill structure, but as some few of my specimens were well preserved and the very minuteness of the objects was of assistance in enabling me to study optical sections under a high power, I have been able to make out some interesting points not hitherto recorded. The individual filaments are slender, and, except for the fact that their interlamellar edges are broader than their frontal edges, they have the usual lamellibranchiate structure. The central cavity is lined by the usual chitinoid layer, thickened at the sides. I could not determine from my sections whether the cavity is divided by a transverse partition into an afferent and an efferent canal, but the appearances seen in optical section lead me to think that it is. The greater number of my specimens when mounted whole and viewed in optical section seemed to possess a large number of closely set ciliated discs, and the late Professor WELDON to whom I showed my preparations was of the opinion that there could be no doubt that ciliated discs were present. Further investigations led me to modify my first opinion, but disclosed an arrangement of the ciliated cells that merits a detailed description.

Figs. 20 and 21 are transverse sections through the gill filaments, the former of a somewhat young and the latter of an adult individual. The triangular shape of the section of the filament with the narrower frontal edge and broad interlamellar base is seen to be due to the great size and thickness of the cells marked *l.c.* Following the usual terminology, the short cilia on the narrow frontal edges may be called the frontal cilia; they are borne on two or three wedge-shaped cells with small nuclei, and the more laterally disposed frontal cilia are longer than the others, so much longer that I was disposed to regard them as latero-frontal cilia, but I do not think that they can be identified as such. The true latero-frontal cilia are very long and rather stiff and are borne on very definite longitudinal rows of columnar cells arranged in single series. These cells are large, with conspicuous round nuclei at their bases, and can be very clearly seen in optical section when the surface of the filament is brought into focus, fig. 22A. Their position and shape is clearly shown in the sections figs. 20 and 21, *l.f.* Following on these are one or two non-ciliated interstitial cells, and the sides of the filaments just above their basal angles are occupied by longitudinal rows of very large oblong cells with flattened elongated nuclei. These cells are best seen in optical section by focussing below the latero-frontal cells, as in fig. 22B, but they are clearly distinguishable in transverse section, though their elongate shape is, of course, not shown in this case. These cells bear a large number of very fine cilia, which interlock with those of adjacent filaments, and the interlocking is so effectual that when the tissues are contracted by the action of reagents the limiting membranes of the cells are torn off and remain adherent to the cilia in the interfilamentar spaces (figs. 20 and 21). The interlamellar bases of the filaments are covered by a few flattened non-ciliated cells with small nuclei. The false appearance of ciliated discs observable in so many of my specimens is due to the fact that in macerated or much contracted gills the large oblong cells become loosened from their attachment to the filament and become bent up in a crescentic form with their convexities outwards. In this condition, when the cilia remain attached to them, they may very easily be mistaken for ciliated discs, and it was only after studying well-preserved preparations with the highest powers of the microscope that I discovered the real state of the case. As far as I am aware, very large elongated cells of this shape bearing the lateral cilia have not been described before, and they seem to be peculiar to *Jousseaumia.* It is, as I have said, possible to regard the longer cilia on the frontal edges as latero-frontal, and in that case the very long stiffer cilia succeeding them would be lateral cilia, and the long fine interlocking cilia borne by the brick-shaped cells might be regarded as occupying the position of and being homologous with ciliated discs. On this view the gill of *Jousseaumia* would have to be regarded as a primitive form of filibranch gill, in which the interlocking cilia are arranged in continuous lines and are not differentiated into isolated ciliated discs. But this view is hardly tenable. The gills of *Jousseaumia* are not filibranch, for they have well-developed interfilamentar junctions. Moreover, the interlocking cilia, in addition to their being arranged in longitudinal lines and not in groups, are actually finer and longer than the fronto-lateral cilia, and lack the short, stiff brush-like character of the cilia of true ciliated discs. The fact remains, however, that they interlock, and that there is therefore a ciliary union in addition to an organic union between the filaments of *Jousseaumia.* It seems to me probable, however, that the physiological rôle of the interlocking cilia is rather to form a barrier preventing solid particles from passing between the filaments than to give mutual support to the filaments, and this view is supported by their extreme fineness, while the coarser latero-frontal cilia projecting from the corners of the frontal edges are evidently effective in sweeping solid particles over the surfaces of the gills towards the labial palps and mouth.

The interfilamentar junctions are arranged in regular rows. In most specimens there are three such rows in the anterior part of the direct lamella and one or two rows in the reflected lamella. As has been stated, these junctions are non-vascular and are formed as secondary outgrowths from the filaments, bridging across the fenestræ at regular intervals. As may be seen in figs. 17 and 21, these interfilamentar junctions are curved bars, continuous with the chitinoid lining of the central cavity of the filament, but the junctions themselves are solid, and as they are only clothed by a very thin protoplasmic sheath, they do not establish any vascular connection between adjacent filaments. As seen in section, the interlamellar edge of each filament appears to be prolonged to form a pair of bars which curve round to unite with corresponding outgrowths from the adjacent filaments. The lower part of fig. 22 shows the interfilamentar junctions as viewed in optical section under a very high power of the microscope. As a rule the interfilamentar bars are single, but occasionally they are double, as shown in the middle of the figure. The chief point of interest is that the bars are clearly shown to be formed by the agency of special cells, whose nuclei are grouped about the broad bases of attachment of the bars to the filaments. These nuclei are visible in section in fig. 21*x*. There can be no doubt that the interfilamentar junctions are formed by the agency of these cells, for their position at the attached ends of the bars is invariable, and they are not to be distinguished elsewhere. Moreover, by looking through numerous preparations, I have been able to recognise these groups of cells at points where the interfilamentar junctions are in process of formation, and have seen in optical section the processes formed by the cells projecting from, but not yet bridging over the interval between adjacent filaments. These chitin-forming cells do not appear to have been recognised by previous observers, but they are probably included in the general and somewhat vague term "sub-filamentar" tissue. BERNARD (2) gives a drawing of groups of stellate cells in *Scioberetia*, which appear to coincide in position with those which I have described, but he does not attribute any special function to them, and merely refers to them as components of a "substance conjonctive transparente à nombreuses cellules" (*loc. cit.* p. 374). It is evident from a comparison of the sections drawn in figs. 20 and 21, that these junction-forming cells in *Jousseaumia* are differentiated from the flat non-ciliated cells covering the interlamellar edges of the filaments.

THE PERICARDIUM AND RENAL ORGANS.—Owing to the minute size and the contracted state of my specimens, the relations of these organs presented great difficulties. The pericardium is a more or less triangular sac, relatively of considerable size, lying above and in front of the posterior adductor muscle. It is traversed obliquely by the rectum, and the ventricle of the heart surrounds the latter for a considerable part of its course through the pericardium. The whole of the inner lining of the pericardial walls is glandular, constituting an extensive pericardial gland, but the glandular epithelium does not appear to extend to the investment of the ventricle and auricles. Glandular epithelia are the first to suffer from the effects of long immersion in spirit, and the preservation of my specimens was not good enough to allow me to make out the details of the pericardial glandular cells with any certainty. The most that I am able to say is that they are rather large irregularly shaped cells with oval nuclei, and coarsely granular contents which stain faintly blue in picro-indigo-carmine.

The kidneys are conspicuous from the large concentrically striated concretions which they contain. These concretions are contained in a highly vacuolated protoplasmic lining of the renal sacs. The right and left renal sacs are fused together for such a considerable extent in the middle line, below the floor of the posterior end of the pericardium, that their paired nature is obscured, and can only be recognised by an examination of the paired ducts and the paired anterior and posterior horns into which the median sac is produced. Such an extensive fusion of the two kidney sacs is characteristic of the more specialised forms of Lamellibranchia, particularly of the Myacea, Pholadidæ and Anatinacea (PELSENEER, 12), and my sections through this region of the body bear a considerable resemblance to the section through the kidneys of *Lyonsiella abyssicola* and *L. norvegica* figured by PELSENEER (**11**). The median sac formed by the fusion of the right and left kidney sacs in *Jousseaumia* lies just in front of and above the posterior retractor pedis muscle, near where the latter bifurcates to be attached to the right and left valves of the shell. The two posterior horns of the sac are of considerable length, and extend along the outer sides of the diverging bundles of the retractor pedis muscle, extending blindly just below the anterior end of the posterior adductor muscle. The anterior horns of the sac are smaller and pass to the outside of the retractor pedis muscle. The median sac and its anterior and posterior prolongations are lined throughout by a thick vacuolated layer of protoplasm containing relatively large oval nuclei, but I was unable to distinguish any cell outlines. The renal concretions lie in the vacuoles and are similar to those described and figured by PELSENEER (**11**). The relations of the renal ducts and the reno-pericardial canals are shown in fig. 23, and the renal ducts are shown in section in figs. 25 and 26, *Re.d.* They are short canals lined by a cubical ciliated epithelium and open into the supra-branchial cavity, in close contiguity to the genital apertures, on a small papilla situated to the outside of the visceral commissure. The reno-pericardial ducts are very minute, and it was difficult to discover them even with the aid of the highest powers of the microscope. They are extremely fine ciliated ducts opening into the floor of the renal sac not far in front of the uroducts. Each reno-pericardial duct runs forward close below the external part of the floor of the median renal sac, and, passing to the inside of the uroduct, turns upwards and opens by a minute ciliated aperture into the pericardial cavity.

THE NERVOUS SYSTEM.—This is of the usual lamellibranchiate type, and presents few features of interest. The nerve ganglia are relatively of great size, as may be seen in figs. 9, 12, and 19. Their proportions, relatively to the whole size of the animal, may be described as larval, and this, coupled with the fact mentioned below (p. 257), suggests that the sexual products in *Jousseaumia* are precociously developed, and that we have, in fact, an example of pædogenesis. In the cerebro-pleural ganglia the separate groups of nerve ganglion cells forming the cerebral and pleural moieties of the ganglia are easily recognisable, but the cerebro-pedal and pleuro-pedal connectives leave the fused ganglia as a single nerve. The otocysts are situated above the hinder part of the large nerve mass formed by the fused pedal ganglia, and are quite separate from the ganglia and contained in special compartments of the general body-cavity or hæmocele (fig. 13, *ot.*). Each otocyst contains a single large otolith. The visceral ganglia are of great relative size, and the posterior pallial nerves are very stout. I was unable to find any trace of an osphradium in the form of a specialised patch of epithelium in the neighbourhood of the visceral ganglia, or on the course of the posterior branchial nerves.

THE GONADS AND GONADUCTS.—*Jousseaumia* is monœcious, and, as is usual among hermaphrodite lamellibranchia, is protandric. By far the greater number of the individuals examined by me contained spermatozoa only, but in some few both ripe spermatozoa and developing ova were present in the gonads, and in about half a dozen cases the gonads contained ova only and were enormously enlarged, displacing the other viscera in the visceral mass. It would appear that *Jousseaumia* is also, to a certain extent, pædogenetic, for I discovered ripe spermatozoa in a considerable number of young forms which were clearly immature as regards the structure and development of the shell and gills.

The gonad itself shows very few traces of paired structure, and varies very much in shape and extent, according as it contains spermatocytes and spermatozoa only, or developing ova or ripe ova. It may be described as consisting of a median vestibule lying in front and ventrad of the kidney and pericardium, opening behind by paired ducts on the reno-genital papillæ, and produced anteriorly into a dorsal and a ventral tubular diverticulum. The diverticula are lined by the germinal epithelium, from which first spermatocytes, then, when the spermatozoa have ripened, oocytes, are produced. In the first stage, when the protandric phase is in evidence, the extent of the gonad is small, as is shown in fig. 1. The dorsal diverticulum extends forward and upward from the vestibule below the floor of the anterior part of the pericardium, and is continued forward below the rectum as far as the point where the latter bends sharply back on itself. The ventral diverticulum is a very short tubular outgrowth from the lower and anterior face of the vestibule, and lies ventrad of the stomachal cæcum. The dorsal or anterior end of the dorsal diverticulum is bifurcated, and the two branches often lie on either side of the rectum, this and the existence of paired gonaducts being the only evidences of paired structure in the body of the gonad. The ventral diverticulum is never bifurcated. Spermatogenesis is effected mainly, though not exclusively, in the dorsal diverticulum, which in many specimens is filled with spermatocytes and spermatids in different stages of development, but the state of my preparations did not admit of my making minute investigations on this subject. The vestibule, in this phase, is filled with ripe spermatozoa, and at a somewhat later period the whole gonad contains a mass of ripe or nearly ripe spermatozoa. This was the most common condition in the numerous specimens I examined ; only in two of them could I find evidence of the simultaneous formation of ova and spermatozoa, and in those there were many ripe and a few developing spermatozoa in the dorsal diverticulum, the vestibule was filled with ripe spermatozoa, and developing ova were observed in the ventral diverticulum. The more usual course appears to be that the protandric phase is followed by a short resting stage, during which the diverticula of the gonad are empty and reduced in size, though the vestibule may remain full of spermatozoa. This is succeeded by an active development of ova in both diverticula, which become enormously distended and push their way forward among the viscera, displacing the latter to a very considerable extent. Posteriorly the vestibule bifurcates to form the right and left gonaducts. These ducts, wide at first (fig. 24, *go.d.*), rapidly diminish in diameter, and passing outwards and backwards, open just to the outside of and behind the renal apertures on the reno-genital papillæ on either side. The most remarkable feature about the gonaducts is that each, just before its external opening, is joined by the short and contracted duct of an ovoid vesicle (*Vs.*, figs. 1, 24, 25) which, in nearly all cases, is filled with ripe spermatozoa, and is clearly a seminal vesicle, in which the ripe spermatozoa are stored up pending the development of the ova. These seminal vesicles, which form very conspicuous objects in sections, are lined by a well-defined, flattened, and as far as I could determine, non-ciliated epithelium, and their relations to the gonaducts are best seen in the series of sections, figs. 24, 25, and 26, drawn under a high power of the microscope. The presence of specialised accessory organs in the shape of vesiculæ seminales on the gonaducts is, as far as I know, a unique feature among the Lamellibranchia, though PELSENEER (**12**) makes mention of an accessory gland on the male duct of *Cuspidaria*, but this gland is not described in his detailed account of the anatomy of the genus. The numerous specimens of *Heteropsammia* and *Heterocyathus*, sent me by Professor HERDMAN, were collected in February and March, and as the more mature individuals of *Jousseaumia* inhabiting them are nearly all in the same sexual condition, viz., in the protandric phase, it seems probable that in this genus there is a seasonal alternation of male and female maturity. If this conjecture is right, it is evident that the vesiculæ seminales serve as reservoirs for the spermatozoa, which are stored up until the ova are ripe and ready to be discharged from the gonaducts.

Hermaphroditism, though it is not uncommon among the Lamellibranchia, is only characteristic of a single sub-order, the Anatinacea. In all the hermaphrodite forms protandry is the rule, as in *Jousseaumia*, and this is markedly the case in the Anatinacea, as shown by PELSENEER (**11**). In this sub-order, the ovaries and testes are separate, the ovaries being dorsally and the testes ventrally situated in the visceral mass. In *Pandora*, *Thracia*, and *Lyonsia*, the oviducts and spermiducts open separately by contiguous orifices on each side of the body, and the same is the case in *Lyonsiella*, but in this last genus the male and female apertures open very close together on a small genital papilla (PELSENEER, **11**). In *Jousseaumia* the conditions are different; the gonad is single and alternately male and female in function, and there is only a single gonopore on each side. But its structure is interesting as indicating the manner in which the separate ovaries and testes of the Anatinacea may have been evolved. The dorsal and ventral diverticula of *Jousseaumia* correspond in position with the ovaries and testes of the Anatinacea, and, as I have shown, they are to a certain extent specialised, since the production of spermatozoa is nearly exclusively confined to the dorsal diverticulum. If the two diverticula were to become separate and acquire separate openings to the exterior and the function of producing ova were confined to the one, and the function of producing spermatozoa to the other, we should have a condition of things nearly identical with that of the Anatinacea. It must be observed, however, that in the latter group the testes are ventral, whereas in *Jousseaumia* the male diverticulum is dorsal, and at a later stage both diverticula become female.

Although I made a careful search, I was unable to find any ova or embryos in the supra-branchial chamber. It does not necessarily follow that *Jousseaumia* is not incubatory, and that the ova are not fertilised, and undergo the earlier stages of development in the branchial cavity, for as I have pointed out, there is probably a seasonal alternation of sexual maturity, and the specimens at my disposal were mostly in the male condition. Even those which had advanced beyond this stage and contained numerous ova in the gonads, did not give evidence of complete female maturity. In one specimen of *Heteropsammia* I found, in the *Aspidosiphon* chamber, a number of small ovoid ova, each surrounded by a thick radially striated egg-membrane, but I have no evidence that these are the ova of *Jousseaumia*. Nor was I successful, after a prolonged and careful search, in finding any larval or embryonic forms much younger than the specimen shown in fig. 27, though in every coral there was an abundance of young forms representing every stage of later growth. The specimen depicted in fig. 27 displays clearly the larval shell or prodissoconch, with its rectilinear hinge-line and internal ligament. A single-growth lamina has been added at the edge of the prodissoconch, so the animal cannot have passed very far beyond the larval stage. The principal organs of the body are, however, well developed. The anterior and posterior adductor muscles are fully formed, as is usual in young Lamellibranchs; the foot has the geniculate characters of the adult; the retractor and protractor muscles of the foot have the same relative size and importance as in the adult; the labial palps are well formed, and in the alimentary canal all the features of the adult—pharynx, œsophagus, stomach, cæcum, liver and intestine—are clearly distinguishable. Only the nerve centres and the gills retain embryonic characters. In the nervous system the ganglia are still larger, relatively to the whole size of the animal, than they are in adult, and the connectives are relatively very thick. In the cerebro-pleural ganglia the double nature of each member of the ganglion-pair, only recognisable in section in the adult, is evident in a surface view (fig. 27, *cg.*). The gills are in an early stage of development and show five fenestrations, with a commencement of a sixth. The organisation is much more advanced than, for instance, in the youngest *Scioberetia* figured by Bernard (**2**, plate xv., fig. 4). Not only is the internal organisation well advanced, but the hinge does not show the characteristic teeth of the prodissoconch, although the valves have hardly grown beyond the prodissoconch stage. On the contrary, there is no trace of a provinculum, the anterior cardinal teeth are clearly developed, and the large lateral teeth are being formed by folds of the mantle edge just above the anterior and posterior adductor muscles. In the specimen shown in fig. 28 there are four growth laminæ outside the prodissoconch. The organisation is somewhat more advanced than in fig. 27; in particular the nervous system and labial palps have assumed their adult proportions and the gills are larger and have acquired seven fenestrations, but as yet no interfilamentar junctions. The anterior cardinal teeth of the hinge are more distinct and clearly interlock with one another, and a deposition of calcareous matter round the attachments of the ligament foreshadows the formation of the posterior cardinal tooth and the ligamentar fossa. In later stages, with seven or eight growth laminæ outside the prodissoconch, the adult characters of the hinge are fully established. It would appear, then, that, as compared with the size of the shell, the visceral organs and the permanent hinge teeth are precociously developed in *Jousseaumia*, and the suppression of the provinculum and consequent abbreviation of the several stages in the evolution of the heterodont hinge may account for the ligament remaining internal and therefore in its larval condition instead of being shifted to an external position.

CONCLUSION.

I have given a full description of this interesting little Lamellibranch, because, as it seems to me, it is incumbent on students of this class to give a full anatomical account of the various forms that come under their notice. A detailed account of the anatomy of various Lamellibranchs is needed before many questions of classification can be finally settled. The researches of PELSENEER (**10**) have broken ground in this direction, but subsequent authors have not followed his example by dealing with the whole anatomy of the species they have investigated. The work of RIDEWOOD (**15**), dealing with a large number of species of all orders of the Lamellibranchia, is confined to a detailed exposition of the gill-structure, and though it forms a valuable contribution to our knowledge of this single feature of Lamellibranch anatomy, its main result has been to show how little the characters of a single organ are to be relied upon in framing the smaller subdivisions of a system of classification. There are at the present time few malacologists who will question the importance of gill-structure as a basis of the general classification of the Lamellibranchia and their division into the orders Protobranchia, Filibranchia, Eulamellibranchia and Septibranchia meets with general acceptance, the more so because these orders correspond very closely with those based upon a study of the hinge characters. But when we come to subdivide the orders into sub-orders and to arrange the latter in families, and especially when we attempt to estimate the relationship and probable lines of descent of the various families grouped together in the sub-orders, the structure of the gills becomes of less value to us. Thus, to take a single instance, in the family Donacidæ we find plicate and non-plicate, homorhabdic and heterorhabdic gills with almost every variety of interfilamentar and interlamellar connection. In the large sub-order Submytilacea, we find the simple Astartiform gill at one end of the order and the extremely specialised complex gills of the Unionidæ at the other, and no very definite series connecting the two. PELSENEER (**10** and **12**) characterises the Submytilacea as Eulamellibranchs with smooth, *i.e.*, non-plicate gills, but RIDEWOOD (**15**) has shown that the gills of *Diplodonta oblonga* and *Monocondylæa* are slightly and those of *Corbicula lydigina* markedly plicate. On the other hand, smooth or non-plicate gills are common among other sub-orders of Eulamellibranchia. The detailed study of gill structure has therefore proved disappointing for classificatory purposes, and in trying to trace the connections between the sub-groups of the Eulamellibranchia we are once more thrown back on a criticism of the *ensemble* of the anatomical characters of each family. The difficulty of placing any given genus in its proper position in the system is well illustrated by *Jousseaumia.* Its heterodont hinge, sub-equal adductor muscles, entire pallial line, single pallial suture and very simple gill structure leave no doubt that it must be placed in the Submytilacea, but when one looks for its nearest allies in this very heterogeneous sub-order, the difficulties are considerable, and they are not lessened by the fact that some systematists give a certain character as diagnostic of a family, and then proceed to describe as members of that family genera in which this diagnostic character is wanting.

Thus, *Jousseaumia* shows undoubted affinities to the Erycinidæ (Leptonidæ, Pelseneer, **12**). The members of this family are hermaphrodite, the ligament is internal, the foot linguiform, elongated and byssiferous, the gills simple and astartiform, with very little sub-filamentar tissue and scattered interlamellar junctions. Many members of the family are of minute size and some (*Lepton*) are commensal. Bouvier identified *Jousseaumia* as a *Kellia*, and E. A. Smith identified it with Angas' genus *Mysella*, which Fischer (**6**) regards as closely allied with *Kellia.* I have shown that it cannot be placed in either of these genera, and though it might be regarded as having affinities with *Lepton* or *Lasæa*, because of the single pallial suture, it differs from the whole of the Erycinidæ in the absence of the external demibranch. This last character suggests an affinity with the Lucinidæ, and more particularly with the genus *Montacuta* placed in this family by Pelseneer; *Montacuta* has a single pallial suture, a very long, linguiform, byssiferous foot and a shell which is in many respects similar to that of *Jousseaumia.* The ligament is internal, the anterior adductor impression longer than the posterior, the cardinal teeth have analogous characters, and the anterior border is longer than the posterior, and as a small point of resemblance Pelseneer describes a protractor pedis ventral to the anterior adductor (**11**, p. 203) which is paralleled by the slip of the protractor in *Jousseaumia. Montacuta bidentata* has the habit of living in old shells, and *M. substriata* is parasitic on an Echinid, and the former habit is suggestive of the manner in which *Jousseaumia* may have come into association with the Sipunculid inhabiting the basal chambers of corals. So similar is the shell of *Montacuta* to that of the Erycinidæ that Fischer places it in this family, but its gills not only lack the external demibranch, but the filaments have considerable interlamellar extrusions, the interfilamentar junctions are vascular and in these and other respects so closely resemble the gills of *Lucina* that there can be no doubt that it should be placed, as Pelseneer has placed it, in the Lucinidæ. And for the same reason that *Montacuta* is placed in the Lucinidæ, *Jousseaumia* must be excluded from this family. Its gill structure is different and it is monœcious whereas the Lucinidæ are diœcious, and there are other anatomical characters in which it differs from *Montacuta* (see PELSENEER, **11**, pp. 203, 204).

The only other members of the Submytilacea in which the external demibranch is wanting are the Corbidæ and *Scioberetia*. *Jousseaumia* has clearly no affinities with the Corbidæ, but, as has been pointed out, it has certain features in common with *Scioberetia*. Both are hermaphrodite, commensal or semiparasitic, have a similar gill structure and a single pallial suture, but in *Jousseaumia* the mantle is not reflected over the shell and it therefore must be excluded from the Galeommidæ, to which *Scioberetia* belongs.

The balance of evidence is in favour of placing *Jousseaumia* among the Erycinidæ in spite of the absence of the external demibranch. This last character, taken by itself, is of no systematic importance, since it occurs in forms as far apart as *Lucina*, *Scioberetia*, and *Teredo*. RIDEWOOD has shown that the external demibranch is liable to modification and partial suppression in a large number of widely separated genera, and its total suppression may well be accounted for by changed conditions of life affecting the respiratory and alimentary functions. I have shown that there is evidence that the gill is degenerating in *Jousseaumia*, and that the reflected lamella of the existing demibranch, never very well developed, is rudimentary in a certain number of adult individuals. The conditions which are causing the degeneration of the reflected lamella of the inner demibranch may well have caused the total suppression of the outer demibranch. On the other hand, the details of the gill structure agree very closely with those of the Erycinidæ, particularly with that of *Lasæa*, and the internal ligament, the shell characters, the hermaphroditism and other anatomical features point to a close relationship, particularly to the last-named genus, in which the external demibranch is very short and has no reflected lamella. It may be further observed that *Jousseaumia* presents an interesting example of the admixture of primitive and specialised characters which is so puzzling to the systematist. RIDEWOOD rightly regards the gills of *Astarte* as being among the most primitive of all Eulamellibranch gills. In their essential structure the gills of *Jousseaumia* are still more primitive, but at the same time they are specialised, and specialised in the direction of reduction and degeneration, as is shown by the absence of the outer demibranch, the slight development, and even the suppression of the reflected lamella of the inner demibranch, which in some individuals is only represented by a continuous sheet of tissue reflected and attached to the body wall in the region of the foot. It is obvious that this kind of reduction, if carried still further, would lead to the condition found in the Septibranchia, though I do not mean to suggest that *Jousseaumia* is closely related to this order.

As other evidences of primitive characters we may note, in *Jousseaumia*, the relics of paired œsophageal pouches (if I am right in regarding the lateral grooves in the œsophagus as such), the obvious cerebral and pleural moieties of the cerebro-pleural ganglia in the young forms, the simplicity of the alimentary tract (but this may be due to degeneration), and such minor characters as the persistence of the internal embryonic hinge ligament, the single pallial suture, &c. On the other hand, the extensive fusion of the kidney-sacs in the middle line is characteristic of more highly specialised Eulamellibranchs, such as the Anatinacea, and the presence of vesiculæ seminales is a unique feature of specialisation in connection with the reproductive apparatus.

Taking all these facts into consideration, we must regard *Jousseaumia* as an offshoot of a primitive Eulamellibranch stock, which in consequence of its commensal habits has been largely modified in the directions indicated, and that its nearest allies are the Erycinidæ and Galeommidæ, which are similarly primitive Eulamellibranchs modified in various directions in relation to their different habits of life.

It is interesting to note that the commensalism between a coral, a sipunculid, and a lamellibranch must be still further extended. In almost every specimen examined, whether of *Heterocyathus* or *Heteropsammia*, I found in the *Aspidosiphon* chamber one or two specimens of a small copepod belonging to the family Harpacticidæ, but as I am obliged to bring this paper to a close to be in time for the issue of the last volume of the "Reports on the Ceylon Pearl Oyster Fisheries," I have not had time to identify the genus and species. Furthermore, *Jousseaumia*, minute as it is, and protected within the *Aspidosiphon* chamber of the coral, is liable to the attacks of parasites. In one series of sections I found a minute trematode, distinguishable as such by its well-developed suckers, encysted in one of the dorsal lobes of the liver, and in another series a larger specimen of what is apparently a trematode, but I could not easily determine its nature from the sections, lying free in the supra-branchial cavity.

EXPLANATION OF PLATES.

Lettering in all the Figures.

A.ad., anterior adductor muscle.
A.ap., anal or exhalant aperture.
An., anus.
A.r.p., anterior retractor pedis muscle.
Br.m., branchial muscles.
Bucc., buccal cavity.
By., byssus.
By.c., byssus cavity.
By.g., byssus groove.
By.gl., byssus gland cells.
Cæc., cæcum.
C.g., cerebro-pleural ganglion.
Cr.s., crystalline style.
Cu., cuticular lining of stomach.
Dbr., internal demibranch.
F., foot.
fr., frontal cilia.
gl.c., glandular cells of stomach.
Go., gonad.
Go.a., genital aperture.
Go.c., gonaduct.
Go.d.[1], dorsal diverticulum of gonad.
Go.d.[2], ventral diverticulum of gonad.
Ht., ventricle of heart.
if.j., interfilamentar junctions.
il.j., interlamellar junctions.
l., lateral cilia.
l.c., oblong cells bearing lateral cilia.
l.f., latero-frontal cilia.
Li., liver.
Lig., hinge ligament.
Lm.int., internal lamella of demibranch.
Lm.ext., external lamella of demibranch.
L.p., labial palps.
M., mantle.
Oe., œsophagus.
or.exh., exhalant or anal pallial orifice.
ot., otocyst.
P.ad., posterior adductor muscle.
Pc., pericardium.
P.g., pedal ganglion.
P.r.p., posterior retractor pedis muscle.
P.s., pallial suture.
Ptr., protractor pedis muscle.
Ptr.[1], ventral slip of the protractor pedis muscle.
R., rectum.
Re., kidney.
Re.a., renal aperture.
Re.d., renal duct.
R.pd., reno-pericardial canal.
St., stomach.
Spz., spermatozoa.
Vb., vestibule of gonad.
Vc., visceral commissure.
Vg., visceral ganglion.
Vs., vesicula seminalis.
x., cells of the interfilamentar junctions.

PLATE I.

Fig. 1. An adult specimen of *Jousseaumia heteropsammiæ* lying in the right valve of the shell. × 85.

„ 2. Valves with hinge teeth of *J. heterocyathi.* × 85. *c.*, the single cardinal tooth of the right valve; *c.a.*, the anterior, and *c.p.*, the posterior cardinal teeth of the left valve; *foss.*, ligamentar fossa; *lig.*, ligament; *l.ant.*, anterior lateral, and *l.post.*, posterior lateral teeth; *L.V.*, left valve; *R.V.*, right valve.

„ 3. Valves with hinge teeth of *J. heteropsammiæ.* × 85. Lettering as in the preceding figure.

„ 4. Section through the byssus groove of *J. heterocyathi* highly magnified, showing the ciliated demicanal, *d.c.*, in the depth of the groove; *mus.*, muscle fibres of the foot.

„ 5. A section through the duct of the byssus cavity, higher up than fig. 4. The ciliated demicanal, *d.c.*, retains the same shape as in fig. 4; the remainder of the duct is not ciliated, but lined by a thick cuticle formed by the underlying epithelial cells.

Fig. 6. A section through the byssus cavity. The demicanal, *d.c.*, is still apparent, but the whole cavity is lined by a similar ciliated epithelium. *m.sp.*, median septum; *l.sp.*[1], the thick lateral septa on either side of the demicanal; *l.sp.*[2], smaller lateral septa.

„ 7. A portion of a section through the byssus cavity, somewhat anterior and oblique to the section drawn in fig. 6. The byssus gland cells, *By.gl.*, are seen to be breaking up, and the granular secretum stained red with safranin is passing between the epithelial cells. The granular secretion in the cavity itself is omitted. ZEISS' $\frac{1}{12}$ hom. imm. Comp. Oc. 4.

„ 8 A transverse section through the œsophagus of *Jousseaumia heterocyathi*. *lat.div.*, lateral diverticula of the œsophagus, resembling the œsophageal pouches of Protobranchia. ZEISS' $\frac{1}{12}$ hom. imm. Comp. Oc. 4.

PLATE II.

Figs. 9 to 19. A series of transverse sections through *Jousseaumia heteropsammiæ*. Fig. 9 passes through the cerebral ganglia and fig. 19 through the visceral ganglion pair. All the figures are fully lettered.

PLATE III.

Fig. 20. A section through the ventral end of the demibranch of an immature individual of *J. heteropsammiæ*. ZEISS' $\frac{1}{12}$ hom. imm. Comp. Oc. 4.

„ 21. A section through two adjacent gill filaments of a mature individual of *J. heteropsammiæ*, showing the interfilamentar junctions.

„ 22. Optical sections of two gill filaments of *J. heterocyathi*. A represents the filaments as seen with a high focus, and shows the latero-frontal cilia, *l.f.*, borne on columnar cells. B represents a section as seen with a somewhat deeper focus, and shows the lateral cilia, *l.*, borne on the large oblong cells, *l.c.* C, taken at a still deeper focus, shows the interfilamentar junctions, which are occasionally double, as in the centre of the figure, and the cells *x*, which give rise to the outgrowths forming the junctions.

„ 23. A diagram showing the relations of the kidney, pericardium, and gonads in *Jousseaumia*, from a reconstruction of a series of sagittal sections.

„ 24. A horizontal section through the gonaducts, vesiculæ seminales, and posterior part of the kidney of *J. heteropsammiæ*. ZEISS' $\frac{1}{12}$ hom. imm. Comp. Oc. 4. *Con.*, renal concretions.

„ 25. A section somewhat lower down from the same series as fig. 24, showing the renal duct, *Re.d.*, and the opening of the vesicula seminalis into the gonaduct; *br.*, attachment of branchial filament to the body-wall.

„ 26. A section next but one in the series to that shown in fig. 25, showing the renal (*Re.a.*) and genital (*Go.a.*) apertures.

„ 27. A young individual of *J. heterocyathi* with one growth lamella outside the prodissoconch, and with five gill fenestrations and the commencement of a sixth; *pr.diss.*, outline of the prodissoconch; *Card.a.*, anterior cardinal hinge tooth. × 150.

„ 28. A somewhat older individual of the same species with seven gill fenestrations and four growth lamellæ outside the prodissoconch. × 150.

REPORT

ON THE

MOLLUSCAN SHELLS

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

ROBERT STANDEN (ASSISTANT KEEPER, MANCHESTER MUSEUM), AND
ALFRED LEICESTER (LIVERPOOL),
MEMBERS OF THE CONCHOLOGICAL SOCIETY OF GREAT BRITAIN, AND IRELAND.

PROFESSOR HERDMAN has placed in our hands the collection of Mollusca* obtained during his dredgings around the coasts of Ceylon, and of these we have now identified 373 Gastropoda, 5 Scaphopoda, and 142 Pelecypoda. In addition we have still unidentified 1 *Eulima*, 1 *Marginella*, 1 *Amphiperas*, 2 *Rissoina*, 2 *Triforis*, 1 *Dentalium*, 2 *Cardium*, and a few bivalves which may possibly all prove new to science; also some juvenile forms of doubtful identity; and we much regret that the time at our disposal, for the compilation of this Catalogue, does not allow of their more critical examination. We propose at an early opportunity to investigate these "remainders," and hope to publish the results in the 'Journal of Conchology.'

The material chiefly consists of the larger-sized and well-known species, with a few of the smaller forms described in recent years by the numerous workers on the Molluscan Fauna of the Indo-Pacific region. The absence from Professor HERDMAN'S dredgings of the *minutiora* which have yielded such an abundance of new forms, mostly endemic, in other collections, is somewhat remarkable, and can only be accounted for on the supposition that the mesh of the dredge nets was too large to retain such small objects. The Pyramidellidæ, Rissoidæ, and the smaller Pleurotomidæ, &c., are barely represented, whilst such genera as *Scala*, *Litiopa*, *Tornatina*, *Cyclostrema* and *Bullia* do not occur at all in this collection, common as they have

* Separate Reports on the POLYPLACOPHORA, by Mr. E. R. SYKES, on the CEPHALOPODA, by Dr. W. E. HOYLE, and on the OPISTHOBRANCHIA, by Mr. G. P. FARRAN, have already appeared in this series. The present Report deals with the shells of the remaining Mollusca collected.—ED.

proved to be on the Indian coasts generally. The chief rarity worthy of note is *Mitra tankervillei*, hitherto a unique shell of unknown locality.

In the Catalogue we have quoted localities only, as found in the various jars and bottles, or as furnished by Professor HERDMAN. Particulars as to nature of bottom, and conditions under which the specimens were obtained, are so fully given under the several headings in the "Narrative" itself (Part I., p. 17) that we do not consider it necessary to repeat them.

We must thank Professor HERDMAN for the care bestowed in the collection and preservation of his specimens, and for his help in the general assortment of the material. Also we must record our deep indebtedness to Mr. EDGAR A. SMITH, F.Z.S., Mr. J. COSMO MELVILL, M.A., F.L.S., F.Z.S., and Mr. J. M. WILLIAMS and Mr. W. J. HALLS for much valuable assistance and for advice in the case of certain critical species.

In the classification adopted, we have followed the general sequence proposed by P. PELSENEER in his 'Introduction à l'étude des Mollusques' (1892), and have also referred often to P. FISCHER'S 'Manuel de Conchyliologie' (1887). For the characters of the species we have, to a certain extent, followed TRYON'S 'Manual of Mollusca,' at the same time allowing our own views fair latitude. We have considered it quite unnecessary in this instance to burden the Catalogue with the synonymy of each species, but have endeavoured in every case to give the name sanctioned by the laws of priority.

CATALOGUE OF SPECIES.

CLASS: CEPHALOPODA.

(In addition to the species of Cephalopoda recorded by Dr. HOYLE in his report, Part II., p. 185, the shell of *Spirula peroni*, LAMARCK, was obtained at Watering Point, Galle, and at Trincomalee.)

CLASS: GASTROPODA.

ORDER: PROSOBRANCHIATA.

FAMILY: PATELLIDÆ.

Helcioniscus testudinarius (LINN.).—S. of Modragam Paar.

FAMILY: FISSURELLIDÆ.

Fissurella tenuistriata, SOWERBY.—S. of Modragam Paar.

Glyphis salebrosa, REEVE.—Trincomalee.

Family: EMARGINULIDÆ.

Emarginula puncticulata, A. Adams.—Off Galle.

Macrochisma compressa, A. Adams.—S. of Modragam Paar.

Macrochisma scutiformis, Nevill.—S. of Modragam Paar.

Scutus corrugatus, Reeve.—Gulf of Manaar.

Scutus unguis (Linn.).—N. of Gulf of Manaar; off Galle; S. of Cheval Paar.

Family: HALIOTIDÆ.

Haliotis rufescens, Sowerby.—Gulf of Manaar.

Haliotis varia, Linn.—Trincomalee.

Family: STOMATELLIDÆ.

Stomatia phrymotis, Helb.—N. of Gulf of Manaar.

Gena lentricula, A. Adams.—Off Kaltura.

Family: DELPHINULIDÆ.

Delphinula formosa, Reeve.—N. of Gulf of Manaar.

Delphinula laciniata, Lamarck.—Gulf of Manaar, Modragam Paar.

Family: LIOTIIDÆ.

Liotia cidaris, Reeve.—S. of Cheval Paar; S. of Modragam Paar; Gulf of Manaar.

Family: TROCHIDÆ.

Trochus (Tectus) obeliscus, Gmelin.—Galle.

Trochus (Infundibulum) radiatus, Gmelin.—Pearl banks, Gulf of Manaar; off Aripu; off Galle; Trincomalee.

Trochus (Lamprostoma) sacellum, Philippi.—Off Galle.

Trochus (Lamprostoma) maculatus, Linn.—Gulf of Manaar; S. of Modragam Paar; Trincomalee.

Clanculus ceylanicus, Nevill.—Off Galle.

Clanculus depictus, A. Adams.—Trincomalee.

Clanculus microdon, A. Adams.—Palk Bay; S. of Modragam Paar.

Gibbula fanuloides, Fischer.—Palk Bay.

Gibbula pulcherrima, A. Adams.—Gulf of Manaar; off Aripu; off Galle.

Monilea callifera, Lamarck.—Gulf of Manaar.

Monilea callifera, var. **masoni**, Nevill.—Chilaw Paar.

Minolia gradata, Sowerby.—S. of Adam's Bridge.

Minolia variabilis, A. Adams.—Off Galle.

Solariella variabilis, A. Adams.—Pearl banks, Gulf of Manaar.

Calliostoma scobinata, A. Adams.—Jokkenpiddi Paar.

Calliostoma tranquebarica, Chemnitz.—From stomach of *Astropecten*, off Chilaw.

Euchelus asper, Gmelin (**Aradasia**, Gray).—S. of Modragam.

Euchelus atratus, Gmelin.—Pearl banks, Gulf of Manaar.

Euchelus proximus, A. Adams.—Gulf of Manaar; Palk Bay.

Euchelus pullatus, Anton.—Between Negombo and Chilaw.

Euchelus tricingulatus, A. Adams.—Gulf of Manaar.

Umbonium (Rotella) vestiarium, Linn.—Tampalakam Lake, Trincomalee.

Ethalia carneolata, Melvill.—Gulf of Manaar; off Galle; S. of Adam's Bridge.

Ethalia guamensis, Quoy.—N. of Gulf of Manaar.

Family: TURBINIDÆ.

Phasianella variegata, Lamarck.—Pearl banks, Gulf of Manaar; S. of Cheval Paar.

Phasianella variegata, var. **nivosa**, Reeve.—S. of Adam's Br.; Modragam; off Galle.

Turbo radiatus, Gmelin.—Pearl banks, Gulf of Manaar; S. end of Cheval Paar.

Turbo radiatus, var. **chemnitzianus**, Reeve.—Cheval Paar, Gulf of Manaar.

Turbo (Marmorostoma coronatus, Gmelin.—Trincomalee.

Turbo (Senectus) argyrostomus, Linn.—Welligam Bay.

Astralium stellatum, Gmelin.—S. of Adam's Bridge; Galle lagoon.

Family: NERITIDÆ.

Nerita (Thelicostyla) albicilla, LINN.—Galle.

Nerita polita, LINN.—Welligam Bay.

Nerita (Thelicostyla) chlorostoma, LAMARCK.—Trincomalee.

Nerita (Pila) plicata, LINN.—Tampalakam Lake, Trincomalee.

Nerita (Odontostoma) rumphi, RECLUZ.—Galle.

Family: IANTHINIDÆ.

Ianthina fragilis, LAMARCK.—Trincomalee.

Family: NATICIDÆ.

Natica ala-papilionis, CHEMNITZ.—Pearl banks, Gulf of Manaar; Tampalakam Lake, Trincomalee; off Galle.

Natica antoni, PHILIPPI.—Tampalakam Lake, Trincomalee.

Natica dillwyni, PAYR.—Palk Bay.

Natica euzona, RECLUZ.—Jokkenpiddi Paar; Tampalakam Lake, Trincomalee.

Natica queketti, SOWERBY.—Pearl banks off Aripu, Gulf of Manaar.

Natica trailli, REEVE.—Off Galle.

Natica zanzibarica, RECLUZ.—Tampalakam Lake, Trincomalee.

Natica (Eunatica) tela-araneæ, MELVILL.—Cheval Paar, Gulf of Manaar.

Natica (Mamma) albumen, LINN.—N. of Gulf of Manaar.

Natica (Mamma) candidissima, LEGUIL.—Gulf of Manaar; deep water off Galle.

Natica (Mamma) columnaris, RECLUZ.—Deep water off Galle.

Natica (Mamma) mamilla, LINN.—Trincomalee.

Natica (Mamilla) melanostoma, GMELIN.—S. of Adam's Bridge; Trincomalee.

Natica (Mamilla) simiæ, DESHAYES.—Gulf of Manaar.

Sigaretus neritoideus, LINN.—Pearl banks, Gulf of Manaar.

Family: TRICHOTROPIDÆ.

Lippistes helicoides, Montfort (**Separatista chemnitzii**, A. Adams).—Donnan's Muttuvaratu Paar, Gulf of Manaar.

A fine specimen, with the animal. The exact position of this genus is not yet quite fixed, but it seems to have a certain amount of affinity with the Trichotropidæ.

Family: XENOPHORIDÆ.

Xenophora corrugata, Reeve.—Pearl banks, Gulf of Manaar; off Aripu; S. of Adam's Bridge; deep water off Galle; Trincomalee.

Xenophora indicus, Gmelin.—S.E. of Ceylon.

Family: CAPULIDÆ.

Crucibulum (Bicatillus) extinctorum, Lamarck.—Deep water off Galle; off Aripu.

Crucibulum (Bicatillus) morbidum, Reeve.—Pearl banks, Gulf of Manaar.

Crucibulum violaceum, Carpenter.—Off Cheval Paar.

Calyptræa layardi, Reeve.—S. of Adam's Bridge.

Calyptræa (Galerus) edgariana, Melvill.—Pearl banks, Gulf of Manaar; off Aripu; Trincomalee.

Crepidula (Siphopatella) walshi, Herm.—Gulf of Manaar.

Capulus lissus, E. A. Smith.—S. of Modragam Paar.

Amathina tricostata, Gmelin.—S. end of Cheval Paar.

Family: HIPPONYCIDÆ.

Mitrularia equestris, Linn.—Gulf of Manaar.

Family: SOLARIIDÆ.

Solarium lævigatum, Lamarck.—Deep water off Galle.

Solarium impressum, Nevill.—Trincomalee.

Solarium modestum, Philippi.—Pearl banks off Aripu, Gulf of Manaar.

Solarium perspectivum, Linn.—Trincomalee.

Solarium (Torinia) variegatum, Gmelin.—Gulf of Manaar.

Family: LITTORINIDÆ.

Littorina scabra, Linn.—Backwater, Manaar Island.

Family: CERITHIIDÆ.

Cerithium armatum, Phil.—Trincomalee; Periya Paar.

Cerithium citrinum, Sowerby.—Pearl banks, Gulf of Manaar.

Cerithium morus, Lamarck.—Deep water off Galle.

Cerithium tuberosum, Fabricius.—Off Mutwal Island.

Cerithium yerburyi, E. A. Smith.—S. of Adam's Bridge.

Cerithium (Vertagus) aluco, Linn.—S. of Modragam Paar.

Cerithium (Vertagus) articulatum, Adams and Reeve.—N. of Gulf of Manaar.

Cerithium (Vertagus) fasciatum, Brug., var. **martinianum**, Pfr.—Backwater, Manaar Island; Galle; S. of Modragam Paar.

Cerithium (Vertagus) kochi, Phil.—Pearl banks off Aripu, Gulf of Manaar; Trincomalee; Modragam Paar; Galle.

Cerithium (Vertagus) obeliscus, Brug.—Backwater, Manaar Island; off Galle.

Colina selecta, Melvill and Standen.—Galle.

Potamides (Tympanotonus) fluviatilis, Pot. and Mich.—Muddy Creek, N. of Manaar Island.

Potamides (Telescopium) fuscum, Schumacher.—Trincomalee.

Pyrazus palustris, Linn.—Pearl bank off Aripu; Trincomalee.

Family: PLANAXIDÆ.

Planaxis sulcatus, Born.—Deep water off Galle; Trincomalee.

Family: TURRITELLIDÆ.

Turritella carinifera, Lamarck.—Trincomalee.

Turritella triplicata, Studer.—Trincomalee.

Turritella (Haustator) candida, Reeve.—S. of Adam's Bridge.

Turritella (Haustator) columnaris, Kiener.—Deep water off Galle.

Turritella (Haustator) maculata, Reeve.—S. of Adam's Bridge ; Trincomalee.

Turritella (Zaria) duplicata, Linn.—S.E. of Ceylon ; Welligam Bay ; Trincomalee ; N. of Gulf of Manaar.

Turritella (Eglisia) vittulata, Adams and Reeve.—N. of Gulf of Manaar.

Family : VERMETIDÆ.

Vermetus (Thylacodes) dentiferus, Lamarck.—Gulf of Manaar.

Siliquaria cumingi, Mörch.—S. of Modragam Paar.

Siliquaria tostus, Mörch.—S.E. of Ceylon ; S. of Modragam Paar.

Family : STROMBIDÆ.

Strombus papilio, Chemnitz.—N. of Gulf of Manaar.

Strombus (Gallinula) isabella, Lamarck.—Trincomalee.

Strombus (Gallinula) marginatus, Linn.—N. of Gulf of Manaar ; Trincomalee.

Strombus (Gallinula) succinctus, Linn.—Pearl banks off Aripu, Gulf of Manaar ; S. of Adam's Bridge ; off Mutwal Island ; Trincomalee.

Strombus (Canarium) canarium, Linn.—Gulf of Manaar ; Trincomalee.

Strombus (Canarium) elegans, Sowerby.—Pearl banks off Aripu, Gulf of Manaar ; deep water off Galle ; Modragam Paar ; S. of Adam's Bridge.

Strombus (Canarium) floridus, Lamarck.—Trincomalee.

Strombus (Canarium) gibberulus, Linn.—Gulf of Manaar ; Trincomalee.

Strombus (Canarium) pulchellus, Reeve.—N. of Gulf of Manaar ; pearl bank, Aripu ; S. of Adam's Bridge ; Donnan's Paar ; Trincomalee ; deep water off Galle.

Strombus (Canarium) samarensis, Reeve.—N. of Gulf of Manaar.

Strombus (Canarium) urceus, Linn.—Pearl banks, Gulf of Manaar ; Trincomalee.

Strombus (Canarium) yerburyi, E. A. Smith.—N. of Gulf of Manaar ; S. of Adam's Bridge ; deep water off Galle ; pearl banks off Aripu ; Trincomalee.

Strombus (Monodactylus) auris-dianæ, Linn.—N. of Gulf of Manaar ; off Aripu.

Strombus (Monodactylus) gallus, LINN.—Modragam Paar.

Pterocera lambis, LINN.—Trincomalee.

Pterocera (Millepes) scorpio, LINN.—S. of Modragam Paar.

Rostellaria (Rimula) crispata, SOWERBY.—Pearl banks, Gulf of Manaar; Trincomalee; S.E. of Ceylon; S. of Modragam Paar.

Seraphs terebellum, MONTFORT.—Pearl banks, Gulf of Manaar; S.E. of Ceylon; S. of Modragam Paar; Trincomalee.

FAMILY: CYPRÆIDÆ.

Cypræa arabica, LINN.—Gulf of Manaar; Tampalakam Lake; Trincomalee.

Cypræa caput-serpentis, LINN.—Welligam Bay; Trincomalee.

Cypræa clandestina, LINN.—Pearl banks, Gulf of Manaar; Donnan's Paar; Palk Bay; deep water off Galle; Trincomalee.

Cypræa coffea (SOWERBY).—Trincomalee.

Cypræa caurica, LINN.—Gulf of Manaar. One typical example.

Cypræa caurica, LINN., var. **cairnsiana**, MELVILL and STANDEN ('Jour. of Conch.,' vol. xi., 1904, p. 118).—S. of Adam's Bridge; Modragam Paar; S. end of Cheval Paar; Trincomalee.

This beautiful form bears precisely the same relation to typical *caurica* that *coloba*, MELVILL (= *greegori*, FORD) does to *cruenta*, GMELIN. The Ceylonese examples are quite as fine, but slightly smaller, than the Karachi ones, and far surpass in coloration others of this same variety from Borneo and the East Indies.

Cypræa erosa, LINN., var. **straminea**, MELVILL.—S. of Modragam Paar.

Cypræa errones, LINN.—Trincomalee.

Cypræa fimbriata, GMELIN.—Gulf of Manaar.

Cypræa gangrenosa (SOLANDER), var. **melanosema**, MELVILL.—Gulf of Manaar; Modragam Paar; off Galle.

Cypræa lutea (GRONOV.).—Gulf of Manaar.

Cypræa lynx, LINN.—Trincomalee.

Cypræa moneta (LINN.).—Tampalakam; Trincomalee; Galle; S. of Modragam.

Cypræa neglecta, SOWERBY.—Gulf of Manaar; Trincomalee.

Cypræa ocellata (Linn).—S. of Adam's Bridge; Donnan's Paar; S. end of Cheval Paar; off Galle; Trincomalee; S. of Modragam Paar; off Aripu.

Cypræa onyx (Linn.), var. **adusta** (Chemnitz).—Pearl banks, Gulf of Manaar.

Cypræa tigris, Linn.—Gulf of Manaar.

Cypræa vitellus, Linn.—S. of Modragam Paar; Trincomalee.

Cypræa ziczac, Linn.—S. of Adam's Bridge.

Trivia annulata, Gray.—S. of Adam's Bridge.

Trivia brevissima (Sowerby).—Deep water off Galle.

Trivia cicercula (Linn).—Trincomalee.

Trivia globosa (Gray).—From stomach of *Astropecten*, off Chilaw, 10 fathoms.

Trivia nucleus, Linn.—Gulf of Manaar; Trincomalee.

Trivia fibula, Kiener.—Two "live" examples from Gulf of Manaar. We quite agree with Mr. J. M. Williams, to whom we submitted these specimens, that they are not the same as *Trivia globosa* (Gray).

Trivia rubinicolor (Gaskoin).—S. of Adam's Bridge. A dead shell, more like a fossil, as recently-dead *Triviæ* are invariably glossy or polished, but Mr. Williams identifies it without any doubt as this species.

Trivia staphylæa (Linn.).—S. of Adam's Bridge; Trincomalee.

Trivia staphylæa, var. **limacina**, Lamarck.—S. of Modragam Paar.

Ovula (Volva) volva, Linn.—Pearl banks, Gulf of Manaar.

Amphiperas pyriformis, Sowerby.—S. of Modragam Paar.

Family: DOLIIDÆ.

Dolium maculatum, Lamarck.—Gulf of Manaar; Trincomalee.

Dolium olearium, Bruguière.—Gulf of Manaar; Trincomalee.

Family: CASSIDIDÆ.

Cassis canaliculata, Lamarck.—N. of Gulf of Manaar; S.E. of Ceylon.

Cassis (Casmaria) vibex, H. and A. Adams.—S. of Adam's Bridge; off Galle.

Cassis (Phalium) glauca, Linn.—Pearl banks, Gulf of Manaar.

Pyrula ficus, LAMARCK (**P. lævigata**, REEVE).—Trincomalee ; off Aripu.

Pyrula reticulata, LAMARCK.—Gulf of Manaar ; off Galle ; Trincomalee.

FAMILY: TRITONIIDÆ.

Lotorium canaliferus, LAMARCK (**Triton**, MONTFORT).—Trincomalee.

Lotorium lotorium, LINN.—Pearl banks off Aripu, Gulf of Manaar ; S.E. of Ceylon ; S. of Adam's Bridge.

Lotorium olearium (LINN.).—Off Aripu, Gulf of Manaar.

Lotorium tripus, CHEMNITZ.—Trincomalee.

Lotorium (Simpulum) chlorostomum (LAMARCK).—Galle.

Lotorium (Simpulum) labiosum (WOOD).—Deep water off Galle ; S. of Cheval Paar.

Lotorium (Simpulum) pileare (LINN.).—Pearl banks, Gulf of Manaar ; Trincomalee.

Lotorium (Simpulum) rubecula, LINN.—Pearl banks, Gulf of Manaar.

Lotorium (Gutturnium) cynocephalus (LAMARCK).—Galle.

Lotorium (Gutturnium) exilis, REEVE.—Pearl banks, Gulf of Manaar.

Lotorium (Gutturnium) gallinago, REEVE.—Trincomalee.

Lotorium (Gutturnium) retusum (LAMARCK).—Pearl banks, Gulf of Manaar.

Lotorium (Gutturnium) tuberosum (LAMARCK).—Galle.

Lotorium (Gutturnium) vespaceum (LAMARCK).—Pearl banks, Gulf of Manaar ; S. of Modragam Paar.

Lotorium (Lagena) cingulatum (PFR.).—Off Aripu, Gulf of Manaar ; off Galle.

Lotorium (Epidromus) testaceum (MÖRCH).—Cheval Paar ; S. of Adam's Bridge ; pearl banks, Gulf of Manaar.

Gyrineum crumena (LAMARCK).—Palk Bay ; pearl banks off Aripu, Gulf of Manaar ; off Kaltura.

Gyrineum (Bursa) albivaricosum, REEVE.—Gulf of Manaar ; S. of Adam's Bridge.

Gyrineum (Lampas) bufonia, GMELIN.—Pearl banks, Gulf of Manaar.

Gyrineum (Lampas) graniferum, LAMARCK.—Pearl banks off Aripu, Gulf of Manaar ; S. end of Cheval Paar ; S. of Modragam Paar ; Trincomalee.

Gyrineum (Argobuccinum) bituberculare (Reeve).—Pearl banks off Aripu, Gulf of Manaar; off Mutwal Island; S. of Modragam Paar; S. of Adam's Bridge; deep water off Galle; off Mount Lavinia; Trincomalee.

Gyrineum (Argobuccinum) margaritula, Deshayes.—Pearl banks, Gulf of Manaar; deep water off Galle.

Gyrineum (Argobuccinum) pusillum, Broderip.—S. of Adam's Bridge; Donnan's Paar; S. of Modragam Paar.

Gyrineum (Argobuccinum) tuberculatum, Broderip.—Pearl banks, Gulf of Manaar.

Distorsio cancellinus, Roissy.—N. of Gulf of Manaar; Trincomalee.

Distorsio cancellinus, var. **decipiens,** Reeve.—Deep water off Galle.

Distorsio ridens, Reeve.—Pearl banks off Aripu.

Family: PYRAMIDELLIDÆ.

Pyramidella acus, Gmelin.—Trincomalee.

Family: CORALLIOPHILIDÆ.

Coralliophila violacea, Kiener.—Donnan's Paar.

Family: MURICIDÆ.

Murex malabaricus, E. A. Smith.—Gulf of Manaar.

Murex nigrispinosus, Reeve.—Deep water off Galle.

Murex ramosus, Linn.—Palk Bay; N. of Gulf of Manaar.

Murex rectirostris, Sowerby.—Deep water off Galle.

Murex tenuispina, Lamarck.—Deep water off Galle.

Murex ternispina, Lamarck.—N. of Gulf of Manaar; Palk Bay; off Galle.

Murex (Chicoreus) aculeatus, Lamarck.—N. of Gulf of Manaar; off Galle.

Murex (Chicoreus) adustus, Lamarck.—N. of Gulf of Manaar.

Murex (Chicoreus) adustus, var. **huttoniæ,** Wright.—Off Aripu, Gulf of Manaar.

Murex (Chicoreus) palmiferus, Sowerby.—Deep water off Galle; Gulf of Manaar; S. of Modragam Paar.

Murex (Chicoreus) sauliæ, Sowerby.—Deep water off Galle.

Murex (Phyllonotus) anguliferus, Lamarck.—Gulf of Manaar; Periya Paar.

Murex (Pteronotus) pinnatus, Wood.—Pearl banks off Aripu, Gulf of Manaar; S. of Modragam Paar.

Murex (Homalacantha) varicosus, Sowerby.—Donnan's Paar.

Murex (Haustellum) haustellum, Linn.—N. of Gulf of Manaar; Galle; Palk Bay; deep water off Galle; Trincomalee.

Urosalpinx contracta, Reeve.—Palk Bay.

Urosalpinx innotabilis, E. A. Smith.—Galle; S. of Adam's Bridge.

Rapana bulbosa, Solander.—N. of Gulf of Manaar.

Latiaxis diadema, Sowerby.—Off Galle.

Purpura coronata, Lamarck.—Backwater, Manaar Island.

Purpura persica, Linn.—Welligam Bay.

Purpura (Thalessa) hippocastanum, Lamarck.—Galle.

Purpura (Stramonita) bufo, Lamarck.—Welligam Bay.

Purpura (Polytropa) sacellum, Chemnitz.—Pearl banks, Gulf of Manaar.

Pinaxia coronata, A. Adams.—Pearl banks off Aripu, Gulf of Manaar; S. of Adam's Bridge; Modragam Paar; Jokkenpiddi Paar; S. end of Cheval Paar.

Cuma carinifera (Lamarck).—Tampalakam Lake, Trincomalee.

Ricinula horrida, Lamarck.—Off Galle.

Sistrum elongatum, Blainville.—N. of Gulf of Manaar.

Sistrum chrysostoma, Deshayes.—Gulf of Manaar.

Sistrum konkanense, Melvill.—Gulf of Manaar.

Sistrum spectrum, Reeve.—Pearl banks, Gulf of Manaar; Aripu Reef; Trincomalee; S. end of Cheval Paar; S. of Adam's Bridge; Jokkenpiddi Paar; off Chilaw, 10 fathoms; off Mutwal Island; S. of Modragam Paar.

Sistrum tuberculatum, Blainville.—N. of Gulf of Manaar.

Family: COLUMBELLIDÆ.

Columbella propinquans, E. A. Smith.—Jokkenpiddi Paar; Trincomalee; S. of Adam's Bridge; Donnan's Paar.

Columbella (Pygmæa) flavida, Lamarck.—Gulf of Manaar; Jokkenpiddi Paar; off Mutwal Island.

Columbella (Pygmæa) pardalina, Lamarck.—S. of Modragam Paar; pearl banks, Gulf of Manaar.

Columbella (Pygmæa) turturina, Lamarck.—Cheval Paar; Donnan's Paar; S. of Modragam Paar.

Columbella (Pygmæa) tyleri, Gray.—S. of Modragam Paar.

Columbella (Pygmæa) versicolor, Sowerby.—Off Galle.

Columbella (Conidea) flava, Brug.—Pearl banks, Gulf of Manaar; Cheval Paar.

Family: NASSIDÆ.

Nassa arcularia, Linn.—Trincomalee.

Nassa nevilliana, Preston.—Trincomalee.

Nassa pulla, Linn.—Pearl banks, Gulf of Manaar; S. of Adam's Bridge.

Nassa (Arcularia) thersites, Brug.—Tampalakam Lake, Trincomalee.

Nassa (Tritia) crenulata, Brug.—Welligam Bay.

Nassa (Alectryon) elegans, Kiener.—Gulf of Manaar; Trincomalee.

Nassa (Alectryon) glans, Linn.—Pearl banks, Gulf of Manaar.

Nassa (Zeuxis) pallidula, A. Adams.—Deep water off Galle.

Nassa (Niotha) gemmulata, Lamarck.—Pearl banks, Gulf of Manaar; off Kaltura; deep water off Galle; S. of Modragam Paar.

Nassa (Niotha) marginulata, Lamarck.—Trincomalee.

Nassa (Niotha) splendidula, Dunker.—Pearl banks, Gulf of Manaar.

Nassa (Niotha) stigmaria, A. Adams.—Pearl banks, Gulf of Manaar; S. of Adam's Bridge; deep water off Galle.

Nassa (Hima) frederici, MELVILL and STANDEN.—Gulf of Manaar; Trincomalee.

This is **Nassa (Hima) townsendi**, MELV., 'Mem. Manch. Soc.,' vol. xli., part iii. (1897), No. 7, p. 4, plate 6, fig. 1 (*non* DALL).

Cyllene grayi, REEVE.—S. of Adam's Bridge; Chilaw Paar; from stomach of *Astropecten* off Chilaw, 10 fathoms.

FAMILY: BUCCINIDÆ.

Pisania ignea, GMELIN.—Deep water off Galle; S. of Modragam.

Pisania marmorata, REEVE.—Gulf of Manaar.

Pisania picta, REEVE.—N. of Gulf of Manaar.

Tritonidea melanostoma, SOWERBY.—Pearl bank, Aripu; N. of Gulf of Manaar; S. of Modragam Paar.

Tritonidea rubiginosa (REEVE).—Galle.

Tritonidea tissoti, PETIT.—Off Galle.

Tritonidea tranquebarica, GMELIN.—Gulf of Manaar.

Tritonidea undosa, LINN.—Pearl banks off Aripu; Trincomalee.

Engina zea, MELVILL.—N. end of Manaar.

Nassaria acuminata, REEVE.—Pearl banks, Gulf of Manaar.

Nassaria nivea, GMELIN.—Palk Bay; S. of Adams' Bridge.

Nassaria suturalis, A. ADAMS.—Pearl banks off Aripu, Gulf of Manaar; S. of Adam's Bridge; deep water off Galle; Palk Bay; S. of Modragam Paar.

Phos blainvillei, DESHAYES.—Trincomalee.

Phos nodicostatus, A. ADAMS.—Gulf of Manaar; S. of Modragam Paar.

Phos retecosus, HINDS.—Gulf of Manaar.

Phos roseatus, HINDS.—Gulf of Manaar; deep water off Galle; Palk Bay; S. of Adam's Bridge.

Latrunculus spirata, LAMARCK (**Eburna**, LAM.).—Deep water off Galle; Welligam.

Latrunculus zeylanicus, BRUG.—Pearl banks, Gulf of Manaar.

FAMILY: TURBINELLIDÆ.

Turbinella pyrum, LINN. (**Turbinella rapa,** GMELIN.).—Pearl banks off Aripu, Gulf of Manaar; deep water off Galle; Trincomalee.

The "Chank" occurs in the collection from its egg-capsules, through all stages of growth, to the large and swollen spotless form distinguished by most authors as *T. rapa*, GMEL., = *gravis*, DILLW., = *clavata*, WAGN., = *napus*, LAM.; but the distinction does not hold good, the shell becoming more swollen and less spotted with increase in size.

Vasum turbinellum, LINN.—Trincomalee.

Tudicla spirillus, LINN.—Pearl banks, Gulf of Manaar; off Mutwal Island; Palk Bay; deep water off Galle; Trincomalee.

Melongena vespertilio, LAMARCK.—Gulf of Manaar.

FAMILY: FASCIOLARIIDÆ.

Fusus colus, LINN.—Pearl banks, Gulf of Manaar; Trincomalee.

Fasciolaria filamentosa, MARTYN.—Pearl banks, Gulf of Manaar; Galle.

Fasciolaria trapezium (LINN.).—N. of Gulf of Manaar; Trincomalee.

Latirus lancea, GMELIN.—Gulf of Manaar.

Latirus (Peristernia) pagodiformis, MELVILL.—Gulf of Manaar.

Latirus (Peristernia) pulchellus, REEVE.—Pearl banks, Gulf of Manaar; S. end of Cheval Paar; S. of Adam's Bridge.

Latirus (Peristernia) turritus, GMELIN.—Gulf of Manaar; Trincomalee; Mudalaikuli Paar; S. of Modragam Paar.

Latirus (Plicatella) polygonus, GMELIN.—S. end of Cheval Paar.

FAMILY: MITRIDÆ.

Mitra guttata, SWAINSON.—N. of Gulf of Manaar.

Mitra versicolor, MARTYN.—Gulf of Manaar.

Mitra (Scabricola) crenifera, LAMARCK.—Off Galle; Aripu; S. of Modragam Paar.

Mitra (Scabricola) antoniæ, H. ADAMS.—Gulf of Manaar; Trincomalee.

Mitra (Scabricola) scabriuscula, LAMARCK.—Pearl banks, Gulf of Manaar.

Mitra (Cancilla) insculpta, Reeve.—Off Galle; Trincomalee.

Mitra (Cancilla) interlirata, Reeve.—Pearl banks, Gulf of Manaar.

Mitra (Turricula) melongena, Lamarck.—S. of Modragam Paar.

Mitra (Costellaria) acupicta, Reeve.—Trincomalee.

Mitra (Costellaria) exasperata, Gmelin.—S. of Adam's Bridge.

Mitra (Costellaria) clathrata, Reeve.—Gulf of Manaar.

Mitra (Costellaria) crebrilirata, Reeve.—N. of Gulf of Manaar; Trincomalee.

Mitra (Costellaria) militaris, Reeve, var. **antonelli**, Dohrn.—Gulf of Manaar.

Mitra (Costellaria) mucronata, Swainson.—Gulf of Manaar.

Mitra (Costellaria) modesta, Reeve.—Gulf of Manaar; S. of Adam's Bridge; deep water off Galle; S. end of Cheval Paar.

Mitra (Costellaria) revelata, Melvill.—Gulf of Manaar; S. of Modragam Paar.

Mitra (Costellaria) tankervillei, Melvill,* **Mitra rugosa**, Swain.—Deep water off Galle.

Hitherto this species has been unique in the collection of Mr. J. Cosmo Melvill, and was obtained by him from the collection of the late Dr. Prevost, of Alençon, who had acquired it from the Norris collection. This last collection was celebrated for its *Mitræ*, and this was one of its most particular rarities. The figures given by both Reeve and Sowerby are, of course, taken from this specimen when it was in the celebrated collection of shells belonging to the Earl of Tankerville, dispersed in 1825. Professor Herdman's specimen is in a dead condition, and unfortunately has the apex broken, otherwise it exactly harmonises with the type. This is a most interesting discovery, establishing Ceylon as the locality for this rare shell.

Mitra (Costellaria) zebuensis, Reeve.—S. of Adam's Bridge.

Mitra (Pusia) osidiris, Issel.—S. of Modragam Paar.

Mitra (Swainsonia) fissurata, Lamarck.—S.E. of Ceylon; S. of Modragam Paar.

Family: HARPIDÆ.

Harpa conoidalis, Lamarck.—Trincomalee.

Harpa minor, Rumphius.—Tampalakam Lake, Trincomalee.

* 'Journal of Conchology,' vol. v., p. 332.

Harpa nobilis, Rumphius.—Trincomalee.

Harpa ventricosa, Lamarck.—N. of Negombo, 9 fathoms.

Family: MARGINELLIDÆ.

Marginella (Cryptospira) angustata, Sowerby.—Pearl banks, Gulf of Manaar; deep water off Galle; S. of Adam's Bridge; Palk Bay; Chilaw Paar; S. of Modragam Paar; Trincomalee; off Aripu; off Mutwal Island.

This species seems to show considerable variation; in several localities specimens of a very beautiful golden brown colour occur.

Marginella (Cryptospira) mabellæ, Melvill and Standen.*—Pearl banks off Manaar; S. of Adam's Bridge.

In form this is distinct from any near ally, but most recalls the West Indian *M. oblonga*, Sowb. It is gracefully oblong, very shining, straw-coloured, with white shining callous deposit over the columellar region and outer lip; the dorsal margin thick, with straw-coloured callus; mouth narrow, columella four-plaited.

Family: OLIVIDÆ.

Oliva (Strephona) caroliniana, Duclos.—Off Galle.

Oliva (Strephona) elegans, Lamarck.—Trincomalee.

Oliva (Strephona) irisans, Lamarck.—Trincomalee.

Oliva (Strephona) ispidula, Lamarck.—Trincomalee; S. of Adam's Bridge.

Oliva (Strephona) lepida, Duclos.—Pearl banks off Aripu, Gulf of Manaar; Galle; S. of Modragam Paar. Many beautiful colour varieties.

Oliva (Strephona) polita, Marratt.—Gulf of Manaar.

Oliva (Strephona) mantichora, Duclos.—Gulf of Manaar; Modragam Paar.

Oliva (Strephona) maura, Lamarck.—Trincomalee.

Oliva (Strephona) pacifica, Marratt.—Pearl banks off Aripu.

A dark variety, interesting as being from a new locality.

Oliva (Strephona) picta, Reeve.—Gulf of Manaar; S. of Modragam Paar.

Oliva (Strephona) reticularis, Lamarck.—Pearl banks off Aripu.

Oliva (Strephona) tremulina, Lamarck.—Pearl banks off Aripu; off Galle.

* "Moll. Pers. Gulf," 'Proc. Zool. Soc.,' 1901, p. 452, pl. xxiii., fig. 20.

Oliva (Agaronia) nebulosa, LAMARCK.—Welligam; Modragam Paar; Trincomalee.

Olivancillaria gibbosa, BORN.—Trincomalee; S. of Modragam; Aripu; off Galle.

Ancilla ampla, GMELIN.—Gulf of Manaar; S. of Modragam Paar; Trincomalee.

Ancilla albisulcata, GMELIN.—N. of Gulf of Manaar.

Ancilla cinnamomea, LAMARCK.—Gulf of Manaar; S. of Adam's Bridge.

Ancilla fasciata, REEVE.—S. of Adam's Bridge.

Ancilla tindalli, MELVILL.—Deep water off Galle; Cheval Paar; S. of Adam's Bridge; pearl banks, Gulf of Manaar; S. of Modragam Paar.

FAMILY: TEREBRIDÆ.

Terebra duplicata, LINN.—Pearl banks off Aripu, Gulf of Manaar; Jokkenpiddi Paar; S. of Adam's Bridge; deep water off Galle.

Terebra straminea, GRAY.—Off Galle; off Kaltura and Mount Lavinia.

Terebra triseriata, GRAY.—Off Galle; Trincomalee.

Terebra (Subula) crenulata, LINN.—Tampalakam; deep water off Galle.

Terebra (Subula) hastata, GMELIN.—Pearl banks, Gulf of Manaar; Palk Bay.

Terebra (Hastula) strigilata, LINN.—S. of Adam's Bridge.

FAMILY: CONIDÆ.

Conus marmoreus, LINN.—S.W. of Negombo, 20 fathoms.

Conus (Stephanoconus) lividus, BRUG.—Off Aripu; S. of Adam's Bridge.

Conus (Puncticulis) obesus, HWASS. (**Conus ceylonicus**, CHEMNITZ).—Pearl banks off Aripu, Gulf of Manaar; S. of Modragam Paar.

Conus (Dendroconus) figulinus, LINN.—S.E. of Ceylon.

Conus (Lithoconus) augur, BRUG.—Off Aripu; Modragam Paar; off Galle.

Conus (Lithoconus) literatus, LINN.—Deep water outside banks, Gulf of Manaar; S. of Modragam Paar.

Conus (Lithoconus) tesselatus, BRUG.—N. of Gulf of Manaar; S. of Modragam Paar; Trincomalee.

Conus (Lithoconus) vitulinus, Brug.—Pearl banks off Aripu; Trincomalee.

Conus (Leptoconus) elegans, Sowerby.—Modragam Paar; off Aripu; Palk Bay.

Conus (Leptoconus) lentiginosus, Reeve.—Pearl bank, Aripu.

Conus (Leptoconus) longurionis, Kiener.—Off Galle.

Conus (Leptoconus) planiliratus, Sowerby.—Pearl banks off Aripu, Gulf of Manaar; deep water off Galle.

Conus (Rhizoconus) generalis, Linn.—Pearl banks off Aripu, Gulf of Manaar; S. of Adam's Bridge; deep water off Galle.

Conus (Rhizoconus) lithoglyphus, Meusch.—Deep water off Galle.

Conus (Rhizoconus) maldivus, Linn.—Modragam Paar.

Conus (Rhizoconus) miles, Linn.—Modragam Paar; Trincomalee.

Conus (Rhizoconus) monile, Linn.—N. of Gulf of Manaar; Trincomalee; S. of Modragam Paar.

Conus (Rhizoconus) virgo, Linn.—Trincomalee.

Conus (Chelyconus) amabilis, Lamarck.—Off Aripu.

Conus (Chelyconus) catus, Brug.—Modragam Paar.

Conus (Chelyconus) lignarius, Reeve.—Gulf of Manaar.

Conus (Chelyconus) nimbosus, Brug.—Pearl banks off Aripu; Modragam Paar.

Conus (Nubecula) striatus, Linn.—Off Aripu, Gulf of Manaar; Trincomalee.

Conus (Nubecula) termineus, Lamarck.—Trincomalee.

Conus (Cylinder) amadis, Chemnitz.—Pearl bank, Aripu; Modragam Paar.

Pleurotoma crispa, Lamarck.—S. of Adam's Bridge.

Pleurotoma marmorata, Lamarck.—S. of Adam's Bridge.

Pleurotoma tigrina, Lamarck.—N. of Gulf of Manaar; off Galle; Trincomalee.

Pleurotoma (Turris) undosa, Lamarck.—Pearl banks off Manaar.

Pleurotoma (Gemmula) carinata, Gray.—Off Mutwal Island.

Pleurotoma (Oligotoma) violacea, Hinds.—S. of Modragam Paar.

Surcula cingulifera, Lamarck.—S.E. Ceylon.

Surcula javana, Linn. (= **nodifera**, Lamarck).—Galle.

Drillia crenularis, Lamarck.—Pearl banks, Gulf of Manaar; S. of Modragam.

Drillia spectrum, Reeve.—Deep water off Galle.

Cythara hypercalles, Melvill.—N. of Shoal Buoy.

Family: CANCELLARIIDÆ.

Cancellaria (Trigonostoma) articularis, Sowerby.—Jokkenpiddi Paar.

Cancellaria (Trigonostoma) crenifera, Sowerby.—Pearl banks, Gulf of Manaar.

Cancellaria (Trigonostoma) hystrix, Reeve.—S. of Adam's Bridge.

Cancellaria (Trigonostoma) lamellosa, Hinds.—Pearl banks, Gulf of Manaar.

Order: OPISTHOBRANCHIATA.*

Family: ACTEONIDÆ.

Solidula affinis, A. Adams.—Pearl bank, Aripu; Trincomalee; off Galle.

Family: SCAPHANDRIDÆ.

Atys naucum, Linn.—Trincomalee.

Family: BULLIDÆ.

Bulla ampulla, Linn.—Pearl banks, Gulf of Manaar; Trincomalee; S. of Adam's Bridge; pearl banks off Aripu; deep water off Galle; Trincomalee; S. of Modragam.

Family: APLUSTRIDÆ.

Aplustrum thalassiarchi, Martyn.—S. of Modragam Paar.

Family: RINGICULIDÆ.

Ringicula encarpoferens, Folin.—Galle.

Class: SCAPHOPODA.

Family: DENTALIIDÆ.

Dentalium attenuatum, Sowerby.—Off Galle.

* See also Mr. Farran's Report, Part III., p. 329.—Ed.

Dentalium eburneum, Linn.—Palk Bay.

Dentalium formosum, Adams and Reeve.—Off N. end of Manaar Island; S. of Adam's Bridge.

Dentalium octogonum, Lamarck.—Gulf of Manaar; S. of Adam's Bridge; Palk Bay; Trincomalee; Welligam Bay.

Dentalium subtorquatum, Fischer.—S. of Adam's Bridge.

Class: PELECYPODA.

Family: OSTREIDÆ.

Ostrea cuculata, Born.—Back water, Manaar.

Ostrea (Lopha) crista-galli, Linn.—Deep water off Galle; Trincomalee.

Ostrea (Lopha) hyotis, Linn.—Trincomalee.

Family: ANOMIIDÆ.

Anomia achæus, Gray.—S. of Adam's Bridge.

Placuna placenta, Linn.—Tampalakam Lake, Trincomalee.

Family: SPONDYLIDÆ.

Plicatula ceylanica, Sowerby.—Gulf of Manaar.

Spondylus exilis, Sowerby.—Gulf of Manaar; Trincomalee.

Spondylus flabellum, Reeve.—Trincomalee.

Spondylus imperialis, Chemnitz.—Deep water off Galle.

Spondylus layardi, Reeve.—Mutwal Island; Trincomalee.

Family: LIMIDÆ.

Lima squamosa, Lamarck.—S. of Cheval; Galle; Trincomalee; Muttuvaratu Paar.

Lima (Ctenoides) fragilis, Gmelin.—Gulf of Manaar.

Lima (Ctenoides) scabra, Born.—Gulf of Manaar.

Family: PECTINIDÆ.

Pecten flabelloides, Reeve.—Modragam Paar.

Pecten histrionicus, Gmelin.—Trincomalee.

Pecten irregularis, SOWERBY.—Galle.

Pecten layardi, REEVE.—Off Negombo, 20 fathoms.

Pecten miniaceus, REEVE.—Galle.

Pecten pallium, LINN.—Gulf of Manaar.

Pecten pseudolima, SOWERBY.—Modragam Paar.

Pecten pyxidatus, BORN.—Mudalaikuli Paar; Muttuvaratu Paar.

Pecten senatorius, GMELIN.—Trincomalee.

Pecten singaporinus, SOWERBY.—Trincomalee.

Pecten squamatus, GMELIN.—Galle.

Pecten (Pallium) pes-anatis, REEVE.—Galle; Modragam; Gulf of Manaar.

Pecten (Pallium) plica, LINN.—Trincomalee; Modragam; Gulf of Manaar.

Pecten (Pallium) velutinus, SOWERBY.—Off Mutwal Island.

FAMILY: AVICULIDÆ.

Avicula inquinata, REEVE.—Off Negombo, 20 fathoms.

Avicula iridescens, REEVE.—Off Negombo, 20 fathoms.

Avicula zebra, REEVE.—Gulf of Manaar.

Margaritifera vexillum, REEVE.—Palk Bay; Trincomalee; off Negombo.

Margaritifera vulgaris, SCHUMACHER.—Trincomalee; Gulf of Manaar, and many other localities (*vide* "Narrative").

Margaritifera margaritifera (LINN.).—Gulf of Manaar.

Malleus vulgaris, LAMARCK.—Off Mount Lavinia; W. of Pantura; Trincomalee; Gulf of Manaar.

Vulsella rugosa, LAMARCK.—Gulf of Manaar; Trincomalee.

Perna fimbriata, REEVE.—Gulf of Manaar.

Pinna attenuata, REEVE.—Gulf of Manaar.

Pinna bicolor, CHEMNITZ.—Trincomalee; Chilaw Paar; off Negombo; Gulf of Manaar.

Pinna chemnitzi, Hanley.—Trincomalee.

Pinna fumata, Hanley.—Gulf of Manaar; Trincomalee; Palk Bay.

Pinna zebuensis, Reeve.—Gulf of Manaar; Trincomalee.

Pinna (Atrina) nigra, Chemnitz.—Gulf of Manaar.

Family: MYTILIDÆ.

Mytilus dunkeri, Reeve.—Trincomalee.

Mytilus smaragdinus, Chemnitz.—Tampalakam, Trincomalee.

Septifer bilocularis, Linn.—Jokkenpiddi Paar.

Septifer nicobaricus, Chemnitz.—Modragam Paar.

Modiolus barbatus, Linn.—Gulf of Manaar; Palk Bay.

Modiolus (Volsella) japonicus (Dunker).—Gulf of Manaar; S. of Adam's Bridge, &c.

This mollusc forms a curious nest of gelatinous threads in which are entangled fragments of shell and grains of sand. These Ceylon specimens are less brightly marked, and the periostracum is darker than in specimens we have seen from Muscat.

Modiolus metcalfei, Wood.—Trincomalee.

Modiolus tulipa, Lamarck.—Aripu; Cheval Paar; Muttuvaratu Paar; Trincomalee.

Lithophagus caudigerus, Lamarck.—Gulf of Manaar; Trincomalee.

Lithophagus gracilis, Philippi.—Muttuvaratu Paar.

Lithophagus obesus, Philippi.—Gulf of Manaar.

Crenella (Modiolaria) cœnobita, Vielliot.—Gulf of Manaar.

Crenella (Modiolaria) cumingiana, Dunker.—Gulf of Manaar.

Family: ARCIDÆ.

Arca navicularis, Brug.—S. of Adam's Bridge; Aripu; Gulf of Manaar.

Arca noë, Linn.—S. of Adam's Bridge.

Arca zebra, Reeve.—Trincomalee; deep water off Galle.

Barbatia decussata, Sowerby.—Trincomalee; Muttuvaratu Paar; Gulf of Manaar.

Barbatia imbricata, Poli.—Gulf of Manaar; Muttuvaratu Paar.

Barbatia barbata, Linn.—S. of Adam's Bridge; Palk Bay.

Barbatia (Barbata) fusca, Brug.—Trincomalee; Welligam.

Barbatia (Barbata) lima, Reeve.—Galle; Trincomalee; Modragam; Navakaddu Paar; Gulf of Manaar.

Barbatia (Barbata) obliquata, Gray.—Trincomalee.

Anadara deshayesi, Hanley.—Gulf of Manaar.

Scapharca compacta, Reeve.—Palk Bay; Galle.

Scapharca pilula, Reeve.—Trincomalee.

Trisis (Parallelipipedum) tortum, Lamarck.—Palk Bay.

Cucullæa concamerata, Chemnitz.—S.E. of Ceylon; Gulf of Manaar.

Axinæa nodosa, Reeve.—Aripu; Gulf of Manaar.

Limopsis multistriata, Forskal.—S. of Adam's Bridge; Gulf of Manaar.

Family: CARDITIDÆ.

Cardita abyssicola, Hinds.—Muttuvaratu Paar; Modragam.

Cardita antiquata, Poli.—S. of Adam's Bridge; Trincomalee; Galle; Aripu; Gulf of Manaar.

Cardita radula, Reeve.—Mudalaikuli Paar; Gulf of Manaar.

Cardita variegata, Brug.—Trincomalee; Navakaddu.

Family: CRASSATELLIDÆ.

Crassatellites radiata, Sowerby.—Chilaw Paar; Trincomalee; Gulf of Manaar.

Crassatellites rostrata, Lamarck.—Gulf of Manaar; Aripu; Trincomalee.

Family: TRIDACNIDÆ.

Tridacna elongata, Lamarck.—Trincomalee.

Tridacna squamosa, Lamarck.—Trincomalee.

Family: CARDIIDÆ.

Cardium pulchrum, Reeve.—Deep water off Galle.

Cardium sueziense, Issel.—Off Negombo; Gulf of Manaar; Galle.

Cardium (Trachycardium) flavum, Linn.—Galle; Trincomalee; off Negombo.

Cardium (Trachycardium) lacunosum, Reeve.—Trincomalee; off Galle.

Cardium (Trachycardium) maculosum, Wood.—Aripu; Trincomalee.

Cardium (Trachycardium) oxygonum, Sowerby.—Trincomalee.

Cardium (Trachycardium) unicolor, Sowerby.—Trincomalee.

Cardium (Acanthocardia) asiaticum, Chemnitz.—Trincomalee.

Cardium (Cerastoderma) latum, Born.—Trincomalee.

Papyridea papyracea, Chemnitz.—Gulf of Manaar; S. of Adam's Bridge; Chilaw Paar; Galle.

Lævicardium attenuatum, Sowerby.—Trincomalee.

Lævicardium lyratum, Sowerby.—Gulf of Manaar.

Cardium (Serripes) muticum, Reeve.—Trincomalee.

Cardissa hemicardium, Linn.—Trincomalee.

Cardissa (Lunulicardia) subretusa (Linn).—Gulf of Manaar; Galle.

Family: CHAMIDÆ.

Chama foliacea, Quoy.—Trincomalee.

Chama macrophylla, Chemnitz.—Galle; S. of Cheval Paar; Gulf of Manaar.

Family: CYPRINIDÆ.

Isocardia lamarcki, Reeve.—Galle.

Family: VENERIDÆ.

Meretrix castanea, Lamarck.—Trincomalee; Tampalakam.

Meretrix sinensis, Chemnitz.—S.E. of Ceylon.

Lioconcha picta, Lamarck.—Off Negombo; Gulf of Manaar; Aripu; Trincomalee.

Circe scripta, Linn.—Aripu.

Crista pectinata, Linn.—Trincomalee.

Sunetta effossa, Hanley.—Galle.

Sunetta meroë, Linn.—Trincomalee.

Dosinia ceylonica, Dunker.—Galle.

Dosinia histrio, Gmelin.—Off Negombo ; deep water off Galle.

Dosinia radiata, Reeve.—Gulf of Manaar ; off Mutwal Island.

Chione (Omphaloclathrum) lamarcki, Gray.—Gulf of Manaar ; off Galle ; off Negombo.

Chione (Omphaloclathrum) layardi, Reeve.—Galle.

Chione (Omphaloclathrum) reticulata, Linn.—Trincomalee.

Callista phasianella (Deshayes).—Gulf of Manaar.

Anaitis foliacea, Philippi.—Off Negombo ; Modragam.

Tapes textrix, Chemnitz.—Palk Bay ; S. of Adam's Bridge.

Tapes (Amygdala) bruguierei, Hanley.—Welligam ; Trincomalee.

Family : PETRICOLIDÆ.

Petricola cultellus, Deshayes.—Modragam.

Family : CYRENIDÆ.

Cyrena tennentii, Hanley.—Trincomalee.

Family : UNGULINIDÆ.

Diplodonta bullata, Dunker.—Trincomalee.

Diplodonta indica, Deshayes.—Galle.

Family : DONACIDÆ.

Donax (Hecuba) scortum, Linn.—Welligam Bay.

Donax (Latona) cuneatus, Linn.—Trincomalee.

Family : GARIIDÆ.

Gari amethystina, Reeve (**Psammobia**, Lamarck).—Trincomalee.

Gari præstans, Deshayes.—Aripu.

Gari squamosa, LAMARCK.—Galle.

Hiatula diphos, LINN. (**Soletellina**, BLAINVILLE).—Tampalakam.

Hiatula (Psammotæa) radiata, DESHAYES.—Trincomalee.

Asaphis deflorata, LINN.—Trincomalee.

FAMILY: MACTRIDÆ.

Mactra antiquata, SPENGLER.—Gulf of Manaar.

Mactra luzonica, DESHAYES.—Gulf of Manaar; Galle.

Mactra ornata, GRAY.—Off Negombo; Aripu; E. of Ceylon.

Hemimactra (Oxyperas) triangularis, LAMK.—Off Negombo; G. of Manaar; Galle.

FAMILY: GASTROCHÆNIDÆ.

Gastrochæna clava, LAMARCK (**Fistulana**, BRUGUIÈRE).—Palk Bay.

Rocellaria lagenula, LAMARCK (**Gastrochæna**, LAMARCK).—Modragam.

FAMILY: PHOLADIDÆ.

Martesia striata, LINN.—Between Negombo and Chilaw.

FAMILY: MYIDÆ.

Corbula crassa, HINDS.—Muttuvaratu Paar.

Corbula modesta, HINDS.—Modragam; Gulf of Manaar.

Corbula scaphoides, HINDS.—Navakaddu Paar.

FAMILY: TELLINIDÆ.

Tellina (Tellinella) rostrata, LINN.—S.E. of Ceylon.

Tellina (Tellinella) virgata, LINN.—Gulf of Manaar.

Tellina (Peronæa) cygnus, HANLEY.—Gulf of Manaar.

FAMILY: CUSPIDARIIDÆ.

Cuspidaria chinensis, GRAY.—Trincomalee.

FAMILY: SCROBICULARIIDÆ.

Semele crenulatum, SOWERBY.—Modragam.

FAMILY: ANATINIDÆ.

Anatina labiata, REEVE.—Five miles N. of Cheval Paar.

REPORT

ON THE

TUNICATA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

W. A. HERDMAN, D.Sc., F.R.S.,
PROFESSOR OF ZOOLOGY IN THE UNIVERSITY OF LIVERPOOL.

[WITH NINE PLATES.]

THIS collection of Tunicata is not a large one and yet it is by far the largest that has, so far as is known, ever been brought from the Ceylon seas, and it more than trebles the number of species recorded from the northern part of the Indian Ocean. Most of the Tunicata known to science have been described from specimens found on the coasts of Europe and of North America, in Malaysian seas, in the Antarctic or on the Australian shores; and it is curious how few have been found in tropical seas outside the West Indies and the Malay Archipelago.

In 1891, in the 'Revised Classification of the Tunicata,' I was able to record only 13 species as known from the Indian Ocean, and of these three were Salpidæ—the species of Ascidiacea being only *Molgula martensii*, TRAUSTEDT, *Microcosmus claudicans* (SAVIGNY), *Rhabdocynthia mauritiana* (V. DRASCHE), *Rh. pallida* (HELLER), *Polycarpa nigricans*, HELLER, *Styela areolata*, HELLER, *Corella novaræ*, V. DRASCHE, *Ascidia depressiuscula*, HELLER, *Ecteinascidia thurstoni*, HERDMAN, and *Polyclinum constellatum*, SAVIGNY.

If, however, the "Indian Ocean Area" in a wide sense be extended so as to embrace the Red Sea, the seas of Malaysia and the coasts of Australia, a very large number of additional species will be brought in. On the other hand, the 1891 list contains only three species recorded actually from the coast of Ceylon, viz., *Ascidia* *depressiuscula*, HELLER, and *Styela areolata*, HELLER, both collected by Professor SCHMARDA, and *Ecteinascidia thurstoni*, which I described, in 1890, from a colony obtained by Mr. EDGAR THURSTON on the pearl banks in the Gulf of Manaar. Another species of *Ecteinascidia* described below, although from the same locality, seems to be quite a distinct form.

Since 1891, SLUITER has described 28 new species of Ascidians from the shores of South Africa (mostly Capetown, Durban and Mozambique), but these, although in the Indian Ocean, are still between two and three thousand miles distant from Ceylon. SLUITER has also described a large number of new species from Malaysian seas, as the result of the "Siboga" expedition. A few of these occur in the present collection, but the majority of the Ascidians of the Malay Archipelago seem to be distinct from those of the coast of Ceylon, although closely allied forms. It is interesting to have re-found the two species originally brought from Ceylon by SCHMARDA, and also to have obtained the recently described, curious, compound Ascidian *Hypurgon*, I. B. SOLLAS, which forms a skeleton with its own hardened fæcal pellets.

SLUITER and I seem to have expressed somewhat divergent views, in our recent works, on the geographical distribution of Tunicata, but the differences may possibly be more apparent than real. They are due to the vibrations of the scales, as first one and then the other of us brought to be weighed fresh batches of new species from different parts of the world. Successive advances in knowledge led to changes in opinion. As the result of my examination of the "Challenger" material, I came to the conclusion, quite justified by the facts then known, that the fixed Tunicata were more abundant and larger in southern than in northern or tropical seas. A few years later SLUITER, as the result of his explorations round the island of Billiton (Dutch East Indies) described a large number of tropical new species of Ascidians, and so was led to correct my opinion—which he did vigorously. After another interval of years, the large collections belonging to the Sydney Museum passed through my hands, and this enabled me to describe such a considerable number of additional southern species as to cause me, after careful weighing of the evidence, including, of course, SLUITER'S tropical forms, to come to the conclusion that the balance was again in favour of the far south. Since then several notable additions have been made to our knowledge of the Indo-Malayan fauna; and the rapidity with which the number of known species is being added to by each successive expedition indicates that our knowledge of the distribution of the group is still far from complete. But whatever result the actual number of species from the tropics and from the polar regions may give us in the future, I believe that the Ascidian fauna of the far south is characterised by the abundance of individuals and by their large size.

Believing that in the present state of our knowledge of the species of Tunicata careful drawings are quite as important as descriptions, and realising from my own experience how valuable some detail of an illustration may be in the identification of a species, I have endeavoured, in the present case, to illustrate fully the appearance and structure of the new species, and even in some cases to give additional figures of species that are known to science.

In regard to the classification, I have arranged the species under their Families, and have not made use of any higher groupings. There is still some difference of opinion amongst authorities as to the correct position and divisions of that polyphyletic group, the compound Ascidians, and until these matters are settled there can be no practical inconvenience in omitting, in a report of this nature, the names of larger groups and in making use merely of the "Family" designations.

Sluiter, in 1900, remarked upon the scarcity of Ascidiidæ in the Pacific Ocean, and stated that the "Schauinsland" collection of 36 species contained no representative of that family. Since then, however, he has described a large number of new species of *Ascidia* from Malaysian seas in his '"Siboga" Report.' I was also struck, when in Ceylon, by the paucity of Ascidiidæ, especially when compared with northern and southern seas, where, in places, they constitute the characteristic feature of the Ascidian fauna. Another family most feebly represented in the tropics is the Botryllidæ, which contains, perhaps, the most abundant of colonial forms in northern temperate seas. The most notable character of the Ceylon Ascidian fauna is the wide distribution and abundance of the genus *Leptoclinum*, and, in fact, of calcareous and sandy forms in general. Species of *Leptoclinum*, and to a less degree of *Psammaplidium*, are found nearly everywhere around Ceylon, and are the largest and most conspicuous, as well as the most abundant of compound Ascidians. Species of *Rhabdocynthia* with calcareous spicules are also abundant, and some of them have a sandy covering. Sandy simple Ascidians are very numerous, and belong to at least three distinct families. Although most of them at first sight might be supposed to be Molgulidæ, the majority are Cynthiidæ, and some are Ascidiidæ. Sandy balls of very similar appearance have proved to belong to the genera *Ascidia*, *Styela*, *Polycarpa*, *Rhabdocynthia*, *Microcosmus*, *Molgula* and *Ctenicella*. As is usual in warmer seas, the majority of the simple Ascidians are species of *Polycarpa* and *Styela*, but *Rhabdocynthia*, *Ecteinascidia* and the Polystyelidæ may also be mentioned as characteristic forms.

Sluiter, in his '"Siboga" Report,' estimates that there are about 200 species of Tunicata in the Malaysian seas, and nearly the same number (183 recorded in 1899) are known from the coasts of Australia. Compared with these figures, the 64 species described below seem to represent rather a poor fauna, but even if this be the case in regard to species, it is certainly not true of individuals. Both on the coral reefs of Galle and Aripu, and also on some of the paars in the Gulf of Manaar, compound Ascidians are abundant, and in some places fine specimens of *Leptoclinum* bulk large in the dredge and the collecting jars.

About three-fourths of the species found seem to be new to science, but that is to be expected on a coast where the Ascidian fauna has not before been specially investigated.

As an example of the number of Tunicata that live along with, and may be said to infest, the pearl oyster, I give the following list of species found on examining the oyster-cages suspended from the ship when on the Cheval Paar: *Ascidia donnani*, *Rhabdocynthia ceylonica*, *Diandrocarpa brakenhielmi* var. *ceylonica* (many colonies), *Botryllus ater*, *Botrylloides chevalense* (many colonies), *Diplosoma gelatinosum*, and several smaller colonies of *Leptoclinum*, and other compound Ascidians undetermined. In addition, many other species were found attached to and encrusting the pearl-oysters on the bottom. Notable cases are *Styela areolata*, *Rhabdocynthia pallida*, *Psammaplidium ceylonicum*, and *Leptoclinum margaritiferæ*.

Even colonies attached to other objects on the bottom, such as the Leptoclinids growing over the sand, must have their influence in competing for microscopic food, and thus the fixed Tunicata may fairly be classed amongst the enemies of the pearl oyster in the passive struggle for existence.

DESCRIPTION OF THE TUNICATA.

Family: CLAVELINIDÆ.

Perophora hornelli, n. sp.—Plate I., figs. 1 to 8.

External Appearance.—Small colonies of a few Ascidiozooids and buds each (fig. 1), attached to a slight stolon which is encrusted with sand (fig. 3). The atrial aperture has five or six lobes (fig. 6). Colour, dull greenish brown (in spirit). Size, 4 millims. in length by 2 to 2·5 millims. in breadth.

Test very thin.

Mantle with numerous fine interlacing muscle bands, mostly transverse in direction.

Branchial Sac with rather short wide stigmata (figs. 4, 5). Some parts of the sac are papillated and others not. The papillæ split at their ends and send prolongations anteriorly and posteriorly to form incipient bars (fig. 5). In some parts of the sac the bars are complete and bear small papillæ (fig. 4).

Dorsal Languets short and triangular in shape (fig. 8).

Tentacles in three series (fig. 8). There are about 10 of each of the two larger series. Those of the third, most anterior, series are very much smaller.

Dorsal Tubercle with a simple circular aperture (fig. 8).

Alimentary Canal showing a simple stomach and several differentiated regions in the short wide intestine (fig. 7).

Locality:—On Navakaddu Paar, in the southern part of the Gulf of Manaar; depth, 8 fathoms.

This species agrees with Verrill's *Perophora viridis*, from the East Coast of North America, which is possibly the same as Lahille's *P. banyulensis* from the Mediterranean, in having the more or less complete system of internal bars in the branchial sac shown in the figures (Plate I., figs. 4 and 5).

The tentacles, however, are more numerous than in *P. viridis*, and are arranged distinctly in three rows (fig. 8). The zooids are of unusually large size, and the stolon is encrusted with sand. The atrial aperture is distinctly five-lobed. This species thus presents a combination of characters seen separately in several other species, and does not agree entirely with any. I have pleasure in associating this new species with the name of my colleague in the pearl fisheries investigation, Mr. JAMES HORNELL, F.L.S., who was with me on the barque "Rangasami-Poravi" on April 2, 1902, when the specimens were collected.

Ecteinascidia thurstoni, HERDMAN.—Plate I., figs. 18 to 23.

This species was originally found in the Gulf of Manaar by Mr. EDGAR THURSTON, and was described by me in 1890* and named in honour of its discoverer. The type specimen is in the Government Central Museum, Madras. The species has since been recorded from Bermuda by VAN NAME, and from the Bay of Djibouti, Somali-land, by GRAVIER.

The colonies which I now refer to this species were collected on Aripu coral reet on March 18, 1902, and are attached to fragments of a massive sponge. One colony (fig. 18) has about 14 Ascidiozooids, another has two or three only, the third has half a dozen large and small with a few buds in addition; and there are also a few loose Ascidiozooids (fig. 19) detached from colonies.

All the Ascidiozooids, although transparent, are of a slightly pink colour, like the sponge they grow over; but it is possible this may be a *post-mortem* effect produced by staining with the pigment dissolved out from the sponge. The largest Ascidiozooid measures 8 millims. × 3 millims.—a more usual size is 5 millims. in length. In THURSTON's specimens the Ascidiozooids were rather larger, and ranged from 7 millims. to 2 centims. in length. Otherwise the appearance of the colonies is very similar, and the internal structure is also very much the same in the two cases. In our specimens the branchial aperture may be seven-lobed and the atrial six-lobed (fig. 23). The meshes of the branchial sac generally contain three stigmata; four is the number given in the description of *E. thurstoni*. The rest of the branchial sac and the dorsal languets (fig. 21) seem to agree well; but the tentacles are not so numerous and closely placed in our present form (fig. 20), where there seem to be about 60 in all, of three sizes. Possibly the rather smaller size, fewer stigmata and less closely placed tentacles may all be co-related characters indicating merely a younger stage in growth. The course of the alimentary canal and gonads (fig. 22) seem alike in the two cases.

Ecteinascidia (? Rhopalopsis) solida, n. sp.—Plate I., figs. 15 to 17.

External Appearance.—Shape, a cylindrical finger-like mass somewhat bent at the free end, attached posteriorly by a broad base and with both apertures at the anterior end. Surface smooth; size about 2·5 centims. × 1 centim.

* 'Trans. Biol. Soc., Liverpool,' vol. v., p. 144.

Test thick and stiff, forming a more solid mass than is usual.

Mantle delicate, with about ten slight longitudinal muscle-bands on each side.

Branchial Sac with internal bars supported by wide triangular connecting ducts (fig. 16). Meshes each contain two or three rather wide stigmata.

Dorsal Lamina represented by a series of closely placed rather large triangular languets (fig. 17).

Tentacles rather long, eight larger and eight smaller.

Dorsal Tubercle very small and simple.

Locality :—Coral Reef, Galle, February 14, 1902 ; one specimen.

Ecteinascidia sluiteri, n. sp.—Plate I., figs. 9 to 14.

External Appearance.—A small transparent colony consisting of two individuals and an empty test, and some buds attached to a slender creeping stolon (fig. 9). The stolon is marked with constrictions or joints, and has some adhering sand (fig. 10). The Ascidiozooid is oblong and erect, with both siphons at the anterior end, and rapidly narrowing at the posterior end to the attachment with the stolon. The apertures are not lobed, but have many slight creases. The Ascidiozooid measures 7 millims. in length by 3·5 millims. in breadth at the atrial siphon. The stolon is about 4 centims. in length.

Test thin and colourless, allowing the branchial sac to be seen through.

Mantle thin, and for the most part transparent. The muscles are arranged in three longitudinal bands (one dorsal and two lateral) of short, transversely running forked bundles. The dorsal band is interrupted in its posterior three-fourths by the rectum (fig. 11).

Branchial Sac large, and runs the whole length of the body. The transverse vessels are narrow and all alike ; the internal bars are very narrow and the connecting ducts are slight. The stigmata are long and regular, one or two to a mesh (fig. 12).

Tentacles of two sizes, and there are about twenty in all. Those at the ventral edge are the largest (fig. 13). A large number of Acinetan parasites are seen attached to the tentacles and to the peripharyngeal band.

Dorsal Lamina represented by a series of very small languets. There is very little interruption of the stigmatic network on the dorsal edge.

Dorsal Tubercle a small simple rounded opening (fig. 13).

Alimentary Canal slender. The stomach has slight longitudinal folds and narrows at the pyloric end, where the intestine is constricted (fig. 14).

Locality :—Station LVIII., off north end of Karativo Island, 9 to 26 fathoms.

The chief peculiarities of this species are the constricted stolon and the peculiar short forked muscle bundles suggesting the condition seen in some species of *Corella* (*e.g.*, *C. japonica*), and the well-marked siphons which caused us to enter the animal when dredged as an "Ascidia-like Clavelinid" in our field-notes.

Omitting from consideration those species described as "Ecteinascidia," which have since been separated off into the allied genera *Rhopalæa*, *Rhopalopsis*, and *Sluiteria*, there remain seven closely allied species amongst which the present one must take its place; they are:—*Ecteinascidia turbinata*, Herdman, from Bermuda; *E. diaphanis*, Sluiter, from Malaysia; *E. moorei*, Herdman, from Alexandria; *E. thurstoni*, Herdman, from the Gulf of Manaar; *E. garstangi*, Sluiter, from Mozambique; *E. euphues*, Sluiter, and *E. psammodes*, Sluiter, both from the Australian Coast. From all these the present species appears to differ either in external characteristics or in internal structure. The two last-named species were described by Sluiter from Semon's collections, and are very minute forms (the Ascidiozooids being only 2 to 3 millims. long) which show some resemblance, as their author has pointed out, to the genus *Perophora*, and especially to such a species as *P. hutchinsoni*, Macdonald. The two remaining species of *Ecteinascidia*, *E. nexa*, Sluiter, and *E. multiclathrata*, Sluiter, from the "Siboga" expedition, are both somewhat exceptional forms showing an approach in some of their characters to the genus *Sluiteria*, although differing from that genus in other essential points. From these, and from all other described species of *Ecteinascidia*,* the present species differs notably in having distinct and prominent siphons (Plate I., fig. 9) which give to the anterior end of the body very much the appearance of a *Ciona*. Another noteworthy feature is the arrangement of the muscles in the mantle (fig. 11) which is quite unlike that in any other known species of this genus.

Ecteinascidia seems to be a tropical type of Ascidian structure, occurring, so far as we know at present, only between Bermuda to the north and the north coast of Australia to the south, and having its main development in eastern seas. Out of ten known species, eight occur in the Indian Ocean and Malaysian seas, viz., *E. garstangi* (Mozambique), *E. psammodes* (Australia), *E. diaphanis* (Malay), *E. euphues* (Malay), *E. nexa* (Malay), *E. multiclathrata* (Malay), *E. thurstoni* (Gulf of Manaar), and the present new species, *E. sluiteri*, from the coast of Ceylon.

I have much pleasure in naming this species in honour of Professor Sluiter, of Amsterdam—the author who has described most of the species of this genus.

Family: ASCIDIIDÆ.

Rhodosoma ceylonicum, n. sp.—Plate I., figs. 24 to 33.

External Appearance.—Body, when retracted, of short cylindrical, ovate, or deep cup-shaped form, with a rounded posterior and a flattened anterior end forming the operculum over the apertures. Attached by the anterior part of the right side just below the test that forms the hinge of the operculum. The siphons are close together and are directed forwards, a slight fold rises behind each siphon (fig. 27). Surface covered with small sharp papillæ on the anterior half, especially round the

* Such as *E. diligens*, Sluiter, from the Pacific, which seems an exceptional form.

edges of the opening, smooth on the posterior half of the body. Colour a translucent pinkish grey, or sometimes grey-green, rather redder on the anterior end and especially on the siphons which are bordered with yellowish green. Size, 1·7 centims. × 1·2 centims. × 1 centim.

Test of a soft cartilaginous consistency, semi-transparent, echinated around the anterior end, smooth posteriorly, with an occasional little tubercle; a few small shell fragments adhering to test near area of attachment.

Mantle with five pyriform muscle masses on each side; the one set run towards the atrial siphon (fig. 28) and the other set towards the branchial. In addition to these there are finer bundles and the siphons are strongly muscular (fig. 29), having both longitudinal and transverse bands of considerable bulk.

Branchial Sac with wide, regular, rounded stigmata arranged two (rarely three) in a mesh (fig. 30). The transverse vessels are all of one size. The internal bars are narrow and have short papillæ. Along the dorsal edge of the sac the internal bars are imperfect, the branches arising from the transverse vessels forming triradiate processes (fig. 31) which do not meet across the mesh to form a bar.

Dorsal Lamina a series of long narrow pointed languets (fig. 32).

Tentacles of three sizes, closely placed; about sixteen of each of the two larger sizes and about double that number of very much smaller ones.

Dorsal Tubercle deeply crescentic, the horns pointing towards one another across the opening (fig. 33).

Localities:—(1) Palk Bay, March 16, trawling, one specimen 1·7 centims. long, and one 8 millims. long; (2) Gulf of Manaar, adhering to a fragment of a large chank shell, 10 fathoms, 2 specimens, also on coral fragments; (3) off Mount Lavinia, Station XLVI., 30 fathoms, one specimen in a crevice on coral mass, "pale grey-green, apertures bordered with yellowish green."

It is not easy to say whether the specimens of *Rhodosoma* from Ceylon can be safely identified with any of the species already named (we can scarcely say "known"). In 1855 STIMPSON very briefly described two species, *Schizascus pellucidus* and *S. papillosus*, both from China, which seem to differ so little, if we may judge from the published descriptions, that they may well be one species—belonging to the genus *Rhodosoma* of EHRENBERG (1828); but not to EHRENBERG'S species *R. verecundum*. In 1878 HELLER described, almost equally briefly, *Rhodosoma seminudum* from Jamaica, and gave a figure of the exterior which, however, shows no very distinctive features; so much so that TRAUSTEDT, in 1882, describing specimens of the genus from the same neighbourhood (West Indies), hesitated to refer them to HELLER'S species, and gave them the name *Rhodosoma pyxis*, followed by a detailed description. He distinguished this species clearly from *R. callense* (LAC. DUTH.), the only other sufficiently described form. SLUITER, however, in 1898, took a different view and refused to share TRAUSTEDT'S doubts. He appropriates TRAUSTEDT'S accurate anatomical description to HELLER'S diagnosis of *R. seminudum*, and is satisfied that his own specimens (from the "Chazalie" expedition) belong to that species. The Australian forms *Pera* and *Peroides* of MACDONALD probably also belong to this genus. HARTMEYER, in 1901, re-described with anatomical details EHRENBERG'S *Rhodosoma verecundum* and STIMPSON'S *Rh. papillosum;* and SLUITER, in 1904, in reporting on the Tunicata of the "Siboga" expedition, accepts HARTMEYER'S adequate description as applying to STIMPSON'S brief diagnosis, and refers all his specimens (about a dozen) from nine localities in eastern seas to the species *Rh. papillosum*, STIMPS. He notes, however, a certain amount of difference between some of his specimens and HARTMEYER'S description. I find also certain points of difference in detail between the Ceylon specimens and the descriptions of HARTMEYER and SLUITER, and, so far as external appearance goes, my specimens when alive agreed rather better with STIMPSON'S three lines on *Schizascus pellucidus* than with his two lines on *S. papillosus.* Consequently one course open to me, if I consider my specimens distinct from *Rh. papillosum*, as re-described by HARTMEYER, would be to refer them to STIMPSON'S *Rh. pellucidum* and so place my new description under his specific name. But although there is nothing prohibitive of this in STIMPSON'S words, neither is there anything very characteristic that leads us to identify the species without doubt. Consequently, I believe it will be least confusing for future workers, and most conducive to scientific clearness, if the Ceylon specimens are described as a distinct species under a new name, as above. The characters are sufficiently given in the description and shown in the figures on Plate I. The branchial sac (fig. 30) will be seen to differ from both that of *Rh. papillosum* and that of *Rh. verecundum*, as figured by HARTMEYER ('Arch. f. Naturges.,' 1901, Beiheft, Taf. iv.).

Ascidia donnani, n. sp.—Plate II., figs. 1 to 9.

External Appearance.—Shape irregularly ovate, posterior end rounded, anterior narrower and truncated. Attached by the posterior half of the left side. Branchial aperture on dorsal part of anterior end, atrial aperture on dorsal edge of body, one-third back; both apertures somewhat prominent, lobed. Test drawn out into several jagged processes, especially on dorsal and ventral edges (fig. 1). Surface roughened with small asperities. Colour grey (in spirit). Size, 2·4 centims. × 1·5 centims.

Test thin, cartilaginous; thickened in places to form the irregular processes shown in the figure. It contains the usual vessels and bladder-cells.

Mantle with moderately developed musculature and prominent siphons. The atrial siphon is directed backwards, so as to give the body when removed from the test (fig. 2) a somewhat triangular shape. Under the microscope the muscle bands are seen to narrow very abruptly (fig. 7) and end in fine bundles of connective-tissue fibres spirally coiled.

Branchial Sac with rather large square meshes containing each about half a dozen long narrow stigmata (fig. 5). The transverse vessels are mostly narrow and nearly all of much the same size, but every fourth one is in places wider than the three intermediates and has a rather wider horizontal membrane. The papillæ on the rather narrow internal bars are large. They vary in length, but on the average extend about half-way across the mesh.

Dorsal Lamina a wide membrane with well-marked shelf-like ribs, and marginal points (fig. 6). The ribs die away as they approach the free edge.

Tentacles numerous and rather slender, 50 to 60, larger and smaller, but none very small (fig. 9).

Dorsal Tubercle large, cordate in outline, with the posterior end pointed, the opening anterior and both horns rolled inwards (fig. 4).

The Viscera occupy the ventral half of the rather wide posterior end of the body (fig. 3). The intestine is relatively wide.

Locality :—(1) Navakaddu Paar, Gulf of Manaar, 8 fathoms, 1 specimen ; (2) outer Chilaw Paar, Station LXIX., depth 8 to 11 fathoms, 2 specimens ; (3) Cheval Paar, attached to oyster cages, 2 specimens.

This species is described above from the single large specimen obtained on Navakaddu Paar ; but the couple of Ascidians from Cheval Paar and those from Chilaw Paar are probably also specimens of the same species. They have not all the same external appearance, but the internal organisation appears to correspond fairly well. One of the larger specimens is partly overgrown by a colony of *Botrylloides*, and that may account for some difference in shape and appearance, while a couple of smaller specimens (1 centim. long) are probably young and still undeveloped. The body of the larger specimen from Chilaw Paar when removed from the test is shown in fig. 8. The siphons are especially long and are ridged longitudinally and provided with slight tag-like processes of connective tissue. The muscle bundles are especially prominent round the edges of the right side of the mantle. Fig. 9 shows the dorsal tubercle and tentacles of this specimen from Chilaw Paar. In the shape of the body and especially in the long siphons, and also in the distribution of the muscle bundles round the edges of the right side (fig. 8), this specimen recalls the "*Ascidia canaliculata* (Heller) ?," described by Sluiter, in 1885, from Billiton, which he later (1898) decided to recognise as a distinct species under the name of *Ascidia divisa*—but differs markedly from that form in the structure of the dorsal tubercle. Nor does it agree with the true *A. canaliculata*, Heller, as described by Sluiter and others ; nor yet with *A. bisulca*, Sluiter, which it resembles superficially, but differs from in the details of the branchial sac and dorsal lamina. The species to which it is most nearly related is *Ascidia longitubis* (Traustedt) from the West Indies. The agreement extends to the body form, the musculature, and the dorsal tubercle ; but the two species differ in the details of the branchial sac. It is possible, however, that several of these species which have been mentioned above may come to be united when a larger range of specimens and of variations have been studied.

This new species is named in honour of Captain Donnan, C.M.G., for many years

Inspector of the Pearl Banks, Ceylon, and who was with me in the Gulf of Manaar performing his last inspection in the spring of 1902 when these specimens were collected.

Ascidia depressiuscula, Heller—Plate II., figs. 10 to 22.

Although I refer these specimens to Heller's species, I consider it desirable to give a detailed account of them with figures, as Heller's description was brief and had no illustrations of the internal structure.

External Appearance.—Body flattened, ovate in outline, attached by the whole of the left side and posterior end. Apertures both on right side, on the anterior half of the dorsal edge, small, not projecting. Right side of body rather depressed in centre with more prominent rounded edges. Surface smooth; colour (in spirit), grey, with a slight brownish tinge. Size, 2 centims. × 1 centim. to 1·5 centims. × 3 millims. to 5 millims. in thickness.

Test cartilaginous, but rather thin, semi-transparent.

Mantle with moderate siphons. The visceral mass on the left side is rather large.

Branchial Sac having the meshes square or a little elongated transversely. All the transverse vessels are very narrow, so that the ends of the adjacent rows of stigmata are very close. Every eighth transverse vessel has, however, a wider horizontal membrane than the intermediate seven. The stigmata are of moderate size and about five or six to a mesh. The internal longitudinal bars are stout with large knob-like papillæ and occasionally smaller ones between (fig. 17); there are also intermediate horizontal membranes crossing the meshes in places.

Dorsal Lamina a plain membrane with slight, but distinct, transverse ribs and small marginal denticulations (fig. 18).

Tentacles numerous, about 60 to 80, much the same size, with an occasional very much smaller one (fig. 21).

Dorsal Tubercle large, horse-shoe-shaped (figs. 19 and 20), with the opening anterior and both horns coiled inwards. The nerve ganglion is placed close up under the dorsal tubercle. The prebranchial zone is papillated.

Alimentary Canal rather bulky, intestine wide, and full of fine mud (fig. 22).

Gonads well developed. Vas deferens swollen.

Localities:—(1) Galle Bay, from a basket of pearl oysters attached to a buoy, seven specimens; (2) Station LIV., north of Gulf of Manaar, depth 4 to 40 fathoms; one specimen along with many Cynthiidæ.

The specimens from Galle are all very much alike in their characters, and figs. 10, 11 and 12 give the appearance and range in size. Fig. 14 shows the specimen from the Gulf of Manaar, measuring 2 centims. × 1·5 centims. × 5 millims.

The branchial sac of the Manaar specimen (fig. 15) differs a little from that of the Galle specimens. It has the papillæ relatively longer, the stigmata rather shorter, and the meshes squarer. But as pieces of the branchial sacs from Galle differ a little in such characters amongst themselves (figs. 16, 17), the matter is probably of no systematic importance and the whole series may be regarded as one species.

One point of interest belonging to these specimens from Galle is that, from the circumstance of their attachment to the basket which was put out on April 17 and brought in on May 9, it is known that they grew to a length of 2 centims. and became sexually mature within a period of three weeks.

This is one of those troublesome species that show no very striking characteristics and yet do not agree exactly with any other species. In external appearance the specimens agree in general with several common species of *Ascidia*, such as *A. prunum*, O. F. M., *A. obliqua*, Ald., *A. scabra*, O. F. M., and *A. mollis*, Ald. and Hanc., but they differ from all these northern species in some details of organisation. With some hesitation I have decided to identify them with Heller's *Ascidia depressiuscula* obtained in Ceylon by Schmarda. The external appearance agrees fairly well with Heller's figure ('Sitzb. Akad. Wiss. Wien.,' Jahrg. 1878), and the internal structure does not differ from Heller's brief description except in regard to the number of tentacles.

The very small number of species of the large and usually abundant genus *Ascidia* found in the Ceylon collection is remarkable, especially when we remember that Sluiter describes no less than 24 species of *Ascidia* (11 of them new to science) in the results of the "Siboga" expedition through the Indian Archipelago further east.

Ascidia (?) mikrenterica, Sluiter—Plate I., figs. 38 and 39.

There is a single specimen of an *Ascidia* with a thick sandy covering, obtained at Station LXII., 13 fathoms, which I refer with some doubt to this species. It has been torn open, probably by the dredge when captured, and the anterior end is absent. In the thick coating of sand, and in the relatively minute alimentary canal (fig. 38), it resembles the "Siboga" species, but the structure of the branchial sac (fig. 39) is different. However, I have seen so many abnormal branchial sacs, or portions of branchial sacs, amongst known species that I cannot attach much importance to the reduced size and number of the stigmata seen in this specimen.

Ascidia polytrema, n. sp.—Plate I., figs. 34 to 37.

External Appearance.—Oblong-ovate, with the posterior end rounded, the branchial aperture on the anterior end and the atrial projecting from the dorsal edge about one-third of the way back (fig. 34). Surface sandy; size, 3·3 centims. × 1·6 centims.

Test thin, with large grains of sand and shell fragments embedded in it.

Mantle thin and weak; delicate muscle bundles running transversely (fig. 36).

Branchial Sac exceedingly thin and delicate. Internal longitudinal bars bearing slight papillæ. Meshes about square, with four stigmata in each. Occasional horizontal membranes cross the meshes (fig. 37).

Dorsal Lamina with slight ribs and minute marginal denticulations.

Dorsal Tubercle with one minute opening at the apex of a deep triangular peri-tubercular area and about 20 supplementary ciliated funnels further back, but in front of the ganglion, and opening into the peribranchial cavity (see fig. 35). Pre-branchial zone with slight papillæ scattered over it.

Alimentary Canal rather large, with very weak walls, and having the wide intestine distended with mud containing many diatoms.

Locality:—South ends of Cheval and Periya paars, Station XLIX., 8 to 12 fathoms; one perfect specimen and a broken fragment of another, much larger, with no viscera.

Family: MOLGULIDÆ.

Molgula taprobane, n. sp.—Plate IV., figs. 14 to 19.

External Appearance.—Erect, rounded oblong, unattached, with the two short siphons near together on the anterior end, not diverging. Covered with fine sand (fig. 14); size, about 1 centim. across.

Test thin and soft, with a thin coating of sand.

Mantle thin and transparent (figs. 15 and 16).

Branchial Sac with seven folds on each side. Each fold shows three bars. The stigmata are for the most part straight or very slightly curved between the folds, but on each side of the dorsal lamina (fig. 17) they are well coiled.

Tentacles, 12 of one size, moderately branched, not bushy, with much smaller intermediate ones, and very minute simple tags between these.

Dorsal Lamina a plain narrow membrane (fig. 17).

Dorsal Tubercle obliquely cordate, with the aperture directed laterally and backwards (fig. 19).

Gonads present on both sides.

Localities:—(1) Station LIII., 10 miles north of Cheval Paar, 9 fathoms; (2) Station XXII., Trincomalee, 13 fathoms; (3) Station XLVI., off Mount Lavinia, 30 fathoms. Fig. 18 shows the specimen from Trincomalee.

The specific name of this first *Molgula* recorded from Ceylon is the ancient classical name of the island.

Ctenicella ridgewayi, n. sp.—Plate IV., figs. 20 to 23.

External Appearance.—Body globular, free, covered with sand. Both siphons at anterior end divergent (fig. 20). Size, 1·3 × 1 centim.

Test thin, covered with adhering sand.

Mantle with muscular siphons, and having the marginal lobes pinnate (fig. 22).

Branchial Sac with seven folds on each side. There are four bars on each side of the fold and the anterior extremities of the folds are papillose. The meshes are large and each contains many well-coiled stigmata (fig. 23).

Tentacles much branched, and at least 12 in number.

Dorsal Lamina a plain membrane.

Dorsal Tubercle a simple horse-shoe, with the opening on one side (fig. 21).

Locality :—Station LIII., 10 miles north of Cheval Paar, 9 fathoms.

This little Molgulid is externally very similar to the Polycarpa (*P. decipiens*), the *Stycla* (*S. lapidosa*), and the *Rhabdocynthia* (*Rh. ceylonica*), with which it is found.

I have named this species after Sir West Ridgeway, who was Governor of Ceylon at the time when it was collected.

Family: CYNTHIIDÆ.

Notwithstanding Michaelsen's remarks ('Zool. Jahrb.,' Suppl. viii., 1905, p. 79), and the fact that several recent writers have seen fit to relinquish the genus *Rhabdocynthia*, I believe it is both useful and natural to group together those species of "Cynthia" that show echinated unbranched calcareous rods or spindles in the connective tissue of the body. The grouping of species into genera is largely a matter of convenience, and if a set of closely related species can be defined and recognised by the possession of a common character, the application of a generic name seems justifiable, and is certainly an aid in classification. On these grounds I make use of *Rhabdocynthia* as the generic designation of the set of species which may be grouped around Heller's *Cynthia pallida.*

Rhabdocynthia pallida (Heller)—Plate II., figs. 36 to 39.

The shape is irregularly ovate or pyriform, the anterior end being rather the wider. It is attached by the posterior end and a part of either side, and the lower half may be more or less encrusted with sand and shell fragments. The four-lobed apertures are both anterior, placed on long siphons, moderately far apart and turned away from one another (fig. 36). The colour in the preserved specimens is dull milky white, becoming pale yellow in places; it was of a reddish tint when alive, and traces of pink are still to be seen in some specimens, especially at the branchial and atrial siphons.

The *Test* is of a soft leathery texture, much wrinkled on the outer surface, smooth and glistening on the inner and white in section. It is mostly from 1 to 3 millims. in thickness, but may be thickened at the posterior end up to nearly 3 centims.

The *Mantle* is rather thin and weak over the viscera, soft but opaque and muscular on the anterior half of the body and very muscular on the siphons (fig. 37). It bristles with minute calcareous spicules in all parts, which renders it rather easily torn, and very unpleasant to manipulate.

The *Branchial Sac* has nine wide folds on each side. They converge to the œsophageal opening.

The *Dorsal Lamina* is represented by a series of about 20 short curved pointed tentacular languets.

The *Tentacles* are of three sizes. There are about eight large and much branched, alternating with others half the size, while a variable number of much smaller ones occur between. If a little more regular the formula would be eight large, eight medium, and sixteen small, but the latter are not all present and the large and medium ones may vary from six to nine each.

The *Dorsal Tubercle* is large, prominent and hemispherical. It is marked with two spiral coils (fig. 38).

Localities:—(1) Five specimens were trawled at Station XIX. in northern part of Palk Bay, depth 4½ to 8 fathoms; (2) one at Station I., off Negombo, 12 to 20 fathoms; and (3) one is labelled "Gulf of Manaar."

The largest specimen measures 9 centims. × 6 centims. × 3 centims., the two next each 5 centims. × 5 centims. × 2 centims., the next 3 centims. × 3 centims. × 1 centim., and the smallest 2 centims. × 1·5 centims. × 1 centim. These specimens agree fairly well in most characteristics with *Rhabdocynthia pallida* (HELLER) to which v. DRASCHE'S *Cynthia mauritiana* is closely related. These species are described as having only eight branchial folds, while the present one has nine. They also differ in the dorsal tubercle, the tentacles and other details, but these are all points subject to individual variation. The large branchial and atrial siphons have strong sphincter muscles, from under the lower edge of which very strong radial muscle bundles emerge. There are about 16 of these on each side at the atrial sphincter, and about 30 on each side at the branchial. The arrangement of these muscles is seen in fig. 37. Large lobed gonads are present on both sides, and show through the mantle as a number of rounded masses (fig. 39), rather different in appearance from the figures of *Rh. pallida* given by SLUITER and MICHAELSEN; however, I believe the difference is only due to stages of growth. The ova occupy the wide central part of the mass, and the spermatic cæca are grouped in clumps around the margin.

I thought at first, because of the red colour when alive, that this species might be SLUITER'S *Cynthia rosea*—which is a *Rhabdocynthia*—but a closer examination showed that it differed from that form in the details of the branchial sac, in the form of the dorsal languets, and the dorsal tubercle, as well as in the shape of the body and relative positions of the apertures. However, the two species are closely related, and it is a question whether fuller knowledge of both in the future will enable us to unite them.

This large Ascidian is said by the natives to be characteristic of the West Cheval Paar, but is also found at other places in the Gulf of Manaar.

Rhabdocynthia ceylonica, n. sp.—Plate III., figs. 1 to 19.

External Appearance.—Body of globular or ellipsoidal form, covered with clear pale yellow sand and small shell fragments, except around the apertures. Siphons prominent, the atrial rather the longer; both on anterior end, and connected by a ridge of test, which, like the siphons themselves, is bare of sand (fig. 3). The lobes of the apertures are marked with white radial lines (see figs. 18, 19); size about 2 centims. × 1·5 centims.

Test thin, transparent; containing branched vessels with knobs and also spicules.

Mantle transparent except for the muscle bundles and the spicules. There is a loose felt-work of fine spicules all over the surface, and the mantle is flecked with white on the siphons. There are four lines of white pigment dots down the inside of each siphon (fig. 18).

Branchial Sac with seven folds on each side, the most ventrally placed one on the left side being very slight. The transverse vessels are of three sizes (fig. 7), in the wider of which spicules are found. There are six internal bars on a fold, and the meshes, between the folds, are square and contain about six stigmata. They are crossed and sometimes interrupted by the third order of transverse vessel.

Dorsal Lamina represented by moderate-sized triangular languets (fig. 17).

Tentacles.—About ten large, branched, with smaller ones between (figs. 10, 11). Another specimen showed eleven larger and eleven smaller alternately placed, with occasional still smaller ones (figs. 10, 11).

Dorsal Tubercle large, but simple; horse-shoe shaped, with both ends turned in (figs. 8, 9). One specimen showed, as an abnormality, a double tubercle (fig. 16).

The *Alimentary Canal* forms a long open loop on the left side of the body.

Gonads are present on both sides. Each is hermaphrodite, the spermatic cæca being arranged around the masses of ova.

Localities:—(1) Alentura Paar, Station LVIII., 26 fathoms, two specimens; (2) Station I., off Negombo, 12 to 20 fathoms, two specimens (of a reddish colour when alive); (3) Station IV., off Karkopani, 6 to 9 fathoms, one specimen (1·6 centims. × 1·2 centims., with atrial siphons 6 millims. long, and very little sand); (4) Galle Bay (from basket hung to a buoy), one specimen about 1 centim. long (the fixation and growth must have taken place entirely between April 17 and May 9; (5) Station LIII., 10 miles north of Cheval Paar, 7 to 8 fathoms, four specimens; (6) Trincomalee, 11th February, one small specimen; (7) Aripu Reef, 18th March, one small specimen. The two specimens from Alentura Paar are entered in our field-notes as "Two transparent Cynthias with red edges to the siphons and sand on the test." These two specimens were preserved in strong formol and are still very soft and transparent. The inside of the test is in a gelatinous condition, is continuous with the mantle, and adheres strongly to it round the anterior end. In dissecting, the animal is as soft and gelatinous as when alive.

A sandy *Rhabdocynthia* is a novelty, and if we consider the allied species of *Cynthia* we find that this species differs from *Cynthia arenosa*, Hrdn., in the details of the branchial sac and in the spicules and the dorsal tubercle.

The spicules are of the usual *Rhabdocynthia* type, and are sufficiently illustrated in the figures (figs. 12 to 15). I have considered the possibility of this form, the largest specimen of which is only 2·5 centims. in length, being a young stage of *Rh. pallida* (Heller) which attains a size of 9 centims.; but there are in the collection small specimens of the latter species measuring only 2 centims. across, and these have already the characters of the adult and are entirely different from *Rh. ceylonica* of corresponding size. It differs from *Rhabdocynthia tenuis*, HRDN., in the external appearance and in the dorsal tubercle.

Microcosmus manaarensis, n. sp.—Plate II., figs. 23 to 31.

External Appearance.—A rough mass of sand, foraminifera, and shell fragments, stiff but brittle, with more or less of the anterior end and two short siphons projecting, and having the posterior end thickly covered and prolonged into root-like sandy wisps (figs. 23, 24). Size about 2 centims. in diameter; colour varying with the sand. The siphons may be echinated with slight projections.

Test white in section, leathery, but more or less completely buried in the crust of sand, which may extend to nearly 1 centim. in thickness. The inside of the test is quite firm and glistening, and is marked by the impress of the strong muscle bundles of the mantle. The outside of the test bears numerous hair-like processes which run out into the sandy coating (fig. 25).

Mantle yellowish brown and very strong. The siphons are long and muscular (fig. 28). Atrial aperture bilobed on inside (fig. 27).

Branchial Sac with six folds on each side. There are five bars on a fold and three in the interspace. The meshes are elongated transversely and contain about 10 stigmata. There are seven narrower transverse vessels between each pair of very much wider; narrow horizontal membranes cross some meshes (fig. 31).

Dorsal Lamina a plain membrane.

Tentacles six large and six smaller alternately, much branched (fig. 29).

Dorsal Tubercle small, cordate in outline, with the opening anterior and both horns turned in (fig. 30).

The peripharyngeal bands have a characteristic undulating course.

Localities:—(1) Station LIII., 10 miles north of Cheval Paar, 7 to 8 fathoms, two specimens which differ in the amount of sand they bear; (2) Station XLVI., off Mount Lavinia, 30 fathoms, two specimens; (3) "Gulf of Manaar," three specimens; (4) Trincomalee, Station XXIV., 30 fathoms, three specimens.

This species differs from those already known from eastern seas, such as *M. helleri*, *M. ternatanus*, *M. propinquus*, *M. affinis*, and *M. ramsayi*, and also from the two new species found by the "Siboga" expedition, *M. hæmisphærium* and *M. arenaceus*. The last-named species is a sand-covered form like the present one, but differs notably in the dorsal tubercle, which is broken up into several separate openings, and in having papillæ on the horizontal membranes at each longitudinal vessel.

The species to which the present seems most nearly allied is *M. gleba*, TRAUSTEDT, from the Pacific; a species which differs in having 10 large tentacles and in some details of the branchial sac.

This species forms dark sandy balls about the size of a walnut, and in most specimens the fringe of sandy rootlets at the posterior end is conspicuous (fig. 23).

The coating of sand is so thick and dense that in some cases it can be peeled off the test as a coherent shell, so as to give the appearance of one test lying within another (fig. 26). In life the siphons are very long, and their terminations are yellow tubes, marked with dark red bands.

Eleven young fishes were found in the peribranchial cavity of one specimen from off Mount Lavinia.

Microcosmus longitubis, n. sp.—Plate II., figs. 32 to 35.

External Appearance.—The body is ovate, with two very long siphons diverging from the narrow anterior end. It is encrusted with sand and shell fragments, which are especially large and thickly placed on the rounded posterior half of the body (fig. 32). Size, about 5 centims. from the end of the branchial siphon and 3 centims. across the wider posterior part of the body.

Test stiff and leathery, ranging up to 2 millims. in thickness. Greyish white and glistening on the inner surface, white in section. There are numerous large vessels, and there are long branched processes on the surface to which the sand is attached.

Mantle strong, very muscular (fig. 33), the body with the test removed having the appearance of a ball of tightly wound threads, with the two very long siphons protruding. The branchial is the longer and straighter, the atrial being curved dorsally.

Branchial Sac with six folds on each side; rather narrower than those of the last species, and having four or five bars, but none in the interspace. There are five to seven narrow transverse vessels between the very much wider ones. The meshes may extend the whole distance from fold to fold and then contain 20 to 24 stigmata, or may be interrupted by irregular oblique or curved vessels (fig. 34). The stigmata are rather short and neatly shaped.

Dorsal Lamina a plain membrane.

Tentacles branched. There are 10 of large size, some rather larger than others, and a few very small additional ones placed between.

Dorsal Tubercle having a symmetrical semicircular outline, with both ends lightly rolled in (fig. 35).

Locality :—Tampalakam, Trincomalee.

Cynthia transversaria, Sluiter, var. **manaarensis,** nov.—Plate III., figs. 20 to 24.

External Appearance.—Shape ovate or pyriform, with widely divergent prominent apertures at the narrower anterior end (fig. 20). Attached by posterior half of left side. Surface even, but closely encrusted with fine sand grains all over. Siphon square in section, with slight ridges at the angles. Colour, greyish-yellow; size, 3 centims. × 1·5 centims. × 1 centim.

Test thin, but tough and stiffened by the embedded sand; a little thickened at posterior end; dirty white on inside and in section.

Mantle yellow; strongly muscular on the long siphons and the anterior half of body, less so over the viscera and posteriorly (fig. 21).

Branchial Sac with six well-formed folds on each side converging to the œsophageal aperture. Stigmata running transversely in place of longitudinally, so as to cross the internal bars at right angles (fig. 24). There are thus no meshes, and the wide vessels between the rows of stigmata run more or less parallel with the folds in place of across them. The folds have six to eight bars, and the interspaces two or three each. The connecting ducts supporting the bars sometimes come from the transverse vessels, and are sometimes interstigmatic.

Dorsal Lamina represented by a row of closely placed small tentacular languets (fig. 22), smaller and more distant in front, rather stouter and much closer together further back.

Tentacles compound, of three sizes: six of the largest, six of the second, and twelve of the smallest size.

Dorsal Tubercle having a simple ovate slit (fig. 22) placed in the mouth of a deep triangular peritubercular area.

Alimentary Canal forming a long narrow loop placed transversely to the body (fig. 21); stomach ridged longitudinally.

Gonads one on each side (fig. 21), long irregularly lobed yellow bodies, lying transversely in a curve concave anteriorly.

Locality:—Station LIV., in the north part of the Gulf of Manaar, 10 fathoms.

This form is certainly closely related to Sluiter's *Halocynthia transversaria* from Ki Island and Banda, in the Malay Archipelago, but differs in so many minor points from the "Siboga" specimens that I place it as a distinct variety, "*manaarensis*." The Ceylon specimen agrees with Sluiter's description in the remarkable transverse arrangement of the stigmata and in the general characters of the tentacles and the dorsal tubercle, but differs in the following points:—The sandy investment of the body is much slighter and the shape is different, allowing the two siphons to stand out prominently (Plate III., fig. 20). The interspaces between the branchial folds have only two or three internal longitudinal bars each (fig. 24) in place of seven as in Sluiter's specimens. The examination of further material will, no doubt, show whether these differences are bridged by intermediate conditions, or whether they are maintained as the characters of two closely related species.

The living specimen is described in our field-notes as "milky grey, mottled and streaked with dull purple; thin coating of hairs with mud on surface."

Cynthia crinitistellata, Herdman.—Plate III., figs. 25 to 29.

One small specimen from Station IV., off Karkopani, 6 to 9 fathoms. Size, 1·4 centims. in length × 1·5 centims. in breadth × 7 millims.

This species is only known from Port Jackson.

The five specimens in the collection of the Australian Museum, Sydney, were described in 1899.* The present little specimen from Ceylon (fig. 25) agrees perfectly in external characters, including the spines and the remarkable stellate hairs (figs. 26 to 29), forming a fine down over the surface of the test, with the Australian specimens.

Cynthia aripuensis, n. sp.—Plate III., figs. 30 to 39.

External Appearance.—Body of irregularly globular or pyriform shape, with the narrower anterior end cleft into the two long crumpled siphons. The branchial siphon is especially long (fig. 31). Attached by the posterior end. Surface corrugated. Colour, creamy yellow, browner in places; some specimens have a pink tinge. Size of a large specimen, 4 centims. × 2·5 centims. × 1·5 centims.

Test leathery and tough, up to 2 millims. in thickness, wrinkled on the outer surface, creamy yellow, smooth and glistening on the inside, white in section. The invaginated test lining the siphons bears slender sharp-pointed scales (fig. 33).

Mantle strong, opaque anteriorly, more membranous and transparent posteriorly, of a yellowish colour becoming red on the siphons. Strong muscle bundles radiate from the bases of the siphons (fig. 35).

Branchial Sac with six folds on each side. About nine to twelve internal bars on the fold, and four to six rows of meshes in the interspace. There are three smaller transverse vessels between each pair of much larger ones (fig. 32). The mesh is transversely elongated, contains about six rather small stigmata, and is divided by a horizontal membrane. Parasitic Copepoda are present in the branchial sac.

Dorsal Lamina represented by closely placed long tentacular languets (fig. 37).

Tentacles large, much branched, and closely placed; about 18 larger ones and the same number of very much smaller ones placed so that the bases touch (fig. 36).

Dorsal Tubercle simple, ovate in outline, with the opening anterior or lateral, and the horns coiled slightly inwards (figs. 38, 39).

Gonads large, yellow; present on both sides, in a double row of about 20 masses.

Locality:—(1) Aripu coral reef, shallow water, about a dozen specimens; (2) "Gulf of Manaar," four specimens; (3) Station LXVI., off Mutwal Island, 10 to 35 fathoms, three specimens; (4) Station IV., off Karkopani, 6 to 9 fathoms, two specimens.

This is probably a fairly common *Cynthia* in the Gulf of Manaar, as a number of specimens were obtained while wading on Aripu coral reef, of which about a dozen were preserved. The specimens dredged off Mutwal Island are certainly the same species, although the shape is a little longer and less globular (fig. 30). That slight difference may well be due to the place of attachment or to the accidents of preservation. The internal organisation is the same as in the Aripu specimens.

This species recalls SLUITER's *Halocynthia polycarpa* from the "Siboga" expedition, but differs notably in the tentacles and the dorsal tubercle, and in the details of the branchial sac. From ROULE's *H. corallina* this species also differs in several

* 'Descriptive Catalogue (No. XVII.) of Tunicata in Australian Museum,' Sydney, 1899, p. 34.

particulars. The spines of the branchial aperture, moreover, are characteristic (figs. 33 and 34).

Cynthia lanka, n. sp.—Plate IV., figs. 1 to 13.

External Appearance.—A sandy mass of ovoid form, with a narrower anterior end raised to form a slight ridge, at the extremities of which the apertures are placed (figs. 3 and 4). Size, 2·5 centims. × 2 centims.

Test closely encrusted with a layer of sand, not thick.

Mantle thin and transparent, with prominent muscular siphons, atrial the longer (figs. 5, 6). Branchial siphon lined by closely placed, sharp-pointed spines (fig. 12).

Branchial Sac with six folds on each side. There are five to seven internal bars on a fold and about three to five rows of meshes in each interspace. The meshes are square, contain each four stigmata, and may be crossed by a narrow horizontal membrane (fig. 11).

Dorsal Lamina in the form of short curved tentacular languets (fig. 10).

Tentacles much branched.

Dorsal Tubercle small, widely cordate, with the opening anterior (figs. 7 to 9).

Gonads a double row on each side opening into a zig-zag duct (figs 5, 6, 13).

Localities:—(1) Station XLIX., south-west of Cheval Paar, 8½ fathoms, one specimen; (2) Station LXVI., off Mutwal Island, 10 to 35 fathoms, two specimens; (3) Station XIX., Palk Bay, 8 fathoms, five specimens; (4) Station XXIV., Outer Bay, Trincomalee, 24 to 46 fathoms, half a dozen specimens.

This sandy *Cynthia*, to which I have given the ancient native name of Ceylon, seems undescribed. The appearance of the alimentary canal and gonads, as seen when the test is removed (figs. 5 and 6), recall *Cynthia jacatrensis*, Sluiter, from Malaysia, *C. molguloides*, from Australia, and Van Name's var. *munita* of Traustedt's West Indian *C. riiseana*, from Bermuda, but our Ceylon species differs from all of these. Notwithstanding the very complete armature of spines lining the branchial siphon (fig. 12), there were several parasitic Copepoda in the branchial sac.

The zig-zag arrangement of the oviduct connecting the gonads is a conspicuous feature. Fig. 13 shows a portion of the organ enlarged.

Family: STYELIDÆ.

Styela lapidosa, n. sp.—Plate V., figs. 7 to 15.

External Appearance.—Of oblong, ovate form, apparently unattached, with the anterior end rather the wider, and covered closely and uniformly with coarse quartz sand grains (figs. 7 to 9). Apertures both on the rounded anterior end, not prominent, inconspicuous. Surface and colour due to the sand; size, 2·3 centims. long by 1·2 centims. wide.

Test thin, but stiffened by the sand, brittle, transparent on inner surface letting the sand grains show through distinctly.

Mantle thin, transparent and very slightly muscular, except on the two short siphons, where there are strong sphincters.

Branchial Sac with four slight but well-formed folds on each side. About six bars on a fold, and four to six rows of meshes in the wide interspaces (fig. 14). The meshes are square, contain each about five rather large closely placed regular stigmata, and are divided horizontally by a membrane. Narrower and wider transverse vessels alternate.

Dorsal Lamina is a corrugated membrane.

Tentacles of three sizes (fig. 15), eight of the largest, eight of the second, and sixteen of the smallest.

Dorsal Tubercle with a simple but wide funnel-shaped opening (fig. 15). Peri-tubercular area narrow.

Alimentary Canal with a wide intestinal loop (fig. 10); stomach ridged.

Gonads a curved, slightly lobed organ on each side of the body, having the ovary along the middle and the spermatic cæca on the edges.

Localities:—(1) Stations LIII. and LIV., in north part of Gulf of Manaar, 4 to 40 fathoms, a few specimens; (2) Station XLVI., off Mount Lavinia, 30 fathoms, four specimens; (3) Station XXIV., Outer Bay, Trincomalee, 24 to 46 fathoms, a dozen specimens; (4) Station XLIX., South Periya Paar, 13 fathoms, eight specimens; (5) Station LXIII., West of Periya Paar, 17 to 55 fathoms, nine specimens.

This seems to be a common species around Ceylon, as a number of specimens were found at localities on both sides of the island.

The appearance of the tentacles and of the dorsal tubercle (fig. 15) is very suggestive of a Polystyelid or a Botryllid.

The apertures are striped with yellow and red when alive. The stiff brittle sandy test and the large curved gonad on each side are characteristic features.

Styela areolata, Heller—Plate IV., figs. 24 to 33.

It is necessary to re-describe this species, with figures, since Heller's description was very brief and no illustrations have been published showing the structure.

External Appearance.—Body ovate, attached by a few slight tag-like processes at the posterior end. Siphons slight, both on dorsal edge, apertures small, cross-slit. Surface uneven, but smooth. Colour, milky white. A little sand adhering towards the posterior end (fig. 24). Size about 2 centims. × 1·5 centims.

Test thin and semi-transparent, smooth on the surface except where encrusted with sand. The test may be reduced to a very thin layer in the middle of the posterior end, and has thickened edges round the area of attachment. There are vessels in the test.

Mantle semi-transparent, allowing the viscera to show through. The muscle bundles are very fine.

Branchial Sac with four wide folds on each side. There are five internal bars on a fold and three rows of meshes in the interspace. The transverse vessels are of three orders. The meshes are elongated transversely and contain eight or nine stigmata, and may be crossed by a narrow horizontal membrane (fig. 33).

Tentacles simple, numerous, large and small alternately.

Dorsal Lamina a plain membrane.

Dorsal Tubercle having a simple rather angular horse-shoe curve with a wide opening. The ends turn slightly either in or out (figs. 31 and 32).

Alimentary Canal large, stomach ridged longitudinally, intestine wide, forming a close loop.

Gonads four to six on the right side, one or two on the left (figs. 27 to 30).

Localities:—(1) Aripu coral reef, four specimens; (2) Station LIII., 10 miles north of Cheval Paar, 7 to 8 fathoms, four specimens; (3) Station I., off Negombo, 12 to 20 fathoms, four specimens (one of these is almost bare of sand and another is more than half covered with reddish brown large sand grains so as to closely resemble in appearance the sandy *Rhabdocynthia, Rh. ceylonica*, found in the same neighbourhood); (4) Station X., East of Cheval Paar, 6 fathoms, three specimens—one large (fig. 26) with half a dozen young pearl oysters adhering, almost free from sand, test milk-white and corrugated at anterior end, one smaller half-covered, and one wholly covered with red-brown sand except the two siphons and a strong ridge of test connecting them; (5) Station LIV., North end of Gulf of Manaar, half a dozen small specimens from 1 centim. to 2·5 centims. in length; (6) Station XLIX., South end of Periya Paar, 13 fathoms., one specimen.

Although HELLER'S description is very brief, the name he gives the species inappropriate, and his single figure of the external appearance not characteristic, still I have no doubt that his specimen, brought from Ceylon by SCHMARDA, belonged to the same species as those I have now before me. The milk-white colour and the long tubular gonads, about four on the right side and two on the left, are characteristic features mentioned by HELLER which render the identification fairly certain. He does not mention the sand which is usually present on the surface, and the areolation of which he makes so much is by no means always present. However, feeling confident that it is the same species that is in question, I have re-described and figured HELLER'S *S. areolata* from the specimens in the present collection.

The few prominent tubular gonads on each side of the body in this species recall the arrangement seen in SLUITER'S eastern species *Styela oligocarpa* and *Styela sedata*; but in other points of structure and in external appearance the Ceylon specimen differs from both of these, although they must be regarded as allied forms.

Styela ascidioides, n. sp.—Plate V., figs. 27 to 32.

External Appearance.—Body oblong, erect, attached by a short narrow stalk or posterior thickening. Branchial aperture on anterior end, atrial on dorsal edge, one-third of the way back. Both apertures very regularly four-lobed (fig. 28). Colour, grey. Size, 2·5 centims. × 1 centim.

Test cartilaginous, full of bladder cells (fig. 30) and pigment cells (blue, black, red and yellow).

Mantle having a fine network of fibres running in all directions.

Branchial Sac large and loosely disposed, with four folds on each side. Transverse vessels rather wide, of three sizes. Internal bars wide, ribbon-like; from eight to sixteen on a fold and six to eight in the interspace. Meshes square, containing each four or five stigmata (fig. 32).

Tentacles large and closely placed, about 30 (fig. 31).

Dorsal Lamina a plain membrane.

Dorsal Tubercle small and inconspicuous, placed close to the tentacles (fig. 31).

Nerve Ganglion and neural gland forming a conspicuous spot.

Alimentary Canal forming a narrow loop at posterior end of left side (fig. 29); stomach simple, ovate.

Gonads nine prominent yellow masses on each side, closely packed, pyriform, with ducts directed towards the atrial aperture.

Locality :—Station LVIII., Alentura Paar, Gulf of Manaar, 9 to 26 fathoms.

The cartilaginous test, with its *Ascidia*-like structure, and the minute dorsal tubercle placed close to the tentacles, are special features of this species.

Styela pigmentata, n. sp.—Plate VI., figs. 24 to 26.

External Appearance.—Of quadrate shape, broader than long, attached by a wide base (fig. 24); somewhat encrusted and covered with growths of weed, &c., but not stiff. Colour dark; size, about 3 centims. × 3 centims.

Test leathery, but rather soft and flexible, with *Crenella* embedded in its thickness; yellowish grey and glistening on the inside.

Mantle soft, and opaque dark brown; not muscular; inner surface pigmented yellow and white.

Branchial Sac pigmented with yellow and white, with four well-marked folds on each side. There are at least six internal bars on a fold and three in the interspace. The meshes contain each eight stigmata (fig. 25).

Endostyle with very wide, white pigmented lips.

Dorsal Lamina a plain membrane.

Tentacles pigmented yellow and white.

Dorsal Tubercle represented by a diffused triangular area covered with minute pores (fig. 26).

Locality :—Jokkenpiddi Paar, Gulf of Manaar, 8½ to 10 fathoms.

Polycarpa aurata, Quoy and Gaimard—Plate V., figs. 1 to 6.

External Appearance.—Shape oblong, erect, with both apertures at anterior end, sessile, not distant (fig. 1). Attached by posterior end, and having a little encrusting sand or shell fragments; surface more or less corrugated. Colour from dull brownish grey to blackish brown; size, 2·3 centims. × 1·3 centims. × 0·5 centim.

Test leathery, but rather soft; dark grey in the interior, and pigmented with minute black spots to varying degrees having numerous pigmented vessels (fig. 2).

Mantle moderately thick, but not very muscular, of a dark colour (fig. 3) and having the gonads embedded in it; apertures and siphons black.

Branchial Sac nearly black in colour, with four large closely placed folds on each side; six internal bars on a fold, and three in each interspace (fig. 6).

Dorsal Lamina a narrow plain membrane.

Tentacles about 30, all of same size.

Dorsal Tubercle an indefinite spongy mass with many small apertures (fig. 5).

Alimentary Canal small, intestine slight.

Gonads, 10 to 12 round polycarps, sunk in the mantle on each side.

Localities:—(1) Station IV., off Karkopani, 6 to 9 fathoms, one specimen; (2) Station XLVI., off Mount Lavinia, 30 fathoms, one specimen; (3) Gulf of Manaar, three specimens adhering in a clump.

It is possible that these Ceylon specimens of this widely distributed and somewhat variable species ought to be separated off as a distinct variety. As they have some distinct characteristics, I have drawn up the above description. All the specimens have more brown and black pigmentation than I have seen in the species before, which gives them a "tanned" appearance both inside and out, while the apertures are practically black. In all these characters they agree with HELLER's *Polycarpa nigricans*, from Mauritius, which, however, is described as having a basal stalk and root-like processes which are not present in the Ceylon specimen. It is possible that HELLER's species is the same as QUOY and GAIMARD's, in which case *aurata* remains as the name of the species and *nigricans* becomes a synonym.

Polycarpa mutilans, n. sp.—Plate IV., figs. 34 to 44.

External Appearance.—Shape oblong or trapezoidal, with a narrow anterior end and a sloping dorsal edge. Apertures both moderately prominent, but not on long siphons; branchial anterior and atrial about the middle of the dorsal edge (fig. 38). Surface uneven and corrugated. Colour, dirty greyish yellow; size, 3·5 centims. × 2·2 centims. × 1·5 centims.

Test tough and leathery, very irregular on outer surface, smooth on inner, white in section.

Mantle moderately muscular, with fine, but numerous, bundles of fibres running both longitudinally and transversely.

Branchial Sac, when present, with four folds on each side. The fold has about six internal bars and there are about three in each interspace. The meshes are nearly square and contain each four to six long narrow stigmata (fig. 37).

Dorsal Lamina a narrow plain membrane (fig. 37).

Tentacles large and numerous, all one size, bases touching, about 80 in all (fig. 39).

Dorsal Tubercle simple, with an anterior opening and the horns rolled slightly inwards in one specimen (fig. 44) and turned outwards in another (fig. 43).

Alimentary Canal with an open loop and a closely ridged stomach; but it may, like the branchial sac, be completely absent.

Gonads.—A row of about 14 yellow sausage-shaped polycarps on the right side of the body and fewer on the left. Many endocarps on both sides.

Locality:—Station LIV., in north part of Gulf of Manaar, 4 to 40 fathoms, three specimens.

Of the three specimens of this species obtained together at the one spot, two are in an interesting condition. The specimen shown in fig. 38, and from which the above description has been drawn up, is perfect and normal in all its organs; but the other two which, externally, seem as well grown and as complete (see fig. 34), were found on dissection to have no alimentary canal and no branchial sac (see fig. 35).

Sluiter, in 1885, described a single specimen of a *Styela* which he found at Billiton, in the Malay Archipelago, under the name *Styeloides abranchiata*, as a new species belonging to a new genus because of the absence of branchial sac and alimentary canal. As it was scarcely possible to believe that such could be the normal condition of the species, in my 'Revised Classification of the Tunicata' (p. 578), in 1891, I expressed some doubt and suggested that Sluiter's specimen was an individual abnormality.

In 1895, Sluiter, in his "Report on the Tunicata of the Semon Expedition," described a new species, *Styela solvens* (Semon, 'Forschungsreisen,' Bd. v., p. 182), in which, out of three specimens found at Amboyna, the branchial sac was absent in two and the intestine in all. This observation caused Sluiter to relinquish his genus *Styeloides*, and suggest that in the species of *Styela* in question the branchial sac, &c., might become lost as a normal process. The following year, however, Willey, in his "Letters from New Guinea" ('Quart. Journ. Micr. Sci.,' 1896, p. 161), described the ejection of the viscera which he had actually observed in a species of *Styela* which he, following Sluiter, named *Styeloides eviscerans*. Sluiter refers further to the three mutilated species, *Styela abranchiata*, *St. solvens*, and *St. eviscerans* in his paper on Weber's South African Tunicata ('Zoolog. Jahrb.,' 1898), and raises the question whether regeneration can be in progress in such cases. Finally, two additional specimens of *Styela abranchiata*, both also in the mutilated condition, were obtained by the "Siboga" expedition.

The condition of affairs in the three specimens from Ceylon, which I am now describing as *Styela mutilans*, confirms the impression I expressed in the 'Revised Classification' in 1891, and upon which agreement seems now to be general.

The Ceylon specimens do not belong to any of the previously described species of Sluiter or Willey. They differ from all in various particulars, and belong clearly to the genus *Polycarpa*; but here is a case where, if the first specimen which I examined had alone been found, or even if the first and second only had been known, the species might have been described as destitute of branchial sac, stomach, and intestine. And yet the third example, which there is no reason to think belongs to a different species, shows a perfectly normal structure. I have no doubt that specimens one and two have lost their alimentary tract. From WILLEY's observations it seems possible for an Ascidian by a powerful contraction of the mantle under some abnormal conditions to perform evisceration and get rid of the entire free portion of the canal, from the peripharyngeal bands to the anus, and that seems to be the best explanation of all such abranchiate specimens.

The tentacles remain, as they are firmly attached to the muscular body-wall, and they are alike in all the three Ceylon specimens. Fig. 39 shows the appearance of a stained preparation of a tentacle, where (*a*) indicates a band of ciliated columnar epithelium, the rest of the surface being covered with squamous cells, while (*b*) is a tract of solid connective tissue, along the convex edge, which stains a bright red with picro-carmine, and is probably skeletal in function. The rest of the interior contains lacunæ with many blood corpuscles (*c*).

The only difference that is apparent between the normal and the abranchiate specimens is that the latter have a more abundant crop of endocarps projecting from the body-wall (fig. 36), and as these are individually larger (figs. 40 to 42) and contain lacunæ in connection with those of the mantle outside (fig. 36), and show many blood corpuscles in their interior, I would suggest that this greater development of these thin-walled vascular processes has taken place in order to compensate for the absence of the branchial sac by promoting respiration. SLUITER, in his original mutilated specimen, *Styela abranchiata*, found that the mantle was thickened and highly vascular, and he recognised that its condition compensated for the absence of the normal respiratory organ. In *Styela solvens*, however, no unusual development of the mantle is described. Whether any nutrition can be effected by amœboid cells in the body-wall absorbing particles brought into the single large cavity by the branchial and atrial apertures, and whether the animal can maintain life for long in this abnormal state, there is no evidence to show. Experimental work on eviscerated specimens would be necessary to determine such points.

If the animal is able to carry on existence in this mutilated condition, two physiological points arise: the one as to respiration and the circulation of the blood, the other as to digestion and nutrition. The heart and the chief blood-vessels have gone with the other loose viscera. The abundant thin-walled endocarps containing blood lacunæ and projecting freely into the sea-water in the peribranchial cavity no doubt perform respiration effectively, and it is possible that they pulsate like the ampullæ in the test of *Botryllus* and so keep the blood in movement. The other possibility is that contraction of the muscles in the mantle squeezes the blood irregularly from place to place in the body-wall and so prevents stagnation.

In regard to nutrition, it seems possible that amœboid cells in the connective-tissue of the body-wall, and from the blood lacunæ, might take up nutrient particles brought in by the water and ingest and digest them in an intracellular manner. Although, in the absence of the branchial sac, there can be no strong current through the animal, still the muscles of the mantle, and especially the sphincters of the siphons, will no doubt suffice to draw in and to expel supplies of water, and the cilia of the peripharyngeal bands and of the tentacles will be able to separate out, guide, and retain the diatoms and other nutrient particles.

If the food can be brought within reach of the amœbocytes and ingested, there is probably no difficulty in regard to digestion. Such cells are probably able to form the necessary ferments and effect solution and absorption of the food. It is known that ordinary tissue-cells in even a higher animal contain erepsin, and possibly other ferments, and can exercise a slow proteolytic action. It seems highly probable* that leucocytes and other undifferentiated cells—especially in plastic organisms like the Ascidians, where tissue differentiation is not highly marked—contain amylolytic and proteolytic ferments sufficing for intra-cellular digestion of microscopic organic food.

Polycarpa sluiteri, n. sp.—Plate V., figs. 16 to 21.

External Appearance.—Shape pyriform or oblong with a narrower anterior end terminated by the branchial aperture. Atrial aperture half-way down dorsal edge (fig. 16). Surface rough, corrugated, having a few shell fragments and other foreign bodies adhering. Attached by posterior end and parts of left side. Colour, very dark grey, nearly black in places. Size, 3 centims. × 2 centims. × 1·5 centims.

Test tough and leathery, rough and irregular on outer surface, quite opaque, smooth, but rather dark on the inner surface and grey in section.

Mantle dark coloured, not thick, with strong muscular siphons.

Branchial Sac with four wide folds on each side, with about nine or ten bars in the folds and five rows of stigmata in the interspace. Transverse vessels alternately larger and smaller. Meshes square, containing each seven or eight rather long narrow stigmata (fig. 21).

Dorsal Lamina a plain membrane with no ribs and no marginal teeth.

Tentacles of two sizes, six very large and six much smaller.

Dorsal Tubercle rather small and slight, in a deep narrow triangular peritubercular area, with the opening anterior and the horns turned one in and one out but not coiled (fig. 17). Two other tubercles are shown in figs. 18 and 19.

Gonads numerous; from 15 to 20, dull yellow, sausage-shaped polycarps on each side of the body, arranged roughly in a row facing the atrial aperture (fig. 20). A few dark-coloured endocarps projecting between them.

Locality:—(1) Station V., Chilaw Paar, 10 fathoms, three specimens; (2) Aripu coral reef, one specimen.

This species in some respects resembles *Polycarpa mutilans*, but differs from it so

* In the light of recent work by Ascoli and Mareschi, Vernon, Rulot, and the Ladisls.

completely in the tentacles, as well as in other points, that there can be no question of their distinctness. It is, however, exceedingly like the form described by SLUITER from Billiton (Malay) under the heading "*Styela elata* (HELLER) (?)," in 1885. MICHAELSEN, in his revision of HELLER'S types, dealt with *Polycarpa elata*, HELLER, assured us that SLUITER'S form does not belong to that species and suggested the name *P. seriata* for it. The agreement of the Ceylon form with SLUITER'S description extends to the gonads, the branchial sac and the dorsal tubercle, but the tentacles are not alike, and there are other differences in detail, so I consider it safest to give the above full description of my specimens under the name *P. sluiteri*. In the dorsal tubercle this species closely resembles *Styela ambonensis*, SLUIT., of the "Siboga" expedition.

Polycarpa chalmersi, n. sp.—Plate V., figs. 22 to 26.

External Appearance.—Shape rounded or quadrate, somewhat flattened; attached to lumps of coral or to the tubes of the large Foraminifera *Ramulina herdmani* in such a way that the anterior end, dorsal edge, and a large part of both sides is exposed (fig. 23). Apertures sessile, cross-slit when closed, opening out into short siphons with wide square ends when alive. Surface somewhat creased, produced into roughened lobes about the anterior end. Colour, red and grey when alive, siphons streaked with red and white; dull bluish-grey in spirit. Size, 1·8 centims. × 1·3 centims. × 6 millims.

Test thin, but tough and leathery, thickening to over 1 millim. on the roughened anterior end.

Mantle very thin, closely adherent to test. Muscle bands very fine, forming a close net-work.

Branchial Sac with four well-marked folds on each side. There are about nine internal bars on a fold, and about three rows of meshes in each interspace (fig. 24). The meshes are nearly square and contain half a dozen stigmata. There are three narrower transverse vessels between each pair of larger ones.

Dorsal Lamina a plain narrow membrane.

Tentacles long and slender, of two sizes, about 30 in all.

Dorsal Tubercle small and simple, in the form of a narrow U-shaped slit, with the opening anterior and placed in a small triangular peritubercular area (fig. 25).

Alimentary Canal rather short and wide, stomach ridged.

Gonads small hermaphrodite bottle-shaped polycarps (fig. 26), 10 or 12 on each side.

Localities:—(1) Station XLI., 12 miles south of Galle, 100 fathoms, several specimens; (2) Station XXXV., Galle Bay, 7 fathoms, four specimens on a bit of old coral (fig. 22).

These specimens show the change which may occur of an Ascidian which is bright red in life into a bluish-grey colour when preserved in alcohol. I have noticed this so frequently in both simple and compound Ascidians that when, in a preserved collection, one comes upon specimens showing this opaque dull bluish-grey appearance, there is at least a strong probability that the colour in life was red. I have pleasure in dedicating this interesting little species to my friend Dr. A. J. CHALMERS, Professor in the Medical College at Colombo.

Polycarpa alentura, n. sp.—Plate V., figs. 33 to 37.

External Appearance.—Body conical or dome-shaped (fig. 33), attached by a broad base at the posterior end. Apertures on the narrow anterior end, not projecting, inconspicuous. Colour, yellowish grey; size, 2 centims. × 1·5 centims.

Test smooth, slightly wrinkled, leathery.

Mantle thin, pigmented, having a very fine felting of delicate muscle fibres.

Branchial Sac with four wide folds on each side, about 15 internal bars on a fold, and about seven rows of meshes in the interspace. Transverse vessels of several sizes; meshes narrow, containing three to five stigmata each (fig. 37); the stigmata are crossed by a narrow horizontal membrane.

Dorsal Lamina with a few slight denticulations at the anterior end (fig. 35), behind that a plain membrane.

Tentacles rather short and irregular, 14 in number, differing a little in size.

Dorsal Tubercle curiously shaped (fig. 36) with the aperture posterior, one end turned in and the other out.

Alimentary Canal with a widely open intestinal loop; stomach yellow-brown, striated longitudinally (fig. 34).

Gonads consisting of a few polycarps only. Large numbers of small endocarps engorged with opaque yellow blood corpuscles project from the body-wall.

Locality:—Station LVIII., off Alentura Paar, 9 to 26 fathoms, one specimen.

Polycarpa decipiens, n. sp.—Plate VI., figs. 33 to 39.

External Appearance.—Body rounded and covered with sand like a *Molgula*, unattached. Both siphons on the anterior end, but rather distant (fig. 33); size, about 1 centim. across.

Test thin, but covered with a soft, rather loose, coating of sand.

Mantle thin and transparent.

Branchial Sac with four slight folds on each side (fig. 34). Each fold has only three or four internal bars, and there are no bars in the interspaces. Between the endostyle and the 1st fold are 16 stigmata, between the 1st and 2nd 8, between the 2nd and 3rd 8, between the 3rd and 4th 10, and between the 4th and the dorsal lamina 14. The stigmata are shown in fig. 35.

The *Dorsal Lamina* is a plain membrane.

The *Tentacles* are about 20 large, not all quite the same size, and intermediate very much smaller ones.

Dorsal Tubercle simple, ovate, with the opening slightly on one side and the horns turned in (fig. 36).

Alimentary Canal forming an open loop; intestine short and wide.

Gonads flattened, ovate, hermaphrodite polycarps, placed on both sides of the mantle, 10 on left side and 12 on right (fig. 37). The oviduct and vas deferens are shown in fig. 38, and part of the testes in fig. 39.

Locality:—Station LIII., 10 miles north of Cheval Paar, 9 fathoms, one specimen.

Polycarpa palkensis, n. sp.—Plate VI., figs. 5 to 8.

External Appearance.—An ovate sandy mass, attached by a large area to a dead chank shell. Apertures inconspicuous, at opposite ends of the body. Size about 2 centims. in length by 1·5 centims. in breadth.

Test stiff, entirely encrusted with sand to a thickness of about 5 millims.

Mantle opaque. When the test is removed the body is of fusiform shape with the two prominent siphons almost at opposite extremities and directed away from one another (fig. 5).

Branchial Sac with four folds on each side; about six bars on each fold, and three rows of meshes in the interspace. The transverse vessels are of two sizes (fig. 7), the meshes are transversely elongated, with six or seven stigmata in each.

Dorsal Lamina a very narrow plain membrane.

Tentacles rather long, about 30, not all same length.

Dorsal Tubercle rather large and complicated (fig. 6). The opening is anterior, both horns are rolled inwards and one is much larger than the other.

Alimentary Canal forming a small canary-yellow compact mass.

Gonads, numerous elongate ovate polycarps (fig. 8), about 20 on each side.

Locality:—Trawled at Station XIX., in Palk Bay, 8 fathoms, one specimen.

This species shows some resemblance to SLUITER's *Styela floccosa* obtained by the "Siboga," but differs in the gonads and other details of structure.

Polycarpa colletti, n. sp.—Plate VI., figs. 1 to 4.

External Appearance.—Shape erect, cylindrical, almost rod-like; attached by the posterior end with the branchial aperture on the anterior end and the atrial about half-way down the dorsal edge (fig. 1). Surface finely creased or corrugated. Colour, creamy white; size, 2·5 centims. × 8 millims.

Test leathery.

Mantle strong, opaque, yellow, closely adhering to the test.

Branchial Sac with four low, rounded folds (fig. 3) on each side. Each fold has 14 or more closely placed bars, and there are two bars in the interspace separating a very wide central row of meshes from two lateral narrower rows. The wider mesh contains about eight stigmata and the narrower half that number. The transverse vessels are of three sizes, arranged with regularity, and there may also be narrow horizontal membranes crossing the stigmata (fig. 4).

Dorsal Lamina a low plain ridge.

Tentacles of two sizes, about 20 larger and the same number of smaller, placed alternately (fig. 2).

Dorsal Tubercle a large circular area with a small opening at one side, around it is a swollen spongy area.

Locality :—Station XLIX., South-west of Cheval Paar, 13 fathoms, one specimen.

This species is named in honour of the late Mr. Oliver Collett, an excellent naturalist in Ceylon, much interested in the pearl oyster investigation.

Polycarpa willisi, n. sp.—Plate VI., figs. 9 to 15.

External Appearance.—Elongated ovate, almost fusiform, with the large siphons at opposite extremities of the body (fig. 9); each opening very distinctly four-lobed and surrounded by a square rim (fig. 11). Surface sandy; size, 1·4 centims. in length.

Test thin, sparsely covered with adhering sand.

Mantle opaque, pigmented with orange and pale yellow; siphons long (fig. 10).

Branchial Sac with four folds on each side. About five bars on each fold, and two rows of meshes between. The stigmata (fig. 12) are very short, and rather irregular; they form ovate or rounded holes from two to four in a mesh.

Dorsal Lamina a narrow plain membrane.

Tentacles of three sizes arranged regularly (fig. 13), there being eight large, eight medium, and sixteen smaller between.

Dorsal Tubercle a rounded mass with no distinct horns (fig. 13).

Alimentary Canal a narrow, short loop; stomach smooth, and coloured yellow.

Gonads about 12 elongated orange-brown polycarps on each side of the endostyle (fig. 14), and a number of more rounded pale lemon-yellow endocarps (fig 15) scattered between. Each gonad has the ova in the centre and the testes placed around.

Locality :—Station LXII., Periya Paar, 13 fathoms, three specimens of about the same size.

The interior of the body is much pigmented with opaque yellow, especially the alimentary canal, the endocarps, and the mantle.

I have pleasure in naming this species after my friend Dr. J. C. Willis, Director of the Royal Botanic Gardens at Peradeniya, Ceylon.

Polycarpa twynami, n. sp.—Plate VI., figs. 27 to 32.

External Appearance.—Body erect, oblong, attached by the rather narrower posterior end. Branchial aperture anterior atrial a little way along dorsal edge, both sessile (fig. 27). Surface somewhat corrugated and wrinkled. Colour, brown; size, 3·5 centims. × 1·5 centims.

Test leathery but soft, and irregularly thickened, brown inside.

Mantle opaque brown, adhering closely to the test.

Branchial Sac of a dark brown colour, with four folds on each side. About six internal bars on the fold and eight rows of stigmata in the interspace. There are three or four narrower transverse vessels between much wider ones. The meshes are nearly square, with 3 or 4 stigmata in each (fig. 31).

Dorsal Lamina a plain membrane.

Tentacles at least 30 in number, large, with occasional smaller ones (fig. 32).

Dorsal Tubercle simple, horse-shoe-shaped, with the opening anterior and the horns not coiled (fig. 29).

Alimentary Canal dark brown, anus surrounded by about eight finger-like processes (fig. 28).

Gonads, numerous polycarps and endocarps, all of a very dark brown colour, partly sunk in mantle.

Locality.—(1) Jokkenpiddi Paar, Gulf of Manaar, 10 fathoms, two specimens; (2) Station LXIX., Chilaw Paar, 11 fathoms, one specimen.

Two larger and several smaller specimens of a *Crenella* were embedded in one test. This species is dedicated to Sir WILLIAM TWYNAM, of Jaffna.

Polycarpa manaarensis, n. sp.—Plate VI., figs. 16 to 22.

External Appearance.—Somewhat quadrate in shape, with the apertures on two equal projections, giving the anterior end a cleft appearance (fig. 16). Surface corrugated and encrusted with sand and shell fragments. Colour, dark brown on surface, with a pearly lustre inside; size about 4 centims. × 3·5 centims.

Test leathery, hard and stiff. In section it is seen that the sand-grains are embedded in, as well as attached to, the test.

Mantle thick, opaque, ruddy brown.

Branchial Sac with four folds on each side. There are about nine bars on a fold and six in the interspace. The transverse vessels are of three orders with still smaller ones crossing the stigmata frequently and irregularly (fig. 22). The meshes are nearly square and have about four stigmata each.

Dorsal Lamina a narrow plain fold (fig. 21).

Tentacles placed a long way in front of the peripharyngeal band (figs. 17, 20); about 40, larger and smaller alternately.

Dorsal Tubercle a widely open horse-shoe, with the opening anterior and the horns not turned in (figs. 18, 19). Pre-branchial zone pigmented.

Alimentary Canal a wide loop, stomach globular.

Gonads, many large rounded polycarps sunk in the thick mantle.

Locality:—(1) Station LXII., Periya Paar, 13 fathoms, one specimen; (2) Station LXVI., off Mutwal Island, 10 to 35 fathoms, one specimen; (3) Jokkenpiddi Paar, Gulf of Manaar, 10 fathoms, one specimen.

Specimens of *Synalphæus comatulorum* were found in either the branchial sac or the atrium of all the specimens.

Polycarpa, sp.—Plate VI., fig. 23.

External Appearance.—Body oblong-ovate with a dorsal projection; posterior end pointed; branchial aperture on anterior end, atrial on dorsal edge about one-third of the way back. Surface covered with sand and shell fragments. Size, about 6 centims. × 3 centims.

The single specimen dredged at Tampalakam, Trincomalee, on February 11, is found on examination to be in bad condition, so that the internal structure cannot now be determined. It was probably dead when collected. The test is quite stiff and is strengthened by embedded sand. The mantle is thin and appears to have few muscle bundles. The branchial sac is slight, but beyond the four folds on each side little can be made out. There are numerous small polycarps scattered over the body-wall.

It is impossible to identify this with any described form, and the condition prevents it from being described as new. But it may be useful to place on record that a *Polycarpa* with these general characters (fig. 23) was found at Trincomalee.

Family: POLYSTYELIDÆ.

Some writers, led by Michaelsen, have of recent years substituted a new term "Polyzoidæ" for the above well-known family name Polystyelidæ. I cannot follow them. Even if it be proved that Lesson's "*Polyzoa opuntia*" is the same animal that Cunningham described later as *Goodsiria coccinea*, it by no means follows that because *Goodsiria* becomes *Polyzoa*, Polystyelidæ must become Polyzoidæ. The type-genus of the family Polystyelidæ is, of course, not *Goodsiria*, but is *Polystyela*. But it is premature to change even the generic name. It is by no means certain that Lesson's "*Polyzoa*" belonged to this family. His description would apply at least as well to a species of *Colella*, such as one resembling the "*Aplidium pedunculatum*" of Quoy and Gaimard, which is found in the same neighbourhood (Straits of Magellan and Falkland Islands) as to *Goodsiria coccinea*.

Michaelsen has recently asked* why Heller's term Polycynthiæ should not have priority over Polystyelidæ as the name of the family or sub-family. The answer is simply because Heller did not propose that term as the title of a family or sub-family, nor did anyone else, until Michaelsen, in 1904. According to the 'International Rules of Zoological Nomenclature' (Paris, 1905): "Art. 4. The name of a family is formed by adding the ending *idæ*, the name of a sub-family by adding *inæ*, to the root of the name of its type-genus." Heller did not do that. He formed no family or sub-family. He merely remarked that the group Cynthiæ fell into simple and compound forms (Monocynthiæ and Polycynthiæ). There was no question here of naming or defining a family or a sub-family. No family for this group of genera existed previous to 1886. In that year, in the 'Report on the "Challenger" Tunicata,' Part II., I formed and defined the new family Polystyelidæ, choosing as

* 'Deutsche Tiefsee-Expedition, 1898–1899,' Bd. vii., 1904.

my type-genus *Polystyela*, GIARD, and naming the new family in strict accordance with the rules of nomenclature. After the definition I added: "I form this family for a very interesting little group of Ascidians, the position of which is difficult to determine. I regard them as Compound Ascidians which are allied to the Cynthiidæ amongst Simple Ascidians, and have been evolved from the sub-family Styelinæ." I then gave an outline of the history of the genera which I considered would find their place along with *Polystyela* in the family. The family was properly constituted in 1886, and the name cannot be altered until the name of the type-genus (*Polystyela*) is changed. If MICHAELSEN can prove that LESSON'S "*Polyzoa opuntia*" is the same as GIARD'S *Polystyela lemirri*,* then *Polystyela* will become a synonym of *Polyzoa* and the family name will change to Polyzoidæ, or, if it be regarded as a sub-family, to Polyzoinæ—but not till then. In the meantime, if it is placed as a sub-family of Cynthiidæ the name of the sub-family must be Polystyelinæ.

I may add that in the 'International Rules for Nomenclature,' now generally recognised and followed, there is no direction that in forming a new family the oldest generic title within the bounding line is to be selected as the type and give its name to the family. The oldest genus may be quite unsuitable for such a purpose as it may be an aberrant form very far from typical of the family. Surely it is only common sense that it should be left to the founder of a new family to choose as the type-genus that central form or assemblage of species which seems to him best to typify the new group which he is defining.

So far as to the family name—now let me add a few remarks as to some generic designations formed recently.

MICHAELSEN, in 1900, expressed his dissatisfaction with the definitions of the existing genera in this family, and introduced a new generic term, "*Alloeocarpa*," of a provisional nature (he says†: "Dieser neue Name kann nur als provisorisch angesehen werden") for those species which have a certain character of reproductive organs. But he adds: "Als Typus der Gattung *Alloeocarpa*, MCHLSN., mag *A. incrustans* (HERDMAN) (= *Synstyela incrustans*, HERDMAN) gelten." He does not sub-divide the old genus and does not retain any portion under the old name. He merely substitutes a new name because he wishes to emphasize a new character. Surely a better course would have been, if he finds that my *Synstyela incrustans* will serve as a type of what he desires to put forward, to add the new characters (if necessary) to the definition of the genus, retaining the old name *Synstyela*. As a matter of fact, the unisexual character of the polycarps was described and figured in the case of *Synstyela incrustans* in the '"Challenger" Report' (1886), and in all probability holds for other species of *Synstyela*. It would be simple to restrict the

* MICHAELSEN has suggested ('Mitteil. Naturh. Mus. Hamburg,' xxi., 1904) that GIARD'S genus possibly does not belong to the Polystyelidæ, but I find no basis in fact for this idea.

† "Die holosomen Ascidien des magalhaensisch-südgeorgischen Gebietes"; in 'Zoologica,' Bd. xii., Heft 31; Stuttgart, 1900.

genus to such forms. I prefer, therefore, to retain the old generic title in that sense and to add the word "unisexual" before "polycarps" in the definition. MICHAELSEN'S *Gynandrocarpa*, as he first defined it, would then be the corresponding genus containing those species which have hermaphrodite polycarps. More recently ('Mitth. Naturh. Mus. Hamburg,' XXI.) MICHAELSEN has introduced still further generic sub-divisions of *Gynandrocarpa* based upon details of arrangement of the reproductive organs which seem to me to be of only specific value. If similar details were to be recognised in the genera *Styela* and *Polycarpa* almost every species would become a separate genus.

Gynandrocarpa nigricans, SLUITER.

This is a very dark coloured species which the "Siboga" found at the Island Sarassa, in Malaysia, at a depth of 16 fathoms. Our Ceylon specimens were from Talaivillu Paar, in the Gulf of Manaar, where we obtained a number of colonies from 6 centims. × 3 centims. downwards, in size, growing over coral and shell fragments. The ascidiozooids are very closely placed, there being little or no common test except at the edges of the colony. The general appearance of the animal when alive is black and white, the parts that are not deeply pigmented being transparent.

The arrangement of the vessels in the branchial sac and other points in the internal structure agree with SLUITER'S description. The darkly pigmented blood channels in the marginal parts of the colony are a remarkable feature in this species.

Gynandrocarpa (Eusynstyela) imthurni, n. sp.—Pl. VII., figs. 1 to 9; Pl. IX., fig. 4.

Colony encrusting, forming a thin sheet 1 millim. to 2 millims. in thickness (Plate VII., figs. 1 to 3), and over 9 centims. × 7 centims. in greatest extent (Plate IX., fig. 4).

Ascidiozooids from 6 millims. × 3 millims. on the surface down to 1 millim. in diameter, much flattened from above downwards, so as to form at most slight rounded elevations on the free surface. Ascidiozooids not quite closely placed, leaving some spaces of free test between. Colour (in alcohol) a dull slate-blue, pinkish-red when alive; the test nearly white, with a slight pearly lustre.

Mantle moderately muscular, not pigmented, with well-marked siphons. The atrial siphon has about 20 very delicate tentacles at its base (fig. 7) and there are also some convoluted thread-like outgrowths from the mantle hanging into the peribranchial space.

Branchial Sac with four well-marked folds on each side, with four to six internal bars on each (Pl. VII., fig. 4). The dorsal interspace has one bar, close to the first fold, the next interspace has one, the next two have each two bars, and the ventral interspace has no bar dividing its row of eight or nine stigmata. Most of the meshes contain four or five stigmata each (fig. 4).

Dorsal Lamina a plain narrow membrane.

Tentacles 20 to 22 in number, of two sizes, placed a little irregularly (fig. 5). The tentacles have large swellings at their bases, and the interior of the branchial siphon is marked out into rectangular areas by slight depressions.

Dorsal Tubercle of small size, horse-shoe-shaped (fig. 6).

Gonads hermaphrodite, about 12 on left side of endostyle and six on right. Each gonad has ova in the centre and two testes, one on each side (figs. 8 and 9).

Locality:—Station LXIX., outer Chilaw Paar, 8 to 11 fathoms; along with large colonies of *Leptoclinum*.

This is a handsome species which, from its hermaphrodite gonads, belongs to the genus *Gynandrocarpa* and differs in internal structure from all the described species. It belongs to that section which Michaelsen would separate as the genus *Eusynstyela*, and is allied to Sluiter's two species *Gynandrocarpa maxima* and *G. latericius*, both obtained in Malaysian seas by the "Siboga" expedition. From *G. maxima* our species differs in the smaller size of the ascidiozooids, in the arrangement of the longitudinal bars of the branchial sac and in having fewer tentacles. From *G. latericius* it differs in the details of the branchial sac (see fig. 4), and also in the dorsal tubercle (fig. 6), which is more like that of *G. maxima*. In the tentacles our form agrees with *G. latericius*, and it possesses also those curious long, coiled, thread-like outgrowths from the mantle (fig. 7) to which Sluiter has drawn attention. In fact, the Ceylon species, while possessing a characteristic branchial sac of its own, is in other characters intermediate between the two "Siboga" species. It differs also in details of branchial sac, dorsal tubercle, tentacles, &c., from both the species of *Eusynstyela* described by Michaelsen, viz., *E. tincta* (Van Name) from Bermuda, and *E. hartmeyeri* from the Red Sea, Gulf of Suez, and African coast.

I have great pleasure in dedicating this interesting form to my friend Sir Everard im Thurn, K.C.M.G., who was Colonial Secretary and Lieut.-Governor of Ceylon at the time of my expedition, and who did much to encourage and promote scientific work in the colony.

Other species of Polystyelidæ have been found in far eastern seas and also in the southern part of the Indian Ocean, on the Agulhas bank, but none of these are closely related to the present species.

My "Field-notes" contain the following record as to the colour of this species when alive:—"March 20th, 1902, on outer Chilaw Paar, masses of coral and calcareous tubes covered with colonies of *Leptoclinum* (white, pink, dark neutral tint, &c.), and also a large colony of a Polystyelid of a pink or pale-crushed strawberry tint over the general surface with red apertures and a few red dots between the apertures; between the ascidiozooids the test has a slight bluish-grey tint."

Diandrocarpa brakenhielmi, Michlsn., var. **ceylonica**, n.—Plate VII., figs. 10 to 18.

There are several colonies of a beautiful transparent Polystyelid from the Gulf of Manaar which, from the condition of its gonads, falls, according to Michaelsen's system

('Mitth. Naturh. Mus., Hamburg,' 1904), into the genus *Diandrocarpa*, VAN NAME, and agrees fairly well in details of structure with the species *D. brakenhielmi*, MICHAELSEN. It shows a single hermaphrodite gonad (fig. 12) on each side of the body, and the spermatic sacs are deeply cleft into lobes (fig. 15). There are, however, some points of difference. There are only about 12 folds in the stomach-wall, certainly not so many as 14 or 15, the ducts from the spermatic cæca are certainly longer than MICHAELSEN represents, and, finally, the Ceylon species appears to be more transparent and does not in life, at least, show the bluish grey and other colours noted in the described forms of *D. brakenhielmi*. I do not attach much importance to the last point, since it is probable that MICHAELSEN'S specimens from the Berlin and Hamburg Museums were preserved colonies which had lost their transparency and changed their colour. And as I find that individuals vary somewhat in the folds of the stomach wall, in the proportions of the tentacles, and in other details of structure, I think it best to refer this to the described species with which it closely agrees, calling it the Ceylon variety and figuring its peculiarities. I have specimens in the collection from three localities, and my field-notes in regard to two of these are as follows:—

(1) North end of Periya Paar, Station LXII., 12 fathoms.—"(?) Polystyelid on young pearl oyster shell, translucent grey with lemon-yellow pigmentation, especially along a line (? endostyle) between the apertures, and also around the atrial siphon. Line of red around the edge of each aperture. Under low power of microscope surface is seen to have a reticulum of yellow, pale-blue and red-brown lines which are sinuses filled with pigment corpuscles."

(2) Cheval Paar, 6 fathoms, several colonies.—"A very thin transparent (?) Polystyelid with large ascidiozooids up to 4 millims. long, with very conspicuous branchial sac because the vessels are all engorged with coloured corpuscles. One colony covers a large area in the interior of an old pearl oyster shell and allows the nacre to show through distinctly. Ascidiozooids slightly grey, test between transparent, with a few meandering coloured lines which are vessels."

The third locality is—Attached to oyster cages suspended from the ship on the Cheval Paar; about 20 colonies ranging from 1 centim. × 1 centim. to 7 centims. × 6 centims. over all.

These specimens, although differing a little in appearance, are clearly the same species, and figs. 10 to 18, on Plate VII., show the leading points in structure. There are 10 to 12 rows of stigmata in the branchial sac, and the transverse vessels are very conspicuous from being filled with coloured corpuscles. The vessels in the test, and especially in the marginal parts of the colony, are a conspicuous feature (figs. 11 and 17). There are 12 oral tentacles of three orders, which show, however, some variation in arrangement (figs. 14 and 18). They may be 1, 3, 2, 3, 1, &c., or 1, 3, 3, 3, 1, 3, 2, 3, 3, 3, 2, 3, or 1, 3, 3, 2, 3, 3, 1, &c. There are about 20 much more delicate atrial tentacles (fig. 18) which have not been previously noticed. Fig. 13 shows the alimentary canal and fig. 15 the gonads.

In examining a very simple Polystyelid such as this, with no folds in the branchial sac, one cannot but be struck with the resemblance not merely to the Styelidæ and to the Botryllidæ, which has often been insisted upon, but also to such Clavelinidæ as the genus *Ecteinascidia.* The fact is, that the Polystyelids are an annectant group, and such simple forms as *Diandrocarpa* lead on from the more advanced Clavelinids (such as SLUITER'S *Ecteinascidia nexa*) to the Botryllids and the Styelids.

FAMILY: BOTRYLLIDÆ.

Botryllus ater, n. sp.—Plate VII., figs. 19 and 20.

Colony a small irregular, encrusting patch from the oyster cages on the Cheval Paar.

Test clear and transparent, crowded with terminal knobs in its marginal part.

Ascidiozooids small, and especially narrow; pigmented very darkly and having the branchial aperture so black that it appears to the eye as a distinct dot upon the outer end of the ascidiozooid. From five to ten ascidiozooids in a system.

Mantle and *Branchial Sac* densely crowded with dark pigment.

Botrylloides chevalense, n. sp.—Plate VII., figs. 21 to 24.

Colony thin and encrusting, of irregular form; six colonies range from 3 centims. × 1 centim. to 5 centims. × 3 centims.; of a red colour (in formol), varying from pale brick red to purple.

Ascidiozooids, measuring 1·5 millims. × 1 millim., arranged in elliptical or linear, rarely branching systems (fig. 21).

Branchial Sac richly pigmented, and having about 10 rows of stigmata (fig. 23).

Test clear and transparent, but having a large number of terminal knobs of vessels in its marginal part (fig. 22).

Tentacles of two sizes (fig. 24), four larger and four smaller.

Locality:—Attached to pearl oysters from the oyster cages suspended from the ship while on the Cheval Paar.

Botrylloides nigrum, n. sp.—Plate VII., fig. 25.

Colony small smooth glossy black patches encrusting the branches of *Colella arenosa.* Systems forming a net-work of branching lines (fig. 25).

Test very tough on surface, deeply pigmented.

Mantle with longitudinal muscles only.

Branchial Sac with many rows of stigmata.

Locality:—South of Modragam Paar, 6 fathoms.

Family: DISTOMIDÆ.

Colella arenosa, n. sp.—Plate VII., figs. 26 to 29.

Colony consisting of branched masses (fig. 27) growing through sponges and other attached organisms, and partly encrusted with the black *Botrylloides niger.* The base and larger branches are thickly covered with attached and embedded sand. The twigs terminate in rounded knobs of a pale violet colour and nearly free from sand (fig. 26). Some of the larger masses measure 6 centims. × 3 centims. over all; the branches are 2 millims. to 3 millims. in diameter; the knobs are about 4 millims. across the free end.

Ascidiozooids placed in the free ends of the knobs, from 12 to 20 in each, and having the usual structure of the genus (fig. 26).

The violet pigmentation of the test in these specimens is found, even in the branches, under the sandy coating.

Locality:—South of Modragam Paar, 6 fathoms; half a dozen colonies and fragments. There are also three colonies from Station LXIX., Chilaw Paar, 8 to 11 fathoms, which have exactly the appearance and structure of the above except that the violet pigment is absent, and the free ends of the knobs are dark grey.

Cystodytes ceylonensis, n. sp.—Plate VIII., figs. 23 to 25.

About a dozen small, rounded, or lobed (fig. 23), encrusting colonies belonging to the genus *Cystodytes* were obtained from Talaivillu Paar, 8 fathoms. They were of a bright red purple colour when alive, and range in size from 1 centim. across to 2 centims. × 1·5 centims. The thickness from the attached to the free surface is 5 millims. The colour now, after preservation in alcohol, is a dark greyish brown, and the ascidiozooids show through indistinctly as dirty yellow streaks. Each ascidiozooid has the usual thick calcareous envelope (fig. 24), and the component discs are marked with delicate radial striæ (fig. 25).

A group of several little similar brown colonies, which are indistinguishable from the above in the preserved condition, were dredged at the south-east end of Ceylon on February 13. The colour when alive was not noted.

In structure this form closely resembles *Cystodytes philippinensis*, Hrdn., obtained by the "Challenger" expedition, but differs in colour and in having the discs relatively thinner and more finely striated.

Family: POLYCLINIDÆ.

? Polyclinum nigrum, Hrdn.

A large black colony and some smaller pieces from the pearl banks, Gulf of Manaar, measuring about 6 centims. × 6 centims. and extending up to 1·5 centims. in thickness, may be this Australian species. Our colony has a very smooth shining black surface, and occurs growing over masses of sponges, &c. The surface is marked by large circular depressions, about 1·5 millims. across, which probably correspond to the ends of the ascidiozooids, but no distinguishable remains of the latter are visible on dissection. It is probable that the colony was either dead or regenerating at the time when it was collected.

Amaroucium sp. ?—Plate VIII., fig. 43.

There are several small colonies from the Gulf of Manaar which probably belong to this or one of the allied Polyclinid genera. The largest colony is shown in fig. 43. They are mostly in poor condition, or have lost the ascidiozooids, and consequently I only refer to them for the purpose of stating that a species belonging to this group occurs in the locality.

Psammaplidium ceylonicum, n. sp.—Plate VIII., figs. 8 to 11, and Plate IX., fig. 9.

Colony a large and very sandy mass of rather flabellate form, with vertical walls and buttresses, recalling the appearance of some sponges (see Plate IX., fig. 9); surface lobed, uneven and rough, divided up into small areas (Plate VIII., fig. 11) and very thickly encrusted with sand; size, 15 centims. × 10 centims. × 8 centims.

Ascidiozooids small for the size of the colony, scarcely 3 millims. in length, and less than 1 millim. in greatest breadth; abdomen and post-abdomen very slender, thorax wide (Plate VIII., fig. 8).

Test densely crowded with sand-grains, having the ascidiozooids arranged in its superficial layer only (fig. 10).

Mantle with both longitudinal and transverse muscle bands on the thorax; over the abdomen the longitudinal bands coalesce into two strong bundles which course along the post-abdomen and terminate in two projecting points (fig. 8), which show strong echinations under a high power (fig. 9).

Alimentary Canal long and slender (fig. 8); stomach folded longitudinally.

Tailed larvæ are present in the colony (taken March 7).

Locality:—Station LIV., in north part of Gulf of Manaar, 10 to 30 fathoms.

There are several smaller colonies, and fragments, from various parts of the Gulf of Manaar which are indistinguishable in structure from this species, although they may differ somewhat in appearance on account of the colour or size or amount of the sand-grains taken up by the test.

Psammaplidium aurantiacum, n. sp.—Plate VIII., figs. 2 to 6, and Plate IX., fig. 8.

Colony a large rounded mass (Plate IX., fig. 8), slightly lobed, with a smooth surface only slightly sandy; of a dull orange colour; size, 9 centims. × 7 centims. × 4 centims.

Ascidiozooids up to 3 millims. in length, and rather less than 1 millim. in greatest breadth; dull yellow in colour, embedded in a clear orange-grey test. The anterior ends of the ascidiozooids as seen on the surface are grey.

Test with a few sand-grains scattered on the surface and others embedded in the superficial layers (fig. 2); numerous pigment cells present which give the orange colour to the colony (figs. 3 and 4).

Mantle with strong muscle bundles running both longitudinally and transversely, and causing considerable corrugation of the thorax (fig. 5).

Alimentary Canal forming a large loop, stomach with longitudinal folds, rectum wide (fig. 6).

Locality :—Cheval Paar, 7 fathoms, one colony.

There are two other colonies in the collection from the Gulf of Manaar which, notwithstanding their rather different appearance, I am inclined to refer also to this species. The one is a grey *Psammaplidium* measuring 7 centims. × 5 centims. × $1\frac{1}{2}$ centims., rounded, smooth, and only slightly sandy. The test is grey and transparent, allowing the more opaque grey ascidiozooids to show through, and only differing from the test of *Ps. aurantiacum*, as described above, in the absence of pigment cells.

The other colony is a hemispherical mass, 4 centims. × 4 centims. × 2 centims., of grey colour, but not so transparent as the last and having a yellowish tint. The thorax, abdomen and post-abdomen are each about 1 millim. in length; there are eight large tentacles; the stigmata are small and of rounded form.

Psammaplidium, spp., A and B (? n. spp.)—Pl. VIII., fig. 7: Pl. IX., figs. 10, 11.

In addition to the two species of *Psammaplidium* described above, there are two others which may possibly be distinct from all known species, and from one another, but which I do not feel sufficiently certain of to describe from the present specimens. Both species are densely sandy, and of both one or two large colonies were found in addition to fragments.

The first form (A) is a plano-convex mass, the largest colony measuring 9 centims. × 6 centims. × 3 centims., and probably attached by the whole of the flat surface. The upper rounded surface is divided up into many lobes (Plate IX., fig. 10) which, however, are closely packed together. The mass is most closely impregnated with sand, both on the surface and throughout its depths, so as to appear on section like a consolidated mass of sand. The ascidiozooids are small, not at all abundant, and can only be separated in fragments. They show nothing unusual or specially characteristic in their structure. This colony was dredged in the Gulf of Manaar in February, 1902; and a second, measuring 6 centims. × 5 centims. × $2\frac{1}{2}$ centims., is from Station LIII., 10 miles north of Cheval Paar, 10 fathoms.

The second colony (B) measures 7 centims. × 4 centims. × 3 centims., and is irregularly lobed and produced into bars which join, leaving holes. The surface is covered with a reddish sand, formed of very fine and uniform grains of ellipsoidal shape and quite smooth, which surround the anterior ends of the ascidiozooids (Plate VIII., fig. 7). In addition to these uniform red granules, which are singularly like fæcal pellets, there are a few ordinary irregular sand-grains embedded in the test.

The ascidiozooids are very small, of a translucent grey colour, rather closely placed, and are mainly in the superficial 2 millims. This colony (fig. 11) was dredged at Station LIV., in the northern part of the Gulf of Manaar; depth, 10 to 30 fathoms.

A few other smaller *Psammaplidium* colonies were found which are too fragmentary or imperfect to describe. Some of these are from Muttuvaratu Paar (Station LIX.), 9 fathoms. Others are small sandy lobed masses with areas of black test showing at the ends of the lobes. The test is densely pigmented black, the branchial aperture is eight-lobed, and the atrial has a languet. The masses are about 3 centims. × 1 centim., and the locality is Gulf of Manaar.

Family: DIDEMNIDÆ.

Hypurgon skeati, I. Sollas—Plate VIII., fig. 1, and Plate IX., fig. 5.

This remarkable form was described by Miss I. B. J. Sollas from a specimen found at Pulau Bidang in the Malay Peninsula; and my specimen, from the pearl banks in the Gulf of Manaar, agrees sufficiently closely in detail to be referred not only to the genus but to the same species.

The single Ceylon colony measures over 8 centims. × 4 centims. between its extremes, but is spread over a slightly branched tube and some tufts of Algæ, as seen in Plate IX., fig. 5. The surface is of a warm grey-green colour; and the ascidiozooids, measuring 0·3 millim. across their free ends, are arranged in single lines on each side of the branched cloacal tubes which meander over the surface, with some few occasionally scattered between (Plate VIII., fig. 1)—a more regular arrangement than is described by Miss Sollas.

Didemnum areolatum, n. sp.—Plate VIII., figs. 26 and 27.

Colony encrusting, about 6 centims. × 4 centims. over all, of irregular shape, and 2 millims. thick; with numerous small systems of four, six, or more ascidiozooids (figs. 26), which gives the surface an areolated appearance.

Ascidiozooids of a dirty white colour, due to the calcareous spicules that surround them, while the test between is an amber brown. The branchial apertures show as conspicuous dark points. Ectodermal processes run out into the test.

Test much vacuolated in the lower part (fig. 27) and having many small pigment cells in the upper part giving the brownish colour. There are also spherical calcareous spicules which in some places become stellate with blunt rounded points, but in others are merely knobbed (fig. 27).

Tailed larvæ are present in the test (taken March 20).

Locality:—Station LXIX., Chilaw Paar, 8 to 11 fathoms.

Leptoclinum margaritiferæ, n. sp.—Plate VIII., figs. 19 to 22, and Plate IX., fig. 7.

The *Colony* is a large, moderately thick encrusting mass covering a clump of four pearl oysters (Plate IX., fig. 7). The surface is smooth and soft. The colour when alive was greyish, mottled and streaked with black and white; now, after preservation, it is of a pale pink or crushed-strawberry tint. The size of the mass of oysters and Ascidian together is 9 centims. × 7 centims. × 6 centims. over all.

The *Ascidiozooids* are numerous all over the surface of the colony, and are usually scattered irregularly. In some places they are in double rows, or there are vacant tracts between them (see fig. 7). Common cloacal apertures are few and small. The anterior ends of the ascidiozooids are about 0·5 millim. across.

The *Test* is soft and not opaque. It is of a greyish colour with a slightly pink tint. The calcareous spicules are stellate (fig. 20), but are not very abundant. A thin layer is found on the surface, and in deeper sections they occupy the lines of test which separate the ascidiozooids (fig. 19). There is also a clump of spicules on each side of the thorax of the ascidiozooid. Rounded masses of pigment granules are also present in abundance in the test (fig. 20), as well as small branched test-cells.

The *Branchial Sac* has four rows of short rounded stigmata (fig. 22).

The *Tentacles* are short and thick, 16 in number.

The *Testis* is lobed, with the usual spiral vas deferens (fig. 21).

Locality:—Station XIX., Palk Bay, south of Mandativu, trawl, 5 fathoms.

Leptoclinum pantherinum, Sluiter.

One colony measuring 12 centims. × 6 centims. and several smaller fragments, obtained from Talaivillu Paar at a depth of 8 fathoms, appear to belong to this species. They are of a dirty cream colour streaked with brown. The colour is due to aggregations of pigment corpuscles in the test. There were fully developed tailed larvæ in the colony when collected (April 1). Another small colony was dredged at Station LXIX., Chilaw Paar, 8 to 11 fathoms.

Leptoclinum ceylonicum, n. sp.—Plate VIII., figs. 15 to 18; Plate IX., figs. 1, 2.

A number of colonies, large and small, of a white *Leptoclinum*, which occurs growing over the coarse sand and calcareous fragments of the sea-bottom both in the Gulf of Manaar and in the lagoon at Galle, are so similar in their general characters that, although they show some variation, I think it right to unite them as one species. Two somewhat divergent colonies are reproduced about half natural size, from photographs, in figs. 1 and 2 on Plate IX. Fig. 1 is a colony measuring 16 centims. × 15 centims. × 8 centims., from Station XIX., in Palk Bay, 8 fathoms; while fig. 2 is a mass of about 12 centims. × 10·5 centims. × 6 centims., of plano-convex form, from Station II., off Chilaw, 14 fathoms (the flat surface is shown). In each case those figured are samples of several other colonies, and they show well the characteristics of the species. Colonies were also obtained from the coral reef at Galle and from Aripu reef in the Gulf of Manaar.

The included coarse sand-grains and shell fragments are readily seen, especially in fig. 1, and the interior of the mass contains others which render the substance very brittle. In macroscopic structure this species is sponge-like, there being numerous passages and spaces bounded and crossed by bars of tissue (Plate VIII., fig. 15). The walls of the deeper passages are raised up to form numerous tubercles, as shown in Plate VIII., fig. 16, which represents an optical section.

There are very few cloacal openings visible on the colony, and the ascidiozooids, which show as greyer and more translucent spots on the opaque white surface, seem quite irregularly scattered over the surface (fig. 17). They are small and numerous and have no marked characteristics. The stellate spicules are very abundant, especially near the surface, and as a result the colony has a gleaming white appearance. The rays of the spicules are short and blunt or even rounded at the end (fig. 18).

Leptoclinum ceylonicum, var. **planum**—Plate IX., fig. 4.

I place in this variety two large colonies, measuring 18 centims. × 11 centims. and 12 centims. × 12 centims., and one smaller (12 centims. × 7 centims.), which (along with a colony of *Gynandrocarpa imthurni*) is figured from a photograph (fig. 4) about half natural size. All three occur encrusting dead corals and masses of *Vermetus* tubes from Station LXIX., Chilaw Paar, depth 8 to 11 fathoms, in the Gulf of Manaar. They are very similar to the colonies of *L. ceylonicum* in structure and as seen in thin sections, but differ in forming more of a flat continuous sheet in place of lobes and bars. That difference, however, may be due to the firmer sub-stratum which they encrust. They have not quite the same gleaming white appearance, but this is a character in which parts of the same colony may differ; so I cannot consider these colonies from Station LXIX. as being of more than varietal rank.

Leptoclinum ramosum, n. sp.—Plate VIII., figs. 12 to 14, and Plate IX., fig. 3.

This species is represented by a single very large colony growing over the dead sclerobase of an Alcyonarian coral dredged just outside the pearl banks in the Gulf of Manaar. The colony measures about 20 centims. in length and is about 7 centims. across at the widest, an average width is 5 centims. The colony branches and anastomoses in a characteristic manner (Plate IX., fig. 3) so as to leave numerous spaces and passages. The branches or bars are about 5 millims. in diameter on the average. The colour is a dead milk-white. Very few cloacal openings are visible, and the ascidiozooids are not conspicuous. In most parts they are few and distant, in some few places they are more abundant and more conspicuous. The marks caused by the ascidiozooids vary in size from 0·5 millim. to 1 millim. across.

The spicules are much larger than those of the last species and are more densely packed on the surface, where they form an opaque layer even in thin sections (fig. 12), and less densely deeper down, where they frequently run in lines so as to form a reticulation (fig. 13). The rays of the spicules are much more regular (fig. 14) and more sharply pointed than in the case of the last species.

Leptoclinum viride, n. sp.—Plate VIII., figs. 28 to 33.

Colony small encrusting masses (fig. 28) covering the stems of the large zoophyte *Campanularia juncea;* extent about 3 centims. × 2 centims.; of a green colour when alive, dull white when preserved.

Test with the surface layer packed with small rounded cells containing green granules (fig. 29); deeper layer (fig. 30) contains many stellate calcareous spicules.

The surface of the colony is marked off into areas by branching grooves, along the sides of which the ascidiozooids are arranged (fig. 28). The distribution of the ascidiozooids and spicules, as seen in a surface section, is shown in fig. 33. The spicules are placed most densely between the ascidiozooids, and only sparingly over the surface in lines radiating from the branchial aperture.

Fig. 31 shows one of the round cells containing green granules highly magnified, and fig. 32 is one of the larger spicules to show the characteristically blunt points.

Locality:—Station XLIX., south of Periya Paar, 13 fathoms.

Leptoclinum, spp. (?).

In addition to the species of *Leptoclinum* described above, there are many smaller colonies and fragments in the collection which seem too indeterminate and imperfect to be identified. Some of them may be undescribed forms, but if so they are probably poor specimens which possibly do not show well some characteristics of their species. It may be worth while, however, to mention the localities of some of these colonies in order to give a more correct impression of the abundance of the genus round the coast of Ceylon.

On Chilaw Paar:—

A smooth yellow-brown *Leptoclinum.*
A snow-white solid species.
An echinated form (Plate VIII., figs. 41 and 42) with many cloacal apertures.
Also an ordinary dull white form.

On Cheval Paar:—

Small white colonies encrusting sponges.
A snow-white densely calcareous form.
Pieces of a brown *Leptoclinum.*

On Navakaddua Paar:—

Some small fragments of an ordinary white form in which the spicules are spherical, with low flat knobs in place of projecting points.

Off Negombo:—

Ordinary dull creamy-white colonies.

Off Mutwal Island, March 19:—

Mottled dark blue-black and white form.

Off Mount Lavinia, 30 fathoms:—

Ordinary white *Leptoclinum.*

On the Coral Reef, Galle:—

Fragments of white, grey, drab and dark purple Leptoclinids too small to describe satisfactorily.

Family: DIPLOSOMATIDÆ.

Diplosoma viride, n. sp.—Plate VIII., figs. 34 to 40, and Plate IX., fig. 6.

Colony rounded to elongate, moderately thick, encrusting on Algæ and Coral fragments (Plate IX., fig. 6); surface even and soft; colour, rich green; size, from 2 millims. in diameter up to 4 centims. in length × 1 centim. in breadth × nearly 1 centim. in thickness.

Ascidiozooids about 0·5 millim. across anterior end; arranged irregularly, in the smaller colonies forming a single row round the edge (Plate VIII., fig. 34).

Test having two distinct layers; the spreading margin of the colony, often drawn out into delicate processes (fig. 36) for attachment, is formed of highly vesicular test, full of bladder cells, while the deeper part in which the ascidiozooids are embedded is much denser, has no bladder cells, and is crowded with small test cells and with large spherical green bodies which give the colour to the colony.

Branchial Sac with four rows of rather small rounded stigmata (figs. 37 and 38). The transverse vessels have muscle fibres.

Tentacles six in number, all one length.

Alimentary Canal large, stomach smooth-walled, rectum conspicuous, containing three or four fæcal pellets (fig. 36).

Localities.—(1) On Coral Reef, Galle; (2) Talaivillu Paar, 8 fathoms.

The colonies of this small dark green *Diplosoma* are very abundant at both localities where they were found. On Talaivillu Paar they occur growing over broken fragments of Madrepores and other dead corals, and in the lagoon at Galle they are abundant, encrusting calcareous and other Algæ. Most of the colonies are small and rounded, but some become more elongated and form small encrusting sheets. The usual occurrence, however, is numerous small rounded colonies, closely placed, which may cover an area up to 8 centims. × 5 centims. When alive, the centre of the colony where the common cloacal aperture is placed is depressed and of a paler green colour. The zone of ascidiozooids is also paler, while the outer ring of the colony, outside the ascidiozooids, is the darkest and is usually of a very rich green colour (see fig. 40). The preserved specimens have entirely lost their colour and are now opaque white.

The green colour is due to immense numbers of small round bodies which are probably symbiotic Algæ. They have a central clear space (fig. 35), while around that is a finely granular pigmented layer. These pigmented cells are specially abundant in the outer layers of the test; they are also around the bodies of the ascidiozooids, and they extend more sparsely scattered through the loose lacunar test that occupies the centre of the colony (fig. 40). Vessels with swollen terminal knobs (fig. 36) are a conspicuous feature in the thin expanded margin of the colony.

Diplosoma crystallinum (Giard).

A number of small colonies of a grey semi-transparent *Diplosoma* which were found encrusting pearl oysters and sponges, &c., in the oyster cages suspended from the ship at the Cheval Paar, are indistinguishable from the common European *D. crystallinum*. There are long pointed lobes to the branchial siphon, the ascidiozooids have large eggs, and many tailed-larvæ are embedded in the test (taken in April). Ten colonies range from 1 centim. to 3 centims. in length.

Diplosoma, sp. (?)—Plate VIII., fig. 44.

Four small reddish-brown colonies were dredged from Muttuvaratu Paar (Station LIX.), 9 fathoms, which resemble *D. viride*, from Galle, in structure, but have pigment spherules of a different colour in the test. The colony is fixed by a small base, has overhanging edges and a flat upper surface with a little central tubercle which probably marks the position of the common cloacal aperture (fig. 44). The ascidiozooids show as dots on the surface, and in profile on the margin. The test is very tough, is vacuolated as in the case of *D. viride*, and contains many rounded pigment masses of a reddish colour.

Family: SALPIDÆ.

Salpa cylindrica, Cuvier.

Some individuals of both the solitary and the aggregated forms of this species were obtained in tow-net gatherings on the West Cheval and the Periya paars, and in Palk Bay. The solitary forms extend up to 29 millims. in length, and single members of the chain form up to 14 millims.

My "Field-notes" contain some observations on the specimens of this species taken in Palk Bay. "The body is nearly cylindrical, when alive, with projecting ridges along the sides. The 'nucleus' is marked with yellow, brown, and red. The stomach is brown with yellow cæca around it. When swimming, the tubular orifices are drawn in and shot out again almost simultaneously. They certainly do not alternate. If not quite simultaneous the order is:—oral, atrial, long pause, oral, &c. The aggregated forms are arranged longitudinally in chains and are iridescent when in movement, and look pale blue on a black background."

Salpa runcinata-fusiformis, Cham.-Cuv.

Considerable numbers of both the solitary and the aggregated forms were found along with the last species both in Palk Bay and also on the West Cheval and Periya paars. The solitary form reaches 30 millims. and the aggregated 24 millims.

In some hauls of the tow-net taken off Negombo at Station I. some small specimens of both the solitary and the aggregated form (reaching only 9 millims. or 10 millims.) were obtained.

Salpa democratica-mucronata, Forsk.

Some of the aggregated form were taken in the bay at Galle in February. Many of both solitary and aggregated forms were obtained off Negombo at Station I. with the last species. A few occurred also in Palk Bay.

Family: DOLIOLIDÆ.

Doliolum sp. (?).

Unfortunately the specimens of *Doliolum* are no longer in the collection, but the genus was noted as being present at the following localities :—

On West Cheval and Periya paars (" nurse-form with broad bands").

Galle Harbour, February 17 (" small adult form").

The genus can therefore be recorded from both ends of the island.

Family: APPENDICULARIIDÆ.

Oikopleura sp. (?).

A small species of *Oikopleura*, with no noticeable characteristic features, occurred :—(1) off Negombo, Station I.—many small individuals ; and (2) Galle Bay, February 17.

One of the specimens obtained at Galle was larger than the rest, had a large flat pointed tail bearing two crimson spots near the end. There is some violet pigment in the branchial sac and a yellow spot at the anterior end of the endostyle. We do not yet know the permanence and the value of these pigments in classification. Dr. A. Willey got bright yellow and brilliant blue specimens in New Britain, and Mr. E. T. Browne found an *Oikopleura* with crimson pigmentation at Valencia, in Ireland. All that I can do at present is to record that the genus *Oikopleura* (probably two species) occurs round the coast of Ceylon.

REPORT

ON THE

BRACHYURA

COLLECTED BY

PROFESSOR HERDMAN, AT CEYLON, IN 1902.

BY

R. DOUGLAS LAURIE, B.A. (OXON.),
DEMONSTRATOR OF ZOOLOGY IN THE UNIVERSITY OF LIVERPOOL.

[WITH TWO PLATES AND TEXT-FIGURES.]

INTRODUCTORY.

THE collection comprises 208 species, of which 15 are described as new, and of the latter, three are referred to new genera. Of the three new genera, two are Xanthids (one a large crab which I place near to *Zozymus*—the other a curious little animal with a *Kraussia*-like carapace and a most remarkable hand); the third belongs to the interesting group of Rhizopinæ.

The new species belong to the following genera :—*Dromia* (1), *Tlos* (1), *Achæus* (1), *Halimus* (2), *Cryptopodia* (1), *Doclea* (1), *Actæa* (1), *Euxanthus* (1), *Neptunus* (2), *Pinnoteres* (1), and the three new genera, *Demania* (1), *Mertonia* (1), and *Calmania* (1).

Descriptions of some little known forms have been revised in the light of examples contained in the collection. Among these may be mentioned *Philyra adamsi*, about which there has been misunderstanding. Many of the species and even some of the genera in the collection are new to the India fauna, and the majority had not previously been recorded from the coast of Ceylon.

A matter of considerable interest—both general and systematic—is well illustrated among the Oxyrhyncha collected. I refer to the phenomenon which GEOFFREY SMITH has recently* investigated very thoroughly in *Inachus scorpio* (= *dorsettensis*)

* 'Mittheil. Zool. Stn. Neapel,' xvii., p. 312; see also H. A. HAGEN, "N. Amer. Astacidæ," in 'Ill. Cat. Mus. Comp. Zool. Harvard,' 1870; W. FAXON (1) 'Amer. Journ. Sci.,' xxviii., p. 42, and (2) 'Revision of the Astacidæ,' part i., 1885.

and termed by him facultative dimorphism. SMITH has shown that in males of this species there are at least two breeding periods ("low" and "high" respectively) characterised by well-developed secondary sexual characters, and that between these is intercalated a non-breeding phase ("middle") in which the secondary sexual characters are not evident. What SMITH has concluded for *Inachus scorpio* from statistical evidence, WALTER FAXON had found in a *Cambarus* reared by him in an aquarium. HAGEN had previously described two types of male *Cambarus* and considered them to be characteristic of different individuals, but FAXON, observing aquarium-kept animals, found that the two conditions detailed by HAGEN were alternate phases in the life-history of the same individual correlated with the breeding and non-breeding period respectively; the breeding male with pronounced secondary sexual characters changed by a moult to the non-breeding form with much resemblance to the young. A very beautiful example of facultative dimorphism is added to the above by a series of *Menæthius monoceros* in the present collection. There is evidence that the same kind of thing is of wide occurrence amongst the Oxyrhynchs.

The importance of the matter for systematic zoology may be emphasised by reference to *Simocarcinus simplex* and *S. pyramidatus*, one of the very few differentia between which is the cheliped character—a difference for which the theory of facultative dimorphism offers an alternative explanation.

In working over a large collection of crabs, attention is constantly attracted by the considerable amount of growth and of correlation-change which commonly occurs after sexual maturity.

Certain contractions have been found convenient in the following pages:—

C. = carapace. Ch. = cheliped, W.L. = walking leg, F. = finger (dactylus of cheliped), H. = hand, l. = length, b. = breadth, Bord. = border, R. = rostrum. Unless otherwise stated, Ch.l. is measured along the morphological ventral border, and is the sum of (1) a straight line uniting the base of the appendage to the distal end of the merus, and (2) a straight line uniting the last-named point to the tip of the fixed finger. In Oxystomata it is measured along middle of posterior surface.

Measurements are in all cases given in millimetres.

Colonel ALCOCK'S "Materials for a Carcinological Fauna of India" is indispensable to the student of Indian crabs. I have followed him where possible in matters of nomenclature and classification.

Space forbids synonymies; I have in most cases made reference to one good account only of the species in question. A useful list of the literature will be found in KLUNZINGER (1906). The following contractions have been employed:—

A.1.–A.6. = ALCOCK, "Materials, &c.," No. 1–No. 6, in 'Journ. Asiat. Soc. Bengal, 1895 to 1900.

A.Cat. = ALCOCK, 'Cat. Ind. Decap. Crust. Ind. Mus.' Part I. Brachyura. Fasc. 1. Dromiacea, 1901.

A.Invest. = ALCOCK, "Crust." in 'Illusts. Zool. "Investigator."'

B.I.–B.XIII. = BORRADAILE'S Crust. in GARDINER'S 'Fauna, &c., Mald. and Lacc.'

N. = NOBILI, 'Bull. Sci. France et Belg.,' vol. xl., 1906.

K. = KLUNZINGER, 'Spitz- u. Spitzmund-Krabben d. Rothen Meeres.' Stuttgart, 1906.

C. = CALMAN, 'Trans. Linn. Soc.,' ser. 2, Zool., vol. viii., 1900.

H. = HENDERSON, 'Trans. Linn. Soc.,' ser. 2, Zool., vol. v., 1893.

R. = RATHBUN, 'Bull. U.S. Fish. Comm. for 1903.'

My thanks are due in the first instance to Professor HERDMAN for entrusting to my examination this large and interesting collection. Much of the work has been done at the British Museum, and my indebtedness is great to Dr. CALMAN for the courtesy and kindness with which he has facilitated my work among the collections under his charge. Finally, I thank Miss WOODWARD for her excellent drawings and Mr. H. HERRING and Mr. W. J. DAKIN for valuable photographic aid.

DESCRIPTION OF THE SPECIES.

DROMIACEA.

Dromia intermedia, n. sp.

Locality :—Deep water off Galle, one specimen.

Description :—Female, non-ovigerous, but quite possibly mature.

C.l. 23·50, including frontal teeth.

$C.b._1$ 23·50, straight line uniting tips of last pair of antero-lateral teeth.

$C.b._2$ 23·00, straight line uniting tips of teeth immediately behind cervical groove.

W.L.2.l. 27·25, sum of dorsal borders of (1) meropodite and (2) the three distal segments together (9·0 + 18·25). W.L.3.l. 14·00 (5·5 + 8·5). W.L.4.l. 16·00 (7·0 + 9·0).

It agrees with ALCOCK'S description (A.5, p. 138; A.Cat., pl. ii., fig. 5) of *Dromia cranioides*, DE MAN, except in two very obvious particulars, in which it resembles *Dromia rumphi*, FABRICIUS, 1798 (A.5, p. 137; A.Cat., pl. ii., fig. 4), namely :—(1) Walking leg 4 but little longer than walking leg 3; (2) the sternal grooves of the female terminate on very prominent tubercles set well apart on anterior portion of segment of walking leg 1. A third difference from *D. cranioides* is that the spine on the distal end of the "posterior" border of the propodite of walking leg 4 is slender and only about ½ length of "anterior" spine (*i.e.*, the one opposing the dactylopodite). There are on the same segment various smaller spinules.

Dromidia unidentata (RÜPPELL), 1830—A.5, p. 139; A.Cat., pl. ii., fig. 6.

Locality :—West of Periya Paar, Station LXIII., 17 to 24 fathoms, one specimen.

Description : Ovigerous female, C.l. = 11·00; C.b. ÷ C.l. = 1·00.

The present example is about half the size of those recorded by ALCOCK, DE MAN, and HENDERSON.

Dromidiopsis australiensis (HASWELL), 1882—A.Cat., p. 76.

Localities:—Chilaw Paar, Station LXIX., 8 to 11 fathoms, one specimen (*a*); Jokkenpiddi Paar, 10 fathoms, one specimen (*b*).

Description:—(*a*) Ovigerous female, agrees fairly well with ALCOCK'S description, C.l. = 16·50; C.b. ÷ C.l. = 0·97. (*b*) This is BORRADAILE'S var. *bidens*, 1903 (B.IX., p. 576), C.l. = 9·25; C.b. ÷ C.l. = 0·97.

Cryptodromia canaliculata, STIMPS., 1858—A.5, p. 142; A.Cat., pl. ii., fig. 8.

Locality:—Galle, one specimen.

Description:—Young male, C.l. = 4·25; C.b. ÷ C.l. = 1·12.

In this young specimen the second of the two teeth on the antero-lateral border of the carapace is represented by a bluntly angular lobe.

Cryptodromia bullifera, ALCOCK, 1899—A.5, p. 143; A.Cat., pl. ii., fig. 9.

Locality:—Cheval Paar, one specimen.

Description:—Young female, C.l. = 5·50; C.b. ÷ C.l. = 1·00.

Cryptodromia demani, ALCOCK, 1899—A.5, p. 144.

Locality:—Station LIV., 10 fathoms, south of Manaar Island, two specimens.

Description:—

	(*a*) ovigerous female.	(*b*) ad. non-ov. female.
C.l.	5·40	5·50
C.b. ÷ C.l.	1·02	1·04

I believe the present forms may be placed under the above species, which has not been hitherto figured. The characteristic dorsal hepatic tooth is weak in (*a*), a little more strongly developed in (*b*). The dactylopodite of walking leg 4 is apposed by a quite fairly developed spine of the propodite; the propodite of walking leg 3 bears a similar but smaller spine. A transverse groove runs behind the front and orbits. The sternal grooves end apart, without very obvious tubercles, just behind the segment bearing the chelipeds.

Cryptodromia hilgendorfi, DE MAN, 1887—A.5, p. 145; A.Cat., pl. iii., fig. 11.

Locality:—Mutwal Island, Station LXVI., 30 fathoms, one specimen.

Description:—Ovigerous female, C.l. = 14·50; C.b. ÷ C.l. = 1·03.

There is a slight indication of a second tooth on the antero-lateral border of the carapace, behind the tooth at the antero-lateral angle.

Remarks:—BORRADAILE has in his suggestive revision of the Dromiacea ('Ann. Nat. Hist.,' ser. 7, vol. xi., p. 299, 1903) included the present species in a new genus, *Dromides*. NOBILI (p. 93) criticises this genus

Cryptodromia gilesi, Alcock, 1899—A.5, p. 146; A.Cat., pl. iii., fig. 13.

Locality :—Gulf of Manaar, one specimen.

Description :—Male, C.l. = 8·25; C.b. ÷ C.l. = 1·03 (C.b. = straight line uniting tips of last antero-lateral teeth).

Conchœcetes artificiosus (Fabr.), 1798—A.5, p. 151; A.Cat., pl. iii., fig. 16.

Locality :—Trincomalee, three young specimens (*a*, *b*, *c*).

Description :—

	(*a*)	(*b*)	(*c*)
C.l.	7·00	7·00	7·25
C.b. ÷ Cl.	—	0·96	0·96

Remarks :—New to the Ceylon fauna.

Conchœcetes andamanicus, Alcock, 1899—A.5, p. 152; A.Cat., pl. iii., fig. 17.

Locality :—Pearl banks, Gulf of Manaar, one specimen.

Description :—Male, probably adult. C.l. (frontal teeth included) = 10·25; C.b. ÷ C.l. = 1·00.

It confirms Alcock's doubtfully created species, showing, however, certain additional points of difference from *C. artificiosus* not mentioned by Alcock :—(1) Prominent fringe of longish hairs on antero-lateral borders of carapace; (2) well-marked median longitudinal groove on anterior part of the carapace running back from notch between the frontal teeth (its length ÷ C.l. = 0·19); (3) the well-developed pair of frontal teeth more strongly deflexed; (4) sub-hepatic regions by no means so swollen, in correlation with which one finds that the antero-lateral border of the buccal cavern slopes downwards from the straight anterior border of the same region at a more obtuse angle (80° approximately instead of 65° approximately); (5) a kind of elongated tubercle occupies middle region of a not very well-marked ridge connecting lateral termination of cervical groove and antero-lateral angle of buccal cavern.

The specimen is protected by a *Pectunculus* valve.

OXYSTOMATA.

Calappa lophos (Herbst), 1785—A.2, p. 144.

Localities :—Trincomalee, one specimen (*a*); Gulf of Manaar, one specimen (*b*).

Description :—

	(*a*) young female.	(*b*) young male.
C.l.	8·50	14·75
C.b. ÷ C.l.	1·26	1·36

Remarks.—Recorded as fossil by de Man from post-tertiary of Celebes ('Samm. Geol. Mus. Leiden,' (1), vii., p. 277, 1904).

Calappa philargius (Linnæus), 1764—A.2, p. 145.

Localities :—Gulf of Manaar, one specimen (*a*); Station I., off Negombo, one specimen (*b*); pearl banks, Gulf of Manaar, four specimens (*c*, *d*, *e*, *f*); Galle, one specimen (*g*).

Description:—

	(*a*).	(*b*).	(*c*).	(*d*) young ♀.	(*e*) young ♀.	(*f*) young ♀.	(*g*) adult ♂.
C.l. . .	12·75	12·75	13·50	21·00	22·00	30·00	37·50
C.b. ÷ C.l.	1·25	1·25	1·27	1·32	—	1·38	1·44

Specimens (*f*) young female and (*g*) male answer well to ALCOCK's description. In the young forms (*a* to *e*) the endostome septum is deeply concave anteriorly, and this is to be noted since the strongly *convex* character of this region is one of three characters by which ALCOCK distinguishes adults of *C. philargius* from those of *C. lophos*. A parasitic *Sacculina* is attached to the abdomen of (*g*) male ventrally, in the joint between somite VI. and the telson—it has not produced any obvious change of the secondary sexual characters.

Calappa gallus (HERBST), 1803—A.2, p. 146.

Localities:—Series (A)—Mutwal Island, Station LXVI., one specimen; south of Modragam, one specimen; Chilaw Paar, Station LXIX., one specimen; coral reefs, Gulf of Manaar, two specimens; pearl banks, Gulf of Manaar, six specimens. Series (B)—Coral reefs, Gulf of Manaar, two specimens; pearl banks, Gulf of Manaar, eleven specimens; Gulf of Manaar and Palk Straits, three specimens; off Kaltura, Station XLIII., 22 fathoms, one specimen; west of Periya Paar, Station LXIII., 17 to 24 fathoms, two specimens; ten miles north of Cheval, one specimen.

The specimens fall into two morphological series (A and B) which differ in certain particulars. Members of both series are often obtained from the same locality. The figures of HERBST and of KLUNZINGER (K., pl. ii., fig. 14) answer in general to (A), and that of BRITTO CAPELLO to (B). The differences are as follows:—

Rostrum.—(A) Anterior border blunt and not at all or but little emarginate; indications of two blunt longitudinal ridges on ventral surface.

(B) General appearance more elegant; anterior border sharper and more definitely emarginate; longitudinal ridges of under surface are fairly sharp compared with (A).

Teeth of hepatic region of antero-lateral border small in (A); obsolescent in (B).

Tubercles of Carapace.—(A) The rounded tubercles tend to be rough and fairly prominent; the beaded squamiform tubercles occupy a good deal of posterior half of carapace, and they form lines which curve forward on the clypeiform expansions.

(B) Rounded tubercles smoother and more flattened; the beaded tubercles occupy a more limited region, and form lines which are approximately straight on the clypeiform expansions.

Hepatic region strongly concave in (A); slightly concave in (B).

Hair.—(A) Posterior border of carapace and of clypeiform expansions sparsely fringed; three characteristic tufts placed transversely on abdominal tergum II.; a fringe on under surface of meropodite of walking leg 4. In (B) hair is absent in these regions.

Post-cardiac transverse groove slight but distinct in (A); absent in (B).

Third tooth of clypeiform expansion.—(A) Less acute than in (B); points obliquely forward; has anterior border ÷ posterior border = 0·54 (average of eight specimens).

(B) Acute; points laterally; has anterior border ÷ posterior border = 0·90 (average of nine specimens).

I do not suggest that the above distinctions would be absolute or their correlation perfect for a large series. This would be to separate series (B) as a species apart from *C. gallus*.

In the British Museum is a specimen (adult female, Philippine Islands, 43.6) which combines the (A)-type of front with the (B)-type of the other characters. Another unites the deep hepatic concavity of (A)-type with a more (B)-like front. BRITTO CAPELLO'S figure suggests that his specimen had rougher, more prominent tubercles than (B).

One of present series (B) has a line of hairs posteriorly as in (A) and traces of the same occur in three others.

It is best, I think, for the present, to consider the two groups as varieties which one may call :—(A), var. *gallus*, and (B), var. *capellonis*.

The best distinction between them is perhaps the shape and direction of the 3rd tooth of the clypeiform expansion, which may be expressed by index anterior border ÷ posterior border. Examination of this character in our series shows :—

Var. *gallus* . .	Mean = 0·54;	range of variation = 0·50–0·55 (8 examples).
,, *capellonis* .	,, = 0·90;	,, ,, = 0·83–1·07 (9 ,,).

Growth changes do not affect correlation much in these specimens :—

In var. *gallus*, 10 specimens considered (6 young + 4 adult).

	6 females (1 adult).	4 males (3 adult).
C.l.	9·00–31·50	10·25–33·25
$C.b._1 \div C.l.$.	0·95– 0·98	0·95– 0·96
$C.b._2 \div C.l.$.	0·81– 0·86	0·78– 0·85 (Index decreases with size).

Var. *capellonis*, 19 specimens (1 adult male).

	10 females.	9 males.
C.l.	7·25–25·75	8–33·25
$C.b._1 \div C.l.$ ..	0·98– 1·00	0·95–1
$C.b._2 \div C.l.$.	0·79– 0·88	0·74–0·90 (Index decreases with size).

($C.b._1$ = in front of clypeiform expansions. $C.b._2$ = across 3rd tooth of clypeiform expansions.)

Mursia bicristimana, ALCOCK & AND., 1894—A.2, p. 150; A.Invest., pl. xxiv., fig. 5.

Locality :—Gulf of Manaar and Palk Straits, two specimens.

Description :—	C.l.	C.b. (in front of lateral spines) ÷ C.l.	Lateral spine l. (anterior border) ÷ C.l.
(*a*) Ovigerous ♀ . .	17·00	1·21	0·22
(*b*) Adult ♂. . . .	17·25	1·22	0·22

The specimens are about one-third the size given by ALCOCK.

The hairs on outer parts of pterygostomian and subhepatic regions are not long, nor do they form a dense felt.

Length ÷ breadth of meropods of walking legs 1, 2 and 3 is only about 0·33 (*e.g.*, meropod W.L. 3 of (*a*) ovigerous female = 9·5 ÷ 3·15).

Cryptosoma granulosum (DE HAAN), 1835—A.2, p. 152.

Locality :—Aripu coral reefs, Gulf of Manaar, two specimens.

Description :—(*a*) Adult male, C.l. = 19·50 ; C.b. ÷ C.l. = 0·92.

The granular transverse ridge at distal end of arm bears 2 spines only.

Remarks :—Genus is new to Ceylon fauna.

Matuta lunaris (FORSK.), 1775—A.2, p. 160 (under *M. victor*, FABR.).

Locality :—Galle, one specimen.

Description :—Young female, C.l. = 38·50 ; C.b. (without spines) ÷ C.l. = 1·05 ; lat. spine l. (ant. border) ÷ C.l. = 0·28 ; frontal b. ÷ orbital b. = 1·10.

Remarks :—The *M. lunaris* of ALCOCK (A.2, p. 161) = *M. planipes*, FABR., 1798 (STEBBING, in 'Mar. Inv. S. Africa,' iv., 1905).

Matuta miersi, HENDERSON, 1886–87—A.2, p. 163.

Locality :—Gulf of Manaar and Palk Straits, two specimens (*a*, *b*) ; pearl banks, Gulf of Manaar, three specimens (*c*, *d*, *e*).

Description :—	(*a*) Young ♀.	(*b*) ad. ♀.	(*c*) ad. ♂.	(*d*) ad. ♂.	(*e*) ad. ♂.
C.l.	17·50	20·75	23·75	26·50	27·50
C.b. (without spines) ÷ C.l. .	1·03	1·04	1·03	1·01	1·02
Front. b. ÷ orbit. b. . . .	1·15	1·12	1·11	1·10	1·10
Lat. spine l. ÷ C.l.	0·17	0·14	0·11	0·17	0·12

Cryptocnemus holdsworthi, MIERS ('Trans. Linn. Soc.,' 1877, p. 241).

Locality :—Gulf of Manaar, two specimens.

Description :—	(*a*) ovigerous female.	(*b*) female.
C.l.	7·25	7·25
C.b. ÷ C.l.	1·38	1·48

The carapace outline of this species is subject to some variation. MIERS' specimen and the present ones are the only three recorded so far as I am aware. In treating this genus as non-Indian, ALCOCK overlooks MIERS' locality—Ceylon.

Tlos havelocki, n. sp.—Plate I., fig. 2, and text-fig. 1.

Locality:—Coral reefs, Gulf of Manaar, one specimen.

Description:—An adult male. C.l. = 5·75; C.b. ÷ C.l. = 1·48; Ch.l. ÷ C.l. = 1·09; arm l. (inner border of under surface) ÷ C.l. = 0·48; propus l. (lower border) ÷ C.l. = 0·61; F.l. ÷ H.l. (upper border) = 1·14. (Ch.l. is the sum of arm l. and propus l.)

Carapace broadly pentagonal—the front produced and strongly upturned and having its anterior border flattened and a little emarginate in the middle line—the antero-lateral and postero-lateral angles of the pentagon are rounded—the anterior sides concave—the lateral sides converge posteriorly a little—the posterior side is divided by two deep notches into three lobes which all project backwards to approximately the same level. The branchio-hepatic regions are concave and the post-cardiac region deeply so. There are two marginal sutures on each side—one supra-orbital, the other about midway between this and the antero-lateral angle. The margins of the carapace are a little thickened, a little upturned and bordered by enlarged granules as far forward as the more posterior pair of sutures—between the latter and the supra-orbital pair they are rounded and less distinctly granulated—the frontal margin is merely roughened. The true posterior border of the carapace and the surface rising vertically above it are covered with enlarged granules. A longitudinal ridge runs backward from the front to the cardiac region. The latter is prominent and is crowned by a transverse ridge uniting the anterior ends of a pair of very strongly developed, broad topped, granular ridges which run obliquely backward to be continued into the lateral margins at the postero-lateral angles of the pentagon. The rest of the dorsum of the carapace is smooth to the naked eye (seen under lens to be uniformly covered by obsolescent granules).

Fig. 1. *Tlos havelocki*, n. sp.

The pterygostomian region is prominent, its summit is forwardly directed and surmounted by a couple of granules. The exposed portions of the thoracic sterna are covered with enlarged granules—the rest of the under surface of the body, *i.e.*, pterygostomian, sub-hepatic, and sub-branchial regions, is smooth to the naked eye (obsolescently granular under lens).

The orbits are largely ventral. The eyes are visible in part only, in a dorsal view.

Antennules not remarkable.

External maxillipedes with exposed surface roughened; not remarkable in form.

Chelipeds—Ch.l. ÷ C.l. = 1·48. The distal end of the arm is seen beyond the carapace (arm l. ÷ C.l. = 0·47). The arm is trigonal, with enlarged granules along its borders—its surfaces are smooth to naked eye (obsolescently granular under lens). Wrist rounded—its borders and much of its surfaces granular. Hand with outer and inner borders granular—under surface rounded and bearing granules which tend to run in rows, of which one curves downwards and outwards from the inner side of the proximal end to be continued along the whole under surface of the propus to the tip of the fixed finger. The horizontal upper surface of the hand meets the oblique antero-inner surface at an angle, forming an oblique ridge crowned by a characteristic row of enlarged granules (six in this specimen). The inner surfaces of hand and fingers form together a hollowed area. The fixed finger is not constricted off from the hand and is much more massive than the dactylus. The upper surface of the dactylus is fluted—three granular ridges defining two grooves. There are two longitudinal rows of granules on the fixed finger. The distal two-thirds of the apposed border of either finger is flattened to form a facet which is bordered by a few very sharp denticles; the tip of each finger forms a curved tooth—that of the dactylus closes to the inner side of that of the fixed finger.

The meropodites of walking legs 2, 3, and 4 are concealed by the carapace; the succeeding three segments are short, so that by folding the legs at the joint between meropodite and carpopodite they may be entirely concealed from dorsal view. [The first walking legs are lost.] The basipodites and the three distal segments are granular. The meropodites are trigonal, their borders tend to be granular, and their surfaces smooth (obsolescently granular under lens)—the proximal one-third of the under surface occupies a different plane from the distal two-thirds, and is granular.

Remarks.—The new species is closely related to *Tlos petræus*, A. Milne-Edwards, 1874 (A.2, p. 176), but may be easily distinguished from it by the unbroken character of the oblique post-cardiac ridges. It differs further from *T. petræus* in the following particulars:—(1) The front is more produced and more upturned; (2) the true posterior border of the carapace does not project further backward than the lobe on either side of it; (3) there are two marginal sutures only on each side; (4) there is a stronger contrast between the obsolescent granules of the general surface and the enlarged granules of special areas; (5) in the prominence of the pterygostomian region; (6) the orbits are less ventral; (7) sculpture of cheliped—in particular the presence of the oblique row of granules on the upper surface of the hand; (8) the facets on the apposed borders of the fingers.

Tlos latus, Borradaile, 1903 (B.VI., p. 437), differs in—(1) Absence of marginal sutures of carapace; (2) absence of oblique line of granules on upper surface of hand; and (3) isolation of lateral cardiac hump.

Lithadia sculpta, Haswell, var. **aglypha,** nov.—Text-fig. 2.

Locality:—Coral reefs, Gulf of Manaar, one specimen.

Description:—An immature individual. C.l. = 8·5.

It bears a considerable general resemblance to the already described form of *L. sculpta*, but differs from it in the following particulars:—(1) The carapace is broader in proportion to its length—C.b. ÷ C.l. = 1·26; (2) the two grooves which border the cardiac region laterally are not continued forward until they meet, but terminate apart in the middle region of the carapace; (3) there is a mere trace of an intestino-cardiac groove, quite different from the well-cut channels which the other grooves present; (4) the granules on the arm and hand are not so sharp; (5) the strip of carapace cut off laterally by the skirting channel is narrower; between the slightly broadened portions which lie above the bases of cheliped and walking legs 1 and 3 it forms a quite thin ledge; (6) the sub-hepatic region is swollen, much as in *L. sculptus*, and the small tubercle at point of union of antero-lateral and postero-lateral borders is not double.

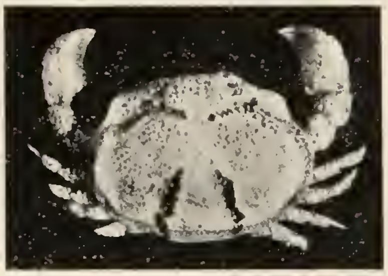

Fig. 2. *Lithadia sculpta*, var. *aglypha*, nov.

Remarks.—The single specimen is immature, but its order of size is much the same as that of a British Museum specimen of *L. sculpta*. This species is of rare occurrence. Only two other examples are known to me, from two localities (Arafura Sea and Eastern seas), but closely resembling each other, suggesting that variability may be low. The present form may turn out to be the representative of a new species.

Nursia plicata (Herbst), 1804, nec auctorum—A.2, p. 180.

Localities:—Adam's Bridge, one specimen (*a*); pearl banks, Gulf of Manaar, one specimen (*b*).

Description:—	C.l.	C.b. ÷ C.l.	Ch.l. ÷ C.l.	F.l. ÷ H.l.
(*a*) adult ♂ . .	10·25	1·27	1·63	0·55
(*b*) adult ♂ . .	12·50	1·20	1·72	0·54

In carapace length the posterior point is the indentation between the two posterior lobes. Carapace breadth measured by straight line uniting indentations between 2nd and 3rd lateral teeth of either side. In both specimens the greatest carapace breadth is given by a straight line uniting tips of 2nd lateral teeth of carapace—not 3rd pair as in *N. hardwicki*.

Nursia hardwicki, Leach, 1817—A.2, p. 181.

Localities:—Pearl banks, Gulf of Manaar, one specimen (*a*); Aripu Reef, one specimen (*b*); coral reefs, Gulf of Manaar, one specimen (*c*).

Description (C.l. and C.b. measured as in *N. plicata*):—

	C.l.	C.b. ÷ C.l.	Ch.l. ÷ C.l.	F.l. ÷ H.l.
(*a*) ♀ . . .	10·25	1·15	1·51	0·61
(*b*) ♀ . . .	10·75	1·12	1·49	0·56
(*c*) ♀ . . .	11·00	1·11	1·50	0·55

The most anterior of the four antero-lateral teeth, just behind the marginal nodule, is quite conspicuous in (*a*), but only slightly developed in the other examples. In all the greatest carapace breadth is given by a straight line uniting tips of 3rd lateral teeth—not 2nd as in *N. plicata*.

Ebalia diadumena, Alcock, 1896—A.2, p. 187.

Locality :—Galle, two specimens.

Description :—	(*a*) young ♀.	(*b*) ♂.		(*a*)	(*b*)
C.l.	4·75	6·50	Ch.l. ÷ C.l. . . .	1·37	2·00
C.b. ÷ C.l. . .	1·05	0·96	F.l. ÷ H.l. . . .	0·83	0·77
			H.b. ÷ H.l. . . .	0·83	0·69

This is first record of male. It differs from Alcock's female (Palk Straits) in a few respects :—(1) the gastro-cardiac groove is hardly to be distinguished ; (2) the cheliped granulation is not so extensive ; (3) about middle of striation on upper surface of immobile finger is a prominent elongated laterally compressed granule ; (4) abdominal tergum VI. is armed with strong terminal tooth.

Ebalia maldivensis, Borradaile, 1903—B.VI., p. 437, fig. 116.

Locality :—Gulf of Manaar, one specimen.

Description :—Ovigerous female, C.l. = 5·75 ; C.b. ÷ C.l. = 1·13 ; Ch.l. ÷ C.l. = 1·22 ; F.l. ÷ H.l. = 0·75. The mounds on dorsum of carapace are all distinct.

Myra* fugax (Fabricius), 1798—A.2, p. 202.

Locality :—Aripu coral reefs, Gulf of Manaar, three specimens (*b*, *d*, *f*) ; Trincomalee, five specimens (*a*, *c*, *e*, *g*, *h*) ; Galle, three specimens (*j*, *k*, *l*) ; off Manaar Island, one specimen (*i*).

Description :—*a–h*, young.

						ovig.	ad.				ad.	ad.
	b (♀).	*d* (♀).	*e* (♀).	*f* (♀).	*h* (♀).	*i* (♀).	*l* (♀).	*a* (♂).	*c* (♂).	*g* (♂).	*j* (♂).	*k* (♂).
C.l. . . : .	9·00	12·00	12·25	12·50	17·00	18·00	26·00	8·75	11·50	16·50	19·00	24·75
C.b. ÷ C.l. .	0·86	0·87	0·88	0·86	0·88	0·86	0·85	0·89	0·87	0·82	0·87	0·86
Ch.l. ÷ C.l. .	1·69	1·79	1·79	1·76	1·98	1·86	2·12	1·83	1·85	1·95	2·33	2·38

F.l. ÷ H.l. .	0·93	0·86	0·78	0·90	0·80	0·79	0·77	0·81	0·86	0·68	0·74	0·72
H.l. ÷ H.b. .	2·29	2·50	2·87	2·50	2·69	2·67	3·16	2·09	2·62	2·83	3·36	3·56

Ch.l. is the sum of lengths of its segments, measured along median line of posterior surface. C.l. is without the spine.

Among the adult specimens considered to be mature, the sexual dimorphism in regard to cheliped length is by no means so marked as Alcock records.

In one specimen the more acutely bidentate and upturned front is somewhat reminiscent of *M. brevimana*. It has also a well-marked median longitudinal carina.

Specimen (*i*), an ovigerous female, is an interesting form which deserves note. It tends to combine characters of *M. fugax*, *M. affinis*, and *M. brevimana*. In slender build of chelipeds and in index F.l. ÷ H.l. it resembles *M. fugax*. In indices Ch.l. ÷ C.l. and H.l. ÷ C.l. it more nearly approaches *M. affinis* and *M. brevimana*. The prominence

* Miss Rathbun unites this genus with the older genus *Persephona*, Leach, 1817.

of the upper hepatic tooth is much as in *M. affinis* ; the *Leucosia*-like front approximates to that of *M. brevimana*. The specimen is conveniently put under *M. fugax*.

Specimens (*d*) and (*f*) are young forms which may perhaps be put with specimen (*i*).

Myra affinis, Bell, 1855—A.2, p. 205.

Locality :—Pearl banks, Gulf of Manaar, five specimens (*g*, *h*, *i*, *j*, *l*) ; Coral reefs, Gulf of Manaar, four specimens (*a*, *d*, *f*, *k*) ; Trincomalee, three specimens (*b*, *c*, *e*) ; off Mutwal Island, one specimen (*m*).

Description :—*a–k*, young.

	a (♀).	c (♀).	d (♀).	f (♀).	h (♀).	i (♀).	j (♀).	k (♀).	ad. l (♀).	b (♂).	g (♂).	ad. m (♂).
C.l. (spine).	7·50	11·25	11·50	12·50	16·50	18·75	19·00	19·75	24·00	8·00	15·75	26·75
C.b. ÷ C.l.	0·93	0·89	0·87	0·88	0·84	0·88	0·86	0·86	0·87	0·91	0·86	0·86
Ch.l. ÷ C.l.	1·50	1·49	1·46	1·50	1·51	1·56	1·53	1·57	1·74	1·53	1·54	1·91
H.l. ÷ C.l.	0·40	0·40	0·39	0·40	0·42	0·44	0·42	0·43	0·49	0·41	0·45	0·56
F.l. ÷ H.l.	0·67	0·67	0·67	0·65	0·61	0·61	0·62	0·65	0·60	0·69	0·57	0·53
H.l. ÷ H.b.	2·00	2·00	2·00	2·00	2·15	2·20	2·13	2·12	2·14	2·17	2·34	2·50

Among the small specimens there is a marked tendency to possession of an additional postero-lateral pair of small spicules, a carina, an intestinal granule, and several enlarged antero-lateral denticles. A similar tendency is found in the small young placed under *M. fugax* and *M. brevimana*.

Specimen (*m*) male is large. Its C.l. is only 0·25 millim. less than that of Nobili's (p. 95) large specimen, but it by no means approaches the latter in cheliped length or in length of hand. It is indeed but little different from Alcock's smaller specimens in Ch.l. ÷ C.l., though in H.l. ÷ C.l. it exceeds his measurement (Nobili's specimen, C.l. = 27·0 ; Ch.l. = 70·0 ; H.l. = 20·0). Measurements taken as in *M. fugax*.

Myra brevimana, Alcock, 1896—A.2, p. 206 ; A. Invest., pl. xxix., fig. 8.

Locality :—Aripu coral reefs, Gulf of Manaar, four specimens (*a*, *b*, *d*, *h*) ; off Kaltura, four specimens (*c*, *e*, *f*, *i*) ; off Galle, two specimens (*g*, *j*). ; Trincomalee, one specimen.

Description :—

	yg. b (♀).	yg. c (♀).	ad. d (♀).	ov. h (♀)	ad. i (♀).	ad. j (♀).	ad. e (♂).	ad. f (♂).	ad. g (♂).
C.l. (spine).	9·50	12·50	16·50	18·50	22·00	25·50	16·00	17·75	18·25
C.b. ÷ C.l.	0·87	0·84	0·83	0·84	0·84	0·84	0·84	0·85	0·79
Ch.l. ÷ C.l.	1·53	1·60	1·67	1·70	1·76	1·75	1·91	1·85	1·88
H.l. ÷ C.l.	0·34	0·38	0·41	0·43	0·43	0·43	0·48	0·45	0·47
F.l. ÷ H.l.	1·00	0·95	0·89	0·84	0·89	0·86	0·77	0·84	0·82
H.l. ÷ H.b.	1·86	1·90	2·08	2·14	1·89	1·84	2·21	2·00	2·00

Variability in size of adults is high. The two smallest specimens have a few scattered hairs. There is a suggestion in the adults of sexual dimorphism as regards cheliped length. Specimen (*h*), though female, has well-marked spinule on penultimate abdominal tergum. Measurements taken as in *M. fugax*.

Myra darnleyensis, HASWELL, 1879—A.2, p. 207.

Localities:—Aripu coral reefs, Gulf of Manaar, four specimens; pearl banks, three specimens.

Description:—There are in all considerable traces of the "cruciform constellation" of five enlarged granules on centre of dorsum of carapace. This is evidently not confined to females and young males, as it occurs in an adult male from "pearl banks."

Leucosia obtusifrons, DE HAAN, 1841—A.2, p. 216.

Localities:—Aripu coral reefs, Gulf of Manaar, two specimens (*a*, *b*); off Kaltura, one specimen (*c*).

Description:—

	(*a*) young ♂.	(*b*) young ♂.	(*c*) adult ♂.
C.l.	12·75	17·25	25·00
C.b. ÷ C.l.	0·90	0·91	0·92
Ch.l. ÷ C.l.	1·10	1·20	1·45

In addition to the two pairs of white gastric spots characteristic of the species there is a third pair of quite small but otherwise similar ones, anteriorly. In specimen (*a*) young male all these spots are faintly ringed and a pair of postero-lateral orange spots is present also.

Leucosia longifrons, DE HAAN, 1841—A.2, p. 217.

Localities:—Trincomalee, two specimens (*a*, *b*); pearl banks, Gulf of Manaar, one specimen (*d*); Station I., off Negombo, one specimen (*c*); Aripu Reef, one specimen (*e*).

Description:—

	(*a*) young ♀.	(*b*) young ♂.	(*c*) young ♀.	(*d*) young ♀.	(*e*) adult ♀.
C.l.	17·00	17·50	17·50	17·75	26·00
C.b. ÷ C.l. . .	0·85	0·87	0·87	0·87	0·87

Specimen (*c*) young female comes under var. *pulcherrima*. Specimens (*a*) young female and (*b*) young male show some tendency to vary in the direction of the same variety (anterior half of carapace is slightly punctate); propodites of walking legs carinate dorsally and tend to be so ventrally also, each of the posterior two of the six spots of gastric shoe is surrounded by red rings.

On the other hand, var. *neocalidonica* characters are hinted at in specimens (*d*) young female and (*e*) adult female, where in addition to dorsal and ventral carination of propodites of the walking legs, common to *pulcherrima* and *neocalidonica*, the chelæ and walking legs have a tendency to the granulation of the latter variety. Thus in (*e*) adult female the wrist has trace of the three granules, the meropodite of walking leg 1 has traces of one dorsal and one ventral row, and that of walking leg 2 has traces of one dorsal row of granules.

Leucosia urania, Herbst, 1801—A.2, p. 220.

Locality :—Galle, one specimen.

Description :—Young male, C.l. = 17·00 ; C.b. ÷ C.l. = 0·84.

A series in the British Museum links this specimen with the adult form, from which latter it differs in certain points :—(1) fingers are crenulate in their distal half only ; (2) hand is cristate on both borders (the lower crest is crenulate—the crenulations swollen into granules).

Leucosia cumingi, Bell, 1855—A.2, p. 226.

Locality :—Coral reefs, Gulf of Manaar, one specimen.

Description :—Ovigerous female, C.l. = 13·00 ; C.b. ÷ C.l. = 1·04.

Leucosia hæmatosticta, Adams and White, 1848—A.2, p. 229.

Localities :—Aripu coral reefs, Gulf of Manaar, two specimens (*b*, *c*) ; Station I., off Negombo, one specimen (*a*).

Description :—	(*a*) male.	(*b*) ovigerous female.	(*c*) ovigerous female.
C.l.	9·75	13·00	13·50
C.b. ÷ C.l. . . .	0·97	1·00	0·98

Leucosia pubescens, Miers, 1877—A.2, p. 233.

Localities :—Galle, one specimen ; pearl banks, Gulf of Manaar, three specimens ; coral reefs, Gulf of Manaar, three specimens.

In an ovigerous female, C.l. = 18·50.

Philyra platychira, de Haan, 1841—A.2, p. 242.

Localities :—Coral reefs, Gulf of Manaar, four specimens ; pearl banks, three specimens ; Trincomalee, three specimens ; Welligam Bay, two specimens ; Galle, six specimens.

An indication of sexual dimorphism is given by index Ch.l. ÷ C.l. :—

For 12 adult males this has mean value 2·32 and range of variation 2·23–2·40.

,, 4 ,, females ,, ,, . 1·83 ,, ,, 1·67–1·92.

To this difference all the segments of the cheliped contribute. Thus

	Arm l. ÷ C.l.	Wrist l. ÷ C.l.	H.l. ÷ C.l.	F.l. ÷ C.l.
Male means	0·93	0·32	0·60	0·47
Female means . . .	0·71	0·26	0·51	0·35

All have some very fine granulation on the posterior and lateral regions of the dorsum of the carapace—the specimens from "Coral reefs, Gulf of Manaar," have in addition some rather large scattered granules on the lateral region.

Some of the specimens fall under Klunzinger's var. *bidentata* (K., p. 72).

Philyra adamsi, Bell, 1855 ('Trans. Linn. Soc.,' xxi., p. 301)—Plate I., fig. 1.

Localities:—Pearl banks, Gulf of Manaar, two specimens; coral reefs, Gulf of Manaar, four specimens, including (*b*); Galle, seven specimens, including (*a*).

Description:—	C.l.	C.b. ÷ C.l.	Ch.l. ÷ C.l.	H.l. (upper border) ÷ C.l.	Fixed finger (inner border) ÷ C.l.
(*a*) Ovigerous ♀	8·00	1·02	1·60	0·34	0·26
(*b*) Adult ♂	9·00	1·03	2·10	0·46	0·36
(*c*) Bell's "type," ♂ .	9·00	1·03	2·25	0·50	0·39

I have compared the specimens with Bell's "type" preserved in the British Museum, and they agree well with it.

Bell's figure gives an inadequate, and in some respects erroneous, idea of his specimen. Henderson amends Bell's description (H., p. 400), but omits reference to any hepatic facet, the presumed *absence* of which has been lately emphasised by Nobili (N., p. 104). In re-figuring Bell's specimen I emphasise (1) general shape of front; (2) presence of a small median frontal tooth, at lower level than rest of front; (3) details of hepatic facet; (4) two tubercles on hand at base of fixed finger; (5) proportions of buccal cavern; (6) exognath of external maxilliped.

Remarks:—Alcock omits this species from his key, observing that it appears to him to be rather a *Pseudophilyra*. It is indeed intermediate in many ways, *e.g.*: (1) production of front; (2) general proportions of buccal cavern; (3) shape of exognath of external maxilliped. But in all these particulars it bears considerable resemblance to *Philyra platychira* and to *Ph. granigera*, Nobili, 1906 (N., p. 102, pl. vi., fig. 30), both of which it further resembles in the presence of the hepatic facet and of the longitudinal grooves of the carapace (the latter more as *P. granigera* than *P. platychira*). It must be placed in the same genus with these, and all three fall under section I.2.1 of Alcock's key of *Philyra*.

Ph. adamsi is at once distinguished from *Ph. platychira* by the entire sub-orbital border of the endostome and by the characters of hand and fingers.

It is more closely allied to *Philyra granigera* than Nobili imagined, since it has in reality a hepatic facet. It differs from *Ph. granigera* in possessing:—(1) line of granules on upper border of inner surface of hand and wrist; (2) the distinct granule on upper surface of hand proximal to base of fixed finger (tendency for a second, less distinct granule just distal to the distinct one); (3) the small median frontal tooth.

Philyra globosa (Fabr.), 1787—A.2, p. 243.

Localities:—Trincomalee, one specimen (immature male); Galle, two specimens (adult females).

Pseudophilyra tridentata, Miers, 1879—A.2, p. 250.

Locality:—Pearl banks, Gulf of Manaar, five specimens (*a*, *b*, *c*, *d*, *e*).

Description :—	(*a*) ad. ♂.	(*b*) ad. ♂.	(*c*) ad. non.-ov. ♀.	(*d*) ovig. ♀.	(*e*) ovig. ♀.
C.l.	5·00	5·00	5·50	6·00	6·00
C.b. ÷ C.l. . .	0·85	0·90	0·86	0·92	0·92
Ch.l. ÷ C.l. . .	1·60	1·60	1·45	1·50	1·46
F.l. ÷ H.l. . .	0·50	0·50	0·50	0·54	0·54
H.b. ÷ H.l. . .	0·50	0·50	0·50	0·54	0·54

The specimens are much smaller than those in the Indian Museum from Persian Gulf. The length of the first pair of walking legs exceeds that of the arms by about the last segment only, as NOBILI (N., p. 105) found in his Persian Gulf specimens. H.b. ÷ H.l. is of same order as ratio recorded by NOBILI and by CALMAN (C., p. 28).

There is no distinct abdominal tooth in the males; just a slight convexity in (*a*) adult male, more marked in (*b*) adult male.

Pseudophilyra melita, DE MAN, 1888—A.2, p. 253.

Localities :—Trincomalee, six specimens; coral reefs. Gulf of Manaar, one specimen; pearl banks, Gulf of Manaar, four specimens.

Description :—*d*, *g*, *h*, *j*, adult.

	(*a*) yg. ♂.	(*c*) yg. ♂.	(*d*) ♂.	(*g*) ♂.	(*h*) ♂.	(*j*) ♂.	(*b*) yg. ♀.	(*e*) ♀ ov.	(*f*) ♀ ov.	(*i*) ♀ ov.	(*k*) ♀ ov.

The gastro-cardiac groove is very inconspicuous in all.

Arcania quinquespinosa, Alcock and Anderson, 1894—A.2, p. 266.

Locality :—West of Periya Paar, 17 to 24 fathoms, one specimen.

Description :—Adult female, C.l. = 11·00 (includes frontal lobes, but not posterior spine) ; C.b. (without spines) ÷ C.l. = 1·05 ; lateral spine l. ÷ C.l. = 3·41 ; Ch.l. ÷ C.l. = 2·23 ; F.l. ÷ H.l. = 1·50. The pair of postero-lateral granules is present.

Arcania erinaceus (Fabricius), 1787—A.2, p. 268.

Localities :—Pearl banks, Gulf of Manaar, two specimens (*a*, *c*) ; coral reefs, Gulf of Manaar, one specimen (*b*).

Description (measurements as in *A. quinquespinosa*) :—

	(*a*) young ♀.	(*b*) ad. ♂.	(*c*) ad. ♀.
C.l.	13·25	18·50	18·75
C.b. ÷ C.l.	0·87	0·84	0·88
Ch.l. ÷ C.l.	1·55	1·57	1·49
F.l. ÷ H.l.	0·73	0·59	0·61

A difference between the adult male and the adult female above is the presence in the latter of a median longitudinal line of hair on the ischium of the external maxilliped.

Arcania tuberculata, Bell, 1855—A.2, p. 268.

Locality :—Pearl banks, Gulf of Manaar, two specimens (*a*, *b*).

Description :—	C.l.	C.b. ÷ C.l.	Ch.l. ÷ C.l.	F.l. ÷ H.l.
(*a*) ovigerous ♀ . . .	9·50	0·89	1·18	0·77
(*b*) ovigerous ♀ . . .	10·25	0·88	1·17	0·85

Arcania pulcherrima, Haswell, 1879—A.2, p. 269.

Localities :—Trincomalee, one specimen (*a*) ; coral reefs, Gulf of Manaar, one specimen (*b*).

Description :—	C.l.	C.b. ÷ C.l.	Ch.l. ÷ C.l.	F.l. ÷ H.l.
(*a*) young ♂	8·00	1·09	2·06	0·82
(*b*) ovigerous ♀ . . .	10·75	1·09	2·16	0·77

There are in both specimens 14 tubercles on the dorsal surface of the carapace in addition to the 10 marginal prominences.

Ixa cylindrus (Fabricius), 1787—A.2, p. 271.

Localities :—Aripu Reef, one specimen (*a*) ; pearl banks, Gulf of Manaar, one specimen (*b*).

Description (lateral spines included in C.b.) :—	(*a*) ad. ♂.	(*b*) ad. non-ov. ♀.
C.l.	14·50	16·75
C.b. ÷ C.l.	2·83	2·88

Dorippe dorsipes (Linnæus), 1764—A.2, p. 277.

Localities :—South end of Cheval Paar, two specimens ; Pearl banks, Gulf of Manaar, six specimens ; Coral reefs, Gulf of Manaar, five specimens ; Galle, one specimen.

Description :—There are no ovigerous females ; probably none of the females are adult. Of the males perhaps two or three of the largest specimens are adult. The largest male has C.l. = 23·50, *i.e.*, two-thirds measurement given by Alcock for large male. In the smallest specimens (C.l. = 8·50 and 9·00) the spine at outer angle of orbit falls far short of level of frontal teeth ; it nearly reaches it in larger specimens ; in the largest of all (C.l. = 23·50) it quite does so. In Alcock's still larger specimens it projects beyond the frontal teeth. In an immature male (C.l. = 12·00) from "Pearl Banks, Gulf of Manaar," there is on abdominal tergum IV. a small acute tubercle on either side of the larger median tubercle. The hands are still symmetrical in a male whose C.l. = 18·00.

Dorippe facchino (Herbst), 1785—A.2, p. 278.

Locality :—Pearl banks, Gulf of Manaar, two specimens.

Description :—	C.l.	C.b. ÷ C.l.	2nd W.L. ÷ C.l.	2nd W.L. ÷ 4th W.L.
(*a*) Young male . .	10·25	1·10	3·25 (approx.)	2·50 (approx.)
(*b*) ,, ,, . .	10·25	1·12	—	—

In neither does the spine at the external orbital angle project so far forward as the level of the frontal teeth. They are less hairy than Alcock describes for the adult ; hair is entirely absent from walking legs 1 and 2. In this respect they suggest the specimens included by Alcock as "? *D. granulata*, de Haan" (A.2, p. 279).

Raninoides serratifrons, Henderson, 1893—A.2, p. 293.

Localities :—South of Galle, deep water, three specimens ; west of Periya Paar, 17 to 24 fathoms, four specimens.

Description :—All are apparently immature. C.l. ranges from 6·50 to 15·25.

OXYRHYNCHA.

Achæus lacertosus, Stimpson, 1857—A.1, p. 172.

Localities :—Aripu coral reefs, Gulf of Manaar, two specimens (adult ♂) ; pearl banks, Gulf of Manaar, one specimen (adult ♂).

Description :—C.l. (exclusive of rostrum) of an adult male = 11·00.

Achæus dubia, n. sp.—Text-fig. 3.

Localities :—Pearl banks, Gulf of Manaar, four specimens (*a*, *d*, *f*, *g*) ; Chilaw Paar, one specimen (*e*) ; west of Periya Paar, 17 to 24 fathoms, one specimen (*b*) ; off Negombo, Gulf of Manaar, one specimen (*c*).

The division between carapace and rostrum is taken to be a line uniting the anterior borders of the orbits; C.b. = a straight line uniting points above base of W.L.1 of either side, which is the region of greatest breadth; posterior border of carapace = a straight line uniting points behind the lateral tubercles of the posterior border; cheliped segments and segments of W.L.2 are measured along upper edge.

Description of Ovigerous Female (*f*).—Carapace sub-triangular, the postero-lateral angles well rounded, and the posterior border concave. The rostral lobes appear to the naked eye to be united to form a single short median dorsally grooved and bluntly pointed projection which reaches forward about as far as the distal end of the first joint of the antennal flagellum. The carapace is narrowed laterally behind the eyes. There is a post-hepatic constriction due to the branchio-cardiac groove. The greatest breadth is in the region above the first pair of walking legs. The regions of the carapace are distinct. The carapace armature consists of (1) tubercles, (2) straight hairs, (3) hooked hairs. The general surface beneath the hairs is smooth; of the tubercles two at once attract the eye—a large conical gastric one and a still larger one on the cardiac region. The tubercles are in detail:—3 gastric, arranged in form of a triangle, of which the two anterior ones, forming the base, are inconspicuous, while the median posterior one is that already mentioned—1 cardiac (median), the

Fig. 3. *Achaeus dubia*, n. sp.

largest on the animal and already mentioned—3 branchial (paired), of which one is lateral while the other two are dorsal, and so placed that a straight line uniting them would on being produced anteriorly pass between the antero-lateral gastric tubercle of the same side and the median gastric tubercle—2 hepatic tubercles (paired), a larger one below and to the outer side of a smaller—1 sub-hepatic (paired)—1 buccal, *i.e.*, the produced antero-external angle of the buccal cavern (paired)—1 pre-buccal tubercle (paired), quite small, just anterior to and a little above the buccal tubercle, its apex points downwards and outwards—finally, 1 at either end of posterior margin of the carapace. The buccal, the sub-hepatic, and the lateral branchial tubercles on either side are united by a low ridge forming an approximately straight line.

The upper margin of the orbit is smooth, there is no dorsal spine in this region.

The sternal surface is devoid of spinules.

Each tubercle tends to be crowned by one or two hairs of the straight variety. A dorso-lateral longitudinal row of hooked hairs is conspicuous on the branchial regions of either side; it commences on the region above the base of walking leg 3 and runs forward below the two dorsal branchial tubercles. On the anterior half of the carapace the hooked hairs are numerous and tend to run in lines which converge anteriorly.

The abdomen has in both sexes six divisions, somite VI. and telson being as usual fused. On its tergal surface are both straight and hooked hairs.

The basal antennal joint is smooth and fixed, being fused distally to the front. The antennal flagellum is fringed feather-wise with long straight hairs.

In the external maxillipeds the inner edge of the ischium and of the merus is fringed with long straight hairs. The inner edge of the ischium is finely toothed and its exposed surface tends to be roughened (under lens); the roughening is most marked along two slight longitudinal carinæ which border a somewhat V-shaped median longitudinal depression. The merus also is grooved longitudinally.

In the chelipeds the under border of the ischium and of the merus, and the upper and under borders of the laterally compressed hand, are carinate and finely denticulate; the denticulation is continued along the proximal half of the under border of the fixed finger. The rest of the cheliped is smooth. The fingers are strongly incurved and are apposable throughout their length. Long straight hairs fringe the upper and under borders of all the cheliped segments. Hooked hairs are arranged in a median longitudinal row on the outer surface of the arm; they occur also on the lower part of the outer surface of the wrist and on the upper portion of the outer surface of the hand.

The dactylopodites of walking legs 3 and 4 are slightly falciform, the curve strongest proximally. The walking legs possess some long scattered straight hairs. A row of hooked hairs is present on the upper border of all the segments of all the walking legs except the dactylopodites of the last two pairs.

Variation among the ovigerous females concerns (1) the size but not the number of the tubercles of the carapace; (2) the measurements, as given above; (3) the extent to which, if at all, the rostral lobes are apposed. Though all appear apposed to the naked eye, variation is seen by aid of a lens. In (*a*) and (*c*) they are apposed throughout their length, in (*d*) and (*f*) they are apposed distally, but are separated proximally by a narrow space, and in (*b*) and (*e*) they are separate throughout their whole length.

In the single male specimen the cardiac tubercle is, as in the females, the largest; but the median gastric and the posterior branchial tubercle of either side are all of approximately the same size, the former being relatively smaller and the latter relatively larger than in the female specimens. All the segments of the cheliped are longer and more swollen than in the females; their denticles are present, very small and set well apart. The fingers are apposable distally for rather less than half their length, a hiatus being left proximally, which is more or less bridged by a couple of blunt teeth, one near the base of each finger, that of dactylus distal to the one on the fixed finger.

I judge *Achæus dubia* to be closely allied to *A. tenuicollis*, differing from it mainly in the following particulars:—(1) Neither tubercles, rostral lobes, chelipeds, nor sternal surface bear spinules; and (2) Character of rostral lobes.

The rostral lobes are noteworthy. They are more sharply pointed than one expects in *Achæus*, making an approach thus to *Stenorhynchus*, *e.g.*, *S. rostratus*, where they are shorter than usual. The essential distinction hitherto recognised between *Achæus* and *Stenorhynchus* has been that in the former the rostrum consists of two short lobes, and in the latter of two long spines.

Paratymolus hastatus, ALCOCK, 1895—A.1, p. 174; A.Invest., pl. xviii., fig. 4.

Locality:—Gulf of Manaar, six specimens (three adult males, one young male, and two adult females, one ovigerous).

Description:—C.l. (exclusive of rostrum) of an ovigerous female = 5·25.

In the above females the genital orifices are, as in ALCOCK's specimen, on the sternum, not on the bases of the 3rd pair of walking legs.

Remarks.—ALCOCK observes that the position of the genital orifices of the female as above confirms ORTMANN's view that the correct place for this genus is among the *Achæus*-like Maiidæ.

Oncinopus aranea, DE HAAN, 1837—A.1, p. 183.

Localities:—Trincomalee, one specimen (ovigerous ♀); pearl banks, two specimens (adult ♂ and ovigerous ♀); coral reefs, Gulf of Manaar, three specimens (ovigerous ♀, adult ♂, and young ♂); south of Galle, deep water, one specimen (with *Sacculina*).

Description:—C.l. (including rostrum) of an ovigerous female = 8·50.

Remarks.—One of the ovigerous females which bears a parasitic *Sacculina* retains the usual broad female type of abdomen, and its abdominal appendages are also well developed.

Camposcia retusa, LATREILLE, 1829—A.1, p. 184.

Locality :—Pearl banks, Gulf of Manaar, one specimen.

Description :—Male, apparently adult, C.l. = 23·50. It has the broad sternum (KLUNZINGER, pl. i., fig. 1) and slender cheliped described for males of this species, giving them a curiously female appearance. The sternum, though broad in the male of this species, is not so broad as in the female.

Apocremnus indicus, ALCOCK, 1895—A.1, p. 188; A.Invest., pl. xx., fig. 1.

Localities :—Coral reefs, Gulf of Manaar, sixteen specimens; south of Galle, deep water, six specimens; Gulf of Manaar, deep water, three specimens.

Description :—In an ovigerous female C.l. (excluding rostrum) = 7·00. A gastric spinule is present—this is figured by ALCOCK, but omitted from his description.

A post-ocular spinule is figured by ALCOCK in his ventral view of the male, but is said by him in his description to be absent. The description—not the figure—is correct for the present specimens.

There is evidence in the present specimens that the male of this species is facultatively dimorphic. The series includes what I believe to be examples of young, non-breeding, and breeding males—the latter I judge to be of the "low" type.

Xenocarcinus tuberculatus, WHITE, 1847, var. **alcocki**, nov.—A.1, p. 192.

Locality :—Dutch Modragam Paar, one specimen.

Description :—An ovigerous female. C.l. (excluding rostrum) = 12·50; Rost.l. ÷ C.l. = 0·32. The present specimen agrees with A. MILNE-EDWARDS' fig. 1 ('Archiv. du. Mus.,' viii., 1872, p. 253, pl. xii., figs. 1 to 1*g*) in character of its legs, and is fairly intermediate in carapace-character between this and WHITE'S "type"-specimen in British Museum which is figured by MIERS ('Zool. Erebus and Terror,' Crust., p. 1, pl. ii., figs. 1 to 1*e*). It thus agrees in general appearance with ALCOCK'S figure of a specimen from Andamans or from Ceylon, but the rostrum is narrower anteriorly and so more conical. A close examination of the carapace surface reveals some obsolescent tubercles in the position of those seen in A. MILNE-EDWARDS' fig. 1, but are not sufficiently developed to affect the general appearance, which is due rather to nine swellings as in WHITE'S "type"-specimen; they are not, however, so strongly developed, so conical, nor so pointed as in the latter, and in particular the gastric and cardiac eminences are very ill-developed.

Remarks.—No second example seems to have been described which is in agreement with WHITE'S "type"-specimen (female) of *X. tuberculatus*. I have examined the five British Museum specimens from Cape Howe, for which MIERS created *X. depressus* in 1874 (reference as above), and find that they come into the series figured by A. MILNE-EDWARDS; one of them in particular is well represented by his fig. 1. CALMAN states (p. 34) that his Murray Island male is in fair agreement with the same figure.

I should recognise a single species within which are (1) a group including specimens figured by A. MILNE-EDWARDS, MIERS' five *X. depressus* specimens from Cape Howe, and CALMAN'S male from Murray Island. This I name var. *depressus*. (2) A group including ALCOCK'S two female examples from Ceylon and Andamans (A. Invest., pl. xxxiii., fig. 3), and the present specimen, also a female. This group is intermediate between (1) and (3). I name it var. *alcocki*. (3) WHITE'S female "type"-specimen figured by MIERS, which stands alone. It is characterised among other ways by having its gastric tubercle transversely divided. This I name var. *tuberculatus*.

Huenia proteus, DE HAAN, 1837—A. 1, p. 195.

Localities:—Aripu coral reef, two specimens (*g*, *m*); Chilaw Paar, one specimen (*a*); Cheval Paar, Gulf of Manaar, nine specimens (*h*, *e*, *d*, *b*, *i*, *l*, *n*, *o*, *k*); Jokkenpiddi, three specimens (*c*, *f*, *j*); Navakaddu Paar, one specimen (*p*). (*o* and *p* adult.)

Ch.l. ÷ C.l. .	—	0·81	—	0·79	0·77	0·76	0·79	0·79	0·78	0·82

The kind of alga carried by the animal varies. In (*a*), which is described by a label as a "green crab tinted similarly to the green alga on which it was found," it is a large piece of foliaceous Halimeda, while in (*e*) it is a branch of filamentous alga.

The hepatic lobes of the female may be horizontal as in (*e*), or they may curve considerably upward as in (*h*). Between these limits the other specimens may be arranged in a good connecting series.

The border of the hepatic lobe of the female is in some entire, in others irregular.

In all the males there is a pair of small transversely placed tubercles in front of the anterior median elevation. This is present also in ovigerous female (*f*), and a trace appears in ovigerous female (*i*).

The carapace-outline of all the males except (*p*) agrees with ADAMS and WHITE'S fig. 4 ('"Samarang" Crust.,' pl. iv., fig. 4). Specimen (*p*), which is the largest male in the collection, more resembles DE HAAN'S fig. 5 of the larger form (Crust. in 'Faun. Japon.,' pl. xxiii., fig. 5), but the anterior border of the epibranchial lobe slopes obliquely backwards, and in the same crab the upper border of the hand and wrist is strongly carinate, and on the upper, under, and outer surfaces of the arm are a few distinct short blunt spines.

In the two largest males Ch.l. ÷ C.l. is rather more than 1, instead of rather less as

ALCOCK describes. There is a difference between the sexes in rostral length. Thus the measurements show that for 6 males the mean value of R.l. ÷ C.l. = 0·41, and range of variation = 0·36–0·45. For 10 females the corresponding figures are 0·32 and 0·29–0·33. Neither the slight variation among the female nor the considerable variation among the male specimens seems to be particularly associated with growth.

Simocarcinus simplex (DANA), 1852, var. **pyramidatus**, nov.—A.1. p. 196.

[**Huenia hellerii**, PAULSON, 'Crustacea of the Red Sea' (Russian), Kiev, 1875, p. 8, pl. iii., figs. 2*a* to *c*.] **Trigonothir pyramidatus**, KLUNZINGER, p. 19, pl. i., figs. 3 to 3*g*.

Localities:—Jokkenpiddi Paar, three specimens (*a*, *b*, *d*); south end of Cheval Paar, one specimen (*e*); coral reefs, Gulf of Manaar, one specimen (*f*); pearl banks, Gulf of Manaar, four specimens (*g*, *h*, *i*, *j*); off Mutwal Island, one specimen (*c*).

All the specimens have three tubercles on the gastric region of the carapace; they are somewhat blunter in the female than in the male.

The rostrum exhibits variability in several respects: (1) In its length, as above; (2) it may be straight or curved, in the latter case the concavity is below; (3) it may arise from the front of the carapace in such a way as to continue the general horizontal plane of the dorsal surface of the carapace, or it may rise upwards somewhat and make an obtuse angle with that plane. In one male the rostrum is straight and its plane horizontal; in two males it is curved and makes an obtuse angle with the post-rostral carapace.

The hands of one male are massive, with fingers which are only apposable at their tips, and which are, when so apposed, separated at the base by a considerable space; in two other males the hands are slender and the fingers when apposed distally are almost in contact basally.

A lobe is present in all the specimens on either side of the posterior border of the carapace. The size of the lobes is intermediate between those of dried specimens of *S. simplex* in the British Museum and HELLER's figure of *pyramidatus*.

The eye is much as in the British Museum specimens of *simplex*, *i.e.*, less prominent than in DANA's figure. In each of the three females which I place with the above males there is a pair of hepatic lobes, *Remarks.*—The present specimens form a group which I believe breaks down the distinction between *Simocarcinus simplex* (DANA), 1852, and *S. pyramidatus* (HELLER), 1861. As set forth by ALCOCK, the characters by which the former is distinguished from the latter are (1) the much shorter rostrum of the male; (2) the presence of three tubercles, disposed in a triangle, on the gastric region; (3) the larger and more prominent eyes; (4) the absence of the lobule on either side of the posterior border of the carapace; (5) the much more massive chelipeds of the male.

In the first place, I may remark that the only other specimen which appears to agree with the single one for which HELLER created *pyramidatus* is the male described by ALCOCK. I have examined MIERS' specimens of *S. simplex* in the British Museum and find that, though they are evidently *S. simplex* in the narrower sense of the term, they show two points of difference from DANA's figure which diminish the value of distinctions (3) and (4) above. There is in each of them a lobe at either end of the posterior border (it is distinct, though not so large as in HELLER's figure of *S. pyramidatus*), and in all the males the eyes are less prominent than in DANA's figure. This doubt cast upon the value of distinctions (3) and (4) is confirmed by the present specimens (see description above). The fifth distinction seems, in view of the evidence of the specimens in the present collection, to be one between young and adult males or between non-breeding and breeding adults. There is, however, some difference between the massive chela of male specimens (*a*) and (*b*) of the present examples and that of the British Museum male (*m*); this may or may not be a difference associated with high and low males respectively. Of ALCOCK's two remaining distinctions, (1) and (2), each specimen of the present group unites the three gastric tubercles of *S. simplex* with the long rostrum of *S. pyramidatus*. CANO ('Boll. Soc. Nat. Napol.,' iii., 1889, p. 173) describes an animal with a similar combination and unites the two species. More recent writers have not followed him, and KLUNZINGER (p. 19) describes a similar male as *pyramidatus*. The additional evidence confirms CANO.

It is difficult to estimate the value of the character rostrum-length referred to above. It holds excellently as between the present individuals and the specimens labelled *S. simplex* in the British Museum (see measurements above); but in KLUNZINGER's figure the index R.l. ÷ C.l. seems to be about 0·62, and HENDERSON describes his specimens as *simplex*, but with longer rostrum. The high variability of this character in *S. camelus*, KLUNZINGER (1906, pl. i., figs. 2*a*–*g*), is to be borne in mind. A further point of difference between my specimens and the British Museum examples of *S. simplex* is the greater length of the first pair of walking legs in the former (see measurements above, under W.L.1.l. ÷ C.l.). The present forms and all those with the three gastric tubercles I name var. *pyramidatus*.

I consider that MIERS' distinction between *Simocarcinus* and *Trigonothir* (the latter genus formed for a single male specimen) must be given up. The slender cheliped of the latter is better considered as the character of a young or of a non-breeding individual. The rostrum is stouter, more swollen and more clumsy in *Trigonothir* than in *Simocarcinus simplex* (includes *S. pyramidatus*) and *S. camelus*, but it is essentially the same otherwise. In all these its under surface is flattened proximally, while distally it is concave and produced into lateral carinæ; and its apex tends to be three-lobed, the lobes set at angles of 120° (very approximately) to each other. I have seen no specimens of *Simocarcinus* with the laterally compressed acute rostrum given by MIERS as a generic character. KLUNZINGER (p. 18) revises MIERS' definition of *Trigonothir*, transferring to it the species *pyramidatus*. As a new generic character he gives the absence of hepatic lobes in the female. The evidence of the present specimens confirms me in doubting the validity of this. As another new generic distinction he points out that in *Trigonothir* the chelipeds of the adult male are unequal. With the additional evidence available to me, I would suggest that this inequality—observed only in a single example (KLUNZINGER, pl. i., fig. 3)—is due to regeneration. I unite *Simocarcinus* and *Trigonothir* under the name of the former and for the present distinguish this genus from *Huenia* by two characters:—

(1) Pre-ocular spine. This is present in *Huenia*, absent in *Simocarcinus*. (2) Rostrum. In *Huenia* this is sharp-edged below and has an acute tip; in *Simocarcinus* it has a flattened under surface which tends to be concave distally, where its lateral edges are produced—the tip of the rostrum tends to be trilobed.

Menæthius monoceros (LATREILLE), 1825—A.1, p. 197.

Localities:—Cheval Paar, Gulf of Manaar, seven specimens (*h*, *f*, *g*, &c.); Aripu coral reefs, ten specimens (*c*, *a*, *e*, *i*, &c.); off Mutwal Island, eight specimens (*j*); Jokkenpiddi Paar, two specimens (*b*, *d*); Navakaddu Paar, one specimen.

Description:—

Males.	(*a*).	(*b*).	(*c*).	(*d*).	(*e*).	(*f*).	(*g*).	(*h*).	(*i*).	(*j*).
C.l. . . .	6·00	7·00	7·50	9·25	9·50	9·75	10·25	12·00	14·25	15·00
R.l. ÷ C.l. .	0·58	0·50	0·37	0·49	0·55	0·51	0·51	0·66	0·72	0·77

Ovig. females.	(*k*).	(*l*).	(*m*).	(*n*).	(*o*).	(*p*).	(*q*).	(*r*).	(*s*).
C.l.	9·75	9·75	9·75	10·25	10·75	12·00	12·25	13·25	13·50
R.l. ÷ C.l. . . .	0·32	0·49	0·51	0·59	0·44	0·50	0·43	0·43	0·50

The first three of the above males are young; there is evidence in the collection that this is a species showing facultative dimorphism.

The specimens show considerable variation in number of tubercles on dorsal surface of the carapace and in the teeth of the lateral border. The majority resemble the variety figured by DANA as *Menæthius sub-serratus* rather than any other variety. Some tend to combine the characters of two or more of DANA's figures, *e.g.*, of the three specimens from Cheval Paar, one agrees fairly with the figure of *M. sub-serratus*, while the other two agree with this figure in character of lateral teeth, but more resemble that of *M. angustatus* in tuberculation. The two specimens from Jokkenpiddi agree fairly with DANA's figure of *M. tuberculatus*.

Variability of rostrum-length is high. Thus for eight ovigerous females the index R.l. ÷ C.l. has mean value = 0·47, and range of variation from 0·32 to 0·59. For the ten males of various ages the corresponding figures are 0·57 and 0·37–0·77.

Specimen *s* (female) stands apart from the others and makes some approach to *Huenia proteus* in the character of its last pair of walking legs. These are comparatively smooth and expanded, and obvious teeth are absent from the dactylopodite. This specimen also has dorso-lateral hepatic swellings.

Acanthonyx macleayi, Krauss, 1843—A. 1, p. 199.

Locality:—Cheval Paar, Gulf of Manaar, one ovigerous female. C.l. = 12·50.

Halimus pleione (Herbst), 1803—A. 1, p. 208.

Localities:—Pearl banks, Gulf of Manaar, two specimens (ovigerous ♀ *a*, *c*); off Mutwal Island, two specimens (ovigerous ♀ *b* and young ♂ *d*).

Description:—	(*a*) ovigerous ♀.	(*b*) ovigerous ♀.	(*c*) ovigerous ♀.	(*d*) young ♂.
C.l.	17·00	20·00	23·00	11·00
C.b. ÷ C.l. . . .	0·75	0·75	0·78	0·80
R.l. ÷ C.l. . . .	[ ]	0·37	0·31	0·41

In the immature male the rostral spines lie in an approximately horizontal plane; in the three ovigerous females they continue the downward anterior slope of the gastric region of the carapace.

Halimus hilgendorfi (de Man), 1888—A. 1, p. 209.

Localities:—Pearl banks, Gulf of Manaar, sixteen specimens (including *d* and *f*); Aripu coral reefs, Gulf of Manaar, eighteen specimens (including *a*, *b*, *c*, *g*, and *e*); off Mutwal Island, two specimens (*h*, *i*).

Description:—	(*a*) ov. ♀.	(*b*) ov. ♀.	(*c*) ov. ♀.	(*d*) ov. ♀.	(*e*) ad. ♂.	(*f*) ad. ♂.	(*g*) ad. ♂.	(*h*) ad. ♂.	(*i*) ad. ♂.
C.l.	11·50	13·50	14·00	16·50	12·50	12·50	13·50	14·50	15·00
Rost.spine l. ÷ C.l. .	0·32	0·44	0·41	0·25	0·52	0·56	0·52	0·52	0·55
D. tips R.sp. ÷ C.l.	0·20	0·33	0·30	0·23	0·42	0·28	0·40	0·34	0·47

The above measurements give an indication of the high variability of the length, and degree of divergence, of the rostral spines. Both the characters named are sexually dimorphic.

A sexual difference is also shown in carapace length.

Halimus spinosus (A. Milne-Edwards), 1872—A. 1, p. 211.

Locality:—Aripu coral reefs, Gulf of Manaar, three specimens (two young ♀ and young ♂).

Remarks.—I unite *H. consobrinus*, A. Milne-Edwards, and *H. spinosus* specifically. The slight points of difference are that in the former (1) the anterior angle of the supra-ocular eave is hardly so much produced; (2) the two gastric spines are not so long: (3) the intestinal tubercle is but slightly represented. The present examples belong to the *consobrinus* variety.

Halimus convexus (MIERS), var. **hendersoni,** nov.

Localities:—Coral reefs, Gulf of Manaar, two specimens (ovigerous ♀ and young ♂); west of Cheval Paar, two specimens (young ♂); Cheval Paar, three specimens (young ♀).

Description:—C.l. of the ovigerous female = 10·50.

They differ from MIERS' form ('"Alert" Expedition,' p. 196 and figure) in having (1) an epibranchial tubercle on either side; (2) the carapace regions less strongly demarkated and less convex; (3) the rostral spines less divergent, straighter and shorter.

Remarks.—The specimens agree with the two dried ovigerous females from Penang in the British Museum, with which HENDERSON (p. 344) describes his Martaban example as almost identical. There is thus a group with a fairly wide distribution which differs from MIERS' form in certain definite respects: I call it var. *hendersoni.*

This variety bears a suspiciously close resemblance to descriptions and figures of *Halimus sub-inermis* (ZEHNTNER) ('Revue Suisse de Zool.,' ii., p. 136, pl. vii., figs. 2, 2*a*), and to *Halimus espinosus*, BORRADAILE (p. 688, pl. xlvii., fig. 4). I have not seen specimens of either of these species. The main difference from *Halimus espinosus* seems to be the form of the rostral spines. I should be inclined to merge both in *Halimus convexus* (MIERS).

Halimus brocki (DE MAN), 1887 ('Arch. f. Naturges.,' liii., p. 22).

Locality:—Off Mutwal Island, one specimen.

Description:—A male, perhaps adult. C.l. (measured anteriorly to the angle between the rostral spines) = 9·50; rostral spine l. ÷ C.l. = 1·0.

The rostral spines diverge less in their distal than in their proximal portions.

Halimus agassizi, RATHBUN, 1902—'Bull. Mus. Comp. Zool.' xxxix., p. 133, fig. 6.

Localities:—Pearl banks, Gulf of Manaar, one specimen (*a*); off Mutwal Island, one specimen (*b*); pearl banks, off Manaar, one specimen (*c*).

Description:—	(*a*) ovig. ♀.	(*b*) ovig. ♀.	(*c*) ad. ♀.
C.l.	8·50	6·00	6·50
R.l. ÷ C.l.	—	0·58	0·54

In specimen (*a*) there are a few inconspicuous hooked hairs, in no way hiding from view the tuberculation of the carapace, which I find to agree with Miss RATHBUN'S description of the male. The walking legs have a smooth appearance. In specimens (*b*) and (*c*) hooked hairs are numerous, obscuring the tuberculation of the carapace and giving the legs a roughened appearance.

As a point of distribution I may note that I found a specimen of this species (an ovigerous female) in the bottle which contains POCOCK'S "type" specimen of *Hyastenus* (*Chorilia*) *tenuicornis*, labelled "China Sea."

The interesting little tooth of the supra-orbital margin is referred to under *H. irami*, n. sp.

Halimus pehlevi, n. sp.—Plate I, fig. 3, 3*a*.

Localities:—Coral reefs, Gulf of Manaar, two specimens (*f*, *g*); pearl banks, Gulf of Manaar, 15 specimens. One is a young female; six are adult females (five are ovigerous); five are young males; five are adult males.

Description of Adult Male (*g*).—Carapace sub-triangular, globular behind the lateral post-hepatic groove. The regions are distinctly defined, and are convex independently of the general convexity of the carapace, and bear certain granules:—a pair at the anterior border of the gastric region internal to the bases of the supra-ocular eaves; 13 posterior to these on the gastric region, of which three are median; one (median) between the gastric and cardiac regions; three on the cardiac region arranged as a triangle with its base turned forward; one (median) intestinal; one in the posterior portion of the groove on either side of the cardiac region; two on each branchial region. The true posterior border of the carapace is convex apart from the general outline of the carapace. The rostral spines are divergent, the distance between their tips divided by the length of one of them = 1·11. Length of rostral spine (inner border) ÷ carapace length = 0·39. The spines are bordered laterally with hooked hairs. The supra-ocular eave is strongly bilobed; the post-ocular tooth has a denticle about the middle of its anterior border. The pterygostomian region bears a couple of tubercles, one to outer side of and behind the other.

The antero-external angle of the basal antennal joint is produced into a stout tooth which is just concealed in a dorsal view of the animal. Behind it the outer border of the basal joint of the antenna presents a slight convexity which is produced ventrally a little. Posterior to this and external to the opening of the green gland is a prominent laterally compressed tubercle, and posterior to this again the antero-external angle of the buccal cavern forms a prominence. The four prominences just named form a longitudinal row. The antennal flagellum does not reach so far forward as the tip of the rostral spine; it is stout and bears a few thick hairs averaging somewhat more than 0·5 millim. in length.

The merus of the external maxilliped has its antero-external angle produced, and its inner border indented by two notches. The inner border of the ischium of the same appendage is serrated.

Chelipeds are smooth beneath the hairs. In this adult male they are a little stouter than the walking legs and 1·2 times as long as the carapace (excluding rostral spines). The fingers gape proximally for about two-thirds of their length, a tooth on the proximal portion of the mobile finger projecting into the hiatus. The distal, apposable portion of the fingers is denticulate.

Walking legs are smooth beneath the hairs. W.L.1.l. ÷ C.l. = 1·74; W.L.2.l. ÷ C.l. = 1·17; W.L.3.l. ÷ C.l. = 1·00; W.L.4.l. ÷ C.l. = 0·91. The dactylopodite of walking leg 1 is almost straight, denticulate, and about half as long as the propodite. The dactylopodites of walking legs 2, 3, and 4 are curved, spinulous, and about the same length as the propodites of the same appendages.

C.l.	C.b. ÷ C.l.	Ch.l. ÷ C.l.	Propus l. ÷ C.l.	Arm l. ÷ C.l.	H.l. (up. bord.) ÷ C.l.	F.l. (up. bord.) ÷ C.l.
11·5	0·78	1·20	0·59	0·52	0·33	0·22

Arm length is measured along under surface from proximal end of ischium to tip of outer distal tubercle. Ch.l. = sum of arm l. and a line uniting outer distal tubercle of arm to tip of fixed finger when elbow is bent at a right angle. Propus l. is measured along lower border by a straight line uniting the proximal tubercle to the tip of the fixed finger.

Remarks.—This species may be recognised by the character of its orbital border.

The bilobed character of its supra-ocular eave is a point of resemblance to *Halimus verrucosipes* and *Halimus gracilirostris*.

The denticle on the anterior border of the post-ocular tooth is referred to under *H. irami*, n. sp.

Halimus irami, n. sp.—Plate I., figs. 4, 4*a*.

Locality :—Muttuvaratu Paar, two specimens—an ovigerous ♀ (*a*) and a *Sacculina*-infested male (*b*).

Description of Ovigerous Female.—Body and legs tomentose. Carapace sub-pyriform; the regions are defined, not very distinctly, by shallow grooves; the grooves defining the hepatic region are well marked; the gastric region shows a fairly prominent convexity. The denuded carapace is seen to be pitted, the pits well apart. The only protuberance on the carapace is a small epibranchial tubercle near the hinder limit of either branchial region. The rostral spines are 0·50 the length of the carapace (0·60 in the male example), fringed with a row of hairs on either side; the distance between their tips is 0·90 the length of one of them; though sloping obliquely downward, their slope is less inclined than that of the anterior surface of the carapace (in the male their slope is more oblique, in the same plane as that of the carapace).

The supra-ocular eave is produced anteriorly into a strong triangular tooth; at the base of the post-orbital tooth, between it and the supra-ocular eave, is a small tooth (it varies in position in the two specimens, as will be remarked later).

The antennal flagellum consists of about eight elongated segments, from the joints between which arise a few isolated stout hairs; it is damaged in this specimen, in the male it just falls short anteriorly of the tip of the rostral spine.

The outer anterior angle of the basal antennal segment is produced anteriorly into a stout tooth, visible from dorsal view, the outer border is a little convex; to the outer side of the aperture of the green gland is a compressed tubercle; behind the latter the antero-external angle of the buccal cavern is produced as a petaloid projection; on the pterygostomial ridge running obliquely backward from this there are two tubercles, and a third still further back just above the base of the cheliped.

The chelipeds are rather more slender than the walking legs. Ch.l. ÷ C.l. = 0·91. The dactylopodites of the walking legs are roughened, hardly denticulate, on their lower borders. Carapace length is 8·75.

The general form of the carapace and of the rostral spines, together with the slight epibranchial tubercle, suggest alliance with the *H. convexus* group. The small but distinct supra-ocular tooth is interesting. It occurs in *H. agassizi*; in *H. pehleri* there is no isolated tooth, but the lower half of the upper anterior border of the large post-ocular tooth bears a smaller tooth, which is perhaps its representative. At all events, the two examples of *H. irami* enable one to make a very pretty series; in specimen (*a*) there is on the right an isolated supra-orbital tooth well separated from both supra-ocular eave and large post-ocular tooth, on the left side it is at the base of the latter, though distinct from it, in (*b*) it is on either side hardly separated from the post-ocular tooth and might be described as situated upon it: this leads to the condition seen in *H. pehleri*.

For purposes of key this new species comes under section II.2.ii.*b*. of ALCOCK's arrangement (A.1, p. 208) with *H. planasius*; from the latter it is easily to be distinguished by its supra-ocular tooth.

The male example of the new species is of interest as exhibiting a condition of abdomen and chelipeds evidently due to the presence of the parasitic *Sacculina*. The chelipeds are much as in the female, the abdomen is much broadened, resembling that of a half-grown female; the larger pair of copulatory appendages reach back about half way along the abdomen.

Naxia investigatoris, ALCOCK, 1895—A.1, p. 218; A.Invest., pl. xxi., fig. 6.

Localities:—Coral reefs, Gulf of Manaar, one specimen (ovigerous ♀); pearl banks, Gulf of Manaar, one specimen (ovigerous ♀); off Mutwal Island, one specimen (♂).

Description:—	C.l.	Rost.sp.l. ÷ C.l.	Ch.l. ÷ C.l.
(*a*) ovigerous ♀ . . .	16·00	0·25	1·00
(*c*) adult ♂	16·00	0·37	1·19

The present male example suggests that facultative dimorphism occurs in the species. It has a well-grown appearance. In spite of its "non-breeding" type of cheliped, it is larger than a male specimen of ALCOCK's in the British Museum, which has chelipeds of "breeding" type; it is perhaps a "middle" male.

Naxia hirta (A. MILNE-EDWARDS), 1865—A.1, p. 218.

Localities:—Aripu coral reefs, Gulf of Manaar, nine specimens; Chilaw Paar, one specimen; pearl banks, Gulf of Manaar, seven specimens; off Mutwal Island, two specimens.

Description :—	C.l.	Rost.spine l. ÷ C.l.	Ch.l. ÷ C.l.
(*a*) adult ♂	35·50	0·30	1·31
(*b*) ovigerous ♀ . . .	31·25	0·24	0·94
(*c*) adult ♂	18·25	0·22	0·88

In adult male (*a*) one notes: (1) The cheliped length exceeds considerably the length of the carapace, whereas ALCOCK describes his specimens as having these measurements equal; (2) the fingers are considerably arched and so are well separated at the base when clenched—again contrasting with ALCOCK's description. ALCOCK does not give the size of his specimens, they are evidently either young or "non-breeding" forms. In the present collection males agreeing with ALCOCK's description in characters of cheliped have C.l. from 18·00 to 21·00.

Doclea gracilipes, STIMPSON, 1857—A.1, p. 229.

Localities:—Trincomalee, three specimens; pearl banks, Gulf of Manaar, two specimens.

Description:—All the examples are young—three are males and two females. They fall under ALCOCK's general description of the species, and are in fairly close agreement with the *Doclea* sp. of DE MAN, from Mergui. The smaller of his two specimens I have seen in the British Museum.

Doclea alcocki, n. sp.—Plate I., fig. 5, Plate II., fig. 2.

Locality:—Pearl banks, Gulf of Manaar, one specimen.

Description:—A female, non-ovigerous, but, judging from the broad abdomen, it is adult. C.l. (a straight line uniting base of posterior spine to posterior end of rostral groove) = 44·5. Body and legs, except the hands and dactylopodites, are covered with velvet.

Carapace sub-pyriform rather than sub-globular (Pl. II., fig. 2); the posterior part of the margin is semicircular, the anterior part (rostrum included) is triangular. Rostrum bifid; its length (a straight line uniting the tip of a rostral spine to the posterior end of the longitudinal dorsal rostral groove) is 0·25 the carapace length; the length of the free portion of a rostral spine is 0·55 the rostrum length; the rostral spines are compressed in an oblique plane and curve a little downwards distally. Inter-orbital breadth (a straight line uniting the fissures between the supra-ocular eave and post-ocular tooth of either side) is 0·25 the carapace length. The anterior angle of the supra-orbital eave is produced obliquely forward and outward as a tubercle. There are numerous tubercles (say 56). Of these, eight are in the median longitudinal line and increase in size from before backwards (four gastric, of which the most anterior is about one-third the size of the other three, one between gastric and cardiac region, one cardiac, one on posterior border; the last named is a good deal larger than any of the others (at its base on either side is a smaller tubercle, that on the right quite minute, that on the left strongly developed). Just anterior to this median dorsal row is a pair of small tubercles, one on either side of the posterior limit of the median longitudinal rostral groove; these and the small anterior one of the median dorsal row form a triangle; the three are sub-equal in size and are roughly one-third the size of the second member of the median dorsal row. The antero-external angle of the buccal cavern is produced into a tubercle, and this is the most anterior member of a row of four, of which the second is on the sub-hepatic region and the third and fourth are on the lateral border of the carapace. Parallel to this a row of four tubercles runs obliquely backwards and outwards from the posterior angle of the orbit; of these, the first is hepatic and the rest branchial. On either side between this row and the mid-dorsal row are twelve tubercles, four gastric and eight branchial. The gastric ones are small and occupy the corners of an antero-posterior oblong, of the branchial ones five follow the groove separating branchial from middle regions (second and sixth well developed, rest small), the remaining three lie to outer side, the posterior one being well developed, and the two anterior very close together. The middle regions of the carapace are separated from the lateral ones by distinct sinuous grooves; the branchio-hepatic groove also is distinct. In addition to the tubercles described above, the basal antennal segment is produced into one, there is another just behind this to the outer side of the opening of the green gland and just in front of the tubercle at the antero-external angle of the buccal cavern, already described. The interantennulary septum is produced ventrally in the middle region to form a much compressed tooth.

The merus of the external maxilliped has a very distinct notch in the anterior part of its inner border, its anterior border is oblique and a little convex, its outer angle rounded and slightly produced, its exposed surface concave; the ischium has its inner border obviously dentate. The length of the buccal cavern (a straight line uniting the inner base of the antero-external tubercle to the outer posterior angle) is 0·98, its breadth (across region of the two antero-external tubercles); outer border of merus ÷ breadth of buccal cavern = 0·48; outer border of ischium ÷ breadth of buccal cavern = 0·60.

Chelipeds slender, about the same degree of stoutness as the 2nd pair of walking legs, but a good deal shorter. Ch.l. ÷ C.l. = 1·15. W.L.1.l. ÷ C.l. = 2·37; W.L.2.l. ÷ C.l. = 1·98; W.L.3.l. ÷ C.l. = 1·64; W.L.4.l. ÷ C.l. = 1·37.

Abdominal segments IV. to VI. are fused (the specimen is female), but grooves representing joints remain very distinct.

Egeria arachnoides (Rumphius)—A.1, p. 223.

Localities:—Coral reefs, Gulf of Manaar, one specimen; south-east of Ceylon, 18 fathoms, one specimen.

Description:—Males—both probably immature.

Tylocarcinus styx (Herbst), 1803—A.1, p. 235.

Locality:—Cheval Paar, two specimens (ovigerous ♀ and young ♀).

Description:—C.l. of the ovigerous female = 16·5.

Paramithrax (Chlorinoides) longispinus (DE HAAN), var. **bispinosus**, nov.

Localities:—Pearl banks, two specimens; coral reefs, Gulf of Manaar, three specimens; off Kaltura, one specimen; Trincomalee, one specimen; south-east of Ceylon, 18 fathoms, one specimen; deep water, off Galle, two specimens.

Description:—C.l. of an ovigerous female = 12·00 (posterior and rostral spines excluded). For characters of the species see A.1, p. 242.

The examples include two ovigerous females, one adult non-ovigerous female, five adult males, one doubtfully adult male, and one young male.

They all differ from DE HAAN's figure ("F. Japon. Cr.," pl. xxiii., fig. 2) in the absence of the most anterior of the three supra-ocular spines. I name them var. *bispinosus*. The "Challenger" specimens included by MIERS under *Paramithrax coppingeri* illustrate a parallel variation in that closely allied species; the *P. coppingeri* specimens of HASWELL have three supra-ocular spines—the "Challenger" examples have two only.

Schizophrys aspera (H. MILNE-EDWARDS, 1834)—A.1, p. 243, pl. XXXV., fig. 1.

Localities:—Off Mutwal Island, two specimens (young ♀ and adult ♂); Jokkenpiddi Paar, one specimen (young ♂); pearl banks, one specimen (young ♂); coral reefs, Gulf of Manaar, one specimen (young ♀).

Description:—C.l. of the adult male = 29.

Cyclax suborbicularis (STIMPSON), 1857—A.1, p. 245.

Locality:—Galle, lagoon, one specimen.

Description:—A young male. It agrees in many points with A. MILNE-EDWARDS' fig. 2 of a young form ('Nouv. Archiv. du Mus.,' viii., p. 236, pl. x., 1872). The orbit, however, is different from his figures, both of young and adult, but as growth-changes are very considerable in this species, I do not exclude my specimen from it.

Stenocionops cervicornis (HERBST), 1803—A.1, p. 248.

Localities:—Jokkenpiddi Paar, one specimen (*b*); Cheval Paar, two specimens (*a*, *c*); pearl banks, Gulf of Manaar, three specimens; Chilaw Paar, three specimens; coral reefs, Gulf of Manaar, four specimens.

Description:—Among the specimens is one ovigerous female, one adult non-ovigerous female, and at least one adult male.

	C.l.	C.b. ÷ C.l.	Rost.spine ÷ C.l.	Sup.-oc.spine ÷ C.l.	Eye stalk ÷ C.l.
(*a*) ovigerous ♀ . . .	34·50	—	0·42	0·41	0·34
(*b*) adult ♀	25·00	0·71	0·35	0·37	0·34
(*c*) adult ♂	42·00	—	—	—	—

The posterior projection is, in all the specimens, blunter and more broadly triangular than in CUVIER's figure in the "Règne Animal" (pl. xxxi., fig. 1), *i.e.*, it is to some extent intermediate between that figure and A. MILNE-EDWARDS' figure of *Stenocionops curvirostris.* Among the present specimens there is nothing further to minimise the somewhat slender specific distinction between *S. cervicornis* and *S. curvirostris.*

In the young examples the tuberculation is less distinct than in the adult, and also the posterior projection of the carapace is less prominent. HENDERSON (p. 343) found in his specimens that the posterior projection was narrower and more upturned in the male than in the female; this does not hold as a distinction between the ovigerous female and the adult male of the present collection.

It would be of interest to re-examine A. MILNE-EDWARDS' "type"-specimens of *Stilbognathus* for the purpose of verifying the generic distinction between that genus and *Stenocionops.*

Pseudomicippa nodosa, HELLER, 1861—'S.B. Ak. Wien,' xliii., p. 303, pl. i., fig. 3.

Locality:—Muttuvaratu Paar, Gulf of Manaar, one specimen.

Description:—An ovigerous female. C.l. (without front) = 9·50. It is labelled "crab with black sponge." The sponge completely covers the dorsum of the carapace.

Remarks.—For remarks on the limits and affinities of the genus, see CALMAN (p. 40). He favours the generic separation of *P. nodosa* and *P. varians* on the grounds that (1) the rostrum is very strongly deflexed in *P. nodosa*—not so in *P. varians*; (2) the anterior angle of the orbit is produced into a long spine in *P. nodosa*—not so in *P. varians*; (3) the distal tooth of the basal antennal joint is directed obliquely forwards in *P. nodosa*—outwards in *P. varians.* With the additional evidence of the present specimen and of some specimens in the British Museum, I find it inadvisable to separate the species generically. Thus the present example combines the strongly deflexed rostrum of *P. nodosa* with an anterior orbital angle which is only drawn out a little more than in *P. varians.* In the British Museum I find specimens which show some variation in the degree to which the rostrum is deflexed. The third distinction does not appear to me to be one of generic value. In the present specimen the antennal angle is *nodosa*-like in pointing obliquely forwards, though it differs from HELLER's figure—the latter agreeing with dried Red Sea specimens in the British Museum. This genus is new to the Indian fauna.

Micippa philyra (HERBST), 1803—A.1, p. 249.

Localities:—Coral reefs, Gulf of Manaar, four specimens (*a*, *b*, *d*, *e*); off Mutwal Island, one specimen (*c*).

Description:—

	C.l.	C.b. ÷ C.l.	Antenn.l. ÷ C.l.	2nd sgt.ant.l. ÷ R.b.	Arm.l. ÷ C.l.	H.l. ÷ C.l.	H.b. ÷ H.l.
(*a*) ovig. ♀.	23·00	0·87	0·43	0·25	0·33	0·24	0·36
(*b*) adult ♂.	20·00	0·87	0·50	0·34	0·39	0·35	0·61
(*c*) adult ♂.	22·50	0·87	0·51	0·28	0·37	0·29	0·46

ALCOCK records a male dimorphism in this species, believing it to be comparable with the phenomenon recorded among the beetles. Dimorphism is illustrated by the males (*b*) and (*c*) above, but it is noteworthy that it is the larger example (*c*) which has the more female-like form of cheliped, while the smaller one (*b*) has a cheliped of strongly marked male character. This seems to be a case of facultative dimorphism, specimens (*b*) and (*c*) being respectively "breeding" (perhaps "low") and "non-breeding" ("middle") forms.

In length of mobile portion of the antenna, the two adult males come under var. *mascarena*. In the ovigerous female this measurement is larger than in females of the species as described by ALCOCK.

The surface of the post-cardiac region of the carapace varies in character. It is smooth in (*b*), it has a trace of granulation in (*a*) which is rather more obvious in (*c*) and (*d*) and quite fairly developed in (*e*). The vertical portion of the carapace plus the rostrum has in (*a*) and (*b*) a flattened surface, in (*c*) the lateral pair of lobes curve forward somewhat, so that the anterior surface is concave from side to side. Example (*d*) is intermediate.

All the specimens possess the following spines on the lateral margins of the carapace:—Three spines on hepatic border, one (a small tubercle) on the antero-lateral branchial border, three on branchial border in the region of the epibranchial angle. In addition, the two males (*b*) and (*c*) have two spines, both obsolescent in (*c*), and anterior one so in (*b*), on the border between the epibranchial angle and the true posterior margin of the carapace, just above the granular ridge.

Micippa thalia (HERBST), 1803—A.1, p. 251.

Localities:—Off Mutwal Island, two specimens; coral reefs, Gulf of Manaar, seven specimens; Cheval Paar, two specimens; pearl banks, Gulf of Manaar, 18 specimens.

Description:—The specimens fall into two groups, corresponding with the figures of A. MILNE-EDWARDS ('Nouv. Archiv. du. Mus.,' viii., p. 238, pl. xi., fig. 1, 1872) and of HERBST ('Krabben,' iii., pl. lviii., 3) respectively. Twenty-eight of them agree very fairly with the former and one with the latter. It may be noted that forms resembling the "type"-specimen of this species have been seldom recorded.

A. The following is the arrangement of the spines in 20 adult individuals of the first variety. The number which occurs in each region with maximum frequency is printed in heavy type.

Dorsal Surface of Supra-ocular Hood.—Fourteen specimens have a mere indication of one granule on each hood, three have a more obvious granule, and three have a small blunt spinule.

Dorsal Surface of Branchial Region.—Nineteen specimens have two spines on each side (may be written **2·2**), one specimen has one on the left side and two on the right side (may be written 1·2).

Gastric Region.—Nineteen specimens have **2** median spines (reduced in one specimen), and one has a spine and a granule.

Upper Margin of the Orbit behind the Supra-ocular Spine.—All have **3·3**, of which the third is the largest.

Hepatic Margin.—All have **3·3**.

Branchial Margin.—Fifteen specimens have **5·5**; one has 4·5; one has 5·6; one has 5·7; one has 6·6; one has 6·7.

B. Specimen (*a*), an ovigerous female, differs from the other examples in the collection in various ways, as set forth below, and goes with HERBST's "type"-specimen of the species:—

(1) The rostral spines are more strongly curved outwards at their tips (see HERBST's figure).

(2) The hepatic regions are not so much pinched in dorsally.

(3) The under surface of the basal antennal segment is smooth and its antero-lateral angle is produced into a longer, more definite spine, the border of which is entire (in the A-specimens the outer half of the under surface of the basal antennal segment is more or less granular, and its antero-lateral angle is produced to form a triangular and less spiniform infra-orbital projection with a crenulate border).

(4) The arrangement of spines is different.

Dorsal surface of the supra-ocular hood of either side has a definite blunt spine. The anterior and posterior angles of the eave form blunt projections.

Dorsal surface of branchial region of each side has three arranged in a longitudinal row; of each row the two anterior members are spinules merely, the posterior one is a well-developed spine. There is also a denticle on the branchial region which would lie about one-third way along a line drawn from the large spine just named to the middle point of the gastro-cardiac groove.

Gastric Region.—Two not very obvious median tubercles.

Upper margin of orbit behind the supra-ocular eave of either side has three spines, the middle one much the strongest.

Hepatic Margin, 0.

Branchial Margin, 7 8 (on the left side the anterior four are granules, the three posterior are larger; on the right side the anterior five and the seventh are granules; the sixth and eighth are larger).

Posterior Border of Carapace.—A pair of spines close together, one on either side of middle point.

Of the above particulars the form of the rostral lobes, the strong development of the middle one of the three supra-orbital spines, the presence of the two spines of the posterior border, and the crenulate margin of the antero-lateral spiniform production of the basal antennal segment, are conveniently conspicuous characters.

Micippa margaritifera, HENDERSON, 1893—A.1, p. 253; A.Invest., pl. xxxv., fig. 3.

Localities:—Jokkenpiddi Paar, two specimens (ovigerous ♀); Aripu coral reef, one specimen (ovigerous ♀); Gulf of Manaar, three specimens (one adult ♂ and two young ♂).

Description:—All the specimens have their walking legs folded beneath them, in which position the expanded meropodites, together with the retroflected tip of the rostrum, enclose a space beneath the body and help to give the animal a rounded ball-like appearance. The space referred to is widely open posteriorly, where a considerable squarish gap is left between the members of the last pair of walking legs. Slits remaining between the successive legs of either side are more or less occluded by fringes of hair which border the appendages.

A variable character to note is the size of the innermost of the three branchial tubercles; in none of the specimens, however, does this exceed two-thirds of the size of the two outer tubercles.

Micippa parca, Alcock, 1895—A.1, p. 253; A.Invest., pl. xxxv., fig. 4.

Locality:—Coral reefs, Gulf of Manaar, one specimen.

Description:—C.l. = 11·25 (a straight line uniting base of the median posterior spinule with the middle point of a faint inter-ocular groove); C.b. ÷ C.l. = 0·98; Inter-orbital b. ÷ C.l. = 0·58 (inter-orbital breadth is measured by a straight line uniting the notches made by the junction of pre-ocular spinule with supra-ocular eave of either side); breadth between the bases of the mobile portions of the antennæ ÷ C.l. = 0·36; Arm l. ÷ C.l. = 0·42; H.l. ÷ C.l. = 0·38.

The present specimen of *M. parca* differs from *Micippa margaritifera*, to which it is closely allied, in the following particulars:—

(1) The median region of the posterior border of the carapace is occupied by a group of spinules (three in a transverse row) instead of by a single pearl-like tubercle; (2) the post-cardiac cluster of granules and the cluster on either side of it are but slightly indicated; (3) the gastro-cardiac groove is more distinct; (4) the difference in size between the inner branchial spinule (a mere rudiment—not a real spinule) and the two outer ones (well developed) is more marked; (5) the meropodites of the walking legs are still more expanded, which is largely due to the greater foliation of their posterior borders; their distal borders are finely and fairly regularly toothed; (6) the walking legs are less hairy; (7) the upper portion of the outer surface of the hand is granular.

Lambrus (Lambrus) longimanus, Leach, 1815—A.1, p. 260.

Localities:—Galle, three specimens (*c*, *e*, *g*); pearl banks, Gulf of Manaar, four specimens (*a*, *b*, *d*, *f*).

Description:—	(*a*) young ♀.	(*b*) young ♀.	(*c*) young ♂.	(*d*) young ♂.	(*e*) young ♂.	(*f*) adult ♂.
C.l. (rost. included)	11·50	17·50	9·75	12·00	17·50	25·50
C.b. ÷ C.l. . . .	1·04	1·01	1·50	1·00	1·11	1·12
Ch.l. ÷ C.l. . . .	3·22	3·31	3·10	3·25	3·64	4·40

In the young male (*e*) the median lobe of the rostrum is reduced to a declivous denticle of approximately the same length as the denticular lateral lobes, which are in this example more strongly developed than usual. Considerable growth-changes in cheliped length for males are indicated by the measurements given above.

Lambrus (Platylambrus) carinatus, H. M.-Edw., 1834—A.1, p. 263.

Localities:—Coral reefs, Gulf of Manaar, four specimens; off Mutwal Island, one specimen; pearl banks, Gulf of Manaar, nine specimens.

Description:—The specimens include four ovigerous females (incl. *f–h*), six non-ovigerous females (incl. *a–e*), and four adult males.

	(*a*) ♀.	(*b*) ♀.	(*c*) ♀.	(*d*) ♀.	(*e*) ♀.	(*f*) ♀.	(*g*) ♀.	(*h*) ♀.	(*i*) ♂.	(*j*) ♂.	(*k*) ♂.	(*l*) ♂.
C.l. . . .	8·75	11·00	11·25	13·00	13·00	9·25	11·25	11·50	9·25	9·25	11·25	11·25
Arm.l. ÷ C.l.	0·80	0·77	0·82	0·65	0·73	0·73	0·73	0·72	0·89	0·86	0·84	1·02
H.l. ÷ C.l. .	0·94	0·93	1·02	0·83	0·92	0·94	0·87	0·83	0·94	0·95	0·96	1·11

Some characters exhibit high variability:—

(1) The mid-dorsal teeth may be large and laterally compressed, or they may be smaller and peg-like. In one example the most anterior of the three is obsolescent.

(2) The branchial ridges vary in number and in character. There may be on each side a single sharp carina, a single granular ridge, a pair of granular ridges, or a pair of smooth ridges; the second ridge may be very inconspicuous, and there may be a granule or two in the middle of such a faint ridge.

(3) The carapace may be free from granules, or granules may be present, but confined to the depression on either side of the cardiac region, or a few may extend over the branchial region also.

Remarks.—I include *Lambrus holdsworthi*, Miers, as a synonym. A. Milne-Edwards' brief diagnosis of *L. carinatus* applies to Miers' "type"-specimens of *L. holdsworthi* in the British Museum. Some of my specimens, which I group as var. *holdsworthi*, agree with the latter; others agree with Alcock's description of his examples of *L. carinatus*—I call these var. *alcocki*.

In var. *alcocki* there is a single carinate ridge on each branchial region; in var. *holdsworthi* there are two low granular ridges.

In var. *alcocki* the mid-dorsal tubercles are more prominent and are laterally compressed; in var. *holdsworthi* they are more peg-like and less prominent.

In var. *alcocki* the carapace tends to be free from granules; a fair number of granules are present in var. *holdsworthi*.

The variations presented by the present forms in regard to median dorsal teeth and branchial ridges—which I have referred to above—minimise or break down two of the distinctions which Alcock draws between his specimens of *L. carinatus* and of *L. prensor*. All my specimens agree with those described by Alcock in the character of the sub-orbital lobe (bilobed, the inner lobe rounded and not produced into spine nor seen in dorsal view) and of the anterior borders of the meropodites of the walking legs (serrate).

Lambrus (Rhinolambrus) contrarius (HERBST), 1804—A.1, p. 266.

Localities:—Coral reefs, Gulf of Manaar, four specimens (*b*, *c*, *g*, *h*); pearl banks, Gulf of Manaar, four specimens (*a*, *e*, *i*, *d*); Chilaw Paar, one specimen (*f*).

Description:—	(*a*) yg. ♀.	(*b*) yg ♀.	(*c*) yg. ♂.	(*d*) yg. ♂.	(*e*) yg. ♂.	(*f*) yg. ♂.	(*g*) ad. ♂.
C.l. (rost. included) .	11·50	24·00	9·50	18·00	19·75	22·75	38·75
C.b. ÷ C.l.	0·89	0·92	0·84	0·92	0·90	0·89	0·93
Ch.l. ÷ C.l.	2·17	2·30	2·18	2·36	2·34	2·58	2·86

The growth-changes in ratio Ch.l. ÷ C.l. will be noted.

Lambrus (Rhinolambrus) longispinis, MIERS, 1879—A.1, p. 266.

Localities:—Pearl banks, Gulf of Manaar, eight specimens; coral reefs, Gulf of Manaar, three specimens.

Description:—The specimens are all young—four of them males. The C.l. of the latter varies from 10·5 to 16; the scanty evidence suggests that no great change in the ratio Ch.l. ÷ C.l. accompanies this growth. There is at this size no very obvious establishment of sexual dimorphism.

	(*a*) yg. ♀.	(*b*) yg. ♀.	(*c*) yg. ♀.	(*d*) yg. ♀.	(*e*) yg. ♂.	(*f*) yg. ♂.	(*g*) yg. ♂.	(*h*) yg. ♂.
C.l. (rost. included) .	12·25	12·25	12·50	19·25	10·50	11·25	12·50	16·00
C.b. ÷ C.l.	0·94	0·98	0·92	1·00	0·98	0·94	0·92	0·97
Ch.l. ÷ C.l. . . .	2·14	2·16	2·06	2·39	2·24	2·11	2·08	2·22

The present specimens agree closely with ALCOCK's example and confirm his belief that the species is more nearly related to *L. contrarius*, HERBST, than to *L. validus*, DE HAAN. Variability is low among the above examples for most characters; the shape of the rostrum is an exception. The latter is acutely pointed in most of the examples, narrowing rather suddenly a short distance in front of the eyes; in one specimen no such sudden narrowing occurs; in another there are two small lateral lobes near the apex; other examples are intermediate.

Lambrus (Rhinolambrus) pelagicus, RÜPPELL, 1830—A.1, p. 267.

Localities:—Coral reefs, Gulf of Manaar, one specimen (young ♀); off Mutwal Island, one specimen (adult ♂).

Description:—

Young ♀ . . . . C.l. = 7·50; C.b. ÷ C.l. = 1·00; Ch.l. ÷ C.l. = 2·63.
Adult ♂ . . . . C.l. = 16·00; C.b. ÷ C.l. = 1·02; Ch.l. ÷ C.l. = 3·16.

Lambrus (Aulacolambrus) hoplonotus, ADAMS and WHITE, 1848—A.1, p. 273.

Localities:—Pearl banks, Gulf of Manaar, four specimens (*a*, *b*, *e*, *g*); coral reefs, Gulf of Manaar, three specimens (*c*, *d*, *f*).

Description :—	(*a*) young ♀.	(*b*) young ♀.	(*c*) adult ♀.	(*d*) young ♂.	(*e*) young ♂.	(*f*) adult ♂.
C.l. . . .	7·00	13·00	15·00	8·50	9·25	13·25
Ch.l. ÷ C.l. .	2·75	2·62	2·77	2·71	2·65	2·57

The above series present but little variation among themselves. They come under var. *planifrons*, with some approach also to var. *granulosus*. Thus adult female (*c*) bears considerable resemblance to MIERS' specimen of var. *planifrons* in the British Museum, excepting that the spines of the posterior border of the hand are neither so flattened nor so broad, *i.e.*, more as in var. *granulosus*, and in the same example the apex of the rostrum is a further point of resemblance to the latter variety.

The number of spines on the outer border of the hand is fairly constant, that of the teeth of the inner border more variable. Thus in all the specimens there are on the outer border of the hand six large smooth spines and four smaller alternating ones (the most distal of the alternating spines is in (*b*) larger than in the others, and in (*f*) it is almost the size of the larger ones); the inner border bears from eleven to thirteen teeth.

Lambrus (Aulacolambrus) curvispinis, MIERS, 1879—A.1, p. 274.

Localities :—Galle, one specimen (adult ♀); Trincomalee, one specimen (ovigerous ♀).

Description :— Adult ♀ . . . . . . C.l. = 21·00; Ch.l. ÷ C.l. = 3·07.
Ovigerous ♀ . . . . C.l. = 24·00; Ch.l. ÷ C.l. = 3·15.

Lambrus (Parthenolambrus) calappoides (ADAMS and WHITE), 1847—A.1, p. 275.

Localities :—Coral reefs, Gulf of Manaar, nine specimens (*a* to *i*); Trincomalee, one specimen (*j*).

Description :—

	(*a*) yg. ♀.	(*b*) yg. ♀.	(*c*) yg. ♀.	(*d*) ad. ♀.	(*e*) ♂.	(*h*) ♀.	(*i*) ♀.	(*f*) ♂.	(*g*) ♂.	(*j*) ♂.
C.l. . . .	9·50	14·50	15·75	19·25	19·00	14·50	17·50	8·00	14·00	16·75
Ch.l. ÷ C.l. .	1·84	1·84	—	—	2·09	1·66	1·71	1·97	1·96	2·04

The present examples show a good deal of variation about two centres; the two groups I call var. *alcocki* (corresponding more or less with ALCOCK'S description of *L. calappoides*) and var. *confragosus* (= *L. confragosus*, CALMAN).

I have seen the "type"-specimens of *L. confragosus* in the British Museum, and find that with the aid of the present forms and of the British Museum examples of *L. calappoides* I can arrange a transitional series which unites the two forms named.

Differences between the two varieties are :—(1) The post-ocular notch is well indicated in var. *confragosus*; absent in var. *calappoides*. (2) The lateral hepatic region is prominent, dentiform and compressed in var. *confragosus*; little prominent and rounded in var. *calappoides*. (3) The post-hepatic notch is well indicated in var. *confragosus*; slightly so in var. *calappoides*. (4) The median dorsal spines are prominent and pointed backward in var. *confragosus*; in var. *calappoides* they are represented by inconspicuous tubercles. (5) The tubercles of the carapace are granulated in var. *confragosus*; in var. *calappoides* they are more or less smooth, low and obsolescent and the general surface of the carapace tends to be pitted and uneven, producing what Alcock aptly terms a "boiled" appearance. (6) The postero-lateral angles are angular and spine-bearing in var. *confragosus*; rounded in var. *calappoides*. (7) The greatest carapace-breadth is in var. *confragosus*, across the region of the postero-lateral angle; in var. *calappoides* it is anterior to this region. (8) There are two large tubercles on the inner border of the arm in var. *confragosus*, one about one-third from its distal end and the other about one-third from its proximal end. The latter is the larger, a good deal compressed from above downwards, and has a small tubercle at its base; in var. *calappoides* there are traces only of both. (9) The rostrum is obliquely deflexed in var. *confragosus*; vertically deflexed in var. *calappoides*.

The above characters show a fair degree of correlation; the transitional forms tend to combine intermediate conditions of most of them. The correlation is, however, by no means perfect, *e.g.*, a "Challenger" female from "off Tongatabu," in the British Museum, combines with most characters of var. *calappoides* a considerable development of the median dorsal spines.

Lambrus (Parthenolambrus) beaumonti, Alcock, 1895—A.1, p. 276.

Localities:—Coral reefs, Gulf of Manaar, three specimens (*a*, *d*, *e*); south of Galle, deep water, one specimen (*b*); Gulf of Manaar, deep water, one specimen (*c*).

Description:—	(*a*) young ♀.	(*b*) ovigerous ♀.	(*c*) ovigerous ♀.	(*d*) adult ♂.	(*e*) adult ♂.
C.l.	6·75	7·75	8·00	9·25	10·00
C.b. ÷ C.l. . . .	1·11	1·06	1·09	1·00	1·07
Ch.l. ÷ C.l. . . .	1·74	—	1·91	2·46	2·90

The difference in ratio Ch.l. ÷ C.l. between the two males—both apparently adult—is interesting. In the present forms there is much variation in the size of gastric and cardiac tubercles. They are both absent in the young female example (*a*), they are both rudimentary in the larger of the two males (*e*), there is a blunt tubercle on each of these regions in ovigerous female (*b*), finally, in the smaller male (*d*), there is a stout spine on the gastric eminence, and a still stouter one on the cardiac.

Lambrus (Parthenolambrus) harpax, Adams and White, 1848—A.1, p. 278.

Locality:—Pearl banks, one specimen.

Description:—A male, apparently young. C.l. = 14·25; Ch.l. ÷ C.l. = 2·79. This individual, belonging to a highly variable species, agrees with Alcock's description of the Indian Museum specimen from the Andamans, excepting that the index Ch.l. ÷ C.l. is considerably higher.

Cryptopodia fornicata (Fabricius), 1793—A.1, p. 282.

Locality:—Pearl banks, Gulf of Manaar, one specimen.

Description:—A young male, C.l. (rostrum included) = 18·0; C.b. ÷ C.l. = 1·46.

Cryptopodia pan, n. sp.—Plate I., fig. 6, and text-fig. 4.

Localities :—Coral reefs, Gulf of Manaar, one specimen (adult ♀ = *a*) ; west of Periya Paar, 17 to 24 fathoms, two specimens (young ♀ = *b* ; young ♂ = *c*).

Description of female (*a*) :—C.l. (rostrum included) = 22·5. Carapace broadly triangular ; antero-lateral margin slightly sinuous, smooth in its anterior third and lacinated in its posterior two-thirds ; the posterior and postero-lateral margins form a single strong curve, the edge of which shows faint traces of crenulation ; the surface of the carapace is fairly smooth to the naked eye, but some obsolescent granules crown the prominences, and there are a few also scattered on the posterior slope ; there are some

Fig. 4. *Cryptopodia pan*, n. sp.

pits, obvious to the naked eye, on the cardiac prominence and on the prominence on either side of it ; the whole surface (as also that of the chelipeds) is dull, which is seen under lens to be due to a fine pitting which covers it ; the triangular depression is shallow ; the oblique branchial ridge of either side is much swollen and rounded ; the rostrum is prominent, obtusely pointed, rather longer than broad, and has the anterior part of the edge faintly crenulate. The carapace is produced beyond the abdomen posteriorly for a distance equal to 0·08 the carapace length. C.b. ÷ C.l. = 1·43.

The third pair of maxillipeds form together a striking bulge. This is due in part to curvature of the appendage, but the most important factor is an actual thickening of the substance of the ischium. The exposed surface of the ischium is glazed, its outer two-thirds particularly are thickened, its inner one-third is ornamented with a double row of granules. The merus is granular on its proximal portion ; distally it is smooth beneath a pubescence. The exopodite is, for the most part, concealed in ventral view by the ischial bulge.

The chelipeds are much as in *Cryptopodia fornicata* (see A.1, p. 282), but the surface is dull, not glazed ; the armature is not so sharp ; the outer border of the wrist has no tooth, but its blunt outer angle is well developed, so that its outer border is made up of two borders of approximately equal length set at right angles to each other. The meropodites of all the walking legs have their upper border, and those of the 1st and 4th pairs their lower border also, armed with a spiniform crest ; the other segments are a little compressed from side to side, but not carinate.

Differences from *Cryptopodia fornicata* are :—(1) The duller surface of the carapace and chelipeds (due largely to fine pitting); (2) the more rounded surfaces of the prominences, and less sharply cut armature ; (3) the angular wrist ; (4) form of rostrum ; and (5) the swollen external maxillipeds. The last-named particular separates the new species at a glance from any other member of the genus known to me.

Heterocrypta petrosa, KLUNZINGER, 1906—(K., p. 53, pl. ii., figs. 9*a*, *b*).

Locality :—Gulf of Manaar, one specimen (*a*) ; off Mutwal Island, one specimen (*b*).

Description :—	C.l.	C.b. ÷ C.l.	Ch.l. ÷ C.l.	Rt.H.b. ÷ Lt.H.b.
(*a*) Ovigerous ♀. . .	13·25	1·47	2·00	1·50
(*b*) Adult ♂	18·00	1·57	2·44	1·35

In the female specimen the true posterior border of the carapace forms a convex bulge. The carapace regions are more rounded in the male specimen than in the female. The latter variation is probably not concerned with sex, for KLUNZINGER's figure of a male bears a stronger resemblance to my female than to my male example in this respect.

Remarks.—This species falls decidedly into the genus *Heterocrypta*, as defined by ALCOCK, but, having conformed so far, its further resemblances are rather to *Cryptopodia spatulifrons* than to any *Heterocrypta*. Such resemblances concern (1) general appearance of cheliped (no crest, however, on outer surface of wrist); (2) general shape of posterior border of the animal (*i.e.*, true posterior border of carapace together with posterior border of clypeiform expansions); (3) sculpture of exposed surface of the external maxillipeds, of uncovered portions of thoracic sterna, and of the abdominal terga.

On its part, *Cryptopodia spatulifrons* (as also *C. dorsalis*) makes some approach to *Heterocrypta* in the slight posterior expansion of its carapace—much slighter, for example, than in *Cryptopodia fornicata*.

Zebrida adamsi, WHITE, 1847—A. 1, p. 287.

Localities :—Gulf of Manaar, one specimen ; south of Manaar Island, two specimens.
Description :—C.l. of an adult male (rostral lobes included) = 8·0.

Harrovia albolineata, ADAMS & WHITE, 1848—(' "Samarang" Zool.,' Crust., p. 56).

Localities :—South of Manaar Island, hauls 3, 4 and 5, two specimens (adult ♂, adult ♀) ; pearl banks, Gulf of Manaar, one specimen (young ♀) ; coral reefs, Gulf of Manaar, one specimen (ovigerous ♀).

Description :—C.l. of ovigerous female = 7·00.

CYCLOMETOPA.

Carpilodes tristis, DANA, 1852—A.3, p. 82.

Locality :—Galle, lagoon, three specimens (one adult ♂, two young ♂).
Description :—C.l. of adult male = 10·0.

Carpilodes pediger, ALCOCK, 1898—A.3, p. 83 ; A.Invest., pl. xxxvi., fig. 4, ♀.

Localities :—Off Mutwal Island, two specimens (one adult ♂ = *a*, one young ♂ = *b*) ; west of Periya Paar, 17 to 24 fathoms, one specimen (adult ♀ = *c*) ; pearl banks, Gulf of Manaar, three specimens (adult ♂ = *d*, ovigerous ♀ = *f*, young ♀ = *e*).
Description :—C.l. of ovigerous female = 5·25.

The third of the four antero-lateral teeth of the carapace may be continuous with the lobe 4L of DANA's nomenclature as in (*b*), it may be separated therefrom by a faint groove as in (*a*), (*d*), and (*e*), or by a more evident groove, agreeing with ALCOCK's figure, as in (*f*).

Carpilodes cariosus, ALCOCK, 1898—A.3, p. 86 ; A.Invest., pl. xxxvi., fig. 7, ♀.

Localities :—Muttuvaratu Paar, 6 to 9 fathoms, one specimen (adult ♂ = *a*) ; Gulf of Manaar, three specimens (young ♂ = *b*, two adult ♀ = *c*, *d*) ; Jokkenpiddi Paar, one specimen (adult ♀ = *e*).
Description :—C.l. of an adult female = 4·50.

There is variation in lobulation of carapace. The lobe 3M (DANA's nomenclature) is entire in all except the young male (*d*), where a groove separates the narrow anterior limb from the posterior broad part. Lobe 2M is completely divided by a longitudinal groove in all except the adult female (*b*), in which the groove is incomplete posteriorly. The outer division of 2M is entire in adult females (*b*) and (*e*) ; its inner border is notched in adult male (*a*) on both right and left sides of the animal ; in adult female (*c*) its inner border is notched on the lobe of the right side of the animal, while on the lobe of the left side there is an indication of a transverse groove ; finally, in young male (*d*) a distinct transverse groove divides the lobe of each side. Lobe 5L is entire in all except adult male (*a*), in which it is divided obliquely. Lobes 2R, 1R, and S are fused in adult male (*a*) and adult females (*b*, *c*) ; in young male (*d*) and in adult female (*e*) there is an indication of their separation by grooves. Variation is not always bilaterally symmetrical. The degree of sub-division of the lobules is the most apparent difference between the present species and *C. monticulosus*. The variations above noted are within the limits allowed to the species by ALCOCK.

Atergatis integerrimus (LAMARCK), 1818—A.3, p. 95.

Locality :—Galle, lagoon, one specimen (very small young).

Lophactæa anaglypta (HELLER), 1861—A.3, p. 102.

Locality :—Gulf of Manaar, two specimens (both males). C.l. = 16·0.

(See RATHBUN, 'Proc. Biol. Soc. Wash.,' xi., p. 159, for *Platypodia* as generic name.)

Zozymus gemmula, DANA, var. **ceylonica**, nov.—Plate I., fig. 7.

Locality :—Trincomalee, three specimens (*a*, *b*, *c*).

Description :—Two males, one of which appears to be adult, and one female, which, though non-ovigerous, has a broad abdomen loosely applied to the sternum and may well be adult. Except in regard to the walking legs, the specimens show a very close similarity in most respects to those described and figured by DE MAN under *Zozymus gemmula*, DANA (DE MAN, 'Abh. Senck. Ges.,' xxv., p. 588). However, the walking legs show considerable differences. The following is a description of these appendages in my specimens :—The four pairs of the same individual are very similar. Dorsal border of the meropodite faintly denticulated. Carpopodite and propodite have well-developed dorsal crests ; that of the carpopodite is deeply fissured about the middle of its extent (a little more distal than the middle). The carpopodite has a longitudinal groove on its posterior surface ; a transverse groove crosses this, continuing the line of the incision of the crest, and marking off a more or less triangular distal area of the segment. The joint between carpopodite and propodite is markedly oblique. The lower border of the propodite curves upward obliquely, approaching the upper border, so that the segment is more or less triangular in shape. The upper part of the flattened posterior surface of the propodite presents a triangular excavation filled with hair. The dactylopodite is narrow and slightly curved, terminating in a dark brown spinule.

The points in which the walking legs differ from DE MAN'S description and figure of those of *Z. gemmula* concern : (*a*) the similarity of the members of the four pairs—in DE MAN'S specimens they show considerable differences ; (*b*) the upper border of the meropodites ; (*c*) the free edges of the dorsal crests of carpopodite and propodite form a continuous even line ; (*d*) the position of the fissure of the upper crest of the carpopodite ; (*e*) the transverse grooves of the posterior face of the carpopodite ; (*f*) the dorsal border of the propodite (for detail compare with DE MAN'S figure).

Further differences from DE MAN'S specimens are :—(1) The most posterior tubercle on the dorsal border of the hand is more prominent, it attracts notice with its flattened surface and its backwardly and inwardly projecting sharpened edge ; (2) the anterior border of the front is a little more horizontal (see figures)—DE MAN found that the front was more prominent in the male than in the female, this does not hold for my specimens ; (3) the ratio of fronto-orbital breadth divided by carapace length is greater in both sexes ; (4) the granules of the outer surface of the fixed finger are more definitely arranged in two longitudinal rows ; (5) they are smaller : it is possible, however, that they are not fully grown.

The value of distinctions (2), (3), and (4) appears to me very doubtful. I only emphasise particularly (1) above, together with the condition of the walking legs, and for the present consider this form a variety of *Z. gemmula*.

I may note that 2M is completely divided into two by a longitudinal groove both in DE MAN'S *Z. gemmula* and in the new variety, while DANA describes it as only partly divided. Another point is that in the present specimens the hollowing of the finger tips is not obvious; I should describe the fingers as blunt merely, DE MAN'S figure indeed represents them very well. A point in the present specimens not mentioned by DE MAN is the presence of a curious little tuft of brown hair (seen well with a lens) which rises from a groove running along the inner surface of the fixed finger.

	(*a*) adult ♂.	(*b*) young ♂.	DE MAN'S ♂.	(*c*) adult ♀.	DE MAN'S ♀.
C.l.	7·25	5·50	14·25	6·25	10·00
C.b. ÷ C.l.	1·48	1·45	1·47	1·48	1·53
Fronto-orbital b. ÷ C.l.	0·93	1·00	0·81	1·00	0·90

Demania, n. gen.

Carapace pentagonal, moderately convex antero-posteriorly, flattened from side to side in its posterior half; the regions well delimited and subdivided into numerous lobules, the surface of which is smooth. The antero-lateral borders are blunt, cut by shallow grooves into four lobes: the border is faintly continued below the eye to the antero-lateral angle of the buccal cavern; the postero-lateral borders are straight and strongly convergent.

Front prominently bilobed, its breadth about one-third the greatest carapace-breadth, its plane is a continuance of the postero-anterior curve of the dorsum of the carapace. Orbits large, the three suture lines near the outer angles distinct; eyes on short thick stalks.

The antennules fold in a transversely oblique direction, making an angle of 40° (approximately) with a transverse line; the inter-antennulary septum is broad. Basal joint of antenna not quite as long as the posterior border of one of the antennulary fossæ; as a whole it stops short of the orbital hiatus, but its antero-external angle is produced into the latter; its antero-internal angle touches a downward projection of the front; the flagellum is short (less than major diameter of orbit), lodged in the orbital hiatus.

No ridges define efferent branchial channels in anterior portion of buccal cavern.

Merus of external maxillipeds pointed anteriorly, its borders sloping obliquely backwards, making together an angle of 90° (approximately). Chelipeds equal in female (male not known); fingers not hollowed at tips. Walking legs with the upper border of the merus, carpus and propus and the lower border of merus and propus cristate.

Abdomen of male not known.

Carapace length (including rostral lobes) of only specimen known is 32·50 millims.

This new genus bears considerable resemblance in general appearance to the genus *Zozymus*; the sculpture of its carapace and chelipeds, and its cristate walking legs, are reminiscent of *Zozymus æneus*. It presents, however, many points of difference from that genus.

These differences concern :—(1) Plane of the posterior half of the dorsal surface of the carapace; (2) antero-lateral borders of the carapace; (3) direction in which the folded antennules lie; (4) antero-external angle of the basal antennal segment; (5) shape of anterior part of merus of external maxillipeds; and (6) finger tips.

The form of the antero-lateral borders of the carapace is, moreover, a point of difference from ALCOCK's description of the Alliance in which he places *Zozymus, i.e.*, Alliance Zozymoida (see A.3, p. 77); the character of the walking legs is a link with this Alliance. The sub-orbital continuation of the antero-lateral borders of the carapace, and the production of the outer angle of the basal antennal joint into the orbital hiatus, are links with the Alliance Euxanthoida. The pentagonal form of the carapace is a point of similarity to the Alliance Halimedoida. (See NOBILI for figure of *Halimede hendersoni*—N., p. 123, pl. vi., fig. 31.)

Demania splendida, n. sp.—Plate I., fig. 8, and Plate II., fig. 1.

Locality :—Trincomalee, a single non-ovigerous, but probably adult, female.

Description :—Carapace roughly pentagonal, with prominent deeply notched front and rounded epibranchial angles; the antero-lateral borders are convex, the postero-lateral borders concave, the posterior border slightly concave.

The general surface is convex fore and aft; it is also convex from side to side —quite obviously so in the hepatic regions, only slightly so in the branchial regions. The regions are well delimited by pubescent grooves, and are themselves broken by similar grooves into numerous lobules; the latter are more numerous and more distinctly demarcated in the posterior half; in the anterior half they are often more or less confluent, the separating grooves dying away. The lobules are all smooth and polished, and the grooves are found on removal of the pubescence to be smooth. The carapace has thus a general resemblance to that of *Zozymus æneus*.

The front is considerably produced and deeply divided to form two prominent bluntly pointed lobes: at the base of the outer border of each of the latter the outer angle of the front is produced as a distinct, blunt, forwardly directed tooth. Frontal breadth $\div$ C.l. = 0·31; length of frontal lobe (inner border) $\div$ frontal breadth = 0·27.

Orbital border smooth. Upper border has tumid inner portion. There are three fissures—one a little to outer side of the middle point of the upper border, the other two are in the neighbourhood of the outer angle, one above and one below. The inner orbital angles, both upper and lower (the latter a blunt tooth), are prominent; the intervening hiatus receives only a narrow projection of the outer angle of the basal antennal segment.

Antero-lateral border of carapace rounded; the actual edge shows a slight sharpening, and there is a suggestion of its continuance anteriorly below the orbit to the antero-external angle of the buccal cavern. It is divided by grooves into four sufficiently distinct, but little-prominent, lobes; the groove between the 1st and 2nd lobe is the least distinct.

Under surface of carapace smooth and polished, and lobulated as dorsal surface. A distinct groove runs obliquely backward from the region of the green gland aperture, to end at the border of the carapace just above the base of walking leg 4. There is a patch of hair above the base of the chelipeds, and a fringe follows the edge of the carapace above the bases of the walking legs, and skirts abdomen.

Thoracic sternal region is in its exposed portion broken by transverse pubescent grooves into regions appropriate to the segments bearing chelipeds and four walking legs. There is some tendency to subdivision of these regions (see figure), and the surfaces are polished and show some dimples.

Abdomen.—The seven abdominal terga are separate. Tergum VI. is about twice as long as any of the first five (which are subequal in length) and of approximately the same length as tergum VII. In addition to a little dimpling, each tergum is traversed by a pubescent transverse groove, before and behind which, in the case of VI., is a slightly marked additional groove. The abdomen is well fringed with hair.

Antennules fold obliquely—making an angle of 40° (approximately) with a horizontal line.

Antennæ.—Basal antennal segment, as a whole, falls short of the inner orbital angles: its outer angle, however, is produced into the hiatus; its inner angle touches a downgrowth of the front. The orbital hiatus thus remains open for the most part, and in it is seen the short antennal flagellum (flagellum length ÷ C.l. = 0·11).

External Maxillipeds.—See figure. The merus is of approximately the same breadth as the ischium and about one half as long; it is pointed anteriorly, its borders sloping obliquely backwards and making together an angle of 90° approximately. The flagellum arises from the inner side of the apex. A longitudinal groove traverses both merus and ischium. The surface of the external maxilliped is polished.

Chelipeds of equal size. The upper, outer, and under surfaces of the arm, wrist, and hand are subdivided by pubescent grooves into polished lobes somewhat reminiscent of brain convolutions. The inner surface of the arm is smooth, and is concave in correlation with the convex under surface of the carapace; on the sharp inner border of the merus are three blunt teeth (exclusive of the distal angle), the same border has a fringe of hair; the upper border is also sharp; the inner border is well rounded. The length and breadth of the upper surface of the wrist are equal, its inner anterior angle is produced into a tooth, to the inner side of which is a much smaller one; the upper and outer surfaces form a continuous curve. The upper border of the hand is armed with a row of six or seven blunt teeth, or tubercles (six on right hand, seven on left hand); the grooves of the hand, transverse in the main, are crossed by two which are longitudinal (one running to the outer side of the base of the dactylus, the other to the base of the inter-digital cleft). The fingers have pointed tips, they meet throughout their length; apposed borders are toothed throughout, the distal teeth being the larger; when clenched, the inner surfaces of the fingers taken together are concave; an irregular pubescent groove runs along the proximal portion of the upper surface of the dactylus.

Walking legs flattened laterally, the dorsal border of meropodite, carpopodite, and propodite in each is expanded as a considerable crest; the ventral border of the meropodite of each has distally two ridges, the anterior of which extends the whole length of the segment, and is more prominent proximally, particularly in walking leg 4; in walking leg 4, also, the ventral border of the propodite is expanded, so that the segment is foliaceous; there are traces of transverse grooves on the posterior surfaces of the meropodites of all the walking legs; the posterior surface of the propodite is dimpled.

The dactylopodites of the first three pairs are fairly similar, somewhat compressed antero-posteriorly, both anterior and posterior surfaces with a longitudinal groove, dorsal border flattened and bearing a mat of short hairs. The dactylopodite of walking leg 4 is foliaceous, but its flattened surface is only 0·36 as broad as that of the propodite of the same appendage. There is a tuft of hair on the dorsal border of the proximal portion of the meropodite of each walking leg.

C.b. (rostral lobes included) = 32·50; Front.b. ÷ C.l. = 0·31; Fronto-orb.b. ÷ C.l. = 0·58. C.b. ÷ C.l. = 1·11; Front.b. ÷ C.b. = 0·32; Fronto-orb.b. ÷ C.b. = 0·50. Ant.lat.bord.C. ÷ C.l. = 0·43; Post-lat.bord.C. ÷ C.l. = 0·58; Post.bord.C. ÷ C.l. = 0·52. Ch.l. (*i.e.*, Arm l. + Propus l.) ÷ C.l. = 1·30; Arm l. (lower border, condyle of basal joint included) ÷ C.l. = 0·58; Propus l. (lower border) ÷ C.l. = 0·72.

Lophozozymus incisus (H. Milne-Edwards, 1834)—A.3, p. 107.

Locality:—Gulf of Manaar, one specimen.

Description:—An adult male. C.l. = 15·0.

Lophozozymus dodone (Herbst, 1801)—A.3, p. 108.

Localities:—Off Mutwal Island, two specimens (adult ♂, adult ♀); coral reefs, Gulf of Manaar, two specimens (adult ♂); pearl banks, Gulf of Manaar, two specimens (♂, ? young); Trincomalee, two specimens (young ♂, young ♀).

Description:—Variability among the specimens concerns:—(1) Index C.b. ÷ C.l.; and (2) the fact that most are somewhat concave laterally, but an adult male has approximately straight sides.

Lophozozymus pulchellus, A. Milne-Edwards, 1867—('Nouv. Arch. Mus.,' ix., p. 205).

Locality:—Galle, one specimen.

Description:—Adult female. C.l. = 10·5. It is covered with a pubescence. The most anterior of the three antero-lateral teeth is obsolescent. Traces of the network of red lines are seen in the posterior and postero-lateral regions with a lens.

Remarks.—This species is new to the Indian fauna. It may conveniently be separated from all other Indian forms by having the edge of the antero-lateral border of the carapace rounded in its anterior portion.

Euxanthus herdmani, n. sp.—Plate I., figs. 9, 9*a*.

Locality :—Pearl banks, Gulf of Manaar, one specimen.

Description :—An adult male. C.l. (including frontal lobes) = 23·00.

The lobules of the carapace are strongly convex, 2L more prominent than the others; they are dimpled, but 3M very slightly so: there is a fine pitting on the anterior part of the surface of the carapace, producing a dull appearance; the posterior part is glazed. The antero-lateral border is cut into four blunt tubercular teeth, the hindermost of which is smaller than the other three, which are of sub-equal size; the sub-orbital continuation of the border is indistinct. The curve of the orbit is unbroken by any denticle at the outer angle, and is seen by the lens to be finely granular.

The exopodite of the external maxilliped is granular, so is the outer proximal part of the ischium and the free border of the merus. The longitudinal groove of the ischium and that of the merus are both deep. The outer surfaces of the wrist and hand, as of the corresponding segments of the legs, are nodular, both nodules and the hollows between them being smooth. The outer surface of the wrist is rounded, with the nodules faintly marked (by no means so obvious as in *E. melissa* or *E. sculptilis*). The inner surface of hand, wrist, and arm is flattened and smooth; the upper surface of the hand has two nodules distally behind the finger joint, and a third posteriorly just in front of the wrist joint. Running obliquely backward and outward from the outer of the two distal nodules is a series of three others, from each of the first and third of which runs forward a wrinkled non-granulated line. The fingers have strongly toothed cutting edges, the distal end of the fixed finger is hollowed on the inner side of the teeth; the proximal portion of the upper surface of the dactylus is granular.

The upper and lower borders of the walking legs and the upper border of the arms are fringed with hair; the fringe is replaced on the upper border of the dactylopodites of the walking legs by a close-set covering of short hairs.

C.l. (rostral lobes included) = 23·00; C.b. ÷ C.l. = 1·33; Fronto-orbital b. ÷ C.l. = 0·71; Antero-lateral border (a straight line uniting the outer angle of orbit with the tip of the 4th antero-lateral tooth) ÷ C.l. = 0·62; Postero-lateral border (a straight line uniting the tip of the 4th antero-lateral tooth with the point at which the carapace border meets the 1st abdominal tergum) ÷ C.l. = 0·53; Posterior border of carapace (line of junction with abdominal tergum 1) ÷ C.l. = 3·04.

Remarks.—Among forms hitherto described the new species comes nearest to *E. melissa* in general character of the lobules of the carapace and in the absence of the denticle at the outer angle of the orbit. It is somewhat intermediate in the sculpture of its hands and fingers, between *E. melissa* and *E. sculptilis*. It differs from forms hitherto described in:—(1) Ratio of C.b.÷C.l.; (2) the more produced frontal lobes (see figure); (3) the antero-lateral border of the carapace has only four tubercles. The latter point is useful for purposes of key. The anterior of the antero-lateral teeth seems to take the place of the first two antero-lateral tubercles of *E. melissa* or of *E. sculptilis* and of a third tubercle to the inner side of these on the dorsal surface of the carapace, which is distinct in both the species named. Correlated with this arrangement is the more regular curve made by the front and the antero-lateral borders.

The form of the front is not unlike that of a specimen of *Hypocolpus rugosus* in the British Museum, in which, moreover, there are only four indistinct lobes on the antero-lateral border. There is a faint depression on the ventral surface behind the orbit and to inner side of 1st antero-lateral tooth. This does not represent the curious deep cavity found in *Hypocolpus*, for both are present in *H. sculptus* (*i.e.*, in British Museum specimen from Mauritius 84.8).

Hypocolpus [= Hypocœlus] rugosus, Henderson, 1893—A.3, p. 111.

Locality:—Coral reef, Gulf of Manaar, two specimens (ovigerous ♀ and adult ♂).

I note (1) granules of carapace are larger than in a specimen of *H. granulatus* in the British Museum instead of smaller as in Henderson's description; (2) the three teeth of the antero-lateral border of the carapace are not so obvious as in Henderson's figure, and in the adult ♂ (*b*) an additional small tooth occurs between the 2nd and 3rd larger ones counting from before backwards. In the adult ♀ (*a*) there is a mere trace of this additional tooth.

A point of difference between the present specimen of *H. rugosus* and the British Museum specimen of *H. granulatus* is that in the former the sternal area on either side of the flexed abdomen has an eroded appearance, while in the latter it is covered irregularly by distinct granules.

Xantho distinguendus, de Haan, 1835—A.3, p. 113.

Localities:—Coral reefs, Gulf of Manaar, one specimen (*a*); south of Galle, deep water, three specimens (*b*, *c*, *d*).

Description:—Specimen (*a*) is an adult male, C.l. = 6·0; specimens (*c*) and (*d*) are non-ovigerous adult females; specimen (*b*) is male, with a parasitic *Sacculina*.

Remarks.—On comparing with de Haan's example, one notes (1) the much smaller size, and (2) that the posterior surface of the meropodite of the walking leg 4 is smooth instead of granulated. They thus tend to agree with Miers' "Challenger" specimens which he called *Lophozozymus bellus*, var. *leucomanus*, but are still smaller. This species is the *L.* (*Lophoxanthus*) *leucomanus* of Lanchester. The *Sacculina* attached to the male specimen (*b*) does not seem to have affected the sexual characters of its host; the male appendages and the general shape of the abdomen are much as in specimen (*a*), and no abdominal appendages appropriate to the female are developed.

Xantho (Leptodius) exaratus (H. M.-Edw., 1834)—A.3, p. 118.

Locality :—Trincomalee, one specimen (female, doubtfully adult).

Description :—It answers to Alcock's description. Comparing with Kossmann's figures, its greatest carapace-breadth is across the region of the 3rd, not the 4th, lateral teeth.

Cycloxanthops [= Cycloxanthus] lineatus, A. M.-Edw., 1867—A.3, p. 124.

Localities : Coral reef, Gulf of Manaar, three specimens (*a*, *b*, *c*) ; Cheval Paar, one specimen (*d*) ; off Kaltura, one specimen (*e*).

Description :—All are males, apparently adult. The spirit has removed the colour, but the specimens give evidence (under lens) that there are colour varieties within the species.

A. In specimens (*b*) and (*d*) there are faint whitish lines on the carapace in the positions represented in A. Milne-Edwards' figure.

B. In specimens (*a*) and (*e*) the carapace is covered with large spots a little darker than the general surface, each of which is surrounded by a whitish ring.

C. Specimen (*c*) has neither lines nor spots.

Polycremnus ochtodes (Herbst, 1783)—A.3, p. 135.

Localities :—Pearl banks, six specimens (three ♂, probably adult, two ♀, one young ♀) ; coral reefs, Gulf of Manaar, three specimens (two ♂, probably adult, and one ♀, probably adult).

Actæa speciosa (Dana, 1852)—A.3, p. 143.

Locality :—Gulf of Manaar, one specimen.

Description :—Female, adult, but non-ovigerous. C.l. = 6·25. It agrees with Kossmann's description and photograph of *Psaumis glabra*. It also agrees with Dana's description, but differs from his figure in some points. In mine (1) the lobe 2M is more deeply subdivided ; (2) though in the posterior portion of the carapace the grooves are very shallow and partly obliterated by granules, it is still possible to distinguish, somewhat indefinitely, the lobes 1R, 2R, 1P and 2P. There is a distinct fissure between the outer angle of the orbit and the sub-orbital border, stated by Alcock to be absent in his specimens (three, from the Persian Gulf, Ceylon, and Andamans). de Man finds this fissure in his specimen ('Abh. Senckb. Ges.,' xxv., 609).

Differences between my specimen of *A. speciosa* and the descriptions of the closely allied *A. rufopunctata* are that in the former :—(1) Carapace is relatively longer and narrower ; (2) carapace, chelipeds, and walking legs devoid of hair ; (3) lobulation of carapace much less complete and bold except on antero-lateral regions, that of chelipeds and walking legs is much as in *A. rufopunctata* ; (4) the anterior tongue of 3M reaches farther forward ; (5) the longitudinal division of 2M is hardly complete posteriorly ; (6) the groove separating 2M from 2L diverges a good deal anteriorly from its fellow of the opposite side; (7) lobe 1P is not subdivided by a longitudinal groove and is more or less top-shaped, an anterior strip being marked off.

Actæa ruppelli (KRAUSS), 1843—A.3, p. 144.

Locality :—Navakaddu Paar, Gulf of Manaar, three specimens.

Actæa alcocki, n. sp.—Text-fig. 5.

Locality :—Gulf of Manaar.

Description :—An adult male. C.l. = 16·5.

The breadth of the carapace across region of last pair of antero-lateral teeth is 1·53 its length; breadth across region of next to last pair of antero-lateral teeth is 1·48 its length; frontal b. ÷ C.l. = 0·36; fronto-orbital b. ÷ C.l. = 0·64; antero-lateral border l. ÷ C.l. = 0·71; postero-lateral border l. ÷ C.l. = 0·60; posterior border l. ÷ C.l. = 0·60 (the junction of the posterior and postero-lat. border is the posterior end of a finely marked groove). The carapace and exposed surfaces of chelipeds and walking legs are covered with a short down which does not conceal the lobulation or granulation: the anterior two-thirds of the carapace are lobulated, the lobules are distinctly though not strongly demarcated by shallow grooves; on the posterior one-

Fig. 5. *Actæa alcocki*, n. sp.

third of the carapace the lobulation is obsolete. The whole dorsal surface of the carapace, grooves and lobules, and the exposed surfaces of chelipeds and walking legs, are covered with crisp, not particularly strong, granules. The lobes of the antero-lateral border are bluntly pointed, increasing in size from before backward; the first is obsolescent. The front is vertically deflexed, continuing the curve of the anterior part of the carapace; it is quite obviously bilobed; at the outer base of each lobe the inner supra-orbital angle is produced vertically downwards to form a distinct tooth. Supra-orbital margin moderately tumid, cut by two fissures in its outer portion and separated from the lower border by a third fissure.

Basal antennal segment does not quite reach the inner orbital angles.

The surfaces of the arm are smooth, a row of small sharp granules borders its lower edge. The upper and lower borders and the outer surfaces of hand and wrist (*i.e.*, the "exposed surfaces") are granular as the carapace; the granules of the hand are the larger and are arranged in longitudinal rows on the lower half of the outer surface; the other surfaces are smooth. There is a slight transverse groove on the outer surface of the wrist behind the joint with the hand. The proximal part of the upper border of the mobile finger is roughened; there is a tooth on the biting border of each finger about one-third of its length from the base; the fingers are grooved and pointed. Distally the upper border of the hand turns abruptly downward at a right angle to the point where the mobile finger is hinged.

There is a longitudinal groove to the outer side of the upper border of the carpopodites of the walking legs. Colours in spirit ($4\frac{1}{2}$ years), yellowish, with a circular brown patch on the gastric region, and brown fingers.

The new species comes most easily into section I.I.2 of ALCOCK's key, A.3, p. 139, though carapace length = 0·66 the breadth. It is distinguished by absence of shaggy hair, the shallow nature of its grooves, the festooned appearance of its antero-lateral borders, and by its general facies.

Actæa variolosa, BORRADAILE, 1902—B.III., p. 256, fig. 54.

Localities:—Jokkenpiddi Paar, one specimen (adult ♂); Navakaddu Paar, three specimens (one adult ♂, two adult ♀).

Description:—The grooves which delimit the cardiac region laterally agree in the adult male (*b*) with their condition in BORRADAILE's figure, but in the other specimens they are more obvious—running back to a slightly indicated transverse groove parallel to and just in front of the posterior border of the carapace.

The tooth on the base of the dactylus is quite small; that on the base of the fixed finger is stout. On either side of the base of each of these teeth is a curious little tuft of dark brown hair.

Actæa peroni (H. M.-EDW.), var. **squamosa**, HENDERSON, 1893 (H., p. 357).

Localities:—Coral reefs, Gulf of Manaar, one specimen (adult ♀); Navakaddu Paar, two specimens (adult ♀ and young ♀).

Description:—Add to HENDERSON's description that there are tubercles on the front and on the antero-lateral border.

Remarks.—These specimens, from two localities, fall under HENDERSON's description of var. *squamosa*—*i.e.*, the only specimens recorded from India fall into a group having varietal distinction from ALCOCK's description (A.3, p. 150). The latter applies to the Australian variety, of which I have seen 13 specimens in the British Museum from various parts of the coast of Australia.

Actæa calculosa (H. M.-EDW., 1834)—A.3, p. 152.

Localities:—Pearl banks, Gulf of Manaar, nine specimens; off Kaltura, one specimen; Galle coral reef, one specimen; Navakaddu Paar, two specimens.

Remarks.—I consider *A. calculosa* and *A. granulata* to be distinct species. Comparing the present series of the former with a series of over 20 specimens of the latter in the British Museum, I find that though the differences are individually slight, they are numerous, constant and highly correlated. A series of differences between the two species has been set forth by CALMAN (C., p. 8).

I have seen MIERS' specimens in the British Museum, for the reception of which he made *Euxanthus tuberculosus*; as CALMAN points out, they certainly = *A. calculosa.*

Actæa granulata (AUDOUIN, 1826)—A.3, p. 151.

Localities:—Off Negombo, Gulf of Manaar, two specimens; coral reefs, Gulf of Manaar, one specimen.

Xanthias [= Xanthodes] lamarcki (H. M.-EDW., 1834)—A.3, p. 157.

Locality:—Galle, lagoon, four specimens (two adult ♂, two young ♀).

Xanthias [= Xanthodes] notatus, DANA, 1852—A.3, p. 158.

Locality:—Chilaw Paar, one specimen.

Description:—Adult male; agrees well with ALCOCK'S description. In comparing with DANA'S figure it may be noted that, both in ALCOCK'S description and in the present specimen, the last two antero-lateral teeth are procurved and spine-like. The 3rd tooth is in this specimen the longest.

Chlorodiella [= Chlorodius] niger (FORSKÅL, 1755)—A.3, p. 160.

Localities:—Trincomalee, one specimen (*a*); Palk Bay, one specimen (*b*).

Description:—Specimen (*a*) is a small male (? immature), C.l. = 6·50; specimen (*b*) is an ovigerous female, C.l. = 9·25. In both examples the last two antero-lateral prominences are blunt teeth (sharper than the 1st and 2nd teeth of the series in (*a*), much as 2nd tooth in (*b*)). They do not terminate in "procurved spine-like points" as in the examples described by ALCOCK. In specimen (*a*) there is neither spine nor tubercle on the anterior border of the arm.

Phymodius sculptus (A. M.-EDW., 1873)—A.3, p. 164.

Locality:—Coral reef, Galle, two small males.

Chlorodopsis areolata (H. M.-EDW., 1834)—A.3, p. 166.

Localities:—Galle, two specimens (adult ♀ and adult ♂); Galle, lagoon, one specimen (young ♀).

Description:—In the adult female, C.l. = 9·50; C.b. ÷ C.l. = 1·42; Frontal b. ÷ C.l. = 0·66; Frontal l. ÷ C.b. = 0·46.

The female of this species is figured by DANA under the name *Etisodes cœlatus.*

Chlorodopsis pilumnoides (White, 1847)—A. 3, p. 167.

Localities:—Coral reefs, Gulf of Manaar, six specimens; Navakaddu Paar, four specimens; Jokkenpiddi Paar, two specimens; Muttuvaratu Paar, six specimens.

Description:—The above include six adult males, one young male, three ovigerous females, six adult non-ovigerous females, and two young females. C.l.ovig. ♀ = 9·5.

Pilodius pugil, Dana, 1852—('U.S. Expl. Exp.,' Crust., I., 1852, p. 219, pl. xii., fig. 8.)

Locality:—Gulf of Manaar, one specimen.

Description:—An adult male. C.l. = 10·0.

Cymo andreossyi (Audouin), 1826—A. 3, p. 173.

Locality:—Gulf of Manaar, one specimen.

Description:—Adult male, C.l. = 6·50.

Calmania, n. gen.

Carapace subcircular, its length and breadth about equal; it is convex antero-posteriorly, less so from side to side; the only region distinctly indicated is the cardiac, which is delimited anteriorly and antero-laterally by an obvious groove. The antero-lateral border is indistinctly four-lobed.

Fronto-orbital breadth about two-thirds the greatest carapace breadth. Frontal breadth about one-third the greatest carapace breadth. The front is rounded anteriorly, continuing the general antero-lateral curve of the carapace: it is very distinctly bilobed; the lobe of either side is not separated by notch or groove from the orbital border. One of the two supra-orbital grooves is present, the other indicated merely. Eyes on short thick stalks.

The fold of the antennules is longitudinally oblique, making an angle of a little less than 45° with a perpendicular line.

The basal antennal segment falls short of the orbital hiatus, into which its outer angle is not produced. The antennal flagellum slender and naked; it is about $\frac{1}{4}$ C.l.

No ridges define efferent branchial channel in anterior portion of buccal cavern.

The merus of the external maxillipeds is broader than long. The ischium is slightly longer than broad. The outer angle of the merus is rounded.

Chelipeds equal (a non-ovigerous, but quite probably mature, female only known), not long, but very massive, the fingers remarkably large, gaping proximally, their tips pointed; the upper border of the hand bears two prominences—the distal of the two is particularly enlarged. The walking legs are approximately the same length as the cheliped; they are fringed with silky hair.

It is a little difficult to find relatives for the new genus. I place it among the Xanthidæ, as having the anterior epistomial margin of the buccal cavity well defined and not overlapped by the external maxillipeds, and the antennal flagellum slender; it differs, however, from the usual Xanthid form in the greater length of its antennal flagellum and in the longitudinally oblique fold of the antennules. The latter characters and the general *Kraussia*-like shape of the carapace suggest Cancrid affinities. It may possibly fall into the sub-family Chlorodinæ (A.3, p. 78); but it does not agree with any of the three Alliances into which ALCOCK divides the sub-family, but the obliquely folding antennules of *Cymo* are to be remembered. From *Cymo*, however, the new genus presents many points of difference.

Calmania prima, n. sp.—Plate I., fig. 12, *a–c*.

Locality :—Gulf of Manaar, one specimen.

Description :—A female, non-ovigerous, but quite probably adult.

C.l. = 7·0 ; C.l. ÷ C.b. = 0·93 ; the only region distinctly indicated is the cardiac, which is delimited anteriorly and antero-laterally by a well-marked groove ; a fainter groove completes the isolation of the branchial regions anteriorly, a groove runs back in the middle line from the notch between the frontal lobes. There are four tufts of hair on the dorsal surface of the carapace, one on each side of the gastric region and one behind and to outer side of each of these. The antero-lateral border of the carapace is sharpened, almost cristate, and has three slight teeth behind the external orbital angle, which faintly indicate a division into four lobes.

Fronto-orbital b. ÷ C.b. = 0·71 ; frontal b. ÷ C.b. = 0·46. For further description of front see generic description ; it is fringed by long silky hairs.

The folded antennule makes an angle of 40° approximately with a perpendicular line. The antennal flagellum is slender and naked. Ant.flag.l. ÷ C.l. = 0·25, approx.

For external maxillipeds, see description of genus. The ischia do not quite meet.

Ch.l. ÷ C.l. = 1·22 ; the massive hand and fingers are remarkable ; the fingers are bent on the hand somewhat as in *Lambrus* ; when closed, the distal halves of the fingers meet, but between the proximal halves there is a rounded gap left ; the distal apposable part of both fingers is dentate. The inner surface of the hand is smooth and polished ; the outer surface of hand and fingers is richly sculptured ; both above and below an intermediate region of outer surface of hand is a groove bordered on both edges by a granular line. On the upper border of the wrist is a row of granules. The sculpture of the hand and fingers is hidden a good deal by hair ; long silky hairs are found also on the upper border of the hand, and a tuft on the outer surface of the wrist.

The walking legs are of approximately equal length, 2nd walking leg l. ÷ C.l. = 1·20 ; they are a little compressed laterally ; their surface is smooth and glazed ; their borders are fringed with silky hair.

Ozius rugulosus, STIMPSON, 1858—A.3, p. 182.

Locality :—Galle, one specimen (adult ♀).

Ozius tuberculosus, H. M.-EDW., 1834—A.3, p. 183.

Locality :—Trincomalee, one specimen.

Description :—An adult male. The central part of the carapace is smooth, *i.e.*, the pearly tubercles are here absent.

Epixanthus frontalis (H. M.-Edw., 1834)—A.3, p. 185.

Locality :—Trincomalee, two specimens (*a*, *b*).

Description :—	C.l.	C.b. ÷ C.l.	Frontal b. ÷ C.l.	Frontal b. ÷ C.b.
(*a*) adult ♂ . . .	13·25	1·64	0·57	0·34
(*b*) ovigerous ♀ . .	16·00	1·62	0·56	0·35

Pilumnus vespertilio (Fabricius), 1793—A.3, p. 192.

Locality :—Trincomalee, one specimen.

Description :—An adult male, C.l. = 19·0. The sub-hepatic denticle of the right side is double, and that of the left side is represented by a group of three granules.

Pilumnus longicornis, Hilgendorf, 1878—A.3, p. 193.

Locality :—Gulf of Manaar, two specimens.

Description :—Both adult males.

Pilumnus cursor, A. M.-Edw., 1873—A.3, p. 195.

Locality :—Gulf of Manaar, one specimen.

Description :—Female, probably adult. C.l. = 8·00.

This specimen agrees very fairly with Alcock's description of the samples which he puts with a query under this species. However, an area occupying the distal part of the lower portion of the outer surface of its larger chela (say one-third of whole outer surface) is naked and polished. Its fingers are dark brown.

Actumnus setifer (de Haan), var. **tomentosus** (Dana), Miers—A.3, p. 202.

Locality :—Pearl banks, Gulf of Manaar, four specimens (including *a*); off Mutwal Island, two specimens (*b*, *c*); south of Modragam, one specimen.

Description :—The series includes six males—all perhaps adult—and one ovigerous female. C.l. of the latter = 5·5.

In male specimen (*a*) the denuded carapace appears smooth to the naked eye, but fine granules are revealed by the lens. A similar fine granulation occupies the central part of the carapace of males (*b*) and (*c*), in both of which an antero-lateral strip is granular to the unaided eye. Distinctness of areolæ possesses high variability; specimens (*c*), (*a*), and (*b*), together with a Torres Straits specimen in the British Museum, form a series linking *tomentosus* and *setifer* in respect of this character.

Remarks.—The evidence of the British Museum specimens and of those before me compels me to consider, with Miers ("Alert," p. 225), that *tomentosus* and *setifer* are a single species. Alcock kept them apart, however, and in so doing he had before him 32 specimens of the former and 53 of the latter. It would be interesting to have some exact knowledge of variability within such considerable samples.

Actumnus setifer (DE HAAN), var. **setifer**—A.3, p. 202.

Localities:—Pearl banks, Gulf of Manaar, one specimen (adult ♀); deep water off Galle, one specimen (ovigerous ♀); Trincomalee, one specimen (ovigerous ♀).

Description:—In these specimens the areolæ are more distinct than in the figures of either DE HAAN or of A. MILNE-EDWARDS. Moreover, the tomentum gives place to a slight pubescence, and the general appearance is reminiscent of *A. verrucosus*, HENDERSON, from which the specimens may, however, be distinguished as in ALCOCK's key by having the lobule of the lateral gastric region semicircular instead of ω-shaped.

Remarks.—The specimens suggest that an examination into the specific distinctness of *A. setifer*, *A. bonnieri*, and *A. verrucosus* is desirable.

Actumnus verrucosus, HENDERSON, 1893—A.3, p. 203.

Localities:—Pearl banks, Gulf of Manaar, 25 specimens; coral reefs, Gulf of Manaar, five specimens; Muttuvaratu Paar, one specimen.

Remarks.—There is in the British Museum a single adult male specimen of this species labelled in MIERS' (?) writing "*Actumnus ceylonicus*, MIERS—Ceylon. Presented by E. W. H. HOLDSWORTH, Esq.—1875." I am not aware that he published any description of the crab.

A. verrucosus is very closely allied to *A. setifer* on the one hand and to *A. bonnieri*, NOBILI, 1905, on the other.

Actumnus bonnieri, NOBILI, 1905—(N., p. 132, pl. vi., fig. 32).

Localities:—Pearl banks, Gulf of Manaar, two specimens (one adult ♀); deep water off Galle, one specimen (ovigerous ♀).

The present examples of *A. bonnieri* agree well with NOBILI's description and photograph. They are smaller than the average of *verrucosus* specimens known to me. The difference between the two species in question is mainly a difference in the form of the lateral gastric lobe. A similar distinction does not separate it from *A. setifer*, though other differences hold here.

Apart from the characteristic ω-shaped lateral gastric lobe of *A. verrucosus*, the characters which separate *A. setifer* var. *tomentosus*, *A. setifer* var. *setifer*, *A. verrucosus*, and *A. bonnieri* from each other are highly variable. An exact knowledge of the variation within large samples is very desirable. Such variable characters are:—(1) C.b.÷C.l., (2) convexity of carapace, (3) distinctness of areolæ, (4) hairiness of carapace, (5) condition of outer angles of front, (6) condition of fissure in lower orbital margin (?), (7) granulation of wrist.

Actumnus fissifrons, ALCOCK, 1898—A.3, p. 204; A. Invest., pl. xxxvii., fig. 5.

Locality:—Deep water off Galle, one specimen (adult ♂).

Trapezia cymodoce (HERBST, 1801)—A.3, p. 219.

Localities :—Muttuvaratu Paar, four specimens (*e*, *f*, *g*, *h*); Jokkenpiddi Paar, one specimen (*k*); coral reef, Galle, twelve specimens (*m*, *n*, *p*, *q*, *r*, *s*, *t*, *u*, *v*, *w*, *x*, *y*); pearl banks, Gulf of Manaar, eight specimens (*a*, *b*, *c*, *d*, *i*, *j*, *k*, *o*).

Description :—ALCOCK'S observation, that the carapace of the adult female is more curved than that of the male, is reversed in the present series. Variation concerns—(1) size : the size of adult specimens varies a good deal, *e.g.*, two adult males C.l. = 6·25 and 16·0, and two ovigerous females C.l. = 5·75 and 10·75; (2) the outer angles of the frontal lobes : these are entire in most, but crenulate in adult male (*i*) and in ovigerous female (*b*), and they tend to be so also in (*j*) young ♀, (*m*) ovigerous ♀, and (*n*) adult ♂; (3) the outer orbital angle is in most cases produced and pointed, but in the adult male (*k*) and also in (*p*), (*q*), and (*r*) it is blunt, in ovigerous ♀ (*v*), ovigerous ♀ (*x*), and adult ♂ (*y*) it is only slightly produced, and in adult ♂ (*w*) it is not produced; (4) the lateral epibranchial spine is quite obvious and sharp in most cases, but in (*k*), (*p*), (*q*), and (*r*) it is blunt, while in (*v*), (*x*), and (*y*) it is obsolescent. It will be noted that variation of outer orbital angle and of lateral epibranchial spine are correlated.

A specimen (*z*) from "Lagoon, Galle, 1903," may be conveniently included here as a variety. In it the lateral epibranchial tooth of the carapace is absent, the antero-lateral borders diverging posteriorly to form a continuous curve with the anteriorly divergent postero-lateral borders. The hand is naked. The front agrees fairly with that of *T. ferruginea* or *T. cymodoce*. I would name it var. *edentula*.

Another specimen (*z''*), a doubtfully mature male, has the merest trace of a lateral epibranchial tooth and a rather strongly reflected front.

Remarks.—The specimens (*p*), (*q*), and (*r*) combine the outer orbital angle, the lateral epibranchial tooth, and the inner sub-orbital tooth of *ferruginea* with the hand of *cymodoce*. The front is intermediate in character. The specific distinction between the two species is thus minimised. Judging from my specimens and from those in the British Museum, the best distinction is the hair of the hand.

Trapezia ferruginea, LATREILLE, var. **areolata,** DANA, 1852—A.3, p. 221.

Localities :—Coral reef, Galle, two specimens; Trincomalee, one specimen; Cheval Paar, two specimens; Jokkenpiddi Paar, two specimens.

Description :—C.l. of an ovigerous female = 12.

Trapezia maculata (MACLEAY, 1838)—A.3, p. 221.

Locality :—Jokkenpiddi Paar, two specimens (young ♂ and young ♀).

Trapezia rufopunctata (HERBST, 1799)—A.3, p. 222.

Locality :—Jokkenpiddi Paar, one specimen.

Description :—An ovigerous female, C.l. = 13.

Tetralia glaberrima (Herbst, 1790)—A.3, p. 223.

Localities :—Galle, one specimen ; pearl banks, Gulf of Manaar, two specimens ; Navakaddu Paar, two specimens ; Muttuvaratu Paar, one specimen ; off Mutwal Island, one specimen.

Description :—The above include three ovigerous females, one young female, one adult male, and two doubtfully young males.

Quadrella coronata, Dana, var. **granulosa,** Borradaile, 1902 (B.III., p. 266).

Locality :—Gulf of Manaar, six specimens ; Galle, deep water, three specimens.

Description :—C.l. of two ovigerous females = 7·0 and 13·75.

Portunus tuberculatus, Roux, 1830.

Locality :—Deep water off Galle and onwards, one specimen.

Remarks.—This genus (*i.e.*, the *Portunus* of Fabricius) is new to the Indian fauna.

Lissocarcinus polybioides, Adams and White, 1848—A.4., p. 19.

Localities :—South-east of Modragam, on weed-bearing oyster spat, one specimen (adult ♂) ; Gulf of Manaar, two specimens (ovigerous ♀ and young ♂).

Description :—C.l. of ovigerous female = 9·5.

Lissocarcinus orbicularis, Dana, 1852—A.4, p. 20.

Localities :—Negombo, one specimen (ov. ♀ *a*) ; Galle, lagoon, one specimen (adult ♀ *b*).

Description :—C.l. of ovigerous female = 12·00.

Specimen (*a*) is labelled "black crab from mouth of Trepang," and specimen (*b*), which is wound about with Holothurian threads, bears the label "black and white crab from rectum of black Holothurian."

Lissocarcinus lævis, Miers, 1886—A.4, p. 21.

Localities :—Pearl banks, Gulf of Manaar, ten specimens (*a* to *g* and *n* to *p*) ; coral reefs, Gulf of Manaar, six specimens (*h* to *m*).

Description :—The difference in size between (*a*) and (*b*), both adult females (the latter ovigerous), is to be noted. C.l. of (*a*) = 11·00 ; C.l. of (*b*) = 7·00. Apart from this, variability is low in the above series.

Lupocyclus rotundatus, Adams and White, 1848—A.4, p. 23.

Localities :—Off Kaltura, two specimens (*a*, *b*) ; deep water off Galle, four specimens ; coral reef, Gulf of Manaar, ten specimens (including *c*).

Description:—The series includes three ovigerous females, three adult non-ovigerous females, three young females, five adult males, and two young males. C.l. of an ovigerous female = 10·00.

In the above specimens there are indications of ridges in similar positions to those of *Neptunus* (*Lupocycloporus*) *whitei*, except that the anterior gastric ridge of the latter is not represented.

In ovigerous female (*c*) and in adult male (*a*) the three posterior of the interdental denticles are excessively rudimentary; a character described by ALCOCK for the young (*i.e.*, the absence of these denticles) tends thus to survive in the adult.

Lupocyclus strigosus, ALCOCK, 1899—A.4, p. 24.

Locality:—Gulf of Manaar, three specimens (2 adult ♂ and 1 young ♀).

Description:—C.l. of an adult male (front included) = 12·00. The present examples have only five teeth on the antero-lateral margin of the carapace (outer orbital angle included) instead of six. It is the second tooth which is absent.

Neptunus (Neptunus) sanguinolentus (HERBST, 1783)—A.4, p. 32.

Localities:—Gulf of Manaar, one specimen; Trincomalee, two specimens.

Description:—Two females and a male—all young.

Neptunus (Neptunus) pelagicus (LINN.), 1764—A.4, p. 34.

Locality:—Off Chilaw, $2\frac{1}{2}$ to 4 miles off shore, one specimen (adult non-ovigerous ♀). (RATHBUN, 'Proc. Biol. Soc. Wash.,' xi., for genera of this and last species.)

ALCOCK unites *N. pelagicus* and *N. trituberculatus*. Miss RATHBUN keeps them apart ('Proc. U.S. Nat. Mus.,' vol. xxvi., p. 26, 1902). The present specimen comes under *N. pelagicus* in Miss RATHBUN'S sense. WHITELEGGE'S notes on variability should be consulted ('Mem. Austral. Mus.,' iv., p. 154, 1900). He concludes, after an examination of some hundreds of examples from Port Jackson, that the character of the median tooth is not to be used as a specific distinction between the two species. Perhaps the granulation of the carapace is much a matter of sex. This character is in the present specimen of the type described by WHITELEGGE as essentially female. ORTMANN and CALMAN have cast doubt upon the specific distinctness of *N. armatus* from the present species (C., p. 21).

Neptunus (Amphitrite) gladiator (FABRICIUS, 1798)—A.4, p. 35.

Localities:—Off Negombo, Gulf of Manaar, one specimen; off Kaltura, two specimens; Galle, one specimen; pearl banks, Gulf of Manaar, thirty specimens; coral reefs, Gulf of Manaar, four specimens; Chilaw Paar, one specimen.

Description:—There are five ovigerous females, six adult but non-ovigerous females, fifteen young females, one adult male, and twelve young males.

The present specimens are small compared with some I have seen from Madras. I give some measurements of three of the ovigerous females:—

C.l.	22·00	20·00	20·00
C.b. ÷ C.l.	1·45	1·46	1·49
Rt. lat. spine l. (anterior border) ÷ C.l. . . .	0·12	0·17	0·17

C.b. is measured by a straight line uniting the notches between teeth 8 and 9.

Neptunus (Amphitrite) argentatus, WHITE, 1847—A.4, p. 36.

Localities:—Deep water off Galle, one specimen (ovigerous ♀); coral reefs, Gulf of Manaar, two specimens (adult ♀, adult ♂); off Kaltura, five specimens (one ovigerous ♀, one adult non-ovigerous ♀, and three adult ♂).

Description:—C.l. of an ovigerous female = 15·50.

Neptunus (Amphitrite) petreus, ALCOCK, 1899—A.4, p. 37.

Locality:—Gulf of Manaar.

Description:—A young specimen (C.l. = 5·00) which I put a little doubtfully in this species. Its wrist has the strikingly elongated inner spine. A point in which it differs from ALCOCK'S figure (A. Invest., pl. xlvi., fig. 2) is the still more blunt nature of the frontal lobes, the notches between them being wider and shallower.

Neptunus (Amphitrite) euglyphus, n. sp.—Text-figs. 6 and 7.

Localities:—Pearl banks, Gulf of Manaar, 13 specimens (*a* to *e* and *m* to *t*); coral reefs, Gulf of Manaar, four specimens (*f* to *i*); off Negombo, three specimens (*j*, *k*, *l*).

Description:—The association of a strong lateral production of the antero-external angle of the merus of the external maxilliped with rounded posterior carapace angles, and a much enlarged last spine of the antero-lateral series, show *N. euglyphus* to be a member of the sub-genus *Amphitrite* (*i.e.*, I.A.1.ii. of ALCOCK'S key. A.4, p. 31).

Fig. 6. *Neptunus euglyphus*, n. sp.

Fig. 7. Ventral view, external maxilliped and cheliped.

It differs from *Neptunus* (*Amphitrite*) *gladiator* in the following particulars:—(1) The grooves which delimit the several regions of the carapace are more strongly marked; (2) the two median frontal teeth are closer together: they meet the dentiform process of the epistome, so producing an appearance not unlike a single dorsally grooved median tooth; (3) the large last spine of the antero-lateral series has a very characteristic appearance: it is very broad proximally, flattened dorso-ventrally, and its posterior border is strongly recurved downwards and forwards;

(4) correlated with (3) is the short postero-lateral border of the carapace; (5) the middle region of the posterior border of the arm is considerably expanded—the inner surface of the hand and of the fixed finger is granular, and the under surfaces of all segments of the cheliped have a glazed appearance; (6) walking legs 1, 2, and 3 are, as a whole, glazed, there are a few hairs along the upper border, walking leg 4 is more or less tomentose.

Remarks.—The new species is distinguished at a glance from all other members of the sub-genus by its very characteristic last pair of lateral spines. It will be noted from (5) above that the cheliped bears a considerable resemblance to that of *Neptunus* (*Achelous*) *granulatus* (H. MILNE-EDWARDS).

I append the measurements of three adult males:—

	C.l.	C.b. ÷ C.l.	Lat. sp. (post. bord.) ÷ C.l.	Front. b. ÷ C.l.	Front.orb. b. ÷ C.l.	Ant.lat. bord. ÷ C.l.	Post.lat. bord. ÷ C.l.	Post. bord. ÷ C.l.
(*a*) . .	12·50	1·64	0·46	0·36	0·88	0·68	0·32	0·56
(*n*) . .	13·00	1·58	0·54	0·38	0·85	0·73	0·37	0·58
(*o*) . .	13·00	1·58	0·50	0·37	0·85	0·73	0·33	0·58

Antero-lateral border is from outer angle of orbit to notch between teeth 8 and 9.

Postero-lateral border is from base of posterior border of large spine to point of junction with abdomen.

Neptunus (Hellenus) hastatoides (FABRICIUS, 1798)—A.4, p. 38. Text-fig. 8.

Localities:—Galle, one specimen; pearl banks, Gulf of Manaar, nine specimens; off Mutwal Island, two specimens; coral reefs, Gulf of Manaar, twelve specimens; Palk Bay, two specimens.

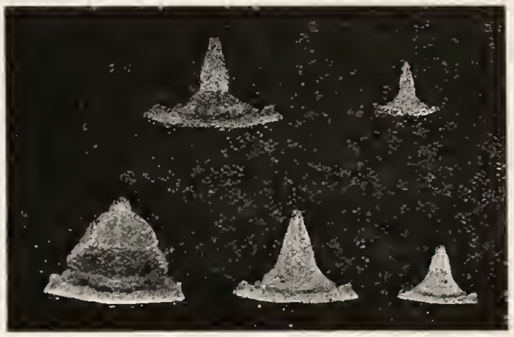

Fig. 8. Growth stages in abdomen of *Neptunus hastatoides*—upper row males, lower three females.

Description:—C.l. of an ovigerous female = 18·0.

Remarks.—LANCHESTER gives some account of sexual differences obtaining in this species. In view of the specimens before me I judge his figure ('Proc. Zool. Soc.,' 1900, p. 745, pl. xlv., figs. 7*a*, 7*b*) of a female abdomen to be evidently that of a young example. It agrees well with that of the young males of the present collection (see text-fig. 8).

Neptunus (Hellenus) hastatoides (FABRICIUS), var. **unidens**, nov.

Locality:—Coral reefs, Gulf of Manaar, one specimen.

Description:—A male, doubtfully adult, both chelipeds missing; C.l. = 12·25.

This specimen differs from other specimens of *N. hastatoides* known to me in the following particulars:—

(1) It possesses a single median frontal tooth instead of a pair, so that the front is cut into three teeth only. (This median tooth is somewhat smaller and less prominent than the lateral teeth, and its apex is flattened.)

(2) The tip of the dactylopodite of walking leg 4 is not darkened in colour (one must, of course, not overlook the possible agency of the spirit in producing this appearance).

(3) The carina of abdominal segment III. is more prominent in its middle portion and its median notch is deeper, approaching in appearance that of *N. macrophthalmus*, RATHBUN, 1903 (R., p. 871, fig. 31).

The granulation of the sternum of this male closely resembles that of the adult male of *N. hastatoides*.

Remarks.—I call attention to the absence of both chelipeds. It is therefore impossible to ascertain various essential characters. Leaving these necessarily out of consideration, the specimen is so closely similar to *N. hastatoides* (except in particulars given above) that it may be conveniently included as a varietal example of that species, in which the pair of narrow median frontal teeth have coalesced. This latter particular seems of sufficient interest to warrant my putting the specimen on record. I append the following measurements :—

$C.b._1$ (a straight line uniting the notches between the 8th and 9th antero-lateral teeth of either side)÷C.l. = 1·51 ; $C.b._2$ (a straight line uniting points immediately behind the great lateral spines)÷C.l. = 1·10 ; Posterior border of C.÷C.l. = 0·65 ; Frontal b.÷C.l. = 0·41 ; Fronto-orb.b.÷C.l. = 0·82 ; lateral spine l. (posterior border) ÷C.l. = 0·49 ; antero-lateral border of C. (a straight line uniting outer orbital angle with notch between the great lateral spine and the tooth in front of it)÷C.l. = 0·69 ; postero-lateral border of C. (a straight line uniting base of great lateral spine with postero-lateral angle)÷C.l. = 0·39.

Neptunus (Hellenus) spinipes, MIERS, 1886—A.4, p. 39.

Locality :—Galle, one specimen.

Description :—An adult male, C.l. = 11·00.

Remarks.—I have examined the Martaban specimens placed by HENDERSON as *N. andersoni*, and which are preserved in the British Museum, and find that in reality they are *N. spinipes* of MIERS, whose "Challenger" specimens I have also consulted.

Neptunus (Hellenus) longispinosus (DANA), var. **bidens**, nov.—(See A.4, p. 40).

Localities :—Off Negombo, one specimen (adult ♂) ; off Mutwal Island, one specimen (adult ♂) ; Gulf of Manaar, one specimen (ovigerous ♀).

Description :—C.l. of an ovigerous female = 6·50.

In all three specimens the hand has only two spines, a point of resemblance to *Neptunus* (*Hellenus*) *tuberculosus*, A. MILNE-EDWARDS. I suggest for them the varietal name *bidens*.

The antero-external angle of the merus of the external maxillipeds and the shape of the male abdomen are evidently characters with high variability in this species if ALCOCK is correct in including both the forms figured by DANA. The present examples agree in combining a merus resembling DANA's fig. 2*c* with a male abdomen in which the borders are still more sinuous than in his fig. 3*b*—abdominal segment VI. being the one chiefly involved.

Neptunus (Hellenus) tenuipes (DE HAAN, 1835)—A.4, p. 42.

Locality :—Pearl banks, Gulf of Manaar, one specimen.

Description :—Adult male. C.l. = 16·00.

Behind the single distal spine of the outer border of the arm is a sub-terminal tubercle marking the position of the second spine of some allied species.

Neptunus (Lupocycloporus) whitei (A. M.-EDW., 1861)—A.4, p. 44.

Localities :—Coral reefs, Gulf of Manaar, two specimens (adult ♂ and adult ♀); pearl banks, Gulf of Manaar, one specimen (young ♀); off Mutwal Island (young ♀).

Description :—C.l. of adult female = 18·00.

In both the adult specimens (a ♂ and a ♀) one notes :—(1) The cardiac ridge is broken in the middle line so that it takes the form of two low broad tubercles, granulated on their posterior slope; (2) there is a small granulated protuberance on the post-gastric region; (3) there is a longitudinal row of granules on the middle line of the carapace; its anterior commencement is just in front of the break in the anterior gastric ridge, and runs back across the second gastric ridge, to terminate posteriorly between this and the third gastric ridge.

Neptunus (Achelous) granulatus (H. M.-EDW., 1834)—A.4, p. 45.

Localities :—Off Negombo, one specimen; Gulf of Manaar, 17 specimens; off Mutwal Island, one specimen.

Description :—The above specimens include four ovigerous females, five adult females, seven adult males and three young males. C.l. of an ovigerous female = 13.

There is a pearly sheen, much as in *N. argentatus,* on the crests of abdominal terga II. and III., the terminal spine of the arm, the crest of the outer surface of wrist, and the upper surface of the dactylus.

The spinule on the hand, in front of the apex of the wrist, is said by ALCOCK to be blunt. Among the present examples it is sharp, except on the left hand of two and the right hand of three specimens.

Neptunus (Achelous) dubia, n. sp.—Text-fig. 9.

Localities :—Coral reefs, Gulf of Manaar, one specimen; oft Negombo, one specimen.

Description :—Adult ♂ C.l., 13; C.b. ÷ C.l., 1·31; front.b. ÷ C.l., 3·85; front.-orb.b. ÷ C.l., 0·85; ant.lat.bord. C. ÷ C.l., 0·54; post.bord. C. ÷ C.l., 0·62; post.lat.bord. C. ÷ C.l., 0·58; Ch.l. ÷ C.l., 2·00.

It differs from *Neptunus* (*Achelous*) *granulatus* in the following characters:—(1) The outer fissure of the supra-orbital margin is obsolete; (2) the nine teeth of the antero-lateral border gradually decrease in size from before backwards; (3) the antero-lateral angle of the merus of the external maxillipeds is rounded and but slightly produced in a lateral direction; (4) the chelipeds in the male are about twice the length of the carapace, the posterior border of the arm is more expanded than in *N. granulatus*, the anterior border of the arm bears three well-developed spines and a fourth inconspicuous one posterior to these, the posterior border bears one spine only in the position of the distal one of *N. granulatus*; (5) the outline of the abdomen of the male is triangular, abdominal terga II. and III. both have well-marked carinæ, across abdominal tergum V. runs a transverse ridge just anterior to the joint between terga V. and VI.—this is correlated with the form of the copulatory appendages; (6) the form of the male copulatory appendages is characteristic.

Fig. 9. *Neptunus dubia*, n. sp., adult male.

It will be noted that in characters (1), (2) and cheliped-length the new species agrees with *Neptunus* (*Achelous*) *orbicularis*, but it differs from the latter and resembles *N. granulatus* in the granulation of its carapace and chelipeds, in the open character of the inner fissure of the supra-orbital margin, and in ratio C.b. ÷ C.l. I have not seen any specimen of *N. orbicularis*, but as points (3), (5), (6) and spines of hand, *i.e.*, part of (4), are not specified by Alcock as differences from *N. granulatus* in his description of *N. orbicularis* (A.4, p. 47), I conclude that the new species is sufficiently distinct from the latter.

The characters of the antero-lateral angle of the merus of the external maxilliped may be conveniently used to separate *N. dubia* from the other two members of the sub-genus given in Alcock's key (A.4, p. 32).

I may note here that I judge *Achelous rubro-marginatus*, Lanchester ('Proc. Zool. Soc.,' 1900, p. 746, pl. xlvi., fig. 8), to belong to the sub-genus *Amphitrite*, linked to the *gladiator* group by *Neptunus* (*Amphitrite*) *petreus* (A.4, p. 37). The latter species may have been unknown to Lanchester: its description did not long precede that of *rubro-marginatus*.

Neptunus (Pontus) convexus, de Haan, 1833.

Localities:—South of Modragam, one specimen; off Mutwal Island, two specimens; coral reefs, Gulf of Manaar, nine specimens; pearl banks, eleven specimens.

Description :—The above include one ovigerous female, six adult non-ovigerous females, nine young females, five adult males, and two young males. The specimens from "Coral reefs, Gulf of Manaar," are larger than those from the other localities.

Neptunus convexus is not definitely included in the Indian fauna by ALCOCK (A.4, p. 32). He suggests that its affinities are with the sub-genus *Neptunus*. It seems advisable to keep it apart, however, as the single representative of *Pontus*, a sub-genus re-defined by DE MAN ('Abh. Senckenb. Ges.,' xxv., pt. iii., p. 643, pl. xxi., fig. 27, 1902).

Charybdis (Goniosoma) natator (HERBST, 1794)—A.4, p. 61.

Localities:—Off Mutwal Island, two specimens; pearl banks, Gulf of Manaar, thirteen specimens.

Description :—The above include four females and eleven males, all young.

Charybdis (Goniosoma) orientalis, DANA, 1852—A.4, p. 63.

Localities:—Coral reefs, Gulf of Manaar, five specimens; pearl banks, Gulf of Manaar, fifteen specimens; south of Galle, one specimen; off Mutwal Island, one specimen.

Description :—C.l. of ovigerous female = 9·50.

Charybdis (Goniohellenus) ornata, A. M.-EDW., 1861—A.4, p. 64.

Locality:—Coral reef, Galle, one specimen.

Description :—The specimen is a male, C.l. = 9·75.

The last of the antero-lateral teeth is a little larger than the others instead of smaller as in ALCOCK's description. A parasitic *Sacculina* is attached to the abdomen. On comparing the crab with one of similar size in the British Museum (ref. 73.28) I find that this has had little effect upon the form of the abdomen, but that the copulatory appendages are sensibly less developed.

Thalamita prymna (HERBST), var. **crenata** (= **T. crenata,** LATR.)—A.4, p. 76.

Locality:—Trincomalee, three male specimens.

Description :—

C.l.	29·00	38·00	41·00
C.b. ÷ C.l. . . .	1·47	1·49	1·50

The high variability in size is to be noted, as all three are possibly adult.

Thalamita prymna (HERBST), var. **annectans,** nov.

Locality:—Trincomalee, two specimens.

Description :—One is a small, but quite probably adult, male, C.l. = 16·00.

The following are its most interesting characters for systematic purposes:—(1) The fourth tooth of the antero-lateral margin of the carapace is rudimentary; (2) the ridge on the basal joint of the antenna bears spines; (3) the four middle lobes of the front are more or less squarely cut; (4) the transverse mid-gastric ridge is not continued to the notch between the first and second teeth of the antero-lateral border of the carapace; (5) there are four ridges on the hand: two of these are ill-defined and unite the two rows of spines on its upper surface—a third corresponds in position to the third ridge of var. *crenata* and is similarly continued on to the fixed finger—the fourth is smooth, runs above the third, and ends distally just behind the cleft between the fingers; (6) there are three spines in the upper row on the palm—the distal one is smaller than the other two; (7) there is a distal spine on the wrist, just behind the upper row of spines of the palm; (8) the lower border of the propodite of walking leg 4 bears obvious spines distally; these become smaller proximally and disappear on the proximal third.

The second specimen is an immature female (Cl. = 10) which may probably be correctly put with the above. The fourth tooth of the antero-lateral margin of the carapace is seen under the lens to be excessively minute—still more rudimentary than in the male. The ridges of the hand are granular, and there is a trace of an additional ridge above the position of the one which ends interdigitally in the male.

Remarks on the species *Thalamita prymna* (HERBST). ALCOCK (1899) supports KOSSMANN'S view of the specific identity of *T. prymna* (HERBST)—*T. crenata* (LATREILLE) (including *T. crassimana*, DANA)—*T. danæ*, STIMPSON—*T. stimpsoni*, A. MILNE-EDWARDS—and *T. picta*, STIMPSON—*i.e.*, those forms with an eight-lobed front combined with a very broad basal antennal joint. Material recently described tends to justify this view. Thus CALMAN describes three series of Torres Straits forms (C., p. 22), of which two at least evidently belong to the group, and tend to combine characters of the other members rather than to belong decidedly to any recognised division. The same kind of thing occurs in the specimen of the present collection described above. It is allied by characters (1), (2), and (3) to var. *prymna*, by (4) to var. *crenata* and var. *danæ*, while characters (6) and (7) separate it from varieties known to me. ALCOCK'S key brings the present variety under var. *prymna*, from which it may readily be distinguished by characters (6) and (7) above.

Thalamita chaptali, AUDOUIN and SAVIGNY, 1826—A.4, p. 80.

Localities:—Pearl banks, Gulf of Manaar, 23 specimens; coral reefs, Gulf of Manaar, 26 specimens; off Mutwal Island, one specimen; 10 miles north of Cheval, one specimen.

Description:—C.l. of an ovigerous female = 8·25.

Thalamita poissoni, AUDOUIN and SAVIGNY, 1826—A.4, p. 81.

Localities:—West of Periya Paar, one specimen (ovigerous ♀); pearl banks, Gulf of Manaar, one specimen (adult ♂).

Description:—C.l. of the ovigerous female = 7·50.

The fourth tooth of the antero-lateral border is very rudimentary in both examples.

Thalamita admeta (HERBST, 1803)—A.4, p. 83.

Localities :—Pearl banks, Gulf of Manaar, 58 specimens ; coral reefs, Gulf of Manaar, four specimens ; off Negombo, one specimen ; off Mutwal Island, four specimens ; Muttuvaratu Paar, two specimens.

All the above specimens come under var. *admeta* as defined by BORRADAILE (p. 202). The fourth tooth of the antero-lateral border of the carapace, considerably reduced in all, is very rudimentary in some—particularly among the females. It is, perhaps, most rudimentary, however, in one of the adult males.

Thalamita exetastica, ALCOCK, 1899—A.4, p. 86 ; A.Invest., pl. xlvii., figs. 2, 2*a*.

Localities :—Pearl banks, Gulf of Manaar, two specimens (adult ♀, one ovigerous) ; south of Galle, deep water, one specimen (adult ♀).

Description :—As in BORRADAILE'S specimens (p. 203), the squamiform markings of the cheliped are almost absent ; a trace only is present, on the upper distal portion of the arm. On the upper surface of the arm and on the upper portion of the outer surface there are more or less rounded granules ; the inner surface, the under surface, and the lower portion of the outer surface are smooth. The ridges of the carapace are well marked.

In the ovigerous female there are one or two spinules on the posterior border of the propodite of walking leg 4. This is an approach to *Charybdis orientalis*, DANA.

Thalamita integra, DANA, 1852—A.4, p. 85.

Locality :—Pearl banks, Gulf of Manaar, six specimens.

Thalamita investigatoris, ALCOCK, 1899—A.4, p. 85 ; A.Invest., pl. xlvii., fig. 1.

Localities :—Off Mutwal Island, one specimen ; Gulf of Manaar, deep water, three specimens ; deep water off Galle, four specimens ; coral reefs, Gulf of Manaar, one specimen (*a*).

Description :—There are five ovigerous females, one young female, one adult male, and two young males. C.l. of an ovigerous female = 7·00.

Spines are present on the propodite of walking leg 4 as described by ALCOCK, but omitted from his figure. As differences from ALCOCK'S description of the single male for which he creates the species one notes that the median lobes of the front tend to have a straight rather than a rounded anterior border, and are not obviously more prominent than the sub-median pair, the latter point agreeing with ALCOCK'S figure, however. I should not describe the fifth tooth of the antero-lateral margin of the carapace as "very" small. The wrist and hand bear more numerous spines.

The fourth tooth of the antero-lateral margin of the carapace is absent in one of the ovigerous females (*a*).

Thalamita sexlobata, MIERS, 1886—A.4, p. 87.

Localities :—Pearl banks, Gulf of Manaar, eight specimens ; coral reefs, Gulf of Manaar, four specimens ; off Mutwal Island, one specimen.

Thalamita wood-masoni, Alcock, 1899—A.4, p. 90.

Locality:—10 miles north of Cheval Paar, one specimen (young ♀).

Description:—The fourth tooth of the antero-lateral margin of the carapace, which Alcock describes and figures (A.Invest., pl. xlviii., figs. 1, 1*a*) as rudimentary, is absent in the present example.

Thalamita oculea, Alcock, 1899—A.4, p. 91.

Localities:—Coral reefs, Gulf of Manaar, 10 specimens; pearl banks, Gulf of Manaar, 19 specimens; off Mutwal Island, three specimens; deep water off Galle, two specimens; off Kaltura, one specimen; Trincomalee, one specimen.

Description:—C.l. of an ovigerous female = 10·00.

Kraussia nitida, Stimpson, 1858—A.4, p. 98 (*pars*).

Localities:—Off Mutwal Island, one specimen (*a*); pearl banks, one specimen (*b*); west of Periya Paar, 17 to 24 fathoms, one specimen (young ♀).

Description:—

	C.l.	C.b. ÷ C.l.	Fronto-orb.b. ÷ C.l.
(*a*) adult ♂	12·00	1·04	0·62
(*b*) adult ♀	10·00	1·10	0·62

Miss Rathbun ('Bull. Mus. Comp. Zool.,' Harvard, xxxix., No. 5, 1902, p. 132) separates Henderson's *nitida* from this species and makes for it a new species, *Kraussia hendersoni*. The specimens of the present collection come under *K. nitida* in Miss Rathbun's sense. They agree with her figure. Miss Rathbun's photographs of species of *Kraussia* are useful (*loc. cit.* and R., 1903).

This genus is new to the Ceylon fauna. The only other genus of the family Cancridæ which I know to have been recorded from Ceylon is *Trichopeltarium*, represented by a single species (? *T. ovale*, A.4, p. 99).

I may note here that I have seen in the British Museum the "type"-specimens described by Adams and White in the 'Voyage of the "Samarang"' (p. 59, 1850) as *Trichocera porcellana*, and find that the latter name is a synonym of *K. rugulosa*. Dana puts it as such with a query (Crust., 'U.S. Expl. Exped.,' I., p. 302, 1852).

Gomeza bicornis, Gray, 1831.

Localities:—Deep water, off Galle, one specimen (*a*); pearl banks, Gulf of Manaar, six specimens (*b* to *g*).

Description:—Examples (*b*), (*c*), and (*g*) are ovigerous females, (*a*) is an adult but non-ovigerous female, and (*d*) to (*f*) are adult males.

Variability is high within the species. The present specimens fall into three groups:—(1) The non-ovigerous female (*a*, C.l. = 20) approaches A. Milne-Edwards' figure under name *Gomeza viginti-spinosa* ('Nouv. Archiv. du Mus. Paris,' vol. x., p. 52, pl. iii., fig. 5, 1874); (2) examples (*b*, C.l. = 15·5) to (*f*) agree with de Haan's figure

(Crust. in 'Fauna Japonica,' p. 44, pl. ii., fig. 5, 1835); (3) the ovigerous female (*d*, C.l. = 23) goes with the "Challenger" specimens preserved in the British Museum.

Some variable characters of the species may be set forth in the form of a key.

I. Inner sub-orbital spine small . . . . var. A.

II. Inner sub-orbital spine large.

a. Carapace strongly pilose . . . . var. B.

b. Hairs on carapace few or absent.

i. Spiniform outer angle of orbit as well developed as first antero-lateral spine . . . . var. C.

ii. Spiniform outer angle of orbit much shorter than the first antero-lateral spine . . . . var. D.

The family Corystidæ is new to the Ceylon fauna.

CATOMETOPA.

Catoptrus nitidus, A. M.-Edw., 1870—A.6, p. 307.

Locality :—West of Periya Paar, 17 to 24 fathoms.

Description :—Male, apparently adult, C.l. = 3·80 ; Ch.l. (smaller) ÷ Ch.l. (larger) = 0·92 ; C.b. ÷ C.l. = 1·51 ; F.l. (larger) ÷ C.l. = 1·05 ; Ch.l. (larger) ÷ C.l. = 0·33 ; F.l. (smaller) ÷ F.l. (larger) = 0·75.

Remarks.—The small size of the specimen may be noted—Alcock refers to some

	G. inæqualis, Rath.	*C. nitidus* : A.6, p. 307.	Present specimen.	*C. nitidus* (= *G. truncatifrons*, de Man).
	♂.	(Sex ?)	♂, probably adult.	♂, young.
(1) C.l.	7·00	9·50	3·80	6·20
(2) C.b. ÷ C.l.	1·51	1·53	1·51	1·66
(3) Ant. lat. region. . .	Finely granular	Finely granular	Finely granular	Coarsely granular
(4) Denticle betw. ant. lat. teeth 1 and 2	Absent	(Not mentioned)	Absent	Present
(5) Ch.l. (larger) ÷ C.l. .	3·00	—	3·03	2·50
(6) Ch.l. (smaller) ÷ C.l. .	3·40	About 3·00	3·29	Much as larger Ch.l. ÷ C.l.
(7) Ant. border arm . .	"Coarsely granulous," no spines.	Finely serrulate, one serration at either or both ends enlarged and spiniform.	Finely serrulate, one serration at prox. end enlarged and spiniform.	Granular, a spine distally in larger Ch. In smaller Ch. one behind middle also.

similarly small examples. *Goniocaphyra inæqualis*, RATHBUN, is, I believe, a synonym—her photograph gives an excellent impression of the present specimen. The preceding table shows comparative characters in these forms. ALCOCK'S description was based on 19 specimens from various localities. His measurements refer to Mauritius specimens in particular. A. MILNE-EDWARDS' "type"- specimen was large (C.b. = 23·00).

Goniocaphyra inæqualis comes under *Catoptrus nitidus* as described by ALCOCK except as regards characters (6) and (7) of table, and of these (7) is admittedly variable (even in Miss RATHBUN'S photograph there seems to be some indication of a proximal tubercle). My specimen is intermediate in regard to character 6.

Dr. DE MAN points out ('Notes, Leyden Mus.,' xii., p. 67, 1890) that his *Goniocaphyra truncatifrons* is young and = *Catoptrus nitidus*. The evidence suggests a single species for the forms included in the table, within which DE MAN'S *truncatifrons* specimen stands somewhat apart.

Mertonia, n. gen.

Description :—Carapace rudely semicircular in outline, the posterior border being the longest, and the postero-lateral borders anteriorly convergent, to form a common curve with the well-arched antero-lateral and anterior borders; it is but little broader than long, is convex fore and aft, and strongly declivous anteriorly. Regional distinctions are almost imperceptible. Fronto-orbital border more than one-half (about 0·6 in the two specimens), and front one-quarter, the greatest breadth of the carapace; front is prominent and bilobed.

Orbits somewhat ventral, completely filled by immovable elongated eye-stalks; eyes small.

Antennules small; they fold obliquely into proper pits.

Basal antennal segment fairly long, its antero-external angle stands well in the orbital hiatus; the anterior portion of the hiatus is occupied by the flagellum, which is stout and markedly plumed and half the carapace length.

The epistomial wall of the buccal cavern is well formed and prominent; the buccal cavern is not completely closed by the external maxillipeds, a considerable space being left between their inner borders, particularly those of the meri; the flagellum articulates with the antero-internal angle of the merus; the antero-external angle of the merus is produced.

Chelipeds a little unequal, much more massive than, but about the same length as, the 3rd pair of walking legs; palm short, deep, and compressed, with sharp edges.

Walking legs slender, unarmed; dactylopodites styliform: the 3rd and 4th pair of approximately equal length (the 2nd pair missing).

For key purposes *Mertonia* comes under division I.1.ii.b. of ALCOCK'S key to the Indian genera of the Rhizopinæ (A.6, p. 317). The other occupant of the same division is *Xenophthalmodes*, from which the new genus is distinguished readily by the lateral production of the outer angle of the merus of the external maxillipeds; additional differences from the same genus concern: (1) ratio of fronto-orbital breadth ÷ C.b.; (2) ratio of frontal b. ÷ C.b.; (3) the more ventral position of the orbits: (4) eyes, though very small, are distinct; (5) direction of fold of antennules; (6) relations of basal antennal segment and orbital hiatus (associated, no doubt, with more ventral position of orbit); (7) the markedly plumed antennal flagellum. Characters (4) and (5) approach the condition found in *Typhlocarcinus*: (2) and (3) are intermediate between the latter genus and *Xenophthalmodes*.

Mertonia lanka, n. sp.—Plate I., fig. 11, *a*, *b*.

Locality:—Gulf of Manaar, two specimens (♀ and ♂).

Description:—C.l. = 4 in ♂, 4·5 in ♀; C.b. = 5·5 in ♂, 6 in ♀.

Carapace has practically smooth surface, polished, with some irregular dimpling; its free edges fringed with longish silky hairs; C.b. ÷ C.l. = 1·37 in ♂, 1·33 in ♀: frontal b. ÷ C.b. = 0·27 in ♂, 0·28 in ♀; fronto-orbital b. ÷ C.b. = 0·64 in ♂, 0·58 in ♀: front strongly declivous and decidedly bilobed.

Orbits elongated; long diameter of orbit ÷ C.l. = 0·25 in ♂, 0·28 in ♀.

The antennal hairs are numerous and long; antennal flagellum l. ÷ C.l. = 0·5 in ♂.

The buccal cavern increases slightly in breadth anteriorly; the merus of the external maxilliped has its length and breadth about equal (the measurements taken along the middle line in each case); its outer border somewhat convex; its antero-lateral angle produced and rounded; the ischium is not much longer than broad; its breadth is as that of the merus; a space is left between the ischia and a larger one between the meri (see Pl. I., fig. 11, *a*).

Chelipeds about same length as walking leg 4; hands sub-equal; inner angle of wrist acuminate; upper and lower edges of hand sharpened, its surfaces polished, with some dimpling; the edges of the chelipeds are fringed with silky hairs, these are long on the wrist, shorter on the hand. Walking legs fringed with silky hairs.

Scalopidia spinosipes, Stimpson, 1858—A.6, p. 325.

Locality:—Gulf of Manaar, one specimen.

Description:—A young male, C.l. = 5·75; C.b. ÷ C.l. = 1·30.

Pinnoteres margaritiferæ, n. sp.—Text-fig. 10, 10 *a*.

Locality:—Pearl banks, Gulf of Manaar, one specimen.

Description:—An adult male. C.l. = 5·25.

Carapace well calcified, circular, smooth, and polished; seen under lens to be pitted, more markedly so towards the margins; it is flattened a good deal, though a little convex; its margins are rounded and ill-defined. Front produced, with straight anterior border in dorsal view; its tip is really, however, deflexed acutely, and its true anterior border, seen in anterior view, is obtusely pointed. Eyes small, well pigmented; not entirely visible in a dorsal view of the animal. Propus of external maxilliped spathulate; dactylus slender and inconspicuous, arising from about the middle of the flexor surface of the propus, which arises before the termination of the carpus, and the latter before the termination of the merus. Cheliped slightly longer than the carapace (Ch.l. ÷ C.l. = 1·12); two or three times as stout as walking leg 1, but rather shorter (Ch.l. ÷ W.L.1.l. = 0·86); the segments inflated, smooth, and

Fig. 10. *Pinnoteres margaritiferæ*, n. sp. × 3.

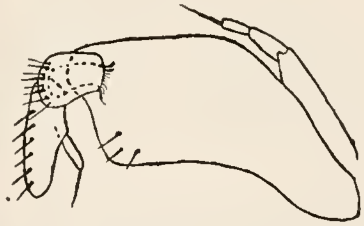

Fig. 10A. External maxilliped.

polished; dactylus is about two-thirds as long as the upper border of the hand; its tip is strongly bent down; there is a stout tooth near its base, on its apposable border.

Walking legs slender; lower borders fringed sparsely with hair. W.L.1 ÷ C.l. = 1·33; W.L.2 ÷ C.l. = 1·38; W.L.3 ÷ C.l. = 1·38; W.L.4 ÷ C.l. = 1·05. The dactyli of walking legs 1, 2, and 3 are sub-equal in length (about 0·2 of C.l.); that of walking leg 4 is about one-half as long again.

Gelasimus* annulipes, Latreille—A.6, p. 353—Text-fig. 11.

Locality:—Off Mutwal Island, two specimens (*a*, *b*).

Description:—	C.l.	C.b. ÷ C.l.	Post. bord. C. ÷ C.l.	Front bord ÷ C.l.	Larger propus l. ÷ C.l.
(*a*) ♂ . . .	8·75	1·66	0·91	0·29	2·17
(*b*) ♀ . . .	9·25	1·62	0·95	0·28	—

C.b. is measured by a straight line uniting produced post-orbital angles.

Posterior border C. is measured by a straight line uniting points just above and to inner side of bases of 4th pair of walking legs.

Propus length is measured along lower border.

Nobili (in 'Boll. Mus. Torino,' xvi., No. 397, p. 13, figs. A, B, 1901) has distinguished two varieties of the species—differentiated by presence or absence of a large triangular tooth at distal end of fixed finger.

A, var. *orientalis*, Nobili, 1901. Large tooth present.

B, var. = *Gelasimus perplexus*, A. M.-Edw., 1852. Large tooth absent.

Fig. 11. *Gelasimus annulipes*, the larger chela × 2.

* I retain the generic name *Gelasimus*—sanctioned by tradition—to avoid confusion with the distinct group of land crabs known as *Uca*.

The photograph (fig. 11) should be compared with NOBILI's figures. It might conceivably be included under var. *orientalis*, but does not agree well with either.

Length of large propus is in adult male (*a*) much less than that given by ALCOCK, who had before him 300 Indian specimens (ALCOCK's index, large propus l. ÷ C.l. = 3·00).

Ocypoda ceratophthalma (PALLAS, 1772)—A.6, p. 345.

Localities:—Trincomalee, mangrove swamps, two specimens (*b*, *c*); Galle, one specimen (*a*).

Description:—	(*a*) ad. ♀.	(*b*) ad. ♀.	(*c*) ad. ♂.
C.l.	13·50	30·00	36·50
C.b. ÷ C.l.	1·02	1·13	1·07
Projection of eye stalk beyond eye (lower border) ÷ C.l.	0·0	0·10	0·29

C.b. is a straight line uniting points of lateral borders where the serrulate line forks.

In adult female (*b*) the outer band of granules of the ischium of external maxillipeds is somewhat obsolescent, tending, in conjunction with a specimen of *O. platyarsis* in the present collection, to cast doubt upon granulation of this region as a character of specific value.

Ocypoda platyarsis, H. M.-EDW., 1852—A.6, p. 348.

Localities:—Gulf of Manaar, one specimen (*d*); Trincomalee, mangrove swamps, three specimens (*a*, *b*, *c*).

Description:—	(*b*) young ♀.	(*c*) young ♀.	(*d*) adult ♂.
C.l.	15·00	24·00	50·00
C.b. ÷ C.l.	1·27	1·34	1·26
Projection of eye stalk beyond eye (lower bord.) ÷ C.l.	0·10	0·19	—

The distinction between this species and *O. ceratophthalma* in regard to C.b. ÷ C.l. holds, in the present specimens, for both adult and young. In adult male (*d*) the granulation of ischium of external maxillipeds approaches the condition recorded above for an adult female specimen of *O. ceratophthalma*.

Dotilla myctiroides (H. M.-EDW., 1852)—A.6, p. 368.

Localities:—Off Mutwal Island, three specimens; coral reefs, Gulf of Manaar, three specimens; Galle, twenty-three specimens.

Description:—C.l. of an adult male = 8·50.

All the specimens are males except a single immature female from "Coral Reefs, Gulf of Manaar." All the males are mature save one, or perhaps two.

The immature female has seven separate abdominal terga.

Remarks.—Is the striking preponderance of males over females in the collection correlated with a difference in habit, the latter staying at home in the mud?

DE HAAN'S use of the division of the female abdomen into five movable parts only, as a generic character, is not to be considered as contradicted by the present specimen, as the latter is immature (C.l. = 5·50).

Macrophthalmus latreillei (DESMAREST), 1822—Plate II., fig. 3, text-fig. 12.

Locality:—Gulf of Manaar, one specimen.

Description:—Ovigerous female. C.l. (front included) = 21·00; C.b. ÷ C.l. = 1·33; front.b. ÷ C.l. = 0·13. (C.b. = straight line uniting points where the granulated line which borders the carapace bends above the bases of walking legs 1. Front.b. is measured across the "neck.")

The carapace, particularly in its grooves, has traces of hair, but there is by no means a hairy covering such as ORTMANN describes for *M. laniger*. The lateral teeth of the carapace are both in flatness and in outline more as ORTMANN'S description and figure of *M. laniger* than as MIERS' figure of *M. serratus* (= *latreillei*).

Remarks.—I agree with DE MAN in uniting *M. polleni*, HOFFMANN, 1874, with *M. latreillei*—also with ORTMANN in adding *M. serratus*, ADAMS and WHITE, to the union. I believe further that *M. laniger*, ORTMANN, 1894, is not specifically distinct. The main characters in which ORTMANN describes *M. laniger* as differing from *M. latreillei* (= *serratus*) are that the former has:—(1) Well-developed hairy covering of carapace; (2) flat, not thorn-like, teeth of lateral margin of carapace; (3) almost straight under border of chela; (4) cheliped of male not very strongly developed.

I have before me a series which makes it difficult to accept these as distinctions of specific value. Another male B.M. specimen (D) is figured (pl. ii., fig. 3).

	A. ♂ (dry). "Challeng." *serratus.* B. Mus. 43–6. Phil. Isds.	C. ♂ (dry). B. M. 83–24. Singapore.	B. ♂ (dry). B. M. 43–6. Phil. Isds.	C'. ♂ (dry). B. M. 83–24. Singapore.	E. ♀ (spirit). Present form. Ceylon.	F. ♂. *laniger* (ORT.'s descr. and figure).
C.l.	41·50	29·00	30·25	27·50	21·00	small
C.hair	absent	much	absent	much	little	much
Arm l. ÷ C.l. . .	0·84	0·74	[0·45]	0·71	0·45	—
P.l. ÷ C.l. . . .	1·37	1·28	[0·65]	1·20	0·62	—
H.l. ÷ C.l. . . .	1·00	0·88	[0·36]	0·82	0·32	—
H.height ÷ C.l. .	0·46	0·47	[0·22]	0·45	0·14	—
F.l. ÷ C.l. . . .	0·54	0·56	[0·31]	0·53	0·35	—
F.l. ÷ H.l. . . .	0·54	0·64	[0·86]	0·64	1·07	—

P.l. = Propus length (under border). H.l. is measured along upper border. Specimen (B) has only one cheliped, and that is a regenerated one.

Examining the above table and the plate one notes that a hairy type of carapace is associated indifferently either with "flat, not thorn-like" carapace-teeth (F), or with acute upturned carapace-teeth (C), or with a somewhat intermediate form (C'). On the other hand, the character of the marginal teeth of the carapace, the male cheliped measurements and the size of the crab (measured by C.l.), are correlated.

The cheliped differences in the males have the appearance of being growth-changes. The appearance of regenerated cheliped of (B) is suggestive (Pl. II., fig. 3, B). Possibly the differences in the character of the marginal teeth are also growth-changes; one

D. C.

A.

Fig. 12. *Macrophthalmus latreillei*—growth stages of male chela.

requires more evidence. It may be noted that in all the males the copulatory appendages appear to be well developed; it would be difficult to say that the smaller specimens are not sexually mature.

I have seen MIERS' small "Challenger" specimens from Japan, referred to by ORTMANN, and put them with the example in the present collection. In one of them the degree of development of hair on the carapace is much as in my specimen. Specimens of this variable species are often found as sub-fossils (HENDERSON, p. 389).

Elamena truncata, A. M.-EDW., 1873—A.6, p. 386.

Locality:—Galle Bay, "From bags hung from buoy," three specimens.

Description:—	(*a*) young ♀.	(*b*) young ♀.	(*c*) adult ♀.
C.l.	5·00	5·25	6·25
C.b. ÷ C.l.	0·95	0·95	1·00

The front is "broadly truncated," but its anterior border cannot be described as "quite straight." BORRADAILE (B.X., p. 682) follows ORTMANN in placing the Hymenosomidæ among the Oxyrhyncha.

Geograpsus crinipes (DANA, 1851)—A.6, p. 396.

Locality:—Galle, in tow-net, one specimen.

Description:—An adult male, C.l. = 32·00. The label gives colours in life:—"Dorsum of carapace very dark purplish-red, ventral surface red (except dactylopodites of walking legs—which are nearly white), eye stalks dark purplish-red (as dorsum of carapace), lens black."

The exopodite of external maxilliped bears a slender flagellum—a point which is to be noted, for ALCOCK uses the absence of a flagellum as a generic character, speaking of it in his key as present in *Grapsus* and absent in *Geograpsus*. The two genera are, however, distinguished at once by the very striking fringe of hair on the apposed borders of the coxæ of walking legs 2 and 3—present in *Geograpsus*, absent in *Grapsus*.

Metopograpsus messor (FORSKÅL, 1775)—A.6, p. 397.

Locality :—Trincomalee, four specimens.

Description :—C.l. of an ovigerous female = 16·00.

Sesarma edwardsi, var. **brevipes,** DE MAN, 1889 ('Zool. Jahrb. Syst.,' iv., p. 425).

Locality :—Mouth of a stream near Galle, one specimen.

Description :—An adult male, C.l. = 9·50.

Leiolophus planissimus (HERBST, 1804)—A.6, p. 439.

Locality :—Galle, lagoon, two specimens (small, immature).

Plagusia depressa (FABR.), var. **immaculata,** LAMK., 1818.

Localities :—Cheval Paar. four specimens (*a*, *b*, *c*, *d*); Navakaddu Paar, one specimen (*e*).

Description :—	C.l.	C.b. ÷ C.l.	Post.bord.C. ÷ C.l.	Fronto-orb.b. ÷ C.l.
(*a*) ovigerous ♀ . .	29·00	1·09	0·59	0·66
(*b*) ovigerous ♀ . .	24·25	1·08	0·58	0·70

All come definitely under *P. immaculata* of MIERS' revision ('Ann. Mag. Nat. Hist.,' (5), i., p. 150, 1878). The tubercles are naked in all.

Remarks.—There is some confusion of terminology in regard to this and allied forms. ALCOCK writes "*Plagusia depressa*, var. *squamosa* (HERBST)," which is interpreted by BORRADAILE as "*Plagusia depressa* (HERBST), 1783 [misprinted as 1793], var. *squamosa*, HERBST, 1790." This can hardly be ALCOCK's meaning, for then (1) *squamosa* would = *depressa* and (2) FABRICIUS had already used *depressa* in a different sense. I take ALCOCK to mean "*Plagusia depressa* (FABR.), 1775, var. *squamosa*, HERBST, 1790," which implies two things: (1) a development of MIERS' views in bringing together under one species the three (*P. depressa* (FABR.), 1775, *P. tuberculata*, LAMARCK, 1818, and *P. immaculata*, LAMARCK, 1818) recognised by the latter in his excellent revision of the Plagusiidæ; (2) a union of the *P. tuberculata* and *P. immaculata* as a single variety within the species so formed. I agree with the first suggestion, but cannot accept the second.

Plagusia depressa (FABRICIUS), 1775, may be divided as follows :—

1. Carapace covered by numerous—often more or less squamiform—tubercles, each bordered by a fringe of short stiff hairs :
   - *a.* Posterior coxal process of 2nd and 3rd walking legs entire . . . . var. *tuberculata.*
   - *b.* Posterior coxal process of 2nd and 3rd walking legs dentate . . . . var. *depressa.*
2. Carapace tubercles more depressed—those on gastric region obsolescent :
   - *a.* Posterior coxal process of 2nd and 3rd walking legs entire . . . . var. *immaculata.*

The few specimens hitherto described show that the above distinctions are average, not absolute, *e.g.*, MIERS' "Challenger" specimen of *depressa* is hardly dentate, and DE MAN describes an example of *immaculata* which has a few hairs on some tubercles. The amount of material is not sufficient to enable one to estimate the exact degree of overlapping.

Additional differentia requiring investigation are :—

1. MIERS points out that carapace is more convex in *immaculata* than in *depressa* or *tuberculata.* This holds in general, but is broken in two instances known to me among the collections of the British Museum, in which *tuberculata* shows approximately same degree of convexity as *immaculata.*

2. Degree of fusion of abdominal terga 3, 4, 5 and 6. I have before me only 4 males (1 *immaculata* + 2 *depressa* + 1 *tuberculata*), which suggest that the tendency for such fusion may be found to be greater in *depressa* and *immaculata* than in *tuberculata.*

3. Shape of abdomen.

4. Size of carapace—*immaculata* being smaller than the others.

Of the above, the first at least is of value—possibly all are so. I retain for the varieties the names used by MIERS, entirely avoiding *squamosa.* If used, the latter should apply to the *tuberculata* series only, but it has the grave disadvantage of having been used by HERBST to denote in the text a form with entire coxal process, and in his figure one with coxal process dentate.

Palicus jukesi (WHITE, 1847)—A.6, p. 451—Plate I., fig. 12.

Locality :—Coral reefs, Gulf of Manaar, one specimen.

Description :—An adult male. C.l. = 14·25 (frontal lobes included). C.b. ÷ C.l. = 1·11.

Remarks.—This specimen confirms CALMAN'S inclusion of *Cymopolia carinipes,* PAULSON, 1875, in the synonymy of the species—for, while answering to ALCOCK'S description, it has, instead of the sub-hepatic tubercle described by CALMAN for his

Torres Straits specimen, a transverse row of four granules (*cf.* PAULSON's ridge), from outer end of which a row of granules runs backward for a short distance parallel to the lateral margin of the carapace. With my figure should be compared that of Dr. CALMAN (C., pl. i., fig. 10).

I follow ALCOCK in emphasising the probably catometope affinities of the genus *Palicus.* On this matter see CALMAN, p. 29.

Palicus serripes (ALCOCK and AND., 1894)—A.6, p. 454 ; A.Invest., pl. lxvii., fig. 1.

Localities :—Trincomalee, one specimen (*a*) ; Gulf of Manaar, deep water, one specimen (*b*).

Description :—(*a*) ovigerous ♀ . . C.l. = 10·50 ; C.b. : C.l. = 1·10
(*b*) ovigerous ♀ . . C.l. = 9·00 ; C.b. ÷ C.l. = 1·11

NOTE.—In the above pages 196 species are named. There remain 12 undetermined forms in the collection, making 208 in all. Of these 12, one is an Oxystome, one an Oxyrhynch, seven are Xanthids, one is a Portunid, and the remaining two are Catametopes.

DISCUSSION OF FAUNISTIC RESULTS.

BY

W. A. HERDMAN, F.R.S.

[WITH TWO PLATES AND TEXT-FIGURES.]

THE preceding forty Supplementary Reports, along with the four upon Parasites, have made known 2615 species of marine animals from the coasts of Ceylon. Of these, 575 species are described as new to science, and have required the formation of 65 new genera and three new families. The distribution of these species in the chief groups of animals is shown in the following table :—

Group.	Number of species.	New species.	New genera.	Group.	Number of species.	New species.	New genera.

Amphipoda . . .	85	37	6				
Carried forward	1436	449	58	Totals . . .	2615	575	65

The majority of the previously known species are new records for the Ceylon fauna and a large number of them are new to the fauna of the Indian Ocean, and, consequently, the Reports have added considerably to the recorded distribution of many of the older species. It is almost impossible to get exact numbers in such a case, but it is probably fairly correct to say that 1500 species have been added to the

Ceylon list and about 900 to that of the Indian Ocean. Such information, although, perhaps, as uninteresting as the description of new species, is of real importance in science, as it is impossible to draw conclusions as to geographical distribution, and the origin and past history of faunas, until we have a detailed knowledge of the animals now present in many different localities.

In comparing with other seas, we find that about 250 of our species* extend into the Malay region and 300 on into the Pacific. At least 240 are known from the Red Sea and 130 from the Mediterranean. About 280 species extend southwards to the Australian coasts, and a few are found elsewhere in southern latitudes. Finally, 90 Ceylon species are found also in the West Indian region, and may indicate a closer connection by sea in a former period than exists at the present day. This interesting relation between these two far-distant regions—the East and the West Indies—has been pointed out by several writers, and in 1899, ALCOCK† published an interesting chart (after E. KOKEN) showing a direct connection by means of a great inland basin stretching east and west from the Gulf of Mexico to the Arabian Sea. This indicated the supposed relations of land and water in Tertiary times, and was put forward by Dr. ALCOCK to elucidate the theory he advanced as to the origin of a considerable part of the Fish fauna of India from a Tertiary extended Mediterranean stretching across the present mid-Atlantic to the West Indies.

Fig. 1. Map to show the equatorial seas and the relative positions of: I. Gulf of Manaar, II. Mergui Archipelago, and III. the Maldives.

Restricting our attention now to the northern part of the Indian Ocean, there are three recent series of faunistic explorations with which we may compare our results, viz., (1) the Reports on the Mergui Archipelago, off the coast of Lower Burma (see

* Possibly a good many more. These numbers are all minimum estimates.

† Descriptive Catalogue of Indian Deep Sea Fishes in the Indian Museum, Calcutta.

'Journ. Linnean Soc., Zool.,' vols. xxi. and xxii.), (2) the series of Reports and "Illustrations" issued from the Calcutta Museum as the result of work by Colonel ALCOCK and others in the "Investigator," and (3) Mr. STANLEY GARDINER'S series dealing with "The Fauna and Geography of the Maldive and Laccadive Archipelagoes." The map (fig. 1) will serve to recall relative positions and distances.

The Mergui marine fauna is, as might be expected, not unlike that of Ceylon, but differs in the details of the species that occur. It is, however, if we may judge from the published records, not so rich a fauna, as the following summary will show—using only those groups which are common to the two reports. The predominance of Actinozoa, in the case of Mergui, is due to the large number of species of Corals described by Professor MARTIN DUNCAN. The other groups of fixed organisms—Sponges, Hydroids, Alcyonaria and Polyzoa—show markedly in favour of Ceylon.

	Sponges.	Hydroida.	Alcyonaria.	Actinozoa.	Echinodermata.	Gephyrea.	Polychæta.	Polyzoa.	Stomatopoda.	Macrura.	Anomura.	Brachyura.	Marine shells.	Totals.
Mergui.	30	6	23	86	48	4	5	21	4	19	26	116	328	716
Ceylon.	146	43	120	78	109	10	112	116	12	53	48	208	530	1585

As an indication that the fauna of the Indian Ocean is gradually becoming known, in, at least, some groups, it may be noted that in Dr. DE MAN'S account of the Mergui Podophthalmata (1888) out of 166 species, 38 (about 23 per cent.) were new to science, while 18 years later, in the present report, out of the much larger number (321) of Ceylon Podophthalmata, only 22 (less than 7 per cent.) were previously unknown. In Brachyura, 39 species (nearly $\frac{1}{5}$) are common to the two lists.

Colonel ALCOCK'S magnificent series of monographs and the accompanying fasciculi of "Illustrations," have done much to elucidate the fauna of the northern part of the Indian Ocean, but they deal largely with deep-water forms, and I find it difficult to make any comparison between my restricted, but, perhaps, more intensive, study of a small shallow-water area (the Gulf of Manaar) and his extended gleanings all over the three seas of India. Perhaps the most important conclusion to be drawn is the extreme richness of the fauna, since so little is common to the two series of results. Some groups have not yet appeared in the "Investigator" series, but even in the case of those that have been monographed, the shallow waters of Ceylon have here and there added something to the list. These reports cannot be compared in number of novelties with the "Investigator" monographs, but they may be regarded as in some respects supplementing them.

The comparison with the Maldive fauna ought to be more satisfactory and interesting:—first, because STANLEY GARDINER'S reports are almost as recent as these, and are therefore presumably done on very much the same lines, so as to be fairly comparable with ours; and, secondly, because the Maldives are a group of Coral-formed oceanic islands in contrast to Ceylon, which is continental and geologically a part of India. The comparison between a shallow-water (under 100 fathoms), continental-coast fauna and that of a group of oceanic coral islands, only, on the average, some 400 miles apart, in the same latitudes and the same sea, but separated by deep water, ought to be instructive.

The following table shows the number of species in the chief groups which are recorded in both series of Reports :—

	Hydroida.	Medusæ.	Alcyonaria.	Actinozoa.	Echinodermata.	Platyelmia.	Gephyrea.	Cirripedia.	Copepoda.	Amphipoda.	Isopoda.	Stomatopoda.	Macrura.	Anomura.	Brachyura.	Mollusca.	Cephalochorda.	Pisces.	Totals.
Maldives . . .	23	44	39	112	49	28	25	16	120	19	14	6	79	34	189	431	4	65	1297
Ceylon . . .	43	29	120	78	109	74	10	11	289	85	34	12	53	48	208	530	7	117	1857

There are evidently marked differences here, and some of them at least seem susceptible of explanation. A group of oceanic coral islands must clearly have been populated from some of the surrounding older continental coasts,* and the nearest of these to the Maldives are Ceylon and the southern end of India, some three to five hundred miles distant.† There are two dominant factors that will play an important part in determining which animals from the neighbouring continent will form part of the new population, viz :—(1) The means of transport possessed by the animals either in the adult or the larval condition, and (2) whether or not the conditions existing on the island are sufficiently favourable to the migrating animal on its arrival either as an adult or a larva.

Looking at the table we find that the total number of animals is much greater in the recorded Ceylon fauna than in that of the Maldives, but that in certain groups —the Medusæ, Actinozoa, Gephyrea, Cirripedia, and Macrura—the Maldivian numbers are the greater; while in other groups—such as Hydroida, Alcyonaria, Echinodermata, Platyelmia, Copepoda, Amphipoda. Isopoda, and Mollusca—the Ceylon list markedly predominates.

Oceanic or pelagic groups, as would be expected, and coastal animals of active

* We may assume that even if Mr. Gardiner's view is correct, that the Maldives are based upon an old continental platform cut down by currents to a depth of some 2000 fathoms, none of the original continental animals have lived on to appear amongst the inhabitants of the coral reefs.

† Of course, some species may have come from the much more distant African coast.

habit, possessing the necessary means of transport in the adult condition, are well represented in the Maldive fauna. For example, Fishes, Medusæ, and Chætognatha are all fairly abundant. The Cirripedia also, some of which are almost cosmopolitan in their distribution on the high seas, are more numerous than in Ceylon. The Copepoda might be expected to bulk larger than they do. The pelagic and more active forms are, however, present, and the deficiency is in the bottom-living species, many of which are associated with Sponges, Tunicates, and other fixed colonies which are probably much more abundant at Ceylon than in the Maldives. The high number in the case of Actinozoa is due to species of Madreporaria which are, of course, abundant in a Coral archipelago, and the species of which were especially studied by Mr. STANLEY GARDINER. In the case of Macrura the 79 species includes 76 Alpheidæ, and the species of *Alpheus* being closely associated in habitat with Corals would naturally be obtained in abundance amongst the reefs.

Turning now to the groups of animals which are more abundant at Ceylon, we find that it is the fixed and the more or less sedentary, bottom-living forms that are poorly represented in the Maldivian fauna—*e.g.*, Hydroida, Alcyonaria, Echinoderma, and Mollusca. I should expect this result to apply also to Sponges, Polyzoa, and Tunicata, and I have little doubt that it does, but these groups in the case of the Maldivian fauna have not yet been reported on. Most of these groups are dependent for dispersal upon minute, feeble, and short-lived embryos or larvæ to which 400 miles of open sea may be a formidable obstacle. In marked contrast to some of these groups there is the case of the Brachyura, where the numbers in the two faunas (Maldives 189 and Ceylon 208) are not very different. The probable explanation is that the larvæ of the crabs are powerful, locomotory, comparatively long-lived animals which are frequently taken in the tow-net in the open sea, and are therefore much better fitted to survive the journey from the continental coast. The most feebly represented of Crustacean groups are the Amphipoda and Isopoda, and I would suggest that the explanation is to be found in the unsuitability of their young stages for distribution to oceanic islands. Those that do cross in safety are probably carried accidentally on larger objects. It may conceivably be easier for a shallow-water species, which neither in the adult nor in larval life is adapted to a prolonged pelagic existence, to spread in the course of ages from India to Australia along the stepping-stones of Malaysia than to cross the stretch of open sea from Ceylon to the Maldives.

There is, however, not only the numerical but also the specific constitution of the two faunas to be considered, and, undoubtedly, many species are common to the Maldives and Ceylon. Probably all the Corals collected in the Gulf of Manaar have been recorded in Mr. STANLEY GARDINER'S reports, and nearly all their associated Alpheidæ. The Foraminifera seem to be very much the same in the two localities, at corresponding depths. Out of 131 species found at Ceylon, 68 occur in CHAPMAN'S list from the Laccadives, and the latter collection was mainly, if not wholly, a deep-water one. An analysis of the recorded Echinoderms gives us the following result :—

Crinoidea . .	10 Maldivian species,	16 Ceylon species,	5 in common	
Asteroidea . .	13 ,, ,,	25 ,, ,,	8 ,,	
Ophiuroidea .	12 ,, ,,	13 ,, ,,	5 ,,	
Echinoidea . .	15 ,, ,,	28 ,, ,,	12 ,,	

In the Amphipoda 11 species out of the 19 found in the Maldives occur also in Ceylon. Even in the Isopoda a few species, such as *Cirolana sulcaticauda*, *Lanocira gardineri*, and *Cymodoce inornata*, are common to both faunas. Mr. LAURIE considers that the Ceylon crabs show a marked resemblance to those of the Maldives, over 70 of the species being identical.

In some groups little relationship is shown. In the Nudibranchiata only one Ceylon species extends to the Maldives; amongst the Hydroids there are two, but in addition we find several pairs of representative or closely allied species which might by some be regarded as identical forms. The Maldive Cephalopoda, according to Dr. HOYLE, exhibit a "remarkable likeness" to those of Ceylon, and several species are identical. Mr. BROWNE, on the other hand, calls attention to the dissimilarity of the Medusæ, but we must remember that two successive collections of Medusæ (GARDINER'S and AGASSIZ'S) made in the Maldives were also very dissimilar.

Confining our attention now to the Ceylon marine fauna, we may conveniently divide our records into three sets of localities :—

1. Trincomalee and the north-east coast (Stations XX. to XXXI.*).
2. Galle and the south end of the island up to Colombo (Stations XXXII. to XLVI.).
3. The Gulf of Manaar and around Adam's Bridge, from Colombo to Palk Bay (Stations I. to XIX. and XLVII. to LXIX.).

Of these three regions of the coast, the first two have deeper water and a more varied fauna than is found in the pearl-bank region of the Gulf of Manaar. But, on the other hand, we have more stations in the third district, where much more time was spent and where the fauna, on the pearl banks, was consequently studied much more closely than elsewhere. The following table gives the number of species in each group of animals found in each of the three districts :—

* See "Narrative," in Part I. (1903), for details as to the Stations.

Group.	Trincomalee.	Galle.	Gulf of Manaar.	Group.	Trincomalee.	Galle.	Gulf of Manaar.

Carried forward	133	408	1147	Totals	376	717	2043

The great majority of the shallow-water forms have spread all round the island. To take the pearl oyster as an index, while its home may be said to be the Gulf of Manaar, it occurs in fair quantity in shallow water at Trincomalee, and sparingly at Galle. In regard to the rarer and finer things, such as Solitary Corals, branched Alcyonaria, Antipatharia, and some Echinoderms, Crustacea and Mollusca, I am inclined to think the distribution is a question of depth rather than locality. They have been found at Trincomalee and off Galle where rather deeper water was obtained, but probably occur also in the depths outside the pearl bank plateau in the Gulf of Manaar.

Let us now pass the various groups in review so as to ascertain the general impression given by the fauna in each case; and I desire here to acknowledge that, while I am alone responsible for any opinions that are not quoted from others, I am indebted directly or indirectly to my friends the authors of the special Reports for most of the facts upon which these opinions are founded.

The Foraminifera figure largely in the deposits round the Ceylon coast. Two extreme examples may be given. At the 100-fathom line, south of Galle, the bottom seems to be practically composed of masses of the new species *Ramulina herdmani*, Dakin; and at several points in the Gulf of Manaar up to 40 per cent. of the deposit is formed of *Heterostegina depressa*. Other species, such as *Amphistegina lessoni*, *Orbitolites marginalis*, and *Alveolina melo*, are also so abundant that to the eye the deposit, when it comes up in the dredge, appears to be formed mainly of Foraminifera. *Polytrema miniaceum* is also of very frequent occurrence, and grows to a large size.

But beyond this abundance of certain species there is no special feature to be noted. The collection is an ordinary assemblage of shallow-water tropical forms, including a few rare species and three new to science—the most remarkable of which is the *Ramulina* found in such abundance in deep water off Galle. Most of the species are new records to Ceylon, and 50 are new to the Indian Ocean. Many of them have a wide distribution in other seas, and at least 57 species are common to Ceylon and the West Indies.

Fig. 2. *Ramulina herdmani*, DAKIN. Nat. size.

The collection of SPONGES is a very large one, containing about 150 species, nearly 80 of which are new to science. Moreover, the individuals of some of these species are numerous, so that sponges bulk large in the fauna, especially in the Gulf of Manaar. The Calcarea are few and small and the Hexactinellida not represented, but the Tetractinellida, the Monaxonellida, and the Euceratosa present a rich and varied assemblage of forms. Some of the species are cosmopolitan, many are common Indo-Pacific forms; only a few extend to the Red Sea, a few more to the Mediterranean, and as many to the North Atlantic (Azores and even the British seas), half-a-dozen are represented in the West Indies, and a dozen extend eastwards through the Malay Archipelago. But much the closest affinity is shown with the fauna of Australia, as no less than 30 of the species in our collection are found also on the Australian coast. Adding to this the other known Ceylonese species, Professor DENDY finds that 47 in all out of the 75 species of sponges whose range is known to extend beyond Ceylon seas are found in the Indo-Australian region. About two-thirds of the total number of species are, however, peculiar to the Ceylon area which Professor DENDY speaks of as "an extremely rich centre of sponge distribution." Some of the most notable species from the Gulf of Manaar are shown on Plate II., figs. 1 to 4.

The Ceylon MEDUSÆ comprise 29 species, 12 of which were new to science. They are represented sparingly in all the other seas of the world, including the West Indies, and rather more fully in the Malay archipelago. But there is no indication of marked affinity with any other fauna. In fact, the differences are more evident than the resemblances. Even in the case of two such neighbouring localities as the Maldives and Ceylon, Mr. E. T. Browne, after considering the figures, writes: "the Medusoid fauna of Ceylon is quite distinct from that of the Maldives." But the fact that the genera and species of Gardiner's and Agassiz's successive expeditions to the Maldives "were quite distinct," and that there is a well-marked difference between the two collections "which is quite as great as if they had come from localities a thousand miles apart" (Browne) shows that we must not attach too much importance to such differences. Seasons and methods of collecting must be taken into account, and we have probably still much to learn in regard to each of these faunas.

The Hydroida are fairly abundant at Ceylon, and some of them are of large size (see Plate II., figs. 5 and 6). Outside the Indian Ocean the affinities of the Ceylon forms are distinctly with those of Australian seas—out of 43 species, 11 extend to Australia, and only nine of the other species are found beyond the Ceylon seas; four of these occur in the West Indies, and only one in the Mediterranean.

The Alcyonaria form a rich collection, dealt with in three reports (Nos. XIX., XX., and XXVIII.). Miss Pratt points out the similarity with the Maldive fauna, nine species of the fleshy forms, out of 17, being common to the two districts; but Professor Arthur Thomson, dealing with the Gorgonoid, Pennatulid, and other non-fleshy forms, lays stress upon the great difference between the present collection and those from Zanzibar (Crossland), Maldives (Gardiner), New Britain (Willey), and the deeper waters of the Indian Ocean (Alcock). I believe this merely indicates that the Alcyonarian fauna of these regions is so rich that we are still far from having completed the survey. Each new expedition brings in an abundant harvest, and in our present state of knowledge it is probably more profitable to base any tentative conclusions upon resemblances in the fauna rather than upon differences which may merely be due to negative evidence.

Many of the species are familiar Indo-Pacific forms, a few are represented in the Malay region; but perhaps the closest affinity is with the Red Sea fauna, on the one hand, and with that of Australian seas on the other. As in the case of so many other groups, at least one species is represented in the West Indies.

Corals are, of course, exceedingly abundant round the coast of Ceylon. The reef-building forms were not specially collected and have not been reported on, but over 30 common species have been brought home. There are in the collection about 21 species of Solitary Corals, five of which are described as new, along with two new genera—*Rhodocyathus* and *Cyathotrochus*.

The Actiniaria, although not reported on, have been examined by Mr. Southwell, who finds about 14 species, of which several are probably undescribed forms. A beautiful green, colonial form, *Zoanthus shackletoni*, is very abundant on the reef at Galle and in some parts of the Gulf of Manaar. A species of *Palythoa* (*P. tuber-*

culosa) is also common at Galle. But, perhaps, the most noteworthy form is the remarkable, free, sand-encrusted anemone *Sphenopus marsupialis*, which is apparently abundant at several localities in the Gulf of Manaar.

ANTIPATHARIA are amongst the most striking forms brought up from the deeper water outside the pearl banks or at Trincomalee and Galle. Most of the smaller colonies obtained were new species; but the finest belonged to the well-known *Antipathes abies*. Several of our Ceylon species occur in the Maldives.

The ECHINODERMATA are an ordinary Indo-Pacific series presenting a few rarities, a few novelties, and some extensions of distribution, but no other notable features. It may be of interest to show the numbers of the orders separately in the case of several allied Indian Ocean faunas :—

	Mergui.	Maldives.	THURSTON (Manaar).	Ceylon collection.	ALCOCK (deep-sea).
Crinoidea	6	10	4	13	(?) few
Asteroidea.	9	13	18	25	60
Ophiuroidea	13	12	12	14	56
Echinoidea	6	15	21	28	(?) 60
Holothuroidea	14	—	10	30	(?) 20

Probably, on the whole, the Echinodermata of Ceylon present most affinity with those of the Malay region and of the Pacific, but they also show resemblances to the Australian fauna.

In turning to the VERMES, it is found impracticable to institute any comparisons with other faunas in the case of the lower parasitic groups, since, in the first place, from the nature of our enquiry on the Ceylon expedition it was clearly of importance to collect and identify such forms as Cestode, Trematode, and Nematode parasites which are very usually neglected by the general zoologist; and, in the second place, these worms seem in many cases to be confined to particular hosts, and their distribution will therefore be determined by that of the Fishes and Molluscs they infest. Consequently the fact that 54 Cestoda are recorded from Ceylon seas and none from the Mergui or from the Maldives, must not be taken to indicate that parasitic worms are more abundant in the one locality than in the others. That these Platyelmian groups yielded a very large proportion of new species, no less than 17 new genera and one new family, is due first to our comparative ignorance of the fish Cestodes and Trematodes from tropical waters, and, secondly, to the special attention paid to them during our expedition on account of their possible bearing upon the problem of pearl production.

The 10 species of GEPHYREA, one new and the type of a new genus, are nearly all additional records for Ceylon, and half of them are new to the Indian Ocean. Their affinities seem mainly with those of the Malaysian seas to the East.

The POLYCHÆTA comprise over 112 species, of which at least 36 are new to science. In regard to these higher worms, Dr. WILLEY writes that the Polychæte fauna of Ceylon bears a circumtropical stamp in contrast, for example, with the northern and the southern faunas: a good many of the species are identical with Philippine forms. The occurrence of a species of *Grymæa* (a characteristic Scandinavian genus) is rather singular. Perhaps the most remarkable form of all is the new *Thalenessa stylolepis* obtained from coral masses in the Gulf of Manaar.

The POLYZOA form a large collection with a comparatively small proportion of novelties, 16 species out of 116. Some are cosmopolitan, and a considerable number extend into other seas, no less than 19 being British species. The chief indication of affinity is, however, with the Australian fauna, as 32 species are in common. Seven species are West Indian forms, and at least 85 are new records to the Indian Ocean, and probably about 100 are new to Ceylon.

Minute CRUSTACEA, such as Copepods and Ostracods, swarm both on the surface and in the deposits at the bottom.

The COPEPODA fauna is enormous, and the collection contained many novelties. Nearly 300 species (289 have been identified) were collected; 80 of these are new to science, and 12 new genera have been required. Nearly all the species found were additions to the known fauna of Ceylon and of the Indian Ocean. The majority (over two-thirds) of the species are from the Gulf of Manaar, about one-fourth are from Galle, and a few only from Trincomalee.

It is difficult to institute any comparisons with other faunas, as in most seas the more minute Copepods are still very imperfectly known. There was no report on Copepoda in the case of the Mergui Archipelago, and in respect of some expeditions it is known that while free-swimming Copepoda were collected in tow-nets from the surface and intermediate waters, no steps were taken to explore the very abundant fauna living in the bottom-deposits or in and upon the dredged larger animals, or to secure the parasitic forms attached to fish. In the case of the Gulf of Manaar these two last faunas yielded a rich harvest of unknown forms.

The results brought out by our records that the Ceylon Copepod fauna shows most affinity with that of the Red Sea and of the Mediterranean is largely due to the fact that we have a better knowledge of these regions than, for example, we have in the case of the Malaysian or Australian seas. Dr. NORRIS WOLFENDEN* has recently remarked upon the very striking difference in the Copepod fauna between Ceylon and the Maldives. This difference, however, seems to be chiefly confined to the littoral Harpacticidæ, which are only represented by five or six species from the Maldives, while in the Ceylon collections they are very abundant.

In the case of the Ceylon OSTRACODA, out of 77 species 35 were new to science, and nearly all were obtained from the Gulf of Manaar. The majority of the species are new to the Ceylon fauna and that of the Indian Ocean. There is no clear indication

* "Fauna and Geogr., Maldive," &c., vol. II., suppl., 1, p. 989.

of affinity with other regions. The CIRRIPEDIA are a somewhat cosmopolitan group, but our Ceylon assemblage shows some affinity with the Red Sea and the Australian faunas.

The AMPHIPODA and ISOPODA were both large collections containing a number of new forms. The individual animals in both were of small size compared with those from temperate and polar seas. In the Amphipoda 85 species gave 37 new to science, requiring the formation of six new genera. A few of the species extend to the Red Sea, the West Indies, the Malay Archipelago, and the Pacific, seven are found in the Australian fauna, and ten in the Mediterranean. In the case of the Isopoda, out of 34 species 14 proved to be new, requiring three new genera and two new families. Here, also, there is indication of Australian affinities, and two species extend to the West Indies.

The CUMACEA, being a comparatively unknown group, are all new records for the Indian Ocean, and out of the 16 species nine are new and one has required a new genus. We do not know enough of the distribution in this case, or in that of the STOMATOPODA and SCHIZOPODA, to make comparisons with other seas.

In the MACRURA, out of 53 species, three of which are new, a large proportion, 24, extend into the Pacific, 10 are common to the Malaysian fauna, and 10 also reach the Australian seas, nine are found in the Atlantic, four in the Red Sea, three in the Mediterranean, and one in the West Indies.

The ANOMURA, as a group, have, to the collector, the appearance of being very abundant, but that is due chiefly to great numbers of a few common species. At Galle, and at Trincomalee, ten times the present collection might easily have been made without adding to the number of species. Out of 48 species collected only two are new, and they present no features of special interest. ALCOCK has pointed out that the littoral Paguridæ of the Maldives and India are Indo-Pacific forms, while the sub-littoral forms of Indian seas are most closely related to those of the West Indies.

The BRACHYURA form a very large and interesting assemblage, in which only a comparatively small proportion, 15 out of 208 species, have proved to be unknown, but three of these are so remarkable as to require new genera. About 60 per cent. of the species are new to the Ceylon fauna, and 35 per cent. extend to the Maldives.

The PANTOPODA and HEMIPTERA both contain new forms that seem to be common at Ceylon, but call for no further remark.

The MOLLUSCA are an ordinary Indo-Pacific assemblage, most of which have been made known in the past from shell collections. The chief novelties are naturally in those divisions of the group which have not been studied by conchologists. The Nudibranchs present us with at least nine new species in 30 collected, and, in addition, there are some small Eolids and Dotos undetermined that show, at least, that these families are not so rare as was supposed in tropical seas. The Opisthobranchs, as a whole, show some affinity with Red Sea and Mediterranean forms, but still more with the Pacific and Australian faunas. Two new species of Pelecypoda, living with the *Aspidosiphon* in the basal cavities of Solitary Corals, are described by BOURNE under the new genus *Jousseaumia* (Report XXXVII.). The profusion of young Octopods, of undetermined species, on the pearl banks in the Gulf of Manaar was a notable feature during our exploration. Some of the same forms occur at the Maldives.

The TUNICATA are not numerous (66 species), although some of the commoner forms are so abundant that the group bulks large in the general fauna; 44 species are new to science, and nearly all the species (about 60) are new records for the Ceylon fauna. Calcareous and sandy genera, such as *Leptoclinum*, *Rhabdocynthia*, and *Psammaplidium*, are especially abundant and large. *Ecteinascidia*, *Rhodosoma*, *Hypurgon*, and the Polystyelidæ are other noteworthy forms. As is usual in tropical seas, the Cynthiidæ and Styelidæ are especially abundant, and the Ascidiidæ and Botryllidæ are few and of small size. Very few Molgulidæ were found, but several other kinds of Simple Ascidians belonging to other families have sandy coverings so as to look superficially like species of *Molgula*. *Pyrosoma*, though no doubt sometimes present, was not seen; and the Thaliacea were not especially abundant. The commonest genera are *Polycarpa* amongst the Simple Ascidians and *Leptoclinum* in the Compound forms. Although most of the species are peculiar to Ceylon or the Indian Ocean, there are allied forms elsewhere, and it may be said that the fauna shows affinity with that of the Malay Archipelago and that of the Australian seas.

Seven species of CEPHALOCHORDA were obtained, four of which are new to the Ceylon fauna. The collection of FISHES has added considerably to the Ceylon list, but does not call for any special remarks. Adding THURSTON's list to our own, the total number of fishes recorded from the Gulf of Manaar is over 226, but I do not doubt that even that could be largely added to by further work. The Maldive list is 57 named species, but of these only 17 extend to Ceylon. Thus the percentage of Ceylon fishes recorded from the Maldives is small. The Pleuronectidæ are well represented in both faunas, but there are no species common to the two lists.

On the whole it seems probable from this survey of the groups that the Ceylon marine fauna is more closely related to that of the Malay region and Australia than to that of the Maldives or the Red Sea.

THE FAUNISTIC CHARACTERS OF THE PEARL BANKS.

The physical and the leading biological characters of the individual paars were given in the section entitled "Description of the Pearl Oyster Banks of the Gulf of Manaar," in Part I. at p. 99, and it is only necessary now to point out the general faunistic features of the region as a whole. It will be remembered that it is a shallow plateau, lying for the most part between the contours of 5 and 10 fathoms, and having on the whole a sandy bottom. Where the ground is hard it is a modern calcrete formed by the cementing together of sand and shells, and where the sand is not derived from the disintegration of the granitoid rocks of Ceylon it is mainly Foraminifera and shell fragments. The large amount of a few species of Foraminifera in some deposits is a notable feature, which has been already discussed above. In some parts, as on the South Cheval, balls of *Lithothamnion fruticulosum*, large and small, are very abundant and are useful as cultch for the pearl oyster.

Sponges are a very dominant group, and probably exercise considerable influence upon the welfare of the oyster beds. The most important in this connection is *Cliona margaritiferæ*, the ravages of which have been described and figured in previous sections of this report. Other characteristic forms are the large black *Spongionella nigra* and the four species of Sponge shown on Plate II. Fig. 1 is the huge crater-like *Petrosia testudinaria* which occurs on the Cheval and especially on the Periya Paar. Fig. 2 shows the two characteristic forms, the cup-like and the flabellate, of *Phakellia donnani*, a brick-red Sponge found in great abundance on many parts of the pearl banks, but especially on the Modragams, the Cheval, and the Periya Paar. Fig. 3 is the scarlet spherical mass *Aulospongus tubulatus*, a Sponge in which the minute Polychæte worm *Polydora armata* lives as a commensal. Fig. 4 is the remarkable "umbrella" Sponge, *Phyllospongia holdsworthi*, which is said by the divers to be characteristic of the "Koddai Paar" to the west of the Cheval. It is, however, found also on various parts of the Cheval, Muttuvaratu, and Periya paars, and elsewhere.

Amongst Cœlenterates, corals are the most conspicuous and important forms. Living reefs composed of many common species compete successfully with the pearl oysters at many places and prevent the formation of beds, while solitary forms such as *Fungia* are found alive scattered over the sandy bottom on the Cheval and other paars. In some places there are great aggregations of *Heterocyathus aequicostatus* and *Heteropsammia michelini*, both of which have in their base commensal species of *Aspidosiphon* and of *Jousseaumia*. Many of the reef-building corals, such as species of *Madrepora*, *Porites*, *Pœcilopora*, *Montipora*, *Favia*, *Goniastrea*, *Galaxea*, and *Cœloria*, are also found growing over the shells of living oysters. This is especially the case on the Muttuvaratu Paar. *Turbinaria cinerascens* and *T. crater* are especially common on some parts of the northern paars.

Some of the fleshy Alcyoniidæ are very common on the coral reefs at the pearl banks, and form enormous colonies several feet in diameter. The Gorgonoid Alcyonaria are for the most part found in deeper water outside the pearl-bank plateau, but a few species such as *Juncella juncea* and *Suberogorgia suberosa* occur on the Cheval Paar.

One of the Hydroid Zoophytes, *Campanularia juncea*, Allm., which grows to a large size (Plate II., fig. 6), is especially characteristic of the East Cheval Paar. Another handsome species from the pearl banks is *Halicornaria insignis*, Allm. (Plate II., fig. 5).

Some of the Echinodermata are amongst the commonest and most conspicuous of animals both on the oyster beds and on the sandy stretches between. The huge black trepang, *Holothuria atra*, and the flat urchins, *Clypeaster humilis* and *Laganum depressum*, eat their way through the sand, and the star-fishes, *Pentaceros lincki* (Plate I., fig. 1), *Luidea maculata*, and *Astropecten hemprichi* prowl over the surface and devastate the pearl oysters.

Amongst the worms, in addition to the numerous parasites that infest the oyster, there are two abundant species of *Polydora* that call for special mention—*P. hornelli*, found burrowing in the oyster shells, and *P. armata*, a commensal in the globular scarlet sponge, *Aulospongus tubulatus* (Plate II., fig. 3). Polyzoa are especially abundant, and are a factor of importance in the building up of the calcareous masses on the reefs and the paars—*Schizoporella viridis* may extend for several feet, and *Lepralia cucullata* is abundant, encrusting oyster shells, ascidians, sponges, and almost all other objects with its dark purple spots and patches.

Crustacea of various kinds abound, but so many species are represented that there seem to be no specially notable ones. The Alpheidæ are common, Pagurids are very abundant, and crabs, mostly of small size and many of them inconspicuous from their protective shapes and colouration, are found in every haul of the dredge.

In addition to common Gastropod and Lamellibranch shell-fish, there are several Opisthobranchs—notably *Philine aperta* and *Aplysia cornigera*—that congregate in great numbers in some parts of the Gulf of Manaar. *Pinna* is abundant in places and of large size. Species of *Pinaxia*, *Sistrum*, *Nassa*, and *Purpura* are found boring into the smaller pearl oysters, and the large "Chanks" (see Plate I., fig. 3, A, B, C, D) are of importance both as damaging the large oysters and also as constituting a fishery themselves. *Modiolus barbatus* (Plate I., fig. 2), from its habit of weaving entanglements, is another molluscan enemy of the younger pearl oysters.

The large simple Ascidian *Rhabdocynthia pallida* is abundant on some parts of the Cheval Paar. Several species of Amphioxus burrow in sand, the commonest on the Cheval and Periya paars being *Branchiostoma lanceolatum*, var. *belcheri* and *Asymmetron cingalense*. Over 200 species of fishes frequent the pearl banks, and many of these are carnivorous, including especially the file and the trigger fishes and the gigantic rays. In addition to the species that have been mentioned as especially common, characteristic, or important, there are enormous numbers of the smaller organisms belonging to many invertebrate groups that are found encrusting and attached to the shells of the older pearl oysters. Fig. 7 on Plate II. shows a photograph of such a "microcosm" from the Cheval Paar.

Such are the animate surroundings, including both friends and foes, amid which the pearl oyster habitually lives in the Gulf of Manaar, and seems, if left in comparative peace, able to hold its own in the struggle for existence; but the balance, as we have shown in previous parts of this report, is liable to be seriously disturbed by three all-powerful factors: devastating hordes of voracious fishes which come up from the deeper waters and leave crunched shells and torn byssus in their wake; storms, currents, and over-washes of sand which may sweep away or bury a promising bed; and lastly man who comes periodically from above on his diving stones and clears the bank of its tens of millions of oysters, old and young. The carnivorous fishes and the monsoons cannot be controlled; but to show that much can be done by man to mitigate their influence, and to compensate for the decimation necessarily caused by his own operations, has been the chief object of the present Report.

EXPLANATION OF THE PLATES.

PLATE I.

Some Enemies of the Pearl Oyster.

Fig. 1. *Pentaceros lincki*, de Bl. Reduced to one-third natural size.
,, 2. *Modiolus barbatus*, Linn. The "Suran," in its nests or entanglements.
,, 3. A, B, C, D, the following four large Chanks, from left to right:—
A. *Murex ramosus*, Linn. The elephant chank.
B. *Fasciolaria trapezium* (Linn.). Chank.
C. *Turbinella pyrum*, Linn. The common chank.
D. *Turbinella rapa* (Linn.). The sacred chank—possibly only a form of the last species.

PLATE II.

Some Characteristic Animals of the Pearl Banks.

Fig. 1. *Petrosia testudinaria* (Lamk.). Reduced one-half.
,, 2. *Phakellia donnani* (Bowerb.). Nat. size. A, flabellate; B, cup-shaped form.
,, 3. *Aulospongus tubulatus* (Bowerb.). Nat size.
,, 4. *Phyllospongia holdsworthi* (Bowerb.). Reduced one-half.
,, 5. *Halicornaria insignis*, Allman. Reduced to one-fourth.
,, 6. *Campanularia juncea*, Allman. Reduced to one-third.
,, 7. A living pearl oyster, *Margaritifera vulgaris*, Schum., covered with many encrusting and adhering organisms; slightly reduced.

CHARACTERISTIC ANIMALS OF THE PEARL BANKS.

CORRECTIONS AND ADDITIONS.

PART I.—(LIFE HISTORY, &c.), p. 142, ll. 30, 31, 33, *for* "acres" *read* "sq. yards."

,, II.—(HYDROIDA), p. 119, ll. 17, 30, *for* "*Desmoeyphus*" *read* "*Desmoseyphus.*"

,, II.—(CRINOIDEA), p. 157, l. 20, *for* "*Antedon anceps*, CARPENTER," *read* "*Antedon bengalensis*, HARTLAUB."

,, II.—(CUMACEA), p. 175, l. 22, *for* "exopod" *read* "endopod."

,, II.—(CEPHALOPODA), p. 186, *et seq.*, *for* "*Polypus aculeatus*" *read* "*Polypus horridus.*"

,, III.—(SPONGES), Professor DENDY adds the following records:—

(1) *Sycon raphanus*, var. *chevalensis*, n., characterised by spear-shaped ends to some of the dermal oxea. The species is recorded from Ceylon by HAECKEL.

(2) *Iotrochota baculifera*, RIDLEY.—Palk Bay.

(3) *Spongelia fragilis*, variety.—Reef, Galle; several large colonies.

(4) *Spirastrella tentorioides*, DENDY.—A second specimen, confirming the characters given on p. 126.

,, III.—(ALCYONARIA), p. 317, l. 4, *for* "Plate III." *read* "Plate IV."

,, III.—(ALCYONARIA), p. 325, l. 2, *for* "cylindrical" *read* "quadrangular."

,, III.—(ALCYONARIA), p. 325, l. 14, *for* "the axis is round not square" *read* "the axis is quadrangular not cylindrical."

,, IV.—(MACRURA), pp. 65, 67, 76, 92, *for* "*Caradina*" *read* "*Caridina.*"

,, IV.—(MACRURA), pp. 66, 67, 79, 92, *for* "*Nauticaris grandirostris*, n. sp." *read* "*Saron gibberosus* (M. EDW.)."

,, IV.—(POLYZOA), p. 108, l. 25, *for* "his private collections," &c., *read* "the collection in the Univ. of Cambridge Zool. Museum."

,, IV.—(POLYZOA), p. 110, l. 8, *for* "*Membranipora favus*, HINCKS," *read* "*Membranipora normaniana*, D'ORB."

,, IV.—(POLYZOA), p. 110, l. 14, *for* "*Membranipora hastilis*, KIRKPATRICK," *read* "*Membranipora coronata*, HINCKS."

,, IV.—(POLYZOA), p. 110, l. 16, *for* "*Amphiblestrum cervicorne*, BUSK," *read* "*Amphiblestrum radicifera*, var. *intermedia*, KIRKP."

PART IV.—(POLYZOA), p. 113, l. 3, *for* "*Bercnicea prominens*, LX. [= *Ch. brongniartii*]" *read* "*Chorizopora brongniartii* (AUD.)."

,, IV.—(POLYZOA), p. 114, l. 17, *for* "*ceeilia*" *read* "*cecilii*."

,, IV.—(POLYZOA), p. 116, l. 5, *for* "*avieularis*, n. sp.," *read* "*inelusa*, n. sp." [name changed to avoid possible confusion with *Cellepora avieularis*].

,, IV.—(POLYZOA), pp. 117, 118, *for* "*Rhyncopora*" *read* "*Rhynehozoön*."

,, IV.—(POLYZOA), p. 121, l. 6, *for* "*nitida*, n. sp." *read* "*adhaerens*, n. sp." [to avoid possible confusion with *Membraniporella nitida*, JOHNST.].

,, IV.—(POLYZOA), p. 122, l. 18, *for* "*fissa*, n. sp." *read* "*gallensis*, n. sp." [to avoid possible confusion with *Schizotheca fissa*, BK.].

,, IV.—Add to POLYZOA : *Alcyonidium mytili*, DALYELL.—Galle.

,, IV.—(SOLITARY CORALS), p. 192, Professor BOURNE adds :—

A fixed specimen of *Cyathotrochus herdmani* has been found (off Galle, 100 fathoms). This necessitates the following correction in the diagnosis of the genus :—*For* "Corallum simple, free, without a trace of adherence" *read* "Corallum simple, free or fixed by a narrow base, the basal scar completely filled up in the free forms so as to form a short laterally compressed cone."

PART IV.—(POLYCHÆTA), p. 248, l. 4, *for* "1887" *read* "1878."

,, IV.—(POLYCHÆTA), p. 281, l. 29, *for* "*acquabilis*" *read* "*aequabilis*."

,, IV.—(POLYCHÆTA), Plate VI., fig. 139.—An extra bundle of setæ has been inserted by the lithographer on the right side in front of the normal row of fascicles.

,, IV.—(POLYCHÆTA), add: A few additional forms have been examined by Mr. ARNOLD T. WATSON, who reports the following :—

(1) *Palmyra herdmani*, n. sp.—Found in the tube of the large Foraminifer, *Ramulina herdmani*, from Galle. The characters are: Head, darkish brown and iridescent, distinctly globular (instead of more or less rectangular, or an oval placed transversely to the body). Eye-spots four, light brown, oval; posterior pair contiguous and situate slightly behind apex of the head; anterior pair just beneath a very short, stumpy, cone-like, unpaired tentacle. (Immediately behind the head was a brown, oval capsule, or caruncle, which may possibly have been adventitious.) Head and caruncle almost completely hidden beneath the pale yellow paleæ. Back completely covered, the inner edges of opposite flabella overlapping in the middle. No elytra apparent. Dorsal paleæ serrated on edge, about 21 in the largest flabella, almost linear at the outer edge of flabellum, gradually becoming falciform towards the centre. Both dorsal paleæ and ventral serrated compound setæ somewhat similar to those of *Palmyra debilis*, GRUBE, but the appendix is slender and very much longer. Ventral cirri springing from a basal tubercle on neuropodial lobe and bearing a

reddish-brown band especially in the anterior segments. Cirri, both ventral and dorsal, tapering away to a slender filament. Specimen, a fragment 3·5 millims. long, 1 millim. broad over setæ, consisted of the anterior 17 pairs of parapodia only.

(2) *Ascidicolous Nereid from Galle.*—This worm, the identity of which has not yet been satisfactorily determined (though apparently allied to *Nereis vexillosa*, GRUBE), was found in the crevices of an Ascidian. The specimen is 22·5 millims. long, 3·5 millims. broad over the setæ, and consists of the head and anterior 64 segments only, the hinder part of the body being in course of regeneration. The head differs greatly from that of *N. vexillosa* and is very remarkable, being rather longer than broad and almost rectangular in form. It is dark brown and iridescent, as are also the succeeding 12 segments. Eyes large and black, the anterior pair before and the posterior pair just behind the bases of the longest cirri. Tentacles widely separated and half length of the head. Longest tentacular cirrus about twice as long as head, others much shorter. Palps large brown bases with pale tips. First four body segments twice as long as the succeeding ones. The proboscis being retracted, the paragnaths have not yet been examined. The setæ are somewhat similar to those of *Nereis melanocephala*, their general distribution being two slender spinigers in each dorsal lobe, and two or three spinigers, accompanied by five to seven stout setæ with pectinate falces, in each ventral lobe. The outline of the enlarged dorsal ligules of the posterior parapodia differs greatly from the figures of *N. vexillosa* given by GRUBE and EHLERS; the cirrus, moreover, is long and blade-like instead of filiform. This is probably a new species.

(3) *Brown, Parchment-like Branched Tube of one of the Eunieidæ.*—The main trunk 11 millims. calibre, 70 millims. long, with two short branches from one side. The terminal half of trunk sinuous, much like the tube of *Eunice tibiana*, EHLERS, with numerous openings in corresponding positions. The lower half of tube is partially enveloped by a compound Ascidian, *Leptoclinum* sp., the colony being perforated at intervals for openings into the tube. No worm accompanied the specimen.

PART V.—Add the following list of ACTINIARIA identified by Mr. T. SOUTHWELL:—

Cerianthus sp.—Tampalakam, Trincomalee.

Zoanthus shackletoni, HADD. and DUER.—Reef Galle and Gulf of Manaar.

Zoanthus (? n. sp.).—Reef Galle.

Isaurus duchassaigni (ANDRES).—Coral reef, Gulf of Manaar.

Gemmaria variabilis, DUERDEN.—Reef Galle.

Palythoa tuberculosa, KLUNZ.—Reef Galle.

Sphenopus marsupialis, STEENSTR.—Station LVIII., 9 to 26 fathoms, and elsewhere in Gulf of Manaar.

Halcampa sp.—Tampalakam, Trincomalee.

Sagartia sp.—Reef Galle.

Phellia sp.—Cheval Paar, Gulf of Manaar.

Calliactis sp.—Pearl banks, Gulf of Manaar.
Chondractinia digitata (MÜLLER).—Station XX., 11 to 13 fathoms, Trincomalee.
Actinauge sp. (? n. sp.).—West of Periya Paar.
Another form, not identified, from Gulf of Manaar, shallow water.

Several of the unidentified species in the above list are in all probability new to science. Out of these 14 species 11 are new records to Ceylon, those previously known being *Zoanthus shackletoni*, *Palythoa tuberculosa* and *Sphenopus marsupialis*.

The only specimens in the Ceylon Collection that now remain unidentified and unexamined, so far as I am aware, are about half a dozen ENTEROPNEUSTA, belonging apparently to three species.—W. A. H.

Our deck laboratory on the "Rangasami-Poravi."
