## INTRODUCTION

Carbon nanotube (CNT) is an attractive material for the development of biosensors because of its capability to provide strong electrocatalytic activity and minimize surface fouling of the sensors. This entry reviews the recent successful development of biosensors based on CNT materials. Specifically, biosensors from two fabrication regimes have been investigated: 1) the coimmobilization of CNTs and enzymes on electrode surfaces and 2) the growth of controlled-density aligned CNTs for the fabrication of nanoelectrode arrays. In the first regime, the CNTs are either dispersed in solvents [e.g., sulfuric acid, dimethylformamide (DMF)], dissolved in Nafion solution for electrode coating, or mixed with Teflon as an electrode material for reagentless biosensors. In the second regime, the nanoelectrode arrays consisting of millions of vertically aligned CNTs, each acting as an individual electrode, have been fabricated through a non-lithographic method. We also demonstrate the capability of CNTs to promote the oxidation/reduction (redox) reactions of hydrogen peroxide and nicotinamide adenine dinucleotide (NADH), which are involved in a wide range of amperometric biosensors associated with oxidase and dehydrogenase enzymes, respectively. With these electrocatalytic properties of CNTs, the applications of CNT-based biosensors examined in our laboratories include the low-potential detections of glucoses, organophosphorous compounds, and alcohol.

## BACKGROUND

There has been enormous interest in exploiting CNTs in electrochemical and biological sensors<sup>[1–21]</sup> since they were first introduced in 1991.<sup>[22]</sup> CNTs are distinguished according to their structural properties.<sup>[23]</sup> A single-wall CNT (SWCNT) consists of a single graphitic sheet rolled into a cylinder (with 1 to 2 nm o.d. and several microns in length), and multiwall CNT (MWCNT) consists of graphitic sheets rolled into closed concentric tubes (with 50 nm o.d. and microns in length), each separated by van der Waals forces to have a gap of 3.4 Å. Carbon nanotubes have been known to promote electron-transfer reactions of cytochrome *c*,<sup>[2]</sup> NADH,<sup>[1,6]</sup> catecholamine neurotransmitters,<sup>[3]</sup> and ascorbic acid.<sup>[4]</sup> This is attributed to their electronic structure, high electrical conductivity, and redox active sites. Carbon is also a versatile electrode material that can undergo various chemical and electrochemical modifications to produce suitable surfaces for high electrode responses. Carbon electrodes have a wide useful potential range, especially in the positive direction, because of the slow kinetics of carbon oxidation. These excellent properties of CNTs have been successfully exploited in our laboratories to develop either amperometric biosensors based on the immobilization of CNTs,<sup>[1,5]</sup> coimmobilization of CNTs and enzymes,<sup>[6,8]</sup> or the growth of controlled-density aligned CNTs into the nanoelectrode arrays<sup>[7,9,10]</sup> for the detection of glucoses,<sup>[5,6,10]</sup> organophosphorous compounds,<sup>[8]</sup> and alcohol,<sup>[6]</sup> as summarized in the following sections.

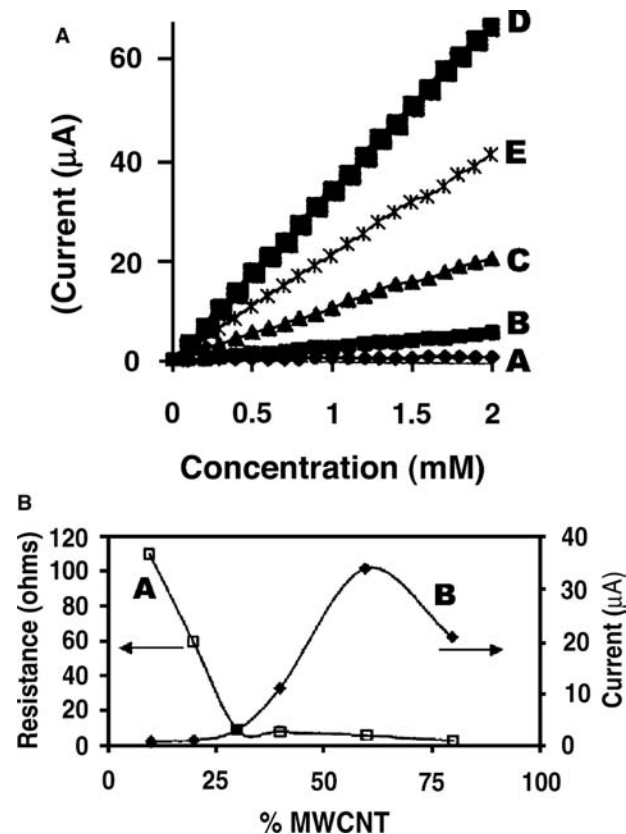

## BIOSENSORS BASED ON IMMOBILIZATION OF CNTS

### Solubilization and Immobilization of CNTs

CNTs have shown potential for applications in chemical/biological sensors and nanoscale electronic devices. A major barrier for developing such CNT-based devices is the insolubility of CNTs in most solvents. This challenge has been addressed through covalent modification<sup>[24,25]</sup> or non-covalent functionalization<sup>[26,27]</sup> of the CNTs. A “wrapping” of CNT in polymeric chains (i.e., poly(*p*-phenyl-enevinylene)<sup>[26]</sup> or poly{(*m*-phenylenevinylene)-*co*-[2,5-dioctyloxy-(*p*-phenylene)-vinylene]})<sup>[27]</sup> has improved the solubility of CNTs without impairing their physical properties.<sup>[28]</sup> In our work,<sup>[5]</sup> a well-known perfluorosulfonated polymer, Nafion, has been used to solubilize single-wall and multiwall CNTs. Because of their unique ion-exchange, discriminative, and biocompatibility properties, Nafion films have been used extensively to modify electrode surfaces and to construct amperometric biosensors.<sup>[29,30]</sup> Similar to other polymers used to wrap and solubilize CNTs, Nafion bears a polar side chain. We have found that CNTs can be suspended in solutions of Nafion in phosphate buffer or alcohol. Increasing the Nafion content from 0.1 to 5 weight percent (wt.%) results in a dramatic enhancement of the solubility of both single-wall and multiwall CNTs, which can be observed by the naked eye. A homogeneous solution of the Nafion/CNT complex is observed in Nafion solution, but no such solubilization is observed in ethanol or phosphate-buffer solutions containing no Nafion. The CNT/Nafion association does not impair the electrocatalytic properties of CNTs with respect to the redox reaction of hydrogen peroxide. The Nafion-induced solubilization of CNT thus permits a variety of applications, including the modification of electrode surfaces for preparing amperometric biosensors.

Because CNTs are insoluble in most solvents, previously reported CNT-modified electrodes have relied on casting a CNT/sulfuric acid solution onto a surface of electrodes,<sup>[1,31]</sup> a procedure that is not compatible with the immobilization of biocomponents. Therefore we have developed a new and simple method for preparing effective CNT-based biosensors from CNT/Teflon composite material.<sup>[6]</sup> Carbon composites, based on the dispersion of graphite powder within an insulator, offer convenient bulk modification for the preparation of reagentless and renewable biosensors. Teflon has been used as a binder for graphite particles for various electrochemical-sensing applications.<sup>[32,33]</sup> Our approach relies on CNTs as the sole conductive component rather than as the modifier cast on other electrode surfaces. The bulk of CNT/Teflon composites hence serve as a reservoir for the enzymes, in

the same manner as their graphite-based counterparts. The preparation is very simple: a certain amount of CNTs is hand-mixed in the dry-state with granular Teflon to obtain a desired composition of CNT/Teflon. The CNT content of the new composites has a large effect upon their electrochemical behavior. Fig. 1A compares the calibration plots for potassium ferricyanide obtained at electrodes containing different MWCNT loadings. All electrode compositions yield highly linear calibration plots over the entire concentration range. The sensitivity increases with the CNT loading between 10 and 60 wt.% and decreases thereafter. The influence of the CNT content was also examined using cyclic voltammetry (CV) experiments. The CV ferricyanide cathodic and anodic currents increased linearly with the CNT content between 30 and 70 wt.% (Fig. 1B). Composites containing more than 70 wt.% CNTs are too dry and porous and have

**Fig. 1** (A) Calibration plots for potassium ferricyanide using electrodes with varying MWCNT/Teflon ratio (by weight) of 10:90 (A), 30:70 (B), 40:60 (C), 60:40 (D), and 80:20 (E). Operating conditions: potential, +0.1 V; supporting electrolyte, phosphate buffer (0.05 M, pH 7.4); stirring rate, 400 rpm. (B) Influence of the CNT loading upon the electrode resistance (A) and amperometric response to 1 mM ferricyanide (B) measured with the 60:40 wt.% MWCNT/Teflon electrode. Other conditions are as in (a). Source: From Ref.<sup>[6]</sup>.

poor mechanical stability. Electrode resistance leading to a poorly defined and negligible CV is observed at the electrodes containing low CNT content. Fig. 1B shows the sensitivity-loading (B) and resistance-loading (A) profiles. Too high Teflon (<30 wt.% CNTs) leads to high resistance to a nearly insulating matrix and low sensitivity, while too high CNT (>75 wt.% CNT) leads to an operation beyond the mass-limiting plateau associated with the shift of the voltammetric signal. Therefore a CNT content of 40 to 60 wt.% is suggested.

The CNT/Teflon composites have the combined advantages of CNTs and bulk composite electrodes that permit a wide range of applications without the need for a graphite surface. Certain amounts of enzymes [e.g., glucose oxidase ( $\text{GO}_x$ ) and alcohol dehydrogenase (ADH)] and cofactor (e.g.,  $\text{NAD}^+$ ) can be mixed with the CNT/Teflon composite and used as electrode materials, depending upon specific needs. The CNT/Teflon coating was later investigated in our laboratory and displayed a marked electrocatalytic action toward hydrogen peroxide and NADH and hence is promising for the development of biosensors for glucose (in connection with oxidase enzymes) and ethanol (in connection with dehydrogenase enzymes), respectively.

### Electrocatalytic Activity of CNTs to Redox Reactions of Hydrogen Peroxide

Hydrogen peroxide is involved in a wide range of biosensing applications associated with oxidase enzymes. In our laboratories, the enhancement of the redox activity of hydrogen peroxide by CNTs is investigated using the previously described CNT/Nafion<sup>[5]</sup> and CNT/Teflon<sup>[6]</sup> electrode materials.

To study the electrocatalytic activity of CNTs for hydrogen peroxide oxidation/reduction, the CNT/Nafion (from a 0.5 wt.% Nafion solution containing 2 mg/mL of CNTs) is coated on a glassy carbon (GC) electrode surface. Fig. 2 displays the cyclic voltammograms for  $5 \times 10^{-3}$  M hydrogen peroxide recorded at a bare GC electrode (A) and the CNT/Nafion-modified GC electrode (B). Significant oxidation and reduction currents starting around +0.20 V are observed on the CNT/Nafion-coated electrode, while none is observed at the bare GC electrode. The CNT/Nafion-coated electrode offers a marked decrease in the overvoltage for hydrogen peroxide reaction and hence allows low-potential amperometric detection. The inset of Fig. 2 shows the amperometric response at 0.0 V to successive additions of hydrogen peroxide. While the modified electrode (B) responds very rapidly and favorably to the changes in hydrogen peroxide concentration, no response is observed at the bare GC electrode (A). A similar decrease in hydrogen

**Fig. 2** Cyclic voltammograms of  $5 \times 10^{-3}$  M hydrogen peroxide at unmodified (A) and MWCNT/Nafion-modified (B) GC electrodes. Operating conditions: scan rate, 50 mV/sec; electrolyte, phosphate buffer (0.05 M, pH 7.4). Upper inset shows the amperometric response after increasing hydrogen peroxide concentration for  $1 \times 10^{-3}$  M incrementally while potential is held at 0.0 V. Source: From Ref.<sup>[5]</sup>.

peroxide overvoltage is observed at other CNT-modified electrodes (not shown), indicating that Nafion does not impair the electrocatalytic properties of CNT. The CNT/Nafion-coated electrode is reliable and not affected by regenerating the surface; six successive measurements of hydrogen peroxide, each recorded on a freshly polished surface, show reproducible results with % RSD of less than 4.

Similar substantial lowering of the detection potential and significantly improved current signals for hydrogen peroxide by CNTs have also been found at CNT/Teflon electrodes, obtained by packing

**Fig. 3** Hydrodynamic voltammograms for 1 mM hydrogen peroxide at the 60:40 wt.% graphite/Teflon electrode (A) and the 60:40 wt.% MWCNT/Teflon electrode (B). Other conditions are as in Fig. 1A. Source: From Ref.<sup>[6]</sup>.

60/40 wt.% of CNT/Teflon into the electrode cavity of a glass sleeve with a copper wire as the electrical contact. Control experiments, using graphite-based Teflon composites, were performed in parallel. Fig. 3 compares the hydrodynamic voltammograms (HDVs) for 1 mM hydrogen peroxide at the graphite/Teflon (a) and CNT/Teflon (b) electrodes. Compared to the graphite/Teflon electrode, the CNT/Teflon electrode responds more favorably to hydrogen peroxide over the entire potential range (0.0 to 1.0 V) with significant response starting at +0.20 V. The Teflon binder is proven to not impair the electrocatalytic properties of CNTs.

### Electrocatalytic Activity of CNTs to Redox Reactions of NADH

$\beta$ -Nicotinamide adenine dinucleotide (NADH) is a cofactor in several hundred enzymatic reactions of  $\text{NAD}^+$ /NADH-dependent dehydrogenases. The electrochemical oxidation of NADH has thus been the subject of numerous studies related to the development of amperometric biosensors.<sup>[34]</sup> Problems inherent to such anodic detection are the large overvoltage encountered for NADH oxidation at ordinary electrodes<sup>[35]</sup> and surface fouling associated with the accumulation of reaction products.<sup>[36]</sup> CNTs have thus been used in our recent work<sup>[1,6]</sup> as the new electrode material to reduce the overpotential for NADH oxidation and to alleviate surface fouling problems.

In the previous study,<sup>[1]</sup> single-wall and multiwall CNTs were dispersed in concentrated sulfuric acid, and each was subsequently cast on a glassy carbon electrode. Fig. 4A shows the cyclic voltammograms of NADH measured at unmodified (A), MWCNT-modified (B), and SWCNT-modified (C) glassy carbon electrodes. Both modified electrodes yield an approximately twofold larger NADH peak, compared to the unmodified electrode. The oxygen-rich groups on the CNT surface, introduced during the acid dispersion, are perhaps responsible for such electrocatalytic behavior for the oxidation of NADH. Fig. 4B shows a HDV of  $1 \times 10^{-4}$  M NADH, which reflects the electrocatalytic behavior of the CNT coating with varying potentials. The MWCNT-coated electrode (B) responds to NADH over the entire 0.0- to 1.0-V range, while the bare electrode (A) responds only at potentials higher than +0.6 V. Fig. 4C shows that successive additions of  $1 \times 10^{-4}$  M NADH result in increasing response detected at the CNT-modified electrode (B) but no response at the unmodified electrode (A) when the detection potential was kept low (i.e., 0.3 V). Evidently, the electrocatalytic action of CNT enables the fast response (i.e., 10 sec to reach the steady state) to the change of NADH concentrations at the

low-detection potential. The amperometric response of  $5 \times 10^{-3}$  M NADH appears to be very stable; the decay of the signal is less than 10% and 25% after a 60-min period at the MWCNT-modified and SWCNT-modified electrodes, compared with 75% and 53% at the graphite-coated and acid-treated electrodes, respectively. This shows the capability of CNTs in resisting the fouling effects and in preventing the diminishing of signals in successive cyclic voltammetric detections. The resistance to fouling of CNT-based electrodes has yet to be understood.

In our more recent study,<sup>[6]</sup> the electrocatalytic effect of CNTs to facilitate low-potential amperometric measurements of NADH has been investigated using CNT/Teflon electrodes. Fig. 5 compares the amperometric response (at +0.40 V) of the graphite/Teflon (a) and CNT/Teflon (b) electrodes to successive additions of 0.1 mM NADH. Only the CNT/Teflon electrode responds very rapidly to the changes in the level of NADH, producing steady-state signals within 8 to 10 sec. The favorable signals are accompanied by a low noise level.

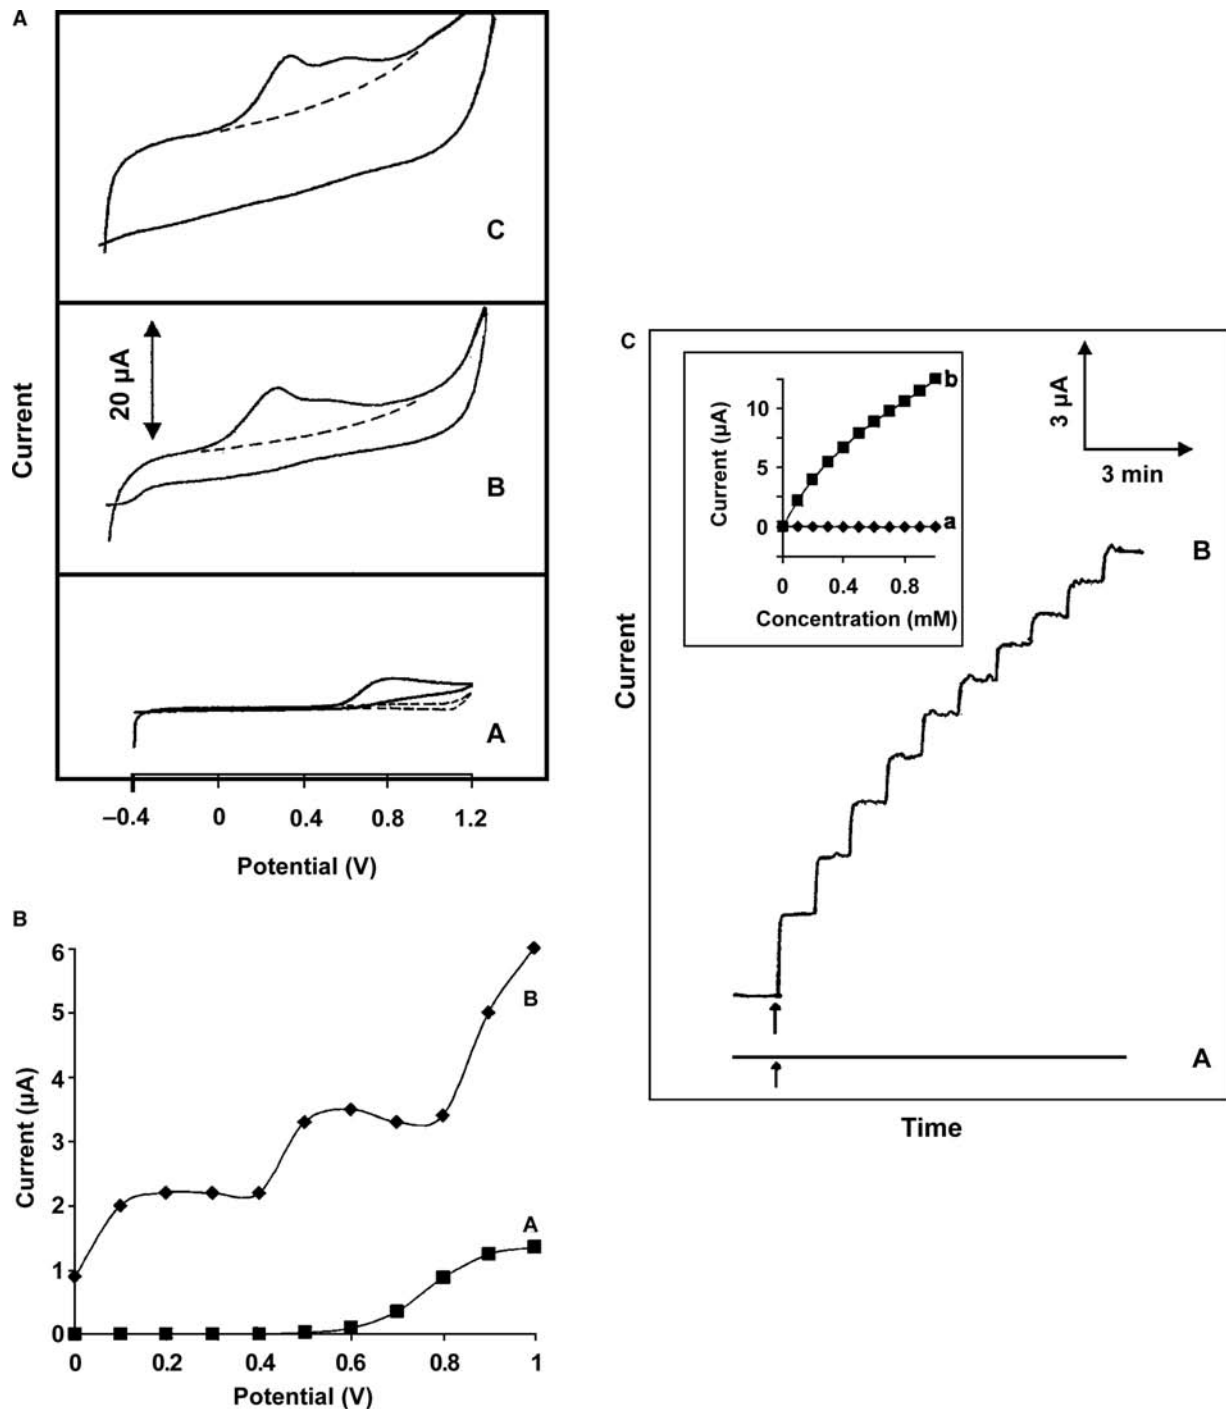

The CNT coating offers remarkably decreased overvoltage for the NADH oxidation as well as reduced surface fouling effects of the electrodes. These characteristics indicate the great promise of CNTs for developing highly sensitive, low-potential, and stable amperometric biosensors based on dehydrogenase enzymes.

### Applications of CNT-Immobilized Biosensors

Our laboratories have exploited the capability of CNTs to promote redox activity of hydrogen peroxide to develop oxidase-based amperometric biosensors, including those for detecting glucose<sup>[5,6,10]</sup> and organophosphorous compounds.<sup>[8]</sup> Similarly, the electrocatalytic properties of CNTs in reducing the overpotential for the redox reaction of NADH suggest their potential use in dehydrogenase-based amperometric biosensors such as those for alcohol detection.<sup>[6]</sup> These applications of CNT-based biosensors are summarized as follows.

#### Glucose detection

The CNT/Nafion/ $\text{GO}_x$ -modified GC electrode was used in a flow-injection system to measure glucoses.<sup>[5]</sup> Fig. 6 compares the amperometric responses for relevant physiological levels of glucose, ascorbic acid, acetaminophen, and uric acid at the CNT/Nafion/ $\text{GO}_x$ -modified GC electrode (B) and Nafion/ $\text{GO}_x$ -modified GC electrode (A). In Fig. 6, the accelerated electron-transfer reaction of hydrogen peroxide at the CNT/Nafion/ $\text{GO}_x$ -modified GC electrode allows for

**Fig. 4** (A) Cyclic voltammograms for  $5 \times 10^{-3}$  M NADH at unmodified (A), MWCNT-modified (B), and SWCNT-modified (C) GC electrodes. Operating conditions: scan rate, 50 mV/sec; electrolyte, phosphate buffer (0.05 M, pH 7.4). Dotted lines represent the background response. (B) Hydrodynamic voltammograms for  $1 \times 10^{-4}$  M NADH at the unmodified (A) and the MWCNT-modified (B) GC electrodes. Operating conditions: stirring rate, 500 rpm; electrolyte, phosphate buffer (0.05 M, pH 7.4). (C) Current–time recordings obtained after increasing the NADH concentration of  $1 \times 10^{-4}$  M (each step) at unmodified (A) and MWCNT-modified (B) GC electrodes. Inset shows the corresponding calibration curve. Operating conditions: potential, + 0.3 V; others as in (B). *Source:* From Ref.<sup>[1]</sup>.

glucose measurements at very low potentials (i.e.,  $-0.05$  V) where interfering reactions are minimized. As a result, a well-defined glucose signal (d) is observed, while the signals of acetaminophen (a), uric

acid (b), and ascorbic acid (c) are negligible. No such discrimination is obtained at the Nafion/ $\text{GO}_x$  biosensor (without the CNT) (A) held at +0.80 V, where large oxidation peaks are observed for all interferences,

**Fig. 5** Hydrodynamic voltammograms for 1 mM NADH at the 60:40 wt.% graphite/Teflon electrode (A) and the 60:40 wt.% MWCNT/Teflon electrode (B). Other conditions are as in Fig. 1A. Source: From Ref.<sup>[6]</sup>.

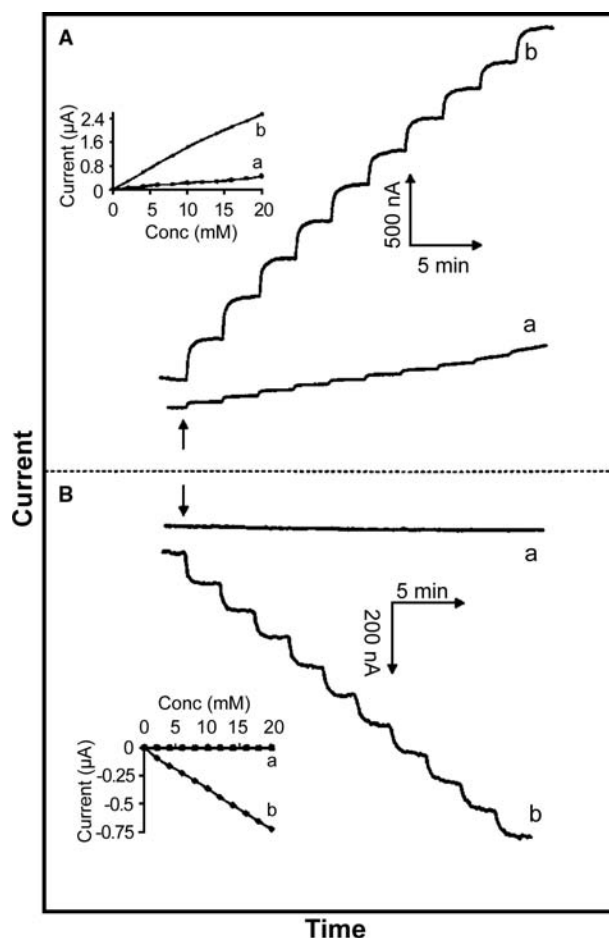

indicating that the permselective (charge-exclusion) properties of Nafion are not adequate to fully eliminate anionic interferences. In short, the coupling of the permselective properties of Nafion with the electrocatalytic action of CNT allows for glucose detection with effective discrimination against both neutral and anionic redox constituents. Similarly, the CNT/Nafion-coated electrodes have also been demonstrated to dramatically improve the signal of dopamine in the presence of the common ascorbic acid interference.

The detection of glucose has also been performed on CNT/Teflon-based electrodes, which are immobilized

**Fig. 6** Flow-injection signals for  $2 \times 10^{-4}$  M acetaminophen (A),  $2 \times 10^{-4}$  M ascorbic acid (B),  $2 \times 10^{-4}$  M uric acid (C), and  $1 \times 10^{-2}$  M glucose (D), at the Nafion/ $\text{GO}_x$ -modified GC electrode (A) at +0.8 V, and the MWCNT/Nafion/ $\text{GO}_x$ -modified GC electrode (B) at -0.05 V, and flow rate of 1.25 mL/min. Source: From Ref.<sup>[5]</sup>.

with  $\text{GO}_x$  enzyme.<sup>[6]</sup> Fig. 7 compares the amperometric response to successive additions of 2 mM glucose at the graphite/Teflon/ $\text{GO}_x$  (a) and the MWCNT/Teflon/ $\text{GO}_x$  (b) electrodes using operating potentials of +0.6 V (A) and +0.1 V (B). The CNT-based bioelectrode offers substantially larger signals, especially at low potential, reflecting the electrocatalytic activity of CNT. Such low-potential operation of the CNT-based biosensor results in a highly linear response (over the entire 2- to 20-mM range) and a slower response time (~1 min vs. 25 sec at +0.6 V). The glucose biocomposite based on single-wall CNTs results in a more sensitive but slower response than that based on multiwall CNTs. The low-potential detection also leads to high selectivity (i.e., effective discrimination against coexisting electroactive species). Despite the absence of external (permselective) coating, the glucose response at +0.1 V was not affected by adding the common

**Fig. 7** Current-time recordings for successive 2-mM additions of glucose at the graphite/Teflon/ $\text{GO}_x$  (A) and the MWCNT/Teflon/ $\text{GO}_x$  (B) electrodes measured at +0.6 (A) and +0.1 V (B). Electrode composition, 30:69:1 wt.% carbon/Teflon/ $\text{GO}_x$ . Other conditions are as in Fig. 1A. Source: From Ref.<sup>[1]</sup>.

acetaminophen and uric acid interferences at 0.2 mM. A similar addition of ascorbic acid resulted in a large interference, reflecting the accelerated oxidation of this compound at the CNT surface.<sup>[4]</sup> Reproducible activity was observed after 2 weeks of dry storage at 4°C, which is in good agreement with the high stability of enzymes in Teflon-based carbon composites.<sup>[33]</sup>

### Organophosphorus compound detection

Organophosphorous (OP) compounds are very toxic and are thus widely used as pesticides and chemical-warfare agents (CWAs). Recently, we have successfully used MWCNTs in developing an amperometric biosensor for OP compounds.<sup>[8]</sup> Specifically, the MWCNT is used to modify screen-printed carbon electrodes, which are subsequently coimmobilized with acetylcholinesterase (ACHE) and choline oxidase (CHO) enzymes. The MWCNT-modified electrode has demonstrated a significant catalytic effect for the redox reaction of hydrogen peroxide, leading to the development of a novel biosensor for the assay of OP compounds with enhanced sensitivity.

The ACHE enzyme is known to play an important role in cholinergic transmission as a catalyst for the rapid hydrolysis of the neurotransmitter acetylcholine to acetate and choline as follows:

However, in the presence of OP compounds, the rate of choline production is reduced. The capability of OP compounds to inhibit ACHE activity is well known<sup>[37–41]</sup> and thus is being exploited in developing biosensors for OP compound detection. In our work, the amperometric biosensor for OP compounds is based on coimmobilization of ACHE and CHO on a printed CNT electrode. In the biosensor based on ACHE/CHO enzymes, choline that is produced in reaction (1) serves as a substrate for the CHO enzyme in the presence of oxygen to produce hydrogen peroxide as follows:

The hydrogen peroxide that is produced in reaction (2) can be detected amperometrically, and the amperometric response is negatively proportional to the amount of an OP compound that is introduced into the system.

The inhibition of ACHE activity by OP compounds is an irreversible process; once exposed to the OP compounds, the enzyme is inactivated, and the sensor can be reused only after an appropriate enzyme reactivation.<sup>[42]</sup> Therefore we have attempted to develop

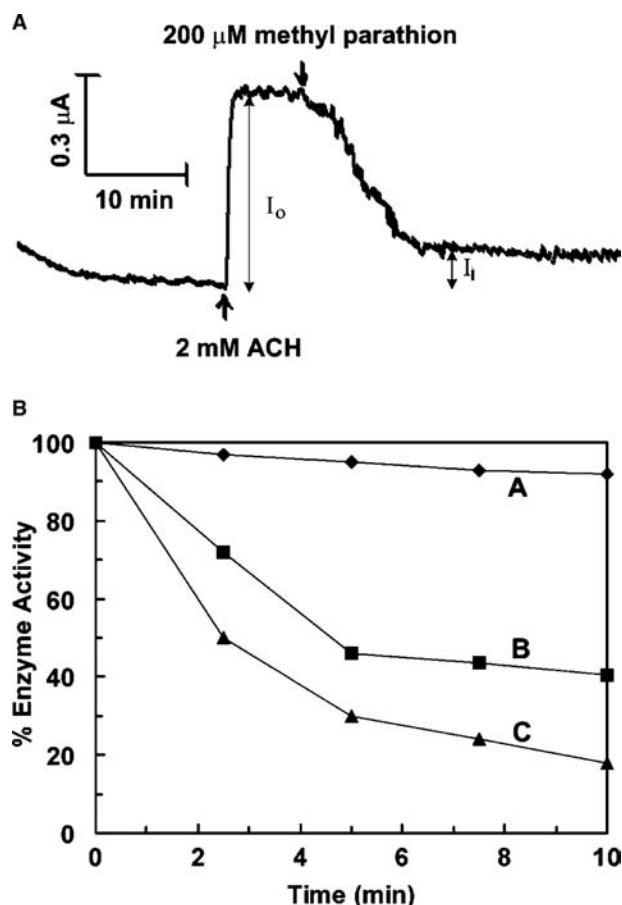

biosensors that are low-cost and disposable using screen-printed carbon electrodes.<sup>[8]</sup> To make the sensor, the suspension of MWCNTs in *N,N*-DMF was cast on the surface of screen-printed carbon electrodes to form a thin-film of CNTs. The screen-printed carbon only serves as a conducting base for the CNT electrode. The electrochemical method was used to oxidize CNTs to create a carboxylic acid group. Both enzymes, ACHE and CHO, were then coimmobilized on the CNTs via carbodiimide chemistry by forming amide linkages between their amine residues and carboxylic acid groups on the CNT surface.<sup>[10,43]</sup> The optimum biosensor was found to contain a loading of 0.8 mU ACHE and 1.5 U CHO on the electrode, with a 2-mM ACH as the substrate.

An amperometric method was employed to study the sensor response time of the ACHE inhibition after the spike of methyl parathion, as a representative OP compound. In Fig. 8, the amperometric response was rapid (i.e., within 30 sec) after the ACH addition, reflecting the fast diffusion of enzyme substrates and the products (as the CNTs are membrane-free porous). When methyl parathion was successively added to the test area of the biosensor, the response decreased significantly and rapidly in the first 10 min and more slowly thereafter. The significant inhibition effect of methyl parathion to the catalytic activity of ACHE reduces the production of hydrogen peroxide, leading to low signals.

In addition to methyl parathion, the inhibition effects of the other two OP compounds were investigated using the CNT-modified, ACHE/CHO-immobilized electrode. Fig. 8B compares the enzyme activities with a function of time after the spike of each OP compound, including (A) chlorpyrifos, (B) fenitrothion, and (C) methyl parathion.

The enzyme activity is the ratio of  $I_i$  (a steady-state current obtained in the presence of a given OP compound) to  $I_o$  (that obtained in the absence of the OP compound). After spiking with OP compounds, the enzyme activity decreases with time. The high inhibition effect of OP compounds can be correlated to low enzyme activity of ACHE. Their inhibition effects are in the following ascending order: methyl parathion > fenitrothion > chlorpyrifos.

The relative inhibition of methyl parathion at the CNT-modified, ACHE/CHO-immobilized biosensor as a function of methyl parathion concentration was investigated using a preincubation method in which the biosensor was exposed to the incubation solution containing methyl parathion for 10 min before the change in enzyme activity was measured. Successive incubation measurements were performed with varied methyl parathion concentrations. The CNT/ACHE/CHO biosensor has good analytical characteristics for methyl parathion, including a broad dynamic linear

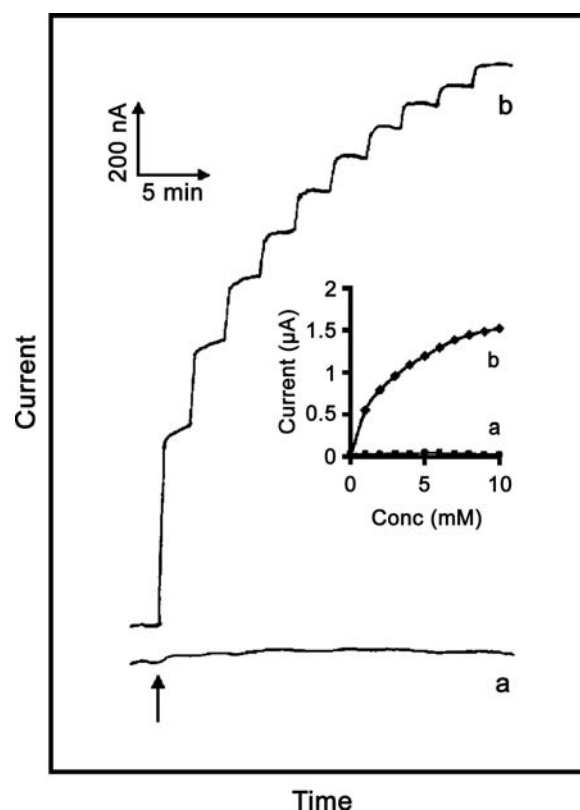

**Fig. 8** (A) Amperometric response of methyl parathion at the CNT/ACHE/CHO-immobilized screen-printed biosensor. Operating conditions: 0.1 M phosphate buffer/0.1 M NaCl (pH 7.4), potential of +0.50 V. (B) Inhibition effects by three organophosphates, chlorpyrifos (A), fenitrothion (B), and methyl parathion (C) on the enzyme activity, measured with the CNT/ACHE/CHO-immobilized screen-printed biosensor. Other conditions are as in (A). *Source:* From Ref.<sup>[8]</sup>.

range (up to 200  $\mu\text{M}$ ,  $r^2 = 0.96$ ), high sensitivity (0.48% inhibition/ $\mu\text{M}$ ), and low detection limit (LDL = 0.05  $\mu\text{M}$ ). These improved characteristics reflect the catalytic activity of CNTs that promotes the redox reaction of hydrogen peroxide produced during ACHE/CHO enzymatic reactions with their substrate, as well as the large surface area of CNT materials. The hand-held electrochemical detector (i.e., CHI1232 from CHI Instrument, Inc.) coupled with the disposable biosensor developed in this work will potentially facilitate the field screening of OP pesticides and nerve agents with fast speed, high efficiency, low cost, and small sample size needed.

#### Alcohol detection

The attractive low-potential detection of NADH, along with minimal surface fouling, makes CNT

extremely attractive for amperometric biosensors of ethanol through the incorporation of ADH/NAD<sup>+</sup> within the three-dimensional electrode matrix. Specifically, the reagentless biocomposite was prepared by mixing the desired amounts of the ADH enzyme and the NAD<sup>+</sup> cofactor with the CNT/Teflon composite to obtain the final composition of 28.5:65:1.5:5 wt.% CNT/Teflon/ADH/NAD<sup>+</sup>. The mixture was then packed firmly into the electrode cavity of a glass sleeve with a copper wire as the electrical contact. Fig. 9 compares the performance at a low detection potential (i.e., +0.20 V) of the CNT/Teflon-based electrode (b) to that of graphite/Teflon-based electrode (a). Only the CNT/Teflon-based electrode (b) responds favorably to successive additions of 1 mM ethanol. The response is relatively fast ( $\sim 60$  sec to reach steady state) and non-linear. The greatly enhanced biosensing of ethanol at the CNT-based electrode suggests the accelerated oxidation of NADH at low-potential detection. In addition to being reagentless, the biosensor does not require a redox mediator (to shuttle the electrons from the NADH product to the surface), which is commonly used for such low-potential detection of ethanol.

**Fig. 9** Current-time recordings for successive 1-mM additions of ethanol at the graphite/Teflon/ADH/NAD<sup>+</sup> (A) and the MWCNT/Teflon/ADH/NAD<sup>+</sup> (B). Operating potential, +0.2 V; electrode composition, 28.5:65:1.5:5 wt.% carbon/Teflon/ADH/NAD<sup>+</sup>. Other conditions are as in Fig. 1A. *Source:* From Ref.<sup>[6]</sup>.

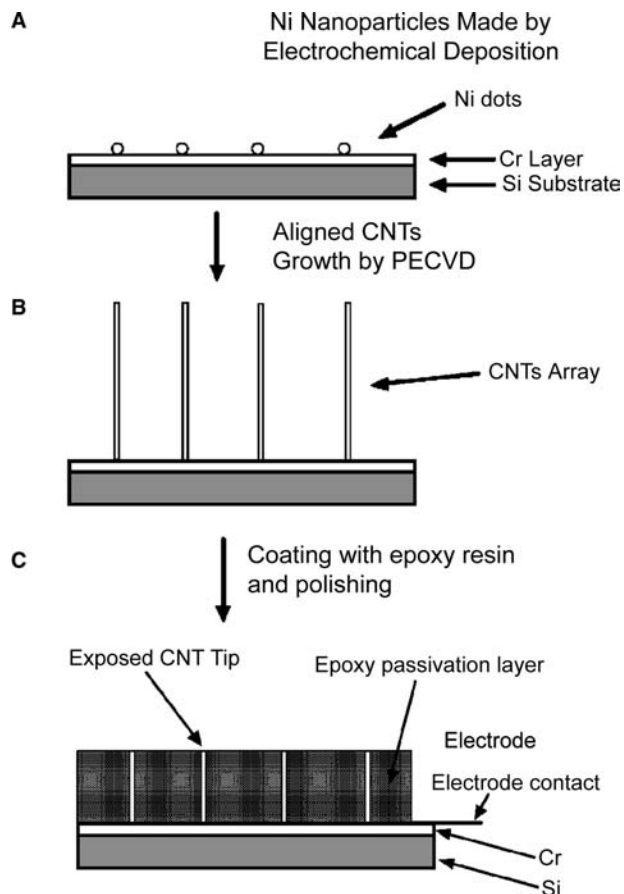

## BIOSENSORS BASED ON CONTROLLED-DENSITY ALIGNED CNTs

### Fabrication

Although vertically aligned CNTs have good material properties<sup>[44]</sup> (e.g., good electrical conductivity, ability to promote electron transfer reactions) and are of the right size (20 to 200 nm) for nanoelectrode arrays (NEAs), they lack the right spacing. To make each nanotube work as an individual nanoelectrode, the spacing needs to be sufficiently larger than the diameter of the nanotubes to prevent the diffusion layer overlap from the neighboring electrodes.<sup>[45]</sup>

Recently, a nonlithography method that allows the fabrication of low-site-density aligned CNT arrays with an interspacing of more than several micrometers has been developed.<sup>[46]</sup> From these low site density CNTs, the NEAs consisting of millions of nanoelectrodes with each electrode being less than 100 nm in diameter were successfully fabricated.<sup>[7,9,10]</sup> As the total current of the loosely packed electrode arrays is proportional to the total number of individual electrodes, having the number of the electrodes up to millions is highly desirable. The size reduction of each individual electrode and the increased total number of the electrodes result in improved signal-to-noise ratio ( $S/N$ ) and detection limits.<sup>[47,48]</sup>

In growing the low-site-density aligned CNT arrays, Ni nanoparticles were randomly deposited on a 1-cm<sup>2</sup> Cr-coated silicon substrate (Fig. 10A) by applying a pulse current to the substrate in NiSO<sub>4</sub> electrolyte solution. The size and the site density of the Ni nanoparticles were controlled by the amplitude and the duration of the pulse current. On these Ni particles, the CNTs were grown [Fig. 10B] in the plasma-enhanced chemical vapor deposition (PECVD) system at 650°C for 8 min with 160 sccm NH<sub>3</sub> and 40 sccm C<sub>2</sub>H<sub>2</sub> gases with a total pressure of 15 Torr and a plasma intensity of 170 W. The aligned CNT arrays had a site density of  $1 \times 10^6$ – $3 \times 10^6$ /cm<sup>2</sup>, a length of 10 to 12 μm, and a diameter of 50 to 80 nm. In the early days of fabricating the electrode arrays,<sup>[7,46]</sup> a thin layer of SiO<sub>2</sub> was coated on the surface by magnetron sputtering to insulate the Cr layer. This was followed by applying M-Bond 610 coating (epoxy-phenolic adhesive from Vishay Intertechnology, Inc., Shelton, CT) to further insulate the Cr and provide mechanical support to the CNTs. This insulation is sometimes not sufficient to prevent current leakage, which results in the distortion of the cyclic voltammetry curve. Recently,<sup>[9,10]</sup> we improved the fabrication method using better insulating materials and packing procedures that solve the leakage problem, coupled with a pretreatment of the electrode to reduce the peak separation. We replaced the SiO<sub>2</sub> and M-bond coatings used as the passivation

**Fig. 10** Fabrication scheme of a low-site-density aligned CNT nanoelectrode array. *Source:* From Ref.<sup>[7]</sup>.

layer in our previous attempts with Epon epoxy resin 828 (Miller-Stephenson Chemical Co., Inc., Sylmar, CA) and *m*-phenylenediamine (MPDA) as a hardener. After these steps, the CNTs were half-embedded in the polymer resin, and the protruding part of the CNTs beyond the polymer resin was mechanically removed by polishing with a lens, followed by ultrasonication in water. Then the electronic connection was made on the CNT-Si substrate to make the CNT nanoelectrode arrays (Fig. 10C). Finally, the electrode arrays were pretreated by electrochemical etching in 1.0 M NaOH at 1.5 V for 90 sec prior to the electrochemical characterizations. The lifetime of the NEAs employing new epoxy is significantly improved: there is no degradation for several weeks because of the excellent stability of the epoxy layer.

### Applications of Controlled-Density Aligned CNT Electrodes

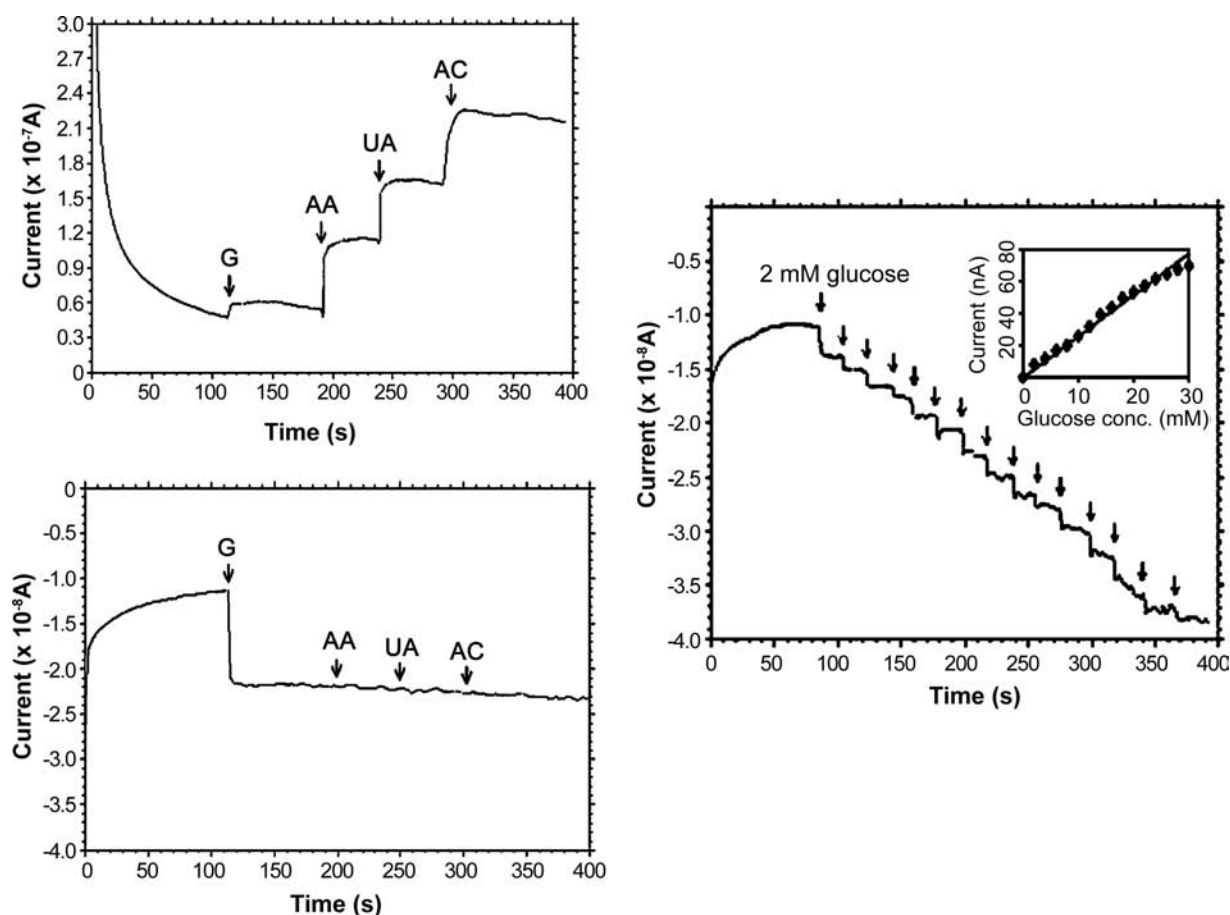

The nanoelectrode array, consisting of millions of CNT electrodes, yields an excellent sigmoidal voltammogram for K<sub>3</sub>Fe(CN)<sub>6</sub> and a low  $S/N$ .<sup>[9]</sup>

The sigmoidal voltammogram is a characteristic of microelectrodes having radial diffusion. The steady-state current arises because the rate of electrolysis approximates the rate of diffusion of an analyte to the electrode surface.<sup>[49]</sup> The scan-rate-independent limiting current behavior was observed up to 500 mV/sec at the nanoelectrode array. This indicates that there is no diffusion layer overlapping between the electrodes because most of the CNTs are separated from their nearest neighbors by at least 5  $\mu\text{m}$ , much larger than the diameter of each nanotube (50 to 80 nm).

The CNT-NEAs have a wide range of applications. They have been investigated in our laboratory as electrochemical sensors without further modification for the detection of drugs, such as 4-acetamidophenol, and metal ions, such as lead.<sup>[9]</sup>

For use as a glucose biosensor,<sup>[10]</sup> the  $\text{GO}_x$  enzyme molecules were attached to the broken tips of the CNTs via carbodiimide chemistry by forming amide linkages between their amine residues and carboxylic

acid groups on the CNT tips. Fig. 11A and B compares the amperometric responses for 5 mM glucose (G), 0.5 mM ascorbic acid (AA), 0.5 mM acetaminophen (AC), and 0.5 mM uric acid (UA) at the  $\text{GO}_x$ -modified NEA and the potentials of +0.4 V (a) and -0.2 V (b). Well-defined cathodic and anodic glucose responses are obtained at the CNT/ $\text{GO}_x$ -based biosensor at both potentials. However, the glucose detection at lower operating potential (-0.2 V) is significantly less influenced by interferences, indicating high selectivity toward the glucose substrate. Such a highly selective response to glucose is obtained at the CNT/ $\text{GO}_x$ -based biosensor without the use of mediators and permselective membranes. The amperometric response at the CNT/ $\text{GO}_x$ -based biosensor for each successive addition of  $2 \times 10^{-3}$  M glucose is presented in Fig. 11C with the corresponding calibration curve in the inset. The linear response to glucose is up to 30 mM, and the steady state is reached within 20 to 30 sec.

**Fig. 11** (A–B) Amperometric responses for 5 mM glucose (G), 0.5 mM ascorbic acid (AA), 0.5 mM acetaminophen (AC), and 0.5 mM uric acid (UA) at the  $\text{GO}_x$ -modified, CNT-nanoelectrode array and the potentials of +0.4V (A) and -0.2V (B). Electrolyte: 0.1 M phosphate buffer/0.1 M NaCl (pH 7.4). (C) Amperometric response at the  $\text{GO}_x$ -modified, CNT-nanoelectrode array for each successive addition of  $2 \times 10^{-3}$  M glucose. Inset shows the corresponding calibration curve. Potential: -0.2 V, other conditions are as in (A–B). Source: From Ref.<sup>[10]</sup>.

For many years, numerous researches have emphasized the use of anti-interference layers or artificial electron mediators for improving the selectivity of amperometric biosensors. CNTs eliminate potential interferences through the preferential detection of hydrogen peroxide at the CNT-based electrodes. Such development of interference-free transducers will significantly simplify the design and fabrication of biosensors. The biosensors based on low-site-density aligned CNTs are also suitable for the highly selective detection of glucose in a variety of biological fluids (e.g., saliva, sweat, urine, and serum).

## CONCLUSION

The electrocatalytic properties of CNTs in promoting the redox reaction of hydrogen peroxide and NADH are being exploited in our work in developing biosensors based on oxidase and dehydrogenase enzymes, respectively. With our CNT-based biosensors, low-potential detections of alcohol, organophosphorous compounds, and glucose are possible with many advantages over conventional devices. The capability of CNTs to reduce the overvoltage for the oxidation of hydrogen peroxide and NADH allows the detection of these species at low potential. At such low potential, most interfering species in the test samples do not undergo oxidation, thus eliminating potential interference. CNTs also minimize the surface fouling of biosensors, thus imparting higher stability onto these devices. While the CNT/Nafion-based biosensors use the electrocatalytic activity of CNTs and the permselectivity of Nafion to detect glucose with effective discrimination against most neutral and anionic redox constituents, the CNT/Teflon composite allows the reagentless approach to fabricate biosensors with flexible coimmobilization of enzymes and cofactors for specific biosensing needs. Owing to the CNTs' capability to promote electron-transfer activity, the artificial mediators that shuttle electrons between the enzymes and the electrodes are not required at the CNT-based biosensors, thereby eliminating the dependence upon the electroactive species and enhancing the reproducibility.

For future work, we will investigate the capability of CNTs to promote electron-transfer reactions of other biologically and environmentally important compounds. The biosensor fabrication technology demonstrated in this work holds a great future for developing routine, onsite amperometric biosensors based on both oxidase and dehydrogenase enzymes, such as those for cholesterol, alcohol, lactate, acetylcholine, choline, hypoxanthine, and xanthine. Although this entry focuses on biosensors based on CNTs, other oriented conducting nanowires, e.g., oriented conducting

polymer nanowires recently synthesized in our laboratory,<sup>[50,51]</sup> should also provide an alternative ideal platform for biosensing applications.

## ACKNOWLEDGMENTS

# Biosensors: Fractal Analysis of Binding Kinetics

Harshala Butala

Ajit Sadana

*Department of Chemical Engineering, University of Mississippi,  
University, Mississippi, U.S.A.*

## INTRODUCTION

Biosensors find increasing applications in different areas such as the detection of biological agents, chemicals, explosives, food safety, environmental, and energy applications. The main reasons for the growing popularity of the biosensor-based applications are the simplicity of use, monitoring of the reactions in real time and radiolabel free detection of the binding or breakdown of complexes. There is a continual need to enhance the sensitivity, selectivity, stability, regenerability, and decrease the response time of the biosensor. Also, it is significant to obtain kinetic and dissociation rate coefficients for analyte–receptor interactions in order to obtain better physical insights into functionally dissimilar processes they are involved in. An analysis of the interaction wherein the receptor is immobilized on the sensor chip of a surface plasmon resonance (SPR) biosensor and the corresponding analyte is in solution is an initial step in this direction. This is an *in vitro* application. However, one recognizes that the receptor may not be immobilized in real-life application in the human body (for e.g., cellular interactions).

## Surface Plasmon Resonance Biosensor

The SPR biosensor protocol requires one of the components (receptor) to be detected to be immobilized on the biosensor-chip surface and the other component (analyte) to be in solution. The protocol analyzes the analyte–receptor interaction kinetic curves using classical saturation models under diffusion-free conditions. The analysis also assumes that the receptors are homogeneously distributed over the sensor surface. Computer programs and software that come with the equipment provide values of the rate coefficients (for e.g., Biacore 2002<sup>[1]</sup>). Although a careful analysis and experimental protocol may eliminate or minimize the

influence of diffusional limitations, realistically speaking, it is more appropriate to include a heterogeneous distribution of receptors on the sensing surface.

The immobilized receptor–analyte in solution system by its design is heterogeneous. Elimination of this heterogeneity may result in incorrect interpretation of the kinetics of the interactions. One possible way of accounting for the presence of heterogeneity that exists on the surface is by using fractals.<sup>[2]</sup> A characteristic feature of fractals is the self-similarity at different levels of scale and dilatational symmetry. Fractals are particularly useful for this type of analysis because they help characterize the heterogeneity on the biosensor surface and other factors such as mass-transport limitations. The heterogeneity on the surface can be described by a lumped parameter; the fractal dimension.

An alternate analysis is used in this manuscript to reanalyze the data obtained from literature that incorporates theoretically in the kinetic model the heterogeneous distribution of receptors on the sensing surface. This is a more realistic approach to the real-life situation. This would become more significant if the degree of heterogeneity of the receptors on the surface affects the binding and the dissociation rate coefficients to a large degree.

Osmond et al.<sup>[3]</sup> investigated protein–heparin interactions using BIAcore 2000. Protein interactions with heparin are widespread and mediate many biologically important processes. An understanding of the affinity and kinetics of these interactions is of considerable importance. Biotinylated heparin derivatives were immobilized on streptavidin sensor chips and several heparin-binding proteins were examined. In this entry we discuss the binding and dissociation interaction of lactoferrin (protein) binding to three biotinylated heparins, namely, EP–heparin, NH<sub>2</sub>–heparin and CO<sub>2</sub>H–heparin.

Along with the above example, drug–liposome interactions are analyzed using the fractal approach.

Baird, Courtenay, and Myszka<sup>[4]</sup> used both BIAcore 2000 and 3000 to study drug interactions with liposome surfaces. They used this study for predicting intestinal permeability of a drug. Liposomes captured on the biosensor chip surface create a lipid barrier representative of the membrane of an intestinal epithelial cell. As the drug flows over the chip surface, lipid interactions can be monitored in real time without any labeling.

## THEORY

Havlin<sup>[5]</sup> reviewed and analyzed the diffusion of reactants toward fractal surfaces. The details of the theory and the equations involved for the binding and the dissociation phases for analyte–receptor binding are available.<sup>[6]</sup> The details are not repeated here. A brief outline of the equations is given to permit an easier reading.

### Single-Fractal Analysis

#### Binding rate coefficient

Havlin<sup>[5]</sup> considered the diffusion of a particle (analyte) from a homogeneous solution to a solid surface (e.g., receptor-coated surface) on which it reacts to form a product (analyte–receptor complex). The concentration of the product [analyte–receptor] increases with time as follows:

$$\begin{aligned} & \text{(Analyte} \cdot \text{receptor)} \\ & \sim \begin{cases} t^{(3-D_{f,\text{bind}})/2} = t^p & (t < t_c) \\ t^{1/2} & (t > t_c) \end{cases} \quad (1a) \end{aligned}$$

Here  $D_{f,\text{bind}}$  is the fractal dimension of the surface during the binding step;  $t_c$  is the cross-over value. The cross-over value may be determined by the relationship  $t_c^2 \sim r_c^2$ . Above the characteristic length,  $r_c$ , the self-similarity is lost. Hence, above  $t_c$ , the surface may be considered homogeneous and “regular” diffusion is now present. For the present analysis,  $t_c$  is chosen arbitrarily and we assume that the value of the  $t_c$  is not reached.

In Eq. (1a) the concentration of the (analyte–receptor) complex on a solid fractal surface scales at two different scales with time: 1) with the coefficient,  $p = (3 - D_{f,\text{bind}})/2$ , at short timescales and 2)  $p = 1/2$  at intermediate timescales.<sup>[5]</sup> Note that the value of the coefficient,  $p$ , is different from the “normal” case,  $p = 0$ , which is the consequence of two different phenomena, the fractality (heterogeneity) and

the imperfect mixing (diffusion-limited) condition. For a homogeneous surface,  $D_{f,\text{bind}}$  is equal to 2.<sup>[5]</sup> When only diffusional limitations are present,  $p = 1/2$  as it should be. Another way of looking at the  $p = 1/2$  case is that the analyte in solution views the fractal object, in our case the receptor-coated biosensor surface, from a “large distance.” In essence, in the binding process, the diffusion of the analyte from the solution to the receptor surface creates a depletion layer of width  $(Dt)^{1/2}$ , where  $D$  is the diffusion constant. This gives rise to the fractal power law, [analyte–receptor]  $\sim t^{(3-D_{f,\text{bind}})/2}$ .

It is worthwhile commenting on the units of the binding and the dissociation rate coefficient(s) obtained for the fractal analysis. In general, for SPR biosensor analysis, the unit for the [analyte–receptor] complex on the biosensor surface is RU (resonance unit). One thousand resonance units is generally 1 ng/mm<sup>2</sup> of surface, or one resonance unit is 1 pg/mm<sup>2</sup>. Then, the unit for the binding rate coefficient,  $k_{\text{bind}}$ , from Eq. (1a) is pg mm<sup>-2</sup> sec<sup>( $D_{f,\text{bind}}-3$ )/2</sup>. Note that the unit of dependence in time exhibited by  $k_{\text{bind}}$  changes slightly depending on the corresponding fractal dimension obtained in the binding phase,  $D_{f,\text{bind}}$ . The fractal dimension value is less than or equal to three. Three is the highest value of the fractal dimension because the system is embedded in a three-dimensional system. Note that  $k_{\text{bind}}$  and  $k_{\text{diss}}$  are interchangeably used as  $k$  and  $k_d$ , respectively.

It would be useful to specify what the carrier of fractal properties is. It could be either the analyte surface, the receptor surface, or the immobilizing (in our case, the biosensor) surface. There is a considerable body of work on fractal surface properties of proteins.<sup>[7–10]</sup> Daily et al.<sup>[11]</sup> indicate that the active sites (in our case the receptors on the biosensor surface) may themselves form a fractal surface. Furthermore, the inclusion of non-specific binding sites on the surface would increase the fractal dimension of the surface. At present, we are unable to specify what the carrier of the fractal properties is. This is exacerbated by our reanalysis of kinetic data available in the literature. Presumably, it is because of a composite of some or all of the factors mentioned above.

#### Dissociation rate coefficient

The diffusion of the dissociated particle (receptor or analyte) from the solid surface (e.g., analyte–receptor complex coated surface) into solution may be given, as a first approximation by:

$$\begin{aligned} & \text{(Analyte} \cdot \text{receptor)} \sim -t^{(3-D_{f,\text{diss}})/2} \quad (t > t_{\text{diss}}) \\ & = -k_{\text{diss}} t^{(3-D_{f,\text{diss}})/2} \quad (1b) \end{aligned}$$

Here  $D_{f,diss}$  is the fractal dimension of the surface for the dissociation step;  $t_{diss}$  represents the start of the dissociation step. This corresponds to the highest concentration of the analyte–receptor complex on the surface. Henceforth, its concentration only decreases.  $D_{f,bind}$  may or may not be equal to  $D_{f,diss}$ .

The units for the dissociation rate coefficient,  $k_{diss}$ , are obtained in a similar manner as done for the binding rate coefficient. The unit for the  $k_{diss}$  is  $\text{pg mm}^{-2} \text{sec}^{(D_{f,diss}-3)/2}$ . Again, note that the unit dependence on time exhibited by  $k_{diss}$  changes slightly because of the dependence on  $D_{f,diss}$ .

## Dual-Fractal Analysis

### Binding rate coefficient

The single-fractal analysis has been extended to include two fractal dimensions. The concentration of the analyte–receptor complex is given by:

$$\begin{aligned} & (\text{Analyte} \cdot \text{receptor}) \\ & \sim \begin{cases} t^{(3-D_{f1,bind})/2} = t^{p1} & (t < t_1) \\ t^{(3-D_{f2,bind})/2} = t^{p2} & (t_1 < t < t_2 = t_c) \\ t^{1/2} & (t > t_c) \end{cases} \quad (1c) \end{aligned}$$

The time ( $t = t_1$ ) at which the first fractal dimension “changes” to the second fractal dimension is assumed to be arbitrary and empirical. One of the reasons for the “change” in fractal dimension is the fact that the analyte–receptor binding is different from catalytic reactions. In catalytic reactions, the catalytic surface exhibits an unchanging fractal surface to the reactant in the absence of fouling and other complications, whereas for analyte–receptor binding the biosensor surface exhibits a changing fractal surface to the analyte in solution. This occurs because as each binding reaction takes place, smaller and smaller amounts of “binding” sites or receptors are available on the biosensor surface to which the analyte may bind. Furthermore, as the reaction proceeds, there is an increasing degree of heterogeneity on the biosensor surface for some reaction systems. This is manifested by two degrees of heterogeneity, or two fractal dimensions on the biosensor surface.<sup>[12]</sup> In the theoretical limit one might envisage a temporal fractal dimension wherein there is a continuous change in the degree of heterogeneity on the surface, although of course, such situations would be rare.

At present, the dual-fractal analysis does not have a basis at the molecular level. This represents two different levels of heterogeneity on the biosensor surface. For the most part the use of dual fractal analysis is dictated by the data analyzed and the experience gained

by handling a single-fractal analysis. The  $r^2$  (regression coefficient) value obtained is also used to determine if a single-fractal analysis is sufficient to provide an adequate fit. Only if the  $r^2$  value is less than 0.97 for a single-fractal analysis do we use a dual-fractal model.

The binding rate coefficients,  $k_1$  and  $k_2$ , in the dual-fractal analysis have the same units,  $\text{pg mm}^{-2} \text{sec}^{(D_{f1,bind}-3)/2}$  and  $\text{pg mm}^{-2} \text{sec}^{(D_{f2,bind}-3)/2}$ , respectively, as the binding rate coefficient,  $k$ , in the single-fractal analysis.

### Dissociation rate coefficient

In this case the dissociation rate coefficient is given by:

$$\begin{aligned} & (\text{Analyte} \cdot \text{receptor}) \\ & \sim \begin{cases} -t^{(3-D_{f1,diss})/2} & (t_{diss} < t < t_{d1}) \\ -t^{(3-D_{f2,diss})/2} & (t_{d1} < t < t_{d2}) \end{cases} \quad (1d) \end{aligned}$$

Here  $D_{f,diss}$  is the fractal dimension of the surface for the dissociation step;  $t_{diss}$  represents the start of the dissociation step. This corresponds to the highest concentration of the [analyte–receptor] on the surface.  $D_{f,bind}$  may or may not be equal to  $D_{f,diss}$ . The dissociation rate coefficients,  $k_{d1}$  and  $k_{d2}$ , in the dual-fractal analysis have the same units,  $\text{pg mm}^{-2} \text{sec}^{(D_{f1,diss}-3)/2}$  and  $\text{pg mm}^{-2} \text{sec}^{(D_{f2,diss}-3)/2}$ , respectively, as the dissociation rate coefficient,  $k_d$ , in the single-fractal analysis.

The affinity,  $K = k_{diss}/k_{bind}$ , can be calculated using the above models. The  $K$  value is frequently used in analyte–receptor reactions occurring on biosensor surfaces. This ratio, besides providing physical insights into the analyte–receptor system, is of practical importance because it may be used to help determine (and possibly enhance) the regenerability, reusability, stability, and other biosensor performance parameters. The affinity  $K$  has the unit  $\text{sec}^{(D_{f,diss}-D_{f,bind})/2}$ . This applies to both the single- as well as the dual-fractal analysis. Note the difference in the units of affinity obtained for the classical as well as the fractal-type kinetics. Although the definition of affinity is the same in both types of kinetics, the difference(s) in the units of the different rate coefficients eventually leads to a different unit for the affinity in the two types of kinetics. This is not entirely unexpected because the classical kinetic analysis does not include the characteristics of the surface in the definition of the affinity  $K$ , whereas the present fractal analysis does. Thus, one may not be able to actually compare the affinities in these two types of systems. This is a significant difference in the kinetic analysis of binding and dissociation reactions on biosensor surfaces from what is available in the literature.

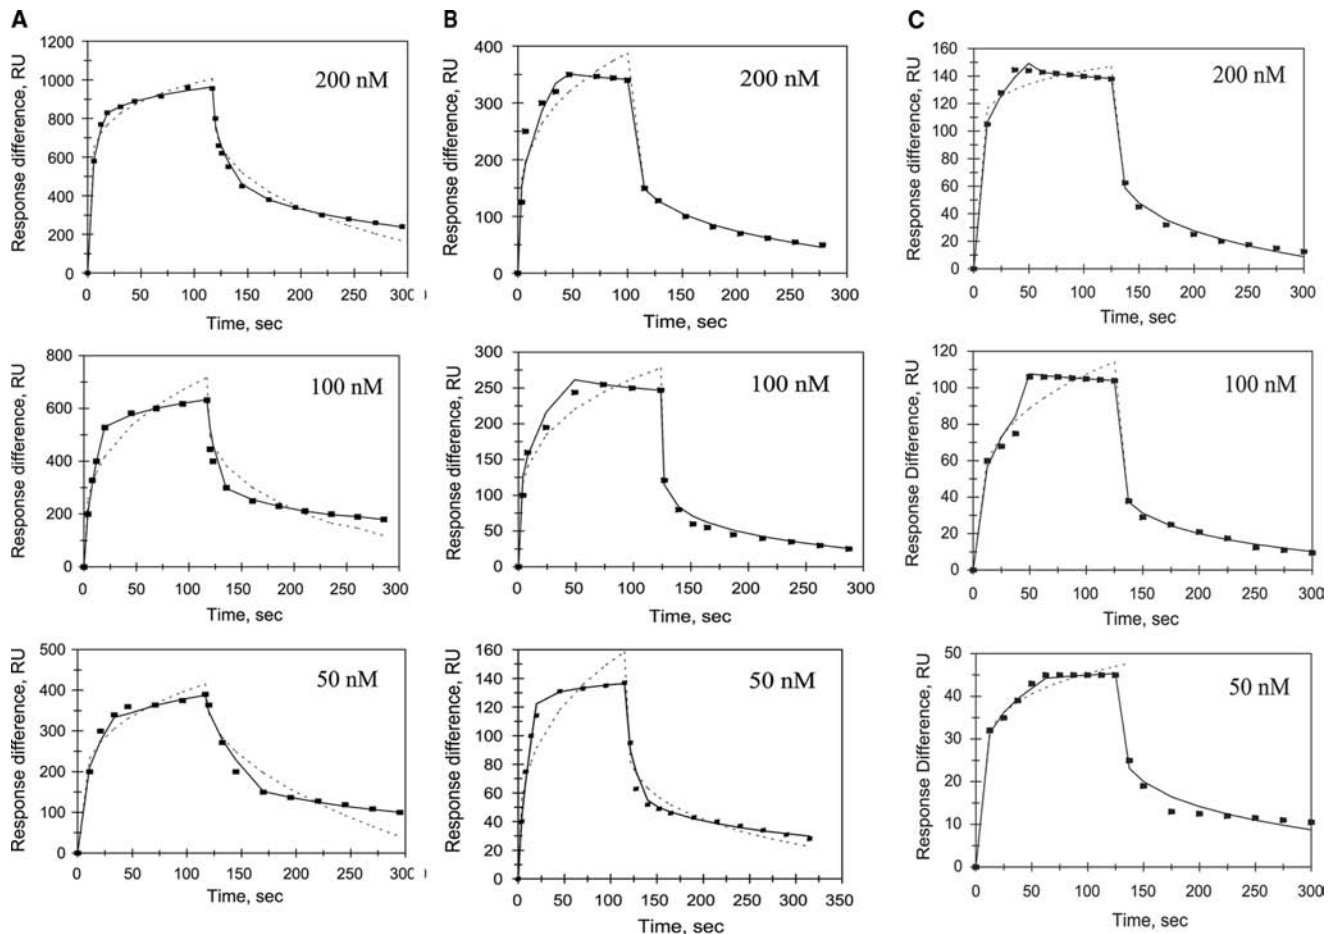

## RESULTS

A fractal analysis is applied to the data obtained for protein–heparin<sup>[3]</sup> and drug–liposome interactions<sup>[4]</sup> taken from the literature. Alternate expressions for fitting the data are available. These include saturation, first-order reaction, and no diffusion limitation cases, but these expressions are apparently deficient in describing the heterogeneity that inherently exists on the surface. The method widely used for modeling data is the Langmuirian approach. This approach may be used to model the data presented if one assumes the presence of discrete classes of sites (e.g., double-exponential analysis as compared with a single-exponential analysis).

Lee and Lee<sup>[13]</sup> indicate that the fractal approach has been applied to surface science, e.g., adsorption and reaction processes. These authors emphasize that

the fractal approach provides a convenient means to represent the different structures and morphology at the reaction surface. They also emphasize using the fractal approach to develop optimal structures and as a predictive approach. Another advantage of the fractal technique is that the analyte–receptor binding (as well as the dissociation reaction) is a complex reaction, and the fractal analysis via the fractal dimension and the rate coefficient provides a useful lumped parameter(s) analysis of the diffusion-limited reaction occurring on a heterogeneous surface. The parameters obtained by this analysis of the diffusion-limited binding kinetics occurring on heterogeneous surfaces provide a useful comparison of different receptor–analyte biosensor systems.

In the classical situation, to demonstrate fractality, one should make a log–log plot, and one should have a large amount of data. It may also be useful to

**Fig. 1** Binding curves of lactoferrin at various concentrations to immobilized heparin. (A) Lactoferrin binding to EP–heparin. (B) Lactoferrin binding to NH<sub>2</sub>–heparin. compare the fit to some other forms, such as exponential, or one involving saturation, etc. At present, we do not present any independent proof or physical evidence of fractals in the examples presented. It is a convenient means (because it provides a lumped parameter) of making the degree of heterogeneity that exists on the surface more quantitative. Thus, there is some arbitrariness in the fractal model to be presented.

Our analysis at present does not include the non-selective adsorption of the analyte. We do recognize that in some cases this may not be a significant component of the adsorbed material and that this rate of association, which is of a temporal nature, would depend on surface availability. If we were to accommodate the non-selective adsorption into the model, there would be an increase in the heterogeneity on the surface because by its very nature non-specific adsorption is more heterogeneous than specific adsorption. This would lead to higher fractal dimension values because the fractal dimension is a direct measure of the degree of heterogeneity that exists on the surface.<sup>[14]</sup>

For a first-order reaction, as expected, an increase in the degree of heterogeneity on the surface because of non-specific binding would lead to lower values of the (specific) binding rate coefficient. The deletion of this non-specific binding in the analysis would lead to (artificially) higher values of the binding rate coefficient for first-order reactions. Our reactions are, in general, higher than first order. Sadana and Chen<sup>[14]</sup> showed that for reaction orders higher than one a certain amount of heterogeneity is beneficial for the binding rate coefficient. There is apparently an optimum range because of steric factors. Thus, depending on whether one is inside or out of this optimum range, the deletion of non-specific binding in the analysis would lead to either an increase or a decrease in the binding rate coefficient. In other words, if one is in the optimum range for a particular reaction order, then the presence of non-specific binding would lead to higher values of the (specific) binding rate coefficient. In this case, the deletion of the non-specific binding leads to lower than real-life values of the binding rate coefficient.

The previous analyses used the software provided by the SPR biosensor manufacturer (Biacore 2002) to obtain the values of the rate coefficients and the affinities. The model did not take into account the heterogeneity present on the sensor chip surface. Here we present the reanalysis of these interactions using the above equations.

Osmond et al.<sup>[3]</sup> have analyzed binding and the dissociation of protein-heparin interactions. These authors have used SPR biosensor for the analysis of the kinetics. Biotinylated heparin derivatives were immobilized on streptavidin sensor chips and their effect was analyzed. Fig. 1A, B, and C shows the

binding curves of lactoferrin at various concentrations (200, 100, and 50 nM) to CO<sub>2</sub>H-heparin, NH<sub>2</sub>-heparin, and EP-heparin, respectively, immobilized on the sensor chip surface.

For EP-heparin, a dual-fractal analysis is adequate to describe the binding as well as the dissociation kinetics for all of the concentrations analyzed. A dual-fractal analysis was adequate to describe binding kinetics for NH<sub>2</sub>-heparin and CO<sub>2</sub>H-heparin complex immobilized on sensor-chip surface. However, a single-fractal analysis was sufficient to describe the dissociation of these reactions with an exception for 50 nM lactoferrin concentration binding to NH<sub>2</sub>-heparin; a dual fractal analysis was required for this case. The values of the binding and the dissociation rate coefficients are given in Table 1. These values were obtained from a regression analysis using Corel Quattro Pro 8.0<sup>[15]</sup> to model the data using Eqs. (1c) and (1d).

**Fig. 2** Relationship between the affinities and the ratio of fractal dimension for dissociation to that of binding for lactoferrin binding to EP-heparin. (A) Increase in the affinity,  $K_1$ , with an increase in the fractal dimension ratio,  $D_{fd}/D_{f1}$ . (B) Increase in the affinity,  $K_2$ , with an increase in the fractal dimension ratio,  $D_{fd}/D_{f2}$ . Legend: as in Fig. 1 legend.

As the concentration of lactoferrin binding to all three different ligands increases, there is an increase in the binding fractal dimension ( $D_f$ ) and in the dissociation fractal dimension ( $D_{fd}$ ). This leads to an increase in the binding rate coefficient,  $k$ , and the dissociation rate coefficient,  $k_d$ . The higher receptor concentration (200 nM) on the SPR surface leads to a higher degree of heterogeneity on the surface because of the saturation of the active sites on the surface. This leads to a higher binding rate coefficient for EP-heparin and CO<sub>2</sub>H-heparin immobilized on the biosensor surface. However, for the NH<sub>2</sub>-heparin ligand this surface saturation not only leads to increase in rate coefficients but also to a change in mechanism of dissociation, which can be seen by the use of a dual-fractal analysis to describe the process.

The affinity  $K_1$  ( $k_d/k$ ) values are also calculated. There is no trend in these values with respect to different ligands. However, if we compare the affinity values of different concentrations of lactoferrin binding to a particular ligand with the ratio of the fractal dimension for dissociation to the fractal dimension for binding ( $D_{fd}/D_{f1}$ ), we note an increasing trend. Fig. 2A shows that the affinity  $K_1$  ( $k_d/k_1$ ) increases, for the binding of lactoferrin to the CO<sub>2</sub>-heparin immobilized on the sensor surface, as the ratio  $D_{fd}/D_{f1}$  increases. For the data analyzed and presented in Table 1, the affinity  $K_1$  ( $k_d/k_1$ ) is given by:

$$K_1 = (0.6650 \pm 0.0179)(D_{fd}/D_{f1})^{6.196 \pm 0.2025} \quad (2a)$$

The affinity,  $K_1$ , is very sensitive to the degree of heterogeneity that exists on the surface as noted by

**Fig. 3** Relationship between the affinities and the ratio of fractal dimension for dissociation to that of binding for lactoferrin binding to NH<sub>2</sub>-heparin. Increase in the affinity,  $K_1$ , with an increase in the fractal dimension ratio,  $D_{fd}/D_{f1}$ .

the high value of the order of dependence of  $K_1$  on  $D_{fd}/D_f$ .

Fig. 2B relates the affinity  $K_2$  ( $k_d/k_2$ ) to ( $D_{fd}/D_{f2}$ ). The affinity can be given by

$$K_2 = (0.7544 \pm 0.0457)(D_{fd}/D_{f2})^{7.110 \pm 2.065} \quad (2b)$$

A similar analysis is done for binding of lactoferrin on NH<sub>2</sub>-heparin and CO<sub>2</sub>H-heparin ligands. The dependence of affinities on the ratio of fractal dimension is shown in Figs. 3 and 4, respectively. For the data analyzed of different concentrations of lactoferrin binding to NH<sub>2</sub>-heparin, the affinity,  $k_d/k_1$  is given by:

$$K_1 = (1.0158 \pm 0.1074)(D_{fd}/D_{f1})^{1.8256 \pm 0.4650} \quad (3a)$$

For the data analyzed of different concentrations of lactoferrin binding to CO<sub>2</sub>H-heparin, the affinities,

**Fig. 4** Relationship between the affinities and the ratio of fractal dimension for dissociation to that of binding for lactoferrin binding to CO<sub>2</sub>H-heparin. (A) Increase in the affinity,  $K_1$ , with an increase in the fractal dimension ratio,  $D_{fd}/D_{f1}$ . (B) Increase in the affinity,  $K_2$ , with an increase in the fractal dimension ratio,  $D_{fd}/D_{f2}$ . Legend: as in Fig. 1 legend.

Bionanoparticles - Block

$K_1$  and  $K_2$ , are given by:

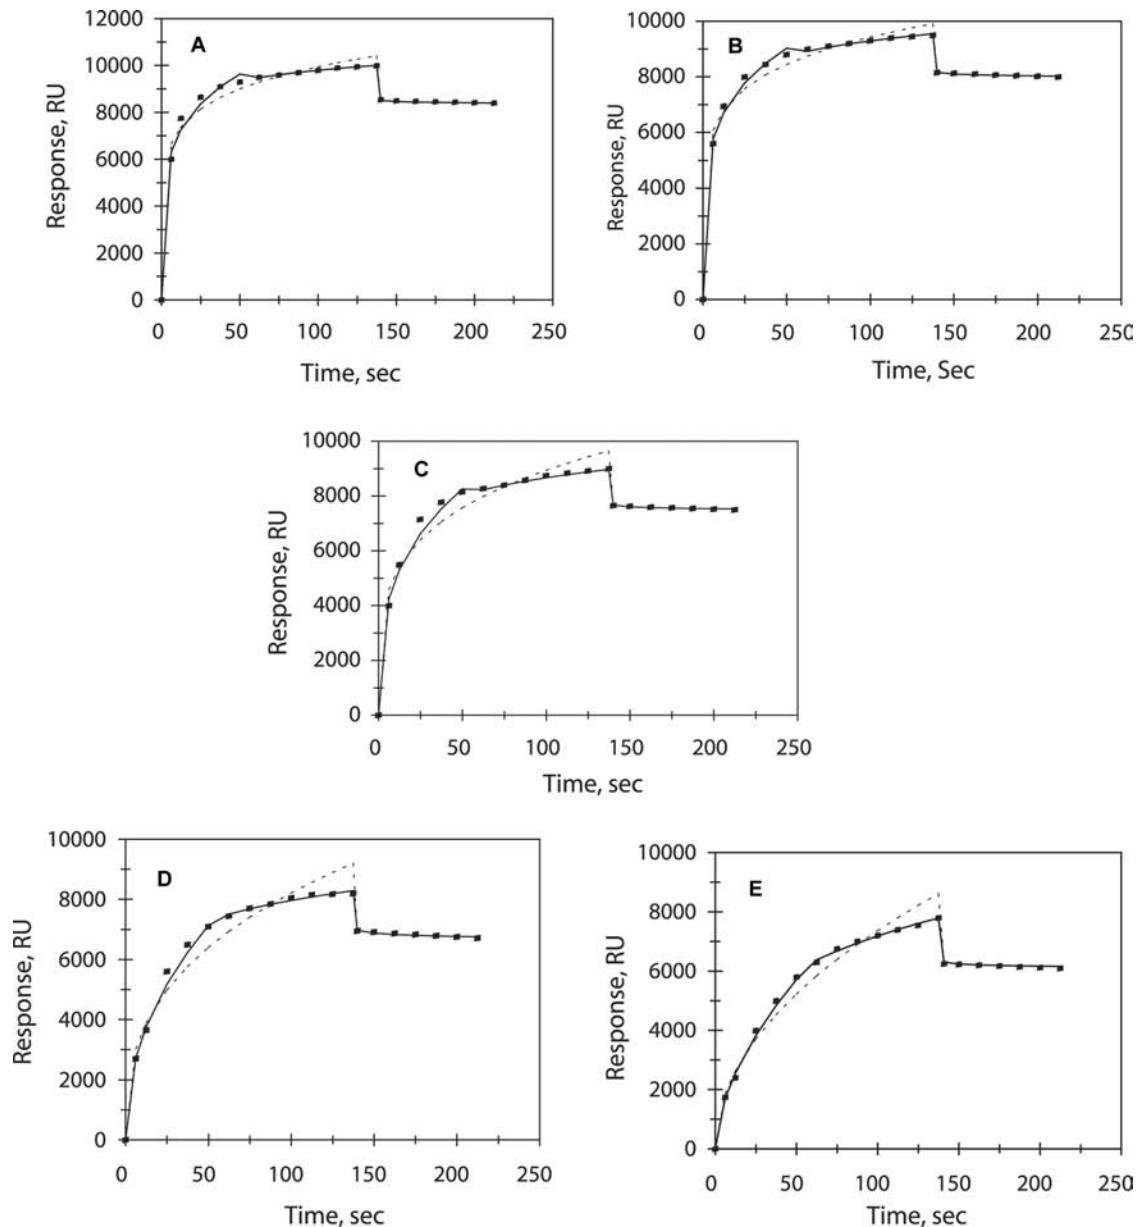

$$(k_d/k_1) = (0.7042 \pm 0.1497) \times (D_{fd}/D_{f1})^{0.8367 \pm 0.6110} \quad (4a)$$

$$(k_d/k_2) = (0.5597 \pm 0.0193) \times (D_{fd}/D_{f2})^{4.728 \pm 2009} \quad (4b)$$

These results suggest heparin attached through the reducing terminus (EP-heparin) had the highest binding capacity followed by heparin immobilized via

intrachain bare amines ( $\text{NH}_2$ -heparin). Heparin immobilized through the carboxylate groups of uronic acids ( $\text{CO}_2\text{H}$ -heparin) had lowest binding capacity. This is in accordance with the results suggested by the authors.

To examine how drug-binding responses were affected by liposome capacity, Baird, Courtenay, and Myszka<sup>[4]</sup> used different amounts of lipids captured on a sensor chip surface by varying the concentration of liposome injected. Fig. 5 shows the binding and dissociation curves obtained for liposome concentrations from 0.25 to 4 mM. For all of the concentrations of

Source: From Ref.<sup>[3]</sup>.

liposome suspension analyzed, a dual-fractal analysis is required to adequately describe the drug–liposome binding kinetics. The dissociation phase is well described by a single-fractal analysis. The values of the binding and the dissociation rate coefficients are given in Table 2. According to the authors there are two types of drugs. Type I drugs dissociate rapidly from the lipid surface and Type II drugs display at least two distinct kinetic phases during the binding and the dissociation. This suggests diffusion of the drug into the phospholipid bilayer. This can be one of the reasons for the need of a dual-fractal analysis (instead of single-fractal analysis) to adequately describe the association (binding) of the drug–liposome interaction. The second reason can be the sigmoidal shape of the binding curve. A sigmoidal curve is usually observed when there is a change in the binding mechanism. For the dissociation case, there is a sharp decrease in the response, suggesting a single mechanism at work, justifying the use of single fractal analysis.

As in the protein–heparin example,<sup>[3]</sup> as the liposome suspension concentration increases, the binding as well as the dissociation rate coefficient increases.

**Fig. 6** (A) Increase in the affinity,  $K_1$ , with an increase in the fractal dimension ratio,  $D_{fd}/D_{f1}$ . (B) Increase in the affinity,  $K_2$ , with an increase in the fractal dimension ratio,  $D_{fd}/D_{f2}$ . Legend: as in Fig. 1 legend.

This leads to an increase in the fractal dimension for binding and dissociation. The reason for this increase in the rate coefficients is the increase in heterogeneity on the sensor chip surface because of increase in density of liposome in solution. An increase in density gives rise to multiple collisions. This in turn increases the effective reaction order, which leads to an increase in the fractal dimension.<sup>[16]</sup>

The affinity values ( $k_d/k$ ) are also calculated and presented in Table 2. Both the affinity values,  $K_1$  ( $k_d/k_1$ ) and  $K_2$  ( $k_d/k_2$ ), exhibit decrease with increase in the concentration of the liposome.

Fig. 6A shows the plot of  $K_1$  vs. the ratio  $D_{fd}/D_{f1}$ . For the data analyzed of different concentrations of liposome, the affinity,  $K_1$ , is given by:

$$(k_d/k_1) = (0.1643 \pm 0.0166) \times (D_{fd}/D_{f1})^{5.638 \pm 0.320} \quad (5a)$$

Note that as indicated earlier, the units of  $k_d$  and  $k_1$  are slightly different.

Fig. 6B shows the plot of  $K_2$  versus the ratio  $D_{fd}/D_{f2}$ . For different concentrations of liposome analyzed, the affinity,  $K_2$ , is given by:

$$(k_d/k_2) = (0.1526 \pm 0.0069) \times (D_{fd}/D_{f2})^{8.896 \pm 0.4046} \quad (5b)$$

Both Eqs. (5a) and (5b) suggest a strong dependence of the affinities on the ratio of fractal dimensions. For correct cell signaling, lower values of  $K$  are beneficial, whereas for incorrect cell signaling higher  $K$  values are beneficial. Knowing the relation of affinity with the fractal dimension (degree of heterogeneity) may suggest useful means by which appropriate interactions (to promote correct cell signaling) and inappropriate interactions (deleterious to health signaling) may be better controlled.

## CONCLUSIONS

A fractal analysis of the binding and dissociation of protein–heparin and drug–liposome interactions along with the influence of different ligands on these interactions occurring on SPR biosensor applications is studied. This analysis provides a quantitative indication of the state of disorder or roughness in terms of fractal dimension on the biosensor chip surface and its effect on the binding and the dissociation rate coefficients and affinity values. This analysis can be considered as an alternate way to understand the kinetics on the heterogeneous surface with diffusion-limited reactions occurring toward structured surfaces.

For example, data taken from the literature<sup>[3,4]</sup> is reanalyzed to include the degree of heterogeneity present on the surface and its influence on the binding and the dissociation kinetics. The analysis of both the binding and the dissociation steps provide a more complete picture of the reaction occurring on the sensor chip surface. The fractal analysis also provides a value of the affinity,  $K$  (the ratio of the dissociation rate coefficient,  $k_d$ , and the binding rate coefficient,  $k$ ). The  $K$  values obtained may give us an idea or provide a basis for *selective modulation* of the surface, thereby changing the binding as well as the dissociation reactions in desired directions. This has biomedical as well as environmental implications.

The degree of heterogeneity can be quantitatively measured in terms of the fractal dimension. The degree of heterogeneity is affected by the presence of ligands on the sensor chip surface. In general, the degree of heterogeneity for the binding and the dissociation phases is different. Both types of examples are presented wherein either a single- or a dual-fractal analysis is required to adequately describe the binding and/or the dissociation kinetics. The dual-fractal analysis is used only when the single fractal analysis did not provide an adequate fit (sum of least squares less than 0.97). This was done by regression analysis provided by Quattro Pro.

Predictive expressions are developed for the affinities,  $K_1$  ( $k_d/k_1$ ) and  $K_2$  ( $k_d/k_2$ ), as a function of the ratio,  $D_{fd}/D_{f1}$  and  $D_{fd}/D_{f2}$ , respectively. The fractal dimension for the binding or the dissociation phase is not a typical independent variable and cannot be directly manipulated. The predictive relationships provide a means by which these binding or the dissociation rate coefficients may be manipulated by changing either the analyte concentration in solution or the degree of heterogeneity that exists on the surface. Note that a change in the degree of heterogeneity on the surface would, in general, lead to changes in both the binding as well as the dissociation rate coefficient. Thus, a careful consideration is required to get the desired result.

It is interesting to note that the fractal surface leads to turbulence, which enhances mixing, decreases diffusional limitations, and leads to an increase in the binding rate coefficient.<sup>[17]</sup> This also applies to the dissociation rate coefficient. For this to occur, the characteristic length of this turbulent boundary layer may have to extend a few monolayers above the sensor surface to affect bulk diffusion to and from the surface. However, given the extremely laminar flow regimes in most biosensors this may not actually take place. A fractal surface is characterized by grooves and ridges, and this surface morphology may lead to eddy diffusion. This eddy diffusion can then help to enhance

the mixing and extend the characteristic length of the boundary layer to affect the bulk diffusion to and from the surface.

In both of the examples discussed above, as the concentration of ligand on the sensor chip surface (for the protein–heparin case) or in solution (for the drug–liposome case) increases, there is an increase in the binding as well as in the dissociation rate coefficient.

Even though the analysis is presented for these interactions occurring on biosensor surfaces, they do provide insights into these reactions occurring on cellular surfaces. More such studies are required to determine if the binding and dissociation rate coefficients are sensitive to the degree of heterogeneity that exists on the biosensor or cellular surfaces. The analysis should encourage cellular experimentalists, particularly people dealing with analyte–nuclear receptor reactions, to pay increasing attention to the nature of the surface and how it may be modulated to control cellular analyte–nuclear receptor reactions in desired directions.

## INTRODUCTION

Science at surfaces and interfaces is central to many phenomena in the life sciences.<sup>[1]</sup> For instance, the topography of the surface of a properly folded protein is almost always more important than its hydrophobic core for functions, such as catalysis, dimerization, or assembly.<sup>[2]</sup> On a higher architectural hierarchy at cellular or tissue level, protein binding at the surface of cell membrane determines the cell physiology including proliferation, differentiation, and viability. This set of biosurfaces bears characteristics that are different from any other man-made surface in both complexity and scale. The surface of a protein contains a wide variety of functional groups, and the surface of cell membrane contains dynamic lipid bilayers imbedded with proteins, which is hardly resembled by any man-made surface such as palladium catalyst. Furthermore, most of the events occurring on these biosurfaces are at nanometer scale. For example, the functional assembly of ribosome executing protein synthesis and the focal adhesion mediating cell adhesion are both on the scale of 40–80 nm. For single protein catalysis, the active side is usually of a dimension larger than 1 nm. In contrast, most man-made surfaces function either at molecular level (catalysis) or at micrometer scale (lithography).<sup>[3]</sup>

The importance of biosurfaces is both highlighted and revealed by the rapid development of biotechnology in recent years.<sup>[4]</sup> In particular, a well-defined problem—bioinertness—first appears as a technological problem, and soon evolves into an intricate puzzle of fundamental science. In this entry, the origin of this unique problem, the development of its solutions and the evolution of theories over a relative short span of time—less than 10 years—will be reviewed. Furthermore, the significance and implication of this problem and its solution will be discussed in the context of life sciences.

## BIOINERTNESS—DEFINING THE PROBLEM

Translating solution assays into arrays on a chip provides an opportunity to accelerate the rate (high

throughput) and scope discovery of biological events and design of drugs. These chip-based, high-content and high-throughput assays are a central theme of contemporary biotechnology. The success of the DNA chip marked one of such example.<sup>[5,6]</sup> However, protein chip technology aimed to decipher the protein–protein binding events in the cell signaling pathways and protein–drug interactions, so called proteomics, faces several challenges that are absent for DNA chips. The key to these challenges lies in the fact that protein's function depends on a folded three-dimensional structure that can easily denature. Hence when immobilizing proteins onto a surface, a number of criteria must be fulfilled to maintain an optimal activity for biological assays.<sup>[7]</sup> The surface should immobilize only desired protein with control of native folding, density, and orientation so that optimal activity or function of immobilized protein is rendered on surface. Among these requirements, the most basic one is the prevention of non-specific protein adsorption, coined by the term bioinertness of the surface. Although the physio-adsorbed protein assays such as enzyme-linked immunosorbent assay (ELISA) has long existed, multiarray chip assays limits the amount of protein immobilized on surface. Thus searching for a bioinert surface that can render the activity of every immobilized protein becomes paramount to the success of proteomics. Bioinertness is defined at two levels. First, resisting protein adsorption; second, resisting cell adhesion.

## RESISTING PROTEIN ADSORPTION

Proteins have a ubiquitous tendency to physically adsorb onto almost all kind of surfaces.<sup>[8]</sup> Biologically active proteins are always folded into three-dimensional structures, burying most of the hydrophobic residues and exposing most of the hydrophilic residues. In vitro, this folded structure is very sensitive to its micro-environment. When the microenvironment such as solvation denies the stabilization of the folded structure, the protein has a high propensity to denature to expose its hydrophobic core that allows interaction with its environment. Hence proteins, by nature, have the

tendency to function as glue to any surface *in vitro*. However, almost all proteins in biological systems depend on properly folded structures. For instance, the protein binding events in the cell signaling processes, cells adhesion, and migration are precisely orchestrated by the activities of proteins through processes such as focal adhesion, fibril formation, and protein binding at the interfaces of cell and extracellular matrix (ECM).

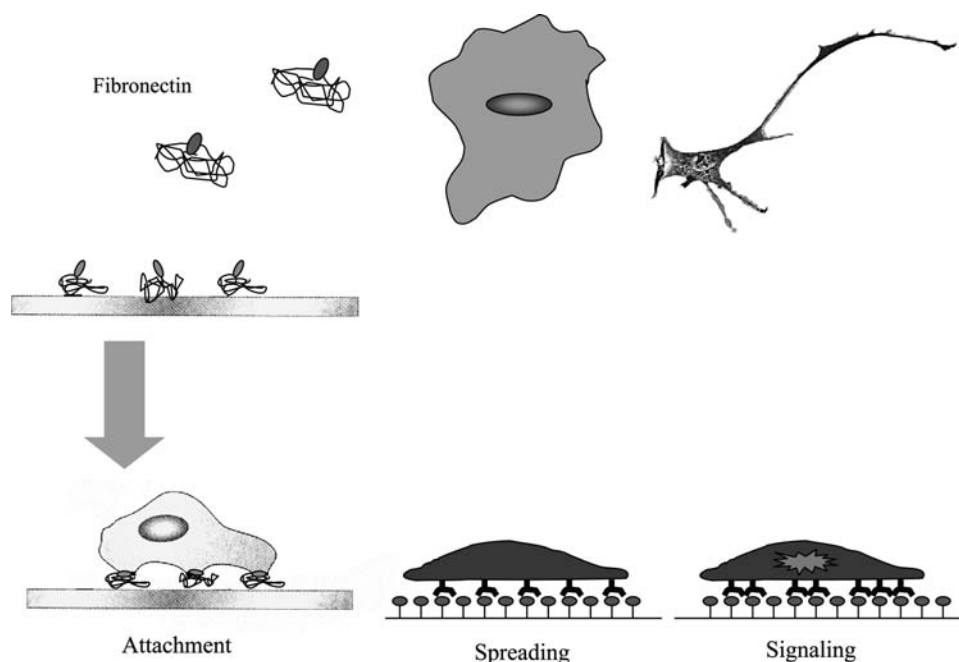

The adsorption of protein under conditions *in vitro* is complicated by various multistage processes (Scheme 1A).<sup>[8]</sup> Depending on the nature of the surface, protein adsorption involves a combination of some of the following processes: 1) dissociation from the surface back to the bulk solution; 2) orientation change; 3) conformation change with retention of activity; 4) denaturation and activity loss; and, 5) exchange with other proteins in the solution. These processes are further complicated by lateral protein-protein interaction on the surface and interactions between the proteins from the bulk and the adsorbed proteins on the surface. An ideal bioinert surface should prevent all of these adsorption processes (Scheme 1B).

## RESISTING CELL ADHESION

For almost all the mammalian cells, their viability depends critically on anchoring and spreading onto a surface, including other cells and the extracellular matrix (ECM). When removed from their animal host, most cells must adhere onto a surface for initiating proliferation. Such anchorage and adhesion is mediated by specific protein binding between various membrane proteins on the cells and external proteins that are produced and secreted by the cells themselves. A membrane protein of cells called integrin specific for fibronectin is responsible for mediating cell adhesion on ECM, as well as on surfaces *in vitro*. The principal recognition sequence in fibronectin for  $\alpha\beta$  receptors in the integrin is just a tripeptide ligand Arg-Gly-Asp (RGD) (Scheme 2). Cell adhesion onto substrate *in vitro* is a complex multistage process including cell attachment, spreading, focal adhesion formation, extracellular matrix deposition, and rearrangement.<sup>[9,10]</sup> When cells are completely denied attachment onto a surface, a suicidal program—apoptosis—is carried out which results in cell death, dissimulation, and release of all its cellular components involving cytolitic

Scheme 1 Resisting protein adsorption.

Scheme 2 Cell adhesion.

and membrane proteins into the medium (Scheme 3). Hence on almost all surfaces, the fibronectin secreted by cells will physically adsorb to surfaces and facilitate cell attachment, adhesion, proliferation, and other cell activities.

Because cell culture in medium lasts weeks or longer, an ideal bioinert surface should resist protein adsorption and subsequent cell adhesion over long periods of time. Therefore resisting long-term cell adhesion is a more stringent requirement than resisting protein adsorption alone. This requirement also sets the standard to differentiate the strength of the bioinertness between surfaces that appear to be equally competent at resisting protein adsorption alone.

Scheme 3 Resisting cell adhesion.

### KNOWLEDGE FROM POLYMER-COLLOIDAL SCIENCE

Efforts using different means have been devoted to identify bioinert surfaces. An early strategy involves grafting a surface with polymers—poly(ethylene glycol)—to resist protein adsorption.<sup>[11]</sup> These polymer-grafted surfaces suffer from the inability to present ligands at the surface with known density, orientation, and degree of exposure. Another widely adopted strategy uses preadsorption of a protein—usually bovine serum albumin (BSA)—that resists the adsorption of other proteins.<sup>[12]</sup> This pretreatment of surfaces with BSA suffers from problems associated with denaturation of blocking protein over time, and exchange with other proteins in solution. In short, both strategies present an undefined microenvironment on surfaces that cannot be controlled with molecular resolution, which is of paramount importance for chip-based protein assays.

For controlling the chemistry of the surface on which protein is to be immobilized, self-assembled monolayers (SAMs) of alkanethiols on gold provides an ideal system to allow for molecular-level control of surface properties.<sup>[13]</sup>

This particular class of SAMs differs from others in that they form a well-packed monolayer, presenting almost a two-dimensional crystalline structure on surface. Furthermore, because organic synthesis provides

**Scheme 4** Self-assembled monolayer of alkanethiols on gold.

a powerful means to tether almost any functional groups (R) to the alkanethiol, this class of monolayer provides a versatile range of functional groups on surfaces, thus the surface chemistry and interfacial properties is rationally controlled.

In an early effort of designing the terminal functional groups of alkanethiols that assemble into a bioinert monolayer, knowledge was brought from polymer/colloidal science. It turns out that poly(ethylene glycol) is known to prevent colloid coagulation, and shows signs of resisting adsorption of proteins. Prime and Whitesides<sup>[14]</sup> synthesized oligo(ethylene glycol)-terminated SAMs and tested their resistance to protein adsorption. This class of SAMs turns out to resist, to a great extent, both non-specific protein adsorption and cell adhesion, and become the current standard for bioinert surfaces (Scheme 4).<sup>[15]</sup>

The mechanistic origin of the bioinertness of this class of surface is not clear. One possible mechanism is the theory of steric repulsion for poly(ethylene glycol) developed by Jeon and coworkers.<sup>[11]</sup> The theory consists of two thermodynamic considerations. First, adsorption of protein to PEG results in a compression of the glycol chains, causing an entropic penalty because of the restriction in conformational dynamics of the polymer chains. Second, this compression also results in desolvation of polymers, thus

transferring solvated water into the bulk, which incurs an enthalpic penalty. However, the validity of translating this theory from polymer science to surface is in question. Feldman and coworkers<sup>[16]</sup> demonstrated some experimental evidence that disputed the relevance of this theory to the bioinertness of an oligo(ethylene glycol)-terminated SAMs.

### SOME EDISONIAN ATTEMPTS

Apart from the ambiguity in the science of how a bioinert surface resists the non-specific adsorption of proteins, it is of both fundamental and practical interest to develop other bioinert surfaces other than oligo(ethylene glycol)-terminated SAMs. Several Edisonian attempts have been carried out to search for a second bioinert SAM that is at least as good as oligo(ethylene glycol)-terminated SAMs (Scheme 5). For instance, Whitesides noted some scattered observation that hydrogen bond acceptors seem to be important for inertness, whereas hydrogen bond donors promote protein adsorption.<sup>[17]</sup> Another consideration is the effect of surface charges by a Zwitterion-terminated SAM, which essentially resembles the "skin" of a protein.<sup>[18]</sup> While all these surfaces resist protein adsorption to some extent, they all

**Scheme 5** Examples of other attempts by an Edisonian approach.

fall short when compared with oligo(ethylene glycol)-terminated SAMs at resisting long-term cell adhesion.

## WONDERS OF AN ANCIENT SCIENCE

When examining all these examples of different bioinert SAMs, more puzzling is the fact that there is no sufficient correlation between the bioinertness and any surface properties such as hydrophobicity, hydrogen bond donors/acceptors, or surface charges. With this seemingly insurmountable puzzle, the hope for finding another bioinert surface that is at least as good as oligo(ethylene glycol)-terminated SAMs seems hopeless. However, a rare phenomenon in the history of protein science leads to a new way of looking at this problem of bioinertness. This rarity centered at an ancient empirical discovery, which is not well understood but still widely used in protein chemistry today.

In 1888 A.D., Frank Hofmeister discovered some stabilizing and destabilizing effects of a series of cations and anions on protein structure, which have been used and unchallenged for the last 115 years in handling protein samples (Scheme 6).<sup>[19]</sup> The observation indicated that the same charge on different metal species bears significant different, sometime opposite, effect on the stability of folded protein structure. The mechanistic origin of this observation is not well understood, and thus the ions are empirically classified into two categories. Chaotropic ions destabilizing protein folding are thought to be, loosely speaking, disruptive to water structure, whereas kosmotropic ions stabilizing protein structure are regarded as enhancing water structure. It is generally believed, without rigorous evidence, that shells of water are induced by the solvated ions.<sup>[20]</sup> Depending on the identity of the ions, the structure of these water layers either disrupts (chaotropic) or enhances (kosmotropic) the stability of the folded structures of protein.

## CUES FROM CONTEMPORARY SCIENCE

An interesting theoretical work by Sharp in 1998 further shed light on the significance and subtlety of these water structures.<sup>[21,22]</sup> Sharp demonstrated by computer simulation that while both amino and hydroxyl groups are hydrophilic, each induced a

Anions:  $\text{SCN}^- > \text{NO}_3^- > \text{Cl}^- > \text{citrate}^- > \text{acetate}^- > \text{phosphate}^- > \text{SO}_4^{2-}$   
 Cations:  $\text{Ca}^{2+} > \text{Mg}^{2+} > \text{Na}^+ = \text{K}^+ > \text{NH}_4^+ > \text{N}(\text{CH}_3)_4^+$

Chaotropic (structure breaker)  $\longleftrightarrow$  Kosmotropic (structure maker)

**Scheme 6** Hofmeister series.

drastically different water structure that can be distinguished by properties such as density and heat capacity. Surprisingly, amino groups behave similarly to that of a hydrophobic methyl group in this regard of inducing water structure in the shells of solvation. From an experimentalist point of view, this theoretical prediction is astonishing, and perhaps bears a profoundness much overlooked. This is because while the hydrophobicity is completely opposite to each other, both amine- and methyl-terminated surfaces are highly “sticky” for protein adsorption.

## WORKING HYPOTHESIS BASED ON WATER STRUCTURE

Lessons from this century-old science and contemporary theoretical work lead me to a perhaps silly question that humanizes protein: “What if proteins are presented to a surface that they cannot ‘see’?” Furthering this concept, if the protein cannot “feel” the presence of any surface, then there is nothing for them to adsorb to.<sup>[23]</sup> With all the past failures providing me the notion that “what else could be worse?,” I translated this idea into a workable system by covalently “fusing” water molecules into the terminal groups of a surface (Fig. 1). Returning to the terminology in chemical science, this system provides a chemically chiral surface presenting self-assembled monolayer of polyol-terminated alkanethiols. The chirality comes from the fact that substitution of each hydroxyl group, except the very last one, causes a chiral tetrahedron carbon center. Natural isomeric forms of sugars—alditols—provide a convenient building block for synthesizing polyol-terminated alkanethiols. D-Mannitol was chosen from 16 possible stereoisomers of alditols primarily for the synthetic feasibility.

## ANALYTICAL TOOLS FOR MEASURING THE BIOINERTNESS

Surface plasmon resonance (SPR) spectroscopy is used to measure the amount of protein adsorbed on a surface.<sup>[24]</sup> SPR is an optical technique that measures the changes in the attenuated total reflection of a thin layer of metal film as a result of the changes in refractive index at the interface of the metal and bulk solution. With a thin layer of metal film, the resonance between the electron oscillation in the metal film and the light at a certain incident angle causes absorption of light and attenuation of the total reflection (ATR). The ATR is extremely sensitive to small changes of the refractive index at the interface of the gold film and the bulk solution, and hence provides a means to accurately measure the adsorption phenomena in the

**Fig. 1** The rationale of creating an analog of water layer at the interface. To mimic a layer of solvated water at the surface (A), water molecules are covalently “fused” into the terminal region of alkanethiols in the form of polyols (B).

medium near (within  $\sim 200$  nm) the metal surface, which causes increase in the refractive index. Fig. 2A shows a schematic representation of the measurement by SPR. Monochromatic, p-polarized light is reflected from the backside of the glass–gold interface. The changes in the refractive index of a solution near the interface with a gold film are measured by changes in the angle ( $\Delta\theta_m$ ) at which p-polarized light reflected from the glass/gold interface has a minimum intensity (Fig. 2B). When the refractive index increases at the interface, the angle of ATR increases.

Fig. 3 shows a hypothetical plot to illustrate an SPR experiment for the irreversible adsorption of a protein to the sensing surface. SAMs were mounted against a flow cell and experiments were performed by first flowing a phosphate-buffered saline (PBS) buffer through the cell for 5 min, then a solution of protein in the same buffer (0.5 mg/mL) for 5 min, and finally the original PBS buffer for 5 min.<sup>[25]</sup> The increase in  $\Delta\theta_m$  upon introduction of the protein solution has

two contributions. The first is a result of the increase in refractive index of the solution caused by the dissolved protein—the “bulk effect”—and does not represent protein adsorption.<sup>[25]</sup> The second contribution is a result of the adsorption of protein to the SAM. The amount of protein that adsorbs irreversibly to the SAM is determined by comparing the shift in  $\theta_m$  before and after the SAM is exposed to protein. An increase in  $\theta_m$  of  $0.1^\circ$  corresponds to an increase in density of adsorbed protein of  $1 \text{ ng/mm}^2$ .

Microcontact printing of monolayers of alkanethiols is used to create spatially resolved islands that are sticky to protein adsorption surrounded by the SAMs, on which the resistance against cell adhesion is to be tested. The procedures for creating microcontact printed patterns are simple and easy to perform (Scheme 7).<sup>[26]</sup> Starting with a commercially purchased (or custom-made) cast, an elastic stamp is molded out of cross-linked polymer polydimethylsiloxane (PDMS) elastomer. The stamp is first inked with a 2-mM

**Fig. 2** A general scheme on the operation of surface plasmon resonance spectroscopy to measure the adsorption of protein to a self-assembled monolayer (SAM) in situ and in real-time (A). The attenuated total reflection by electron oscillation in thin metal film (B). As the incident angle ( $\theta$ ) increases, the intensity of reflected light ( $I$ ) increases until a maximum equal to the intensity of the incident light is reached (total reflection). With a thin layer of metal film, a sharp decrease of the reflected light occurs in the region of total reflection due to the resonance between the light at a certain incident angle and the electron oscillation. This resonance causes absorption of light and attenuation of the total reflection (ATR) at a specific incident angle.

**Fig. 3** A hypothetical plot to illustrate an SPR experiment for irreversible adsorption of a protein to the sensing surface. SPR records the angle of minimum reflectivity of incident light versus time. A buffer flows through the channel, replaced by the same buffer but containing the protein, and then returns to the buffer without the protein.  $\theta_m$  increases when the protein is passed through the cell, as a result of both the increase of bulk refractive index and the irreversible adsorption of protein on the surface, and then decreases to another plateau as the blank buffer is introduced again. The buffer passes through the channel removing all the protein in the bulk but leaving the irreversibly adsorbed protein on the surface. The dashed curve represents the contribution to  $\Delta\theta_m$  of dissolved protein (bulk effect) that increases the refractive index of the buffer. The difference between the two curves at the end of the experiments measures the amount of protein adsorbed to SAM. *Source:* From Refs.<sup>[24]</sup> and <sup>[25]</sup>. American Chemical Society.

ethanolic solution of methyl-terminated alkanethiol. Then, a very brief contact (stamping) of 15–20 sec on the gold film results in a patterned self-assembled monolayer. Followed by soaking in ethanolic solution of a second alkanethiol, the naked gold films surrounding the patterned SAMs are filled with monolayers of the second alkanethiols. The patterned SAMs are placed into a culture medium, in which cells adhered and proliferated on the surface of the SAMs. The inertness of the SAMs (both the microcontact printed and back filled regions) is then monitored by observing the cell adhesion through a light microscope at desired time points over long-term (weeks) cell culture.

### THE BIOINERTNESS OF POLYOL-TERMINATED SAMs—RESISTING PROTEIN ADSORPTION

With the working hypothesis of an invisible wall to the proteins, we compared protein adsorption and cell attachment on seven different SAMs (Scheme 8).<sup>[23,27]</sup> SAMs presenting methyl groups [hexadecanethiol (HDT)] and tri(ethylene glycol) group were again used as standards for sticky and inert surfaces, respectively. The two monolayers presenting the mannitol groups differed in the length of the alkyl chain to which the mannitol group was appended. Alkanethiol **1a** has an alkyl chain of 11 methylene units, which is the standard length in SAMs that are used in biointerfacial science.

**Scheme 7** Microcontact printing.

**Scheme 8** Alkanethiols for bio-inert and sticky surfaces.

Alkanethiol **1b** has three fewer methylene units in the alkyl chain, and was investigated with the goal of finding inert monolayers that are overall thinner. The amine-, hydroxyl-, and diol-terminated SAMs served for evaluating the bioinertness/stickiness by different properties of the surface due to the organized functional groups at the terminus.

Fig. 4 shows data for investigating the adsorption of protein fibrinogen onto the four SAMs by SPR. A complete monolayer of protein, which corresponds to a protein density of  $3500 \text{ pg/mm}^2$ , adsorbs to the SAM of hexadecanethiol. The two monolayers presenting mannitol groups, by contrast, show essentially

**Fig. 4** Data from surface plasmon resonance spectroscopy for the adsorption of fibrinogen ( $0.5 \text{ mg/mL}$  protein in  $10 \text{ mM}$  phosphate,  $150 \text{ mM}$  sodium chloride,  $\text{pH} = 7.6$ ) to each of the seven SAMs (Scheme 8). The monolayer is indicated to the right of each plot. The relative change in angle of minimum reflectivity ( $\Delta\theta_m$ ) is plotted as solutions are flowed over the SAM. Source: From Ref.<sup>[27]</sup>. American Chemical Society.

no adsorption of fibrinogen. This lack of adsorption is indistinguishable from that of monolayers presenting tri(ethylene glycol) groups. Experiments with the four other proteins yielded similar results, and demonstrated that the mannitol group is broadly effective at preventing protein adsorption (Table 1). For all five proteins, the amount of irreversible adsorption on D-mannitol-terminated SAMs was less than 2% of the total amount that adsorbed on the methyl-terminated SAMs (HDT). Fibrinogen, being a tetrameric protein complex, is the most sticky protein known and is used as the most stringent test for bioinertness of a surface toward protein adsorption. This set of results indicates that mannitol-terminated SAMs are highly inert against protein adsorption, and its bioinertness toward protein adsorption is indistinguishable from the current standard—oligo(ethylene glycol)-terminated SAMs. The amount of protein adsorption on other SAMs, amine-, hydroxyl-, and diol-terminated monolayers, is consistent with the working hypothesis of an invisible wall to the proteins. The amine-terminate SAM, a surface thought to disrupt the water structure at interface, bears the greatest amount of adsorbed fibrinogen. The diol-terminated SAMs bear the amount of adsorbed fibrinogen in between hydroxyl- and mannitol-terminated SAMs.

## THE BIOINERTNESS OF POLYOL-TERMINATED SAMs—TWO-DIMENSIONAL JAIL FOR ADHERENT CELLS

The bioinertness of mannitol-terminated monolayers against adhesion and growth of living cells 3T3 fibroblasts are evaluated on patterned SAMs.<sup>[27]</sup> Scheme 9 shows a schematic representation of the patterned SAMs on gold films by microcontact printing. Sets of circular regions of hexadecanethiol of different diameters were surrounded by inert SAMs of **1a**, **1b**, or **2**. The cross section of the mannitol head group occupies a larger area than that of the methyl group of the HDT region. The thiol-gold coordination of D-mannitol-terminated alkanethiols on gold surface is not known, but a close-packed monolayer is expected. The methyl-terminated SAM created by microcontact printing is known to adopt the close hexagonal packing of alkanethiol on gold just as those assembled from free molecules in solution.

Cells are known to adhere to methyl-terminated monolayers, but regions of D-mannitol are hypothesized to be inert. Four different sizes of circular HDT pattern were used on the same gold substrate, as indicated beneath the schematic representation of the pattern. When a suspension of cells is introduced to the patterned SAMs, cells should initially only attach,

spread, and proliferate on the methyl-terminated regions, but over time, may invade the surrounding inert regions. The time period that cells remain confined to the hydrophobic region is a quantitative measure of the bioinertness of the surface.

Patterned cell adhesion of albino 3T3-Swiss fibroblasts was maintained at 37°C in serum-containing media for 4 weeks. Media was exchanged every 5 days, and cells were photographed daily. Fig. 5 shows the cell adhesion confinement in the methyl-terminated region surrounded by inert alkanethiols, **1a** and **1b**, in comparison with surfaces presenting alkanethiol **2**. On all three surfaces, cells remained patterned to the circular regions of hexadecanethiol for at least 6 days in culture. The tri(ethylene glycol)-terminated monolayers began to fail after 7 days, with cells spreading onto the inert regions. After 12 days, cells had migrated from the circular regions and divided to give

a confluent monolayer of cells, with a complete loss of pattern. Monolayers terminated in the mannitol group (**1a**) were substantially more effective at confining cells for longer periods. Even after 21 days, cells remained completely confined to the patterns. After 25 days in culture, the physiology of the adherent cells may have changed extensively, and thus preventing cell adhesion may no longer be relevant. Monolayers presenting the mannitol group on the shorter alkyl chain (prepared from alkanethiol **1b**) were also more effective than monolayers presenting tri(ethylene glycol) group, but were not as effective as monolayers of **1a**. Monolayers of **1b** generally failed at 2 weeks in culture. We have repeated these long-term patterning experiments on three separate occasions with consistent results: monolayers of **2** fail at approximately 1 week, monolayers of **1b** fail at approximately 2 weeks, and monolayers of **1a** are effective for at least 3 weeks.

**Scheme 9** Representation of patterned SAMs by microcontact printing.

**Fig. 5** Comparison of the bioinertness against cell adhesion by D-mannitol-terminated SAMs vs. tri(ethylene glycol)-terminated SAM. 3T3 fibroblast cells were confined to SAMs patterned into circular regions (200  $\mu\text{m}$  in diameter) of hexadecanethiol (HDT) with intervening regions of **1a**, **1b**, or **2**. Optical micrographs are shown for cells attached to each of three patterned monolayers over a period of 25 days. The structures of the alkanethiols comprising the inert regions of the patterned monolayers are indicated above each column of photographs. The number of days that substrates were in culture is indicated to the left. *Source:* From Ref.<sup>[27]</sup>. American Chemical Society.

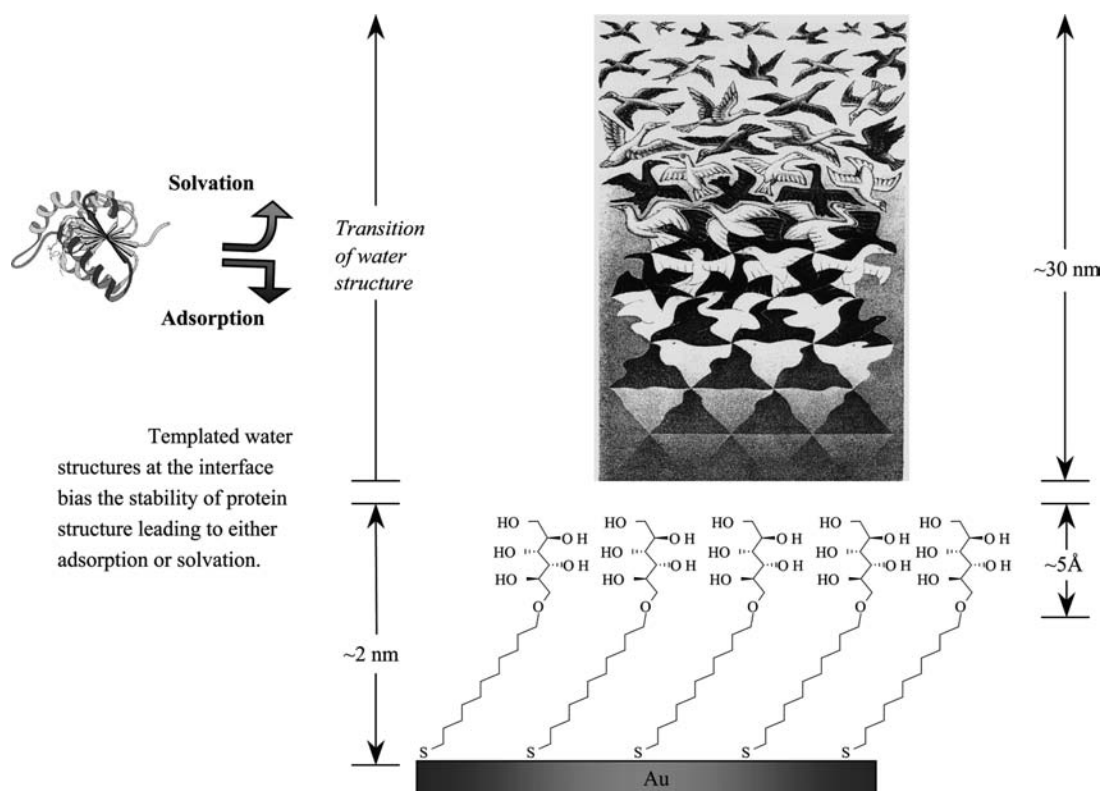

## THEORETICAL CONSIDERATIONS AND PERSPECTIVES

Other approaches using polymer grafted surfaces has also been explored. However, in those cases, the surface chemistry cannot be well defined at molecular level.<sup>[28,29]</sup> For example, the grafted polymer was fabricated into three-dimensional “corrals” having walls of  $\sim 5.2 \mu\text{m}$  in height and lateral dimensions on the order of  $60 \mu\text{m}$ .<sup>[29]</sup> Considering that adherent cells are only  $1\text{--}2 \mu\text{m}$  in thickness, it is difficult to determine whether the resistance of cell adhesion in the later period of cell culture is attributable to geometric confinement or the bioinertness of the surface.

The success in mannitol-terminated SAMs echoes the initial rationale of creating a water layer that the protein cannot “see.” However, extreme caution and rigor must be exercised when correlating bioinertness

and protein stability to water structure. The following mechanism for bioinertness is nevertheless proposed. At the interface of bulk water and any surface, a layer of water templated from the surface possesses a certain organization of hydrogen bonding network that is, in general, different from the hydrogen bond network in the bulk. When a protein is present, this templated water layer at the interface influence the stability of the folded protein structure leading to either adsorption (destabilize protein structure) or solvation (stabilize protein structure). Adopting an artwork by M. C. Escher, **Fig. 6** shows a schematic illustration of this proposed mechanism for bioinertness. The value of  $30 \text{ nm}$  of templated water structure shown in the scheme is adopted based on a force measurement (atomic force microscopy) of protein-coated tip approaching to the tri(ethylene glycol)-terminated monolayers by Feldman and coworkers.<sup>[16]</sup>

**Fig. 6** Schematic illustration of the proposed mechanism for bioinertness. The terminal functionality at the surface of the SAM templates particular water structure at the interface that is different from the bulk water. Such transition of water structure is represented by an artwork by M.C. Escher entitled “Liberation.”

It is very important to note that the study of water structure has been both difficult and controversial.<sup>[30–32]</sup> Notable examples of pathological science related to water structures include the “water memory,”<sup>[33]</sup> and “cold fusion.”<sup>[34]</sup> Both of these two examples have stirred considerable attention and enjoyed a very brief pyrotechnic fame in the scientific community, but were eventually determined as perhaps unintentional, fakery, or misinterpretation of results. Yet a range of discoveries—as early as Hofmeister effect.<sup>[19,20]</sup>—continue to suggest that water structure is at the heart of a range of observations in the life sciences.<sup>[35–38]</sup> In a recent report regarding bioinertness, Kane and coworkers<sup>[39]</sup> updated the surface properties of SAM that gave rise to bioinertness, and summarized that kosmotropes may form the basis of protein-resistant surface. Throughout their article, the authors have entirely avoided using ambiguous terms such as “water structure” or even “hydrogen bonding network.” This rigor is perhaps rightfully justified. However, it is equally important to point out that it is conceivable that certain stereochemical arrangement of hydroxyl group—a kosmotrope—can template a certain water structure at the interface that bias the resistance to protein adsorption and cell adhesion. Some early

experimental results have been obtained with respect to this hypothesis.<sup>[23]</sup>

## CONCLUSION

Biosurfaces is central to many phenomena in the life sciences at the scale ranging from nanometer (protein binding) to micrometers (cell adhesion and behavior). The first and foremost requirement for working with biosurfaces is the control of non-specific adsorption of protein and adhesion of cells. While the empirical chemistry providing a bioinert surface is largely established, the exact mechanism (science) of bioinertness remains to be investigated. These mechanistic studies bear much intricate and valuable science that will have great impact on areas such as drug design, medical implants, as well as scaffold for tissue engineering.

## EXPERIMENTALS

All experimental procedures presented in this entry are well documented in the published journal articles, except the organic synthesis of mannitol-terminated

alkanethiols. Organic synthesis essentially represents a molecular carpentry that allows never-existed molecules to be made. The craftsmanship is then both the design of reactions leading to the final desired product, as well as the technical skill for executing each reaction.

The synthesis of mannitol-terminated alkanethiol is documented below. The synthesis consists of six steps of published discovery that spans across the long history of organic synthesis (Scheme 10). A brief summary of the synthesis consists of bromine oxidation of a mannose to afford mannonic 1,5-lactone, followed by acetone protection of the adjacent diols. Open 1,2:3,4-di-*o*-isopropylidene-alditol was obtained by reducing the protected lactone with lithium aluminum hydride to expose a primary hydroxyl group (and a secondary hydroxyl group in the middle). Alkylation with the alkenylic bromide affords alkyl ether tethering protected polyols. Deprotection by acid hydrolysis of the ether affords the final product of mannitol-terminated alkanethiols. Two-dimensional nuclear magnetic resonance (NMR) experiments were used to establish atomic confirmation of the regioselectivity for the primary hydroxyl group. Each of the protons was assigned by a combination of homonuclear decoupling and correlated spectroscopy (COSY) NMR experiments. Nuclear Overhauser enhancement spectroscopy (NOESY) experiment was also used to confirm the spatial connectivity.

### D-Mannonic- $\gamma$ -1,5-Lactone

To a solution of D-mannose (2 g, 11.1 mmol) in deionized water (30 mL) was added bromine (31 g, 10.5 mL, 194.25 mmol). The solution was sealed by a balloon filled with N<sub>2</sub>, and was stirred for 20 hr at

room temperature. Then the bromine was removed through vacuum until the reddish solution turned colorless. Silver (I) carbonate was added with stirring until the solution turned neutral. The solution was then filtered to remove AgBr and excess Ag<sub>2</sub>CO<sub>3</sub>, and dried by lyophilization to give 1.4 g (7.86 mmol, 71%) of D-Mannonic- $\gamma$ -lactone as a white solid: <sup>1</sup>H NMR (400 MHz, CD<sub>3</sub>OD)  $\delta$  4.60 (d, *J* = 5.54, 1H), 4.43 (dd, 2H), 3.83–3.80 (q, 2H), 3.637 (d, 2H).

### Protected D-Mannonic 1,5-Lactone, 2

To a solution of D-Mannonic 1,5-lactone **1**, (1.62 mmol) in acetone was added 0.04 mL of 12 N H<sub>2</sub>SO<sub>4</sub> and anhydrous CuSO<sub>4</sub> (200 mg). The solution was stirred for 7 hr and dried in vacuo. Purification by flash chromatography (silica gel, 2% methanol/methylene chloride) gave milligrams of desired **2** (1.31 mmol, 80%): <sup>1</sup>H NMR (400 MHz, CDCl<sub>3</sub>):  $\delta$  4.58–4.65 (dd, 1H), 4.40–4.47 (q, 1H), 4.38 (s, 1H), 4.16–4.13 (t, 1H) 3.99–3.95 (dd, 1H), 1.44 (s, 3H), 1.43 (s, 3H), 1.40 (s, 3H), 1.37 (s, 3H).

### 1,2:3,4-di-*o*-Isopropylidene-D-Mannitol, 3

To a solution of protected D-Mannonic 1,5-lactone **2** (1.66 mmol) in THF was added 3.32 mL of LiAlH<sub>4</sub> (1 M in ether). The solution was stirred under nitrogen for 7 hr and dried in vacuo. Purification by flash chromatography (silica gel, 10% methanol/methylene chloride) gave mg (1.25 mmol, 75%) of desired **2**: <sup>1</sup>H NMR (400 MHz, CD<sub>3</sub>OD):  $\delta$  4.38–4.35 (dd, 1H), 4.32–4.27 (m, 1H), 4.14–4.08 (m, 2H), 3.99–3.93 (td, 1H), 3.87–3.75 (m, 2H), 3.62–3.60 (m, 1H), 1.55 (s, 3H), 1.40 (s, 3H), 1.37 (s, 3H), 1.35 (s, 3H).

Scheme 10 Synthesis of mannitol-terminated alkanethiols.

### Undecenyl 1,2:3,4-di-*o*-Isopropylidene-*D*-Mannon Ether, 4

To a solution of 1,2:3,4-di-*o*-isopropylidene-*D*-mannitol **3**, (316 mg, 1.20 mmol) in *N,N*-Dimethyl Formamide (DMF) (10 mL) was added sodium hydride (30 mg, 60% dispersion in oil, 1.20 mmol). The solution was stirred for 10 min at room temperature and then 8-bromo-1-octene (220 mg, 1.20 mmol) was added over a period of 5 min. The solution was stirred for 12 hr and then concentrated in vacuo. The residue was purified by flash chromatography (1.5% CH<sub>3</sub>OH/CH<sub>2</sub>Cl<sub>2</sub>) to give 330 mg (0.883 mmol, 73%) of **4** as a colorless oil: <sup>1</sup>H NMR (400 MHz, CDCl<sub>3</sub>) δ 5.82–5.72 (m, 1H), 4.92 (q, *J* = 10.2, 2H), 4.41–4.30 (m, 2H), 4.12–3.95 (m, 3H), 3.77–3.65 (m, 2H), 3.13 (d, *J* = 6.16, 1H), 2.00 (q, *J* = 7.1, 2H), 1.53 (s, 3H), 1.42 (s, 3H), 1.40 (s, 3H), 1.37 (s, 3H), 1.18 (m, 6H).

### Thioester *S*-(11-Undecenyl 1,2:3,4-di-*o*-Isopropylidene-*D*-Mannon Ether, 5

A solution of **4** (151 mg, 0.41 mmol), thiol acetic acid (91 mg, 1.2 mmol), and 2,2'-azobisisobutyronitrile (AIBN) (80 mg, 0.487 mmol) in tetrahydrofuran (THF) (15 mL) was irradiated with UV light (Rayonet Photochemical Reactor Lamp) in a photochemical reactor for 5 hr with stirring. The solution was concentrated in vacuo and the residue was purified by flash chromatography (1% CH<sub>3</sub>OH/CH<sub>2</sub>Cl<sub>2</sub>) to give 147 mg of **4** (0.328 mmol, 82%) as a colorless oil: <sup>1</sup>H NMR (400 MHz, CDCl<sub>3</sub>) δ 4.41–4.30 (m, 2H), 4.12–3.95 (m, 3H), 3.77–3.65 (m, 2H), 3.57–3.47 (m, 3H), 3.14–3.12 (d, *J* = 6.16, 1H), 2.90–2.85 (t, *J* = 7.38, 2H), 2.33 (s, 3H), 1.64–1.55 (m, 4H), 1.53 (s, 3H), 1.42 (s, 3H), 1.40 (s, 3H), 1.37 (s, 3H), 1.41 (m, 6H).

### 6-(11-Mercapto-Undecyloxy)-*D*-Mannitol, 6

(Mannitol-terminated alkanethiol, **1b**) To a solution of **5** (147 mg, 0.328 mmol) in methanol (15 mL) was added 5 drops of 12 N HCl. The solution was refluxed for 8 hr, cooled to room temperature, and concentrated in vacuo. The residue was purified by recrystallization from methanol to give 61 mg of **1b** (0.187 mmol, 57%) as a white solid: <sup>1</sup>H NMR (400 MHz, CD<sub>3</sub>OD) δ 3.85–3.59 (m, 6H), 3.58–3.46 (m, 4H), 2.52–2.45 (t, 2H), 1.64–1.55 (m, 4H), 1.45–1.28 (m, 8H).

### A POSTLUDE

A little later (on the time scale of scientific publication) after the establishment of the bioinertness of mannitol-terminated SAM, Tan and coworkers<sup>[40]</sup> discovered an

interesting, even anomalous, property of oligo(ethylene glycol)-terminated SAMs with respect to resisting protein adsorption. Using microcontact printing, Tan and coworkers immobilized protein onto a number of SAMs under “dry” condition. That is, the protein are inked on an elastomeric stamp, and then transferred onto SAMs in the absence of any water or solvent. Surprisingly, SAMs presenting oligo(ethylene glycol)s were loaded with more protein than other hydrophobic SAMs under this “dry” condition. This result suggests that protein adsorption on surface is not merely determined by the properties of protein and the chemistry of the surface alone, but the solvent effect, microenvironment of the protein (i.e., solvation), and the interface of the surface must also be taken into account. This microenvironment surrounding the proteins and in the interface above a surface inevitably points to the intricate realm of different water structures.

### ACKNOWLEDGMENT

I would like to thank my advisor, professor Milan Mrksich, for the opportunity of completing this work. He introduced me to the fascinating world of the life sciences, and taught me the use of a valuable tool—bioorganic chemistry—to work in such interdisciplinary areas. I also appreciate his support and encouragement throughout graduate school, and his tolerance of my sometimes excessive free spirit.

## INTRODUCTION

The use of nanoscale objects is a way to enhance properties of materials in a wide range of fields because the small dimensions of the objects can be responsible for high specific surface or for quantum effects. Nanotechnology is consequently of great interest in electronic materials or biomedical applications. The challenge is to realize nanoscale systems with size and morphology control. In this context, our aim is to study the self-assembly of AB block copolymers containing two incompatible polymers to form nanoparticles in solution.

It has been known for many years that when AB block copolymers are dissolved in a solvent that is selective for one of the blocks, colloidal aggregates such as micelles can form as a result of the association of the insoluble blocks. When the insoluble A block is flexible, spherical micelles with an amorphous core are obtained, whereas if the A block is rigid, micelles with anisotropic shapes can result.

In this entry, we study the formation of nanoparticles obtained in solution by cocrystallization of AB and A'B diblock copolymers, where the A and A' blocks can cocrystallize. In a selective solvent (good for B and bad for A and A'), the mixture is expected to self-assemble in particles with a crystalline core (AA') surrounded by a shell (B) swollen with the solvent.

This type of complex can be obtained by mixing optically active polymers with identical chemical structures but opposite optical configurations. Poly(L-lactide) (PLLA) and poly(D-lactide) (PDLA) are semicrystalline polymers that form a racemic crystal called stereocomplex. We have thus synthesized poly(L-lactide)-poly( $\epsilon$ -caprolactone) (PCL) and poly(D-lactide)-poly( $\epsilon$ -caprolactone) diblock copolymers and have studied

their association in a good solvent for the poly( $\epsilon$ -caprolactone) block.

## NANOPARTICLES OF BLOCK COPOLYMERS IN DILUTE SOLUTION

### Organization of Diblock Copolymers in a Selective Solvent

In the case of a diblock copolymer AB dissolved in a solvent selective for one of the two blocks (B in the following), the copolymer spontaneously self-organizes, forming particles of varied sizes and shapes. For coil-coil systems, spherical micelles are commonly obtained.<sup>[1-4]</sup> The resulting structure consists of a core region made up of insoluble A blocks surrounded by a shell region made up of B blocks swollen by the solvent. Non-spherical aggregates of block copolymers in solution such as cylindrical micelles<sup>[5]</sup> or giant wormlike micelles<sup>[6]</sup> have been only rarely observed. Multiple morphologies (spheres, rods, and vesicles) of aggregates prepared from a given diblock copolymer in solution have been reported by Eisenberg et al.<sup>[7,8]</sup> Factors such as the water content in the solvent mixture, the solvent nature and composition, the presence of additives, and the polymer concentration were successfully employed to control the aggregate shape and size.

In the case of rod-coil systems or when the insoluble block is able to crystallize, various morphologies such as spherical micelles,<sup>[9]</sup> vesicles,<sup>[10]</sup> or lamellar platelets<sup>[11]</sup> can be encountered. Besides the nature of the insoluble block, various parameters can influence the size or shape of the nanoparticles. The preparation technique of the solutions, the nature of the solvent, the molecular weight, and the composition of each block in the copolymer<sup>[12,13]</sup> were more specifically studied.

## Complexation of Block Copolymers by Supramolecular Interactions

Complexation by supramolecular interactions of two block copolymers is another way used to develop nanoparticles. An intermacromolecular complex can self-assemble if the two copolymer chains involved in the complexation have specific and complementary sites of interaction. If we consider a mixture of two copolymers A-b-B and C-b-D where the blocks B and D can interact, then nanoparticles can be obtained. The aggregate formed is often a spherical micelle, with the insoluble complex in the core, stabilized in solution by a crown of the other soluble blocks (A and C) swollen by the solvent. Non-covalent specific interactions liable to form a complex can potentially be of a different nature:<sup>[14,15]</sup> van der Waals interactions, hydrogen bonding, metal–ligand bonds, ionic interactions, hydrophobic interactions, aromatic  $\pi$  stacking, and charge-transfer interactions. As studied in the literature, stable and monodisperse polyion complex micelles were thus prepared in an aqueous medium through electrostatic interactions between a poly(ethylene glycol)–polycation block copolymer and a poly(ethylene glycol)–polyanion block copolymer.<sup>[16]</sup> In such systems, molecular recognition based on associative block lengths occurred.<sup>[17]</sup> Furthermore, nanoparticles have been obtained in a non-selective solvent for a block copolymer by hydrogen-bonding complexation of one of the blocks and a complementary polymer. The micellelike structures are very stable because dilution has no effect on their size and molecular weight. Besides, these characteristics are dependent on the initial polymer concentration, indicating that the complexation is a diffusion-controlled process.<sup>[18]</sup>

### Stereocomplexation between Polymers of Opposite Configuration: Case of Poly(lactide)

Besides complexes formed by polymers with different chemical structures and complementary sites of interaction, intermacromolecular complexes can be formed between polymers with identical chemical compositions and different stereochemical structures. This type of interaction is called “stereocomplexation.” The association is a result of weak van der Waals interactions. Stereoassociation of poly(methyl methacrylate) of different tacticity is the most well known. Mixing of solutions of isotactic and syndiotactic poly(methyl methacrylate) in suitable solvents leads to the formation of a stereocomplex by the association between isotactic and syndiotactic sequences. The structure of this complex has long been investigated.<sup>[19]</sup> Another type of stereocomplex can also be formed by mixing optically active polymers with identical chemical

structures but with opposite configurations. Examples of optically active polymers that form stereocomplexes are numerous in the literature.<sup>[20–22]</sup> Polylactide, because of its biodegradability and biocompatibility, was extensively investigated. Equimolar mixtures of isotactic polylactides PLLA and PDLA have been first studied in the solid state.<sup>[23,24]</sup> Results have shown that the stereocomplex obtained with the mixture has a melting point about 50°C higher than the melting points of both polyenantiomers. The influence of various parameters on the formation of stereocomplexes has been investigated. Thus, stereocomplexes without formation of homocrystallites are exclusively obtained with an equimolar mixture of D-lactide and L-lactide,<sup>[25]</sup> with a molecular weight ranging from 500 to 10<sup>5</sup> g mol<sup>-1</sup><sup>[26]</sup> and with optically pure monomers.<sup>[27]</sup> To understand the mechanism of formation of the polylactide stereocomplex, the crystallization behavior of polylactides was studied. It has been reported that the crystals in the homopolymers of PLLA (or PDLA) have a 10<sub>3</sub> helix structure, whereas the stereocomplex forms a more compact 3<sub>1</sub> helix and is more stable.<sup>[28,29]</sup> Several approaches were investigated to design new poly(lactide)-based polymers. Thus, stereocomplexes were observed by differential scanning calorimetry (DSC) for stereodiblocks PLLA-b-PDLA<sup>[30]</sup> and for some copolymers where the poly(lactide) was associated with another polymer sequence. Few studies deal with the behavior of copolymers with a poly( $\epsilon$ -caprolactone) sequence. Stereocomplexation was observed with statistical copolymers,<sup>[31]</sup> with mixtures of triblock polyenantiomers PLA-b-PCL-b-PLA,<sup>[32]</sup> and with diblock copolymers PCL-b-PLA.<sup>[33]</sup> This last study indicates that the melting temperature of the crystalline PCL and PLA phases strongly depends on the composition of the block copolymer. Accordingly, stereocomplexes are observed for copolymers where the poly(lactide) sequence has at least 40 lactyl units.

New properties and applications of the stereocomplexation of enantiomeric poly(lactide) copolymers were investigated. Thus, it was recently reported that the stereocomplex of the two enantiomeric triblock copolymers poly(lactide)-b-poly(ethyleneglycol)-b-poly(lactide) were used to make microspheres for protein release.<sup>[34]</sup> Few studies, however, were carried out on stereocomplexation in solution. In concentrated solutions, an irreversible gel was formed through stereocomplexation of poly(D-lactide) and poly(L-lactide). The PLA complex gel is thermoirreversible and insensitive to dilution.<sup>[31]</sup> In dilute solutions, with a good solvent for the polylactide sequence, stereocomplexation was not observed, but in hot acetonitrile, the turbid solution first obtained precipitated rapidly.<sup>[25]</sup>

We report in this entry on the stereocomplexation of diblock enantiomeric copolymers poly(lactide)-b-poly

( $\epsilon$ -caprolactone) (PLA-*b*-PCL) in solution. The influence of different parameters (concentration, length of the blocks) on the stereocomplexation are discussed.

## FORMATION OF NANOPARTICLES OF BLOCK COPOLYMERS CONTAINING ENANTIOMERIC LACTIDE SEQUENCES IN SOLUTION

### Synthesis and Characterization of Block Copolymers PCL-*b*-PLA

Block copolymer PCL-*b*-PLLA (PCL-*b*-PDLA) was synthesized by addition of L-lactide (D-lactide) to a living poly( $\epsilon$ -caprolactone) (PCL), which was prepared with an yttrium alkoxide initiator [Y(OCH<sub>2</sub>-CH<sub>2</sub>OCH(CH<sub>3</sub>)<sub>2</sub>)<sub>3</sub>] as previously described.<sup>[35]</sup> The structure was confirmed by size exclusion chromatography (SEC) with tetrahydrofuran (THF) as eluent, <sup>1</sup>H and <sup>13</sup>C NMR in CDCl<sub>3</sub>, and MALDI-TOF mass spectrometry and polarimetry in THF. The degrees of polymerization (DP) were determined by combination of SEC of the PCL precursors and the integration of PLA (5.28 ppm) and PCL (4.14 ppm) signals on the <sup>1</sup>H NMR spectra of the copolymers. The use of the yttrium alkoxide initiator allowed us to prepare block copolymers under satisfactorily controlled conditions. Thus we have obtained copolymers with variable compositions in PCL (DP = 60–120) and PLA (DP = 40–120) blocks. The molecular characteristics of PCL-*b*-PLA diblock copolymers are given in Table 1. For the PLA sequences, degrees of polymerization are given in lactyl units.

### Association of PCL-*b*-PLA Block Copolymers and Nature of the Interactions

The nature of the association was first studied for one system where the two blocks PCL and PLA had roughly the same molecular weight (L1 and D1). The formation of the stereocomplex was first checked in the solid state. The mixture of the two enantiomeric copolymers L1 and D1 has a melting point of 207°C, as determined by DSC, against 157°C for both polyenantiomers (Table 2). This indicates the presence of strong interactions between the two enantiomers. Their association in solution in THF was then studied. THF is a poor solvent for the semicrystalline PLA, but a good one for the PCL sequence. It is then possible to solubilize the copolymers PCL-*b*-PLA in a wide range of concentrations. Samples were prepared by dissolving separately the same weight of each copolymer (L1 and D1) in THF at room temperature. After a few minutes, the two solutions were mixed to obtain a 10 g/L S1 solution. To ensure that the association is the result of interactions between the two enantiomeric PLA sequences, the behavior of the mixture was compared to the behavior of the pure copolymer (L1 or D1), called the reference. Study of the reference L1 by light scattering indicated the presence of two species in solution: free chains and aggregates.<sup>[36]</sup> The aggregates involve only a small fraction of the copolymers and the kinetics of their formation is very slow. A two-step mechanism is proposed: first, copolymers self-assemble to form micellelike aggregates, then the aggregates form larger and larger agglomerates.<sup>[37]</sup> In the case of the mixture S1, the formation of the aggregates is much faster and involves a larger fraction of chains than in the case of the reference. Nanoparticles with a radius

of 300 nm were obtained after 10 days and then precipitated after a few weeks. This results from specific interactions between the PLA enantiomeric sequences. The formation of the stereocomplex was proved by the appearance of a new carbonyl vibration ( $1747\text{ cm}^{-1}$ ) on the Fourier transform infrared spectroscopy (FTIR) spectra of the mixture.

### Influence of Different Parameters on the Stereocomplexation of Enantiomeric Block Copolymers

Complexation characteristics, such as association kinetics, conversion of associated sequences, or size of the aggregates, can be potentially tuned by changing the length of each block, the solvent, the concentration, or the temperature. We synthesized various copolymers with relatively good control of the PCL and PLA block lengths (Table 1). Thus, considering systems S1 (70-b-120), S2 (70-b-60), and S3 (60-b-40), which have comparable PCL block lengths, we can evaluate the influence of the complexing block (PLA) length on stereocomplexation. In the same way, to determine the influence of the solubilizing block length on the association, systems where PLA sequences have comparable degrees of polymerization (S1 and S5, S4 and S8) have been studied. For each case, the evolution of the size and stability of the aggregates with time have been determined in solution. Equimolar mixtures of isotactic block copolymers PCL-b-PLLA and PCL-b-PDLA for each system have been first studied in the solid state. Results indicate that the stereocomplex obtained with the mixture has a melting point about 50°C higher than both polyenantiomers. In addition, the melting points are much higher for longer PLA sequences (Table 2).

### Influence of PLA sequence length on stereocomplexation

Equimolar mixtures of each enantiomeric copolymer for the systems S1, S2, and S3 were prepared by dissolving separately the same weight of each copolymer (L1 and D1, L2 and D2, L3 and D3) in THF at room temperature to obtain solutions with a concentration of 10 g/L. For all the systems, the behavior of the mixture in solution was compared to the reference solution. This solution was used to prepare the mixture and contained the single enantiomeric copolymer. The behavior of the reference solutions L1, L2, and L3 was observed by static and dynamic light scattering (DLS). Measurements were performed on filtered solutions (Whatman Anotop filters, porosity 0.2  $\mu\text{m}$ ) with an experimental setup previously described,<sup>[39]</sup> at a wavelength ( $\lambda$ ) of 514.5 nm. Results of the characterization by static light scattering (SLS) for the reference solutions L1, L2, and L3 are represented by the variation of the Rayleigh ratio as a function of time and are reported in Fig. 1. At a given observation angle ( $\theta$ ), the intensity scattered by the solution ( $I_{\theta,\text{solution}}$ ) is proportional to the molecular weight of the particles and is a function of their sizes and the interactions. The Rayleigh ratio ( $\Delta R_{\theta}$ ) using toluene as a reference is defined as:

$$\Delta R_{\theta} = \frac{I_{\theta,\text{solution}} - I_{\theta,\text{solvent}}}{I_{\theta,\text{reference}}} \times R_{\theta,\text{reference}}$$

where  $I_{\theta,\text{solvent}}$  and  $I_{\theta,\text{reference}}$  are the intensity scattered by the solvent and the toluene, respectively. Over the range of time investigated, the Rayleigh ratio of the L1 and L3 solutions increases whereas the Rayleigh ratio of the L2 solution remains constant. Thus, for

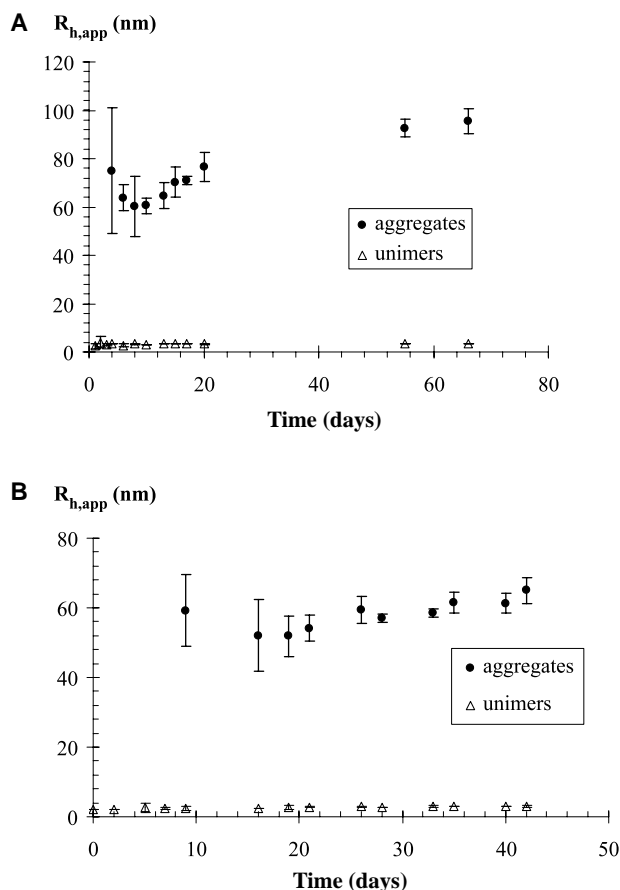

**Fig. 1** Semilogarithmic time dependence of the Rayleigh ratio measured at  $\theta = 90^\circ$  for the solutions L1, L2, and L3 ( $C_T = 10 \text{ g/L}$ ,  $T = 25^\circ\text{C}$ ).

L1 and L3 solutions some aggregation occurs, whereas for solutions containing one enantiomeric copolymer with a small PLA block ( $\text{DP}_{\text{lactyl units}} = 40$ ), no association is observed. The distributions of relaxation times obtained from DLS at different observation times for the L1 and L3 solutions are bimodal, with a fast component corresponding to the individual diblock copolymer chains (unimers) and a slow component corresponding to some aggregates. To characterize these two species in the L1 and L3 solutions, the apparent hydrodynamic radius  $R_{h,\text{app}}^i$  was estimated from the analysis of the normalized autocorrelation function  $g_2(t, q)$  (Fig. 2A and B). For a solution containing two species, the function  $g_2(t, q)$  can be written as:

$$g_2(t, q) = A_{\text{uni}}(q) \exp(-t/\tau_{\text{uni}}) + A_{\text{agg}}(q) \exp(-t/\tau_{\text{agg}})$$

with  $A_i \propto w_i M_i$

where  $w_i$  is the weight fraction of the species  $i$ ;  $A_{\text{uni}}(q)$  and  $A_{\text{agg}}(q)$  are the contributions of the unimers (fast mode) and of the aggregates (slow mode), respectively. The relaxation times  $\tau_{\text{uni}}$  and  $\tau_{\text{agg}}$  are  $q^2$  dependent and are used to calculate an apparent diffusion coefficient  $D_{i,\text{app}} = (\tau_i q^2)^{-1}$ , where  $q$  is the scattering wave vector defined as  $q = 4\pi n/\lambda \sin(\theta/2)$ , with  $n$  the refractive index of the solvent. Finally, an apparent hydrodynamic radius has been estimated using the Stokes–Einstein relation:  $R_{h,\text{app}}^i = kT/6\pi\eta_0 D_{i,\text{app}}$ , where  $k$  is the Boltzmann constant,  $T$  the absolute temperature, and  $\eta_0$  the viscosity of the solvent. The apparent hydrodynamic radius of the unimers remains constant with time ( $R_{h,\text{app}}^{\text{uni}} = 3 \pm 0.5 \text{ nm}$  for L1 and  $2.5 \pm 0.5 \text{ nm}$  for L3). The fraction of aggregates increases slowly with time for L1 and an equilibrium seems to be reached after 2 months with an  $R_{h,\text{app}}^{\text{agg}}$  of 80 nm. For the L3 solution, the same behavior is observed with a weaker

**Fig. 2** Apparent hydrodynamic radius ( $R_{h,\text{app}}$ ) of aggregates and unimers vs. time ( $C_T = 10 \text{ g/L}$ ,  $T = 25^\circ\text{C}$ ) for the solutions (A) L1 (70-b-120) and (B) L3 (70-b-60).

$R_{h,\text{app}}^{\text{agg}}$  (60 nm after 40 days). To estimate the contribution of aggregates to the overall scattered intensity, a suitable method consists in using the variation of the ratio  $A_{\text{agg}}/A_{\text{uni}}$  vs.  $q^2$ .<sup>[40]</sup> Neglecting interactions between unimers and aggregates and taking for the molecular weight of the unimers the apparent one measured before the formation of aggregates, one gets the concentrations of unimers and aggregates:

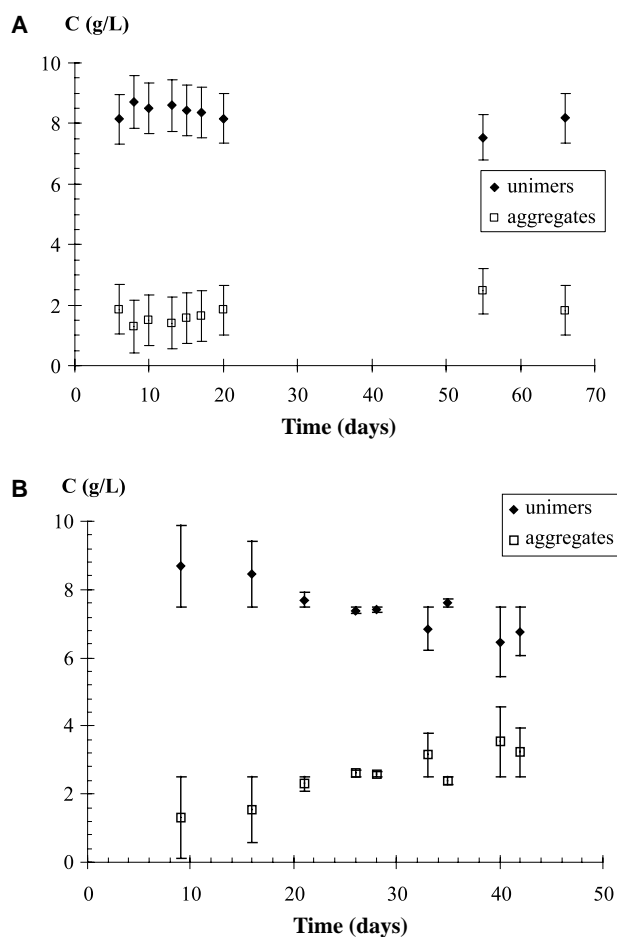

$$C_{\text{uni}} = \frac{(I_{\theta,\text{solution}} - I_{\theta,\text{solvent}})_{\theta \rightarrow 0} [A_{\text{u}}]_{q \rightarrow 0}}{KM_{\text{uni}}} \quad \text{and}$$

$$C_{\text{agg}} = C_T - C_{\text{uni}}$$

where  $K$  is an optical constant.<sup>[40]</sup> The weight average and the aggregation number ( $N_{\text{agg,app}}$ ) were also deduced:

$$N_{\text{agg,app}} = \frac{M_{\text{agg,app}}}{M_{\text{uni,app}}} = \left[ \frac{A_{\text{agg}}}{A_{\text{uni}}} \right]_{q \rightarrow 0} \frac{C_{\text{uni}}}{C_{\text{agg}}}$$

Results are presented in Figs. 3 and 4. A qualitative analysis of the solutions L1 and L3 indicates a similar

**Fig. 3** Concentration of unimers and aggregates vs. time ( $C_T = 10$  g/L,  $T = 25^\circ\text{C}$ ) for the solutions (A) L1 and (B) L3.

**Fig. 4** Aggregation number of the aggregates vs. time for the solutions L1 and L3 ( $C_T = 10$  g/L,  $T = 25^\circ\text{C}$ ).

behavior: aggregates self-assemble in solution and are detected rapidly. Quantitatively, the concentration of aggregates after 20 days is slightly higher for L3 (2.5 to 3 g/L) (Fig. 3B) than for L1 (2 g/L) (Fig. 3A). Thus, the aggregation number (Fig. 4) in L3 is lower than for L1. In contrast to L1 aggregates, which have an aggregation number increasing rapidly with time, the aggregation number of L3 increases slowly over the range of time investigated. The two-step association mechanism proposed for the L1 solution is no more valid for L3. In the latter case, the second step (agglomeration) is not observed.

The length of the PLA block also has a strong influence on the organization of a single enantiomeric copolymer PCL-b-PLA. For a PCL sequence with a degree of polymerization of 70 and at a concentration of 10 g/L, the size of the aggregates increases with the size of the PLA block. With a short PLA block (case of L2 solution) no aggregate is detected by light scattering, whereas for copolymers with sufficient PLA length, aggregates are observed. Complexation kinetics as well as its mechanism depends strongly on the PLA block. Thus, the degree of polymerization of the PLA block is a critical factor that directly influences the organization of the single enantiomeric copolymer in THF.

After studying the behavior of reference solutions L1, L2, and L3, equimolar mixtures of each enantiomeric copolymer were prepared at the same concentration. Systems S1, S2, and S3 were studied by static and dynamic light scattering and by FTIR. Light scattering results for solutions S1, S2, and S3 are very different from those of their respective reference solutions. Rayleigh ratios are much higher, indicating that enantiomeric PLA sequences interact in solution. For solutions S2 and S3, the distributions of relaxation times determined from DLS show the same profile as those of S1 solution: a monomodal distribution with high relaxation time is obtained, indicating the presence of large diffusing objects. The apparent hydrodynamic radius  $R_{h,app}$  relative to the mixtures S1, S2, and S3 and prepared in THF at 10 g/L are presented in Fig. 5. Accordingly, results indicate that the behavior of an equimolar mixture of enantiomeric PCL-b-PLA is strongly dependent on the PLA block length. Qualitatively, after 7 days at room temperature, the S3 and S1 solutions become cloudy whereas the S2 solution remains perfectly clear over many months. Quantitatively, a very strong increase of the apparent hydrodynamic radius is observed for S3 and S1 solutions, followed by stabilization beyond 10 days. However, if the global behavior is similar, the dimensions of the aggregates are strongly affected by the PLA block length. Hydrodynamic radii obtained by DLS are much larger for larger PLA sequences. Thus, the size of aggregates is directly dependent on the degree of polymerization of the complexing block (PLA).

**Fig. 5** Apparent hydrodynamic radius ( $R_{h,app}$ ) of mixtures S1, S2, and S3 vs. time ( $C_T = 10 \text{ g/L}$ ,  $T = 25^\circ\text{C}$ ).

This confirms that the association by stereocomplexation of PLA sequences is the driving force of the copolymer association in solution. To estimate the conversion to stereocomplex, solutions of S1, S2, and S3 were analyzed by FTIR. IR spectra of the mixtures presented three distinctive peaks between 1700 and  $1800 \text{ cm}^{-1}$ : at  $1737 \text{ cm}^{-1}$ , the carbonyl vibration corresponding to PCL sequences; at  $1763 \text{ cm}^{-1}$ , the carbonyl vibration corresponding to the nonassociated PLA sequences; and at  $1747 \text{ cm}^{-1}$ , a vibration assigned to the stereocomplex.<sup>[41]</sup> The signal was deconvoluted into Lorentzian curves. The characteristic parameters of the peaks at  $1737 \text{ cm}^{-1}$  (PCL sequences) and at  $1763 \text{ cm}^{-1}$  (non-associated PLA sequences) were first estimated from values determined for the reference solutions L1, L2, and L3. The conversion was estimated by considering the diminution of the “free” PLA signal ( $1763 \text{ cm}^{-1}$ ).  $R_t$  is defined as the ratio of intensities of signals of non-associated PLA and PCL sequences, respectively [ $R_t = I(\text{PLA})_t / I(\text{PCL})_t$ ]. The conversion is then defined as follows: conversion ( $t$ ) =  $(R_0 - R_t) / R_0$ , where  $R_0$  is taken just after mixing the solutions of enantiomeric copolymers. Variation of the conversion vs. time for the three mixtures is reported in Fig. 6. Again, significant differences between S2 on one hand and S1 and S3 on the other hand are observed. For the solution S2, the proportion of stereocomplex increases weakly before reaching 10% at 60 days. The length of the PLA sequences of this system corresponds to the minimum value reported in the literature that is able to form a stereocomplex.<sup>[32]</sup> In this case, the kinetics of stereocomplexation is slow. For mixtures S1 and S3, the evolution is faster and reaches a value of 30% after 20 days. The difference between S1 and S3 is very small, and the apparently higher conversion for S3 is presently not understood. The solutions S1 and S3 were also studied by LS at a smaller concentration ( $C_T = 1 \text{ g/L}$ ). For solutions S1

**Fig. 6** Conversion in stereocomplex vs. time for the mixtures S1, S2, and S3 (FTIR,  $C_T = 10 \text{ g/L}$ ,  $T = 25^\circ\text{C}$ ).

and S3, aggregates are more stable; no precipitation was observed even after several months. However, the association is very slow and the size of the aggregates is smaller than at the concentration of  $10 \text{ g/L}$ . Once again, if the systems S1 and S3 are compared, apparent hydrodynamic radii are smaller in the case of the copolymer with a shorter PLA block (Fig. 7).

In conclusion, the comparative study of S1 and S3 solutions indicates that the degree of polymerization of PLA sequences strongly affects the size of the aggregates, not only for the single copolymers but also for the enantiomeric equimolar mixtures. For very short sequences (S2) the association of enantiomeric copolymers is relatively slow and leads to the formation of stable particles in solution.

#### Influence of PCL block length on nanoparticle formation

To determine the influence of the solubilizing block lengths on the association, two pairs of systems where PLA sequences have comparable degrees of

**Fig. 7** Apparent hydrodynamic radius ( $R_{h,app}$ ) of mixtures S1 and S3 ( $C_T = 1 \text{ g/L}$ ,  $T = 25^\circ\text{C}$ ).

**Fig. 8** Apparent hydrodynamic radius ( $R_{h,app}$ ) of mixtures S1 and S5 ( $C_T = 1$  g/L,  $T = 25^\circ\text{C}$ ).

polymerization (S1 and S5, S4 and S8) were studied. S1 and S5 mixtures of copolymers, which have each a PLA block of 120 lactyl units, were prepared as previously described at a concentration of 1 g/L in THF. Measurements carried out by DLS on the reference solutions (L1 and L5) indicated (as for all references at this concentration) that there is no association. The association of the equimolar mixtures S1 and S5 at 1 g/L was observed and no precipitation appeared, even after 1 year. The formation of large aggregates as a function of time was confirmed by DLS. The variation of the apparent hydrodynamic radius for the solutions S1 and S5 is represented in Fig. 8. A similar behavior is observed for the two solutions. Nevertheless, for the system S5, the radius of the aggregates seems to be slightly smaller than for the S1 solution. In the same way, the solutions S4 and S8 containing copolymers with a PLA block of 80 lactyl units were characterized at 1 g/L in THF. Results obtained by light scattering for the reference solutions (L4 and L8) indicated that the solutions did not show any association at this concentration, whereas the association of equimolar enantiomeric copolymer mixtures was clearly observed: scattered intensity (SLS) increased and aggregates (DLS) appeared. Furthermore, the solutions were very stable for at least several months. The evolution of the apparent hydrodynamic radius of formed aggregates for systems S4 and S8 vs. time are represented in Fig. 9. The curves obtained for the two solutions S4 and S8 are similar, but the values for the system S8 are slightly higher. The lengthening of the PCL solubilizing block seems to hinder the association but this effect is limited.

## CONCLUSION

We have studied the association of various block copolymers poly(lactide)-b-poly( $\epsilon$ -caprolactone) in THF, a

**Fig. 9** Apparent hydrodynamic radius ( $R_{h,app}$ ) of mixtures S8 and S4 ( $C_T = 1$  g/L,  $T = 25^\circ\text{C}$ ).

selective solvent of the poly(caprolactone) block. Light scattering measurements on solutions of the single PCL-b-PLLA copolymers indicate, in some cases, the formation of aggregates. Complexation kinetics as well as its mechanism depends strongly on the size of the PLA block in the copolymer. With a short PLA sequence, no aggregate was detected, whereas with some large PLA blocks, aggregates were formed. Their size increases with the degree of polymerization of the PLA sequence.

In the case of the mixtures of enantiomeric block copolymers, the association appears more rapidly. Nanoparticles are formed as a result of specific interactions between the PLA enantiomeric sequences. This stereocomplexation is not quantitative because a high fraction of the sequences remains free without being involved in the complex. The degree of polymerization of PLA sequences strongly affects the size of the aggregates (80 to 200 nm), whereas the PCL block length has a limited influence on the stereocomplexation. The concentration is also a parameter that affects the size and the stability of the particles. Optimal conditions to form stable nanoparticles in solution (short PLA block or low concentration) have been identified.

## ACKNOWLEDGMENTS

Alexandre Richez is acknowledged for performing some FTIR measurements. We thank PURAC Biochem for providing the lactide monomers used in this work.

## INTRODUCTION

II–VI semiconductors such as ZnSe, ZnS, and CdSe have wider band gap and larger exciton binding energies as compared with III–V semiconductors. Excitons of II–VI semiconductors still exist at room temperature. Therefore II–VI semiconductor devices indicate a possibility of new devices using excitons, such as optical modulators and self-electro-optic effect devices.<sup>[1–5]</sup> Furthermore, in the field of optical data transmission, green laser is suitable for short- and medium-range communication purposes using plastic optical fibers with polymethyl methacrylate cores, which have an advantage of lower costs than silica fibers. Therefore II–VI semiconductors are also optimum candidates for light source of optical data transmission through plastic optical fibers.

Semiconductor quantum structures have been intensively investigated since Esaki and Tsu<sup>[6]</sup> proposed novel artificial superlattice structures. Recently, quantum dots (QDs) have attracted much attention for the optoelectronic device applications and fundamental physics because they provide zero-dimensional structures with  $\delta$ -function density of states, which dramatically improve performances of optoelectronic devices such as semiconductor lasers. To fabricate lower-dimensional structures, great efforts have been made using various methods, such as selective epitaxial growth, lithography, etching, etc.<sup>[7–12]</sup> However, these techniques give film damages, such as defects and contamination. On the other hand, self-organized QDs have an advantage of fabrication of high-density and high-quality QDs. Especially, InAs QDs of III–V materials have been known to be formed on GaAs surfaces, which are followed by the two-dimensional growth of InAs wetting layer, because InAs has a larger lattice constant by 7% than GaAs.<sup>[13–18]</sup>

CdSe/ZnSe system is expected to naturally form QDs because of large lattice mismatch of about 7% between ZnSe and CdSe. In this session, we have investigated the formation and optical properties of

self-organized CdSe QDs on ZnSe (001) surfaces with the use of photoluminescence (PL) and transmission electron microscopy (TEM) measurements. Moreover, applying the QD system to optoelectronic devices to understand carrier dynamics and energy structures of QDs is very important. For example, relaxation mechanism of InAs QDs has been reported by PL excitation measurements.<sup>[19,20]</sup> As compared with InAs QDs, CdSe QDs have stronger electron–phonon interactions and much larger band-gap energy. Then, the carrier relaxation mechanisms in self-organized CdSe QDs are more interesting subjects. In this study, we have also investigated optical properties of self-organized CdSe QDs by selectively excited PL measurements.

## GROWTH OF CdSe/ZnSe STRUCTURES

ZnSe/CdSe/ZnSe structures were fabricated by molecular beam epitaxy (MBE) on GaAs (001) substrates after GaAs buffer layer growth. Compound sources of ZnSe and CdSe, whose purities are 6N, were used for ZnSe and CdSe growth, respectively.<sup>[21]</sup> In the case of compound materials, the temperatures necessary to obtain beam enough flux intensity for MBE growth are much higher as compared with the temperatures needed in the conventional case for columns II and VI elemental sources. As a result, it is convenient to control the beam flux and to precisely control the composition beam flux ratio. In addition, because only molecules of Se<sub>2</sub> are generated, the sticking coefficient of molecules is enhanced as compared with elemental sources. Therefore high-quality films are expected to be obtained.

The polished GaAs (001) substrates were etched in a 4:1:1 solution of H<sub>2</sub>SO<sub>4</sub>:H<sub>2</sub>O:H<sub>2</sub>O<sub>2</sub> before placing them in the MBE loading chamber with In backing on Mo blocks. The substrates were annealed at 580°C with As irradiation to remove native oxide. First, the 200-nm-thick GaAs buffer layer was grown at 580°C in the MBE system. Next, ZnSe layer

**Fig. 1** RHEED intensity oscillation of ZnSe growth on GaAs (001) surfaces.

(100 nm) was grown on the GaAs surfaces at 290°C. When ZnSe growth starts on the GaAs surfaces, the GaAs ( $2 \times 4$ ) reconstruction pattern disappeared immediately and the reflection high-energy electron diffraction (RHEED) intensity oscillation starts, as shown in Fig. 1. The RHEED intensity oscillation during ZnSe growth on GaAs surfaces continued until more than 100-nm thickness of ZnSe film. This indicates that ZnSe proceeds in layer-by-layer mood on GaAs surfaces and that flat interfaces are formed between ZnSe films and GaAs surfaces. The RHEED patterns during ZnSe growth showed both ( $2 \times 1$ ) and  $c(2 \times 2)$  reconstruction patterns. Therefore ZnSe films with high quality were obtained.<sup>[22]</sup>

Then, a few monolayers (MLs) of CdSe were grown on the ZnSe surfaces at 290°C. The growth rate of CdSe was 1.1 ML/min, which was measured by RHEED intensity oscillation. To confirm the formation of self-organized CdSe QDs, the bulk spot intensity of RHEED was monitored during the growth of CdSe with the use of both a combination of a charge-coupled device (CCD) camera and a photodiode.<sup>[23]</sup> Finally, ZnSe layer was grown after the CdSe growth without growth interruption.

## FORMATION OF CdSe QUANTUM DOTS

Fig. 2 shows PL spectra measured for the samples with various CdSe coverages.<sup>[24]</sup> Photoluminescence measurement was carried out at liquid He temperature using a 32-cm grating monochromator with a cooled CCD camera. A He–Cd laser line of 325 nm was used as an excitation light. With increasing the CdSe thickness from 1.3-ML coverages, the PL peaks shift to lower energy, which is a result of the quantum size effect. The small jump in peak position between 2.2

**Fig. 2** Photoluminescence spectra as a function of CdSe thickness. Source: From Ref.<sup>[24]</sup>.

and 2.4 ML CdSe coverages is also observed. Photoluminescence intensity and full widths at half maximum (FWHMs) gradually increase with increasing the CdSe thickness from 1.3-ML coverages. The maximum PL intensity is obtained at about 2.2 ML CdSe coverages. However, at more than 2.4 ML CdSe coverages, PL intensities dramatically decrease, as shown in Fig. 2. The emission is hardly observed at 2.6 and 3.1 ML CdSe coverages.

Next, cross-sectional TEM images are observed for the samples with various CdSe coverages. The cross-sectional TEM specimens were prepared by mechanical polish and dimpling followed by ion etching. The TEM images were observed by JEOL JEM-3000F electron microscope at 300 kV. Fig. 3A shows a cross-sectional TEM image of CdSe 1.6-ML coverages taken along the [011] direction. The dark region shows the CdSe layer. A lot of CdSe QDs are clearly observed, indicating that CdSe QDs are naturally formed on ZnSe surfaces. Any defects are not found in this image. Fig. 3b shows a cross-sectional high-resolution TEM image of single CdSe QD. Single CdSe QD with several nanometers size is observed. Kirmse et al.<sup>[25]</sup> have reported with plan-view TEM images that two classes of CdSe QDs coexist with an average lateral size of <math><10\text{ nm}</math> (area density of  $100\ \mu\text{m}^{-2}$ ) and  $10\text{--}50\text{ nm}$  ( $20\ \mu\text{m}^{-2}$ ), respectively. However, we did not observe such large CdSe QDs. As compared with the atomic force microscopy image in Ref.<sup>[26]</sup>, the diameter of

**Fig. 3** (A) Cross-sectional TEM image of CdSe 1.6-ML coverage taken along the  $[011]$  direction and (B) cross-sectional high-resolution TEM images of single CdSe QD.

CdSe QDs in Fig. 3 is smaller and the density is much higher. Fig. 4A shows a cross-sectional TEM image of 2.6-ML coverages taken along the  $[0\bar{1}1]$  direction. This reveals that much stacking faults are observed in the ZnSe capping layer. It is found that these stacking faults have an origin at around CdSe/ZnSe interfaces. Fig. 4B shows a cross-sectional high-resolution TEM image at the interface between CdSe/ZnSe. The stacking faults start from the interface between ZnSe capping layer and CdSe QDs. Therefore stacking faults are considered to be induced by large stress after ZnSe cap layer growth.

Photoluminescence and TEM results indicate that the PL intensity at less than 2.2 ML CdSe coverages shown in Fig. 2 comes from CdSe QDs. This is consistent with the result that the defects in the samples reduce dramatically the luminescence intensity of thick samples, as shown in Figs. 2 and 4. Furthermore, CdSe

QDs showed a strong green emission even at room temperature.<sup>[27]</sup> These results indicate that CdSe QDs with high quality are formed on ZnSe surfaces.

To investigate the optical properties for the effect of the QD shape, polarization dependence of PL from CdSe QDs is measured.<sup>[28]</sup> Fig. 5 shows PL spectra of 2.0 ML CdSe coverages at 5 K. The solid curve and the dashed curve are spectra of polarization components, which are parallel to the  $[1\bar{1}0]$  direction and to the  $[110]$  direction, respectively, as shown in Fig. 5. A peak at 2.38 eV comes from the CdSe QDs, and no peak from wetting layers is observed. The intensity for the polarization parallel to the  $[1\bar{1}0]$  direction ( $I[1\bar{1}0]$ ) is larger than that to the  $[110]$  direction ( $I[110]$ ), as shown in Fig. 5. No polarization anisotropy was observed between the  $[100]$  and  $[010]$  directions. Therefore the PL spectra are strongly polarized parallel to the  $[1\bar{1}0]$  direction. The PL peaks shown in Fig. 5

**Fig. 4** (A) Cross-sectional TEM image of CdSe 2.6-ML coverage taken along the  $[0\bar{1}1]$  direction and (B) cross-sectional high-resolution TEM image at the interface between CdSe/ZnSe.

**Fig. 5** Photoluminescence polarization dependence of CdSe QDs at 5 K. *Source:* From Ref.<sup>[28]</sup>.

come from the heavy-hole transition, and the strong polarization is considered to be a result of the heavy-hole confinement in CdSe QDs, indicating that lateral confinement along the  $[1\bar{1}0]$  direction is weaker than that along the  $[110]$  direction. Consequently, CdSe QDs are considered to have the longer axis along the  $[1\bar{1}0]$  direction than the  $[110]$  direction.

From Fig. 5, a PL polarization degree of CdSe QDs was estimated to be 14.6%, which is defined by  $(I[1\bar{1}0] - I[110]) / (I[1\bar{1}0] + I[110])$ . We also discuss about the CdSe coverage dependence of polarization PL spectra. Fig. 6 shows the PL polarization degrees as a function of CdSe coverage from 1.5 to 2.4 ML at 5 K. The PL spectrum for each CdSe coverage was clearly polarized parallel to the  $[1\bar{1}0]$  direction, indicating that the shape of QDs for each CdSe coverage has the long axis along the  $[1\bar{1}0]$  direction. The PL polarization degrees increase with increasing CdSe coverage, as shown in Fig. 6. The result reveals that the PL

**Fig. 6** CdSe coverage dependence of PL polarization degree at 5 K. *Source:* From Ref.<sup>[28]</sup>.

polarization degrees increase with QD formation, suggesting that the ratio of length along the  $[110]$  direction to that along the  $[1\bar{1}0]$  direction increases with CdSe coverage. At 2.2-ML coverages, PL spectrum has maximum polarization degree. At 2.4 ML CdSe coverages, defects were induced and, simultaneously, polarization degree decreases as shown in Fig. 6, which is considered to be a result of the release from the stress in CdSe QDs.

## OPTICAL PROPERTIES OF CdSe QUANTUM DOTS

### Microphotoluminescence

The FWHM of CdSe QDs is about several tens of microelectron volts, which is much broader than that of ZnCdSe quantum well.<sup>[29]</sup> The broad spectral width is considered to be a result of the nonuniformity of CdSe QD structures. The fluctuation in dot size causes the fluctuation in strain, resulting in more nonuniform dot structures and the broad spectral width. So it is impossible to clarify the optical properties of the single CdSe QD by macro-PL. To reduce the number of observed QDs, we put Al masks with submicron size apertures on the sample surfaces.<sup>[30]</sup> The 100-nm-thick Al masks were made by electron-beam lithography and liftoff techniques. The diameters of the apertures were varied from 0.6 to 1  $\mu\text{m}$ . Microphotoluminescence measurements were performed as follows. The sample fixed on a cold finger in a cryostat was cooled down using helium gas. The 458-nm line of Ar-ion laser was used to excite the QDs. The excitation laser was focused to about 0.8- $\mu\text{m}$  spot size through a microscope objective. The CCD camera cooled by liquid nitrogen detected the luminescence through a monochromator. The spectral resolution is  $\sim 500 \mu\text{eV}$ . The micro-PL experiments were performed in the temperature range of 4 to 60 K.

Fig. 7 shows micro-PL spectra of CdSe QDs, which are measured through several different size apertures at 4 K. The excitation power of each spectrum was 100  $\mu\text{W}$ . Fig. 7A shows a spectrum of micro-PL with focusing the excitation laser on the sample surface without Al masks. The wide FWHM of the broad peak is a result of the size distribution of the QDs. With decreasing the size of the aperture from 1 to 0.6  $\mu\text{m}$ , as shown in Fig. 7B and C, respectively, the broad peaks observed through the apertures split into a number of anomalously very sharp lines having linewidths of  $\sim 500 \mu\text{eV}$ . These sharp lines in Fig. 7C indicate zero-dimensional density of states of the QDs. The characteristic features of the spectrum in Fig. 7C are as follows. In lower-energy region ranged from 2.28 to 2.34 eV, the sharp lines are clustered close together

**Fig. 7** Microphotoluminescence spectra of CdSe QDs at 4 K: (A) without Al mask, (B) 1  $\mu\text{m}$ , and (C) 0.6- $\mu\text{m}$  size aperture. *Source:* From Ref.<sup>[24]</sup>.

in comparison with those in the higher-energy region ranged from 2.34 to 2.40 eV. The integrated intensities of the lower-energy lines are larger than those of the higher-energy lines. The linewidths of the lower-energy lines are narrower than those of the higher-energy lines. These phenomena are similar to the result in the report of CdSe QDs by Kim et al.<sup>[31]</sup> They also found that the micro-PL spectra resulted from two different kinds of states. The micro-PL spectrum in Fig. 7c seems to have the broad band under the sharp lines. However, this is not clear at the present stage.

Fig. 8 shows the temperature dependence of micro-PL spectra measured through the 0.6- $\mu\text{m}$  aperture. The temperature was ranged from 4 to 60 K. The excitation power is 100  $\mu\text{W}$ . Fig. 8A and b is obtained from lower- and higher-energy regions, respectively. These spectra reveal that the peaks have Lorentzian line shapes. The linewidths shown in Fig. 8A, which come from larger QDs, are almost constant until 20 K and increase rapidly above 30 K. At 60 K, they are  $\sim 3.5$  meV, which are about six times larger than that at 4 K. The behavior shown in Fig. 8A is similar to the result in the report of InAs QDs.<sup>[32]</sup> With increasing the temperature, excitons in the ground state are gradually scattered into higher states by the absorption of acoustic phonons. The increase in the FWHMs with temperature shown in Fig. 8A is a result of the increase of the scattering rate. On the other hand, the linewidths shown in Fig. 8B, which come from smaller QDs, hardly increase with the temperature. These results reveal that the degree of the linewidth broadening depends on the peak energy position, corresponding

**Fig. 8** Temperature dependence of micro-PL spectra of CdSe QDs taken through the 0.6- $\mu\text{m}$  aperture. *Source:* From Ref.<sup>[24]</sup>.

to the QD size, and that the linewidths of the smaller QDs are less temperature-dependent than those of the larger QDs. The difference shown in Fig. 8A and b might be able to be explained with the use of the energy level spacing of CdSe QDs. The smaller QDs have larger energy level spacing than the larger QDs because the smaller QDs have larger confinement energy, resulting in the reduction in the scattering rate of excitons from the ground state to higher states. As a result, the linewidths of smaller QDs are considered to be less temperature-dependent, as shown in Fig. 8B.

### Selectively Excited Photoluminescence

A 500-W Xe lamplight dispersed with a 0.3-m monochromator served as a tunable light source for selectively excited PL measurements. The light was focused on the sample with rectangle shape using a microscope objective. The spectral width of the dispersed light was about 0.3 nm at 500 nm. The sample was mounted on a cold finger in vacuum in a small, continuous gas flow cryostat. The luminescence was collected using optical glass fibers, dispersed with a 0.5-m single-grating monochromator, and detected with a CCD camera cooled by liquid nitrogen. Fig. 9 shows the PL spectra of CdSe QDs at different

**Fig. 9** Photoluminescence spectra of 1.6 ML CdSe coverage sample at different excitation energies at 4.5 K.

excitation energy at 4.5 K. The spectrum at the bottom of Fig. 9 is measured for excitation above the band-gap energy of the ZnSe barrier layers. In this spectrum, there is a peak at 2.551 eV with a FWHM of 30 meV, which originates from CdSe QDs.<sup>[27]</sup> The shape of this spectrum is almost the same as that excited by a He–Cd laser. The broad spectral width is a result of the inhomogeneous size of CdSe QDs.<sup>[24,28]</sup> When the excitation energy decreases, the PL intensities are dramatically reduced. In addition, the spectra have a number of shape features at higher detection energies, as shown in Fig. 9. These peak positions depend upon the excitation energy. However, the features of the PL spectra in Fig. 9 do not seem to change regularly with decreasing excitation energy. These results are considered to be due to the selective excitation of QDs with different sizes in their ground states or in their excited states.

To clarify the origin of the spectra in Fig. 9, the PL spectra of CdSe QDs are measured successively in the excitation energy range from 2.82 to 2.55 eV at 4.5 K. Fig. 10 shows a contour map of the PL intensity of CdSe QDs as a function of the detection energy and the excitation energy. Energy scale of the abscissa is expanded as compared with that of the ordinate. Horizontal sections at several excitation energies correspond to the PL spectra in Fig. 9. The abrupt and

**Fig. 10** Contour map of PL intensity of CdSe QDs at 4.5 K as a function of detection energy and excitation energy.

quite strong absorption edge is clearly observed at 2.81-eV excitation energy for whole detection energy, which corresponds to the band-gap energy of the ZnSe barrier layer. This reveals that carriers generated in the ZnSe barrier layers diffuse in the sample efficiently into CdSe QDs and then emit luminescence there. This result indicates that CdSe QDs with high quality are formed on ZnSe surfaces.

At lower PL detection energy below approximately 2.54 eV in Fig. 10, a quite weak absorption band is observed at about 2.60-eV excitation energy, which is independent of detection energy, and a step-like broad absorption band above 2.675-eV excitation energy is also found, which continues up to ZnSe barrier absorption edge at 2.81-eV excitation energy. Moreover, several sharp absorption structures appear at higher PL detection energy, as shown in Fig. 10. The energy differences of these peaks are found to be roughly independent of the detection energy. These energy separations are estimated to be about 30 meV, which corresponds to the longitudinal-optical (LO) phonon energy in CdSe/ZnSe systems. Particularly, multiple LO-phonon structures up to the 6th order are clearly observed at around 2.58-eV detection energy. These phonon structures are terminated at the band-gap energy of ZnSe barrier layer. As compared with the PL excitation spectra of ZnCdSe reference quantum wells, absorption peaks from heavy- and light-hole excitons are not observed in that of CdSe QDs. These results indicate that the excitons in CdSe QDs are relaxed by multiple LO-phonon processes, resulting from strong confinement of excitons in zero-dimensional structures. Above the ZnSe band-gap energy, phonon structures in PL spectra are not observed, as shown in the PL spectrum at the bottom of Fig. 9, which is a result of the continuum states in the ZnSe layers.

**Fig. 11** Photoluminescence spectra of CdSe QDs at 4.5 K as a function of the energy difference between the excitation and detection energies. These PL spectra are the same as those in Fig. 9. Photoluminescence spectrum at the bottom in Fig. 9 is not used in this figure.

To investigate the details of the relaxation process, we rearrange the PL spectra of CdSe QDs at 4.5 K as a function of the energy differences between the excitation and detection energies, as shown in Fig. 11. These spectra are obtained by horizontally shifting the PL spectra in Fig. 9 by the amount corresponding to the excitation energies. Although, as mentioned above, the spectra have the peaks at around 30, 60, and 90 meV, the peak positions are slightly dependent on excitation energies, as shown in Fig. 11. A peak is found at 25 meV in spectrum (a) in Fig. 11. This energy agrees with the 1-LO-phonon energy of CdSe bulk. This indicates that pure CdSe region exists in QDs, which seems to be inconsistent with the results of TEM measurements.<sup>[33–35]</sup> The spectra (b), (c), and (d) in Fig. 11 have peaks at 31 meV, and the spectra (e), (f), and (g) in Fig. 11 have peaks at 62 meV, corresponding to the 1-LO- and 2-LO-phonon energies of ZnSe bulk, respectively.

The relationship between phonon energy and detection energy of phonon structures can be obtained from Figs. 9 and 11. Fig. 12 shows the 1-LO- and 2-LO-phonon energies as functions of the detection energy of the phonon structures in PL spectra, which are obtained from Fig. 10. For detection at lower-energy side, the observed 1-LO- and 2-LO-phonon energies

**Fig. 12** 1-LO- and 2-LO-phonon energies as functions of the detection energy of the phonon structures in PL spectra, which are based on the results shown in Fig. 10.

are estimated to be 25 and 50 meV, respectively, which agree with the LO-phonon energies of CdSe bulk. For higher detection energy side, phonon replicas can be resolved with energies of 31 and 62 meV, which correspond to the LO-phonon energies of ZnSe bulk. The size of CdSe QDs at higher detection energy is smaller than that at lower detection energy. This means that the wave functions of excitons at lower detection energy are confined better inside CdSe QDs than those at higher detection energy. Therefore for detection at lower-energy side (larger QDs), excitons are more interacted with the LO phonons of CdSe QDs, resulting in relaxation by using CdSe LO phonons, as shown in Fig. 12. On the other hand, the excitons at higher detection energies (smaller QDs) are weakly localized and their wave functions extend to the surrounding ZnSe barrier layers. Therefore excitons are more interacted with LO phonons of ZnSe barrier layer. As a result, excitons are relaxed by using ZnSe LO phonons, as shown in Fig. 12. At middle detection energy region (from 2.56 to 2.67 eV), phonon energies gradually change from 25 to 31 meV. These phonon energies might be a result of the contributions of both ZnSe and CdSe phonons or of ZnCdSe mixed crystals. The investigations of the Raman spectra of ZnCdSe bulk mixed crystal have shown that the LO-phonon spectra vs. crystal composition are the one-mode type,<sup>[36]</sup> indicating that the LO-phonon energy has changed monotonically with composition. It is difficult to clarify that excitons are relaxed by using both CdSe and ZnSe LO phonons or ZnCdSe LO phonons at middle detection energy region.

**Fig. 13** (A) Photoluminescence spectrum excited at 2.833 eV above the ZnSe band-gap energy at 4.5 K and (B) a distribution curve of PL intensity related with the 1-LO-phonon structure obtained from Fig. 10.

Next, the effect of interactions between CdSe QDs will be discussed. Fig. 13A shows a PL spectrum excited at 2.833 eV for above ZnSe band-gap energy at 4.5 K, which has a peak at 2.551 eV. A distribution curve of PL intensity related with the 1-LO-phonon structure is also shown in Fig. 13b, which is obtained from Fig. 10. This curve has a peak at 2.565 eV. The distribution curve (b) in Fig. 13 shifts to higher detection energy by about 14 meV than the PL spectrum (a) in Fig. 13. In the case of InAs QDs on GaAs substrates, the intensity curves of LO phonons were identical to PL spectra for the above GaAs band-gap excitation.<sup>[30]</sup> This difference in the peak positions in Fig. 13a and b is considered to be a result of the interaction between CdSe QDs.

Because wave functions at higher excited states of CdSe QDs are more extended than those at the ground states, the interactions between the wave function of QDs become stronger. Then, when CdSe QDs are excited at higher excitation energy, carriers can easily move from smaller QDs to larger QDs. As a result, lower detection energy side in PL intensity is enhanced, as shown in the spectrum in Fig. 13A. The broad absorption band at 2.675-eV excitation shown in Fig. 10 is considered to result from the strong interactions between the wave functions of QDs. This broad absorption band is continuous with the ZnSe barrier absorption edge.

On the other hand, because wave functions are confined better at the ground states in CdSe QDs, the interactions between the wave function of QDs are

quite weak. Then, when CdSe QDs are excited at lower excitation energy, PL is obtained from the same CdSe QDs. Consequently, the distribution curve in Fig. 13B is considered to represent real size distribution curve of CdSe QDs. However, the weak absorption, which is independent of detection energy, is obtained at 2.60-eV excitation energy in Fig. 10. This might result from the weak interaction between wave functions of QDs at the ground states.

Recently, carrier relaxation dynamics of CdSe QDs have been investigated by time-resolved PL measurements,<sup>[37]</sup> revealing that the decay time at higher-energy side is decreased with increasing detection energy. This result is considered to be due to the interactions between CdSe QDs, which is consistent with that of the selectively excited PL measurements.

## CONCLUSION

We have investigated the formation and optical properties of self-organized CdSe QDs on ZnSe (001) surfaces with the use of TEM and PL measurements. CdSe QDs with high quality are naturally formed on ZnSe surfaces by MBE when the thickness of CdSe layers is less than about 2 ML. CdSe QDs show a strong green emission even at room temperature. The polarization dependences of PL from CdSe QDs exhibit that the PL spectra are strongly polarized parallel to the  $[1\bar{1}0]$  direction. The CdSe coverage dependence of polarization PL spectra indicates that PL polarization degrees increase with QD formation.

Using micro-PL, single CdSe QD has high-resolved sharp lines, indicating zero-dimensional density of states of the QDs. It is found that the linewidths of the larger-size QDs are more temperature-dependent than those of smaller ones, suggesting to be a result of the difference in the energy level spacing of CdSe QDs.

The carrier relaxation mechanisms in self-organized CdSe QDs have been also investigated by selectively excited PL measurements. The contour map of PL intensity of CdSe QDs reveals that the strong and abrupt absorption edge of the ZnSe barrier layer is clearly observed for whole detection energy. In addition, photoexcited carriers that form excitons are relaxed by emitting multiple LO phonons in CdSe QDs, resulting from the strong confinement of excitons in zero-dimensional structures. At low and high detection energy, LO phonons of CdSe and ZnSe are dominated for relaxation process, respectively. The weak absorption and broad absorption bands observed at lower PL detection energy in the contour map can be interpreted by the interactions between wave functions of CdSe QDs. Stronger interactions between wave functions of CdSe QDs at higher excitation energy induce the difference in the peak positions between

PL spectrum in Fig. 13A and the distribution curve in Fig. 13B. Therefore the distribution curve in Fig. 13B is considered to represent the real size distribution curve of CdSe QDs.

## ACKNOWLEDGMENTS

The authors would like to thank Prof. Koichi Inoue, Dr. Takeshi Ota, Dr. Yasuhiro Murase, and Mr. Nobuhiro Yasui of Osaka University for experimental supports and useful discussions. The authors are also grateful to Prof. Yoshihiko Hirotsu, Dr. Takeshi Hanada, and Mr. Takeshi Ishibashi of Osaka University for TEM operations and Prof. Kazuo Murase and Dr. Kenichi Oto of Osaka University for electron-beam lithography and liftoff techniques.

## INTRODUCTION

Semiconductor nanocrystals, also known as “quantum dots,” have been intensively studied because of their novel properties caused by quantum confinement and their potential to be used in making electro-optical devices.<sup>[1,2]</sup> The colloidal nanocrystals synthesized by wet chemistry methods have in particular drawn much attention because of their chemical processibility<sup>[3,4]</sup> and their capability to be incorporated into various matrices such as conducting polymer<sup>[5–8]</sup> and biological systems.<sup>[9–12]</sup> Studies of CdSe nanocrystals with the wurtzite lattice structure have played an important role in our understanding of quantum confinement<sup>[13,14]</sup> and of the growth mechanism of nanocrystals.<sup>[15]</sup> The recent advances in synthesizing rodlike,<sup>[16–18]</sup> disc-like,<sup>[19,20]</sup> and more exotically shaped<sup>[21,22]</sup> nanocrystals have opened a new field to study the shape dependence of their properties. In this article, we review some of the work on CdSe nanorods (or “quantum rods”) that has been done recently in our group. First, we talk about the synthesis of CdSe quantum rods with tightly controlled variable lengths and diameters and second, their optical and dielectric properties. Because the alignment of the quantum rods is desirable for both fundamental studies and applications, we will also cover our work on the formation of the lyotropic nematic phase of these geometrically anisotropic objects in solution, and the large-scale alignment of the quantum rods by taking advantage of the liquid crystalline phase. Then we will finish by briefly discussing some of their potential applications.

## GROWTH OF CdSe QUANTUM RODS

Generally, CdSe nanocrystals are made by injecting the mixture of precursors (dimethyl cadmium and Se powder dissolved in tributylphosphine) into a hot surfactant protected in inert gases.<sup>[15]</sup> The thermal decomposition of the precursors results in the nucleation of the CdSe particles and the subsequent

crystal growth. Typically, the precursors are injected at 360°C and then the temperature is lowered to 250°C for crystal growth. When trioctylphosphine oxide (TOPO) is used as the surfactant, the CdSe nanocrystals have nearly spherical shape (aspect ratio <1.2). These nanocrystals are coated by organic molecules so that they do not aggregate easily and can be dispersed in organic solvents. These nanocrystals have wurtzite lattice structure, like CdSe bulk crystals. Recently, Peng et al. found that when a mixture of TOPO and hexylphosphonic acid (HPA) is used as the surfactant, rodlike CdSe nanocrystals can be made.<sup>[17]</sup> The CdSe nanorods also have a wurtzite crystalline lattice, and are elongated in the *c*-crystallographic axis. However, the surfactant mixture of TOPO and HPA does not give us the capability to control the monodispersity or to tune the length and width of the quantum rods. This is because the growth of the nanorods is so fast that the growth of the nanocrystals is very sensitive to subtle changes in the reaction conditions such as speed of precursor injection. Consequently, nanocrystals with broad size distribution and even with different shapes are made.<sup>[21]</sup> On the other hand, it was observed that when HPA is replaced with a phosphonic acid with a longer alkyl chain, tetradecylphosphonic acid (TDPA), the speed of the growth of the nanocrystals is dramatically reduced,<sup>[23]</sup> so much so that only nanorods with very small aspect ratio are made without further addition of the precursors during the growth process. To tune the growth rate of the nanorods, we use a mixture of HPA and TDPA with TOPO, and we found that the controllability of the synthesis is greatly improved.<sup>[24,25]</sup> By changing the molar ratio of HPA and TDPA, the speed of growth of the nanorods in both transverse and longitudinal directions can be tuned, so that the nanorods with tightly controlled dimensions can be made reproducibly.<sup>[24,25]</sup> Extraction of part of the reaction solution and subsequent quenching with a large excess of toluene at different time in the early stage of the reaction results in nanorods with different lengths but almost the same diameter. In our study, the HPA/TDPA ratio is

systematically changed and the products examined by transmission electron microscopy (TEM). A HPA/TDPA ratio of 1:3 results in nanorods with large diameter (>4 nm) but small aspect ratio (1–10), whereas increasing the amount of HPA in the mixture but with fixed total molar ratio of the phosphonic acids and TOPO produces nanorods with smaller diameter but large aspect ratio. When the HPA/TDPA ratio is higher than 3:1, the reaction loses control and nanoparticles with broad size and shape distribution are produced. Fig. 1 shows the electron transmission micrographs (TEM) of CdSe quantum rods made with this method. No size selection was performed on the samples after syntheses.

Despite the success in controlling the length and width of CdSe quantum rods, little is known about their microscopic growth mechanism, mainly because of the lack of suitable experimental techniques. However, based on the analysis of the products made by varying the growth conditions, a few observations have been made.<sup>[21,23]</sup> First, rod growth is possible only when the monomer concentration is high enough. The monomers are believed to be some complexes of cadmium that formed at high temperature and may be very different from the species stable at room temperature, and their nature is not yet known. To maintain the monomer concentration for the quantum rods to steadily grow along the *c* axis, the presence of phosphonic acids is required. Second, when the monomers

are depleted, unless more Cd and Se precursors are added the quantum rods will grow fatter and shorter so that eventually nearly spherical nanocrystals are formed. This suggests that the formation of elongated CdSe nanocrystals would be kinetically favored whereas that of nearly spherical ones thermodynamically favored. Third, the growth of the CdSe quantum rods is unidirectional. This is based on the observation that when the amount of HPA in the surfactant mixture is higher than needed for quantum rod growth, nanocrystals with unidirectional shapes such as pencil-, arrow-, or treelike shapes are made.<sup>[21]</sup>

Based on the observations described above, so far two mechanisms have been proposed: selective adsorption<sup>[21]</sup> and diffusion-controlled growth mechanisms.<sup>[23]</sup> The selective adsorption mechanism is based on the different chemical affinity of phosphonic acids to the different faces on the nanocrystals, and thus the different energy of crystal faces in the presence of phosphonic acid molecules. According to this model, all crystal faces except (001) is coated by the phosphonic acid molecules, and therefore the nanocrystals grow unidirectionally to form rods. The diffusion-controlled growth mechanism assumes the mass transport of the monomers to be the determining step of the nanocrystal growth, so that the concentration gradient of the monomers in the bulk solution and the stagnant solution around the quantum rods determines the shape evolution of the CdSe nanocrystals.

**Fig. 1** TEM images of CdSe quantum rods made by using a mixture of HPA, TDPA, and TOPO as the surfactant. By changing the molar ratio of HPA and TDPA, the length and width of the nanocrystals can be systematically controlled. *Source:* Reproduced with permission from Ref.<sup>[53]</sup>. © 2002 American Chemical Society.

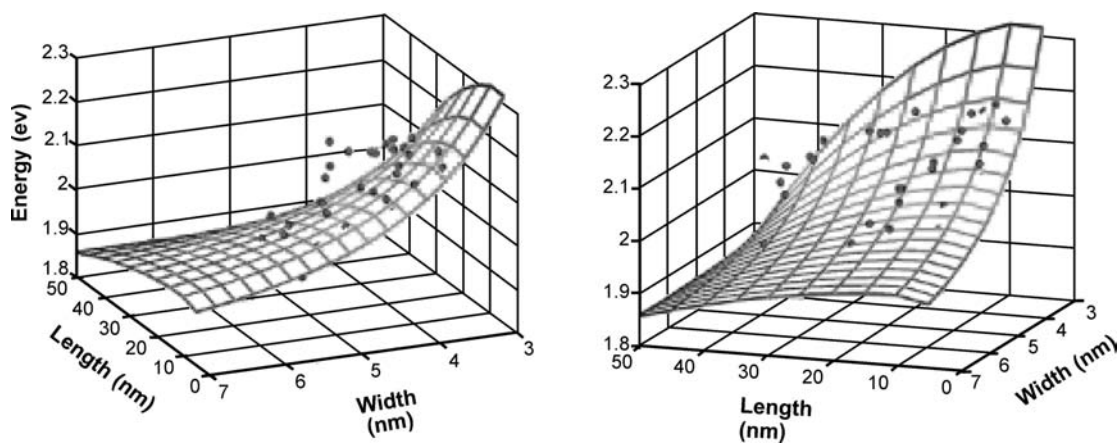

## OPTICAL PROPERTIES

As is well known for (nearly) spherical semiconductor nanocrystals, the absorption and photoluminescence spectra of rodlike nanocrystals are also dependent on their sizes, i.e., both lengths and widths.<sup>[25]</sup> Fig. 2 shows the length and width dependence of the photoluminescence energy of CdSe quantum rods with various lengths and width. The overall tendency is that with increasing length or width, the luminescence shifts to lower energy, which is the same as that of spherical nanocrystals. These figures also show that the width dependence is stronger than the length dependence in the size range we have studied. This is because the confinement of the photo-excited carriers is mainly imposed in the lateral directions.

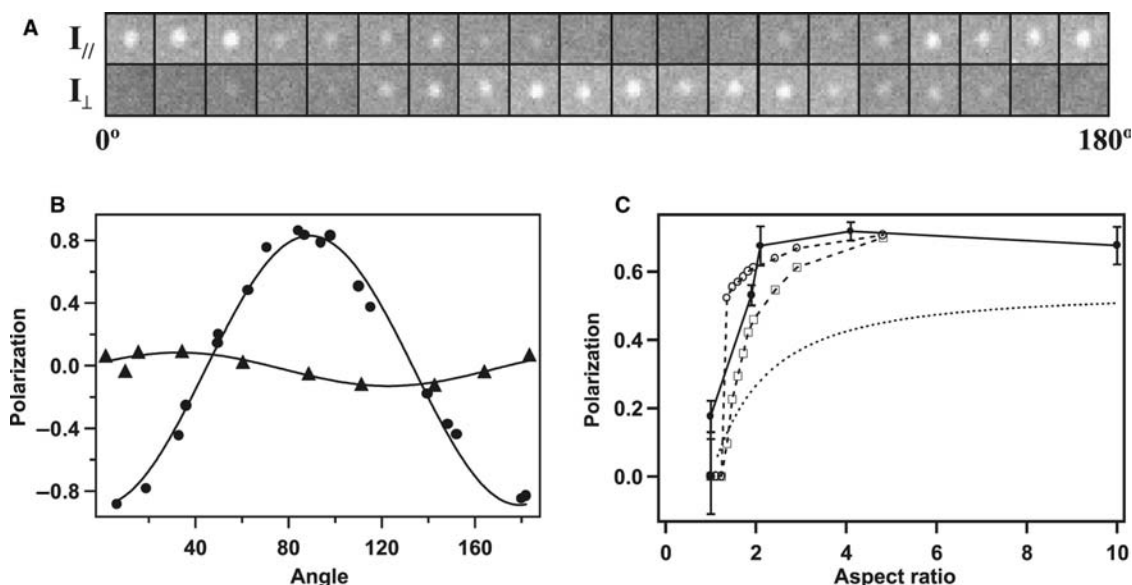

It has been well known that elongation in the shape of nanocrystals results in anisotropy in their optical properties.<sup>[26,27]</sup> Even in the spherical CdSe nanocrystals, polarization of the photoluminescence in the *a*-*b* crystal plane has been theoretically predicted<sup>[28,29]</sup> and experimentally verified,<sup>[30]</sup> because of crystal field splitting in the hexagonal wurtzite crystal structure. The perturbation treatment of the nearly spherical CdSe nanocrystals<sup>[31]</sup> suggested that the ellipticity compensated for the crystal field splitting and even changed the order of the lowest electronic states and thus the polarization of the fluorescence. To study the polarization of the photoluminescence emitted from CdSe quantum rods, single-molecule fluorescence spectroscopy was performed on CdSe quantum rods with variable aspect ratio at room temperature.<sup>[24]</sup> CdSe quantum rods are sparsely deposited on a glass substrate and are excited by a circularly polarized CW Ar<sup>+</sup> laser (480 nm). A beam displacement crystal is used to spatially split the photoluminescence from individual quantum rods into two beams with

perpendicular polarizations and subsequently imaged on a CCD camera at the same time. The rotation of the crystal and therefore the rotation of the polarization directions of the two split beams show the oscillating intensity. Images of luminescence from a single quantum rod with 10:1 aspect ratio (Fig. 3A) demonstrate the change of the fluorescence intensity with detection angle along the two perpendicular polarization directions. The polarization factor *r* for this rod sample is determined to be 86% by fitting the intensity ratio  $r = (I_{\parallel} - I_{\perp}) / (I_{\parallel} + I_{\perp})$  vs. detection angle with a sinusoidal function (filled circle in Fig. 3B). In comparison, the polarization factor of spherical dots is usually less than 10% (filled triangles in Fig. 3B). We have measured samples with aspect ratios from 1:1 to 30:1 at room temperature. The polarization factor changes rapidly from nearly zero to ~70% (e.g.,  $I_{\parallel}:I_{\perp} \cong 5.5:1$ ) when aspect ratio increases from 1:1 to 2:1, then remains almost constant afterward (Fig. 3C).

Semiempirical pseudopotential calculation performed on the CdSe quantum rods<sup>[24,32]</sup> has shown that the linearly polarized photoluminescence from the CdSe quantum rods is indeed a result of the energy level crossing in the highest occupied electronic states. Qualitatively, the lowest excited electronic state of the bulk CdSe semiconductor arises when an electron is excited from an occupied Se 4*p* atomic orbital to an empty Cd 5*s* orbital. This excitation is distributed throughout many unit cells of the solid, and there is a pronounced dependence of the bandgap on the size of the crystals. Because the *p* atomic orbitals are degenerate, the interaction between Se 4*p* orbitals in the crystal field and the effect of spin-orbit coupling play important roles in the electronic structure of CdSe nanocrystals. The empirical pseudopotential calculation was performed to study the evolution of the electronic structure when CdSe nanocrystals evolve

**Fig. 2** The photoluminescence energy of CdSe quantum rods as a function of their length and width. It is more sensitive to width than to length. The meshes drawn are the best polynomial fit. *Source:* Reproduced with permission from Ref.<sup>[25]</sup>. © 2001 American Chemical Society.

**Fig. 3** Luminescence polarization measurements from individual quantum rods at room temperature. (A) Luminescence images of a single rod simultaneously recorded in two perpendicular polarization directions at detection angles changing from  $0^\circ$  to  $180^\circ$ . The rods have an aspect ratio of 10:1. (B) The intensity ratio  $r = (I_{\parallel} - I_{\perp}) / (I_{\parallel} + I_{\perp})$  calculated from the luminescence images in A (filled circles) and fitted with sinusoidal function (solid line) to give a polarization factor of 0.86. The data from spherical dots (filled triangles) show much smaller polarization factors. (C) Polarization factor vs. aspect ratio. The filled circles with error bars are from experiments, unfilled circles from empirical pseudopotential calculations for 0 K, and squares from empirical pseudopotential calculations for room temperature. Each experimental data point was obtained by measuring more than 40 individual rods. The lines simply connect data points, and the dotted line is from the fitting based on the dielectric model proposed in Ref.<sup>[27]</sup> to the data points. *Source:* Reproduced with permission from Ref.<sup>[24]</sup>. © 2001 AAAS.

from a spherical to a rodlike shape. We started from a spherical dot with a diameter of 3.0 nm and increased the aspect ratio by inserting a cylindrical segment along the  $c$  axis. The four lowest unoccupied and four highest occupied electronic states were calculated for quantum rods with aspect ratios ranging from 1:1 to 5:1. As the aspect ratio increases from unity, a crossover of the two highest occupied electronic states occurs at an aspect ratio of 1.25 (Fig. 4). Before this point, the electronic states with predominantly Se  $4p_x$ ,  $4p_y$  components have higher energy than that of states that are mainly  $4p_z$ . The electronic energy levels of these states all increase with increasing size. The  $4p_z$  orbital has greater momentum projected onto the  $c$  axis of the crystal compared to  $4p_x$  and  $4p_y$ , so the energy levels with greater  $4p_z$  component are more sensitive to the rod length. These states exchange position relative to each other at an aspect ratio greater than 1.25. Calculations for the cases of 2.1- and 3.8-nm-wide rods show similar results and the crossing point is 1.25 and 1.36 respectively.

## DIELECTRIC PROPERTIES

In contrast to their well-studied optical and electronic properties, the dielectric properties of CdSe nanocrystals

have been seldom investigated, especially their permanent dipole moment. On one hand, theoretical analyses have suggested the presence of a permanent dipole moment along the  $c$  crystallographic axis because of the lack of inversion symmetry of the wurtzite structure,<sup>[33–35]</sup> on the other hand, dielectric dispersion measurements performed on concentrated solutions of the spherical CdSe<sup>[36,37]</sup> nanocrystals have revealed a permanent dipole moment as a result of surface trapped charges, while the contribution of the noncentrosymmetric lattice is negligible in the size range studied.

However, the surface charge model does not address the direction of the permanent dipole moment, nor does the dielectric dispersion measurement itself because it does not distinguish the uniaxial nature of the spherical nanocrystals. The elongated shape of the CdSe nanorods gives us an opportunity to answer this question.

Transient electric birefringence (TEB) is a method that has been widely used to study the rotational diffusion, size, shape, and polarization properties of objects with anisotropic geometry, especially macromolecules and biological systems such as DNA, viruses, and proteins.<sup>[38,39]</sup> The transient behavior of the birefringence reflects the alignment mechanism of these molecules in response to a pulsed electric field. In particular, for a suspension of elongated objects

**Fig. 4** The four highest occupied electronic states of 3.0-nm-diameter CdSe quantum rods calculated with an empirical pseudopotential method with different aspect ratios. The two highest energy levels have a crossing at an aspect ratio around 1.25. Insets: Contour plots of the two highest occupied states for rods with an aspect ratio of 1.00 and 1.60, respectively. They show the projection of electron density around some Se atoms in a plane, with density increasing from red to blue. This plane intersects the rod in the middle, perpendicular to the long axis ( $c$  axis). The crossing over of the predominantly  $p_{x,y}$  and predominantly  $p_z$  levels vs. aspect ratio can be seen. *Source:* Reproduced with permission from Ref.<sup>[24]</sup>. © 2001 AAAS.

with axial symmetry and a large aspect ratio ( $\geq 5$ ), the rising ( $\Delta n_r$ ) and falling ( $\Delta n_f$ ) edges of the birefringence (difference between the refractive indices of the sample along and perpendicular to the applied electric field) on application and removal of an external electric field are given, respectively, by<sup>[40]</sup>

$$\begin{aligned} \Delta n_r(t) &= \Delta n_s \left( 1 + \frac{\gamma - 2}{2(\gamma + 1)} \exp(-6D_R t) \right. \\ &\quad \left. - \frac{3\gamma}{2(\gamma + 1)} \exp(-2D_R t) \right) \\ \Delta n_f(t) &= \Delta n_s \exp(-6D_R t) \end{aligned} \quad (1)$$

where  $\Delta n_s = \Delta n_r(t \rightarrow \infty)$ ,  $\gamma = \mu_z^2 / [k_b T (\alpha_{\parallel} - \alpha_{\perp})]$ ,  $\mu_z$  is the screened value of the electric dipole moment along the long axis of the rods,  $\alpha_{\parallel}$  and  $\alpha_{\perp}$  the static electric polarizability along and perpendicular to the long axis, respectively, and  $D_R$  the rotational diffusion constant around an axis normal to the long axis of the rods. According to Eq. 1, the rise time of the birefringence will be slower than the fall time only when there is a permanent dipole moment along the long axes of the nanorods. Benoit<sup>[40]</sup> used this method to study tobacco mosaic virus (TMV), and from the symmetric falling and rising edges he concluded that TMVs do not have permanent dipole moment in aqueous solution.

To measure the electric birefringence we use the procedure of O'Konski and Zimm,<sup>[41,42]</sup> as described in detail in Ref.<sup>[43]</sup>. The quantum rods under electric field have birefringence of the same sign as nitrobenzene, indicating that the nanorods align along (rather than perpendicular to) the electric field. Fig. 5A shows a typical transient electric birefringence curve measured for CdSe nanorods.<sup>[43]</sup> As suggested by Eq. 1, the asymmetric falling and rising edges indicate the existence of a permanent electric dipole moment along the long axis. The hexagonal symmetry of CdSe nanorods allows us to approximately treat them as being axially symmetric, thus we can fit the TEB curves with Eq. 1 to obtain the rotational diffusion constants and the ratio of permanent dipole moment to the polarizability anisotropy ( $\gamma$ ).

To get the permanent dipole moment from  $\gamma$ , we calculate the electric polarizability of CdSe nanorods by assuming a revolute prolate shape for the nanorods, so that the principle axes of polarizability coincide with the geometrical axes. The polarizabilities are calculated by<sup>[44]</sup>

$$\alpha_{\parallel(\perp)} = \varepsilon_0 v (\varepsilon_{\parallel(\perp)} - 1) / [1 + A_{\parallel(\perp)} (\varepsilon_{\parallel(\perp)} - 1)]$$

where  $v$  is the volume of individual nanorod,  $\varepsilon$ 's the relative dielectric constants between nanorods and the solvent along ( $\parallel$ ) or perpendicular ( $\perp$ ) to the long axis of the nanorods, and  $A$ 's the geometrical factors that can be calculated from the dimension of the nanorods.<sup>[45]</sup> The dielectric constants of CdSe nanorods are taken as bulk material values ( $\varepsilon_{\parallel} = 10.2$ ,  $\varepsilon_{\perp} = 9.33$ ), and that of cyclohexane is taken as 2.02.

The unscreened permanent dipole moments  $\mu_z$  of five nanorod samples are plotted in Fig. 5B vs. their volume. Considering the ensemble nature of the measurement, these are the root mean square dipole moment of the samples. It is an average not only over the finite size distribution, but also over the possible structural distribution. An empirical pseudopotential

**Fig. 5** (A) A typical TEB curve (in linear scale) on the application and subsequent removal of the electric field. The asymmetric rising and falling edges indicate the existence of a permanent dipole moment along the long axis of the quantum rods. In this particular case, the CdSe quantum rods are 4.8 nm wide and 30 nm long. (B) The unscreened dipole moment of CdSe quantum rods with different sizes. The solid triangles are the values measured with the TEB method, and the straight line is the best fit, with a slope of  $0.19 \mu\text{C}/\text{cm}^2$ . Source: Modified with permission from Ref.<sup>[43]</sup>. © 2003 American Physical Society.

calculation showed that the dipole moment strongly depends on the detailed structure of the nanocrystals and can vary significantly on small structural changes.<sup>[35]</sup> Within the experimental error, however, a linear dependence of  $\mu_z$  vs. volume is obtained, and no correlation between rod length or width and  $\mu_z$  can be realized. This is consistent with theoretical analyses that the polarity is intrinsic to the crystallographic lattice of CdSe because of the lack of inversion symmetry. Our results are not consistent with a random dipole moment resulting from trapped surface charges, as proposed for spherical CdSe nanocrystals. From the slope, we get the polarization of CdSe nanorods to be  $0.19 \mu\text{C}/\text{cm}^2$  along the  $c$  crystallographic axis, which is in good agreement with the value of  $0.6 \mu\text{C}/\text{cm}^2$  as estimated<sup>[34]</sup> from a phenomenological

rule that was proved experimentally only for ferroelectric materials.

### LYOTROPIC LIQUID CRYSTALLINE PHASE OF CdSe QUANTUM ROD DISPERSION

The anisotropic properties of the quantum rods may find applications in devices such as solar cells, polarizing light-emitting diodes, and electro-optical switches. However, to achieve this, it is important to align the quantum rods on a large scale. Recently, enormous effort has been devoted to aligning the geometrically anisotropic nanoscale objects such as nanowires, nanotubes, and nanorods.<sup>[16,46]</sup> On the other hand, it has been well known that rodlike or disclike objects, when dispersed in a solvent to a high enough concentration, will spontaneously form lyotropic liquid crystalline phases in which the geometrically anisotropic objects are orientationally ordered. This is clearly illustrated by the rigid rod model proposed by Onsager in 1949.<sup>[47]</sup> In this model, the free energy of a dispersion of long, thin spherocylinders (aspect ratio  $>100$ ) in a solvent can be obtained by a virial expansion,<sup>[48]</sup>

$$\frac{\Delta F}{NkT} = \frac{\mu^0}{kT} + \ln(\Lambda^3 \rho) - 1 + \left\{ \int f(\Omega) \ln[4\pi f(\Omega)] d\Omega + \frac{1}{2} \rho \iint v_{\text{exclusive}}(\Omega, \Omega') f(\Omega) f(\Omega') d\Omega d\Omega' + \dots \right\}$$

where  $f(\Omega)$  is the orientational distribution function of the rodlike objects, and  $\rho$  the number density of the spherocylinders. The first term in the curved bracket is called orientational entropy, which favors a random orientational distribution; while the second term is called packing entropy, which favors an orientationally ordered phase. The packing entropy term dominates only when the density of the rods is high enough so that a nematic lyotropic phase can spontaneously form. Famous examples include rodlike organic macromolecules such as poly( $\gamma$ -benzyl  $\alpha$ ,L-glutamate) (PBLG)<sup>[49]</sup> rodlike tobacco mosaic virus,<sup>[50]</sup> etc. Lyotropic liquid crystalline mesophases based on all-inorganic minerals have also been known for quite a long time, and have been reviewed by several authors;<sup>[48,51,52]</sup> however, this area has rarely been explored because of the lack of the interest other than purely academic purposes, in contrast with their thermotropic counterpart. The recent success in the synthesis of the highly soluble and processible metallic semiconductors and magnetic nanocrystals with anisotropic geometries<sup>[16–20]</sup> and the need for aligning them in order to use their anisotropic properties have provided us a new opportunity to study these liquid crystalline phases.

The most important requirement for the formation of lyotropic liquid crystalline phases is the high dispersion concentration, which is not trivial for most of the inorganic nanocrystals. Recently, we have succeeded in making the nematic phase of solution of CdSe quantum rods in organic solvent.<sup>[53]</sup> The solvent we use is anhydrous cyclohexane or anhydrous hexanes, which can dissolve CdSe quantum rods to a volume percentage up to 60%. Dilute solutions of quantum rods in a vial are concentrated by blowing with dry nitrogen, and a birefringent phase starts to appear at a certain concentration as observed under an optical polarizing microscope. The solutions are then transferred to NMR tubes or capillary tubes for further study. Special care has to be taken during the process to avoid the exposure of the solution to the air, because the inclusion of even trace amount of water would result in thermoreversible gelation,<sup>[54–56]</sup> which is also often seen in suspensions of organic rodlike polymers and has been attributed to the degradation of the solvent. Fig. 6A shows isotropic-liquid crystalline phase separation in a 300- $\mu\text{m}$ -diameter capillary tube, and the characteristic disclinations for a nematic phase observed in a thin layer of the solution of CdSe  $3.8 \times 40\text{-nm}$  quantum rods. The red color is due to the absorption of this quantum rod sample.

The formation of the liquid crystalline phase allows us to align the quantum rods by taking advantage of the collective behavior in a liquid crystalline solution.<sup>[57]</sup> Various methods have been applied to align the liquid crystalline materials such as electric and magnetic fields as well as curved surfaces. Fig. 7 shows the X-ray diffraction patterns of a liquid crystalline solution of CdSe quantum rods in a 300  $\mu\text{m}$  capillary tube.<sup>[58]</sup> These rods have a length of  $\sim 60$  nm and width of 3.0 nm. In both figures, the capillary tube remains vertical. In Fig. 7A, the sharp arcs in the vertical position are due to (002) planes of the CdSe crystalline lattice within individual quantum rods. The high intensity and sharpness of the arcs are determined by the elongated shape of the CdSe quantum rods. The anisotropy of the pattern demonstrates macroscopic alignment of the long axis of the rods. Consistently, in Fig. 7B the diffuse arcs in the equator direction correspond to the lateral distance of the quantum rods, suggesting the short axis is aligned as well. Together, the patterns demonstrate the preferential alignment of the CdSe quantum rods along the capillary tube axis direction, which is attributed to the curved surface of the capillary tube. It can be estimated that about 70% of the quantum rods are oriented within  $20^\circ$  from the axis of the capillary tube.

Alignment of lyotropic liquid crystalline solution with magnetic fields has been reported.<sup>[59]</sup> Even when none of the components is ferromagnetic, the anisotropy of the magnetic susceptibility of individual

**Fig. 6** (A) Isotropic-liquid crystalline phase separation observed between crossed polarizers. The birefringent liquid crystalline phase is on the bottom due to the high density, while the isotropic phase on the top is not visible because of the complete extinction of the transmitted light. (B) The typical defect structures observed in a thin film of liquid crystalline solution of CdSe nanorod solution. The arrows point to the disclinations. The red color is due to the absorption of the CdSe nanocrystals. *Source:* Modified with permission from Ref.<sup>[53]</sup>. © 2002 American Chemical Society.

constituent molecules adds up because the long-range orientational correlation in the liquid crystalline phases, and therefore the energy gain because of the alignment can easily exceed the thermal fluctuation  $kT$ . The alignment of CdSe quantum rods in a liquid crystalline solution under a magnetic field is observed with NMR. A few drops of deuterated chloroform are added into a solution of CdSe quantum rods in cyclohexane, which has a high enough concentration to have both isotropic and liquid crystalline phases present. Fig. 8 shows our preliminary result of DNMR spectrum observed in a 500-MHz spectrometer at  $30^\circ\text{C}$ . The central peak is confirmed to be due to the isotropic part of the solution, while the other two peaks are due to the quadruple splitting of the deuterium nuclei in the anisotropic liquid crystalline

**Fig. 7** Wide-angle X-ray diffraction and small-angle X-ray scattering of the same nematic solution of CdSe quantum rods in a 300- $\mu\text{m}$ -thick capillary tube show the preferential alignment of these quantum rods along the axis of the capillary tube. In both measurements, the capillary tube is held vertically. (A) Wide-angle X-ray diffraction pattern. The vertical sharp, intense arcs correspond to the (002) planes of wurtzite CdSe lattice. At about the same radius, weak arcs corresponding to the (100) and (101) planes can also be seen, but they are much more diffuse. (B) Small-angle X-ray scattering pattern. The two diffuse arcs at  $Q \sim 1.5 \text{ nm}^{-1}$  on the equator corresponds to the lateral spacing between the rods in the nematic phase. The arcs corresponding to the longitudinal spacing are not resolved. *Source:* Reproduced with permission from Ref.<sup>[58]</sup>. © 2003 Wiley-VCH.

medium. The comparison of the spectrum with a typical Pake powder pattern<sup>[60,61]</sup> indicates the alignment of the C–D bond in  $\text{CDCl}_3$ , presumably as a result of both the alignment of the quantum rods by the magnetic field and the interaction between the nanorods and  $\text{CDCl}_3$  molecules. The exact mechanism is still under investigation.

In spite of the formation of the liquid crystalline phase of the CdSe quantum rod solution, tremendous challenges exist in the alignment of the CdSe quantum rods, especially on a substrate. It is not straightforward to apply the techniques used in liquid crystal display industry such as rubbed surfaces.<sup>[62]</sup> Furthermore, the volatile nature of the solvent in the CdSe liquid crystalline solution and the propensity of the solution to gel on the exposure to the air or water make the solution difficult to handle.

## POTENTIAL APPLICATIONS

Even though the development of the devices with semiconductor quantum rods is still in the early stage, the recent success in using CdSe quantum rods–conjugated polymer composite to make solar cell with high power conversion efficiency<sup>[63]</sup> has demonstrated the huge potential of the nanocrystals as an active component in electro-optical devices. The solar cells made with inorganic–organic composite take advantage of both the high carrier mobility in inorganic semiconductors and the easy processibility of organic polymers. Furthermore, the presence of the interface between two

materials with very different electron affinities enhances the charge separation of the photo-excited carriers. The high extinction coefficient of CdSe nanocrystals makes a very thin film ( $\sim 100 \text{ nm}$ ) of the composite adequate to absorb all of the solar radiation. The application of CdSe quantum rods in the

**Fig. 8** The deuterium NMR spectrum of a solution of CdSe quantum rods at 30°C in which isotropic phase and liquid crystalline phase coexist. The solution is doped with  $\text{CDCl}_3$ . The central peak is caused by the isotropic part of the solution, which significantly broadens because of the high viscosity of the solution, while the two side peaks are caused by quadruple splitting of the deuterium nuclei in the liquid crystalline phase. The comparison with a powder pattern indicates the alignment of the quantum rods in the liquid crystalline solution.

composite, as compared to the nearly spherical nanocrystals, provides a natural path for electrical transport after the charge separation, so that the probability of recombination of photocarriers is reduced. Recently, a power conversion efficiency of 1.7% has been achieved by mixing  $7 \times 60$ -nm CdSe quantum rods with poly(3-hexylthiophene) (P3HT). The rod length dependence study shows that the charge transport improves substantially when the aspect ratio of the quantum rods increases from 1 to 10. Further improvement to the power conversion efficiency is still on the way, which includes the alignment of the quantum rods perpendicular to the film, the improvement to the interface between the nanocrystals and the polymer, and using nanocrystals of other materials such as CdTe. Other possible applications include polarizing light-emitting diodes and electro-optical switches by taking advantage of the anisotropic linear and non-linear optical properties of these quantum rods.

## CONCLUSIONS

In summary, we have discussed the recent development in the study of CdSe quantum rods. It is just the beginning of the investigation of the shape-dependent properties of semiconductor nanocrystals, and we believe the advent of the new methods to make nanocrystals with more complicated shapes, such as tetrapods and even dendritic inorganic nanocrystals,<sup>[21,22]</sup> will further advance this kind of study. In addition, the success in the macroscopic alignment of the nanorods provides us unique opportunities to investigate some anisotropic ensemble properties such as optical or X-ray absorption, surface selectivity of ligands, interaction between nanorods and solvent, etc. However, much work still needs to be done to make the nanorods applicable for devices. Currently work is under way in our laboratory to make the liquid crystalline solutions more robust so that they can survive various processing procedures. Furthermore, methods to align the nanorods on substrates have to be developed.

## INTRODUCTION

The challenge of creating functionalized, robust quantum confined group II–VI semiconductor nanoclusters (NCs) involves the ability to realize size-controlled and size-stable nanocrystallites. The size and stability issues are non-trivial problems that are at the forefront of nanotechnology research.<sup>[1–3]</sup> Several recent and key spectroscopic,<sup>[4–9]</sup> synthetic,<sup>[10,11]</sup> and engineering results have set the stage for timely computational studies that will make significant advances in the atomistic-level and fundamental understanding of the structure, stability, and aqueous assembly of CdS NCs and of higher-order NC architectures with unique physical properties. Building upon previous experimental and computational work, our research objective is to provide both fundamental insights into the aqueous assembly of CdS nanoclusters (our model is shown in Fig. 1), as well as practical knowledge used for the construction of higher-order nanocluster architectures with unique physical properties.

The first four sections of this work briefly review the experimental and theoretical knowledge about semiconductor nanocrystals. A more detailed coverage of experimental and theoretical work in semiconductor nanotechnology has been reported.<sup>[12]</sup> The last three sections cover the application of quantum mechanical (ab initio, DFT, and semiempirical) as well as hybrid quantum/molecular mechanical methods to characterize organic and peptide capped nanocrystals.

## SEMICONDUCTOR NANOCRYSTALS

In general, the chemical and physical properties of a substance do not depend on the amount of the sample.

However, when the size of a material fragment becomes sufficiently small this may no longer be true. It has been demonstrated in a wide range of semiconductors that many properties become dependent on cluster size once the cluster diameter is below some threshold value unique to the material being examined. The size dependency is observed in semiconductor fragments on the order of nanometers in diameter and referred to as nanoclusters. The changes occur as the cluster is transformed from a fragment of bulk material to a “molecule-like” cluster. There are two aspects of the transformation that play a role in this effect. First, as the cluster size decreases, the proportion of surface atoms to interior atoms increases substantially. Consequently, surface effects such as relaxation, rearrangement, dangling bonds, and other defects become more significant as the size of the nanocrystal decreases. Second, the density of states of a nanocrystal is altered as a result of the quantum size effect.<sup>[3,13–15]</sup> The alteration occurs as the cluster size is decreased because excitons that are delocalized over large distances in the bulk are increasingly confined. The electronic and optical properties of the clusters are particularly sensitive to changes in the density of states. These quantum dots with size-dependent electronic and optical properties have important potential applications as LEDs,<sup>[16]</sup> in solar cells<sup>[17]</sup> and for photoswitches. The quantum size effect and surface characteristics have also been shown<sup>[18,19]</sup> to be an important factor in the efficiency of photocatalysis of organic reactions by semiconductor nanocrystals.

The II–VI semiconductors are of interest for a variety of reasons. These materials are direct gap semiconductors with band gap energies in the visible spectrum. In addition, their chemical properties make them good candidates for the preparation of colloidal

**Fig. 1** Structure of  $\text{Cd}_{32}\text{S}_{14}$  coated with 13  $(\gamma\text{-Glu-Cys})_3\text{-Gly}$  units (1066 atoms total) peptides. The yellow-colored spheres represent the sulfur and cadmium, respectively.

dispersions and organically capped clusters. In this entry we focus on the study of the electronic and optical properties of CdS nanoclusters.

### WELL-CHARACTERIZED CLUSTERS OF CdS AVAILABLE FOR STUDY

Over the last three decades experimental studies have demonstrated the effects of varying the size of semiconductor nanoclusters both qualitatively and quantitatively. For the most part, early work<sup>[20–23]</sup> was performed using samples that contained a distribution of cluster sizes. This work clearly demonstrated trends in the values of various properties with cluster size and established similarities between these trends in various materials. However, in order to study systematically the effect of changing cluster size both experimentally and theoretically it is desirable to have well-defined clusters of fixed and known composition. Semiconductor nanocrystals are prepared in different ways<sup>[3,15]</sup> but only one method has led to the preparation of well-characterized clusters of known composition and structure. Chemical synthesis of larger clusters from smaller precursor species has resulted in clusters in the size range of interest that have a core of bulk-like material. The cluster surface is passivated by saturating the dangling bonds with organic ligands. In addition to passivating the surface, the ligands improve the solubility of the clusters and function to maintain their integrity in solution. We describe below several ligand-capped clusters that are available for study.

One of the early significant developments in the synthesis of organically capped nanoclusters of CdS was the synthesis and subsequent characterization of  $[\text{Cd}_{17}\text{S}_4(\text{SPh})_{28}]^{2-}$  by X-ray crystallography,<sup>[24]</sup> where SPh is thiophenolate ( $\text{SC}_6\text{H}_5^-$ ) (Fig. 2). The inner core of this cluster  $\text{Cd}^{\text{I}}(\mu_4\text{-S})_4(\text{Cd}^{\text{c}})_{12}$  consists of CdS in the sphalerite (zincblende) form. This core is capped by four cages  $\{\text{S}(\text{Cd}^{\text{c}})_3(\mu\text{-SPh})_3\text{Cd}\}$  with structure similar to the wurtzite (hexagonal) lattice. Although the size of this cluster is not in the range of interest it was recognized that this species had the potential to serve as a precursor to larger clusters in the same family.

The first CdS cluster with a diameter in the range of interest to be synthesized and characterized<sup>[25]</sup> was  $\text{Cd}_{32}\text{S}_{14}(\text{SPh})_{36}\cdot\text{DMF}_4$ , a homolog of the  $[\text{Cd}_{17}\text{S}_4(\text{SPh})_{28}]^{2-}$  cluster described above. This larger cluster has an 82-atom bulk core similar in structure to that of its smaller homolog and is similarly capped by wurtzite-like (hexagonal) CdS units at four tetrahedral corners. The four solvent molecules are bound at these corners. Excitation, luminescence, and absorption spectra are available<sup>[25]</sup> for the crystallized molecular solid and for clusters dissolved in tetrahydrofuran (THF), *N,N*-dimethylformamide (DMF), and acetonitrile.

Synthesis and characterization of a superlattice structure from units consisting of two  $\text{Cd}_{17}\text{S}_4(\text{SCH}_2\text{CH}_2\text{OH})_{26}$  clusters covalently bound by a  $\mu\text{-SR}$  bridge has also been accomplished<sup>[26]</sup> (Fig. 3). These clusters are identical in structure to the  $[\text{Cd}_{17}\text{S}_4(\text{SPh})_{28}]^{2-}$  clusters described earlier<sup>[24]</sup> with  $-\text{CH}_2\text{CH}_2\text{OH}$  replacing the

**Fig. 2** The structure of  $[\text{Cd}_{17}\text{S}_4(\text{SPh})_{28}]^{2-}$ . Source: From Ref.<sup>[24]</sup>.

**Fig. 3** Basic unit of the superlattice described in Vossmeier et al.<sup>[26]</sup> Each unit consists of two covalently bound  $\text{Cd}_{17}\text{S}_4(\text{SCH}_2\text{CH}_2\text{OH})_{26}$  clusters.

phenyl groups and two vertices of the cluster left uncapped. In the superlattice solid, covalent  $\mu$ -SR bridges connect each  $\text{Cd}_{17}\text{S}_4(\text{SCH}_2\text{CH}_2\text{OH})_{26}$  cluster to four others, one at each of its four vertices. In solution the clusters have been shown to be capped by two thiolate ligands with two vertices remaining unsaturated.<sup>[26]</sup> Photoluminescence and absorption spectra are available for the superlattice solid and solutions of the cluster in water, dimethyl sulfoxide (DMSO), and DMF.<sup>[26]</sup>

Further work by the same investigators resulted in the synthesis and crystallization of the  $\text{Cd}_{32}\text{S}_{14}(\text{SCH}_2\text{CH}(\text{OH})\text{CH}_3)_{36}\cdot 4\text{H}_2\text{O}$  cluster.<sup>[27]</sup> This larger cluster is a structural homolog of the  $\text{Cd}_{17}\text{S}_4(\text{SCH}_2\text{CH}_2\text{OH})_{26}$  cluster and has a diameter in the range of interest. The core structure is the same as that of the  $\text{Cd}_{32}\text{S}_{14}(\text{SC}_6\text{H}_5)_{36}\cdot \text{DMF}_4$  cluster described earlier.<sup>[25]</sup> A superlattice structure is formed in the molecular crystal that is not of the same structure as that formed by the smaller homolog. Absorption spectra are available for the superlattice in thin film form and for the nanocrystals dissolved in DMF.<sup>[27]</sup>

## EXPERIMENTAL OPTICAL AND ELECTRONIC PROPERTIES

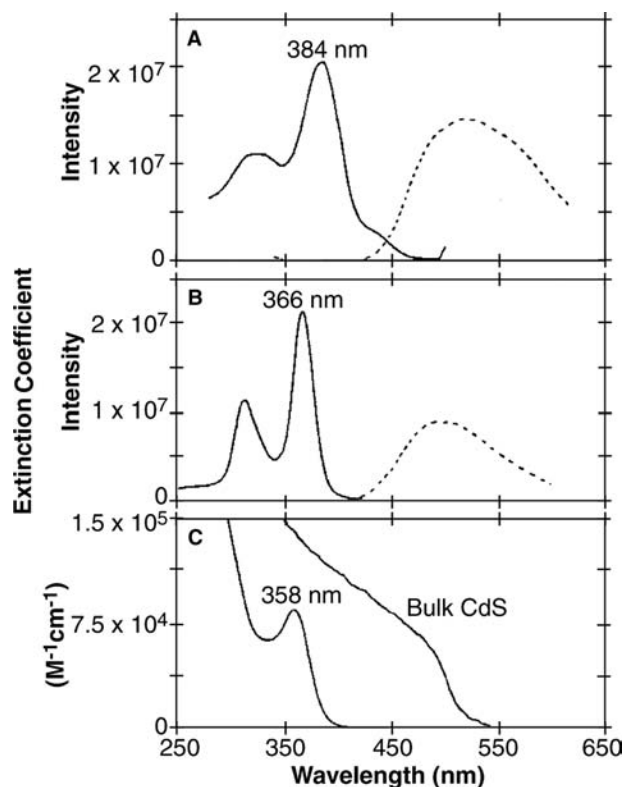

In all semiconductor nanocrystals studied, regardless of the method of preparation, as cluster size is decreased the onset of the lowest energy transition is blue shifted. This corresponds to an increase in the band gap energy with decreasing cluster size. In CdS nanoclusters, this effect is observed for clusters with diameters in the range of approximately 1 to 10 nm.<sup>[13]</sup> The actual value of the observed band gap energy varies depending upon the semiconductor, how the clusters have been prepared, and the characteristics of the cluster surfaces. In CdS, the band gap energy varies from the bulk value of 2.5 eV to about 4.5 eV.

Specific data on the electronic and optical properties of the well-defined crystals described above are available as mentioned earlier. The lowest energy absorption band observed in the optical spectra of solid-state crystals of  $\text{Cd}_{32}\text{S}_{14}(\text{SC}_6\text{H}_5)_{36}\cdot \text{DMF}_4$

occurs at 325 nm, whereas in the spectrum of the dissolved clusters it occurs at 358 nm.<sup>[25]</sup> In the  $\text{Cd}_{32}\text{S}_{14}(\text{SCH}_2\text{CH}(\text{OH})\text{CH}_3)_{36}\cdot 4\text{H}_2\text{O}$  cluster of similar structure, the corresponding band gap energy occurs at about 325 nm in both the thin film and in solution.<sup>[27]</sup> In the spectra of the smaller  $\text{Cd}_{17}\text{S}_4(\text{SCH}_2\text{CH}_2\text{OH})_{26}$  clusters in solution the band occurs at 290 nm.<sup>[26]</sup> In all cases this is a blue shift from the bulk value as expected (Fig. 4). These results suggest that the type of capping ligand is of importance in determining the actual values of the electronic and optical properties of the clusters.

The lowest energy absorption band in all three clusters studied is characterized by a large extinction coefficient (on the order of 84,500, 138,000, and 84,000  $\text{M}^{-1}\text{cm}^{-1}$ , respectively). Whenever absorption spectra were obtained for the same cluster in different solvents, the band was found to vary little as the polarity of the solvent varied.<sup>[25,26]</sup>

The results of photoluminescence studies were also reported for  $\text{Cd}_{32}\text{S}_{14}(\text{SC}_6\text{H}_5)_{36}\cdot \text{DMF}_4$ <sup>[25]</sup> and  $\text{Cd}_{17}\text{S}_4(\text{SCH}_2\text{CH}_2\text{OH})_{26}$ .<sup>[26]</sup> The solid-state crystals of the former structure emit green light at approximately 520 nm, whereas in THF solution the band is

**Fig. 4** Excitation (solid) and luminescence (dotted) spectra of polycrystalline (A)  $\text{Cd}_{32}\text{S}_{14}(\text{SC}_6\text{H}_5)_{36}\cdot \text{DMF}_4$  clusters and the same dissolved in THF (B) and absorption spectrum (C) of the dissolved clusters. *Source:* From Ref.<sup>[25]</sup>. slightly blue-shifted. Luminescence spectra of the superlattice structure based on the latter structure shows a band at 400 nm. When the clusters are dissolved in water the band is blue shifted approximately 5 nm. In none of these spectra is there a peak present that corresponds to the strong band that is observed in the absorption spectra (Fig. 5).

### THEORETICAL STUDY OF QUANTUM SIZE EFFECTS ON ELECTRONIC AND OPTICAL PROPERTIES OF NANOCCLUSERS

It is incumbent upon any theoretical study of the quantum size effect in semiconductor nanocrystals to explain both qualitatively and quantitatively the observed shifts in electronic and optical properties with decreasing cluster size. The earliest theoretical approaches<sup>[28–31]</sup> to describe quantum size effects on the CdS system were variations on a very simple theory. The effective mass approximation to account for the “lattice-like” effects has been used together with a particle-in-the-box treatment to incorporate the quantum confinement. These models readily demonstrated an increase in the lowest energy transition as the cluster size was decreased within the range of interest. However, it has been only possible to achieve quantitative agreement with experiment for large clusters. In part this is because surface effects become increasingly important relative to “bulk-like” effects as the cluster size decreases. These models could not treat the surface in any realistic way.

There are significant challenges in treating these nanosystems with accuracy particularly when the optical and electronic properties are the main interest.

With surface effects clearly playing an important role it is highly desirable to use a method that takes into account individual atoms. As the cluster sizes in the range of interest contain up to several thousand Cd and S atoms, computations can be extremely intensive. When organic ligands are included, as in the ligand-capped clusters, the number of atoms increases even further. In addition, predicting transition energies and probabilities requires a method that has a demonstrated ability to treat excited states with accuracy. These methods add substantially to the computational time.

Several different techniques have been used in succession in an attempt to improve upon the effective mass description. These included the use of empirical pseudopotentials,<sup>[32]</sup> and several techniques based upon tight-binding theory.<sup>[33,34]</sup> In most cases, surface effects have not been incorporated into the method. Further, the majority of the work, including one study in which surface considerations were included,<sup>[34]</sup> focused on bare semiconductor clusters. Working with bare clusters has the advantage of avoiding the additional computation time required to incorporate the ligand atoms and determine the structure of surface ligands. However, samples of bare clusters cannot be prepared that are uniform in composition nor can the surface composition and characteristics be precisely controlled. This complicates the comparison between the theoretical studies using a cluster of fixed composition and the results of experiments performed with a distribution of clusters. Nevertheless, these works did, for the most part, succeed in extending the good agreement between the predicted energy of the band gap and the experimental values for different size clusters to somewhat smaller clusters.

The first theoretical work that used *ab initio* methods to model ligand-capped clusters of CdS for which experimental data were available involved the use of a semiempirical method (complete neglect of differential overlap, CNDO).<sup>[35]</sup> The computationally intensive configuration interaction with single excitations (CIS) method was employed to improve the description of the excited states. Because of the time intensive computational technique employed, the clusters studied had to be very small, in particular the computed systems were  $[\text{Cd}(\text{SPh})_4]^{2-}$ ,  $[\text{Cd}_2(\text{SPh})_6]^{2-}$ , and  $[\text{Cd}_4(\text{SPh})_{10}]^{2-}$ . Agreement between the theoretical and experimental results was good; however, these clusters are substantially smaller than the size regime of interest.

Techniques based on density functional theory (DFT) hold promise for more accurate treatment of larger clusters. DFT has been shown to be capable of giving a good description of the ground state in transition metal systems. Early applications of DFT in the local density approximation to both CdSe and CdS clusters to the determination of transition energies significantly underestimated band gap energies. Recent

**Table 1** Summary of CdS monomer bond lengths and HOMO/LUMO energies at different levels of theory and basis sets

	Cd/S	SVWN	B3LYP	HF	MP2	MP3	MP4	PM3
	Lanl2dz/6-31G*	2.267	2.319	2.290	2.258	2.298	2.278	
	Sadlej/6-31G*	2.243	2.300	2.311	2.265	2.298	2.274	
	PM3							2.312
HOMO	Lanl2dz/6-31G*	-0.2105	-0.2184	-0.3178	-0.3177	-0.3179	-0.3178	
LUMO		-0.1985	-0.1597	-0.0595	-0.0588	-0.0596	-0.0592	
		0.32	1.60	7.03	7.05	7.03	7.04	eV

LUMO		-0.1812	-0.1578	-0.0570	-0.0561	-0.057	-0.0563	
		0.35	1.59	6.66	6.70	6.67	6.69	eV

Band lengths are reported in Angstroms and HOMO/LUMO energies in atomic units.

advances in methodology indicate that DFT will be capable of describing excited states and predicting band gap energies as well as the currently accepted methods while requiring less computer time.<sup>[36]</sup> Application of a time-dependent density functional theory in the local density approximation (TDLDA) has been used with some success to predict the absorption spectra of bare CdSe clusters with sizes in the regime of interest.<sup>[37]</sup>

It seems clear that any theoretical technique that is to describe accurately the optical and electronic properties of CdS nanoclusters over the full range of sizes in which the quantum size effect is evident must explicitly treat the cluster surface. In order to be able to compare the results of the calculations with experimental values, it is highly desirable to model the well-defined organically capped clusters that have been prepared. Optical properties have been shown to be dependant on the ligand structure<sup>[25-27]</sup> and so a method that models the capping-ligands as well as the core structure is needed.

## QUANTUM CALCULATIONS ON CdS

We are undertaking a systematic study of basis sets and computational methods on CdS as well as CdS dimers. The goal of the study is to find the best level of theory that will yield the most accurate results for the least amount of computational effort. Table 1 summarizes our results to date.

One observes from Table 1 that the CdS bond length is much shorter than the bulk CdS bond length of 2.519 Å. The bond length at the highest level of theory (MP4) and the largest all electron basis set sadlej/6-31G\* is 2.274 Å. The DFT functional SVWN using the LANL2DZ on cadmium and 6-31G\* on sulfur appears to be very close to the 2.274 Å value from the “best” level of theory and all electron basis set. The computational time saving is approximately a factor of 100. The semiempirical PM3 bond length is 0.038 Å too large when compared to the MP4/(Sadlej/

6-31G\*) value. The sign of the HOMO/LUMO gaps is reversed to what is typically expected between ab initio and DFT results. The ab initio HOMO/LUMO gaps for this system should be smaller, whereas the DFT numbers should be larger. The experimental band gap for the Cd<sub>32</sub> monocluster is approximately 4 eV. The PM3 HOMO/LUMO gap is 6.76 eV.

We calculated the geometry for the CdS dimer using the LANL2DZ/6-31G\* basis set at different levels of theory (Table 2). Again we see that the DFT functional SVWN performs as well as MP3 using the same basis set. Our conclusion at this point is that we can use the SVWN method and LANL2DZ/6-31G\* basis set on the cadmium and sulfur atoms in our electronic structure calculations. This conclusion is also based on the results from additional calculations using other larger basis sets and higher level of theory.

## SEMIEMPIRICAL CALCULATIONS ON ENCAPSULATED CdS CLUSTERS

Recent advances in computer hardware and semiempirical quantum mechanical codes permit the calculation of large (~2000 atom) systems in a reasonable amount of CPU (2 hr) time. Timings are based on a PM3 single-point calculation using MOPAC2002 on a 2.0-GHz Pentium IV. In order to test how well a semiempirical method will work on CdS nanocrystals we optimized two bare CdS nanocrystals and four

**Table 2** Summary of bond lengths for a CdS dimer at different levels of theory

Lanl2dz/ 6-31G*	SVWN	B3LYP	HF	MP2	MP3	PM3
Cd-S	2.472	2.514	2.453	2.460	2.460	2.411
Cd-Cd	2.821	2.910	2.850	2.786	2.799	2.883
S-S	4.059	4.100	3.992	4.054	4.046	3.865

Bond lengths are reported in Angstroms.

**Fig. 6** PM3 optimized (green) vs. X-ray (red) structures for the  $[\text{Cd}_{17}\text{S}_4(\text{SPh})_{28}]^{2-}$  (left) and  $\text{Cd}_{32}\text{S}_{14}(\text{S-iPrOH})_{26}$  (right) organic capped cadmium sulfide clusters. The RMSD (without hydrogens) for the  $\text{Cd}_{17}$  cluster is 1.65 Å and for the  $\text{Cd}_{32}$  cluster it is 2.0 Å. The average CdS bond length is approximately 2.55 Å for both PM3-optimized structures.

different organic capped CdS nanocrystals. The X-ray structures for two of the organic capped systems have been published and the coordinates were available. We used MOPAC2002 on a 677-MHz alpha processor to perform the calculations. The results from these calculations are summarized in Figs. 6–9.

Fig. 6 shows a remarkable agreement between the PM3-optimized structure and X-ray structure. The CdS nanocrystal core essentially remains unchanged,

whereas the organic ligands have moved slightly. Figs. 7 and 8 are plots of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO), respectively. For the  $\text{Cd}_{17}$  nanocluster, one observes the HOMO to be the capped ligand, whereas on the  $\text{Cd}_{32}$  nanocluster the HOMO electron density resides on the CdS core (Fig. 8). Comparing these results with bare nanocrystal HOMOs (Fig. 9), we see that the larger  $\text{Cd}_{32}$  nanocrystal

**Fig. 7** The highest occupied molecular orbital (HOMO) for the four organic capped cadmium sulfide clusters. The upper left is the  $\text{Cd}_{17}$  cluster with the isopropyl ligands, whereas the upper right is the  $\text{Cd}_{17}$  with the thiophenyl ligands. The lower left is the  $\text{Cd}_{32}$  cluster with the isopropyl ligands, whereas the lower right is the  $\text{Cd}_{32}$  cluster with the thiophenyl ligands. These orbitals were obtained from optimized capped clusters using the semiempirical PM3 method.

systems are similar (a capped vs. bare), whereas in the Cd<sub>17</sub> case the HOMO has moved to capping ligands.

### QUANTUM MECHANICS/MOLECULAR MECHANICS CALCULATIONS ON ENCAPSULATED CdS CLUSTERS

The encapsulation of the nanocluster CdS atoms by 10–30 phytochelatin-like peptides or peptidomimetic ligands (an additional 200–600 non-hydrogen atoms) represents a major obstacle in modeling functionalized nanoelectronic assemblies. Fortunately, classical computations that use molecular mechanics (MM) force fields have been extremely successful in providing valuable and meaningful insights about intermolecular interactions for biomolecules in solution.<sup>[38]</sup> The two independent computational methods, QM and MM, have been combined (known as QM/MM methods) over the last decade to formulate an alternative approach to the ubiquitous size and timescale problem in computational chemistry. Excellent reviews are available.<sup>[39–43]</sup> QM/MM methods have been widely used to study the chemical reactivity in large molecular systems. One of the main areas of concentration has

been in the study of solvation and reactivity of small molecules in the condensed phase,<sup>[44]</sup> but other recent applications include studies of surface reactivity,<sup>[45]</sup> zeolites,<sup>[46]</sup> and crystal formation.<sup>[47]</sup>

The overall scheme of QM/MM methods is to treat the reactive or electronically sensitive portions with quantum mechanics, whereas the stable or unreactive portions are treated with molecular mechanics. Most of the QM/MM methods share a common methodological approach. The system of interest is typically partitioned into two or more subsystems. The nanocluster system will be used to explain the basic ideas. The QM region contains the electronically sensitive portion of the molecular assembly, the CdS core. The MM region contains the solvent and phytochelatin molecules. The Hamiltonian for the entire molecular system is written as.

$$H = H_{QM} + H_{MM} + H_{QM/MM}$$

where  $H_{QM}$  is the QM Hamiltonian,  $H_{MM}$  is the empirical force field, and  $H_{QM/MM}$  is the Hamiltonian that describes the interactions between the QM and MM regions. Consequently, the total energy of

**Fig. 8** The lowest unoccupied molecular orbital (LUMO) for the four organic capped cadmium sulfide clusters. The upper left is the Cd<sub>17</sub> with isopropyl ligands, whereas the upper right is the Cd<sub>17</sub> with the thiophenyl ligands. The bottom left is the Cd<sub>32</sub> with isopropyl ligands, whereas the lower right is the Cd<sub>32</sub> with the thiophenyl ligands. These orbitals were obtained from optimized capped clusters using the semiempirical PM3 method.

**Fig. 9** The highest occupied molecular orbital (left) and lowest unoccupied molecular orbital (right) for the  $\text{Cd}_{17}\text{S}_{32}^{-30}$  and  $\text{Cd}_{32}\text{S}_{50}^{-36}$  nanoclusters. The structures were optimized using the PM3 semiempirical method.

the system is written as a sum of the individual components.

$$E = E_{\text{QM}} + E_{\text{MM}} + E_{\text{QM/MM}}$$

One of the key aspects of the QM/MM method resides in the interactions between the QM and MM regions. Considerable debate has arisen when the partitioning between the two regions cuts across covalent bonds.<sup>[42,48,49]</sup> The most common method in modeling this middle-space is to use the “link atom” method. It consists of adding QM hydrogen atoms in order to fill the free valencies of the QM atoms that are connected to the atoms described by MM. These dummy atoms are treated explicitly during the QM calculations but do not interact with the MM atoms. Whether or not these link atoms should interact by means of Coulombic interactions is still open to debate. This approach is not ideal but in this respect, the problem of describing the phytochelatin coat by molecular mechanics and the CdS nanocluster core by the modified DFT method is well suited for the QM/MM method, as the partition is across intermolecular bonds only. It is typically agreed upon that this type of QM/MM implementation lends itself to greater accuracy and reliability.

Based upon what we have learned from the previous two sections we have begun testing the hybrid QM/MM ONIOM method on the organic capped CdS nanocrystals. In the ONIOM method various QM and MM methods are assigned to different layers.

**Fig. 10** Model peptide encapsulated CdS nanocrystals. The model contains eight  $(\gamma\text{-glucys})_3\text{gly}$  peptides.

**Fig. 11** An illustration of the different regions to be used in an ONIOM calculation on a large peptide encapsulated cadmium sulfide nanocrystal.

Our model peptide encapsulated CdS nanocrystal contains a  $\text{Cd}_{17}\text{S}_{30}$  core with eight  $(\gamma\text{-glucy})_3\text{gly}$  peptides (Fig. 10). The system contains 1078 atoms. In this system the ONIOM inner layer (i.e., the core) will consist of LanL2dz on cadmium and 6-31G(d) on sulfur. A lower-level basis set is placed on the peptides. Based upon this description, the system contains  $\sim 900$  basis functions and requires 1 hr of CPU time on the marvel processors at the Pittsburgh Supercomputing Center. In a “real” peptide encapsulated CdS nanocrystal, we approximate the CdS core to be composed of 693 atoms. In this situation, the plan is to use PM3 on the inner CdS atoms with LanL2dz on the surface cadmium and 6-31G(d) on the surface sulfurs. Again lower-level basis sets will be used on the peptides. Fig. 11 is an illustration of the ONIOM method applied to a “real” peptide encapsulated CdS nanocrystal.

## CONCLUSION

Our goal is to understand the electronic structure properties of large peptide encapsulated cadmium sulfide nanocrystals as a function of molecular size. We have performed a systematic study on different levels of theory on sample CdS monomers and dimers. From these calculations, we have identified the DFT functional SVWN along with the LanL2dz/6-31G\* basis set to give satisfactory results. Using experimentally observed organic capped CdS nanocrystals, we have shown that the semiempirical PM3 method gives reasonable results. Based on these calculations, we propose that a combination of PM3, DFT, and molecular mechanics methods can be used to study

accurately and effectively “real” peptide encapsulated nanocrystals.

## INTRODUCTION

The nanoengineering of colloidal surfaces and the design of functional colloid particles are currently interesting topics of applied chemistry and biochemistry in the field engaged in developing new materials with tailored properties. Research on composite colloidal particles (core-shell structures with size ranging from 1 to 1000 nm) has created interest because of various applications expected in the areas of coatings, electronics, photonics, catalysis, biotechnology, sensorics, medicine, ecology, and others. In general, the research on core-shell structure and encapsulation implies the formation of a colloidal core of defined content and size, and the preparation of a shell providing the required stability, permeability, compatibility, release of core material, and catalytic or affinity properties. Tailoring the different components of one particle becomes important to develop these functionalized colloids (i.e., to combine several properties in one core-shell structure). The desired properties may be adjusted to facilitate the interaction of the core with different solvents or cell membranes. The shell may also have magnetic, optical, conductive, or targeting properties for directing and manipulating the core containing bioactive materials.

A major task in the development of advanced drug formulations deals with the elaboration of delivery systems for providing the sustained release of bioactive materials. Mostly, these systems comprise polymer particles in the size range of 50–100  $\mu\text{m}$ . Drug molecules are embedded in polymer matrices, or in core-shell structures. In the latter case, the shell permeability or degradation rate determines the release rate of the bioactive core material. The composition of the shell may additionally provide certain functionalities.

This review is devoted to the literature on recently introduced novel pathways to fabricate nanoengineered core-shell structures, which can employ a great variety of substances as shell constituents and can be incorporated into hollow spheres. The way the shells are assembled on colloids resembles the formation of ultrathin polymer films by layer-by-layer (LbL)

adsorption on macroscopic flat support, an idea proposed by Iler<sup>[1]</sup> in 1966 and later developed by Lee et al.<sup>[2]</sup> In 1991, Decher and Hong<sup>[3]</sup> proposed a method of forming polyelectrolyte films by using the alternate adsorption of polycations and polyanions. A crucial factor for polyionic LbL assembly is the change of the sign of the surface charge on polyelectrolyte adsorption. Beginning in 1998, this strategy of LbL assembly of charged species was transferred to coat micron-sized and submicron-sized colloidal particles (Fig. 1).<sup>[4]</sup> The idea emerged to employ the nanoengineered properties of multilayers as shell structures formed on colloidal particles.

## MULTILAYER ASSEMBLY ON COLLOIDAL PARTICLES

The main problem in applying the LbL technology to coat surfaces of colloidal particles is how to separate the remaining free polyelectrolytes from the particles prior to the next deposition cycle. Today, there are several approaches for that difficulty, including centrifugation, filtration protocols for washing particles with adsorbed polyelectrolytes, and the so-called sequential adding of polyelectrolytes at matched concentrations. For details of these approaches, their advantages, and their drawbacks, refer to Sukhorukov et al.<sup>[4]</sup> Donath et al.<sup>[5]</sup> and Voigt et al.<sup>[6]</sup> It should be mentioned that the filtration method<sup>[6]</sup> is the only method applicable for scaling up the coating of different colloidal particles in large volumes. The monitoring of the process of film formation (i.e., charge reversal and continuous layer growth) was followed at each step by electrophoresis, dynamic light scattering, single particle light scattering (SPLS), and fluorescent intensity measurements.<sup>[4,7]</sup> Fig. 2 illustrates the typical particle charge ( $\zeta$ -potential) changes recorded on layer deposition for polycation/polyanion pairs. The  $\zeta$ -potential alternates between positive and negative values, indicating the successful recharging of the particle coated with the adsorbed polyelectrolyte multilayer on each layer deposition. The evidence for sequential layer growth has been obtained by means

**Fig. 1** Consecutive adsorption of positively (gray) and negatively (black) charged polyelectrolytes onto negatively charged colloidal particles (A–E). After dissolution of colloidal core (E), a suspension of polyelectrolyte capsules is obtained (F).

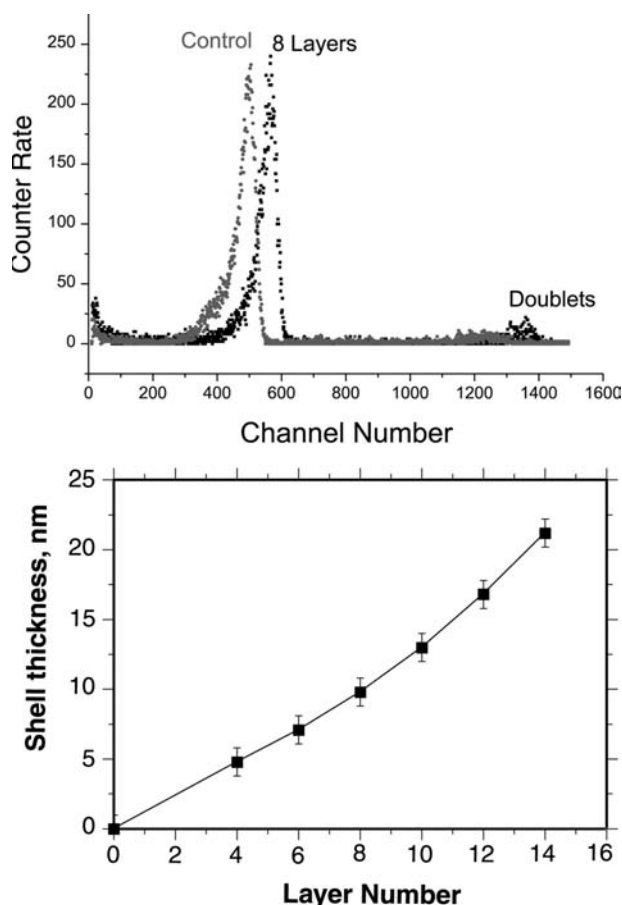

of SPLS.<sup>[4,6]</sup> In Fig. 3, the intensity distribution of the control naked particles is compared with particles coated with eight layers assembled by filtration technique. From the shift of the peak of the intensity distribution, the adsorbed mass can be derived. These data can be converted into a layer thickness of the adsorbed polyelectrolyte multilayers, assuming a given refractive index.<sup>[4]</sup> The increase of polyelectrolyte film thickness is proportional to the layer number (Fig. 3, bottom). Mean polyelectrolyte layer thickness was found to be 1.5 nm for the case of polystyrene sulfonate (PSS) and polyallylamine (PAH) alternatively assembled from 0.5 M NaCl. It should be noted that the average layer thickness of polyelectrolyte multilayers strongly

depends on the kind of polyelectrolytes and the salt concentration used at polyelectrolyte assembly. More rigid polymers and an increased salt concentration lead to a thicker adsorption layer.<sup>[8]</sup>

Multilayer assembly can be performed not only on solid particles such as silica, PS latex particles, or organic crystals, but also on “soft” particles formed just before multilayer buildup, such as protein aggregates and the compact form of DNA. The micron-sized aggregates of proteins (lactate dehydrogenase<sup>[9]</sup> and chemotrypsin<sup>[10]</sup>) were applied as templates for polyelectrolyte multilayer assembly. The polyelectrolyte multilayer coating of these aggregates captures the proteins inside the capsules and, at the same time, provides a selective barrier for the diffusion of different species (substrates, inhibitors) from the exterior. The concept of polyelectrolyte multilayer assembly on aggregates is similar to that on the surface of colloidal particles.<sup>[4]</sup> Here, instead of solid colloidal particles, the preformed protein aggregates have been used as templates for polyelectrolyte multilayer assembly. As shown in Ref.<sup>[10]</sup>, the chemotrypsin aggregates in high-salt solution form particles of 100–300 nm. After these particles are covered with a polyelectrolyte layer, the capsule can be transferred to a low-salt solution, where chemotrypsin is captured by a polyelectrolyte shell. The method of LbL shell formation on protein aggregates provides encapsulation efficiency close to 100%. Indeed, one can always find a condition for protein aggregation (for instance, it usually happens at the isoelectric point). The subsequent release of proteins from the shell can be controlled by certain

**Fig. 2**  $\zeta$ -Potential as a function of layer number for PSS/PAH alternatively coated polystyrene latex particles. Particle diameter = 640 nm.

**Fig. 3** Top: Normalized light scattering intensity distributions (SPLS) of PAH/PSS-coated polystyrene sulfate latex particles ( $\text{\O} = 640 \text{ nm}$ ). Particles with eight layers are compared with uncoated ones. Bottom: Shell thickness as a function of layer number.

polyelectrolyte compositions. It makes such systems very suitable as drug delivery systems with controlled-release properties.

The assembly of three polyelectrolyte layers was performed also on condensed DNA particles with size of about 50–100 nm. A certain polymer composition used for coating DNA particles provides stable suspension<sup>[11,12]</sup> and facilitates the uptake of these particles by biological cells, with the outermost layer bearing certain receptors. Sequential gene expression of cells after the uptake of such particles has been illustrated.<sup>[12,13]</sup>

The method of LbL adsorption of oppositely charged macromolecules onto colloidal particles has been applied already for different templates with sizes ranging from 50 nm to tens of microns, such as organic and inorganic colloid particles, protein aggregates, emulsion droplets, biological cells, and drug nanocrystals. Various materials (e.g., synthetic polyelectrolytes, chitosan and its derivatives, proteins, DNA, lipids, multivalent dyes, and magnetic nanoparticles) have

been used as layer constituents to fabricate the shell. The possibility of using different materials allows the shell to adjust its design based on the required stability biocompatibility and affinity properties of the capsules. The most commonly used methods to monitor LbL deposition on monodisperse PS latex particles for various substances are the SPLS method and microelectrophoresis. Inorganic [magnetite, silica, titania, and fluorescent quantum (Q) dots] nanoparticles,<sup>[14–16]</sup> lipids,<sup>[17–19]</sup> and proteins (albumin, immunoglobulin, and others)<sup>[7,20,21]</sup> were incorporated as building blocks for shell formation on colloidal particles. In Schuler and Caruso,<sup>[21]</sup> the construction of enzyme multilayer films on colloidal particles for biocatalysis was demonstrated. The enzyme multilayers were assembled on submicrometer-sized polystyrene spheres via the alternate adsorption of poly(ethyleneimine) and glucose oxidase. The high surface area of particles coated with biomultilayers was subsequently utilized in enzymatic catalysis. The step-by-step coating of different lipids alternated with polyelectrolytes was performed by the adsorption of preformed vesicles onto the capsule surface. As was shown by Moya et al.<sup>[18]</sup> the lipids form a bilayer structure on the surface of polyelectrolyte multilayers. The fabrication of inorganic shells on colloidal particles envisages the application of such core-shell structures in catalysis and colloidal band gap crystals.<sup>[14,16]</sup> Introducing magnetic particles into the shell composition opens the possibility of manipulating them by applying external field.<sup>[15,17]</sup>

## COLLOIDAL CORE DECOMPOSITION AND FORMATION OF HOLLOW CAPSULE

Different colloidal cores can be decomposed after multilayers are assembled on their surface. If the products of core decomposition are small enough to be expelled out of polyelectrolyte multilayers, the process of core dissolution leads to the formation of hollow polyelectrolyte shells (Fig. 1D–F). Up to now, various colloidal templates, such as organic templates [melamine formaldehyde (MF) particles, poly-D,L-lactic acid (PLA), or poly-D,L-lactic-co-glycolic acid (PDLA) microparticle and nanoparticle organic crystals], and inorganic cores, such as carbonate or silica oxide microparticles and biological cells, have all been used as templates for hollow capsule fabrication. Decomposition can be performed by different means, such as low pH for MF and carbonate particles;<sup>[22]</sup> organic water-miscible solvents for PLA, PDLA, or organic crystals;<sup>[23]</sup> and HF treatment for silica oxide microparticles, and strong oxidizing agents (NaOCl) for biological cells with same the MF particles.<sup>[24,25]</sup>

The formation of hollow capsules was more intensively studied on MF particles.<sup>[5,26]</sup> These particles dissolve onto oligomers at 0.1 M NaCl and in some water-miscible solvents such as DMF or DMSO. Subjecting the coated eight PSS/PAH layers of MF particles to low pH results in solubilization of the core. The MF oligomers, which have a characteristic cross-sectional extension of about 2–3 nm, are expelled from the core and permeate through the polyelectrolyte layers, forming the shells. This observation is consistent with the finding that polyelectrolyte-coated MF particles are readily permeable to molecules of a few nanometers in size.<sup>[4]</sup> The MF oligomers are finally separated from the hollow shells by centrifugation or filtration protocols.

The fabricated hollow polyelectrolyte capsules were characterized using scanning electron microscopy (SEM), transmission electron microscopy (TEM), atomic force microscopy (AFM), and confocal fluorescent microscopy techniques.<sup>[5–7,17,24,27]</sup> An AFM image of hollow polyelectrolyte capsules is shown in Fig. 4. The numerous folds and creases observed are attributed to the collapse of the hollow capsules under drying. The shells are flattened and some spreading is noticed. The diameter of the capsules shown in Fig. 4 is larger than the diameter of the templated MF particle (5  $\mu\text{m}$ ). This increase in diameter is ascribed to collapsing and adhesive forces attracting the polyelectrolyte shell to the surface. From the AFM image, it was also deduced<sup>[27]</sup> that the thickness of the polyelectrolyte film is on the order of 20 nm for the

**Fig. 4** Atomic force microscopy image of the capsules composed of eight PSS/PAH layers templated on MF particles.

eight-layer polyelectrolyte film. This value is consistent with SPLS data on layer thickness obtained for polyelectrolyte-coated polystyrene particles (Fig. 3). Nevertheless, Gao et al.<sup>[26]</sup> reported on the rest of the core materials found in polyelectrolyte shells after MF particles decomposition.

The nature of the colloid does not significantly affect the thickness of the polyelectrolyte layers. It should be noted that the polyelectrolyte capsules completely repeat the shape of the templating colloids, as was shown by the example of echinocyte cells, which have starlike shape.<sup>[24]</sup> The choice of the core is determined by concrete tasks. For instance, carbonate cores are decomposable at  $\text{pH} < 4$ ; they are convenient to fabricate into hollow capsules composed of biological polymers. Calcium and manganese carbonate crystals were used as core materials for the fabrication of hollow polyelectrolyte capsules by means of LbL assembly in Ref.<sup>[28]</sup> The use of inorganic templates is a significant step toward the biocompatibility of polyelectrolyte multilayer capsules. Scanning electron microscopy and energy-dispersive X-ray (EDX) measurements proved the purity of the capsules from the core materials.

Another study proposed the use of decomposable biocompatible templates composed of PLA and PDLA.<sup>[23]</sup> These particles were used to build a shell composed of biocompatible polyelectrolytes. Uniform, complete coating with oppositely charged polyelectrolyte pairs was achieved for different combinations investigated. After core dissolution in water-miscible organic solvents such as acetone, stable hollow capsules with tailored properties were obtained. The results reported in Ref.<sup>[23]</sup> demonstrate that polyester microparticles could serve as viable alternative components to conventionally employed templates to derive hollow capsules with shape and shell thickness exploring a “biofriendly” process. The only drawback of such particles is some polydispersity in the size, but for many uses, this parameter is not important.

At present, hollow polyelectrolyte capsules with diameters varying from 0.2 to 10  $\mu\text{m}$  and with wall thicknesses from a few to tens of nanometers were obtained. Many compounds, such as synthetic and natural polyelectrolytes, dyes, and inorganic nanoparticles, were used as layer constituents to build the hollow capsules. Uniform inorganic and hybrid inorganic–organic hollow microspheres have been produced by coating colloidal core templates with alternating layers of oppositely charged nanoparticles and polymers, and thereafter removing the core by heating to 500°C.<sup>[14,29]</sup> Hollow rigid silica spheres were obtained by calcination of polymer latex spheres coated with multilayers of silica nanoparticles ( $\text{SiO}_2$ ) bridged by polycations.

## Permeability and Release Properties

The potential use of polyelectrolyte coating on colloidal particles as depot systems for controllable release requires data on the permeation of small molecules (molecular weights up to 500) through polyelectrolyte walls. To achieve sustained-release properties for shells, it would be advantageous to be able to decrease the layer permeability for small polar molecules once they are encapsulated. The small polar fluorescent markers, such as fluorescein, are reasonable models for permeability study. The formation of thicker capsule walls composed of polyelectrolyte multilayers with increasing layer number might be a way to decrease permeation. Verification of this approach was performed in Ref.<sup>[30]</sup>. Microparticles of fluorescein of about 5  $\mu\text{m}$  in size were covered with a different number of PSS/PAH polyelectrolyte layers in conditions where fluorescein is not soluble, pH = 2. It should be noted here that when pH = 2, both polyelectrolytes are strongly charged, and hence the resulting multilayer films possess the same amount of amino and sulfur groups. After multilayer formation, core dissolution was initiated by a pH change and monitored by increasing fluorescence in the bulk. The scheme on Fig. 5 illustrates coating fluorescein particles and subsequent fluorescein release when the particles become soluble. After LbL adsorption (Fig. 5A–C), core dissolution is initiated by changing the pH from 2 to 8 (Fig. 5D) and is completed after a certain period of time (Fig. 5E).

Fluorescein particles rapidly dissolve at pH 8. Thus the idea was to slow down the rate of core dissolving by covering the particles with polyelectrolyte multilayers. Shell walls consisting of a different number of layers were fabricated and examined with regard to their fluorescein permeability behavior. Fluorescence

spectroscopy is a convenient tool for the determination of the core dissolving rate because the fluorescence of the core is completely suppressed as a consequence of the self-quenching of the dye. On releasing the dye into the bulk, fluorescence intensity increases. Thus the rate of dissolving can be directly followed by measuring the fluorescence increase in the sample.

Fig. 6 shows typical time-dependent fluorescence curves obtained by switching the pH to 8. Fluorescein particles covered by layers of different thickness (9, 13, 15, and 18 layers) are compared with controls demonstrating the dissolving of naked fluorescein particles. As shown on release profiles after a comparatively short induction period, the rate of dissolving becomes constant before the fluorescence in the bulk finally levels off. The initially slowly increasing fluorescence is related to the start of core dissolving. At this stage of the process, the structure of the polyelectrolyte multilayer may change because of the nascent osmotic pressure coming from dissolved fluorescein molecules. Shortly after the beginning of core dissolution, the concentration of fluorescein inside the capsules becomes constant and almost saturated because a steady-state situation between progressing core dissolution and permeation is established. One may further assume a constant concentration gradient between the shell interior and the bulk because the bulk solution can be assumed as being infinitely diluted. Therefore the rate of fluorescein penetration through the polyelectrolyte layers to the bulk becomes constant. Indeed, a linear increase of the fluorescence is observed. This state corresponds to the stage of dissolution depicted in Fig. 5. The slope of the linear region decreases with the number of polyelectrolyte layers. Obviously, an increasing number of adsorbed layers reduce the fluorescein penetration. After the core is completely dissolved, the fluorescein concentration inside the shell equilibrates

**Fig. 5** Scheme of the polyelectrolyte multilayer deposition process and of the subsequent core dissolution. The initial steps (A, B) involve stepwise shell formation on a fluorescein core. After the desired number of polyelectrolyte layers is deposited, the coated particles are exposed to pH = 8 (C) and core dissolution with fluorescein penetration into the bulk is initiated, resulting finally in fully dissolved cores and remaining empty capsules (D).

**Fig. 6** Fluorescence increase on time, obtained by dissolving fluorescein particles covered with shells of different thickness (9, 13, 15, and 18 layers), compared with naked (0) fluorescein particles. Inset: Time dependence of core decomposition time on the number of layers in the shells.

with the bulk. The driving force for diffusion decreases and the release levels off.

In Antipov et al.<sup>[30]</sup> the permeability value was found to be on the order of  $10^{-8}$  m/sec. Assuming a single polyelectrolyte layer thickness of 2 nm, the permeability can be converted into a diffusion coefficient ( $D$ ) by multiplying the permeability with the shell wall thickness. The calculated diffusion coefficients are on the order of  $10^{-15}$  m<sup>2</sup>/sec.

If the permeability of the polyelectrolyte multilayer is provided by diffusion through the entangled polymer network, it should scale with the inverse of the layer thickness. The behavior of the time of complete release as a function of the number of layers is shown in Fig. 6 (inset). As can be seen in Fig. 6, the increasing layer number sustains the fluorescein release. This effect becomes remarkable when the layer number exceeds eight, which corresponds to 15- to 20-nm-thick shell. This finding is consistent with observations<sup>[13]</sup> where it was shown that the conformation of the first eight layers differs from that of further assembled layers. These deeper layers are more dense and result in a five-fold reduction of the estimated diffusion coefficient. Naturally, these data are only particular to the case of PSS/PAH layers, and the permeation might be

different if the capsules are made of other polyelectrolytes. Nevertheless, the tendency to sustain the penetration of small molecules with layer number is demonstrated.

Polyelectrolyte complexes are known to be very sensitive to the presence of salt.<sup>[31]</sup> Therefore the permeability coefficient of polyelectrolyte multilayers is influenced by ionic strength. In the presence of small ions, ionic couples in multilayers are partially dissolved, which makes the polyelectrolyte film more penetrable for solutes.<sup>[32]</sup> Permeability coefficient data derived from release curves show a dramatic change of an increase of one order of magnitude in NaCl concentration change from 1 to 500 mM.<sup>[33]</sup>

Thus the polyelectrolyte multilayer shells with enough number of layers assembled around cores consisting of low-molecular-weight compounds provide barrier properties for release under conditions where the core is dissolved. Increasing the shell thickness to more than 20 nm might cause barrier difficulties for low-molecular-weight compounds passing through the capsule wall. Multilayer coating on microparticles and nanoparticles is a promising approach for the fabrication of systems with prolonged-release and controlled-release properties. The release can be

adjusted with the number of assembled polyelectrolyte layers. A large variety of synthetic polyelectrolytes with different properties, polysaccharides, and other biopolymers used for multilayer assembly may provide many possibilities to fine-tune the release properties of shells with biocompatibility and possibility of using various cores. The assembly of shells by LbL technique opens new pathways for biotechnological applications, where controlled release and sustained release of a substance are required. Many problems connected with drug formulation, release, and delivery; controlling concentrations in the organism; and the periodicity of its reception might be solved by the formation of shells on precipitates and nanocrystals. This approach has been already explored for drug formulations with controlled-release properties of biocompatible shells.<sup>[34,35]</sup> It seems to be not difficult to add targeting properties to the polyelectrolyte layer. This way, the affinity of polyelectrolyte multilayer-coated drugs to specific or injured tissues can be increased.

Thermal treatment of polyelectrolyte capsules results in the reduction of permeability coefficients. As investigated in Ref.<sup>[36]</sup>, the permeability coefficient of hollow capsules templated on MF cores can be decreased by two orders of magnitude. Thermal annealing of the capsules causes polyelectrolyte rearrangements, which leads to a more compact structure. Some defects in polyelectrolyte shells because of core dissolution processes can be repaired.

### Macromolecules Encapsulation

Basically, the multilayer polyelectrolyte capsules have semipermeable properties. If the film thickness is about

10–20 nm, small molecules can penetrate whereas high-molecular-weight compounds are excluded. However, there are several approaches to introduce macromolecules inside hollow polyelectrolyte capsules, when the core is decomposed. The first approach is opening and closing the pores in capsule walls in a controllable way. One can cause segregation in polyelectrolyte multilayers either by pH or solvent change. Indeed, polyelectrolyte multilayers undergo transition at a certain pH at about the  $pK$  of charged groups. This transition works on segregation because of the accumulation of charges by a network of entangled polyelectrolytes. As a result, such segregation leads to the formation of pores large enough for macromolecules to penetrate the capsule wall.<sup>[22,37]</sup> This process is completely reversible. Changing the pH back, the capsules become non-permeable for polymers again (Fig. 7). Thus the captured polymers stay inside. Several macromolecules, such as albumin, chymotrypsin, and dextran, have been encapsulated by this protocol.<sup>[37,38]</sup> The reversed segregation in polyelectrolyte multilayers can be introduced also by solvent mixtures such as water–ethanol, as was demonstrated by Lvov et al.<sup>[39]</sup> for encapsulation of proteins.

Another approach for encapsulation consists of the precipitation of polymers onto surfaces of colloid particles before the main multilayer buildup. The precipitated materials are harvested on the surface of particles. The proper choice of the concentration of particles, polymers, and the speed of heterocoagulation allows a smooth coverage of colloidal particles to form by precipitating polymers. A polyelectrolyte LbL shell is formed on particles already covered by precipitated polymers. After formation of the stable outer shell, the colloidal template could be decomposed. The

**Fig. 7** Permeation and encapsulation of dextran FITC into polyion multilayer capsules. Left,  $pH > 7$ ; middle,  $pH < 6$ ; and right, the capsule with encapsulated dextran FITC again at  $pH > 7$ .

**Fig. 8** A schematic illustration of the preparation of a capsule loaded with polyelectrolytes.

polymer molecules underneath the stable shell can be dissolved in the shell interior. In fact, this approach comprises of three stages (Fig. 8): 1) precipitation of polymers on a colloidal surface (Fig. 8A–C); 2) capture of precipitated polymers on colloidal particles by stable shell formation (Fig. 8D); and 3) decomposition of the core; the products of decomposition are expelled through capsule wall, whereas the polymers dissolve and float in the capsule interior (Fig. 8E–H). This approach has been tested for encapsulation of non-charged polysaccharides (i.e., dextran and polyelectrolyte as PSS and PAH).<sup>[40]</sup> Dextran was precipitated by adding ethanol drop by drop whereas polyelectrolytes formed an insoluble complex with multivalent ions such as  $\text{Me}^{3+}$  and  $\text{CO}_3^{2-}$  for PSS and PAH, respectively. Some swelling of the capsule after polymer dissolution into the interior was observed because of osmotic pressure. Naturally, the amount of loaded polymers per capsule is the amount of all added polymers divided by the number of colloidal particles harvesting precipitating polymers. The possible loss of used polymers because of breakage of capsules did not exceed 10–15%. The described procedure allows the dosage of macromolecular contents in the capsule in tiny (less than nanograms) amounts.

To summarize the approaches on how to encapsulate the macromolecules by precipitation and then to capture by LbL shell fabrication, the positive and negative features should be stressed. In fact, encapsulation via precipitation could reach encapsulation efficiency close to 100%. Indeed, for encapsulation via harvesting of polymers on colloidal particles as described above, we have achieved about 80–90% encapsulation efficiency.<sup>[40]</sup> The more important peculiarities of using initial colloidal templates as polymer collectors are as follows: 1) the size distribution is

determined by original templates; 2) the amount of loaded polymers can be dosed and homogeneously distributed in each capsule; and 3) there are possibilities to load the capsule with several different substances. The last point has not yet been demonstrated, but one expects no significant difficulties in composing a multicomponent shell, and precipitating on the surface of colloidal particles several macromolecules, sequentially or at the same time, if they could be precipitated at the same condition. One has to consider only the compatibility of conditions for each precipitation step and further LbL fabrication of stable polyelectrolyte shells. The captured macromolecules are kept in the capsule interior until it is non-permeable for macromolecules. This might be utilized for fabricating enzyme microreactors when the substrates and reaction products diffuse through the capsule wall freely. The loaded macromolecules might be released after a certain pH or salt treatment.

## PHYSICOCHEMICAL REACTIONS INSIDE POLYELECTROLYTE CAPSULES

### Caused by pH Gradient

The capsule wall has semipermeable properties that allow for different physicochemical properties of the capsule interior compared to the exterior. Incorporation of polymers into the capsule allows the use of such capsules with modified inner volume for providing chemical reactions only in the capsule interior. Here we describe two possible ways for the precipitation of dyes as drug model substances within capsule interiors loaded with polymers. Precipitation occurs, then solubility dramatically decreases.

One can establish polarity or pH gradient through the capsule wall when the capsules are filled with certain polymers. Indeed, the presence of a polyelectrolyte on only one side of the membrane might significantly change such properties as pH value. For instance, if a polyanion is placed inside capsule, the pH value inside has to be acidic due to electroneutrality because  $H^+$  ions compensate for negative charges of polyanions. The resulting pH has to be closer to the  $pK$  value of charged groups of polyelectrolytes. This situation on pH gradient is considered in more details in Refs.<sup>[41,42]</sup> Here we give an illustration for the precipitation of carboxytetramethylrhodamines (CRs) inside the capsule. Carboxytetramethylrhodamine has pH-dependent solubility and becomes non-soluble at pH lower than 3.5. In the presence of capsules filled with PSS maintaining a pH value near 2.5, the CR molecules penetrate the capsule wall and, when facing lower pH, begin to precipitate. Here we provide typical SEM images of CR precipitates formed in the capsules (Fig. 9). The capsules look filled with solid materials.

As was shown previously, the encapsulated polyelectrolytes can establish pH gradient through the capsule wall. In particular, the capsules containing PAH have more basic pH than that in the outer solution. This method has been utilized for the selective synthesis of magnetic, 20-nm  $Fe_3O_4$  nanoparticles<sup>[43]</sup> and non-magnetic, elongated, 250-nm hematite  $Fe_2O_3$ <sup>[42]</sup> particles inside the polyelectrolyte capsules filled with polycations. The iron oxide particles were visualized by TEM (Fig. 10). The structure of the particles

**Fig. 9** Scanning electron microscopy image of CR precipitates formed in capsules loaded with PSS.

**Fig. 10** Transmission electron microscopy image of Fe-based precipitates (240-nm elongated iron oxide particles) in capsules filled with PAH.

depends on the given  $Fe^{2+}/Fe^{3+}$  ratio in the outer solution as was proven by wide-angle X-ray scattering (WAXS) measurements. These revealed diffraction peaks corresponding to  $Fe_2O_3$  and  $Fe_3O_4$  lattices. Besides magnetite, different ferrites ( $CoFe_2O_4$ ,  $ZnFe_2O_4$ , and  $MnFe_2O_4$ ) were synthesized from corresponding salts exclusively inside polyelectrolyte capsules of 6  $\mu m$  diameter.<sup>[43]</sup> Polyelectrolyte capsules with synthesized ferrite (magnetite) particles possess enough magnetic activity to be easily manipulated in water solution by an external magnetic field. The SEM images demonstrate that capsules with synthesized nanoparticles keep a bulky shape on drying, which is apparently because of the formation of rigid walls presenting inorganic nanoparticles glued to organic polymers.

### Caused by Polarity Gradient

Another way to fill the capsule with small molecules is by establishing a polarity gradient of hydrophilic polymers. These capsules were suspended in a water/organic solvent mixture to keep a higher water content in the interior because of the hydrophilicity of encapsulated polyelectrolytes.<sup>[44]</sup> With the preparation of a water/acetone or water/acetone mixture with an overall high ratio of organic solvents, one can dissolve many poor water-soluble (PWS) molecules. However, inside the capsule, we have media with low solubility and PWS molecules should precipitate there. At slow

evaporation of organic solvents, the PWS molecules are collected in the capsule interior because of lower solubility there. Finally, one has an aqueous suspension of capsules containing precipitates of organic molecules.<sup>[44]</sup> Scanning electron microscopy images of capsules filled with PWS are similar to the image shown in Fig. 9. Incidentally, we found that the precipitates formed inside the capsules did not show any X-ray diffraction signals unless later annealed. Hence they are either amorphous or exist as nanocrystallites. This is a highly desirable feature for many drug applications because it facilitates dissolution and hence release.

## ENZYMATIC REACTIONS

In Lvov et al.<sup>[39]</sup> and Antipov et al.<sup>[45]</sup> the encapsulation of urease by solvent variation and its enzymatic activity were demonstrated. Urease catalyzes the reaction:

In the presence of  $\text{Ca}^{2+}$  ions, calcium carbonate is formed:

Carbonate ions generated by urease in the capsule interior immediately react with calcium ions and freely

**Fig. 11** Optical microscopy image of urease-catalyzed  $\text{CaCO}_3$  crystal growth inside 5- $\mu\text{m}$  polyelectrolyte capsules.

diffuse through the capsule wall. As shown by Antipov et al.<sup>[45]</sup> calcium carbonate crystals presumably grow within the capsule interior until they occupy the whole capsule lumen (Fig. 11). The formation of calcium carbonate particles might also occur outside of the capsule because of the diffusion of carbonates, but in certain conditions, calcium carbonate particles might be found almost only inside the capsule. As investigated by electron diffraction, the lattices of calcium carbonate grown within the capsule interior exhibit vaterite structure. Remarkably, there was no growth of calcium carbonates over the capsule wall. Thus the microcapsules with an imported enzyme can be a suitable model to mimic inorganic processes in biological cells.

Another illustration of enzymatic reactions inside capsules has been reported in Ref.<sup>[38]</sup>. A proteolytic enzyme,  $\alpha$ -chemotrypsin, was homogeneously distributed in the capsule interior with a concentration of 50 g/L. Encapsulated chemotrypsin was found to retain a high physiological activity of about 70%, as shown with fluorescent products.

## CONCLUSION

The uniformity, simplicity, and versatility of possible applications are significant points of the abovescribed technology. The particular aspects coming from the basic concept of the technology are outlined in Fig. 12. As an initial matrix, we have a colloidal template. Organic and inorganic particles, drug nanocrystals, biological cells, protein aggregates, emulsion droplets, and, in fact, any colloidal particles ranging in size from 50 nm to tens of microns are possible templates to fabricate shells. The shell can be composed of a variety of materials. The choice of polymers to build the shell is determined by application to reach the desired stability and comparability. Actually, one could choose the proper line to pursue certain tasks using the scheme in Fig. 12 to achieve the desired characteristics of core-shell structures or capsules.

Selective shell permeability makes it possible to keep macromolecules in the capsules. Macromolecules can be incorporated into the inner volume of the capsule by different means, either through their aggregation in the solution or precipitation onto the surface of collecting colloidal particles, followed by their capture through the formation of stable polyelectrolyte shells afterward, or the opening and closing of pores in the capsule wall by pH, salt, and solvent. These approaches to load macromolecules into the capsules differ by the size of capsules, their monodispersity, low or high macromolecule concentrations in the capsules, encapsulation efficiency, and possibilities

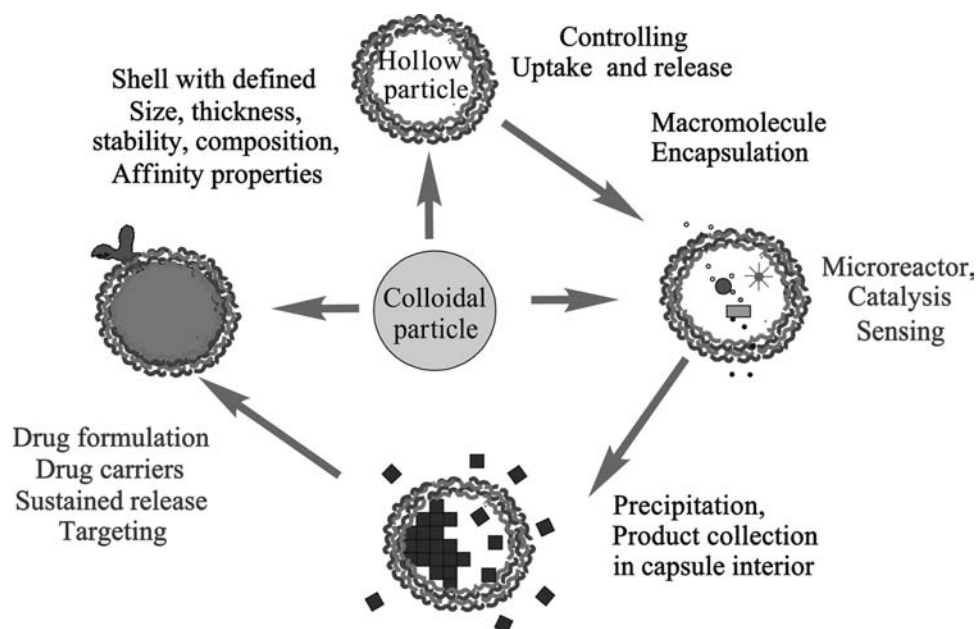

Fig. 12 Comprehensive illustration of applications of stepwise shell formation on colloidal particles.

to incorporate several substances in one capsule. Of course, the macromolecules can be incorporated as layer constituents during shell buildup. Layer-by-layer deposition on colloidal particles at fabrication could supply the LbL degradation of components afterward. One could find the optimum time scale for this process as well. Generally speaking, one also has to choose the most profitable way according to the aims these capsule are supposed to serve. Talking about encapsulation of enzymes, it should be stressed that selective permeability provides the elaboration of enzymatic microreactors where the proteins are placed into the capsule interior, whereas substrates and products of the one-step or multistep enzymatic reactions in the capsules can readily penetrate the capsule wall. In addition, the encapsulated enzymes have higher stability and are protected by the outer shell against high-molecular-weight inhibitors and proteolytic agents. The capsules themselves can be easily withdrawn from one solution, washed, and placed in another by filtration or centrifugation, or they can be driven by applying magnetic fields if the magnetite particles were used as layer constituents. We did not mention here any chemical treatment of the capsules after they have been assembled. Obviously, further modifications, such as cross-linking, can significantly change the properties of the capsules, such as permeability or stability.

The capsules might be used as combinatorial libraries. For instance, Gaponik et al.<sup>[46]</sup> modified the polyelectrolyte capsules with different semiconductor

luminescent nanoparticles (Q-dots). A variety of possibilities to impart fluorescent fingerprint characteristics (labelling with defined mixtures of different Q-dots) open an avenue to make many experiments with capsules in one pot. Indeed, the capsules of each functionality, size, or composition discriminated by unique fluorescent characteristics can be followed at the same time in *in vitro* or *in vivo* testing.

Fundamental research on these capsules should be mentioned. They represent a unique system to study the chemical and physical phenomena in micron-sized and submicron-sized volumes. In comparison with liposomes, the polyelectrolyte capsules, besides their higher stability, give the possibility of varying the content of the inner volume in a controllable way. Defined inner composition allows chemical reactions in restricted volumes, which has been demonstrated up to now only as precipitation reactions for small organic molecules and inorganic salts in the capsule interior. There are no doubts that such a philosophy might be expanded further. Selective permeability and related solubility, pH, and temperature are background parameters to modify the capsule interior. The complexity provides more possibilities. For example, if one establishes a different pH in the capsules loaded with different enzymes to achieve the optimal conditions for catalytic reactions in each capsule, these capsules might either exchange intermediate products or selectively collect them in each tape of capsules. These capsules might be a device to study single-molecule effects. Indeed, the concentration of substances

$10^{-7}$  M means about one molecule of this substance in capsules of 300 nm diameter. Defined inputs into the interior could register discrete chemical reactions occurring in the capsule interior.

The polyelectrolyte capsules could serve also as support for lipid bilayers. As shown in Refs.<sup>[19]</sup> and <sup>[47]</sup>, lipid bilayers assembled on polyelectrolyte capsules reduce the permeation for small ions. Thus there are perspectives to reconstitute channel formers into the lipid bilayer supported by polymeric shells and to use this as a stable model. Such research might aim to construct artificial cells, cell compartments, or artificial organs because of the emerging possibilities to introduce different substances into the capsule and build the shell (i.e., “membrane”) using a variety of compatible materials. The hollow and loaded capsules are novel types of cages for compartmentalization of materials, and are good models for research on biomineralization.

Mimicking the processes in biological cells and cell compartments foresees the involvement of a number of enzymes, which work together at the same time. The method of controllable opening and closing pores provides also a possibility to encapsulate several proteins at the same time and at certain concentrations in the capsules to catalyze sequential enzymatic reactions (for instance, glucose oxidation by glucose oxidase followed by utilization of hydrogen peroxide by peroxidase). The loaded enzyme, as we showed, might be released out of the capsule after a certain pH treatment, which could find some applications for systems with controlled release.

A wide range of possible uses, interplays of several approaches, the solving of different problems, and the focus on fundamental and application aspects in diverse areas of life and material sciences attract interest and stimulate further research on the development of approaches for nanoengineering surfaces of colloidal particles and polymeric capsules.

## ACKNOWLEDGMENT

The author expresses his gratitude to Prof. Dr. H. Möhwald (MPI Colloids and Interfaces, Potsdam) for continuous support of the work on this topic and stimulating discussions. Dr. E. Donath is acknowledged for fruitful collaboration over the years. Members of the group at MPI—Dr. A. Voigt, Dr. D. Shchukin, Dr. K. Glinel, Dr. D. Shenoy, Dr. O. Tiourina, I.L. Radtchenko, and A.A. Antipov—are thanked for providing a creative atmosphere, collaboration, and help in the research on nanoengineered polymeric microcapsules.

## INTRODUCTION

Encapsulation techniques gained great importance during the last decades to protect, store or release materials in well-defined ways. As in other technical fields, the miniaturization of capsules progressed parallel to the development of new materials and techniques. At the present time, microcapsules are already used in many technical applications in the pharmaceutical, cosmetic, food, textile, adhesive, printing, and agricultural industries.<sup>[1–5]</sup>

Several approaches are used to fabricate nanocapsules:<sup>[6]</sup> first, one can use aggregates of lipid molecules in spherically closed bilayer structures, the so-called vesicles or liposomes.<sup>[7,8]</sup> These relatively unstable structures can be stabilized by cross-linking. In a similar fashion, amphiphilic block copolymers in aqueous solution can also aggregate to vesicular structures.<sup>[9]</sup>

Other approaches to prepare capsules concern suspension and emulsion polymerization techniques around latex particles,<sup>[10,11]</sup> dendrimers or hyperbranched polymers.<sup>[12,13]</sup> Finally, one can cover a sacrificial template core with a membrane permeable for the products of core dissolution. Based on this approach, a new type of microcapsule prepared from polyelectrolytes (PE) was developed 5 years ago using the layer-by-layer (LbL) technology for encapsulating dissolvable templates in the micrometer and nanometer range (see Fig. 1).<sup>[14]</sup> The LbL technology enables the nanometer-precise assembling of multilayers. A wide variety of materials can be combined yielding capsules, which can have simultaneously several functions in the capsule wall as well as an adjustable semipermeability. Furthermore, the inner and outer capsule surface can be easily functionalized by biological or chemical binding sites, and the interior can be filled with macromolecules or with precipitates of low molecular weight agents. Monodispersity of the capsules can be achieved by using monodisperse templates.

## PREPARATION OF POLYELECTROLYTE CAPSULES

### LbL Method on Planar Substrates

In polymer thin films research, the most influential domain in the use of non-covalent interactions is the electrostatic layer-by-layer assembly.<sup>[15–18]</sup> This 11-year-old technique<sup>[8]</sup> is based on the alternating adsorption of multiply charged cationic and anionic species driven by electrostatic interactions (Fig. 1). During the self-assembly process of a polyion to an oppositely charged surface, the polymer adsorption proceeds until the surface charge is reversed. This allows in a next step the adsorption of a counterpolyion. The alternating adsorption of polycations and polyanions can be repeated at will. Because of the self-limitation of the process, the amount of polymer adsorbed in one step is constant and yields for usual polyelectrolytes a layer thickness of 1.5 to 3 nm.<sup>[19–21]</sup>

Diverse charged functional polymers have been successfully assembled into thin films by LbL (see reviews<sup>[19–21]</sup> and references therein) and comprise conducting and light-emitting polymers, non-conjugated redox-active polymers, reactive polymers, polymers bearing non-linear optically active dyes, liquid crystalline polyelectrolytes, temperature-sensitive and switchable polymers, and dendrimers. A variety of colloidal objects have also been placed in multilayer films, such as stable colloidal dispersions of charged silica, metal oxides, polyoxometalates, semiconductors, and fullerenes, as well as metal colloids, metallosupramolecular complexes, charged latex spheres, microcrystallites, clay platelets, or charged inorganic sheets. In addition, natural polyelectrolytes such as nucleic acids, proteins, polysaccharides, as well as certain charged supramolecular biological assemblies have been used for LbL.

In principle, all of these materials can also be combined for the preparation of polyelectrolyte capsules. However, some restrictions exist. First, assembling of

**Fig. 1** Preparation of hollow polyelectrolyte capsules: scheme of the polyelectrolyte deposition process and of subsequent MF-core decomposition.

polyelectrolytes on colloids does not allow a drying step after each layer, as it is often described with planar films. Second, colloidal suspensions in the nanometer- and micrometer-size range have to be stabilized against coagulation, which requires charged and hydrophilic surfaces. Third, the dissolution process of the templating core requires special conditions such as low pH, organic solvents, or oxidative environment. Fourth, the permeability of the LbL wall has to be tuned to allow the permeation (evacuation) of core dissolution products.

### LbL Technology on Colloidal Particles

As mentioned above, the initial colloidal substrate as well as each of the PE species have to be sufficiently charged to ensure adsorption and to prevent flocculation.<sup>[22–26]</sup> Moreover, it has to be ensured that the concentration of the adsorbing polyelectrolyte is large enough to provide saturation conditions. Incomplete covering yields charge differences within one colloidal batch, followed by coagulation. Excess polyelectrolyte molecules must be removed before adding the next PE to avoid formation of complexes in solution (Fig. 1). This separation can be achieved either by centrifugation or filtration.<sup>[27]</sup> Centrifugation yields often problems with resuspension, difficulties for smaller particles of low density to settle, loss of materials, and a lengthy process. The filtration method yields problems in filling the filters, in turn producing low yields. However, this method can be practically scaled-up and automated.<sup>[27]</sup> In particular, cross-flow filtration can solve the problems of small-scale batches.

### Removal of the Templates

The decomposition of the encapsulated template is a key step for the capsule fabrication (Fig. 1). Several

templates have been used for the capsule preparation such as weakly cross-linked melamine-formaldehyde lattice,<sup>[14]</sup> organic<sup>[28–30]</sup> and inorganic crystals,<sup>[31,32]</sup> silica particles, polystyrene lattice,<sup>[33]</sup> metal nanoparticles and nanorods,<sup>[34–36]</sup> and biological templates.<sup>[37–39]</sup> None of them has all qualities required for a “perfect” core, i.e., stability toward the LbL process, insensitivity of the multilayers structure at template dissolution conditions, and residues-free dissolution.

The majority of capsules have been prepared up to now with weakly polymerized, monodisperse melamine formaldehyde (MF) templates, produced in the size range from 300 to 10000 nm (Microparticle GmbH, Germany). The template can be dissolved in 0.1 M HCl within seconds into MF oligomers.<sup>[40]</sup> During the decomposition of the MF core, the capsules swell as demonstrated on a sample made with 6 layers of poly(allylamine) (PAH) and 6 layers of poly(styrene-sulfonate) (PSS) (Fig. 2). This swelling is caused by an elevation of the internal osmotic pressure induced by dissolved MF oligomers inside the capsules.<sup>[40]</sup> The capsules show a higher permeability as expected from planar and unstressed polyelectrolyte films of the same material and thickness. Presumably, the high mechanical pressure during the dissolution process induces pores in the capsule wall that determine the permeability more than the intrinsic diffusion properties of the polyelectrolyte films do.<sup>[41]</sup>

To reduce the permeability of MF capsules, further polyelectrolyte layers can be assembled after the dissolution of the core, resulting in a closing of the pores and a decrease of the permeability.<sup>[42]</sup> Another disadvantage of MF capsules is given by cytotoxic MF residues. Otherwise, the presence of MF residues was exploited for trapping water-soluble substances.<sup>[43–45]</sup> However, this encapsulation method is not controlled enough for viable applications.

Colloidal polystyrene (PS) latices have been used as core, which can be dissolved in tetrahydrofuran

**Fig. 2** Swelling of capsules during the dissolution of MF templates encapsulated in 6 PAH/PSS bilayers in 0.1 M HCl (top confocal micrograph: fluorescence of the labelled wall, bottom: transmission micrograph).

(THF).<sup>[46]</sup> The swelling of PS in THF leads to a large volume increase that is directly often responsible for a high percentage of capsule fractures.

Red blood cells present an alternative to MF particles: they are available in nonspherical shapes, are quasi-monodisperse, and are inexpensive.<sup>[37]</sup> Moreover, the encapsulation of cells and cellular materials may have important applications in biotechnology and medicine. The decomposition of the biological templates is achieved by using a pH 12 sodium hypochlorite solution. However, under these harsh conditions, the polyelectrolyte wall is partly oxidized.<sup>[43]</sup>

A current development is the use of inorganic crystals such as  $\text{CdCO}_3$ ,  $\text{CaCO}_3$ , or  $\text{MnCO}_3$  as templates, which can be prepared in the range between 3 and 8  $\mu\text{m}$ . The dissolution is performed under mild conditions, and the products leave the capsule interior without problem.

Silicon dioxide particles have been used recently as templates and subsequently dissolved in hydrofluoric acid.  $\text{SiO}_2$  particles are available over a broad size range and high monodispersity. The core is decomposed in 1 M HF within few seconds into  $\text{SiF}_6^{2-}$  ions, which leave the capsule wall without problems. Confocal imaging of this dissolution process does not show any swelling of the capsule wall. Hence the mechanical stress applied onto the wall during the dissolution is negligibly small, and the polyelectrolyte layer structure is kept almost unchanged. Indeed, such capsules exhibit a lower permeability than capsules based on MF templates.

## PROPERTIES OF SIMPLE HOLLOW POLYELECTROLYTE CAPSULES

### Diameter

In general, the capsules size matches the template diameter. The size of hollow capsules ranges generally

between 500 nm and 5  $\mu\text{m}$ , but it can be extended below 100 nm and up to 15  $\mu\text{m}$ . However, for too thin walls or too large diameters, deviations from the spherical shape are reported.

### Wall Thickness

The wall thickness depends on the layer number and the material. The mostly used combination of PAH/PSS yields a thickness of around 4 nm per layer pair. These values have been measured by scanning force microscopy (SFM) on hollow capsules, dried on a mica substrate. During the drying process, the capsules collapse like an inflatable plastic ball after complete loss of the air. The thickness of the dry double wall can be taken directly from the profile of the atomic force microscopy (AFM) image (Fig. 3).

### Surface Charge

The outer surface charge of the capsules is simply determined by the last layer. The charge of the inner layer is assumed to correspond to the first layer on the former template. For example, in case of MF-templated capsules, the first layer PSS should result in a negative inner-layer surface. However, it is not quite clear how far adsorbed residues of positively charged MF oligomers influence the inner surface.

### Capsule Permeability

Capsule permeability has been tackled by two approaches. One approach consists in encapsulating soluble materials and in measuring their release from the capsule interior. Another approach consists in adding a fluorescence-labeled substance to the outer solution of a hollow capsules suspension and in monitoring the penetration into the capsules by means of confocal laser scanning microscopy (CLSM). Using

**Fig. 3** Scanning force microscopy image of a  $(\text{PAH}/\text{PSS})_4$  capsule, dried on mica and the corresponding height profile.

fluorescence-labeled PAH molecules, first rough estimations gave a cutoff of 5000 g/mol for capsules prepared from (PSS/PAH)<sub>4</sub> on MF cores.<sup>[14]</sup> In case of fast permeating smaller molecules, fluorescence recovery after photobleaching (FRAP) experiments have been performed. The dyes in the interior were bleached and the fluorescence recovery has been measured which is connected with the diffusion of fluorescence molecules from the outside to the interior.<sup>[42]</sup>

For the first approach, several fluorescent dyes were used as model and coated with various numbers of PSS/PAH multilayers under conditions of low solubility of the materials.<sup>[29,32,47]</sup> Results on PSS/PAH-encapsulated fluorescein reveal an increase of the release rate with pH and ionic strength and a decrease with the layer number (Fig. 4).<sup>[47]</sup> The diffusion coefficient per layer was determined to be approximately  $10^{-16}$  m<sup>2</sup>/sec in the presence of salt.

Similar results obtained with ibuprofen release studies support a model of two release channels, one by diffusion and one by pressure through pore-like structures presumably formed during the dissolution process.<sup>[48–52]</sup> Further studies showed that the permeability depends strongly on the polyelectrolyte material as known from planar films.<sup>[51]</sup> PAH/PSS MF capsules are less permeable than poly(diallyldimethylamine)/PSS capsules.<sup>[49]</sup>

The permeability depends furthermore on the environment such as ionic strength, pH and temperature.<sup>[55–62]</sup> It was reported that the permeability of PSS/PAH capsule could be controlled by pH<sup>[53]</sup> and ionic strength.<sup>[14,63]</sup> Capsules could be switched between an open (low pH or high ionic strength) and a closed state (high pH or low ionic strength). This was exploited for the encapsulation of macromolecules under mild conditions.

**Fig. 4** Release of fluorescein from encapsulated fluorescein crystals into a buffer solution as a function of the layer number. *Source:* From Ref.<sup>[29]</sup>.

## Mechanical Stability

Hollow capsules maintain a spherical shape up to a diameter of 15  $\mu$ m although the wall thickness is only 30 nm. The resistance against pressure was quantified by addition of polyelectrolytes to a capsule suspension. Because of the impermeability of the capsules for these molecules, high osmotic pressure from the outside modifies the capsules shape. Above a specific concentration of outside polymer or a critical pressure  $P_c$ , a shape transition from a spherical to a sickle shape was observed (Fig. 5). From this observation, an elasticity modulus between 500 and 700 Mpa was calculated. This value is comparable to macroscopic plastic materials, and reflect a high degree of local interactions between the polyanion and the polycation.<sup>[64,65]</sup>

The elasticity of capsules was investigated by loading microcapsules with 1 M PSS solution and decreasing the polyelectrolyte concentration outside. This leads to a swelling of the capsules proportional to the concentration difference.<sup>[72]</sup> Higher pressure caused the capsules to break. In contrast, at smaller swelling, a partly reversible elastic behavior was reported.<sup>[66]</sup> The investigation of the MF core dissolution, where a reversible swelling of the capsule was observed, also points to an elastic behavior (see Fig. 2).<sup>[40,67]</sup>

The deformability and osmotic properties of hollow PSS/PAH microcapsules assembled on the decomposable template MF were studied by means of the micropipette video microscopic technique.<sup>[68]</sup> The microcapsules reacted to micropipette suction with plastic deformation. The upper limit value of the plastic modulus  $D_p$  was evaluated at roughly 5 kPa. Addition of lipids yields a high degree of plasticity, at least in the range of the applied mechanical forces.<sup>[68]</sup>

## Physicochemical Stability

Standard PAH/PSS capsules are stable in aqueous solution between pH 0 and 13 and at high ionic strength. PAH/PSS capsules were also suspended in various organic media by a gradual solvent exchange with a preservation of shell stability and integrity.<sup>[53,69]</sup> The stability in organic solvents renders possible the preparation of oil-in-water or water-in-oil emulsions without employing any surfactants. The obtained microdrops are highly stable and have a high degree of monodispersity.<sup>[69]</sup>

Combinations of weak polyelectrolytes or of materials with only small amount of charges are more sensitive against pH and ion strength, which lead to strong enhancement of the permeability up to the dissolution of the LbL capsules.

**Fig. 5** Transformation of the spherical capsules to a sickle shape under the osmotic pressure of an outer PSS solution. *Source:* From Refs.<sup>[64]</sup> and <sup>[65]</sup>.

## MODIFICATION OF THE POLYELECTROLYTE CAPSULES

Because of the variable applicability of the LbL process, the capsules can be widely modified. This concerns the interior, the wall, and the inner and outer surface of the capsule wall.

### Permanent Filling of the Interior with Functional Macromolecules

In most cases, precipitation of low molecular weight materials in presence of hollow capsules happens on the wall surface or in the bulk solution but not as desired in the interior of capsules.<sup>[70,71]</sup> A solution to tackle this problem is offered by immobilization of functional macromolecules in the capsule interior. They result in different physical properties of capsule interior and bulk solution and induce preferably precipitation inside the capsules. Three approaches have been followed to immobilize macromolecules permanently in the capsule interior (Fig. 6).

In the ship-in-bottle approach, monomers are incubated together with empty preformed shells (Fig. 6A).<sup>[72]</sup> After diffusion of monomers and initiator inside the shell, the polymerization is started inside and outside the capsule. The resulting polymers are trapped, and after washing, capsules filled with high polymer concentrations are isolated. This is demonstrated in Fig. 7A, where PSS copolymerized with acrylrhodamine is shown. The polymer concentration in the interior can be up to 1 monomolar, although the high osmotic pressure attained induce a remarkable capsule swelling. A drawback of this efficient method is the limitation to synthetic polymers.

For the encapsulation of preformed polymers or biomacromolecules, two other approaches have been developed. In one method, polymers are precipitated with complex-forming auxiliaries or alone under

specific conditions onto the melamine core (Fig. 6C).<sup>[66]</sup> Onto this initial layer, stable classical LbL polyelectrolyte multilayers are assembled. The core is removed, the initial layers are dissolved under specific conditions, and the auxiliaries are washed away. Then the inside of the capsules is filled with the polymer.<sup>[73]</sup> This approach requires for each application specific conditions under which the desired polymer can be precipitated and is difficult to implement practically.

Another approach for encapsulation consists in loading preformed capsules by switching the shell wall

**Fig. 6** Methods to immobilize macromolecules in the capsule interior: (A) ship in bottle synthesis, (B) loading by switching the permeability, (C) loading by controlled precipitation.

**Fig. 7** Confocal laser scanning images of capsules: (A) filled with PSS-rhodamine copolymer 0.5 M;<sup>[72]</sup> (B) capsules after complexation of PSS in the interior with fluorescent pseudoisocyanine J-aggregates;<sup>[54]</sup> (C) scanning electron microscopy image of CaCO<sub>3</sub> crystals grown in the capsule interior by enzymatic reaction. *Source:* From Ref.<sup>[72,54,83]</sup>

permeability through variation in environmental conditions, such as pH<sup>[41,74,75]</sup> or ionic strength (Fig. 6B).<sup>[76]</sup> In the capsule open state, surrounding macromolecules can diffuse into the interior. Switching the pH or ion strength back, the capsule wall closes and the macromolecules in the interior are captured. This method can only be performed with specifically designed capsules of suitable permeability. Furthermore, only low polymer concentrations can be achieved.

Capsules filled with functional polymers or with biomolecules can fulfill many tasks:

1. A gradient of the physicochemical properties between the outer and inner solution such as pH, ion strengths, polarity, charge distribution (Donnan potential), etc. can be used for the accumulation or selective precipitation of low molecular weight substances in the capsules. For example, if PSS-filled capsules (Fig. 7B) are placed in a mixture of water and non-polar solvents, the water content in the vicinity of the entrapped polyelectrolytes increases. This effect has been used for encapsulation of poorly water-soluble drugs.<sup>[77]</sup> Several dyes and inorganic salts, such as fluorescein, rhodamine, calcium carbonate, and barium carbonate, were precipitated inside PE capsules by using such gradients.<sup>[70,71]</sup> Electrostatic adsorption in polymer-filled shells has been used to trap semiconductor nanocrystals, iron oxide, or nanosized magnetic ferrite particles.<sup>[78–80]</sup>
2. The incorporation of polymer-bound catalysts or biocatalysts results in microreaction containers. Small molecular weight educts can diffuse into the capsules and react with the catalyst, and the products are released.
3. The capsule wall can prevent poisoning or destruction of biocatalysts because large molecules such as polymers, enzymes, and bacteria cannot enter the capsules. The concept of

macromolecule encapsulation in MF microshells by opening and closing pores was applied to enzymes. For instance,  $\alpha$ -chymotrypsin was encapsulated in hollow PSS/PAH shells by method 3. The protein in the capsules retained a high activity (50–60%) and long storage stability.<sup>[81]</sup>

Urease was also encapsulated into PSS/PAH shell using a similar approach: the pore-controlling factor was, in this case, the solvent choice.<sup>[82]</sup> Ethanol was added to a urease/microshells suspension and opened the pores.<sup>[44,45]</sup> Using these urease-loaded PAH/PSS capsules, calcium carbonate was synthesized exclusively inside of the capsules (Fig. 7C). The carbonate anions were generated inside of the capsules by a urease-catalyzed urea decomposition. Addition of calcium ions produced precipitation of calcium carbonate, which completely filled the capsule volume. Because of the easiness in varying experimental parameters, such as the wall thickness, internal composition, and influx, these PE capsule-based systems can be used to study fundamental aspects of biomineralization processes.<sup>[83]</sup>

Encapsulation of enzyme crystals or aggregates with the LbL technique<sup>[84,85]</sup> has been performed for chymotrypsin<sup>[86]</sup> and lactate dehydrogenase. The encapsulated lactate dehydrogenase exhibits increased lifetimes due to higher stability to denaturation and is not substrate-inhibited.<sup>[87]</sup>

### Modification of the Wall

So far, the most and best-studied polyelectrolyte association on surfaces, core shells, and capsules has been poly(allylamine)/poly(styrenesulfonate). Nevertheless, shells based on other synthetic polyelectrolytes such as poly(diallyldimethylamine), poly(ethyleneimine), or Nafion have recently been synthesized.<sup>[49,88]</sup> Because of the potential applications in the pharmaceutical industry, there are increasing activities in the

area of naturally occurring polyelectrolytes: recently, LbL capsules containing carrageenan,<sup>[89]</sup> dextran sulfate,<sup>[63]</sup> chitosan/chitosan sulfate,<sup>[90]</sup> sodium alginate, carboxymethyl cellulose,<sup>[48]</sup> or protamine<sup>[91]</sup> were reported. In contrast to planar films from biomolecules, the preparation of polyelectrolyte capsules is limited because of the harsh conditions used for the dissolution of the core. However, the development of new templates such as CaCO<sub>3</sub> particles extends the preparation possibilities. Decomposable hollow capsules based on deoxyribonucleic acid (DNA) and spermidine (SP) were already prepared.<sup>[33]</sup>

Several functionalities can be easily introduced in the capsule wall using polymers which were labeled before the assembly process. Capsules with increased stability have been prepared by cross-linking of water-soluble ionene precursor polymers yielding luminescent conjugated oligofluorenes.<sup>[46]</sup> A copolymer of poly(aniline) and PSS was introduced to obtain walls with reducing properties.<sup>[92]</sup> By using polymers presenting photoreactive diazo groups, the ionic bonds between the negative PSS and the positive diazoresin are converted to covalent cross-links. Cross-linked hollow capsules are mechanically more stable in various chemical environments than their ionically linked counterparts.<sup>[93]</sup> Photochromic hollow shells using an azobenzene-containing polymer were produced.<sup>[89]</sup>

The use of hollow or filled capsules for combinatorial purposes requires a tagging of the capsule wall. Polymers with covalently bound fluorescent dyes have been incorporated in the capsule walls. A luminescent library of (PAH/PSS)<sub>5</sub> capsules were prepared by

assembling four different dyes, each covalently attached in several PAH layers. Different layer combinations yielded 16 tagged capsules (Fig. 8). The intermediate layers minimize perturbing interactions between the layers. Although all capsules have the same size and properties, they can easily be distinguished by multichannel confocal fluorescence microscopy or by flow cytometry.<sup>[94]</sup>

Water-insoluble organic dyes were incorporated in capsule walls by depositing them in nonaqueous solution alternatively with polyelectrolytes in aqueous solution.<sup>[95]</sup> Using different fluorescent dyes, a two-step energy transfer cascade in the wall of hollow microcapsules was constructed.<sup>[96,97]</sup> The dyes were assembled in such a way that fluorescence resonance energy transfer through the capsule wall from outside to inside happened. Nanoporous capsule walls or shell-in-shell structures have been constructed by consecutive alternating adsorption of polyelectrolytes and SiO<sub>2</sub> on melamine formaldehyde particles, followed by removal of MF cores with HCl acid and of the sandwiched SiO<sub>2</sub> particle layers between indestructible PAH/PSS walls with HF. The inner and outer shell could be distinguished by labeling the inner shell with fluorescein and the outer shell with rhodamine B. Although the distance between the two shells is only 50 nm, confocal microscopy could resolve this difference (Fig. 9).<sup>[98]</sup> The two shell walls are separated by an intermediate PAH solution which acts as an osmotic pressure buffer and yields higher mechanical stability against outside pressure.<sup>[98]</sup>

Several inorganic materials can be prepared as charged nanoparticles. SiO<sub>2</sub>, TiO<sub>2</sub>, laponite,<sup>[99]</sup> and

**Fig. 8** Combinatorial library of (PAH/PSS)<sub>5</sub> capsules with different combinations of dye molecules (fluorescein, rhodamine, Cy5, and pyrene) covalently linked to the PAH layers in the capsule wall; the right image shows the fluorescence intensity along a line through the dye tagged capsules. One can clearly differentiate the dye constituents and their amount.

**Fig. 9** Confocal image of a shell in shell structure. The outer shell is labeled by fluorescein and the inner shell is labeled by rhodamine; the right image shows the distance between both shells, analyzed by two-color imaging. *Source:* From Ref.<sup>[98]</sup>.

CdTe nanoparticles have been used for the preparation of capsules.<sup>[100–102]</sup> Incorporation of colloidal dispersion of charged silica nanobeads as one of the wall components led to composite organic/inorganic colloidal materials.<sup>[103–105]</sup> Depending on the method chosen to remove the core, one obtains either a hollow inorganic/organic hybrid wall by dissolution of the MF core in HCl or a hollow silica sphere by thermal decomposition of the organic compounds.<sup>[106,107]</sup> Calcination of a composite between core-shell silica and gold nanoparticles (Au@SiO<sub>2</sub>)/PDADMAC deposited onto polymer spheres gave rise to hollow spheres of Au@SiO<sub>2</sub>.<sup>[110]</sup> Noble metals, such as silver, were incorporated either inside the capsule or in the capsule wall.<sup>[92]</sup>

Functional nanoparticles were incorporated into capsules to introduce magnetic, fluorescent, or catalytic properties. Superparamagnetic magnetite (Fe<sub>3</sub>O<sub>4</sub>) was mounted as a component of the shell wall<sup>[108–111]</sup> or as a part of the capsule interior.<sup>[79]</sup>

The combination of lipids and PE capsules creates an artificial system, mimicking biological membranes. Confocal microscopy images of capsules coated with fluorescent lipids demonstrated, within the resolution of the instrument, a homogeneous coverage of the capsule surface by lipid bilayers or multilayers.<sup>[112]</sup> The permeability for polar substances decreased remarkably after deposition of the lipid bilayer onto the hollow PE capsules. However, studies on electrical properties showed an increase in conductivity with the bulk electrolyte concentration, which was attributed to the presence of pores or defects in the lipid film.<sup>[113]</sup>

### Modification of the Surface

The outer surface of polyelectrolyte capsules can be functionalized using in the last assembling step a polyelectrolyte which contains the desired function. The

simplest example to tune the surface charge is the choice of a cationic or anionic polyelectrolyte. A more sophisticated application is the introduction of a high density of coupling sites, where subsequent functionalization can be performed. The commonly used chemical surface groups such as carboxyl or amino functions can be easily introduced by using poly(acrylic acid) or poly(allylamine). The disadvantage of the last layer is its stability in solution. While the inner layers of LbL films are fully immobilized, the outermost layer equilibrates in a solution because of the high charge density. Hence some of the polymer chains containing functional groups get lost under extreme conditions such as high or low pH, high ionic strength, etc. This problem can be solved by cross-linking the last layer.

### CONCLUSION

One important milestone in the fast development of the LbL polyelectrolyte films<sup>[14,115]</sup> was their use in 1998 for the preparation of hollow capsules. These closed LbL films extended remarkably the application fields of the method. The large versatility and modularity of the LbL capsules led to a fast development in the last 5 years as demonstrated on the selected examples in this review.

The LbL capsules will not substitute all other encapsulation technologies, but due to their specific properties, they can contribute to new applications especially in high technology fields. These properties are summarized in the following paragraph, together with the actual drawbacks and problems:

- The capsule preparation is simple and does not need expensive equipment, but the procedures are rather time-consuming. In addition, an upscaling of the process is under way, but not solved yet.
- The selection of arbitrary templates allows the preparation of capsules in a wide size range, with a well-defined shape and a high monodispersity, but the ideal template has not been found yet. Therefore, the LbL film is stressed during the core dissolution, leading to changes in permeability, size and internal structure as well as to remaining residues of the templates.
- The capsules exhibit semipermeable properties, which can be tuned in a broad region by the layer number, the material, or subsequent crosslinking. However, the permeability could not be lowered enough for the encapsulation of small water-soluble molecules.
- PSS/PAH capsules possess an extremely high physicochemical stability against aggressive media,

like acids, bases, high salt contents and organic solvents. But also instable capsules can be designed, which decompose under defined circumstances and release their interior.

- Interior, wall and outer surface of LbL capsules can be more easily modified than in other capsule systems. The nanometer precise deposition of functionalized layers and intermediate layers allows the combination of many different functions in one capsule without cross-reactions.

Due to the short time of the capsule development and the almost infinite possibilities to vary parameters in the preparation process, there are still many open questions, but also a very high potential for further important developments in this field. Especially in the bio-sciences, many surprises can be expected due to the potential of the capsules to serve as model systems for cells, viruses etc. The use of PE shells as biomimetic systems is under research as for example combinations of capsules and lipid bilayers equipped with ion channels. Research on modifications of the capsule surface in order to recognize specific biological materials or interfaces is started. The use of the capsules as micro-vessels for DNA amplification (PCR) or as non-viral gene transfection systems is planned. One important step is the further miniaturization down to 30 nm which has been recently achieved without aggregation.<sup>[118]</sup>

# Carbon-Based Nanostructures: Hydrogen Storage

Xianxian Wu

Nidia C. Gallego

*Carbon Materials Technology Group, Materials Science and Technology Division,  
Oak Ridge National Laboratory, Oak Ridge, Tennessee, U.S.A.*

## Abstract

The reported hydrogen storage capacities of carbon nanotubes, nanofibers, nanostructured graphite, activated carbons, activated carbon fibers, graphite, and metal-doped carbon nanostructures are widely spread. While some unusually high values were claimed for carbon nanotubes and nanofibers in earlier years, most studies in recent years suggest that the hydrogen storage capacity in carbon materials, including nanotubes and nanofibers, increases with hydrogen pressure, but is less than 1 wt% at room temperature. A capacity of a few percents is only possible at low temperatures, such as 77 K, and high pressures. There is increasing evidence from both experimental and theoretical reports that carbon nanotubes, including high-purity single-wall carbon nanotubes, do not have hydrogen storage characteristics superior to the conventional high-surface area graphite powder and activated carbons. Dispersing small amounts of metals, especially transition metals, in carbons appears to be a promising approach to increase the hydrogen storage capacity at room temperature. However, more efforts are needed in understanding the fundamentals of the storage process, such as what is the exact chemical state of the hydrogen stored in carbon materials. This chapter presents a comprehensive review on the experimentally measured and theoretically predicted hydrogen storage capacities of different nanostructured carbon materials.

## BACKGROUND

There are four technologies available today to store hydrogen for on-board vehicular applications:<sup>[1]</sup> (1) physical storage via compression or liquefaction, (2) chemical storage in irreversible hydrogen carriers (e.g. methanol, ammonia), (3) reversible metal and chemical hydrides, and (4) gas-on-solid adsorption. Although each method possesses desirable characteristics, no one approach satisfies all efficiencies, size, weight, cost, and safety requirements for transportation or utility use. The main drawbacks for physical storage are the need for high-pressure tanks or low-temperature systems for liquefaction and handling of liquefied hydrogen (21 K) as well as the high cost. Chemical storage generally needs a conversion process, which makes the system more complex. Storage by metallic hydrides has the advantage of the low pressure but the storage system is heavy and additional heating is needed for hydrogen release. The last possibility, hydrogen adsorption in porous solids, has been studied since the 1960s,<sup>[2]</sup> and is still being considered as an attractive technology. Carbon materials as adsorbents offer additional advantage because of their low mass density. Hydrogen storage in carbon materials has attracted much attention in recent years owing to the development of novel nanomaterials such as carbon nanotubes and nanofibers and the claims of some unusual high storage capacities.

Several comprehensive reviews on hydrogen storage in carbon nanotubes are available.<sup>[3–6]</sup> However, in

view of the fact that very large differences in hydrogen storage capacities were historically reported for not so much dissimilar materials, this entry is focused on the variation of storage capacities measured for a wide variety of carbon materials and identification of those microstructural parameters that appear to affect the materials' hydrogen uptake. Special attention is given to activated carbons and metal-containing carbon materials, which are receiving increasing attention nowadays. In addition, a review of theoretical predictions and a discussion on issues still not fully clarified, especially related to the fundamentals in hydrogen adsorption, are included. Since reliable measurement methods are always crucial for the experimental evaluation of materials, a brief review on the techniques used for measuring hydrogen storage capacity is presented first.

## TECHNIQUES FOR MEASURING HYDROGEN STORAGE CAPACITY

Hydrogen adsorption measurements on small samples, on the order of several milligrams, need very sophisticated experimental conditions and measurement procedures to carefully eliminate all parasitic effects that may contribute to erroneous hydrogen uptake.<sup>[7]</sup> The evaluation of the reliability of the experimental techniques and data interpretation procedures, therefore, need to be very cautious. The hydrogen storage capacity of an adsorbent is generally expressed as a

percentage of the weight of the materials and can be determined by different techniques.

The *volumetric* method, also known as Sievert's method, measures pressure changes in a calibrated volume caused by hydrogen adsorption or desorption in the presence of the solid specimen. This method typically requires a relatively large amount of sample (>500 mg)<sup>[8]</sup> and highly sensitive pressure sensors to achieve a good accuracy. Possible errors may come from gas leakage or temperature instability of the apparatus, and other sources.<sup>[9]</sup> The majority of the reports that claim high storage capacities at room temperature used this experimental method. The results of measurements using the volumetric method are usually expressed in the form of adsorption isotherms (usually up to 0.1 MPa) or pressure-composition isotherms (PCI).

The *gravimetric* method measures the weight changes of the specimen due to adsorption or desorption of hydrogen. A small amount of sample (in the range of ca. 10 mg) may be enough to achieve good accuracy. Since this technique is based only on the measured weight changes, it is less selective to hydrogen and the presence of other adsorbing impurities in the gas phase may cause errors in the results. Therefore, to achieve reliable results by this method, very high purity hydrogen needs to be used.<sup>[10,11]</sup>

Hydrogen storage capacity can also be measured by *thermal desorption spectroscopy* (TDS) or more often called *temperature programmed desorption* (TPD) technique. The capacity is calculated from the amount of desorbed hydrogen, which is generally monitored by mass spectrometry. This method can be selective and highly sensitive, but a careful calibration using a well-known standard specimen is necessary.<sup>[12]</sup>

Carbon materials can also store hydrogen electrochemically. A capacity of 0.39 wt% at room temperature has been reported for samples containing only a small amount of nanotubes,<sup>[13]</sup> and a capacity of 2.9 wt% has been reported for samples containing 80% of single-wall carbon nanotubes (SWNTs).<sup>[14]</sup> In electrochemical measurements, carbon materials are formed as an electrode by mixing them with a conductive powder (e.g. copper, gold),<sup>[13,14]</sup> and a nickel counter-electrode is generally used. Both electrodes are placed in a KOH electrolyte. The amount of hydrogen stored can then be calculated from the measured discharge capacities. Experiments have shown that the measured hydrogen storage capacities by electrochemical method are comparable with those measured by gas adsorption techniques.<sup>[15,16]</sup>

Hydrogen storage capacity of porous carbons at high pressure and ambient temperatures may also be quantitatively predicted from H<sub>2</sub> adsorption measurements at cryogenic temperature below 0.1 MPa by using a model based on the non-local density functional theory

(NLDFT).<sup>[17,18]</sup> This approach is significant from a practical point of view, in that, if reliable theoretical models can be developed, standard adsorption measurements will be sufficient for predicting hydrogen storage capacity at high pressure.

## EXPERIMENTALLY MEASURED HYDROGEN STORAGE CAPACITY

A large number of carbon materials have been studied for hydrogen storage. Because of the large volume of literature, this section is subdivided into a review of the storage capacities of: (i) single-wall carbon nanotubes (SWNTs); (ii) multi-wall carbon nanotubes (MWNTs) and other nanostructured carbon materials such as graphite nanofibers (GNF), nanostructured graphite (NSG), and carbon nanofibers (CNF) mostly grown from chemical vapor deposition (CVD); (iii) "conventional" carbons including activated carbons (AC), activated carbon fibers (ACF), and graphite; and (iv) metal-doped carbon nanostructures.

### Single-Wall Carbon Nanotubes

Dillon et al.<sup>[19]</sup> first reported the hydrogen adsorption capacity in carbon nanotubes. The experimental results on soot containing about 0.1–0.2 wt% SWNTs were used to extrapolate the hydrogen storage capacity of pure SWNTs. They predicted that SWNTs with diameters of 16.3 Å and 20 Å would meet the Department of Energy's (DOE) H<sub>2</sub> uptake target (6.5 wt%) at near room temperatures if modest H<sub>2</sub> over-pressures compensated for the lower heats of adsorption expected in the larger cavities.<sup>[19]</sup> This estimate, however, was not validated by the experimental observations of Ye et al.<sup>[20]</sup> who reported a capacity of 8.0 wt% at 80 K and 11 MPa in their purified SWNTs and stated that such capacities are not attainable at 300 K and pressures below 0.1 MPa. In addition, a capacity of 4.2 wt% was reported at room temperature ( $T = 293$  K) under high pressure (12 MPa).<sup>[21]</sup> Following these early reports, more controversial results have been reported on carbon nanotubes; however, none of the high capacities reported has been independently confirmed by others.

Table 1 summarizes the reported hydrogen storage capacities of SWNTs synthesized by different methods. It is observed that there exist large discrepancies in these results, which could be attributed to variations of a multitude of factors between various research groups, such as: (i) the structure of the materials used, (e.g., diameter, length, opened or partially opened nanotubes), (ii) sample weight (generally very small samples were used, on the order of micrograms),

n/a—data not available.

**Fig. 1** Hydrogen storage capacity at room temperature and 10 MPa as a function of the surface area of SWNTs. *Source:* Data extracted from Refs.<sup>[22,32–35]</sup>.

(iii) degree of purity (most samples were not completely purified SWNTs, and contained amorphous carbon and metal impurities, generally catalytic residues resulting from their synthesis), and (iv) measurement techniques and measuring conditions. Purification of SWNTs, for example by treatment with acids, removes the catalyst particles left from arc-discharge synthesis. Such a treatment increases the storage capacity of SWNTs slightly,<sup>[15]</sup> but negative effects have also been reported.<sup>[22]</sup>

Several research groups<sup>[22,25,28,32,34,35]</sup> have tried to correlate the hydrogen storage capacity of SWNTs with their effective surface area (calculated by the BET method from nitrogen adsorption data at  $T = 77$  K). A fairly linear relationship has been reported for measurements performed both at liquid nitrogen temperature (77 K) and at room temperature. Figure 1 summarizes the data reported for SWNTs at room temperature and 10 MPa. The slope of the straight line that best fits the data in these conditions is about 0.4 wt% per 1000 m<sup>2</sup>/g. Up to a pressure of 6.6 MPa, a slope of 0.23 wt% and 1.91 wt% per 1000 m<sup>2</sup>/g was reported for room temperature and 77 K, respectively, based on an investigation using different carbon materials including SWNTs.<sup>[35]</sup>

With the exception of the high H<sub>2</sub> uptake values reported by several early works,<sup>[19–21]</sup> most recent results seem to support one main point—the storage capacity of SWNTs cannot meet the DOE targets at room temperature; even though SWNTs can store significant amounts of H<sub>2</sub> at cryogenic conditions (close to the temperature of liquid N<sub>2</sub>). The results also indicate that the SWNTs studied so far do not show improved hydrogen storage characteristics over conventional high surface area graphite powder and

activated carbons.<sup>[28,32]</sup> All claims of high storage capacities (larger than ~1 wt%) at room temperature are doubtful, possibly attributable to experimental errors.<sup>[22]</sup>

### Multi-Wall Carbon Nanotubes and Other Nanostructured Carbons

Multi-wall carbon nanotubes (MWNTs) consist of multiple concentric graphitic layers. The typical diameters of MWNTs vary from 15 to 50 nm. Table 2 lists the hydrogen storage capacities of MWNTs and other carbon nanostructures. An uptake of over 3 wt% of hydrogen was claimed for well-aligned carbon nanotube bundles at room temperature and under moderate pressure (~10 MPa).<sup>[36]</sup> Values as high as 6.3 wt% of hydrogen storage capacities (31.6 kg/m<sup>3</sup> of volumetric capacity) have been reported for bulk MWNT samples at room temperature under an equilibrium pressure of 14.8 MPa.<sup>[37]</sup> The high capacity was attributed to the opening of tubes, large micropore structure, and purification of MWNTs. There are, however, several works where very low hydrogen storage capacities for MWNTs were reported. Values lower than 0.04 wt%,<sup>[29]</sup> and a capacity of around 0.1 wt% have also been measured electrochemically for MWNTs.<sup>[23,28]</sup>

Carbon nanotubes used in most studies were produced by catalytic decomposition of light hydrocarbons at high temperature in the presence of a catalyst. The as-prepared materials contained impurities and other forms of carbon (amorphous carbon). The experimental results showed that the MWNTs purified by water washing and acid treatment had a much higher hydrogen storage capacity than the

as-prepared MWNT products.<sup>[37]</sup> It was also reported that annealing carbon nanotubes at temperatures in the range of 1700–2200°C can remarkably improve the storage capacity.<sup>[39,50]</sup> The as-grown nanotubes only showed a capacity of 1.29 wt% at room temperature and 10 MPa, while the samples annealed at 2200°C showed a capacity of 3.98 wt% at the same conditions.

Besides single- and multi-walled nanotubes, other nanostructured carbons that have been studied for hydrogen storage include graphite nanofibers, nanostructured graphite, and carbon nanofibers. The reported hydrogen storage capacities in these materials are summarized in the lower half of Table 2. A capacity of as high as 67.55 wt% was reported for GNF by the group of Baker and Rodriguez.<sup>[40,51]</sup> The same group claimed that careful pretreatment of GNF samples is a critical procedure to remove chemisorbed gases from edge and step regions of the structures. Failure to achieve this condition results in a dramatic decline in the performance of the materials to subsequently

adsorb hydrogen.<sup>[52]</sup> The reported high capacities were questioned by other researches on both theoretical and experimental grounds. Based on the use of a hypothetical potential, which implied a strong interaction between atomic hydrogen and a graphitic surface and negligible desorption at ambient pressure, Monte Carlo simulation of hydrogen adsorption in graphitic pores<sup>[53]</sup> showed that adsorption values greater than 17 wt% are unreasonable. Several recent independent experiments<sup>[8,20,41,47]</sup> suggested that a high hydrogen storage capacity (e.g., 6.0 wt%) in pure carbon nanostructures can only be achieved at, or near liquid nitrogen temperatures, but not at near room temperatures.

Orimo et al.<sup>[54]</sup> prepared nanostructured graphite (NSG) by mechanically milling graphite powder under hydrogen atmosphere at a pressure of 1 MPa and room temperature. The milling process leads to nanocrystallization, first along the directions perpendicular to the basal plane of graphite (cuttingly milling), and second parallel to the basal plane (cleavingly milling).<sup>[55]</sup> After

the expansion of the graphite interlayer, the long-range ordering of the interlayer disappears gradually with increasing milling time. After milling for 80 h, the crystallite size was estimated to have dropped to only 4 nm and the hydrogen concentration reached up to 7.4 wt% ( $\text{CH}_{0.95}$ ). It was suggested that mechanically prepared nanostructured graphite exhibits a specific interaction with hydrogen, probably due to the partial formation of the defect mediated hydrogen sorption.<sup>[56]</sup> Mechanical milling results in the formation of dangling carbon bonds in graphite, and thus the relative ratio of the  $\text{CH}_x$  covalent bonds increases if milling is performed under hydrogen atmosphere. Using the same mechanical milling process at a pressure of  $2.0 \times 10^{-4}$  Pa, Kajiuira et al.<sup>[45]</sup> also prepared the nanostructured graphite from graphite powder. They found that the untreated graphite adsorbed 0.02 wt% of hydrogen, while the nanostructured graphite was able to repeatedly adsorb 0.20–0.25 wt% hydrogen.

Filamentous carbon materials produced by chemical vapor deposition (CVD) are usually called carbon nanofibers; they may contain a mixture of amorphous carbon, carbon filaments, and carbon nanotubes. As listed in Table 2, the reported hydrogen storage capacities for this type of materials are also diverse. Since this type of materials generally has low porosity and surface area ( $<270 \text{ m}^2/\text{g}$ ), a recent study investigated the effect of activation on the hydrogen storage capacities of carbon nanofibers. The results showed that the increased surface area did not correspond directly to a proportional increase in hydrogen storage capacity.<sup>[57]</sup>

### Activated Carbons and Graphite

“Classical” forms of carbons, such as activated carbons, are relatively inexpensive and readily available. There has been some renewed interest in considering activated carbons as candidate materials for hydrogen storage media because of the controversial reports on the behavior of carbon nanotubes. The hydrogen storage capacities of classical forms of carbon materials (including activated carbon fibers) are summarized in Table 3. At low temperature (78 K), a capacity of 6.8 wt% was reported for activated carbons at 4.2 MPa,<sup>[58]</sup> and the amount of hydrogen adsorbed was found to increase with increasing surface area.<sup>[59]</sup> Under a pressure up to 6.6 MPa, an almost linear relation between the storage capacity and the specific surface area of activated carbon was reported,<sup>[35,60]</sup> and a similar relationship was also reported between the capacity and the micropore volume.<sup>[35,60,61]</sup> It was also found that the presence and nature of surface functional groups may affect the amount of hydrogen adsorbed on the surface, but no correlation has been

found between the amount of oxygen present on the surface and the amount of hydrogen stored per unit area of the carbon sample.<sup>[59]</sup> The amount of hydrogen adsorbed, however, increases as the number of surface acidic groups increases.

As listed in Table 3, the hydrogen storage capacities at room temperature of activated carbons, especially those reported recently, are less than 1.0 wt% even at high hydrogen pressure. Based on these data, a correlation between the BET effective surface area and the hydrogen sorption capacity at 298 K and 10 MPa is presented in Fig. 2. It is seen that the hydrogen uptake of activated carbons, in general, increases with surface area and a linear relation seems to be able to describe such dependence. Actually, such a linear relation was also predicted by a theoretical study based on graphite slit-like pores.<sup>[62]</sup> A capacity of  $\sim 1.4$  wt% at 303 K and 10 MPa was predicted for carbon materials with surface area of about  $2000 \text{ m}^2/\text{g}$ .

Theoretical studies suggested that there exists an optimum pore geometry and pore size for hydrogen adsorption;<sup>[65,70]</sup> however, discrepancies exist regarding the value of this optimum pore size. In general, hydrogen storage is favored in small micropores and it has been suggested that the optimum pore size should be able to accommodate two layers of adsorbed  $\text{H}_2$ .<sup>[71]</sup> Therefore, the micropore ( $<2 \text{ nm}$ ) volume of activated carbons has been correlated to their hydrogen storage capacity at both at 77 and 293 K (Fig. 3). Similar linear relationship has also been reported by Panella et al. at 298 K and 6.6 MPa.<sup>[35]</sup> Such a direct correlation suggests that high microporosity in carbon materials should benefit hydrogen storage at both liquid nitrogen and room temperature. For activated carbon fibers, an experimental study also showed that the storage capacity increased with the degree of activation and that is closely linked to the micropores.<sup>[69]</sup> These authors suggested that micropores of about 0.6 nm are responsible for the greater increase in storage capacity.

Graphite, often used as the reference sample, has also been tested for the hydrogen storage capacity. The results are also presented in Table 3. It is evident that the values are much lower when compared with those of activated carbon.

### Heteroatom-Incorporated Carbon Materials

The two possible storage models considered up to this point include adsorption of hydrogen as a monolayer at the surface of nanostructured carbon materials and condensation in the narrow cavities of carbon nanotubes or in the micropores of activated carbon, at densities comparable with the density of liquid hydrogen. Another possible mechanism to enhance

the adsorption capacity is by dissociation of hydrogen molecules followed by chemisorption of atoms in a tight-binding (covalent) state, or by transfer of an electron to the host material as in metal hydrides,<sup>[25]</sup> or recombination of H atoms to form physisorbed H<sub>2</sub>. These processes could possibly be enhanced by incorporating heteroatoms into carbon structures.

Intercalation of alkalis (Li, K, etc.) into purified carbon nanotubes resulted in absorption of up to 20 wt% hydrogen at room temperature and ambient pressure,

according to Chen et al.<sup>[72]</sup> Such large weight gains, however, were proved in a subsequent experiment to be the result of alkali hydroxide formation from a H<sub>2</sub> stream that was contaminated with water.<sup>[11]</sup> Experiments with ultra-pure dry H<sub>2</sub> indicated that lithium-doped SWNTs were capable of adsorbing about 2.5 wt% and potassium-doped nanotubes of about 1.8 wt%. In addition, a capacity of 0.59 wt% was electrochemically measured at room temperature for Li-doped CNTs, higher than the capacity of the

**Fig. 2** Hydrogen storage capacity at 298 K and 10 MPa as a function of the surface area of activated carbons. *Source:* Data extracted from Ref.<sup>[18,22,32,34,35,49,66]</sup>

corresponding undoped CNTs of only 0.1 wt%.<sup>[23]</sup> While such observations were very encouraging, thermogravimetric measurement of hydrogen adsorption in alkali-modified carbon materials showed no evidence of significant improvement.<sup>[10]</sup>

The possible effect of nitrogen atoms incorporated into carbon on the hydrogen storage capacity of carbon materials synthesized from a CVD process has been tested by adding N<sub>2</sub> gas during synthesis.<sup>[73]</sup> A capacity of 0.7–0.8 wt% at room temperature and under hydrogen pressure of 7 MPa was measured by a thermogravimetric method for materials grown in a gas composition containing a carbon source, H<sub>2</sub>, and N<sub>2</sub>.

Recent works have been focused on dispersing a small amount of transition metals (e.g. Pd, Pt, or Ni) in carbon to aid the adsorption of hydrogen. It is

believed that the hydrogen storage capacity of carbon could be increased by the presence of such metal particles.<sup>[74,75]</sup> Enhanced hydrogen uptakes have been observed when transition metals were added to graphite,<sup>[76]</sup> SWNTs or MWNTs,<sup>[77–84]</sup> carbon nanofibers,<sup>[43,85,86]</sup> and activated carbons.<sup>[68,83]</sup> The results are summarized in Table 4; the hydrogen uptakes listed are, in general, the maximum values of reported overall hydrogen storage capacities. It is, in general, agreed that the improvement of hydrogen storage by adding metal particles is attributed to a well-documented hydrogen spillover mechanism.<sup>[87,88]</sup> The presence of metal particles helps the initial hydrogen adsorption and the dissociation of hydrogen molecules into hydrogen atoms, which then spill onto nearby available carbon sites through the interface between

n/a—not available.

the metal and carbon. Such a spillover is also believed to exist from metal oxide catalysts to MWNTs and is responsible for the increased hydrogen storage capacity of a MWNT/NiMgO system.<sup>[85,89,90]</sup> In addition, experiments showed that initial hydrogen adsorption kinetics for metal-added-CNTs was nearly two times faster than that of pristine samples.<sup>[77]</sup>

While this approach for increasing the hydrogen storage capacity of carbon materials is perhaps promising, a better understanding of the mechanism is still needed. Hydrogen spillover is an accepted mechanism, but other critical issues, such as the effect of metal particle size and dispersion, the nature of the interfacial contact between carbon and metal atoms or nanoparticles, and how to achieve a better dispersion and interfacial contact, are still not well understood. It is also not known what the optimal metal content in a particular system is, which would result in the best improvement of capacity by doping the least amount of metal. In general, carbon-supported metal nanoparticles are better dispersed at relatively low metal content and show improved kinetics of sorption and desorption of hydrogen when compared with their counterparts with larger particle sizes.<sup>[91]</sup> This implies that the reduction in metal particle sizes and the increase in dispersion, in a sense, are more important than to increase metal loading in sample preparation. In addition, loading a large amount of metal usually

results in a tremendous decrease in the effective surface area of carbon materials.

The accessibility of metal particles for hydrogen molecules in various carbon materials, especially carbon nanotubes, is also critical for metal-assisted hydrogen adsorption. The presence of residual metal catalyst particles has been assumed not to influence the values of adsorbed hydrogen in SWNTs since they were encapsulated in graphitic shells, which would prevent any contact between the gas and the metals.<sup>[19]</sup> But the observed sorption of hydrogen in SWNT samples synthesized by the arc-discharge method was found to be highly dependent on the presence of Ni.<sup>[79]</sup>

## THEORETICALLY PREDICTED HYDROGEN STORAGE CAPACITY

All theoretical estimations of the hydrogen uptake by carbon adsorbents must be based on the knowledge of the exact state of H<sub>2</sub> in adsorbed state, but up to now there is no agreement on this point. Currently, most of the calculations are based on either physisorption of hydrogen molecules or chemisorption of hydrogen atoms. The physisorption models generally use grand canonical Monte Carlo simulations to determine the adsorption isotherms, and have the

advantage that the temperature dependence of adsorption can also be predicted. The two basic assumptions of this approach are: (1) there is no chemical transformation taking place during hydrogen adsorption; (2) the interaction between carbon materials and hydrogen molecules can be described via a classical empirical potential. The chemisorption models consider that a chemical process takes place during H<sub>2</sub> adsorption, and simulates the electronic states by employing classical or quantum molecular simulations and the density functional theory; this approach has the advantage of showing the nature of the interaction between atoms.

Hydrogen storage capacities of carbon adsorbents predicted by Monte Carlo simulations are summarized in Table 5. The targeted carbon forms include SWNTs, graphitic nanofibers, activated carbons, and even metal-doped carbon bundles, but most of the calculations were based on SWNTs. In the simulations, SWNTs were mostly considered as open, well-structured tubes, without amorphous carbon and

impurities, having well-determined and chosen diameters and geometrical location in the bundles, while slit pores were used to approximate the structure of nanofibers and activated carbons. The geometry assumed for the adsorbent (the tube diameter and van der Waals gap in the case of tubes, or the pore width and interplanar distance in the case of slit pores) is a critical factor for estimating storage capacities and comparing the results from different investigators; this is only more complicated by the use of different potentials and the consideration of quantum effects by various authors.<sup>[92]</sup> Basically, the numbers listed in Table 5 are the maximal capacities predicted for the optimized adsorbent structures. It is seen that none of the adsorbate configurations studied are able to approach the DOE storage goals at ambient temperatures, with the exception of the unusually high capacity predicted by Yin et al. for triangular arrays of SWNTs.<sup>[93]</sup> Some of the recent theoretical studies are seen to be in good agreement with some experimental data acquired for SWNTs.<sup>[94]</sup>

Cao, Feng, and Wu, <sup>[102]</sup> 2004	Graphitic carbon inverse opal	298	30.4	5.9

Graphitic slit pores are used as a first approximation to the structure of graphitic nanofibers.<sup>[70,103]</sup> Modeling showed that the idealized slit pores give significantly better performance for hydrogen storage than SWNT arrays.<sup>[65,70]</sup> Similar results were also reached by Cracknell.<sup>[53,104]</sup> It is believed that most of the differences can be attributed to the curvature of the pores. In addition, the simulation results also indicated that hydrogen adsorption in carbon nanostructures is strongly influenced by the structure of the porosity.<sup>[101]</sup> When ideal slit pores were used to approximate activated carbon, the amount of absorbed hydrogen depends on the surface area of the sample and the maximum is 0.6 wt% ( $T = 300\text{ K}$ ;  $P = 6\text{ MPa}$ ),<sup>[65]</sup> which was verified experimentally with an excellent agreement.

Grand canonical Monte Carlo computer simulation also predicted that the doping of carbon nanotubes with electron donor and electron acceptor heteroatoms increases the hydrogen storage capacity of SWNTs.<sup>[105]</sup> The total adsorption of hydrogen predicted for metal-doped SWNT bundles, however, is still around 2.0 wt%, which is significantly smaller than the DOE target.<sup>[100]</sup> Calculated isotherms indicate that charged nanotube arrays (by doping) cannot meet the target for hydrogen storage at normal temperatures, unless the charges on the nanotubes are unrealistically large.

Quantum chemistry calculations have shed light into the interaction of hydrogen with carbon sites. One can search for hydrogen chemisorption sites, investigate activation barrier for  $\text{H}_2$  dissociation, study the stability of chemisorbed hydrogen, and predict the (maximum) storage capacity by performing geometry optimization and calculating potential energy surfaces for the dissociative adsorption of  $\text{H}_2$  on carbon sites of graphene or carbon nanotubes. First principles studies suggested that for the case of  $\text{H}_2$  interaction with graphene structures, the adsorption energies of H atoms are sensitive to the carbon sites;<sup>[106]</sup> the activation barriers for  $\text{H}_2$  dissociation on an unrelaxed graphene layer is considerably higher than that on a relaxed structure.<sup>[107]</sup>

Such theoretical calculations on carbon nanotubes have been the subject of several reviews.<sup>[3,5,92,108]</sup> Chemisorption starting from the physisorbed  $\text{H}_2$  molecule is difficult because of the existence of a substantial activation barrier,<sup>[108–110]</sup> however, while hydrogen chemisorption on some sites is energetically more favorable,<sup>[111]</sup> the kinetic energy of hydrogen atoms may affect where hydrogen is adsorbed.<sup>[112]</sup> Chemisorbed hydrogen induces strong deformation in nanotubes and weakens the C–C bond.<sup>[109,113]</sup> In a recent study, Yang, Lachawiec, and Yang<sup>[33]</sup> suggested that the energy of chemisorption decreases with hydrogen coverage. They also predicted that the activation energy of desorption for some adsorbed hydrogen may be below 10–15 kcal/mol, which allows desorption to take place readily at room temperature. Another

study also showed that the interaction of hydrogen with SWNTs is very weak and that a slight increase in temperature may cause hydrogen diffusion from the tube walls.<sup>[110]</sup>

A hydrogen storage capacity of more than 14 wt% was predicted for (10, 10) nanotubes by Lee et al. based on density functional theory.<sup>[113]</sup> This value is much higher than the estimated value of 3.3 wt% from the geometrical model,<sup>[114]</sup> and it is believed to be unrealistic.<sup>[100,112]</sup> A more recent theoretical evaluation by Li et al.<sup>[115]</sup> suggested that contribution from chemisorption has a theoretical upper limit of 7.7 wt% for hydrogen sorption in carbon nanotubes, but this upper limit would be very difficult to achieve in practice. Another theoretical calculation also suggested that maximum hydrogen storage capacity is limited by the repulsive energies between  $\text{H}_2$  molecules inside nanotubes and those between  $\text{H}_2$  molecules and the tube wall.<sup>[112]</sup> The highest volumetric density calculated for hydrogen stored in SWNTs is as high as  $132.4\text{ kg/m}^3$ , which corresponds to about 15 wt%. At this value, the pressure estimated to be imposed on the inner wall of the SWNT capsule is about 40 GPa at room temperature.<sup>[112]</sup> In addition, a theoretical study also suggested that there is no rational reason for carbon nanotubes to have superior hydrogen uptake capacity than other graphitic structures in terms of either binding energies or kinetics.<sup>[115]</sup>

## UNANSWERED QUESTIONS RELATED TO HYDROGEN STORAGE IN CARBON MATERIALS

Although a large volume of experimental and theoretical research has been done on adsorption of hydrogen in carbon nanotubes and other forms of nanostructured carbons, several key issues, especially those related to the fundamental understanding of hydrogen adsorption in nanostructured carbon materials, are still open to discussion.

A basic issue is, what is the exact chemical state of hydrogen when it is adsorbed in carbon materials, or in other words, what is the precise nature of the interaction between hydrogen and a given carbon surface?<sup>[1]</sup> It is generally accepted that hydrogen adsorption at liquid nitrogen temperature (77 K) is a physisorption process, but the extent of physisorption contribution in adsorption at room temperature is still an arguable issue. Hirscher et al.<sup>[34,35]</sup> suggested that room temperature adsorption is a typical physisorption process because both fast kinetics and high reversibility were observed for hydrogen adsorption in different carbon nanostructures, including SWNTs, AC, MWNTs, and a mixture of nanotubes. Additionally, the amount of hydrogen adsorbed depends almost

linearly on the specific surface area of the carbon materials, both at low temperature and at room temperature, and is independent from the type of carbon nanostructure.<sup>[35]</sup> Rzepka et al.<sup>[47]</sup> studied several types of nanofibers and claimed that all experimental results at room temperature can be adequately explained by pure physical adsorption on carbon surfaces. A recent investigation using Raman spectroscopy found that no charge transfer phenomena were involved in the interaction between hydrogen and activated carbons in the range of 40 K to room temperature and at a pressure of up to 10 MPa.<sup>[116]</sup> It was suggested that physisorption is the mechanism of hydrogen adsorption, while chemisorption, if any, should be negligible, because no C–H stretching signals in the region of 2800–3300 cm<sup>-1</sup> were detected.

If the H<sub>2</sub> uptake at room temperature is caused by physisorption, this process alone cannot explain the relatively high hydrogen uptakes measured at room temperature in well-controlled conditions. Thermal desorption studies revealed that weakly bonded physisorbed hydrogen accounts for ca. 90% and chemically bonded hydrogen for ca. 10%. The latter was released at temperatures above 450°C as a result of breaking of the covalent C–H bonds.<sup>[31]</sup> Experiments also showed that 78.3% of the adsorbed hydrogen could be released under ambient pressure at room temperature, while the release of the residual stored hydrogen required some heating of the sample.<sup>[21]</sup> TPD studies<sup>[25]</sup> of hydrogen loaded SWNT with high pressure (2 MPa) hydrogen gas at room temperature showed that there are at least two different sites for hydrogen in the SWNT samples. The physisorbed molecular hydrogen at the surface of the carbon desorbs around 105 K, while tightly bound hydrogen desorbs at temperatures above 500 K. Even though the tightly bound hydrogen was suggested to be incorporated during the synthesis of the nanotubes, the possibility of forming chemisorbed hydrogen during adsorption still cannot be ruled out. It has also been suggested<sup>[56]</sup> that an intermediate state between physisorption and chemisorption may be possible, i.e. “defect-mediated hydrogen sorption,” and this state would possibly participate in hydrogen storage on carbon nanostructures. A better understanding of the role that these possible states play during adsorption is necessary for finding answers to other issues. It would also provide the fundamental support to all other approaches for increasing the gas uptake, such as purification, annealing, increasing specific area of the materials, opening of the tubes, or intercalation of heteroatoms.

Another important parameter is the heat of adsorption of hydrogen. This energetic parameter varies with surface coverage and is very sensitive to any surface irregularities, distribution of pore size, and presence of various chemical groups on the surface. This parameter

may provide quantitative information about the nature of the interaction between hydrogen and the adsorbent. Experiments at 77 K showed that the heat of adsorption of hydrogen on activated carbons is about 4 kJ/mol.<sup>[63]</sup> The values obtained from the van't Hoff isochore at various surface coverages were in the range of 3.9–5.2 kJ/mol.<sup>[117]</sup> These numbers are well supported by theoretical predictions.<sup>[118]</sup> At room temperature, a wide range of values (e.g. between 31.4 kJ/mol<sup>[111]</sup> and 7.54 kJ/mol)<sup>[115]</sup> have been theoretically predicted for the adsorption energies of H atom to graphitic surfaces (nanotubes and graphene), but systematic experimental studies are still missing. In addition, a thermodynamic study suggested that a suitable adsorbent capable of storing hydrogen at ambient temperature should have a heat of adsorption of hydrogen of about 15.1 kJ/mol. This value corresponds to the optimum affinity of hydrogen: strong enough to store a large amount of hydrogen gas at the charging pressure (about 3 MPa) but weak enough to release most of that hydrogen at the discharge pressure (about 0.15 MPa).<sup>[119]</sup>

One question derived from the basic issue is the following: if hydrogen adsorption at low temperature is a physisorption process, is it possible for hydrogen to access and condense inside carbon nanotubes? Or, “is adsorption in nanotubes a reliable mode of hydrogen storage?”<sup>[6]</sup> The main difference between CNTs and high surface area graphite is the curvature of the graphene sheets and the cavity inside the tube. In microporous solids with capillaries that have a width not exceeding a few molecular diameters, the potential fields from opposite walls will overlap, so that the attractive force acting on adsorbate molecules will be larger than that of an open surface. The condensation of hydrogen by such “capillary effect” then allows nanotubes, especially SWNTs, to store more hydrogen than the amount potentially adsorbed only by surface adsorption. But the assumption that hydrogen condenses inside the nanotubes is questionable because the critical temperature of hydrogen is 32.98 K and therefore it would only condense below a temperature of 33 K. In addition, the adsorption isotherms of nanotubes are of type II and no differences in the shape of the isotherm from nanotubes and high surface area graphite were found.<sup>[25]</sup> The specific surface areas calculated from the BET method (using N<sub>2</sub> adsorption at 77 K) on various nanostructured carbon samples range from 73 to 377 m<sup>2</sup>/g. No indication for the condensation of nitrogen inside the tubes was found. It was argued that the inner surface of the tubes was inaccessible because the tubes were possibly capped. This stimulated efforts for opening of the tubes. It is essential to ensure that hydrogen molecules can enter the tube because these molecules cannot penetrate through the carbon atom hexagons.

Other debatable issues are: What is the capacity of carbon surface for chemisorbing hydrogen? Does

chemisorption play a significant role in the hydrogen adsorption or storage process? If hydrogen is able to form a covalent bond with carbon, what are the possible sites for the interaction? Are both edge sites and in-plane sites of graphene sheets the possible sites for chemisorption? The contribution of simulations in answering these questions should guide any practical approach of improving the hydrogen storage capacity in carbons by chemical modification such as heteroatom incorporation. If the answer is positive, introducing metals that can help the dissociative adsorption of hydrogen and “transfer” hydrogen to carbon sites (“spillover” mechanism) in/into carbon adsorbents would certainly be beneficial. In addition, it is suggested that most of the hydrogen species should be adsorbed on carbon, not on metals such as Ni (or Co),<sup>[76]</sup> while metals serve mainly as an active center to assist the dissociative adsorption of hydrogen molecules. A following question, then, is what types of carbon sites are the receivers of hydrogen transferred from metal sites? It was argued that hydrogen molecules adsorbed by metal nanoparticles was subsequently dissociated and spilled over to carbon nanotubes to those defect sites.<sup>[81]</sup> Then, could any carbon site be the receiver for such spillover?

For carbon nanotubes, there are two more arguable issues. One is what are the optimum sizes of nanotubes and their spatial arrangement for reaching high storage capacity. Another one is whether or not nanotubes have better adsorption capacity than “classical” carbon materials such as activated carbons. Related to the former issue, if there is an optimal geometry, then, is it possible to control these structural parameters in practice? Modeling calculations<sup>[25]</sup> showed that the bulk absorption in the cavity of nanotubes is proportional to the diameter of the tubes and is highest for SWNT. Based on the assumption that hydrogen would condense in the nanotube cavity, calculations showed that the mass percentage of adsorbed hydrogen increases with the tube diameter. Monte Carlo simulations have shown that hydrogen adsorption can be optimized by suitable sizes of nanotube diameters and of space between nanotubes in the bundles.<sup>[95,96,100,120]</sup> A definitive answer from experimentation is still not available.

For the question regarding the superiority of carbon nanotubes over “classical” carbon materials, both positive (e.g. Ref.<sup>[93]</sup>) and negative (e.g. Ref.<sup>[115]</sup>) answers have been derived from theoretical studies. On experimental grounds, and disregarding the high but unverified capacities claimed by early studies,<sup>[19,40]</sup> nanotubes did not always show higher capacities than activated carbons. Actually, from the data listed in “Theoretically Predicted Hydrogen Storage Capacity”, almost all results reported recently showed that nanotubes (and nanofibers) have much less

storage capacity than high-surface activated carbons.<sup>[25,28,29,32,67]</sup> In addition, Züttel et al.<sup>[25,28]</sup> studied a large number of different carbon samples and showed that the adsorption of hydrogen on nanotubes is a surface phenomenon, which is similar to the adsorption of hydrogen on high-surface area graphite.

For the experimental study of hydrogen storage in carbon materials, there are three aspects that need attention. First, there is insufficient understanding of the adsorption and desorption kinetics of hydrogen on carbons. Up to now, most studies have been performed at equilibrium conditions. Measurements of the hydrogen adsorption rate at constant pressure and pore-size distribution suggest that the hydrogen molecules are adsorbed through a diffusion process into pores with a diameter less than 1 nm.<sup>[45]</sup> The diffusion process has still not been kinetically defined. Second, systematic experiments are necessary using reliable measurement techniques and sufficient quantities, of high-purity, and well-characterized carbon samples with structures including numerous openings for hydrogen accessibility. Third, more studies on the performance of metal-added carbon materials after the first adsorption/desorption cycle are necessary. A repeatable hydrogen uptake is expected for storage materials used in practice. The reproducibility of hydrogen uptake in repeated cycles then should be another important parameter for evaluating storage materials, especially in the cases where chemisorption is involved. It was observed that<sup>[76]</sup> the high-temperature H<sub>2</sub> uptake and release could be repeated for many cycles in Ni (Co) added graphite composites, with a slight decrease in the H<sub>2</sub> storage capacity after the first cycle. Probably, some of the transition metal particles migrated out from the carbon matrix and agglomerated after the H<sub>2</sub> adsorption/desorption cycles, which may reduce the synergism between the transition metal and carbon, and thus the H<sub>2</sub> storage capacity.<sup>[76]</sup> In the case of CNTs, the amount of hydrogen storage decreased from an initial 1.0 wt% to 0.2 wt% in the second H<sub>2</sub> uptake-release cycle.<sup>[81]</sup> The reason might involve the recrystallization of the defective CNTs on releasing hydrogen by heating to 1100 K,<sup>[81]</sup> because the amount of hydrogen stored in CNTs decreased with increasing annealing temperature.

Besides the large variation of reported storage capacity of carbon adsorbents, and the lack of basic modeling research on the proper conditions, physical and chemical, for optimum hydrogen storage, other challenges still exist for application of carbon materials, especially nanostructural materials, in hydrogen storage. For carbon nanotubes, the main challenges are the high cost and the difficulty of large-scale production. As analyzed by Bunger and Zittel,<sup>[7]</sup> a storage cost of about \$3 million per vehicle is projected if single-wall nanotubes were used at the commercial

price available today. Based on a technical and economic analysis, they concluded “hydrogen storage in carbon nanostructures is still at a research level and not yet mature for industrial application. From today’s point of view, at least for the first generation of direct hydrogen applications (such as fuel cell vehicles, battery replacement), other alternatives such as compressed or liquid storage are required.”<sup>[7]</sup>

## CONCLUSION

The reported hydrogen storage capacities in carbon adsorbents do not converge into a certain narrow range. Most recent experimental observations seem to support the conclusion that carbon nanotubes are not likely to store the amount of hydrogen required for automotive applications at moderate pressures and close to room temperature, and those results are supported by some theoretical studies reported recently. Experimental results reported in the past couple of years implied that different carbon materials, except metal-doped materials, in general only have less than 1.0 wt% hydrogen storage capacities at room temperature (even at high pressure). At both liquid nitrogen temperature and room temperature, the storage capacities of activated carbons increase with the increase in effective surface area and micropore volume, and a broadly linear relationship can describe such dependences. A promising approach to enhance the hydrogen storage capacities of carbon materials may be metal doping, but more systematic studies are necessary. Some key issues related to the fundamentals of hydrogen storage in nanostructured carbon materials are still open to discussion. More fundamental studies using both theoretical and experimental approaches are still needed.

# Carbon Forms Structured by Energetic Species

Yeshayahu Lifshitz

Center of Super-Diamond and Advanced Films, City University of Hong Kong, Hong Kong, China, and Soreq Nuclear Research Center, Yavne, Israel

## INTRODUCTION

Modern materials science aims at the development of controlled ways of structuring novel materials. High-pressure, high-temperature (HPHT) methods (initiated by the legendary pioneering work of Bridgman<sup>[1]</sup>) indeed provide numerous exotic phases for thousands of materials. Among the most important ones that find a billion-size market are diamond and cubic boron nitride. The massive nature of HPHT systems inhibits their use for modern (thin film) technology. An alternative emerging technique (in the past 30 years) for the structuring of materials is the application of energetic species for deposition and surface and bulk modification. It is now very well established that the use of energetic species either by direct ion beam deposition or by bombardment of materials (ion beam-assisted methods) provides a way to structure materials (metals, semiconductors, ceramic, and polymers) controlling a variety of physical properties (including hardness, density, wear resistance, resistivity, optical transparency, surface morphology, and oriented/epitaxial growth).<sup>[2]</sup> Surprisingly, utilization of energetic species sometimes produced metastable phases previously reported only from HPHT experiments. It is most important to note that ion beam techniques currently provide the most controlled technique known to the semiconductor industry for material modification (e.g., doping) and is extensively used.

In the last decade many efforts were dedicated to the emerging field of nanostructuring of materials, which is the topic of this encyclopedia. Top-down and bottom-up techniques have been developed to structure nanosized materials. A crucial issue in most of the approaches utilized, which have successfully produced a host of novel nanosized materials, is the controlled growth, i.e., processes that yield materials with a narrow distribution of size, structure, and composition thus possessing well-defined properties.

The purpose of this entry is to describe how ion beams can be used in a controlled way to nanostructure a wide spectrum of materials: amorphous, medium-range (multiwall tubes and fullerene-like),

and crystalline. Ion beams use the idea of HPHT in a very localized region (nano-HPHT) taking advantage of the control offered by ion beam techniques. Carbon, with its wealth of configurations that will be highlighted in the next section, offers the best study case to demonstrate the idea of ion beam structuring of materials. This entry shortly discusses the experimental systems used for ion beam structuring of carbon and for characterization of the products. It presents the basic physical processes leading to the formation of the nanostructured materials and then describes how amorphous, medium-range, and crystalline forms can be structured and their properties can be tuned accordingly. For additional reading the reader is referred to recent reviews<sup>[2-9]</sup> covering structuring of carbon forms by energetic species, structuring by energetic species in general, and superhard materials in general.

## CARBON—AN IDEAL MODEL SYSTEM TO STUDY STRUCTURING BY ENERGETIC SPECIES

Carbon is unique in the variety of configurations it makes within itself and with other elements.<sup>[3-6,10]</sup> A carbon atom can be involved in three different local configurations ( $sp^1$ ,  $sp^2$ ,  $sp^3$ ). A carbon matrix can be amorphous or have medium and long-range order. It forms large molecules (e.g., fullerenes), one-dimensional structures (e.g., nanotubes), and fibers (exploited for making composite materials). Carbon also has a variety of crystalline forms among which graphite (the  $sp^2$  form) and cubic diamond (the  $sp^3$  structure) are the most known. The richness of carbon forms makes it one of the most important materials, both scientifically and technologically. This is why carbon forms have been applied or are being considered for a large number of mechanical, tribological, optical, and electrical applications. As far as structuring by energetic species, the richness of carbon forms enables to follow the possibilities offered by energetic species in one single system.

## EXPERIMENTAL TECHNIQUES USED FOR GROWTH AND CHARACTERIZATION OF ION BEAM STRUCTURED CARBON

Structuring of materials using ion beams can be performed in two basic ways:<sup>[2-6]</sup> 1) use of ion beams (or energetic species) in the growth process itself (ion impact effects occur simultaneously with the material growth); 2) modifications by ion beams (energetic species) of target materials (i.e., no growth occurs, just modifications because of ion impact). For the first case the minimal species energy required is small (a few tenths of eV). For the second the size of the modified layer is determined by the range of the ions in the target material, i.e., keV ions are required to modify a layer which is, say, several nanometers thick. The variety of systems that use energetic species for nanostructuring of materials during the growth process include: 1) techniques in which energetic species are created first and then bombard the substrate so that most of the energetic species are growth species incorporated in the material (direct ion beams, arc discharge systems, laser ablation systems, sputtering systems); 2) techniques in which the energetic species (e.g., noble gas species) transfer momentum to the evolving material and are not necessarily incorporated (ion-assisted systems). In the latter most of the growth species are not energetic and the modifications are only due to the assisting energetic species. Plasma deposition systems make a special case in which both non-energetic and more energetic species exist and the balance between them is determined by the applied bias. Most systems applying energetic species are characterized by a complex nature in terms of a composition of a variety of different particles with a large distribution of energies. This makes the controlled growth and study very difficult. Mass selected ion beam deposition (MSIBD) systems offer excellent control of all relevant parameters (filtered isotopically pure species, defined energy, and impinging angle). Second best in control are filtered arc systems, which are much cheaper and available than MSIBD systems. Modifications of existing material by energetic species require ion beam systems with energies of several kilo electron volts at least as previously stated.

A variety of characterization methods are applied to study ion beam nanostructured carbon.<sup>[3-6]</sup> The composite nature and the intrinsic non-homogeneity of the carbon nanostructured materials require the use of characterization methods with a very high resolution. The best characterization tool thus available is transmission electron microscopy (TEM), preferably high-resolution TEM (HRTEM) and its derivatives [transmission electron diffraction (TED) and transmission electron energy loss spectroscopy (EELS)]. These methods offer determination of the local configuration ( $sp^3$  fraction), information on  $sp^2$  structures

(carbon nanotubes, nanoions, graphitic domains) and their orientation, and identification of crystalline forms (graphite, diamond). Of special interest also are composite forms (crystalline/amorphous, amorphous  $sp^2$ /amorphous  $sp^3$ , layered structures, etc.). The morphology of the carbon nanostructured materials can be detected by both atomic force and scanning tunneling microscopies (AFM/STM)<sup>[11]</sup> and also by scanning electron microscopy (SEM), preferably high-resolution SEM (HRSEM).

Raman spectroscopy is the most common technique applied for the characterization of nanostructured carbon, very often in an erroneous way.<sup>[3-6,12]</sup> Raman in the visible light is very sensitive to  $sp^2$  carbon forms and insensitive to  $sp^3$  forms, which can be detected only with UV Raman when mixed in amorphous  $sp^2$  forms.<sup>[3-6,13]</sup> The correct identification of  $sp^2$  forms requires expertise and is aided by looking at the dispersion behavior of the spectra at different excitation wavelengths.

Nanostructured carbon characterization including Raman, surface analysis, and other properties characterization (optical, electrical, mechanical) is very useful. Its correct interpretation, however, requires an understanding of the complex nature of the nanostructured material in terms of inhomogeneity, layered structure, and orientation for which the high-resolution methods are essential as a first step.<sup>[14]</sup>

## BASIC PROCESSES INVOLVED IN ION BEAM STRUCTURING

It is now very well established that the deposition process from energetic ( $\sim 10$  eV–1 keV) species is a shallow implantation (“subplantation”) process<sup>[3-6,11,15-17]</sup> and not a surface process. For each deposition scheme the following quantities very well known from ion implantation studies should be considered:

1. The range ( $R$ ) and the distribution ( $\Delta R$ , straggling) of the subplanted species;
2. The trapping efficiency;
3. The sputtering of target material atoms; and
4. The damage created by the bombarding species (no. of atomic displacements or no. of remaining vacancies).

It should also be noted that three different time scales are involved<sup>[4,15-17]</sup> in the actual stopping and trapping of the bombarding species and the resulting material modifications and film growth:

1. Stopping via (atomic) collisions, ionization, and phonon excitations (the “collisional stage,”  $\sim 10^{-13}$  sec);
2. Dissipation of the excess energy in the target (the “thermalization stage,”  $\sim 10^{-12}$  sec); and

3. The long-term relaxation stage ( $\sim 10^{-10}$  sec up to seconds) where diffusion, chemical reactions, and phase transformations take place.

It is currently widely accepted that the subplantation process advances through the following stages:<sup>[3-6,15-17]</sup>

1. Penetration (of carbon species) to subsurface layers;
2. Incorporation (of carbon atoms) inducing local stresses;
3. Sputtering and dilution of the target atoms until a pure carbon layer evolves; and
4. Growth of the pure carbon layer upon successive bombardment.

The C species need a critical energy to penetrate to subsurface layers of the pure C layer in which they are now stopped. The final site, which the C projectile occupies, determines the structure and properties of the evolving carbon film. Trapping of C species in subsurface sites leads to elastic expansion, which is associated with compressive stress. The incorporation of these trapped C species leads to increased density (stress). The increased density (which occurs because of the combined effect of the incorporation of C projectiles and forward displacements of C atoms along the trajectories of the impinging C projectiles) induces an increase of the  $sp^3$  fraction of the amorphous matrix that evolves. When a maximal density (stress) is reached, plastic deformation may occur which sets the density and  $sp^3$  fraction to a constant maximal value upon further incorporation of C species. Local relaxations (e.g., the “thermal spike”<sup>[3-6,17]</sup> relaxation) permit local modifications of the highly dense (stressed) amorphous region in which the C atom is embedded. These modifications may either initiate or suppress  $sp^3$  bonds. Contrary to the previous explanation of density (stress)-driven  $sp^3$  formation, some researchers believe that it is the rapid relaxation (quenching) of the “thermal spike” region that drives the carbon atom to a metastable  $sp^3$  state (claiming that the  $sp^3$  bonding is the thermodynamic stable configuration for the local high-pressure, high-temperature region induced by the “thermal spike”<sup>[3-6,17]</sup>). Relaxation and detrapping processes (thermal migration, radiation damage) may remove some of the densification (stress). The  $sp^3$  fraction is thus determined by the equilibrium between the densification and detrapping processes.

## STRUCTURING OF AMORPHOUS CARBON FORMS

The understanding of the basic processes involved in subplantation enables the further discussion of how

amorphous carbon (a-C) films can be nanostructured. Three important parameters govern the phase evolution and can be used for nanostructuring carbon films:<sup>[3-6]</sup>

1. The ion energy ( $E$ );
2. The substrate temperature ( $T_s$ ); and
3. The deposition rate.

The C ion energy is a key factor in the determination of the  $sp^3$  fraction and the nature of carbon films.<sup>[3-6]</sup> This subsection discusses the role of  $E$  under conditions where the substrate temperature is low enough so that thermal migration of the trapped carbon species is not significant. Four different energy regions were identified<sup>[3-6]</sup> for carbon deposition from energetic species going from low to high  $E$  (Fig. 1):

1. Surface deposition;
2. Tetrahedral amorphous carbon (ta-C) ( $sp^3 > 70\%$ ) deposition;
3. Amorphous carbon with a significant  $sp^3$  fraction decreasing with  $E$ ; and
4. Graphitic films.

Below a certain critical energy  $E_p$  needed to penetrate to subsurface layers amorphous  $sp^2$  films are deposited ( $sp^2$  is the stable C configuration under normal temperature and pressure conditions) via surface growth processes [region (1)]. The surface nature of the deposition in this region is manifested by the rough surface morphology that develops<sup>[4,11]</sup> (as shown in Figs. 1 and 2), which is also affected by an increased adatom surface mobility (compared to thermal deposition) due to the C ion energy. In region (2) the C species penetrate to subsurface layers where they are subplanted. The densification (and stress formation<sup>[3-6]</sup>) due to incorporation of C species leads to the formation of carbon films with a predominant  $sp^3$  fraction ( $>70\%$ ). Such films have a tetrahedral local configuration with a nearest neighbor distance of 1.54 Å and a bond angle of  $\sim 110^\circ$ , which is why they are denoted ta-C. They are the analogue of amorphous silicon and should be distinguished from diamondlike carbon (DLC), a broader family of films for which the  $sp^3$  fraction ranges between  $>0\%$  and 85%. The detrapping and relaxations induced by  $E$  in region (2) are insufficient to decrease the  $sp^3$  fraction below this high value of 70%. This is the optimal  $E$  region for ta-C formation. The internal growth nature of the DLC films leads to a surface morphology identical to the initial morphology of the substrate, so that atomically smooth films can be deposited on atomically smooth Si (100) substrates<sup>[4,11]</sup> (Figs. 1 and 2). In region (3) both the total energy dissipated along the ion trajectory (via phonon excitations and ionizations) and the

**Fig. 1** Properties of carbon films deposited using C ions with different energies onto Si (100) held at room temperature: roughness (AFM), density,  $sp^2$  fraction, and plasmon energy. Left— $5 \text{ eV} \leq E \leq 2 \text{ keV}$ , right— $5 \text{ eV} \leq E \leq 20 \text{ keV}$ . Note: 1) wide energy region for ta-C formation ( $30 \text{ eV} \leq E \leq 600 \text{ eV}$ ) associated with atomically smooth surface (sub-surface growth); 2) for  $E \leq 30 \text{ eV}$  surface roughening occurs associated with  $sp^2$  formation (surface growth); 3) for  $600 \text{ eV} < E \leq 10 \text{ keV}$  radiation damage partially suppresses  $sp^3$  bonding; 4) for  $20 \text{ keV} \leq E$  radiation damage completely suppresses  $sp^3$  bonding and surface roughening occurs.

radiation damage (e.g., displaced atoms and “vacancies”) increase with  $E$ , gradually suppressing the  $sp^3$  fraction of the DLC films.<sup>[3–6]</sup> The films are characterized by a defective layer which is  $sp^2$  rich,<sup>[3–6]</sup> the thickness of which scales with the ion range  $R_p$ . The  $sp^3$ -rich

layer is internally growing below the defective layer, at a depth  $R_p \pm \Delta R_p$  below the surface, in which the C species are incorporated. The size of the excited region around the final sites of the stopped C species, as well as the radiation damage (e.g., density of displaced

**Fig. 2** AFM images of 100-nm C films deposited using C ions with different energies onto Si (100) held at room temperature. Scale:  $1 \mu\text{m} \times 1 \mu\text{m}$ .  $Z = 20 \text{ nm}$  for  $10 \text{ eV}–10 \text{ keV}$ ,  $Z = 200 \text{ nm}$  for  $E = 20 \text{ keV}$ . Note: atomically smooth films for  $E = 50 \text{ eV}–10 \text{ keV}$ , rough films for  $E < 30 \text{ eV}$ ,  $E = 20 \text{ keV}$ .

atoms and vacancies) in this region, increases with energy.<sup>[17,18]</sup> This gradual increase of the damage with  $E$  (in the region where the C is incorporated and densification occurs) leads to a gradual suppression of the  $sp^3$  bonding, but even for  $E = 10$  keV the films still have a significant  $sp^3$  component ( $\sim 40\%$ ).<sup>[4,18]</sup> In region (3) the relaxation processes occur below the surface, the film growth is still internal and the atomically smooth nature of the initial substrate is still retained (Figs. 1 and 2). It is only in region (4) ( $E > 20$  keV) that the damage sufficiently enhances the mobility of the C species (to the surface) to eliminate the densification and completely suppress the  $sp^3$  fraction. Films with  $\sim 100\%$   $sp^2$  and very rough surfaces are formed, indicating the dominant role of surface processes in this  $E$  region.<sup>[4,17,18]</sup> The high mobility also initiates  $sp^2$  clustering to form nanocrystalline graphite, which does not occur at room temperature for  $E < 20$  keV. Fig. 1 shows that all properties of the films ( $sp^3$  fraction, density, surface roughness) vary systematically according to the above discussion, as well as other properties shown in Fig. 3.

The previous discussion assumed that the substrate temperature is low so that the (thermal) mobility of the C species is low as well, and once  $E > E_p$  they are trapped in subsurface positions leading to densification, stress, and the formation of atomically smooth  $sp^3$ -rich films via internal growth. The trapping sites used for DLC deposition are, however, very shallow ( $R_p$  equals  $\sim 5$  and  $\sim 25$  Å for 100 and 1000 eV, respectively<sup>[16,18]</sup>) so that thermal migration to the surface would eliminate the incorporation of C interstitials and the associated stress and densification. It is expected that  $sp^2$ -rich films will be formed via surface processes under such conditions. This was indeed verified by experiments<sup>[4]</sup> showing a sharp transition from  $sp^3$ -rich films to  $sp^2$ -rich films when  $T_s$  exceeds

**Fig. 3** Density, Young's modulus, and optical energy gap of carbon films deposited using C ions with different energies onto Si (100) held at room temperature. *Note:* properties follow the  $sp^2$  fraction (Fig. 1).

a critical temperature  $T_c = 150^\circ\text{C}$  for 120-eV deposition<sup>[4]</sup> (Fig. 4). Atomic force microscopy studies<sup>[4,11]</sup> (Fig. 5) indicate surface roughening of 100-nm-thick C films with increasing  $T_s$  (a transition from subsurface to surface processes), while all other properties (density,  $sp^3$  fraction, Raman, optical properties, elastic modulus) indicate (Fig. 4) an associate formation of nanocrystalline graphitic films.<sup>[4]</sup>  $T_c$  may be dependent on  $E$  and on the rate of bombardment by energetic species. This is because the amount of densification is determined by the equilibrium between the incoming flux of subplanted atoms (bombardment rate) and the outgoing flux of atoms thermally migrating to the surface (from a distance which increases with increasing  $E$ ) to reduce the density gradient formed by subplantation. Films with a significant  $sp^3$  fraction ( $>70\%$ ) have been deposited

**Fig. 4** Density [by Rutherford backscattering (RBS) or ultrasonic surface waves], Young's modulus (ultrasonic surface waves), and roughness (AFM) of 100-nm C films deposited using 120-eV C ions onto Si (100) held at different temperatures.

**Fig. 5** AFM images of 100-nm C films deposited using 120-eV C ions onto Si (100) held at different temperatures. Scale:  $1\ \mu\text{m} \times 1\ \mu\text{m}$ .  $Z = 20\ \text{nm}$ . Note: atomically smooth films for  $T < 150^\circ\text{C}$ , rough films for  $T > 150^\circ\text{C}$ .

using very low energy deposition ( $\sim 10\text{--}20\ \text{eV}$ ) on different substrates held at 77 K, showing a significant increase in the  $\text{sp}^3$  fraction compared to 300-K deposition.<sup>[4,19]</sup> This implies the possible existence of very shallow  $\text{sp}^3$  configurations that are frozen at very low  $T_s$  and are stabilized by coverage of the bombarding C species.

## STRUCTURING OF ORDERED $\text{SP}^2$ FORMS

The previous section details how the  $\text{sp}^3$  fraction of carbon films deposited at room temperature can be tuned between 0% and 85% (the  $\text{sp}^2$  fraction between 100% and 15%). Such films are essentially amorphous and the  $\text{sp}^2$ -bonded carbon can form clusters of different sizes. In ta-C films most of the carbons are  $\text{sp}^3$  bonded so that the few  $\text{sp}^2$ -bonded carbons form pairs and their chances of forming larger  $\text{sp}^2$  clusters are slim.<sup>[3,4]</sup> As the  $\text{sp}^3$  fraction decreases and the  $\text{sp}^2$  fraction increases larger clusters of  $\text{sp}^2$ -bonded carbons may form as chains or as rings. Carbon films with the same  $\text{sp}^3$  fraction may possess different distributions of  $\text{sp}^2$  clusters. Annealing of the DLC films increases the average size of the clusters of  $\text{sp}^2$ -bonded carbons

without necessarily affecting the  $\text{sp}^3$  fraction.<sup>[20,21]</sup> This annealing process in which the size of the  $\text{sp}^2$  clusters increases relieves the stress incorporated in the DLCs during their formation at room temperature.<sup>[12]</sup> Transformation of  $\text{sp}^3$  to  $\text{sp}^2$ -bonded carbon upon annealing is occurring only when the  $\text{sp}^2$  cluster size is large enough to enable graphitization, i.e., the formation of nanometer-sized crystallites of graphite.<sup>[21]</sup> The volume available for  $\text{sp}^2$  clustering increases with decreasing  $\text{sp}^3$  fraction, which is why the graphitization temperature of DLC films decreases with increasing  $\text{sp}^2$  fraction.<sup>[21]</sup> The thermal stability of ta-C films is very high and they can be annealed to  $1000^\circ\text{C}$  without graphitization or a change in their  $\text{sp}^3$  fraction.<sup>[21]</sup> The only effect would be an increase in the size of the  $\text{sp}^2$  clusters embedded in the predominantly  $\text{sp}^3$  skeleton.<sup>[21]</sup> The study of the structural changes occurring in annealed carbon films indicates that different clustering and layering phenomena occur, but it should be noted that this study is just in its initial stage.

Clustering of  $\text{sp}^2$  forms occur not only upon postdeposition annealing of DLC films, but also upon deposition at elevated temperatures, exceeding a critical temperature  $T_c$  as described in a previous section. It was previously explained that in such a deposition

the thermal migration to the surface eliminates the subplantation-induced densification leading to 100%  $sp^2$  films. Structural analysis of the films deposited under carbon ion bombardment at elevated temperatures reveals the formation of graphitic planes that are perpendicular to the substrate.<sup>[22]</sup> These graphitic planes may expand in different directions (i.e., the normal to the graphitic plane may have different directions in a plane parallel to the substrate). Some graphitic planes close to form carbon multiwall tubes, embedded in the graphitic matrix<sup>[23]</sup> (Fig. 6). This is a random process so that some innermost tubes possess the smallest diameter of carbon nanotubes possible, which is 4 Å.<sup>[23]</sup> The relative fraction of multiwall tubes embedded in the graphitic matrix may be controlled by the proper selection of the carbon ion energy and the deposition temperature.

Two possible mechanisms were suggested for the formation of the oriented graphitic planes in carbon ion deposition at elevated temperatures. The first one is a stress-induced mechanism according to which the ion bombardment introduces compressive stress forcing the films to align themselves in the most compressible way, i.e., with graphitic planes perpendicular to the stress vector.<sup>[17,22–24]</sup> Indeed, the graphitic planes in films deposited at 200°C and 120 eV are compressed by 5% with respect to the basal planes of hexagonal graphite.<sup>[22]</sup> The alternative mechanism explaining the oriented formation of graphitic planes perpendicular to the surface involves preferential displacements.<sup>[15–17]</sup> The energy required to displace graphitic atoms in the basal planes (C–C bond energy 7.4 eV) is larger than that required to displace C perpendicular to the basal plane (C–C bond energy 0.86 eV). Under ion bombardment the carbons of those graphitic planes formed in a direction parallel to the surface

(perpendicular to the ion beam) will be easily displaced and these planes will be damaged and their growth suppressed. The graphitic planes aligned perpendicular to the surface (parallel to the beam) will be damaged to a much lesser extent, explaining the preferred orientation. It should be noted that the temperatures involved in the formation of these structured graphitic films are moderate ( $\sim 200$ – $300^\circ\text{C}$ ), and much lower than those necessary for the graphitization of DLC films by postdeposition annealing (ta-C is stable up to  $1000^\circ\text{C}$ ,<sup>[21]</sup> see previous discussion). The effects of deposition at elevated temperatures should be thus distinguished from those due to postdeposition annealing.

Another channel of the formation and clustering of  $sp^2$ -bonded carbon is through energetic ion impact, even at room temperature.<sup>[7,17,18,24]</sup> Carbon ion deposition using very high energies ( $\sim 20$  keV and up) induces complete suppression of the  $sp^3$  fraction and initiates graphitization, i.e., the formation of nanosized graphitic domains. For annealing of DLC films clustering occurs via thermal migration of  $sp^2$ -bonded carbon. Energetic ions bombarding a target are stopped through atomic displacements, ionization, and phonon excitations along their track. Apart from direct removal of atoms from their original positions, ion bombardment induces enhanced diffusion because of the excess energy dissipated along the ion track coupled with the formation of radiation defects. These bombardment effects cause graphitization at low temperatures in which carbon does not regularly graphitize but remains amorphous. For small doses the modified material is arranged in isolated tracks with a width of several nanometers and a length that scales with the ion range, while the surrounding matrix is much less affected. For higher doses all tracks coalesce and the material becomes more homogenous. The graphitic

Cluster indicated by square and its electronic density of states shows the wide energy gap of diamond.

carbon formed by ion impact is oriented with the basal plane along the ion beam. The graphitic layers formed by tens of kilo-electron-volt impact are characterized by spacings larger than for hexagonal graphite,<sup>[24]</sup> so that no compressive stress is associated with their formation. This is in contrast with the oriented graphitic layers formed at energies lower than 1 keV, which are compressed.<sup>[22]</sup> It means that the stress-induced graphitic orientation can be excluded and the graphitic orientation induced by ion beam impact is due to preferential displacement.

### STRUCTURING CRYSTALLINE CARBON FORMS

The last issue considered in this entry is the formation of  $sp^3$ -bonded crystallites by ion impact. It is very well known<sup>[10,25,26]</sup> that it is graphite, the  $sp^2$ -bonded carbon crystalline form, that is stable at ambient temperature and pressure conditions. The  $sp^3$  forms (cubic diamond and hexagonal diamond) are more stable than graphite only at high-temperature, high-pressure conditions occurring on Earth at depths of hundreds of kilometers. Indeed, diamond was first made artificially in GE applying the necessary high-pressure, high-temperature conditions. Later, it was found that diamond can be grown at subatmospheric pressure and medium temperatures by chemical vapor deposition (CVD), applying an excited plasma of ~1%  $CH_4$  and 99%  $H_2$  onto diamond held at ~700–800°C. The only way to nucleate diamond on non-diamond substrates, found by trial-and-error methods, is to apply bias to the above plasma and nucleate diamond through bombardment with energetic species [a process denoted “bias enhanced nucleation” (BEN)].<sup>[25,26]</sup>

The diamond nucleation mechanism, which is an extension of the subplantation process to form metastable crystalline phases, was very recently elucidated.<sup>[25]</sup> The first step of BEN is the formation

of a dense amorphous carbon hydrogenated matrix in a regular subplantation process. This matrix has a density of ~3 g/cm<sup>3</sup> and a hydrogen content of ~20%. The second step of the diamond nucleation is the precipitation of 100%  $sp^3$  C clusters (Fig. 7), most of which are amorphous, but a very small fraction (~10<sup>-5</sup>–10<sup>-6</sup>) are perfect diamond clusters of tens of atoms. These clusters are stabilized by hydrogen

**Fig. 8** Annealing of the faulty cluster to form a perfect diamond: (A) original cluster with its reactive sites into which two carbon interstitials are added (B) and form bonds [(C) and (D)] Decoration by hydrogen (E) relaxes the cluster to perfect diamond as shown in (F) and in a projection (G) rotated by 90° with respect to the cluster in (F).

**Fig. 9** Cross-sectional TEM image of diamond crystallites embedded in an amorphous carbon matrix.

termination and by appropriate nucleation sites. The diamond crystallites are continuously bombarded by energetic ions, which preferentially displace amorphous carbon atoms leaving the more rigid diamond atoms intact. The displaced amorphous carbons at the a-C/diamond interface can occupy diamond positions leading to the growth of the diamond crystallite consuming C atoms from the a-C surrounding matrix. Faults in the diamond crystallites can be annealed by carbon interstitials and hydrogen decoration (Fig. 8). Finally, several nanometer-sized diamond crystallites containing tens of thousands of carbon atoms form (as observed in HRTEM (Fig. 9)). The BEN-treated material can now be exposed to a regular CVD environment in which the diamond crystallites grow to micron sizes and up, and the a-C component is etched away by the atomic hydrogen component of the CVD plasma.

It is interesting to note that ion beam impact induces epitaxial growth of diamond, say, on a step on Si<sup>[26]</sup> (Fig. 10). The Si step serves as a mold to the evolving diamond crystallite (the ratio between the lattice parameters of diamond and silicon is 2:3 and their structure is identical). The two Si surfaces on which the diamond nucleates restrict it to grow in perfect epitaxial relations, i.e., diamond (111)/Si (111). It should also be noted<sup>[27]</sup> that not only cubic diamond [with a stacking 3C of its (111) planes, i.e., ABCABCABC] can be grown by ion beam impact, but also other

**Fig. 10** A HRTEM image of a diamond crystallite (~2 nm) grown directly on a Si step with an epitaxial alignment.

diamond polytypes with a different stacking sequence: hexagonal diamond (2H, stacking sequence ABABAB) and 9R diamond (stacking sequence ABCBCACAB).

## CONCLUSION

Ion beam structuring was shown to be able to grow carbon in a variety of carbon forms: amorphous, ordered sp<sup>2</sup> (including carbon multiwall tubes), and ordered sp<sup>3</sup> (crystalline diamond). The basic mechanisms involved in ion beam structuring were underlined. The capability to tune amorphous carbon to have a specific sp<sup>3</sup> fraction ranging from 0% to 85% by varying the ion energy and the substrate temperature was shown. Formation of different ordered sp<sup>2</sup> structures through ion beam deposition at elevated temperatures and energetic ion beam impact was described and the mechanisms involved (stress induced and preferential displacement) explained. Finally, the nucleation of metastable phases by ion impact was highlighted. The methodology described is not unique for carbon and can be applied to a variety of other materials.

## INTRODUCTION

A great deal of attention has been given to carbon nanotube (CNT)-based electronics. The unique electronic properties of CNTs<sup>[1]</sup> pave the way to future applications in electronics, with a further reduction of weight, size, and power consumption, and a faster switching time. Carbon nanotubes present a paradigm for potential building blocks in nanoscale electronics. This is not only simply because of their small dimensions, but also because of their many superior electronic properties compared with silicon. For example, electrons propagating in a nanotube experience much less scattering;<sup>[2,3]</sup> hence there is a reduction of power consumption and heat dissipation. An individual CNT can sustain a remarkably high current density of more than  $10^9$  A/cm<sup>2</sup>.<sup>[4]</sup> The trans-conductance of a CNT field-effect transistor (CNTFET), which represents how fast the on/off states can be switched, is about one order of magnitude higher than that of a silicon metal-oxide semiconductor FET (MOSFET).<sup>[5]</sup> These unique electrical properties of CNTs stem from the seamlessly curved conjugated structure and drive many researchers to quest for practical nanodevices. In the following sections, we review a broad range of studies on CNTs in transistor devices. The fundamental electronic structure of CNTs as well as different carbon nanotransistors will be discussed in detail.

## BACKGROUND

In 1956, the Nobel Prize was awarded to Shockley, Bardeen, and Brattain for their discovery of the transistor effect in 1947.<sup>[6]</sup> The transistor is one of the most important inventions of the past century and is often cited as an example of how scientific research can lead to useful commercial products. The integration of transistors in modern semiconductor electronics led to another revolution in human history, and the Nobel Prize was awarded for this great contribution in 2000. Half a century after the invention of the first

transistor, the dimensions of the modern transistor have shrunk by a factor of  $10^6$ , jumping from the millimeter scale to the nanometer scale. The number of transistors integrated in a current semiconductor microprocessor readily exceeds 45 million.<sup>[7]</sup> This staggering downsizing rate is based on the continuous improvement of the semiconductor manufacture processing, including precise lithography and reliable lift-off techniques.

The basic function of a transistor is as an electrical switch through which one can define the “0” (off) and “1” (on) states in a logic operation. It was predicted by Gordon Moore<sup>[8]</sup> that for silicon-based integrated circuits, the number of transistors per square centimeter doubles every 12 months. The productivity and improvement of silicon-based electronics have generally followed Moore’s law for the past 40 years. This trend of rapid increase of device density in an integrated circuit will, however, soon reach its “ceiling” owing to the inherent limitations of materials and present technologies. In this respect, many novel nanosystems have been explored intensively over the last few years as potential building blocks for the next generation of electronics. Among them, the CNT serves as a kind of parade horse. It has been demonstrated that semiconducting CNTs, which are only few nanometers in diameter, also exhibit transistor-like behavior. Fifty years after Shockley came up with the first idea of an electrical switch in the Bell labs, the transistor size has been approaching the atomic scale.

## FUNDAMENTAL LIMITATION OF MINIATURIZATION

### Heat Dissipation

Scaling down the dimensions of transistor devices, as well as the integrated circuits into which they are incorporated, causes an abundance of problems. The most intuitive problem is how to reduce the heat generated by charge carriers traveling inside the smaller and more

complicated circuits. The amount of heat given off by many chips can far exceed that of most cooking surfaces, and the situation is progressively worsening owing to the continuous decrease of the device feature size. In addition to seeking more effective coolants to prevent the chips from melting, researchers search for alternative materials such as CNTs and various nanowires, as candidates to be adopted in modern semiconductor processing technology.

### High-Field Effect

Disregarding the aforementioned heat dissipation, the background thermal voltage in an integrated circuit is approximately 25 mV at room-temperature operation. To discernibly recognize a desired signal in a circuit, the operating voltage needs to be several times higher than the thermal noise. In other words, this thermal voltage sets a fundamental constraint upon the lowest operating voltage of a transistor. As the dimensions of a transistor become smaller, the same operating voltage between the drain and source is now applied over a shorter distance. It leads to an increase of electric field between the two contacts. As a consequence, the charge carriers move faster and gain more energy. Once these charge carriers reach a critical energy within the transistor channel, they will cause impact ionization and subsequently launch an avalanche,<sup>[9]</sup> an uncontrollable surge of current that disables the switching function. Therefore, the avalanche breakdown sets a maximum electric field that can be applied in a transistor and is one of the limiting factors to device scaling.

### Gate-Oxide Tunneling

All the transistors integrated in a circuit are separated from each other by an insulator so as not to couple the operation of one transistor to the others. From the perspective of classical physics, if the total energy of an electron in a transistor is less than the height of the potential barrier, the electron is unable to penetrate through the barrier to reach the neighboring transistors. In accordance with quantum mechanics, however, as long as the barrier is thin enough, there is a certain probability for an electron to pass through the barrier even if its energy is less than the barrier height. This process is called “tunneling,” and its probability increases exponentially with the decreasing width of the energy barrier, and thus imposes a limit on the packing density of transistors in a circuit. For a MOSFET with channel length of 100 nm or less, an oxide thickness of greater than 3 nm is needed to prevent tunneling.<sup>[10]</sup> This thickness comprises only a few

layers of atoms and gives rise to a nonnegligible off-state leakage current owing to direct tunneling.

### SHORT-CHANNEL EFFECT

Another severe challenge for future MOSFET device designs is maintaining a required off-state leakage specification while maximizing the device drive current. For conventional MOSFETs, the dominant leakage mechanism is owing to the short-channel effect by which the drain potential lowers the source–junction barrier for charge carrier tunneling.<sup>[9]</sup> The origin of the short-channel effect can be understood by considering the potential barrier at the surface between the drain and the source. In the long-channel case, the potential barrier is flat, except at the very end of the channel that is in contact with the drain and the source. In the “off” state, the potential barrier (p-type region), which is only governed by the gate voltage, prevents electrons from flowing into the drain. As the channel length is shortened, the source–drain field penetrates deeply into the middle of the channel and lowers the potential barrier, so that the electrons can directly tunnel through the channel. This results in a substantial increase of the subthreshold current.

## CNTS AS ELECTRONIC DEVICES

### Electronic Structure of CNTs

An individual single-walled CNT can be thought of as a seamless cylindrical form of a graphene sheet rolled up in a specific orientation. To understand the electronic properties of nanotubes, we begin with the band structure of the graphene, which frames the one-dimensional (1-D) energy dispersion of nanotubes.<sup>[11]</sup> Carbon atoms in a graphene have four valence electrons, three of which form  $sp^2$  bonds with neighboring atoms in  $\sigma$  orbitals. They lie far below the Fermi level and do not contribute to the electrical conduction. The fourth electron occupies a  $\pi$  orbital resulting from a  $2p_z$  bond, through which the transport takes place. In a tight binding approximation,<sup>[12–14]</sup> the energy dispersion for the  $\pi$  electrons in a graphene is shown in Fig. 1. Imposing the boundary condition along the circumferential direction of a rolled-up graphene, we can readily deduce the band structure of nanotubes by slicing the energy dispersion of a graphene sheet. The electron energy is thus quantized in the circumferential direction and the electrons are only free to move in the axial direction. The energy quantization gives rise to discrete numbers of parallel equidistant lines, representing the allowed  $k$  modes in the reciprocal space of the graphene. Each line corresponds to a 1-D

**Fig. 1** Band structure of a 2-D graphene sheet. The bottom hexagon defines the first Brillouin zone and the solid lines present the allowed states in a nanotube, which are obtained by imposing the boundary condition along the circumference of the tube. *Source:* From Ref.<sup>[14]</sup>.

channel for conduction along the nanotube. The distance between adjacent lines,  $2/d_t$ , is inversely proportional to the nanotube diameter  $d_t$ , and the orientation of the lines are given by the chiral angle  $\theta$ . The projection of Fig. 1 shows the energy contours for the bonding band in the first Brillouin zone, which is outlined by the hexagon. The parallel lines through the first Brillouin zone are examples of allowed  $k$  modes in an armchair nanotube. The Fermi energy at the vertices of the Brillouin zone is sitting exactly on the allowed  $k$  modes, giving the metallic nature. In case no cuts pass through the vortices of the Brillouin zone, the tubes are semiconductors. In other words, an  $(n, m)$  tube is metallic when  $n = m$ , or when  $n - m$  is a

multiple of 3, while CNTs with  $n - m$  not a multiple of 3 are semiconducting. This energy gap of semiconducting tubes is inversely proportional to the nanotube diameter and typically ranges from 0.2 eV to 0.6 eV. The spatial resolved atomic structure of CNTs and the corresponding electronic density of states have been confirmed by means of scanning tunneling microscope.<sup>[15–17]</sup>

## FETs

In 1997, the research group in Delft first showed that the tiny nanotubes also exhibited transistor-like behavior.<sup>[18]</sup> The current flowing through the nanotube can be turned on or off by applying a gate voltage, bearing an analogy to the conventional MOSFETs.<sup>[19–21]</sup> The prototype of a CNTFET is shown in Fig. 2A. It is a three-terminal device with the terminals designated as “gate,” “source,” and “drain.” The nanotube spanning the source and the drain contacts is the active “channel” [section B in the cross-sectional view of Fig. 2A] and is critical for current conduction. The substrate, which is usually made of heavily doped polysilicon, acts as a global back gate, with a thin layer of thermally oxidized silicon on top. The gate is used for varying the electrostatic potential of the channel and controls the charge carriers flowing through the channel. Figure 2B depicts the  $I$ - $V_{ds}$  characteristics obtained from a semiconducting nanotube at different gate voltages. Applying a negative gate voltage causes an increase of current, whereas a positive gate voltage suppresses current and forms a current gap at large positive gate values. The semiconducting nanotube behaves as a hole conductor. In the inset of Fig. 2B,

**Fig. 2** (A) Device layout of the prototype of a CNTFET. The tube is lying on a Si/SiO<sub>2</sub> substrate with predefined Pt electrodes. (B) The output characteristics of the transistor at room temperature. The inset shows the gate-dependent conductance changes. *Source:* From Ref.<sup>[18]</sup>.

the zero-bias conductance is plotted against gate voltage. The change of gate voltage, spanning over 10 V, produces a conductance modulation by six orders of magnitude, as pronounced as that produced in a Si-based MOSFET.

In the subsequent studies,<sup>[22–24]</sup> the p-type conducting mechanism of semiconducting nanotubes was attributed to the oxygen adsorption on the tube wall. The oxygen molecules on the wall function as electron acceptors and turn the nanotube that should be intrinsic in nature into p-type. More recently, this argument has been further polished by the IBM group, as will be discussed below. Irrespective of the detailed influence of oxygen molecules on the conduction of semiconducting nanotubes, one can achieve different types of conduction by varying the coverage of oxygen molecules on the tube wall or by applying an appropriate passivation on the tube. On-tube junctions or even logic gates can be hence designed and demonstrated.<sup>[25]</sup>

### Switching Mechanism of CNT Transistors

Although both the output and the transfer characteristics of semiconducting nanotubes much resemble the p-channel MOSFETs, the dominating switching mechanism in nanotubes is, however, distinct. A conventional MOSFET can be thought of as two back-to-back p–n junction diodes with fairly low leakage current present. For a p-channel MOSFET, the channel region is made of n-type silicon. When a sufficiently large negative voltage is applied to the gate, the silicon surface is inverted to p-type. It forms a 2D hole gas at the interface between the gate dielectric and silicon as well as ohmic contacts between the conducting channel and the p + source/drain. The switching in a MOSFET is consequently determined solely by the channel conduction, which is a function of carrier concentration and modulated by the gate voltage. For CNTs, it was shown that Schottky barriers are formed at the contact with electrodes.<sup>[20,26]</sup> With an

**Fig. 3** Band bending at a fixed source–drain voltage. (A) For a gate voltage below threshold voltage, the transistor stays in the “off” state. (B) For a gate voltage above threshold voltage, the transistor is turned on by holes tunneling through the Schottky barriers. *Source:* From Ref.<sup>[26]</sup>.

applied negative gate voltage, holes accumulate in the valance band. Even though there is substantial carrier density in the channel, current will still be blocked by the Schottky barriers. Increasing the voltage difference between the gate and the source electrodes results in the reduction of Schottky barrier width and allow holes to conduct via thermally assisted tunneling. The band structure is suggested in Fig. 3. The current flow in such a device is not limited by the channel as it is in conventional MOSFETs, but instead by the geometry of the contact at which the Schottky barrier forms. In addition to this difference, CNTFETs are sensitive to the gas molecules adsorbed onto the walls of the nanotubes. By annealing a nanotube in vacuum, one can remove the adsorbed oxygen molecules and transform the tube from p-type to n-type. At an intermediate stage of gas desorption, it is turned into an ambipolar transistor where the electrons conduct at a positive gate voltage and holes conduct at a negative gate voltage. The band structures near the metal contact at different oxygen contents are schematically illustrated in Fig. 4. These distinct working mechanisms have important implications for a potential CNTFET-based technology in that CNTFETs obey different scaling rules and are capable of novel designs and functionalities.

**Fig. 4** Schematic drawing of band structures near the contact for p-type (A), ambipolar; (B), and n-type; (C) CNTFETs. The change from (A) to (C) corresponds to the high-to-low oxygen adsorption on the tube. *Source:* From Ref.<sup>[10]</sup>.

## Ballistic Nanotube Transistors

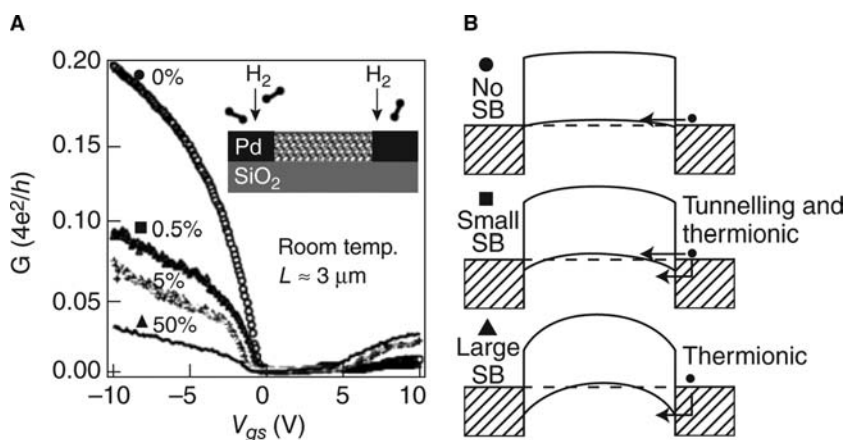

Searching for an ohmic electrical contact for CNTs is one of the goals in realizing high-performance CNTFETs. As aforementioned, the device properties of early prototypes were mainly dominated by the contacts. Some inherent properties like ballistic transport as well as the ability to carry high current density are suppressed owing to the presence of Schottky barriers. Some high work-function metals such as platinum ( $\phi = 5.7$  eV) and Au ( $\phi = 5.2$  eV) were initially anticipated to show ohmic contact to semiconducting tubes. Experimental results, however, indicate that these metals cause high-energy barriers at the contacts. This could be owing to poor sticking or wetting interaction between the metal and the nanotube. Recently, it has been shown that palladium with  $\phi = 5.1$  eV can effectively enhance the nanocontacts and give rise to electrical conductance of semiconducting tubes approaching quantum limit,  $4e^2/h$ , in the charge accumulation regime.<sup>[27]</sup> This fundamental limit in conductance is owing to the mismatch of conducting channels in a nanotube ( $N = 2$ ) and a metal lead. Interestingly, a Schottky barrier-free semiconducting nanotube also behaves like a metallic tube in which the temperature-dependent conductance first increases as temperature is lowered and then turns down below  $\sim 200$  K. This is in contrast to the monotonic decrease of conductance as a function of temperature, which occurs for semiconducting nanotubes with Schottky barriers at the contacts. These properties unambiguously demonstrate that the Schottky barriers are eliminated or minimized by contacting the nanotubes with palladium.

Fig. 5 shows the transfer characteristics of a 3- $\mu\text{m}$ -long semiconducting nanotube at different contact conditions. For a pure palladium contact, the conductance approaches  $0.2(4e^2/h)$  at large negative gate voltages. Exposing the device to hydrogen results in the formation of palladium hydride, which reduces the work function of the electrode. At small

concentrations of hydrogen, small Schottky barriers build up at the contacts, as schematically shown in the middle panel of Fig. 5B, and the conductance drops by a factor of two. Increasing the content of hydrogen up to 50% in the electrodes further enlarges the barriers and hence continues to lower the conductance. It should be noted that scattering in semiconducting nanotubes is more effective than in metallic tubes because the initial and final states are not orthogonal in semiconducting tubes. To reduce the scattering events in semiconducting tubes, one can simply shorten the channel length. It was found that for a 0.3- $\mu\text{m}$ -long semiconducting tube the conductance can be as high as  $0.4(4e^2/h)$ . It is clear that the transistor is now operating in the channel-limiting regime, instead of being blocked by Schottky barriers. In the channel-limiting mode, the transistor is turned on as long as charge carriers populate the two sub-bands responsible for charge propagation, whereas, in the Schottky barrier mode, the transistor is turned on only when the applied gate voltage has lowered the width of barriers sufficiently so that the populated charge carriers can tunnel through the barrier. In the former case, the tube is capable of carrying a higher current density and dissipates much less heat.

## Nanotube Single-Electron Transistors

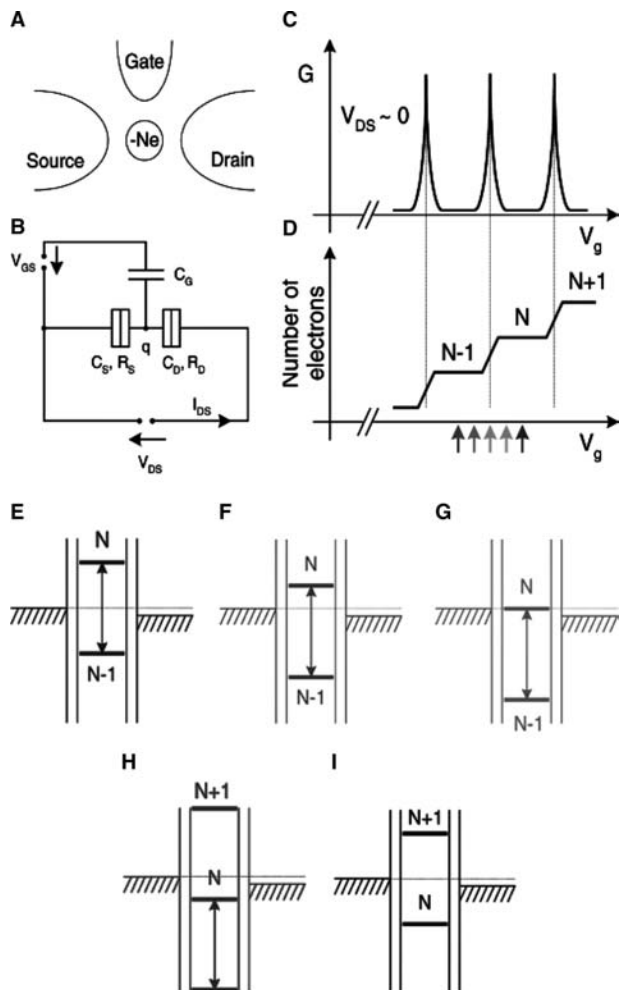

So far we have only addressed the issue of using semiconducting nanotubes as a switching element. In fact, metallic nanotubes also exhibit interesting transistor-like behavior. If we replace the semiconducting tubes with metallic tubes in the same FET configuration, we are able to see the transistor behavior resulting from the single-electron charging phenomena. There are two fundamental prerequisites to observe single-electron tunneling behavior. The first condition is based on the Heisenberg uncertainty relation: The quantum fluctuation in the particle numbers must be

**Fig. 5** (A) Transfer characteristics of a ballistic CNTFET with channel length of 3  $\mu\text{m}$ . The inset is the schematic representation of the device layout. (B) Band diagrams illustrating the underlying principle of p-channel ballistic FETs at different concentrations of hydrogen. Increasing the content of hydrogen in the palladium contacts causes the formation of Schottky barriers at the contacts and lowers the conductance accordingly. *Source:* From Ref.<sup>[27]</sup>.

sufficiently small so that the charge is well localized in the nanotube. This requires the minimum tunneling resistance to be  $R_{s,d} \gg h/e^2 = 25.8 \text{ k}\Omega$ . Another condition is that the energy required to add one electron to the nanotube,  $e^2/C$ , must exceed the thermal energy.

To construct such a single-electron transistor, the nanotube which acts as a quantum island is contacted by a drain and a source electrode, and then coupled to a gate electrode capacitively, as shown in Fig. 6A and B.

**Fig. 6** (A) The three-terminal geometry of a single-electron transistor. (B) Equivalent circuit for a single-electron transistor. The tunnel junction is represented by a parallel combination of the tunneling resistance  $R_{s,d}$  and the capacitance  $C_{s,d}$ . (C) Conductance vs. gate voltage in the linear response regime of a single-electron transistor. The conductance of the device oscillates as a function of gate voltage with a period that corresponds to the addition of a single electron to the island. (D) The number of electrons on the island. The number stays constant in the Coulomb blockade regime and jumps one charge quantum in single-electron tunneling regime. (E)–(i) Band diagrams of the single-electron transistor under different gate voltages indicated in (D).

**Fig. 7** (A) An Atomic force microscope (AFM) image of a metallic nanotube lying on top of two electrodes. In the marked region, two kinks were made by AFM manipulations. The highly doped Si substrate is used as a gate electrode to modulate the electrostatic potential of the island sandwiched by the two kinks for single-electron tunneling at room temperature. (B) Enlargement of the double-junction structure. *Source:* From Ref.<sup>[28]</sup>.

The mesoscopic size of nanotubes significantly reduces the total capacitance of a nanotube required to transport one electron into or out of the island. In combination with high contact resistance, one can readily observe the single-electron effect at a cryogenic temperature.

Recently, room-temperature single-electron transistors were realized within an individual metallic nanotube.<sup>[28]</sup> The devices were constructed “on a tube” within which two tunnel barriers were created by the AFM manipulation technique. A short nanotube section (between 20 and 50 nm) is defined by the two kinks and acts as a “quantum island” in a single-electron transistor configuration. The AFM images of the structure are shown in Fig. 7.

The device is assembled on a highly doped Si substrate that allows one to change the electrostatic potential of the island and to control the transistor in the single-electron tunneling state (on) or in the Coulomb-blockade state (off). A charging energy of about 120 meV has been recorded for such a device, capable of performing single-electron switching at room temperature.

### All-Carbon Transistors

The first generation of the CNTFETs consisted of nanotubes placed over metal leads on a silicon chip.<sup>[18]</sup> The leads served as source and drain and the doped silicon substrate acted as a gate. The on/off ratio of these transistors was about  $\sim 10^5$ – $10^6$ , but the gain

**Fig. 8** Sequence of chemical functionalization in CNTs. First, the chloride acid groups are attached to the ends or sidewalls of the nanotubes. Then diamino groups are incorporated into the nanotubes by replacing the chloride acid. The diamino groups can link two nanotubes to form T junctions.

(defined as the change in output voltage divided by the change in gate voltage) was very low ( $\ll 1$ ), owing to the fairly thick oxide layer needed to prevent leakage currents. This would lead to a problem with implementation when they are integrated into a circuit, because the output of one gate cannot drive the next properly. To solve this problem, Bachtold et al. presented a novel electrode configuration where the gate is an aluminum strip and the native aluminum oxide allows the gate electrode to be so close to the nanotube that the transistor reaches a gain of about 10.<sup>[29]</sup> Later, the IBM group reported on a complementary CNTFET as a logic gate with a gain of 1.6<sup>[25]</sup> and Dai and coworkers have presented an array of some 100 nanotube transistors assembled on a silicon chip.<sup>[30]</sup> The nanotube transistors reported so far are not really “nanoscale” devices. The conducting channel consists of a single nanotube and this is, of course, nanoscale. The source and drain, however, are made by electron beam lithography, and are about 100 nm wide and several micrometers long. In the first generation nanotube transistors, the gate is even macroscopic. The aluminum gate of the second generation transistors is lithographic like the source and drain and still not nanoscale. To take the dimensional advantage of CNTs and to shrink the active channel to few nanometers in all three dimensions, one possibility is to use a nanotube that is located close to the nanotube channel as a local gate, resembling the local gating by an AFM tip. This nanotube gate can be attached to the nanotube channel by chemical functionalization. Taking an insulating chemical linker, one can assemble T-shape interjunctions and construct the device in such a way that the active part of the device is truly confined to the vicinity of the nanotube gate. This device is all-carbon, except for few nitrogen and oxygen atoms in the molecular linkers! To assemble nanotube T junctions, we start with chemical functionalization (Fig. 8). It is well known that graphite is chemically inert. When a graphite layer is rolled up to form a cylindrical structure, its chemical reactivity is modified. This stems from the curvature-induced pyramidalization and misalignment of the  $\pi$ -orbitals of the carbon atoms, giving rise to a local strain in CNTs.<sup>[31–33]</sup> The relief of these

strains accompanies addition reactions in the caps and sidewall of nanotubes. By treating nanotubes with aggressive reagents like nitric acid, phenolic and carboxylic acid groups can be readily derivatized on the end caps or sidewall of nanotubes.<sup>[34–37]</sup> The

**Fig. 9** (A) AFM images of CNT interjunctions. The junctions are indicated by arrows. A more complicated junction structure is shown in (B). Both end-to-side and end-to-end attachments are observable on a tube. In (C) an individual Y junction is clearly discernible. *Source:* From Ref.<sup>[41]</sup>.

carboxylic acid groups can be converted into acylchloride groups by treating with thionylchloride.<sup>[36,38]</sup> The acid chloride-functionalized CNTs are then susceptible to react with amines. The resulting chemically functionalized nanotubes are shown to be able to form a closed ring shape,<sup>[39]</sup> or be attached to a normal Si AFM tip used for a single-molecular sensor or probe.<sup>[40]</sup>

After chemical functionalization, most of the nanotubes form a network and connect side by side.<sup>[41]</sup> To untangle the network, appropriate ultrasonic agitation is applied to the nanotube suspension. Figure 9 shows AFM images of CNTs after functionalization with tripropylentetramin. In most cases, the nanotubes form end-to-side junctions. End-to-end junctions are rarely found. Under an appropriate functionalization process, around one-third of the nanotubes form end-to-side junctions, whereas less than 2% of the pristine nanotubes show similar junctions. The junctions observed in the pristine nanotube samples were mainly the result of the splitting of bundles. The attachment of different chemical groups was identified by x-ray photoelectron spectroscopy, and the induced changes in electronic structure by the functional groups were also studied by Raman and theoretical modeling.<sup>[42]</sup>

**Fig. 10** (A) A schematic representation of an all-carbon transistor where the channel and the gate are both constituted by nanotubes and the gate dielectric is played by an insulating molecule. (B) A 3-D AFM image of the transistor with gold electrodes applied on top. *Source:* From Ref.<sup>[43]</sup>.

Fig. 10A illustrates the device layout of an all-carbon transistor, and B shows a 3-D AFM image of such a device, which consists of two individual nanotubes glued by a bifunctional amine linker. The bar of the “T” is the tube between the leads E1 and E2, and acts as a conducting channel, and the stem connected to E4 is the “nanotube gate.” The resolution of the AFM is not sufficient to exhibit the diamino linker molecule at the junction. The leads E1, E2, and E4 connect to source, drain, and nanotube gate, respectively. As a further diagnostic tool, we can use the (degenerately doped) silicon substrate as a global “back gate” to characterize the electric properties of the various sections of the tubes.

As is well known, there are semiconducting and metallic CNTs, and it is not yet possible to synthesize only one type or to separate the types after synthesis. In an ideal case for an all-carbon FET, the channel and the gate will be composed of an individual semiconducting and metallic tube, respectively. In between the two nanotubes, the long molecular chain and the perpendicular linkage keep the nanotubes in proximity without allowing contact. Figure 11 shows the output characteristics of such a device (channel current vs. voltage across channel for several voltages at the nanotube gate). At a bias of 35 mV between source and drain we can pass a current of 1 nA through the channel tube (An upper limit for a possible leakage current through the linker molecule has experimentally been found to be by two orders of magnitude smaller). If we apply a nanotube gate voltage of 0.3 mV, we can effectively suppress this current. Thus, we see that a

**Fig. 11** Current vs. voltage characteristics of an all-carbon transistor with the semiconducting nanotube as channel, with different voltages at the nanotube in-plane gate. The back gate is kept at 0 V throughout the measurements, and the data were recorded at 4 K.

**Fig. 12** Conductance vs. electric field at the nanotube gate. The channel is composed of a metallic nanotube. Two curves are shown: one ascending sweep and another descending. The latter case is offset by 1 nS for clarity. The sufficiently high electric field applied through the nanotube gate can reversibly switch on or off the metallic nanotube. (From Ref.<sup>[43]</sup>.)

gain of about 100 can be obtained easily in all-carbon transistors.

Because the T junctions are formed nonselectively in the process of chemical reactions, in many cases the bar tubes are metallic. An interesting question that is raised is whether the metallic tubes can also act as “field-effect” channels. Intuitively, this would not work, for a metallic nanotube has a considerably higher electron density than a semiconducting one and, therefore, cannot be modulated by a gate before it runs into dielectric breakdown. To address this question, we constructed the device in a similar way, except that the linker molecule between the bar and the stem was intentionally destroyed by burning it at 150°C. We now have a metallic bar as the conducting channel and a nanotube gate approximately 1.5 nm away from the bar. The conductance vs. the electric field applied through the nanotube gate at liquid helium temperature is shown in Fig. 12. The channel conductance first oscillates as a function of the nanotube gate electric

field, then drops to zero at field strengths higher than 20 MV/cm. The metallic nanotube behaves like a FET when it is subjected to a high electric field. This is owing to the fact that high field causes the redistribution of charge density in the highest occupied molecular orbital and the lowest unoccupied molecular orbital, and eventually results in a gap opening in the metallic tube. Now one can switch off the conductance of a metallic channel by applying a sufficiently high electric field that is normally not accessible with a back gate. The critical field needed to turn the metallic state into an insulating state resembles the threshold voltage in a FET structure.

### Transparent Nanotube Network Transistors

Another novel application of nanotube-based transistors is the network FET, which is transparent and flexible.<sup>[44]</sup> The devices were prepared on a sheet of polyester, as illustrated in Fig. 13A. The nanotubes used for this purpose were first homogeneously dispersed in a 1 wt% sodium dodecyl sulfate solution. A dense nanotube network was subsequently sprayed on the polyester substrate as a gate electrode. A thin layer of parylene N is then evaporated on top of the dense network for gate dielectrics. To form active channels, a diluted nanotube suspension was used for adsorbing a sparse network. The nanotube network transistors exhibit several advantages beyond the conventional transparent transistors, which have been fabricated using polymers<sup>[45–47]</sup> or inorganic oxides.<sup>[48,49]</sup> They have a lighter weight, a higher carrier mobility, and a superior flexibility for bending, and are easy to process at room temperature. One shortcoming of the nanotube network transistor is the low on/off ratio, which is only  $10^2$  for the prototype device. This is owing to the mixture of metallic and semiconducting nanotubes in the network channel and less effective gating. Nevertheless, it opens up a new opportunity for potential applications in the so-called “plastic electronics,” such as paper displays and wearable computers.

**Fig. 13** (A) Schematic representation of nanotube transparent network transistor. (B) The picture shows the prototype of network transistor. *Source:* From Ref.<sup>[44]</sup>.

## CONCLUSIONS

It is clear that plenty of challenges lie ahead before CNT devices could work their way into any practical electronic devices. Two key questions remain unsolved and need to be addressed for implementation into manufacturable nanoscale devices: 1) easy separation of metallic and semiconducting nanotubes or even controllable chirality-dependent growth and 2) integration of nanotubes either by nondirected growth method with subsequent manipulation or directed growth at desired locations. However, on the way to nanotube-based electronic devices, a great deal of new physics that underlies the behavior of nanostructures has been learned, including the distinct device properties of CNTs to Si-based devices, rich quantum transport behavior in confined structures, and the intriguing electronic properties of sophisticated hybrid nanostructures. This demonstrates that the quest for functional nanostructures also greatly contributes to the understanding and the development of the basic science.

# Carbon Nanotube–Conducting Polymer Composites in Supercapacitors

Mark Hughes

Department of Materials Science and Metallurgy,  
University of Cambridge, Cambridge, U.K.

## INTRODUCTION

Supercapacitors, also referred to as electrochemical capacitors or ultracapacitors, are devices used to store and deliver electrical energy in high-power pulses.<sup>[1,2]</sup> With the advent of electric vehicles, digital communication, and other electronic devices that require significant bursts of electrical energy, the need for supercapacitors has expanded rapidly. At present, the most promising materials on which supercapacitors are based can be divided into two categories—those that make use of a double-layer charge storage mechanism (e.g., carbon nanotubes, carbon aerogels, and activated carbon black) and those employing a redox pseudo-capacitive charge storage mechanism (e.g., conducting polymers and transition metal oxides).<sup>[3,4]</sup> Already, the electrical charge that can be stored in each of these materials is typically several orders of magnitude larger than that of most commercially available conventional capacitors. However, it has been shown in recent times that even greater charge storage capacitances can be achieved in composites made by combining carbon nanotubes (a double-layer capacitive material) with a conducting polymer (a redox pseudo-capacitive material). The superior charge storage performance of carbon nanotube-conducting polymer composite supercapacitors arises from their ability to merge the properties that separately make carbon nanotubes and conducting polymers so suited to their respective charge storage mechanisms. That is to say, the composites are able to combine the high surface area and electrical conductivity of carbon nanotubes with the redox electrochemistry of conducting polymers.<sup>[5]</sup>

## CARBON NANOTUBE-CONDUCTING POLYMER COMPOSITES

### Structure and Fabrication

Most carbon nanotube-conducting polymer composites used in supercapacitor devices display a nanoporous network structure in which each nanotube is

coated by a thin layer of conducting polymer. This structure maximizes the exposed surface area of the conducting polymer while retaining the conductive network of the carbon nanotubes.

The nanoporous structures possible for carbon nanotube-conducting polymer composites are generally not observed when making conducting polymer composites with other high surface area forms of carbon such as activated carbon black and carbon aerogels.<sup>[6,7]</sup> In these cases the conducting polymer generally blocks the electrolyte pores. The other carbon structures are also unable to achieve the exceptionally low percolation thresholds possible with carbon nanotubes.<sup>[8]</sup>

Electron microscopy, elemental analysis, X-ray diffraction, nuclear magnetic resonance, and Raman spectroscopy studies indicate that there is good physical interaction between the carbon nanotubes and the conducting polymer (Fig. 1). In general, these techniques give no indication that there is a chemical reaction between the two components.<sup>[9–11]</sup> However, it has been reported that Raman spectroscopy on composites of arc-grown multiwalled carbon nanotubes and polyaniline indicates a site-selective interaction between the quinoid ring of the doped polymer and the carbon nanotubes.<sup>[12]</sup>

Recent reports have shown that composites of carbon nanotubes and conducting polymers such as polypyrrole, polyaniline, poly(3-methylthiophene), poly(3-hexylthiophene), poly(3-octylthiophene), and poly(*p*-phenylene vinylene) can be prepared using a variety of chemical<sup>[9,11,12]</sup> and electrochemical<sup>[13–17]</sup> polymerization techniques or by simply mixing the polymer and nanotubes.<sup>[18–20]</sup> To date, most carbon nanotube-conducting polymer composites have been made using multiwalled carbon nanotubes (MWNTs) as they generally offer uniform conductivity combined with a greater susceptibility to chemical oxidation and a lower cost relative to single-walled carbon nanotubes (SWNTs). The uniformity and thickness of the conducting polymer coating on each nanotube, in addition to the degree of porosity, are crucial in determining the composite's properties and are largely dependent on the fabrication technique employed.

**Fig. 1** Scanning electron microscopy image of the fractured cross section of multiwalled carbon nanotubes coated with polypyrrole. The tubes cleaved during fracture give an indication of the close interaction between the nanotubes and conducting polymer. *Source:* From M. Hughes.

Routes for producing carbon nanotube–conducting polymer composites based on chemical polymerization generally require a solution containing the desired monomer (typically pyrrole or phenylacetylene) and carbon nanotubes in suspension.<sup>[9,11,21]</sup> Polymerization is then initiated by the addition of a dopant such as  $(\text{NH}_4)_2\text{S}_2\text{O}_8$ . While the conducting polymer is observed to coat each individual nanotube using this technique, there have been some reports that the deposit tends to be inhomogeneous with some aggregation of the deposited polymer.<sup>[22]</sup> This in situ method of polymerization offers excellent processing flexibility in that the coated nanotubes can be deposited as a uniform composite film during polymerization or maintained as distinct coated nanotubes in suspension.<sup>[9]</sup> If the coated carbon nanotubes are maintained in suspension, they can subsequently be formed into a film or pellet using techniques such as spin-coating or vacuum drying.

Electrochemical composite growth techniques can be further divided into those that polymerize the conducting polymer onto a carbon nanotube preform<sup>[14–17,23]</sup> and those in which the nanotubes and conducting polymer are simultaneously deposited from the electrolyte<sup>[5,13]</sup> during polymerization. When using an aligned MWNT preform, the conducting polymer (usually polypyrrole<sup>[14,16]</sup> or polyaniline<sup>[24]</sup>) tends to form a continuous, uniform coating over each individual carbon nanotube (Fig. 2). In this way, the basic structure of the carbon nanotube preform is retained, making it possible to produce composites with a very high surface area. While conducting polymers can also be deposited electrochemically on unaligned carbon nanotube preforms, there is a tendency in this case

**Fig. 2** Scanning electron microscopy image of the fractured cross section of an aligned array of MWNTs in which each MWNT has been coated with polypyrrole. *Source:* From M. Hughes.

for the deposited conducting polymer to block electrolyte channels into the preform, preventing uniform coating of each carbon nanotube.<sup>[17]</sup>

For electrochemical synthesis routes in which the carbon nanotubes and conducting polymer are simultaneously deposited, the electrolyte used contains suspended carbon nanotubes in addition to the desired monomer (such as pyrrole or 3-methylthiophene) and any supporting electrolyte required.<sup>[5,25]</sup> Polymerization is then initiated via the application of an applied potential, resulting in the deposition of a nanoporous composite film in which each MWNT is uniformly coated by the conducting polymer (Fig. 3). If the suspended carbon nanotubes used in this technique are functionalized via an appropriate acid treatment step before they are added to the polymerization electrolyte, it is possible for the nanotubes to dope the deposited conducting polymer.<sup>[27,28]</sup> This eliminates the need for a supporting electrolyte during film growth and establishes several other advantages for supercapacitor applications that will be discussed later.

Composites formed by simply mixing the carbon nanotubes and conducting polymer generally make use of a suspension containing carbon nanotubes and a presynthesized conducting polymer such as poly(*p*-phenylene vinylene), poly(3-hexylthiophene), or poly(3-octylthiophene).<sup>[18,20,29]</sup> The suspension is ultrasonicated to mix the two constituents and is then spin-cast to form a carbon nanotube–conducting polymer composite film. The resulting composite structure is quite dense with conducting polymer enveloping the carbon nanotubes and the spaces between them.<sup>[19]</sup> It is worth noting that carbon nanotube–conducting polymer composites have also been produced by

**Fig. 3** Scanning electron microscopy images of nanoporous composite films formed by the simultaneous electrochemical deposition of MWNTs with (A) polypyrrole and (B) poly(3-methylthiophene). *Source:* From Ref.<sup>[26]</sup>.

simply spin coating the conducting polymer directly onto a MWNT preform.<sup>[30,31]</sup>

### Properties and Applications

The responsiveness of conducting polymer films to their external environment makes them very attractive materials for a variety of applications including photovoltaics,<sup>[32]</sup> sensors,<sup>[33,34]</sup> light emitting devices,<sup>[35,36]</sup> actuators,<sup>[37,38]</sup> and supercapacitors.<sup>[4]</sup> However, the response times of these devices are generally restricted by limited electrical conductivity and rates of ionic diffusion in the conducting polymer. The general improvement in electrical conductivity (up to 10 orders of magnitude) observed when carbon nanotubes are introduced into conducting polymers offers some alleviation of this problem.<sup>[18,19,29,39]</sup> Perhaps even more important for electrochemical applications is

the increase in the amount of conducting polymer surface exposed to the electrolyte and the reduced diffusion distances in nanoporous carbon nanotube-conducting polymer composites.<sup>[13]</sup>

Carbon nanotube additions have been observed to increase the strength,<sup>[40]</sup> thermal conductivity,<sup>[41]</sup> stability in air,<sup>[19]</sup> and photodegradation resistance<sup>[11]</sup> of polymers. These properties combine well with the excellent photovoltaic efficiency<sup>[30]</sup> and strong photosensitivity<sup>[20]</sup> exhibited by composites of carbon nanotubes with conducting polymers such as poly(3-hexylthiophene), poly(3-octylthiophene), and poly(*p*-phenylene vinylene), making them suitable for photovoltaic<sup>[31]</sup> and light-sensing<sup>[42]</sup> applications. For light-emitting applications, increasing the electrical conductivity of conducting polymers via the addition of untreated nanotubes is particularly advantageous as this does not introduce states within the polymer bandgap that quench luminescence, as is generally the case when conductivity is increased by doping the polymer.<sup>[19,43]</sup>

Electrochemical devices, such as actuators and supercapacitors, made from carbon nanotube-conducting polymer composites have been shown to display the electrochemical redox behavior of conducting polymers while retaining the conductive network of the carbon nanotubes.<sup>[13,25,44]</sup> This combination of desirable properties is associated with an increase in the storage capacity of the composite supercapacitors relative to the component materials and will be discussed in detail in the following section.<sup>[5]</sup> Unfortunately, reports to date on the actuation of carbon nanotube-conducting polymer films appear to indicate that strain is limited by the nanotubes,<sup>[44]</sup> which are much stiffer than the conducting polymer.

## SUPERCAPACITORS

Capacitors are devices used to accumulate and deliver electrical charge. Capacitors can be divided into conventional capacitors, generally based on a ceramic<sup>[45]</sup> or polymer<sup>[46]</sup> film dielectric, and supercapacitors, which make use of an electrolyte. The most promising supercapacitors at present make use of materials such as high surface area carbons,<sup>[47]</sup> conducting polymers,<sup>[4]</sup> and transition metal oxides<sup>[48]</sup> that are combined with an aqueous or organic electrolyte.

Traditional ceramic and polymer capacitors consist of two parallel conductive plates separated by a ceramic or polymeric dielectric, respectively. When a voltage is applied across the plates one of them adopts a positive charge and the other a negative charge. Conventional ceramic and polymer capacitors are frequently used in lighting, televisions, stereos, induction heaters, computers, and other electronic devices.<sup>[49]</sup> Like their more conventional counterparts, supercapacitors

consist of two opposing electrodes; however, the electrodes are separated by an electrolyte instead of a polymer or ceramic dielectric. While supercapacitors are limited to operating at a few volts, their capacitance far exceeds that of conventional capacitors resulting in significantly higher energy densities.<sup>[50]</sup>

The large capacitance exhibited by supercapacitor systems is related to two main charge storage mechanisms, either double-layer capacitance or redox pseudo-capacitance. Double-layer capacitance involves storing charge in the electrical double-layer formed at the electrode–electrolyte interface. Ions within the electrolyte accumulate at the electrode surfaces, compensating for the electronic charge injected into the electrodes. Depending on the electrolyte used, an electrical double-layer can typically store about 10–40  $\mu\text{F cm}^{-2}$  of interface; hence the surface area of the electrode material is critical.<sup>[51–53]</sup> Supercapacitors based on high surface area carbon electrodes, such as carbon nanotube mats, are of this type.

Redox pseudo-capacitance, on the other hand, involves the storage of charge via the reversible oxidation and reduction of an electrode material. Redox switching is accompanied by the transfer of charge-balancing counterions between the electrolyte and the solid electrode. In this case, charge is stored within the bulk of each redox-active electrode, not just at the interface with the electrolyte.<sup>[54]</sup> Conducting polymer and transition metal oxide-based supercapacitors employ this charge storage mechanism. The comparative performance of supercapacitors based on high surface area carbons, conducting polymers, and transition metal oxides is shown in Table 1.

### Carbon Nanotube Supercapacitors

High surface area carbon electrochemical double-layer capacitors generally exhibit an excellent response time, cycle life, specific power, and stability. Because the capacitance of these devices is related to the amount of available electrode surface area, there has been extensive research aimed at increasing the surface area of carbon electrodes for double-layer capacitors. From this work, several techniques have been reported on the use of additives such as metals and metal oxides,<sup>[50]</sup> the

pyrolysis of carbon-based polymers,<sup>[58]</sup> and the production of carbon foam, paste, and nanotube electrodes.<sup>[74,75]</sup> The molecular dimensions and high aspect ratio of carbon nanotubes in particular enable them to form exceptionally high surface area structures.<sup>[76]</sup>

It has been widely observed that carbon micropores less than 2 nm in size have detrimental effects on the kinetics and amount of charge stored by carbon-based capacitors.<sup>[77]</sup> This limitation arises because the pore dimensions approach that of the double-layer thereby inhibiting double-layer formation.<sup>[74]</sup> In addition to their extremely high surface areas, carbon nanotube electrodes typically exhibit an open structure with pore sizes in excess of 2 nm.<sup>[77]</sup> This is particularly advantageous for the electrolyte accessibility of carbon nanotubes relative to other high surface area carbon electrode materials, such as activated carbon black, which generally possess a significant portion of pores smaller than 2 nm. As a result, carbon nanotube supercapacitors are frequently capable of a greater capacitance, specific energy, specific power, and response time relative to other carbon structures used in double-layer supercapacitors.<sup>[56]</sup>

### Conducting Polymer Supercapacitors

Conducting polymer supercapacitors utilize their reversible redox states to store and deliver charge. While other redox pseudo-capacitors, such as those based on transition metal oxides such as ruthenium oxide, may have higher specific capacitances by mass, conducting polymer supercapacitors generally have comparatively superior rates of response, specific power capabilities, and operating voltages.<sup>[50,78–82]</sup> Conducting polymers are also more amenable to use in complex shapes and lower in cost relative to ruthenium oxide-based supercapacitors.<sup>[83]</sup>

The majority of the promising conducting polymer supercapacitors currently being investigated are based on polypyrrole,<sup>[84]</sup> polyaniline,<sup>[85]</sup> poly(3-phenylthiophene),<sup>[86–88]</sup> and poly(3-methylthiophene).<sup>[61]</sup> While these conducting polymers are generally used in liquid electrolytes, it is possible to employ polymer and gel electrolytes to create solid-state capacitors. It should be noted, however, that the response time

**Table 1** Relative performance of modern supercapacitor materials

Material	Maximum capacitance ( $\text{F g}^{-1}$ )	Maximum capacitance ( $\text{mF cm}^{-2}$ )	Power ( $\text{kW kg}^{-1}$ )	Energy ( $\text{Wh kg}^{-1}$ )	Max voltage (V)
High area carbons <sup>[50–60]</sup>	180	173	20	7	3
Conducting polymers <sup>[17,61–68]</sup>	268	600	11	42	3
Ruthenium oxides <sup>[48,69–73]</sup>	840	500	0.5	27	1

and specific capacitance of solid-state supercapacitors are generally inferior to those obtained when using a liquid electrolyte.<sup>[89]</sup>

## CARBON NANOTUBE-CONDUCTING POLYMER COMPOSITE SUPERCAPACITORS

### Fundamental Findings

While the capacitance and specific energy of supercapacitors far exceed that of conventional capacitors, the charge storage mechanisms of supercapacitors generally result in a rate of charge and discharge that is several orders of magnitude slower than many commercially available conventional capacitors. For example, it can take redox supercapacitors tens of seconds to accumulate and deliver charge, whereas many commercial ceramic and polymer dielectric capacitors can charge and discharge in a matter of nanoseconds. To improve supercapacitor kinetics and specific power, it is essential that the combined resistivity of the matrix and electrolyte be minimized. In the case of redox supercapacitors, it is also important to select a redox reaction that has a large exchange current density.<sup>[1]</sup>

Double-layer capacitors have a natural advantage in terms of capacitance kinetics as their charge storage mechanism does not involve the slower ion intercalation and deintercalation processes observed in redox pseudo-capacitors. In fact, carbon-based double-layer capacitors have been produced that can accept and deliver charge in a period of microseconds.<sup>[57]</sup> In addition, modern double-layer capacitors generally exhibit cycle lives in excess of  $10^5$  cycles and good stability,<sup>[74]</sup> typically surpassing that of redox pseudo-capacitive systems. On the other hand, the three-dimensional adsorption process found in redox pseudo-capacitors enables much higher values of specific energy storage and greater voltage consistency during delivery than is found in processes that are limited to the electrode surface such as double-layer capacitance.<sup>[1]</sup> Supercapacitors based on composites of high surface area carbon nanotubes (a double-layer capacitive material) and a conducting polymer (a redox pseudo-capacitive material) can, to a large extent, bridge the gap between fast capacitor kinetics and substantial energy storage.

To date, investigations into the supercapacitive properties of carbon nanotube-conducting polymer composites have been based on samples made by chemically or electrochemically polymerizing either polypyrrole,<sup>[5,14,22,90]</sup> polyaniline,<sup>[17,91]</sup> or poly(3-methylthiophene)<sup>[26,92]</sup> in the presence of SWNTs or MWNTs. These first studies already indicate that carbon nanotube-conducting polymer composites are capable of specific capacitances per mass and

geometric electrode area as high as  $265 \text{ F g}^{-1}$ <sup>[90]</sup> and  $2.6 \text{ F cm}^{-2}$ ,<sup>[14]</sup> respectively. These reported values are already significantly higher than that of the pure polymer or carbon nanotubes used in each case. It has also been shown that carbon nanotube-conducting polymer composite films are capable of charge and discharge rates that are approximately an order of magnitude faster than similarly prepared and tested samples of the relevant conducting polymer.<sup>[5]</sup>

As the available reports on carbon nanotube-conducting polymer composite supercapacitors were compiled by various researchers, using a range of sample conformations and an assortment of test conditions, it is difficult to compare the relative merits of each composite system. Indeed, even the process of measuring capacitance can be accomplished using a range of techniques including cyclic voltammetry, electrochemical impedance spectroscopy, and charge-discharge analysis—each of which has its own merits, which are too exhaustive to discuss here. However, the collective data available for carbon nanotube-conducting polymer composite supercapacitors do indicate some fundamental deductions that can be applied generally across the range of composite systems studied.

The first of these deductions is the importance of using nanotubes that are able to form a connected three-dimensional network that promotes efficient charge transfer within the composite without inhibiting electrolyte access (i.e., avoids pore sizes  $< 2 \text{ nm}$ <sup>[77]</sup>). It is also advantageous to maximize the surface area of conducting polymer exposed to the electrolyte, thereby optimizing the redox-pseudocapacitive contribution of the conducting polymer. For this reason, it is desirable to obtain a thin, uniform, and continuous coating of conducting polymer over each of the carbon nanotubes. Composite growth techniques in which the carbon nanotubes and conducting polymer are deposited simultaneously have an advantage in this respect relative to techniques that make use of a carbon nanotube preform; polymer deposition onto carbon nanotube preforms, particularly those in which the nanotubes are randomly oriented, can be limited by pore blocking and uneven distribution of the conducting polymer. It has also been reported that electrochemical growth techniques are able to produce a more homogeneous polymer coating with less aggregation than observed for composite synthesis routes that make use of chemical polymerization.<sup>[22]</sup>

Recent work has shown that if MWNTs are acid treated (resulting in the attachment of hydroxyl, carbonyl, and carboxylic functional groups to the tube surface) prior to electrochemical synthesis of MWNT–polypyrrole composite films, the MWNTs are able to partially dope the conducting polymer.<sup>[93]</sup> As mentioned earlier, this eliminates the need for a supporting

electrolyte during film growth. However, the use of functionalized carbon nanotubes also benefits the supercapacitive behavior of the composites produced as will be discussed in the following section.

### Carbon Nanotube Doping of the Conducting Polymer

Fig. 4 shows scanning electron microscopy images of MWNT–polypyrrole composite films made using different concentrations of functionalized MWNTs.<sup>[28]</sup>

**Fig. 4** Scanning electron microscopy images of MWNT–polypyrrole composite films made using polymerization electrolytes containing the indicated concentrations of functionalized MWNTs. *Source:* From Ref.<sup>[28]</sup>.

It can be seen that as the concentration of functionalized MWNTs in the polymerization electrolyte is increased from 0.025 to 0.4 wt.%, the polypyrrole coating thickness on each MWNT decreases, thereby increasing the loading fraction of MWNTs in the composite. For comparison, it is also possible to electrochemically grow MWNT–polypyrrole composite films using pristine (not functionalized) aligned arrays of MWNTs. In this case, the loading fraction of aligned MWNTs can be raised by simply using longer MWNTs with the same amount of deposited conducting polymer.<sup>[14]</sup> The length of the aligned MWNT array can be varied, while keeping the nanotube diameter and packing density approximately constant, via manipulation of the reaction parameters used to synthesize the MWNTs.<sup>[94]</sup>

Fig. 5 shows the specific capacitance vs. film-formation charge (a measure of the amount of polymer deposited) for MWNT–polypyrrole composite films made using functionalized MWNTs and aligned MWNT arrays that were not functionalized. In both cases, the capacitance of similarly prepared pure polypyrrole films (chloride ion doped) is shown for comparison. For the pure polypyrrole samples, it can be seen that as the amount of polymer deposited increased (as indicated by the film-formation charge), the proportion of total polymer that contributed to the measured capacitance decreased. This restriction arises from the limited electronic and ionic conductivity in the conducting polymer. Such limitations are alleviated in the composite films by the high surface area conductive MWNT network that gives rise to reduced diffusion distances, improved electrolyte access, and superior electronic conductivity. As a result, it is possible to deposit significantly more conducting polymer in the composite films without a marked deterioration in the proportion of polymer contributing to the measured capacitance.

It can be seen in Fig. 5A that as the loading fraction of functionalized MWNTs is increased, via an increase in the concentration of MWNTs in the polymerization electrolyte, the specific capacitance also increases for a given film-formation charge. On the contrary, as the loading fraction of aligned MWNTs (not functionalized) is increased by using longer MWNTs, the specific capacitance is not significantly effected for a given film-formation charge (Fig. 5B). Although there are factors to be considered such as the difference in diameter, length, conductivity, and distribution of the functionalized MWNTs relative to the pristine aligned MWNTs, it would appear that such primarily kinetic influences are insufficient to fully account for this difference in behavior. Instead, the increased level of doping provided by the functionalized MWNTs with increasing loading fraction is thought to be linked with the increase in capacitance for a given film-formation

**Fig. 5** The specific capacitance vs. film-formation charge (a measure of the amount of polymer deposited) for MWNT-polypyrrole composite films made using (A) functionalized MWNTs of various concentrations and (B) pristine (not functionalized) aligned MWNT arrays of various lengths. Source: From Ref.<sup>[28]</sup>.

charge. This is an important finding because it indicates that the role of carbon nanotubes can be extended beyond that of a high surface area conductive substrate in carbon nanotube-conducting polymer films. By adopting the additional role of macromolecular dopant, carbon nanotubes can facilitate even greater performance benefits in carbon nanotube-conducting polymer composite supercapacitors.

The doping of conducting polymers with functionalized MWNTs is still under investigation, although there does appear to be some similarities with doping using anions that are relatively immobile within the conducting polymer, such as dodecyl sulphate ions.<sup>[93]</sup> However, large anions such as dodecyl sulphate do not contribute to the formation of a high surface area conductive network as functionalized MWNTs can. Accordingly, dodecyl sulphate-doped polypyrrole does not offer the large capacitances of MWNT-polypyrrole composite films. For the samples shown in Fig. 4, it is

possible to calculate the theoretical maximum thickness of polypyrrole that could be doped by the negatively charged surface groups along the MWNT surface (2.4 meg g<sup>-1</sup>).<sup>[95]</sup> Such calculation yields a polypyrrole coating thickness of approximately 8 nm (assuming there are four pyrrole units per negative surface charge<sup>[96,97]</sup>). This result implies that only a fraction of the deposited polypyrrole is actually in the oxidized state during film-growth when functionalized MWNTs are the only source of dopant anions added to the polymerization electrolyte. Therefore the functionalized MWNTs allow the continuous electrochemical growth of polypyrrole, as does a more conventional anionic dopant, which would otherwise cease due to the insulating nature of unoxidized polypyrrole. However, the mechanism by which this occurs seems to be the formation of a conductive network comprising the MWNTs and adjacent layer of doped polypyrrole, rather than the incorporation of sufficient anionic

dopant to ensure comprehensive oxidation of the polypyrrole.

It is interesting to note the effect of competing dopant anions when growing carbon nanotube-conducting polymer composites using functionalized MWNTs. Adding additional sources of dopant anions to the polymerization electrolyte, such as dodecyl sulphate ions, makes it possible for polypyrrole to grow in areas further displaced from the functionalized MWNT surfaces. Consequently, the porosity of the composite structures produced is significantly reduced.<sup>[28]</sup> In the case of dodecyl sulphate ions, the reduction in film porosity was sufficient to produce a surface morphology quite similar to that observed for pure polypyrrole (Fig. 6). The reduced porosity of composite films grown with dodecyl sulphate additions

**Fig. 6** Scanning electron microscopy images of (A) a MWNT–polypyrrole composite film made using a polymerization electrolyte containing 0.4 wt.% functionalized MWNTs, 0.01 M sodium dodecyl sulphate, and 0.5 M pyrrole; and (B) a pure polypyrrole film made using a polymerization electrolyte containing 0.5 M KCl and 0.5 M pyrrole. Source: From Ref.<sup>[28]</sup>.

is likely to be associated with a decrease in the loading fraction of functionalized MWNTs. These structural changes were accompanied by a sizable decline in capacitance and rate of response relative to composite films grown without competing dopant anions. This finding provides further indication of the importance of the three-dimensional network of nanopores and loading fraction of functionalized MWNTs in carbon nanotube-conducting polymer composites for supercapacitors.

### Prototype Devices

The work described above has primarily aimed at characterizing the charge storage properties of carbon nanotube-conducting polymer composites. Of the carbon nanotube-conducting polymer composite systems investigated to date, those based on polypyrrole have received the widest attention because of the charge storage capabilities, ease of polymerization, relative stability, and processing flexibility of this particular conducting polymer system. While polypyrrole is capable of existing in an oxidized (p-doped) and neutral state, displaying excellent redox properties between these two states, it is unable to redox cycle beyond the neutral state into a truly reduced form (n-doped). While this limitation does not prevent the characterization of charge storage in polypyrrole-based composites, it does inhibit the use of such composites in real supercapacitor devices where it is desirable for one of the two electrodes in the capacitor to be oxidized while the other is reduced during charging. In this case, polypyrrole-based films are ideally only suited to use in the oxidized electrode of supercapacitors.

Several other conducting polymers, such as poly(3-methylthiophene), are capable of being oxidized (p-doped) or reduced (n-doped) from the neutral state and have also been shown to possess excellent charge storage properties.<sup>[6,7,83,98,99]</sup> Carbon nanotube-conducting polymer composites based on such polymers can be used effectively in both electrodes of a supercapacitor. For this reason, current work aimed at developing prototype carbon nanotube-conducting polymer composite supercapacitors is looking closely at the choice of conducting polymer for each of the electrodes within the supercapacitor device. For example, it is possible to produce symmetric supercapacitors based entirely on, say, carbon nanotube-poly(3-methylthiophene) composites, or unsymmetric supercapacitors with, say, a carbon nanotube-poly(3-methylthiophene) composite as the reduced electrode and a carbon nanotube-polypyrrole composite as the oxidized electrode. It is also possible to produce hybrid supercapacitors that combine a carbon nanotube-conducting polymer composite electrode with a simple

carbon nanotube electrode. However, recent work indicates that such hybrid supercapacitors are outperformed by those based on a suitable combination of carbon nanotube-conducting polymer composites.<sup>[92]</sup>

It is recognized that the properties of conducting polymers can deteriorate significantly with prolonged potential cycling, which is of concern for many supercapacitor applications. The cycle life limitations of conducting polymers are often attributed to progressive assimilation of free space by the polymer chains.<sup>[96,100]</sup> This free space is required by the counterions that diffuse in and out of the polymer during potential cycling, hence its assimilation by the polymer chains limits the degree of doping possible for each successive cycle. Cycle life testing on prototype MWNT-polypyrrole composite films indicates that, for as many as 10,000 cycles, the capacitance dropped by less than 36%.<sup>[25,101]</sup> This is a substantial improvement relative to similarly prepared pure polypyrrole films in which capacitance dropped by 95% over 10,000 cycles. It is thought that the rigid nanotubes in carbon nanotube-conducting polymer composites inhibit the expansion and contraction of the composite, thereby limiting progressive compaction with potential cycling. In this way, the deleterious effect of potential cycling on the incorporation of counterions is reduced. The network of nanopores maintained in carbon nanotube-conducting polymer composites also helps to ensure effective electrolyte access over the full potential cycle.

## CONCLUSION

Nanoporous carbon nanotube-conducting polymer composites are able to effectively combine the high surface area electrically conductive network of carbon nanotubes with the three-dimensional charge storage capabilities of redox-active conducting polymers. This combination of properties is particularly advantageous for supercapacitors, which need to be able to store and deliver relatively large amounts of electrical energy in high power pulses. Recent work has shown carbon nanotube-conducting polymer composites to exhibit specific capacitances per mass and geometric electrode area as high as  $265 \text{ F g}^{-1}$ <sup>[90]</sup> and  $2.6 \text{ F cm}^{-2}$ ,<sup>[14]</sup> respectively. These values are already significantly higher than that of the pure polymer or carbon nanotubes used in each case and there is still much room for further optimization. Manipulation of the various composite synthesis techniques available—particularly those producing films in which the nanotubes are able to dope the conducting polymer—is expected to provide many opportunities to build on the exceptional findings discussed in this entry.

# Carbon Nanotube Electrodes

Valentina Lazarescu

I.G. Murgulescu Institute of Physical Chemistry, Bucharest, Romania

## INTRODUCTION

Carbon nanotubes discovered by Iijima<sup>[1]</sup> in 1991 as a by-product of fullerene synthesis by an arc plasma method have entailed extensive theoretical and experimental work, opening a new and rapidly expanding research field on nanoscale materials. Large-scale production of these particularly interesting materials has become, in the meantime, available in gas phase, either by evaporation of pure carbon using high-power energy sources (e.g., electric arc,<sup>[2]</sup> laser ablation,<sup>[3]</sup> and sunlight<sup>[4]</sup>), or by chemical vapor deposition (CVD) techniques (reviewed in Ref.<sup>[5]</sup>), as well as in molten salts via electrolysis.<sup>[6,7]</sup>

Consisting of one or a few graphite (graphene) sheets rolled up into single-walled or multiwalled cylinder-like structures with lengths in the micrometer scale, carbon nanotubes considerably enlarged the family of carbon nanostructures. Single-wall nanotubes (SWNTs) may self-organize into long crystalline “ropes”<sup>[3]</sup> with diameters of 10–50 nm corresponding to 30–600 tubes per rope. Multiwall nanotubes (MWNTs) consisting of manifold wrapping of a single graphitic sheet (Scroll model), or closed concentric cylinders (Russian doll model) have external diameters of up to 50 nm. However, SWNTs arising from the folding of a single graphene sheet have diameters ( $d$ ) of only 1–2 nm, strictly depending on the way the graphene sheet is wrapped up, which is defined by the chiral vector  $C_h = na_1 + ma_2 \equiv (n,m)$ .<sup>[8]</sup>

$$d = \frac{\sqrt{n^2 + m^2 + nm}}{\pi} a \quad (1)$$

where  $a = \sqrt{3}a_{C-C} = 2.46 \text{ \AA}$  is the length of the unit vector. A large number of *chiral* carbon nanotubes can be formed for arbitrary values of  $n$  and  $m$ . The limit cases are the so-called *armchair* tubes (when  $n = m$ ) and *zigzag* tubes (when  $n = 0$ ), taking into account the atomic configuration along the circumference. These remarkable structural features of carbon nanotubes that were thoroughly investigated by local and global probes (reviewed in Ref.<sup>[9]</sup>) were found to be intimately related with most of their unusual properties: electronic,<sup>[10,11]</sup> electrical,<sup>[12,13]</sup> optical,<sup>[14,15]</sup> and

mechanical properties,<sup>[16,17]</sup> as a direct consequence of their 1-D quantum behavior.<sup>[8,12]</sup>

In terms of electronic properties, it has been initially theoretically predicted<sup>[18–20]</sup> and, subsequently, experimentally proven<sup>[21–24]</sup> that  $(n,m)$  nanotubes have either a small band gap and metallic behavior if they satisfy the  $(n - m) = 3l$  ( $l = 0,1,2,\dots$ ) condition, or a moderate band gap if they do not. Thus carbon nanotubes have the unique property to exhibit conductivity, which can be either metallic or semiconducting depending on  $(n,m)$ . Furthermore, Kociak et al.<sup>[13]</sup> have reported that some ropes of SWNTs prepared by an electrical arc method, with a mixture of nickel and yttrium a catalyst, exhibit even superconducting behavior. The peculiar electronic and electrical properties of these novel molecular scale wires not only make them ideal model systems for 1-D solids physics studies, but have also considerable potential for tailoring new field emission and nanoelectronics devices.<sup>[25–28]</sup> Having high surface area, good chemical stability, and significant mechanical strength, SWNTs and MWNTs proved also to be excellent new electrode materials for a wide range of electrochemical applications (such as: energy, lithium ion and hydrogen storage, sensors, and actuators) reviewed in this paper along with their electrochemical properties.

## ELECTRODES IN ELECTROCHEMICAL CAPACITORS

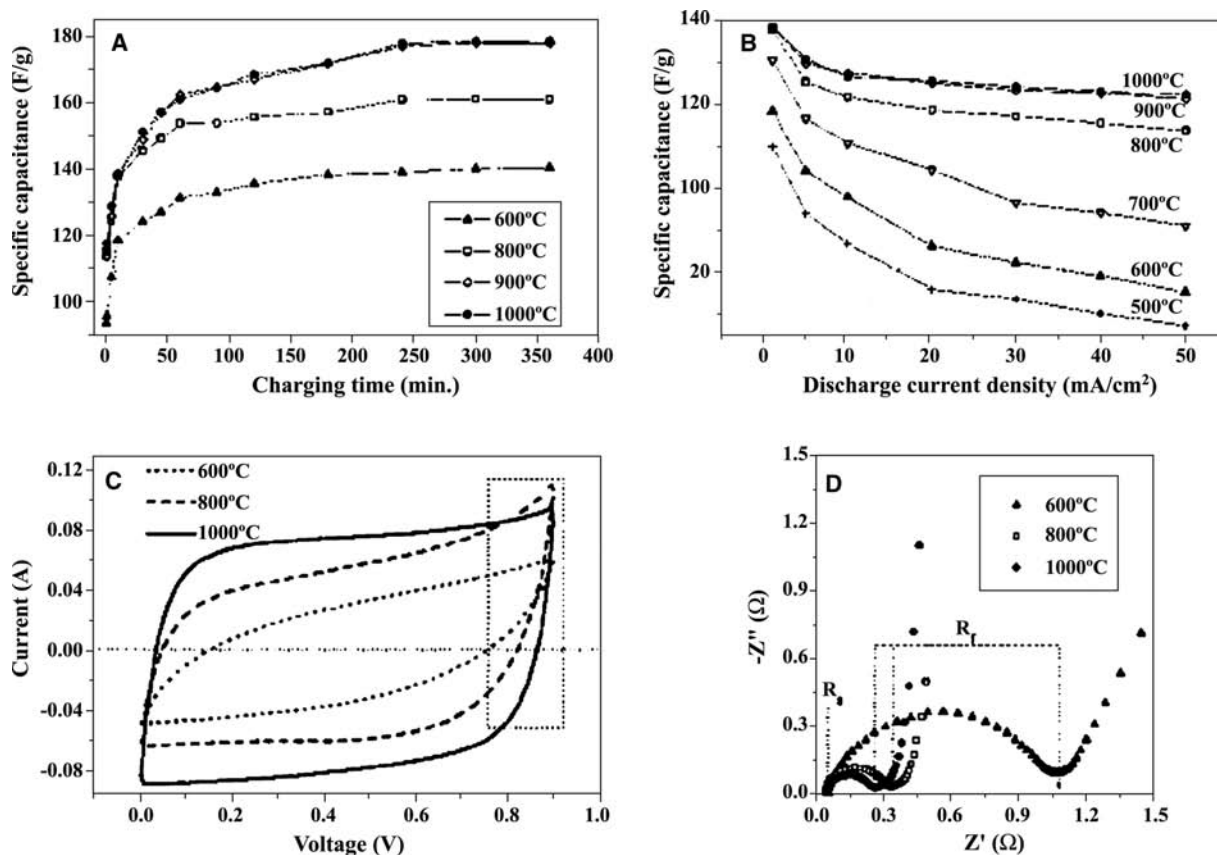

Carbon nanotube electrodes exhibit usually a featureless cyclic voltammogram (CV) over a rather large potential range in aqueous<sup>[29]</sup> and non-aqueous solutions,<sup>[30–32]</sup> showing a typical double-layer behavior that recommends them from the start as excellent candidates for electrochemical capacitors. The featureless aspect of CV was explained as an overlapping of many closely spaced peaks representing electron transfer into each nanotube,<sup>[29,30]</sup> or as double-layer capacitor bulk carbon-like behavior.<sup>[29]</sup> Although the nanotubes' diameter and chirality distribution are expected to be quite large and to involve consequently a fairly large spectrum of electronic properties,<sup>[10,11]</sup> the hypothesis of the averaged multiple peaks is not consistent with the similar curves observed whatever SWNTs or

MWNTs are involved. The second explanation seems more plausible because the double-layer charging current may exceed, by far, the faradaic current<sup>[29]</sup> as a result of high specific surface area, with the total inside and outside specific surface areas of carbon nanotubes being theoretically estimated at 2630 m<sup>2</sup>/g.<sup>[33]</sup> The latter assumption is also in good agreement with the observation that the increase in the total amount of SWNTs deposited on the Pt electrode produced only higher currents keeping strictly the same shape.<sup>[30]</sup> Broad redox responses shifting positively with increasing pH have been sometimes observed,<sup>[34,35]</sup> and were associated with oxygen-containing functional groups attached to the nanotube surface and/or carbonaceous impurities in the sample.<sup>[32,34,35]</sup>

The current potential profiles of SWNTs were found to be practically insensitive to anion or cation molar mass, ion charge, or ion hydrophobicity<sup>[32,34]</sup> displaying the same capacitive dominating behavior. However, the electrochemical quartz crystal microbalance studies revealed<sup>[31,32]</sup> that the applied potential results in sizeable (on average around 1% of the sample weight) electrode mass changes. Because no relation could be established with cation mass, the mass change at negative potentials has been ascribed to changes in relative anion and cation concentrations caused by double-layer charging.<sup>[31]</sup> The mass increase observed at positive potentials in sulfuric acid has been assigned<sup>[31]</sup> to the electrochemical doping of bisulfate ions into SWNTs revealed by the Raman-active tangential mode frequency upshift.<sup>[36]</sup> By analogy with graphite intercalation compounds, SWNT bundles were supposed to be oxidatively (reductively) intercalated, with the guest ions occupying sites in the interstitial channels of the rope lattice.<sup>[36]</sup> Further in situ Raman<sup>[35,37–39]</sup> and Vis-NIR<sup>[37,40]</sup> studies brought conclusive evidence in this respect, proving that the population of the SWNT valence band electronic states is electrochemically tunable. It has been found that changes in the intensity and frequency of both the main Raman-active tangential displacement mode (TDM) and the radial breathing mode (RBM) are dependent on the applied potential and reversible to a great extent.<sup>[35,37,38]</sup> Such effects have been explained by the resonance enhancement of electronic transitions between the first singularities in the 1-D electronic density of states<sup>[39]</sup> and interpreted as depletion/filling of their valence and conduction bands.<sup>[35,37–39]</sup> Electrochemical charging of SWNTs causes also reversible bleaching of the electronic transitions between Van Hove singularities in the Vis-NIR region,<sup>[37,40]</sup> resulting in filling (electroreduction) and depletion (electrooxidation) of electrons in the corresponding occupied bands. The conduction electron spin resonance measurements on K-doped SWNTs in 1 M KCN in (C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>B/THF electrolyte showed

also a continuous and reversible valence electron transfer from K to SWNT, proving once more that electrochemical doping is a powerful and precise technique to control the electronic properties of carbon nanotubes.<sup>[41]</sup> The possibility of alkali ion (Li<sup>+</sup> particularly) insertion into carbon nanotubes has attracted considerable attention from material scientists for its potential use in lithium secondary batteries as discussed in detail below.

The high ability of carbon nanotubes for accumulation of charges makes them one of the most attractive electrode materials for building capacitors. The values of specific capacitance reported in the literature vary over a wide range from 4<sup>[42]</sup> to 180 F/g,<sup>[43,44]</sup> depending on the type of nanotubes or/and their posttreatments. Niu et al.<sup>[45]</sup> have reported that *free-standing mats* of entangled catalytically grown MWNTs with an open porous structure exhibit a specific capacitance of 104 F/g and a power density of 8 kW/kg in a solution of 38 wt.% H<sub>2</sub>SO<sub>4</sub>. By using binding materials, Ma et al.<sup>[46]</sup> prepared *block-type* carbon nanotube electrodes with a specific capacitance of 90 F/g from similarly produced MWNTs and the same electrolyte. With highly pure SWNTs prepared by the HiPco process (thermocatalytic decomposition of CO under high pressure), Shiraishi et al.<sup>[33]</sup> found a rather low value of specific capacitance (per surface area unit) of only 10 μF/cm<sup>2</sup> in a 1-M LiClO<sub>4</sub>/propylene carbonate solution. However, An et al.<sup>[43,44]</sup> obtained a maximum specific capacitance of 180 F/g and measured a power density of 20 kW/kg with bundles of SWNTs produced by arc discharge after a careful optimization of the key factors controlling functional performance, such as annealing temperature, charging time, and discharging current density. As seen in Fig. 1A, specific capacitance increases with heat treatment temperature, reaching the highest saturated value (180 F/g) and the smallest drop (about 10%) even for large discharging current density (Fig. 1B) at 1000°C. The CV (Fig. 1C) is close to the ideal rectangular shape, and the complex plane impedance plot (Fig. 1D) indicates the lowest electrode resistance (equal to the semicircle diameter) and an almost ideal diffusive line (representing the resistivity of the electrolyte within the electrode pores) for such a high-temperature treated sample. The remarkable effect of high-temperature annealing on electrical capacitance has been attributed to specific surface area increase and enhancement of lower pore size (30–50 Å).<sup>[43,44]</sup> The amount of electrical charge accumulated by pure electrostatic forces depends indeed on the electrode/electrolyte interface dimension and the easy access of charge carriers to it,<sup>[47,48]</sup> both of them being adjustable by proper heating procedures. But the effects of thermal treatment are not always beneficial: SWNTs (Tubes@Rice) were found to decrease

**Fig. 1** Electrochemical properties of a supercapacitor built with SWNT bundles produced by arc discharge. Specific capacitance of electrodes heated at various temperatures as a function of charging time at 0.9 V (A); discharging current density at 0.9 V for 10 min (B); CV taken at 100 mV/sec (C); and complex plane impedance plots taken from 7.5 M KOH at an a.c. voltage amplitude of 5 mV for samples annealed at various temperatures (D) ( $Z''$  = imaginary impedance;  $Z'$  = real impedance). *Source:* From Ref.<sup>[43]</sup>.

their capacitance from 40 to 18 F/g after annealing at 1650°C because of a better arrangement of the tubes in the bundles, hindering ion diffusion toward the active surface.<sup>[48]</sup> However, heating is not the only way to increase capacitance. Electrochemical capacitors known as supercapacitors or ultra-capacitors combine actually two kinds of energy storage: the pure electrostatic attraction of ions in the electrical double layer and pseudo-capacitance faradaic surface reactions.<sup>[47–49]</sup> Therefore a distinct manner to increase capacitance values is the enhancement of pseudo-capacitance effects resulting in fast faradaic charge reactions (e.g., H and metal atoms electrosorption, redox reactions of electroactive species).<sup>[47]</sup> This desiderate has been achieved by various chemical and electrochemical modifications. *Chemical oxidation* has been successfully used (e.g., with 69% HNO<sub>3</sub><sup>[42]</sup> when the specific capacitance increased from 80 to 137 F/g) for opening the nanotubes and expanding surface functionality<sup>[48]</sup> and pore size.<sup>[50]</sup> The *chemical insertion of electroactive particles of transition metal oxides* such as RuO<sub>2</sub> raised the specific capacitance up to 560 F/g.<sup>[51]</sup> The *chemical insertion*

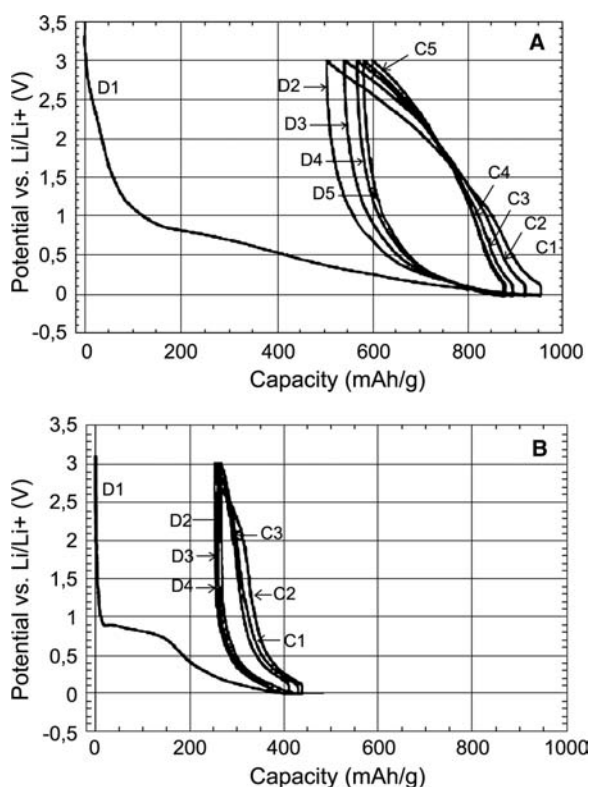

of  *$\pi$ -conjugated conducting polymers* (such as polyaniline<sup>[52]</sup> or polypyrrole<sup>[53–56]</sup>) resulted in specific capacitances as high as 163<sup>[53]</sup> and 192 F/g<sup>[55]</sup> because they can be subsequently further charged by ion insertion.<sup>[53]</sup> Pseudo-capacitance effects were also observed after additional *functionalization* of carbon nanotubes<sup>[54]</sup> that could be electrochemically achieved (e.g., via electrochemical reduction of a variety of aryl diazonium salts).<sup>[57]</sup>

## ANODES IN SECONDARY LITHIUM ION BATTERIES

The electrochemical insertion of alkali ions into carbon nanotubes has attracted much attention not only for the basic interest to control their electronic properties as discussed above, but also for their very promising potential use as anodes in lithium ion rechargeable batteries.

Electrochemical doping with lithium of carbon nanotubes has been largely investigated by galvanostatic

charge–discharge experiments<sup>[58–64]</sup> on Li/carbon nanotube half-cells using organic electrolytes consisting of  $\text{LiClO}_4/\text{LiPF}_6$  dissolved in a mixture of dimethyl carbonate/diethyl carbonate/ethylene carbonate/propylene carbonate. Typically, a large capacity is observed during the first discharge (lithium intercalation) cycle, which considerably decreases in the following ones, as seen in Fig. 2A. The significant hysteresis observed during the extraction of lithium (discharge cycle) is associated with electrolyte decomposition and the formation of a passivate film or solid electrolyte interphase on the carbon surface<sup>[58,61,64]</sup> evidenced by long plateau at about 0.9 V in the first discharge step. Usually, the capacitance of the first<sup>[58,62]</sup> or the second charge<sup>[60]</sup> cycle defines *reversible capacity* (i.e., the amount of intercalated Li that can be deintercalated), whereas the difference between the first discharge and the first charge<sup>[60]</sup> or between the first discharge and the second discharge<sup>[63,65]</sup> denotes *irreversible capacity*. Large irreversible capacity and large voltage hysteresis are limiting factors for using carbon nanotubes for  $\text{Li}^+$  battery applications. Therefore much effort has been invested for understanding the mechanism and for identifying the factors controlling process reversibility to lower these drawbacks.

**Fig. 2** Charge–discharge characteristics of lithium insertion into MWNT before (A) and after heat treatment at  $2000^\circ\text{C}$  (B) at a current of  $17\text{ mA/g}$  in  $1\text{ M LiPF}_6$  in ethylene carbonate/diethyl carbonate (1:1) mixture. *Source:* From Ref.<sup>[58]</sup>.

Galvanostatic charge–discharge and cyclic voltameter indicated that there is no well-defined redox potential for lithium insertion or removal in the nanotube lattice, ruling out the hypothesis of a staging mechanism via interstitial sites,<sup>[64]</sup> in good agreement with information inferred from Raman spectra.<sup>[66]</sup> The spectral changes of the Raman  $\text{E}_{2g}$  band centered around  $1580\text{ cm}^{-1}$ , which corresponds to the vibrations of graphene layers adjacent to intercalates, showed that lithium is intercalated between graphene layers of the MWNTs, bringing about an increase in electron density and hence electrical conductivity.<sup>[66]</sup>  $^7\text{Li}$  nuclear magnetic resonance (NMR) spectroscopy<sup>[65]</sup> has also evidenced intercalated Li species residing between graphene shells, whereas in situ resistance measurements showed a 20-fold decrease upon doping, consistent with charge transfer between lithium and carbon.<sup>[64]</sup> The decrease in the electric resistivity of the electrode upon doping has been confirmed by the lowering of charge transfer resistance in electrochemical impedance spectra (EIS), too.<sup>[64,67]</sup> Electrochemical impedance spectra investigations have identified three distinct steps in Li insertion in SWNT: charge transfer across the electrode/electrolyte interface, mesoscale diffusion through the porous structure of SWNTs, and nanoscale diffusion in individual SWNT ropes, suggesting that Li intercalates in the channels between nanotubes, decorating internal and external rope surfaces.<sup>[67]</sup> This is in a good agreement with the in situ X-ray diffraction proof that Li doping induces irreversible structural disorder inside the rope lattice.<sup>[64]</sup>

However, the origin of the high reversible capacity of SWNTs is not clear yet. As long as the inner core space of the SWNTs is not accessible for intercalation because of the closed structure and because  $\text{Li}^+$  is expected to decorate only the outer surface of the nanotubes (analogous to occupying one side of isolated graphene sheets), the saturation capacity should be close to  $\text{LiC}_6$ . However, the purified SWNTs synthesized by laser ablation exhibited reversible capacities of  $460$ <sup>[64]</sup> and  $600\text{ mA hr/g}$ <sup>[63]</sup> corresponding to a saturation composition of  $\text{Li}_{1.2}\text{C}_6$  and  $\text{Li}_{1.6}\text{C}_6$ , respectively, much higher than the ideal value of  $\text{LiC}_6$  ( $372\text{ mA hr/g}$ ) for graphite. Moreover, after processing the nanotubes by mechanical ball milling, the reversible saturation composition became even higher,  $\text{Li}_{2.7}\text{C}_6$  ( $1000\text{ mA hr/g}$ ).<sup>[63]</sup> The latter data point to structural defects (notably increased during mechanical ball milling processing) as key factors in the mechanism of Li reversible insertion, facilitating  $\text{Li}^+$  diffusion into the nanotube.<sup>[63]</sup> A similar conclusion has been drawn from important morphology modifications induced by Li insertion in MWNTs revealed by X-ray diffraction and transmission electron microscopy (TEM).<sup>[65]</sup>

However, there are many other different opinions with respect to the role played by structural defects

in Li insertion. Yang and Wu<sup>[60]</sup> consider that lithium inserted into the inner core of the nanotubes cannot be deintercalated because of capillary force. By performing charge–discharge measurements on closed and opened MWNTs, they found significant differences in irreversible Li capacity and cycling performances (the first one being much higher and the latter being poorer for the opened nanotubes) but the same reversible capacity (125 mA hr/g),<sup>[60,68]</sup> which led them to the conclusion that lithium is reversibly doped only on the outer surfaces of MWNTs. Such a mechanism might be plausible in the case of their low reversible capacity (corresponding to only  $\text{Li}_{0.33}\text{C}_6$ ), but it is quite improbable for the much higher values reported by other groups (e.g. 700<sup>[69]</sup> and 447 mA hr/g<sup>[58]</sup> corresponding to stoichiometries of  $\text{Li}_{1.87}\text{C}_6$  and  $\text{Li}_{1.19}\text{C}_6$ , respectively). Besides, according to data reported by Ishihara et al.<sup>[70]</sup> the reversible Li capacity decreases when the graphitic nanotube surface area increases.

Gao et al.<sup>[63]</sup> found a diminished irreversible Li capacity on increasing structural defects density, but there are many experimental data proving the opposite. High-temperature heating up to 2800°C (Fig. 2B), which certainly improves structural and microtextural organization, considerably reduces the large hysteresis observed during the extraction of lithium from MWNTs, as seen in Fig. 2B.<sup>[58]</sup> Accordingly, Frackowiak et al.<sup>[58]</sup> and Leroux et al.<sup>[59]</sup> considered microstructural irregularities in the tube walls<sup>[58,59]</sup> along with surface-oxygenated groups generated by the oxidative chemical treatment fully responsible for the irreversible Li sorption phenomena. The substantial increase of the irreversible Li storage in the acid-oxidized MWNTs drove Yang, Wu, and Simard<sup>[62]</sup> to presume also that residual acid traces create defects and pores that contribute to a stronger Li bonding.

Li binding near H atoms present in MWNTs prepared by catalytic decomposition of hydrocarbons is an alternative explanation for their large irreversible Li capacities.<sup>[69]</sup> This assumption is based on the <sup>1</sup>H NMR data reported by Ivanov et al.<sup>[71]</sup> which showed that the total H amount (around 2 wt.%) in such samples saturating all free carbon vacancies in  $\text{sp}^3$  defects of the graphitic structure strongly decreases with an increase in reaction temperature. Other authors correlate the irreversible Li intercalation with the large amorphous carbon content identified by TEM investigations<sup>[72]</sup> and in Raman spectra,<sup>[73]</sup> dependent on MWNT synthesis conditions. The strong tendency of MWNTs for charges cumulating as condensers has been also proposed as an explanation for the large irreversible Li capacity<sup>[58]</sup> because the electrostatic attraction of lithium ions and other charged species during Li insertion at negative polarization may hinder the reverse process and involve higher voltage.

## ELECTRODES IN SECONDARY HYDROGEN BATTERY AND FUEL CELLS

The reversible hydrogen capacity of soot containing 0.1–0.2 wt.% SWNTs reported by Dillon et al.<sup>[74]</sup> draws attention to the possibility of hydrogen storage into the large empty space inside carbon nanotubes. They estimated a maximum hydrogen storage capacity of pure SWNTs of 5–10 wt.%, which was subsequently confirmed by experimental data (4.2<sup>[75]</sup> and 8 wt.%<sup>[76]</sup>) obtained at room temperature and modestly high pressure. Such values suggest carbon nanotubes as attractive candidates for secondary hydrogen battery and fuel cells electrodes. Nützenadel et al.<sup>[77]</sup> were the first to investigate the electrochemical hydrogen storage capacity of SWNTs, which are more practical for such applications. They showed that 20% SWNT-containing electrodes can electrochemically store relatively large amounts (110 mA hr/g corresponding to 0.39 wt.%) of hydrogen in half-cells with 6 M KOH electrolyte and Ni as counterelectrode. The electrodes for these electrochemical measurements were usually produced by mixing the nanotube sample with Ni,<sup>[78–80]</sup> but also with Cu,<sup>[77,81]</sup> Au, and Pd<sup>[77]</sup> as compacting powder for their stabilization. However, higher storage capacities have been obtained, such as 316 mA hr/g (1.2 wt.%) with purified and thermally treated SWNTs of large mean diameter (1.85 nm)<sup>[79]</sup> and 800 mA hr/g (2.9 wt.%)<sup>[81]</sup> by increasing the SWNT weight to 80%, respectively.

The experimental and theoretical studies reported by Lee et al.<sup>[78]</sup> brought valuable information on the electrochemical hydrogen storage of carbon nanotubes.<sup>[78]</sup> They found several steps in the hydrogen discharge cycles (Fig. 3A) suggesting the existence of different adsorption sites in good agreement with complex-shaped CV peaks (Fig. 3B). The peak height proportionality (1:1) to the sweep rate<sup>[80]</sup> proves that hydrogen adsorption/desorption controls the whole process. By using a self-consistent charge density functional-based tight-binding calculation formalism, Lee et al.<sup>[78]</sup> identified possible adsorption sites as top sites at the exterior and the interior of the tube wall for *atomic H*, and in the empty spaces inside the SWNTs for *molecular hydrogen*. The Raman spectra taken for hydrogen-charged samples annealed at high temperatures evidenced the existence of H<sub>2</sub> inside the carbon nanotubes and revealed the enlargement of tube diameters because of hydrogen storage.<sup>[78]</sup> Lee et al.<sup>[78]</sup> concluded that SWNTs are better than MWNTs for hydrogen storage because the hydrogen capacity increases linearly with tube diameters only in the first case, and predicted a maximum value of 14.3 wt.%.

Further theoretical calculations<sup>[82]</sup> have shown that C–H bonding changes the electronic properties of

**Fig. 3** Hydrogen charge–discharge curves of SWNT-based electrodes at a constant current of 0.4 mA for the first seven cycles (A) and typical cyclic voltammetric profile measured at 10 mV/sec in 6 M KOH (B). *Source:* From. Ref.<sup>[78]</sup>.

metallic carbon nanotubes to semiconductors, and have suggested that doping or addition of conductive materials may compensate for such undesirable effects. Qin et al.<sup>[80]</sup> found indeed that Ni used not only as compacting powder but also as porous substrate for preparing a 0.15% MWNT electrode exhibited a high discharge capacity (200 mA hr/g) as well as long charge–discharge cycle life. However, the chemical decoration of the carbon nanotubes with metallic Ni particles turned out to be more effective in improving the discharge capacity, to the prejudice of the cycle life, owing to a dramatic increase of the surface reaction resistance.<sup>[83]</sup>

Carbon nanotube electrodes also revealed interesting electrocatalytic properties in the reduction of dissolved oxygen as well as in methanol oxidation, which are important fuel cell reactions.<sup>[84]</sup> Chemical deposition<sup>[84]</sup> or inclusion of Pd, Ag,<sup>[84]</sup> Pt, and Ru<sup>[85,86]</sup> on/into carbon nanotubes has considerably improved such an electrocatalytic activity. As regards

electrochemical metal deposition on carbon nanotubes, it is surprising that only one report<sup>[87]</sup> exists so far despite the fact that a large number of metals and metal compounds have been inserted/deposited into/on carbon nanotubes (Refs.<sup>[88]</sup> and <sup>[89]</sup> and references therein).

## ELECTRODES IN ELECTROCHEMICAL SENSORS AND ACTUATORS

The electrocatalytic properties mentioned above recommend them as possible competitors for promoting electron transfer reactions in other electrochemical systems, too. Therefore it is not surprising that they have been already found active in the electrooxidation of some important biological molecules, proving their potential for biosensing devices. Britto, Santhanam, and Ajayan<sup>[90]</sup> reported the achievement of a high degree of reversibility in the oxidation of dopamine (an important neurotransmitter) on MWNT electrodes without any pretreatment to induce surface activation. The glassy carbon electrode modified with SWNTs manifested a very stable electrochemical behavior in catalyzing the oxidation of 3,4-dihydroxyphenylacetic acid (the metabolite of neurotransmitter dopamine)<sup>[91]</sup> up to a detection limit of  $4 \times 10^{-7}$  M. Considering their nanometer dimensions, such results may be useful for in vivo studies of neurotransmitters. The films of SWNTs functionalized with carboxylic acid groups showed also very stable cyclic voltammetric profiles in buffer solutions and promising electrocatalytic activity in the oxidation of biomolecules such as dopamine, epinephrine, and ascorbic acid.<sup>[92]</sup> The redox proteins cytochrome *c* and azurin, immobilized on/within open<sup>[93]</sup> and oxidized<sup>[94]</sup> MWNTs or DNA-modified MWNTs,<sup>[95]</sup> were found to give reproducible and well-behaved voltammetric responses, too.

Among the exceptional properties of carbon nanotubes, one counts their electrochemical actuator behavior, allowing for the direct conversion of electrical energy to mechanical energy. Discovered by Baughman et al.<sup>[96]</sup> the property of SWNTs of acting like artificial muscles was shown to generate higher stress than natural muscles and higher strains than ferroelectric actuators under physiological environment (e.g., in salt water) and low voltage.<sup>[97]</sup> Consisting of quantum chemical-based expansion because of electrochemical double-layer charging (Fig. 4), the actuation mechanism of SWNT electrodes was also found superior to that of conducting polymer actuators because it does not involve ion intercalation, which limits rate, cycle life, and energy conversion efficiencies.<sup>[96]</sup> Therefore single-walled carbon nanotubes offer interesting perspectives for

**Fig. 4** Variation of the strain of SWNT (bucky paper) strip vs. applied potential. *Source:* From Ref.<sup>[97]</sup>.

developing high-performance electromechanical transducers required for such diverse needs as robotics, optical fiber switches, or medical prosthetic devices.<sup>[97]</sup>

## CONCLUSION

Discovered in 1991,<sup>[1]</sup> carbon nanotubes unveiled remarkable properties that opened a broad field of possible applications. The electrochemical applications reviewed here propose attractive electrode materials for supercapacitors, secondary lithium and hydrogen batteries, fuel cells, biosensors, and actuators. There are also reports mentioning the possibility of using SWNTs as tips in scanning probe microscopy<sup>[98,99]</sup> and electrochemical NO sensing.<sup>[100]</sup> Many of them require, of course, further research effort to improve performance or to overcome setbacks, but they obviously offer valuable alternative solutions in various technological fields. Therefore carbon nanotube electrodes are expected to remain an inviting subject of study in nanoscience and nanotechnology for many years to come.

## Abstract

Carbon nanotubes (CNTs) have generated a high level of enthusiasm and interest in the nanoelectronics research community due primarily to their promising electrical conductivity and mechanical performance. In particular, theoretical and modeling studies have indicated that CNTs exhibit ballistic (scatter-less) electron transport properties, with minimal heat generation, along the axis of the tube. These projections have led to a wide range of explorative studies to determine the viability and applicability of CNTs as building blocks of nanoscale devices and signal interconnects in emerging integrated circuitry nodes. Accordingly, the current report is designed to provide a comprehensive review of pertinent features and characteristics of CNT technologies, including a description of synthesis, separation, and alignment techniques, a summary of potential inter-nanotube contacts, junctions, and connections, and an overview of possible pathways for nanotube integration in interconnect architectures for computer chips.

## INTRODUCTION

The historical drive toward higher speed and increased density in emerging generations of integrated circuitry (IC) has caused significant interest in innovative interconnect solutions that exploit the electrical properties of carbon nanotubes (CNTs). This interest is driven primarily by the projected property of “ideal” CNTs to sustain ballistic (scatter-free) electron transport, with little energy dissipation along the tube. Accordingly, nanotubes could provide critical performance enhancements in gigascale interconnect architectures, when compared with traditional electrical wires, thus potentially ensuring the continuation of Moore’s law well into the nanoscale regime.

In this respect, significant progress has been reported over the last few years in the development of CNT networks that display promising properties and performance in nanometer-scale devices and wiring schemes.<sup>[1,2]</sup> However, the potential gains presented by CNT-based wiring schemes have been hindered by practical considerations pertaining to challenges with current CNT fabrication and integration protocols.

Strategies to surmount this challenge can be divided into two broad categories, namely, non-directed and directed. The former involves precise postgrowth manipulation into desired positions, whereas the latter consists of directed assembly at desired locations through controlled synthesis. Both strategies share common issues and challenges. Common challenges include tailoring the electrical properties (metallic vs. semiconductor) of the nanotubes, establishing reliable ohmic contacts between nanotubes and metallic leads, and forming tightly controlled internanotube connections in complex wiring architectures. In addition, directed self-assembly still necessitates a high thermal budget that is prohibitive to integration with Si complementary metal oxide semiconductor (CMOS) technologies.

Accordingly, this entry summarizes achievements to-date, highlights ongoing roadblocks in CNT-based interconnect design and assembly, and presents potential prospects for future innovative solutions. It is divided into the following sections: “Synthesis, Separation, and Alignment” deals with CNT synthesis and alignment challenges, and “Internanotube Contacts, Junctions, and Connections” addresses CNT integration into predesigned and useful architectural schemes.

## BACKGROUND

One primary challenge in the implementation of CNTs into interconnect technologies is the ability to position the nanotubes controllably and reproducibly at pre-specified locations with nanometer-scale precision.

## SYNTHESIS, SEPARATION, AND ALIGNMENT

This section is intended as a brief overview of CNT fabrication techniques because the topic has already been discussed in detail elsewhere.<sup>[1]</sup> As indicated

above, CNT synthesis can be divided into non-directed and directed. The first case requires postgrowth positioning, a method that is time-consuming, highly inefficient, not amenable to scale-up procedures for manufacturing, and inconsistent with prevailing silicon fabrication protocols.

In contrast, directed synthesis of tubes at predetermined locations, basically through direct patterning of the substrate or through predeposition patterning of a solid catalyst on the substrate, offers a significantly higher throughput option. However, these approaches are subject to the same lithographic limitations in shrinking design rules as those faced by conventional interconnects. In addition, because directed synthesis is highly surface-sensitive, nanotube orientation is determined, at least in part, by substrate-controlled growth. Alternatively, postsynthesis manipulation offers user-defined orientation, an advantage that may prove to be useful in advanced device architectures.

### Non-directed Synthesis

Various methods for synthesizing tubes in large quantities have been reported, including arc discharge,<sup>[2–4]</sup> laser ablation,<sup>[5]</sup> and chemical vapor deposition (CVD).<sup>[6–9]</sup> All these approaches require a two-step fabrication process, wherein the nanotubes are grown first, then individually transported to the substrate and manipulated into the desired location. This method is sometimes referred to as “Grow-then-Place” technique. In these methods, undesirable materials such as amorphous carbons, residual catalyst particles, partially formed nanotubes, and even fullerenes are present in the resulting product, which typically consists of graphite-like soot that contains embedded nanotubes. Therefore, fully formed nanotubes must be separated prior to use (Fig. 1). In this respect, synthesis-produced impurities, as well as any carbon overcoat on the tubes, can be removed by oxidation purification, either in an oxygen environment at elevated temperatures,<sup>[2]</sup> or by refluxing nanotubes in a nitric acid solution to oxidize amorphous carbon and metal catalyst particles.<sup>[10]</sup> Unfortunately, these treatments require a high thermal budget (exceeding 3000°C), and are time-consuming and inefficient.

As-grown tubes generally stack into a hexagonal lattice with parallel alignment of individual tube axes. In this form, the bundled tubes, sometimes referred to as a rope, resemble a log pile (Fig. 2). Although these as-grown tube bundles may contain impurities, recent work suggests that the ropes could “clean” themselves as they dry up from the solution, forcing previously enmeshed carbon spherules into an outer shell surrounding an inner core of predominantly

**Fig. 1** Bright field TEM image of CNTs grown by non-directed synthesis. The resulting products of non-directed synthesis techniques typically contain residual catalyst particles, partially formed nanotubes, and undesired carbon-based compounds from which fully formed tubes must be separated prior to utilization.

aligned nanotubes.<sup>[11]</sup> Additional solution chemistry-based techniques have been used to grow ropes that self-assemble into periodic cross-bar structures.<sup>[12]</sup>

CVD growth of nanotubes requires a catalyst in the form of solid particles (primarily transition metals such as Fe or Ni) or gaseous compounds (typically ferrocene), which are introduced into the reactor with the precursor hydrocarbon gas. The possibility of patterning either the solid catalyst or the substrate in the case of gaseous precursor will be discussed “Directed Synthesis.”

Once purified (if necessary), tube bundles may need to be separated to use individual tubes.<sup>[13]</sup> This separation is often accomplished through sonication in a surfactant, such as sodium dodecyl sulfate. The surfactant overcomes the van der Waals attraction between the tubes, allowing dispersion on a surface.<sup>[14]</sup> Alternatively, the intertube attractive force can be overcome through the application of a lateral separation force via use of an atomic force microscope tip.<sup>[15]</sup> Still another route under exploration is chemical derivatization. When attached to nanotube sidewalls, large organic groups block bundle formation by intervening between tubes to overcome van der Waals forces.<sup>[16]</sup> This functionalization process may also prove useful at rendering specific types of tubes more soluble than

**Fig. 2** Bright field TEM image showing multiple single-walled CNTs aligned in bundles.

others. For example, in a population of nanotubes with varying diameters, certain metal complexes seem to preferentially solubilize smaller-diameter tubes.<sup>[17,18]</sup>

After separation, individual tubes are dispersed on a substrate and then manipulated into place to form the desired circuit elements. A number of techniques have been used to achieve the desired placement of tubes, including mechanical forces, external electric fields, liquid and gas flows, Langmuir–Blodgett films, and self-assembly. Of these, the first three are the most common and most promising methods, and will be discussed in more detail.

The most common method of manipulation is to physically drive a tube across a surface using the tip of a scanning probe microscope (Fig. 3).<sup>[19,20]</sup> Any desired wiring scheme could be formed in this manner. However, controllability of this mechanical process is achieved in this process at the expense of scalability, and it is highly unlikely that this approach will ever

be considered for applications in nanoscale interconnect fabrication schemes.

More recent demonstrations of tube-positioning methods have involved nanotube functionalization, including connecting biological molecules, such as deoxyribonucleic acid (DNA), to the tubes to form more easily manipulated colloidal suspensions.<sup>[21]</sup> The exploitation of DNA recognition properties provides an elegant pathway to control interactions between nanotubes, and to customize engagements with substrate features, such as DNA-labeled electrodes.<sup>[22]</sup> Similar biological molecules offer a variety of chemical handles to enable both selective surface attachment and electrical/optical behavior modification.<sup>[23]</sup>

More importantly, this functionalization approach offers the potential to utilize the ability of DNA to self-assemble into well-organized molecular helical chains from building blocks called peptides. Peptide self-assembly can occur in various forms, including the well-known DNA helix, and flat, laminar arrays called  $\beta$ -sheets. The latter can self-align to form mesoscopic layered structures called lamellae, a process that is controllable, reproducible, and amenable to scaleup on large area substrates.<sup>[24,25]</sup> Thus, the identification of reliable protocols for integration of nanotubes with DNA molecules could eliminate a key obstacle to their incorporation into mainstream Si electronics by exploiting manufacturable DNA self-assembly techniques that are compatible with prevailing silicon fabrication processes.

Another method used in nanotube processing is often referred to as a field-driven method. In the past, dielectrophoresis has been used for manipulating, trapping and separating micro- and nanoparticles. For example, researchers from Rice University used dielectrophoresis to separate SNW tubes according to their size.<sup>[26]</sup> More recently, this technique has been successfully extended to placement of carbon nanotubes.<sup>[27]</sup> More specifically, when a polarizable object is placed in a non-uniform electric field, due to its interaction with the field, it exhibits a translation motion, which

**Fig. 3** Schematic diagram depicting the manipulation of a single CNT by the tip of an atomic force microscope. Although this method allows for precise control of tube placement, it is inherently slow, inefficient, and not amenable to large-volume manufacturing.

forms the basis of dielectrophoretic assembly. In the presence of the field, nanomaterials are attracted in gaps where the gradient of the electric field is maximum or minimum.<sup>[28]</sup>

Assembly of carbon nanotubes has also been achieved recently in what is referred to as a “flow-directed” process, using either a liquid<sup>[29]</sup> or a gas<sup>[30]</sup> to provide the microfluidic force. Such methods rely on the shape anisotropy of the nanotubes in a droplet of solution to enact the alignment. Tubes that are not parallel to the flow will experience a force in proportion to the projected cross-section they present to the direction of flow, and will thus rotate to align with that flow, much the same as logs being transported down a river align with its flow. The degree of alignment, in other words, the distribution of angular orientations can be controlled by a number of experimental parameters such as flow rate and substrate choice. Use of this technique can result in highly aligned collections of nanotubes, although the ability to place of individual tubes, for example between two electrical contacts, is limited. The combination of a flow-based system in a microfluidic channel may be able to overcome this issue, although the fabrication of the channel system would be subject to the same lithography challenges facing conventional interconnects.

## Directed Synthesis

In contrast to non-directed synthesis, directed synthesis could result in the controlled and selective growth of CNTs in a one-step process on predetermined locations on a substrate. This method is often referred to as “Grow-in-Place” technology. Three principal methods have been employed: 1) template-directed synthesis, in which nanopores constrain tube growth locations; 2) solid catalyst-controlled synthesis, in which tube growth occurs exclusively in catalyst-rich locations; and 3) patterned substrate-driven synthesis, in the case of a gaseous catalyst, in which selective growth occurs only on specific surfaces (e.g., on SiO<sub>2</sub>) but not on Si or native oxide. Relevant details of each method are described below, along with respective advantages and disadvantages as pertaining to interconnect applications.

### Template-directed synthesis

Template-directed synthesis uses preexisting nanopores to constrain the growth of nanotubes. The template material (e.g., aluminum oxide) is anodized to form nanopores.<sup>[31,32]</sup> Individual pore diameter and length are controlled by anodization processing parameters, in particular the applied voltage, duration, and chemistry of the solution to which the aluminum oxide is

exposed.<sup>[33,34]</sup> Carbon nanotubes are then synthesized within the pores. In addition to the physical constraint imposed by pore size, tube thickness is controlled by the concentration of reaction gases.<sup>[34]</sup> Because tubes grow in accordance with the structure of the nanopores, variations in template profiles generate associated changes in nanotube shapes, for example, a template consisting of Y-shaped nanoholes to the growth of similarly branched nanotubes, thus resolving a significant issue for nanotubes, namely, the formation of nanotube junctions. However, it should be noted that the resulting resistance of a branched tube is increased—an effect that is attributed to the formation of a heterojunction with local variations in tube diameter.

### Catalyst-controlled synthesis

In systems employing solid catalysts, the directed growth of nanotubes can be controlled through the predeposition patterning of catalyst particles. This approach has been successful in producing aligned CNT structures,<sup>[35–39]</sup> although growth is generally constrained to one dimension (Fig. 4). In a recent demonstration of this concept, a methodology was developed to grow nanotubes in a direction perpendicular to the surface of a patterned catalyst, and then fill the gaps between tubes with silicon dioxide.<sup>[40]</sup> A subsequent chemical-mechanical polishing step removed the surface of the silicon dioxide to expose the tips of the nanotubes. Electrical contacts could then be patterned to engage individual tubes or rows of tubes, depending on the spacing between the tubes as determined by the spacing within the patterned catalyst matrix.

Another recent method places the catalyst in patterned vias and contact holes.<sup>[41]</sup> This approach eliminates the need for added architectural or processing manipulation, as the wiring scheme used in this approach requires minimal modification from current metallization schemes for electrical interconnects. Because the catalyst is metallic, it can act as one of the electrical contacts to the underlying device layers, although the upper electrode must still be deposited by other means—in this case, focused ion beam (FIB). Using a similar approach, the entire nanotube networks have been synthesized using prepatterned metallic contacts that act as “catalytic anchors.”<sup>[6]</sup> In this case, ropes of single-walled nanotubes (SWNT) self-align in a cross-bar pattern on the surface.<sup>[42]</sup>

### Patterned substrate-driven synthesis

In this case, the catalyst is introduced as a gaseous precursor, such as ferrocene, into the CVD reactant mixture.<sup>[43]</sup> Such a growth often leads to encapsulated

**Fig. 4** Scanning electron microscopy (SEM) images of as-grown MWNTs on (A) 100-nm-diameter catalyst spots; (B) 2- $\mu\text{m}$ -diameter catalyst spots; (C) a catalyst film deposited at aligned markers over 10  $\mu\text{m}$  in size; (D–F) images corresponding to those in (A–C), respectively, after being encapsulated in  $\text{SiO}_2$ ; (G) high-magnification SEM image of an MWNT array; (H) TEM image of the single MWNT from the array; (I) SEM image of the top surface of the embedded CNT array after CMP. The perspective of all the SEM images is  $45^\circ$ . The scale bars are 5, 3, 10, 2, 5, 10, 1, 0.2, and 0.2  $\mu\text{m}$ , respectively. *Source:* From Ref.<sup>[37]</sup>.

catalyst material within the core of the nanotube. Selective nanotube growth is driven primarily by the identity of the substrate surface. For example, in the case of a patterned surface consisting of Si and  $\text{SiO}_2$ , the fabrication process can be customized to grow nanotubes perpendicular to any exposed  $\text{SiO}_2$  surfaces, but not on the native oxide or Si.<sup>[43,44]</sup> Nanotube growth can occur not only perpendicularly to the wafer surface, but also in arbitrary directions, simply by customizing the orientation of the  $\text{SiO}_2$  surfaces prior to nanotube growth<sup>[41]</sup> (Fig. 5). Clever choices in the geometry of the  $\text{SiO}_2$  allow three-dimensional (3D) architectures such as networks.

In one embodiment of this technique, growth was initiated from the facets of magnesium oxide (MgO) crystallites, which also resulted in the encapsulation of Fe particles within the core of nanotubes (Fig. 6). Although the nanotube diameter and shape are unaffected by the crystal orientation of MgO, the nucleation density of tubes is much larger along the (111) plane than the (100) plane.<sup>[43]</sup>

In another embodiment of this technique, vertically aligned nanotube structures were grown under

patterned Ni films, actually lifting the Ni off the underlying Si substrate.<sup>[45]</sup> The concentrations of Ni catalyst and vapor reactants determined the nature of tube growth, which occurs either in oriented bundles or in a “furlike” manner. A key advantage of this method is that patterning of the metallic film prior to nanotube growth not only controls the location of nanotube growth, but also provides metallic (ohmic) contact to the nanotube. The disadvantage is that this approach is restricted by the limitations of current lithography techniques because the latter are applied to pattern the catalyst layer.

In summary, the directed synthesis methodology offers distinct advantages over its non-directed synthesis counterpart for interconnect applications. These advantages include controlled growth of nanotube structures selectively and reproducibly, directly over large-area substrates in a one-step process, and demonstrate customization of nanotube shape, direction, and intertube junction formation. In addition, directed synthesis offers the promise of scalability, and thus the potential for incorporation in nanoscale interconnect fabrication schemes. However, its disadvantages

**Fig. 5** SEM images of nanotube arrays grown on patterned substrates using gaseous catalyst. (A) Columns consisting of tens of nanotubes grown vertically on patterned SiO<sub>2</sub> substrates. No growth occurs on exposed Si surfaces. (B) Higher-magnification image of one set of columns. (C) Repeating patterns of nanotubes demonstrating growth perpendicular to orthogonal silica surfaces. include the need for high processing temperatures that are prohibitive to integration with Si CMOS technologies. In addition, it lacks flexibility in the formation of complex wiring schemes given that nanotubes typically grow in one specific direction relative to the surface.

### INTERNANOTUBE CONTACTS, JUNCTIONS, AND CONNECTIONS

“Synthesis, Separation, and Alignment” highlighted opportunities and challenges in the fabrication of CNT interconnects for incorporation in complex metallization schemes. This section presents progress to-date and associated challenges in the formation of actual intertube contacts, junctions, and connections. Although still in its very early stages of feasibility, the successful demonstration of reliable intertube connections is an essential prerequisite to the successful development of nanotube interconnect schemes.

As described earlier, intertube connections can be formed during growth. For example, Y-shaped tubes

can be made using Y-shaped nanopores during template-based synthesis. Similarly, nanotubes grown on metallic catalysts or patterned metal sites are already coupled to a metallic contact that could be used to input or extract signal from the nanotube. However, postgrowth tube–tube connection methods are also of considerable technological interest. Accordingly, the most promising methods will be described in this section. Tube–tube junctions fall into two categories: crossed-tube junctions, wherein physical contact between two tubes forms the basis of a connection, and on-tube junctions, wherein chemical bonding provides the basis of the connection, with interfacial chemical bonds within individual tubes being rearranged to join the constituent tubes.

### Crossed-tube Junctions

Crossed-tube junction behavior is closely related to that of structures containing multiple tubes, such as multiwalled nanotubes (MWNTs) and SWNT ropes. Although in close physical proximity, the tubes within

**Fig. 6** High-resolution TEM image of a multiwall CNT with an iron-filled core. Because this image is a projection of the structure, the concentric walls of a CNT can be seen as nearly parallel lines in the outer regions of the tube. The core is filled with iron, which was used as a catalyst in the growth of this tube. In the lower right portion of the image, a regular array of dots can be seen, corresponding to individual columns of iron atoms.

such structures are not chemically bonded to one another (Fig. 7).<sup>[46]</sup> Therefore, the conduction mechanism through such assemblages is more complex than the simple ballistic transport expected for a perfect SWNT, and is significantly impacted by intratube and intertube structural deformations.

In the case of crossed tubes, intertube distances can be controlled through the application of pressure, via an AFM tip for example.<sup>[18]</sup> The pressure generates an overlap of the electronic wave functions across the junction, thus favoring intertube tunneling. In the case of small structural deformations that induce only a smooth bending of the tubes, minimal scattering is expected to occur.<sup>[47]</sup> Theoretical calculations also suggest that, at least for these moderate contact forces, electron backscattering is also suppressed.<sup>[48]</sup> However, significant structural deformations may produce appreciable scattering, thus causing resistive losses. In the extreme case that one tube is actually kinked around another, local  $\sigma$ - $\pi$  bond mixing may be induced, which results in electron backscattering similar to that caused by impurities.

In the case of SWNT ropes, recent calculations suggest that intertube couplings within ropes do significantly affect fundamental SWNT rope properties. In simulations of a large, perfectly ordered rope composed of (10,10) tubes, broken symmetry because of intertube interactions resulted in band repulsion and formation of a pseudo-gap in the density of states of approximately 0.1 eV. Because of the presence of this pseudo-gap, electronic transport properties were predicted to be altered.<sup>[49]</sup> Furthermore, recent experimental studies examined the coupling between individual tubes in a rope of SWNTs.<sup>[50]</sup> In this case, the top

**Fig. 7** Schematic representation of crossed nanotube junctions. The contact between tubes can be enhanced by the application of pressure (e.g., by pressing on the junction with an AFM tip). Source: From Ref.<sup>[46]</sup>.

tubes in a rope were deliberately damaged by ion sputtering prior to electrode deposition, which introduced strong scattering centers in the current-carrying tubes at the rope surface. Under low-temperature conditions, the charge tunneled into an undamaged, metallic tube in the bulk of the rope, leading to a dramatic decrease in resistance. Measured intertube resistance indicated direct tunneling transport between tubes with a penetration depth of approximately 1.25 nm.<sup>[50]</sup>

One novel methodology for joining tubes using a “bandage” of double-walled CNTs to bind other strands together has been used to form structures of arbitrary length.<sup>[51]</sup> A wet “bandage” is wrapped around the end of two strands and allowed to dry, during which process it shrinks and binds the other strands together. Electrical testing showed that the joined section had a lower resistivity than the unwrapped segments, and burnout failures occurred away from the joint. These joined strands were capable of carrying current densities as high as  $10^7$  A/cm<sup>2</sup>, although the contact areas between the tubes within the strand still limited the overall performance of the structure.

In the case of MWNTs, the interplanar stacking disorder of adjacent layers decreases the electronic coupling between such layers when compared with graphite.<sup>[52]</sup> Because there is only weak coupling between MWNT shells at low bias or low temperature,<sup>[53,54]</sup> the current applied to the system under these conditions is essentially transported through the outermost layer of the tube—the only shell in contact with electrodes.

One study took advantage of this characteristic by exposing MWNTs to high current densities, exceeding  $10^9$  A/cm<sup>2</sup>, to execute a controlled breakdown of successive outer shells. This allowed a systematic study of the electronic properties of each concentric constituent shell of the MWNT.<sup>[13]</sup> It was determined that leakage current through inner metallic shells contributes to electron transport at room temperature and low bias, whereas all shells in the MWNT contribute to electronic transport under high-bias conditions. In either case, charge transport in the innermost MWNT shells is tunneling barrier-dominated, as these tubes are separated from electrical contacts by a barrier composed of a series of intervening graphitic shells.<sup>[13]</sup>

Accordingly, the theoretical models and experimental findings are in agreement that in their current form, crossed-tube junctions of SWNT ropes and MWNTs might not be appropriate vehicles for nanoscale interconnect applications, primarily because of the inability to control intratube and intertube electron transport mechanisms, leading to adverse and undesirable conductivity characteristics.

### On-tube junctions

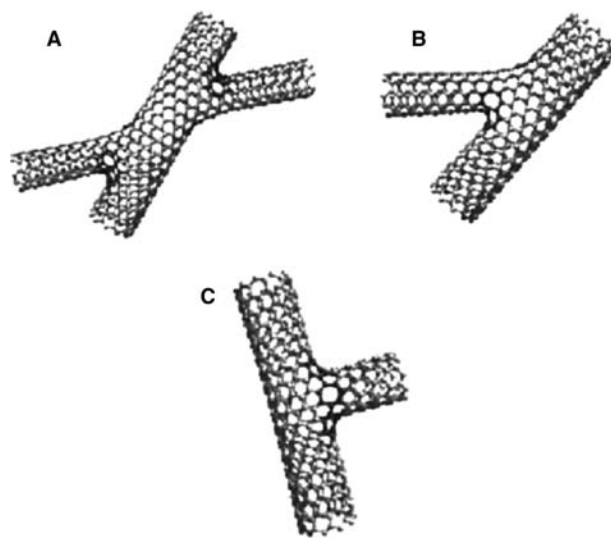

On-tube junctions, although more difficult to fabricate than their crossed-tube junction counterparts, are more desirable because of their potential to provide innovative, diverse, and flexible approaches to the formation of nanotube interconnects with the desired conductivity behavior. The simplest form of an “on-tube junction” can result from bending a straight tube sufficiently to introduce a pentagon–heptagon structural pair into the graphitic matrix.<sup>[55]</sup> This action results in a permanent bend in the tube, which could be considered a junction between two tubes meeting at a small angle, thus resulting in some quite interesting electron transport characteristics.

For instance, a symmetric pentagon–heptagon junction tends to resist the flow of electrons, whereas its asymmetrical analog allows electronic flow. In this respect, topology alone cannot determine the electrical behavior of a junction because a bent junction may provide a better electrical path than a straight one. In theory, it is possible to connect two metallic nanotubes using pentagon–heptagon pairs by choosing appropriate tube diameters. Theory further predicts

that “X,” “Y,” and “T” SWNT junctions are stable and could be used as multiterminal electronic devices or joined wiring structures (Fig. 8).<sup>[45,56–58]</sup> However, theoretical predictions indicate the possible existence of localized interference states at these junctions, depending on tube diameter and chirality. The effect of such states on the stability and use of these junctions is still not clear.<sup>[57,58]</sup>

Although several such junctions have been observed experimentally,<sup>[13,17]</sup> the controlled synthesis of these structures remains challenging. As was previously described, it is possible to form “Y”-shaped nanotubes during growth by using a template with suitably shaped nanopores.<sup>[33]</sup> Other growth processes and nanofabrication manipulations have been used to make one-dimensional (1D) and two-dimensional (2D) connections with such nanotubes.<sup>[34,59,60]</sup> However, a majority of current methods for creating such junctions focus on postgrowth formation by connecting tubes that were not initially joined during synthesis. These methods also require a high thermal budget and necessitate additional processing steps, such as concurrent electron irradiation.

For example, SWNT “X” junctions were fabricated by irradiation of crossed nanotubes at 800°C in a 1.25-MeV, 10-A/cm<sup>2</sup>, 100-nm-diameter beam in a transmission electron microscope “X.”<sup>[48]</sup> By adjusting the irradiation conditions, one of the “arms” was removed to create stable Y or T junctions. Thus, junction geometry can be tailored as needed, albeit slowly because of the serial nature of the process. In this respect, heat-assisted irradiation is necessary to avoid significant sputtering effects that would have taken

**Fig. 8** Atomic model of the CNT “on-tube” junctions: (A) “X”-like, (B) “Y”-like, and (C) “T”-like junction, respectively. Source: From Refs.<sup>[45,48]</sup>

place at room temperature irradiation, leading to undesirable dimensional changes and surface reconstructions.<sup>[61,62]</sup> The application of elevated temperature allows recombination of vacancy-interstitial pairs prior to the formation of interstitial agglomerates.<sup>[56,63–65]</sup> Although the topology of the resulting junctions matched those predicted from idealized molecular modeling, the latter structures could not be confirmed. Furthermore, theoretical calculations of local density of states for “treated” and perfect junctions suggest that the latter do not alter the metallic or semiconducting behavior of the tubes, although no experimental confirmation has been provided yet.<sup>[48]</sup>

Unfortunately, on-tube junction fabrication processes continue to be a challenge in terms of complexity, scalability, and adaptability to prevailing large-volume semiconductor manufacturing protocols.

## NANOTUBE INTEGRATION IN INTERCONNECT ARCHITECTURES

### Densification

Carbon nanotubes are promising candidates for IC interconnect because in addition to their ability to carry a very high current density ( $\sim 10^9$  A/cm<sup>2</sup>) exhibit a ballistic transport along the tube, and resist against electromigration,<sup>[66–68]</sup> they can potentially have higher conductivity than copper. However, a high nanotube site density (i.e., tubes per unit growth area) and closely packed structures are required for interconnect applications since the more the conduction channels are available, the less is the resistance expected.<sup>[68]</sup> Unfortunately, the reported CNT site densities<sup>[69–71]</sup> are still one or two orders of magnitude below the ideal one. Therefore, densification techniques have been investigated targeting growth of CNTs to prove their potential benefits over traditional copper interconnect technology.

The first method is based on CNT densification after their growth process. It has been noted that after immersing CNTs into a liquid and drying, CNTs can aggregate into “hut”-like structures<sup>[72–74]</sup> or cellular patterns<sup>[74,75]</sup> due to capillary coalescence. Liu et al. immersed the as-grown CNT bundles in the organic solvent isopropyl alcohol and then dried out the samples by evaporation in atmosphere at room temperature. Isopropyl alcohol (IPA) evaporation lowers the liquid level pulling CNTs toward each other by the capillary forces, bringing them close enough for the van de Waals force to dominate and result in sticking of the tubes to each other. It was observed that for optimized length of the CNTs (in the range of 30–65  $\mu$ m), good densification was obtained, and bundle

diameter reduced from the original 20  $\mu$ m to 8.3  $\mu$ m, increasing site density 5.8 times.<sup>[76]</sup> The site density value was still  $\sim 20$  times less than the theoretical value for tube with these dimensions, but since it was noted that densification is affected by the bundle height, diameter, pitch, and the CNT properties (e.g., diameter, shell number, density, alignment, and uniformity), the assumption is that densification method could be further improved by process optimization.

The second approach to densification of aligned carbon nanotubes (ACNTs) focuses on filling the interstitial space between nanotubes with solid materials.<sup>[77–79]</sup> One of the methods employed uses chemical vapor infiltration (CVI), which extends the commonly used chemical vapor deposition (CVD) process by altering the deposition kinetics toward a mass-transfer limited process.<sup>[80,81]</sup> Two approaches have been taken, one in which infiltration of ACNT films were conducted in a separate CVD/CVI process,<sup>[77,78]</sup> and second in which a simultaneous growth of nanotubes and their densification by carbon infiltration was performed in one process step.<sup>[82]</sup> Measurements of CNTs grown using the simultaneous CVD/CVI densification method showed increased by an order of magnitude in both diameters and bulk density (defined as the mass of the film divided by its volume) of the ACNT films. This simplified densification method resulted in conformal coating of ACNTs by partially graphitized pyrolytic carbon and when optimized (longer growth times  $>1$  hr) showed more than five times increased total film conductivity.<sup>[82]</sup>

### Contacts

Clearly, the successful development of nanotube interconnect architectures requires nanotube integration with more traditional metal and semiconductor leads and contact pads. However, the significantly different physical, chemical, and electrical properties of nanotubes, when compared with conventional metals and semiconductors, add another level of complexity to the challenges facing their potential use. Material compatibility issues are further compounded by the adverse effects that current metal, lead, and contact deposition processes could exert on the structure and chemistry of the nanotubes, and on the stability of the nanotube–metal interface.

A novel approach to studying this nanotube–metal interface was recently reported by Avouris et al. Inhomogeneities, such as defect sites or the Schottky barriers found at metal–nanotube interfaces, produce resistance and can thus generate local electric fields capable of accelerating carriers and generating electron–hole pairs “through an intra-nanotube impact-excitation process.”<sup>[83]</sup> A fraction of this energy can

then be emitted in the form of photons, much as in the widely known electroluminescence process currently employed in devices such as light-emitting diodes (LEDs). Further study of this radiative emission and of the reverse process, photoconductivity, could provide useful insight into the nature and effects of CNT contacts on electrical properties.<sup>[84]</sup> Such information is vital to successful integration of nanotubes into traditional material sets.

First integration attempts involved nanotube dispersal on lithographically defined contact pads on an insulating surface. However, it was later shown that a tunneling barrier formed at the metal/CNT interface, which hampered transport studies.<sup>[60,85]</sup> More recent approaches involved the deposition of electrodes, typically by electron- or ion-beam induced deposition (EBID or IBID, respectively) in an FIB, directly onto the CNTs (Fig. 9).<sup>[41,86–90]</sup> The IBID approach produced partial collapse at the edges of the tube,<sup>[91]</sup> thus resulting in improved physical and electrical contact, although the potential exists for significant ion-implantation damage to the CNT, which can be avoided through the use of EBID.

The charged-particle beam methods can provide an elegant approach to nanomodulate the interfacial structure and electrical characteristics of a nanotube through location-specific doping of a narrow transition region between a nanotube and a metal or semiconductor. One key advantage of this methodology is the successful integration of nanotubes within a metal or a semiconductor matrix through the formation of a

**Fig. 9** FIB image of CNT-Pt contacts. The Pt leads were fabricated directly on the multiwall CNT by IBID in an FIB microscope. The contacts were connected by intermediate leads (one of which is visible at the top of the image) to large ( $150 \times 150 \mu\text{m}^2$ ) probe pads patterned by conventional lithography on a  $\text{SiO}_2$  substrate. Source: From Ref.<sup>[87]</sup>.

gradual transition region between these two dissimilar material systems. Another advantage is the ability to use a dual-beam FIB/SEM system as an in situ alternative to ex situ electron beam (e-beam) lithography for the fabrication of ultrathin metal lines for the formation of reliable CNT-metal contacts.

These advantages are exemplified in Fig. 10, which displays an IBID-grown MWNT-Pt pad.<sup>[85,87]</sup> In particular, the transmission electron microscopy (TEM) image of the MWNT-Pt contact (Fig. 10B) highlights the buildup of Pt along the sides of the MWNT, whereas the associated high-resolution TEM image of the Pt/MWNT interface demonstrates the presence of Pt nanocrystals only on the outermost wall of the nanotube, with the overall integrity of the MWNT preserved.

Alternatively, tube nanocontacts can be fabricated by e-beam lithography and subsequent liftoff of metal electrodes, such as Ti or Au.<sup>[92]</sup> As in the case of IBID, these techniques require further investigation to document the effects of the metal deposition process on nanotube structure and chemistry, and stability of the CNT/metal interface. In some cases, these effects can be minimized by post-treating the samples by rapid thermal annealing (RTA) to form an ohmic contact at the metal-nanotube junction,<sup>[33]</sup> or through the use of an Au coating on the electrodes to reduce contact resistance to the nanotube.<sup>[93]</sup>

One recent publication offers yet another alternative for creating well-bonded contacts to CNTs using an ultrasonic wire bonder.<sup>[94]</sup> A droplet of solution containing nanotubes was allowed to dry on top of the electrodes, then fortuitously positioned CNTs were chosen for bonding using a clamping force of 78.4 mN with an ultrasonic vibration of 60 kHz applied through a transducer. This combined action of the vibrations and normal clamping force embedded the ends of the CNTs into the Ti electrodes. Subsequent electrical testing deduced an effective barrier height of  $\sim 6.6$  meV, less than half of what has been reported for the high-temperature annealing method ( $\sim 15$  meV). The Schottky barrier width was estimated at  $\sim 0.9$  nm at  $V = 0$ , two orders of magnitude lower than has been previously reported in the literature. The feasibility of implementing a technique over large areas has yet to be studied, but the results are quite encouraging.

On the other hand, Kumar et al. used a more traditional packaging-like approach in which the as-grown CNTs were transferred onto the contact pads using low temperature solder alloys such as eutectic AuSn and SnAg.<sup>[95]</sup> This process involved the annealing of solder substrate in tight contact with carbon nanotube substrate. The carbon nanotube bundles penetrated into the molten solder surface and were entrapped during solidification of the solder pads.

**Fig. 10** (A) Low-magnification TEM image of a Pt pad deposited on top of an MWNT using an 11-pA ion beam current and a  $\text{Ga}^+$  dose of  $10^{16}$  ions/ $\text{cm}^2$ . (B) A higher-magnification section of the MWNT-Pt contact highlights the buildup of Pt along the sides of the MWNT. (C) Associated selected area diffraction pattern shows both a diffused ring pattern attributed to amorphous Pt, and an arc pattern ascribed to the 0.34-nm interwall distance of the MWNT. (D) High-resolution TEM image of the Pt/MWNT interface demonstrates the presence of Pt nanocrystals on the outermost wall of the nanotube. *Source:* From Ref.<sup>[87]</sup>.

In this method, the final nanotube structure is defined simply by the solder pattern predefined on the substrate. The electrical and field emission measurements show that good contacts of CNTs can be made with the conducting substrates after solder-based transfer. Similar observations were made by the Zhu et al. study in which the CNTs were transferred using PbSn solder.<sup>[96]</sup>

## CONCLUSIONS

The knowledge base in materials, processing, and integration necessary for the design and fabrication of specific nanotube structures continues to grow steadily, but has not yet matured to the level necessary for implementation into manufacturable nanoscale interconnect schemes.<sup>[97]</sup> Researchers today are faced with some of the same fundamental challenges faced in early investigations of these materials, including the lack of reliability and reproducibility in the large-scale, high-volume fabrication of nanotubes with predefined diameter and chirality, and therefore controlled electronic properties.

Beyond the issue of nanotube synthesis lie serious engineering challenges in the application of nanotubes as interconnects. Ongoing research has focused on two main pathways for integration: 1) non-directed growth

approach with subsequent manipulation of tubes to desired locations, and 2) directed growth at desired locations through exploitation of surface selectivity of prepatterned substrates or catalysts. Several recent reports have demonstrated organized assemblies of CNTs in architectures analogous to conventional interconnect topographies, such as vias and contact holes; however their use is limited at the moment by non-sufficient site density (i.e., tubes per unit growth area).

A corollary to the integration issue is the need for better control of nanotube–nanotube and nanotube–contact-joining methods. In particular, current assumptions suggest that perfectly straight tubes may be required to achieve ballistic transport in interconnects.<sup>[54]</sup> Therefore, to minimize losses at junctions, it is crucial to develop and optimize reliable methods, such as electron irradiation, template-mediated growth, and nanotube manipulation. Similarly, advances have been made regarding the quality and integrity of metal/tube interfaces, a key prerequisite that will ultimately determine whether the promising electrical and optical properties of CNTs will ever be realized.

# Carbon Nanotube–Metal Matrix Composites

Efraín Carreño-Morelli

Design and Materials Unit, University of Applied Sciences of Western Switzerland, Sion, Switzerland

## INTRODUCTION

Metal matrix composites (MMCs) are currently employed in high-performance applications in the transportation, aerospace, defense, and electronic industries. They combine the most attractive properties of their constituents such as the formability and toughness of the metal matrix and the high strength and stiffness of the ceramic reinforcement, or the high thermal conductivity of the matrix and the low thermal expansion of the reinforcement. In particular, aluminum- or magnesium-based MMCs offer a unique combination of lightweight, high specific stiffness, good fatigue properties, and good electrical and thermal conductivity. Titanium-based MMCs exhibit high strength and stiffness and elevated temperature performance. Copper matrices are of interest when high thermal conductivity and temperature resistance are required, for example, in electronic packaging applications.

Most MMC fabrication is carried out by melt infiltration of ceramic preforms, slurry casting, powder compaction, and spray deposition methods. By an appropriate selection of matrix, reinforcement, processing route, and postprocessing thermomechanical treatment, the final material properties can be designed for specific applications. In structural applications, a good *interfacial strength* ensuring effective *load transfer* between matrix and reinforcement under an external applied stress is essential for the overall mechanical performance.<sup>[1–5]</sup>

The discovery of carbon nanotubes (CNTs) by Iijima<sup>[6]</sup> opened new perspectives for the development of composite materials, because of their remarkable mechanical, electrical, and thermal properties. As a matter of fact, high Young's modulus up to 1.3 TPa makes CNT the ultimate high strength fibers to be used as reinforcements in composite materials.<sup>[7,8]</sup> Moreover, CNTs have very high thermal conductivity and excellent electrical conductivity. In recent years, the research has been focused in the development of nanotube reinforced polymers and ceramics.<sup>[9–11]</sup> In addition, several papers deal with nanotube coated with metals and nanotube decorated or filled with metal particles.<sup>[12–14]</sup> On the other hand, only few

works have been concerned with the manufacturing and properties of bulk metal–nanotube composites, which remain almost a virgin field. This entry presents both original results and a literature review of the recent advances in the field.

## HISTORICAL BACKGROUND

The literature on bulk CNT–MMCs is limited to about 20 papers.<sup>[15–32]</sup> A pioneering work on processing CNT reinforced aluminum was published by Kuzumaki et al. in 1998.<sup>[15]</sup> They produced composite wires by hot extrusion of CNT–Al powder blends, which were previously mounted on a silver sheath. The resulting wire microstructure consisted of partially aligned nanotubes on a metal matrix. Transmission electron microscopy (TEM) observations showed that the nanotubes were not damaged by the processing method, and that no reaction at the nanotube/aluminum interface was visible after annealing for 24 hr at 983 K. The tensile strength of the composite wires was similar to that of pure aluminum produced in similar powder metallurgy process, but the wires retained the strength by annealing at 873 K, while the strength of aluminum wires significantly decreased with time. The same authors published a further work on CNT reinforced titanium<sup>[16]</sup> that was prepared by hot compaction at 1208 K for 2 hr, at 30 MPa, in vacuum. TEM observations revealed that the nanotubes did not react with the Ti matrix. A significant increase in microhardness and elastic modulus (evaluated by ultrasonic spectrum microscopy) was measured and compared with pure titanium obtained by the same processing route.

In 1999, Xu et al. published a work on the electrical properties of Al–CNT composites.<sup>[17]</sup> The manufacturing method was hot pressing of hand-blended CNTs and Al powders. A slight increase in resistivity was observed, which was attributed to scattering of charge carriers by nanotube agglomerates at grain boundaries, porosity, and to the presence of carbide phases. The most interesting result of this work was a kind of “superconducting” transition at low temperatures: an abrupt resistivity drop of more than 90% measured

at about 80 K. These results remain unexplained, and no additional experimental evidence has been reported.

Zhong, Cong, and Hou<sup>[18]</sup> and Tang et al.<sup>[19]</sup> processed Al–CNT composites by using Al nanopowders of mean size 50 nm and single-wall arc-discharged nanotubes, which were soaked in alcohol and stirred ultrasonically in different volume fractions. The blends were compacted at 1.5 GPa at room temperature, followed by compaction at 1.0 GPa at 380°C in vacuum. The hardness of the composites was up to twice the hardness of unreinforced Al processed from nanopowders at the same conditions. In addition, the coefficient of thermal expansion of Al–15 vol.% CNTs was reduced by 65% when compared with unreinforced aluminum.

The powder metallurgy processing of both Mg–CNT and Al–CNT composites by Carreño-Morelli et al.<sup>[20–22]</sup> will be presented in the next section. In addition, these authors have suggested the use of metal-coated nanotubes to improve the matrix–reinforcement bonding strength. For instance, a coating method of nanotubes with magnesium has been described,<sup>[20,33]</sup> which would be promising to improve the Mg–CNT interface bonding strength.

The liquid metal infiltration route was explored by Yang and Schaller.<sup>[23]</sup> The authors processed a hybrid ceramic preform by growing nanotubes on a short Al<sub>2</sub>O<sub>3</sub> SAFFIL fiber preform. The hybrid preform was infiltrated with magnesium in a gas pressure infiltration device. The nanotubes, which act as interface modifiers, are responsible for a slight decrease in the transient damping during thermal cycling. In addition, an increase of 20% in the elastic shear modulus of Mg–25 vol.% SAFFIL–CNTs was reported when compared with Mg–25 vol.% SAFFIL.

Several techniques of mixing and consolidation have been used to prepare CNT–copper composites. Dong, Tu, and Zhang,<sup>[24]</sup> Tu et al.,<sup>[25]</sup> and Chen et al.<sup>[26]</sup> used catalytic chemical vapor deposition (CCVD) nanotubes, which were nickel coated by electroless plating to improve adherence with the copper matrix. After wet ball milling, Cu–CNT blends were isostatically pressed at 350 MPa, followed by sintering at 850°C for 2 hr in vacuum, rolling, and annealing at 600°C for 3 hr<sup>[24]</sup> or isostatically pressed at 600 MPa and 100°C, followed by sintering at 800°C for 2 hr in vacuum.<sup>[25,26]</sup> Both hardness and tribological tests were performed. The coefficient of friction and weight loss were measured on a block-on-ring apparatus. Compared with carbon fiber reinforced copper, nanotube–copper composites had a lower coefficient of friction and wear rate. The optimum nanotube content for hardness and tribological behavior was about 12%. In addition, Ni–P–CNT coatings were applied by electroless plating on carbon steel.<sup>[26]</sup> Compared with

Ni–P–SiC and Ni–P–graphite coatings, Ni–P–CNT exhibited higher wear resistance and lower friction coefficient.

Ahn et al.<sup>[27]</sup> processed Cu–CNT composites by different methods. Ball milling followed by sintering–rolling–sintering consolidation was found to give the best results concerning density, uniform distribution of nanotubes, and low resistivity. The consolidation was achieved by spark-plasma sintering at 350 MPa and 900°C for 2 hr, followed by cold rolling and a second sintering at 900°C for 1 hr. The authors also found that high-energy ball milling resulted in nanotube degradation to amorphous carbon, a problem which has been also found after attrition milling of Al–CNT mixtures.<sup>[28]</sup> Kim et al.<sup>[29]</sup> processed Cu–CNT composites by ball milling of nanosized Cu powders ( $D_{50} \sim 40$  nm) and multiwall CNTs blends, followed by spark-plasma sintering at 700°C for 1 min, at a pressure of 40 MPa. The hardness of the composites increases as the volume fraction of CNTs increases from 0% to 10%. In addition, the hardness of composites processed from Cu nanopowders was about 2.2 times the hardness of composites processed from coarse Cu powders.

Recently, some novel manufacturing routes have been explored. Laha et al.<sup>[30]</sup> processed nanotube reinforced Al–Si parts by plasma spray forming. Al–Si powders and CCVD CNTs were mixed by ball milling. The blended composite powder was plasma sprayed on a cryogenically cooled, rotating, smooth, tapered 6061 Al mandrel. Near-net shape cone-shaped parts were manufactured. Density measurements, X-ray diffraction, and energy dispersive spectroscopy microanalysis showed the presence of graphite and aluminum oxide that is formed during the deposition process. The formation of other carbon allotropes from CNTs was also probable. No aluminum carbide, Al<sub>4</sub>C<sub>3</sub>, was detected by TEM observations. Despite the high temperatures involved in the process, which can melt or sublime the nanotubes, a fraction of them was retained as revealed by scanning electron microscopy (SEM) observation of fracture surfaces. This is because big Al–Si/CNT agglomerates were only partially molten during the spray deposition process. An increase in microhardness was measured, but it is still not clear if this is because of the presence of nanotubes or other phases developed during spray forming.

Noguchi et al.<sup>[31]</sup> have developed a new method to obtain a uniform dispersion of nanotubes in aluminum matrix. It consists of two steps: first, elaboration of a “precursor” consisting of nanotubes dispersed in an elastomer matrix; and second, displacement of the elastomer by aluminum. The precursor was prepared by mixing in a two-roll mill multiwall CNTs, Al powder, Mg powder, natural rubber, and a free-radical initiator. Precursor sheets of 2-mm thickness were

placed in molds and formed by compression molding at 80°C. In the second step, the precursor was placed between Al plates and heated up to 800°C under nitrogen. The rubber is decomposed and gasified while molten Al fills the pores. After cooling, the resulting material shows a rather uniform microstructure without nanotube agglomerates. A significant improvement in the compression resistance, strain, and elastic limits was measured in Al/1.6%CNT and Al/0.8%CNT specimens when compared with pure Al specimens prepared by the same method. To explain these results, the authors consider the radicals resulting from the decomposition of elastomer molecules as responsible

for two key features: 1) the reduction of the Al<sub>2</sub>O<sub>3</sub> layer covering the Al powders and 2) a reaction that activates the surfaces of multiwall nanotubes and improves the wettability by molten Al.

Finally, an interesting concept for creating ultralow resistivity composites has been suggested by Hjortstam et al.<sup>[32]</sup> The authors show that a room-temperature resistivity 50% lower than copper is achievable. This would be possible because of ballistic conduction in single-wall nanotubes, which can have an electron mean free path of several orders of magnitude more than metal conductors such as Al, Cu, and Ag. Among the problems to solve for the development of such ultralow resistivity composites, one can notably cite the need for a processing method that guarantees good contact and alignment of nanotubes on a metal matrix, and the production of bulk quantities of ballistically conducting CNTs.

### CNTs FOR MMCs

The current processing routes of CNTs are electric arc discharge, CCVD, and laser ablation, which have been extensively described in the literature.<sup>[34]</sup> These processes differ in nanotube structure and quality, price, and scaling-up capability. Laser ablation produces high quality and almost free-of-defect CNTs, but the cost of producing large amounts of nanotubes by this technique would be prohibitive. On the other hand, CCVD offers a great potential for scaling-up. Fig. 1 shows multiwall CNTs processed and purified at the Swiss Federal Institute of Technology, Lausanne. Long nanotubes are entangled, and some remaining

**Fig. 1** TEM images of CCVD-processed multiwall nanotubes. *Source:* A. Magrez.

**Fig. 2** TEM image of arc-discharged multiwall nanotubes. *Source:* V.A. Ryzhkov.

catalyst particles are visible. The processing technique is the catalytic decomposition of acetylene in a fixed-bed flow reactor at 720°C over  $\text{Fe}_{1-x}\text{Co}_x$  catalyst supported by  $\text{CaCO}_3$ . The concentration of metal catalyst is about 5% relative to calcium carbonate. A further purification step by sonication in a nitric acid solution is necessary to remove catalyst particles, support the material, and amorphous carbon. For continuous production, a method based on a rotary tube furnace has been developed. It provides high-purity CNTs, less damage to graphitic walls, and high yield up to 500 g/day.<sup>[35]</sup>

Arc-discharge processed multiwall CNTs have a much better purity, because no magnetic materials are used in their production. Nevertheless, they have to be separated from carbonaceous by-products as amorphous carbon, polyhedral particles, and fullerenes. A rather low yield and high specific energy consumption have been common issues in this

processing technique. However, recent developments allow production with a mean average yield up to 1–3 g/min with low specific consumption of electricity. Fig. 2 shows multiwall CNTs processed at Rosseter Holdings Ltd. by cracking of liquid hydrocarbons, driven by a self-regulated, low-voltage contact arc discharge.<sup>[36]</sup>

The mechanical properties of CNTs strongly depend on their structure that is determined by the fabrication process. Both theoretical and experimental studies have shown that arc-discharged and laser ablation single-wall CNTs exhibit Young's modulus up to 1.3 TPa.<sup>[7,8,37]</sup> Arc-discharged multiwall CNTs contain very few defects and have modulus comparable to single-wall nanotubes. On the other hand, catalytic CNTs can be one to two orders of magnitude less stiff; their Young's modulus decreases as the number of defects and disorder within the graphene walls increases.<sup>[38]</sup>

## POWDER METALLURGY PROCESSING OF CNT–METAL COMPOSITES

Among the current methods for processing MMCs, liquid metal infiltration can be ruled out because of the poor wettability of nanotubes by molten metals,

the difficulty of manufacturing CNT preforms, the difficulty in infiltrating loose CNT beds, and the easy formation of nanotube agglomerates.

Uniform dispersion of reinforcement in the metal matrix is of prime importance in the manufacturing of MMCs with controlled properties. Powder metallurgy seems to be the most promising route to accomplish this goal, provided that uniform mixing of matrix powder and CNTs is performed before compaction and sintering. Fig. 3 shows typical aluminum powder morphology and size distribution measured by laser diffractometry. Fig. 4 shows agglomerates of CCVD grown nanotubes. Nanotube agglomeration occurs because of entanglement, high specific surface area, and the action of van der Waals attraction and electrostatic forces. In general, agglomeration makes packing, flow, mixing, compaction, and sintering more difficult.<sup>[39]</sup> De-agglomeration can be achieved by ball milling, i.e., rolling a jar partially filled with powder and balls, and allowing the balls to fall and impact

Fig. 6 Scanning electron micrographs of Mg–CNT ball-milled powders, CCVD grown nanotubes: (A) composite powder; (B) details of a particle surface; and (C, D) nanotubes partially embedded in the surface of metal particles.

on the powder (Fig. 5). Different types of mills can be used, e.g., drum mills, planetary mills, and shaker mills. The efficiency of ball milling depends on the ball-to-powder mass ratio and on the energy of individual ball–powder–ball collisions.<sup>[40,41]</sup> Depending on the powder properties, ceramic or metallic balls can be used. Because CCVD multiwall nanotubes contain remaining catalyst particles that are magnetic, Al<sub>2</sub>O<sub>3</sub> balls have to be used for de-agglomeration and mixing. On the other hand, for arc-discharged multiwall nanotubes steel balls can be used, which allows one to increase the ball-to-powder mass ratio and achieve a better mixing.

Fig. 6 and 7 show composite powders obtained after ball milling in a Turbula type shaker mill. Multiwall CCVD CNTs and Mg powders were milled with ceramic balls for 5 hr, with a ball-to-powder mass ratio of 3. In addition, multiwall arc-discharged CNTs and Al powders were milled with steel balls for 12 hr, with a ball-to-powder mass ratio of 5. Fig. 6C and D show

nanotubes partially embedded in the surface of metal particles. Fig. 7A and B show composite particles in which nanotubes are uniformly dispersed. In addition, emerging nanotubes are visible in some small composite particles (Fig. 7C). These results demonstrate the potential of ball milling to disperse nanotube agglomerates and produce a new composite powder for better sintering.

An effective method of sintering metal–nanotube powders is hot compaction. The blends are placed in a double-action graphite tooling consisting of a die and two cylindrical pistons. Heating to sintering temperature is achieved by direct resistive heating while applying compaction pressure. An optional further consolidation step by hot isostatic pressing can be performed to improve sintering and ductility. In this way, disk-shaped compacts (Ø53 mm × 5 mm) are obtained by hot pressing at 600°C in vacuum under a pressure of 50 MPa for 30 min, followed by hot isostatic pressing at 600°C for 60 min under an argon

**Fig. 7** Scanning electron micrographs of Al–CNT ball-milled powders, arc-discharge grown nanotubes: (A) composite powder; (B) details of a broken composite particle showing uniform dispersion of CNTs; (C) composite particle showing emerging nanotubes; and (D) nanotube on the surface of a metal particle.

**Fig. 8** Hot pressed Mg–2%CNT compacts (A) and metallographic observation (B).

pressure of 1800 bar (Fig. 8A).<sup>[20]</sup> The density of Mg–2%CNT compacts (CCVD nanotubes) is about 98% of the theoretical density calculated from a mixture law (values of about 96% are measured for Al–2%CNT). Metallographic observations reveal a microstructure consisting of Mg grains with nanotubes along grain boundaries and nanotube clusters (Fig. 8B). It is a goal to reduce the number of such clusters that are detrimental for mechanical properties. These results show that both mixing and sintering conditions need to be improved.

Mg–CNT composites exhibit a ductile behavior, which suggests good bonding between nanotubes and the metal matrix. Yield strength (89 MPa), ultimate strength (140 MPa), and strain after fracture (~3%) are similar to the values measured for sintered magnesium under similar conditions. Resonant measurements of the Young modulus show an improvement of about 9% for Mg–2%CNT ( $38.6 \pm 0.7$  GPa) when compared with unreinforced sintered Mg ( $35.3 \pm 0.8$  GPa). SEM observations of fracture surfaces reveal a rather uniform distribution of nanotubes and nanotube pull-out from the metal matrix (Fig. 9).<sup>[20–22]</sup>

Sintering of Al–CNT composites is difficult, because of the aluminum oxide layer at the powder surface, which acts as a diffusion barrier. Despite good density after hot compaction, the result is usually a brittle

**Fig. 9** Rupture surface of Mg–2%CNT (CCVD nanotubes) after tensile tests.

material. The material properties should be improved by sintering blends of prealloyed aluminum powders and arc-discharged CNTs. The research is in progress, and the results will be published elsewhere.<sup>[42]</sup>

## CONCLUSIONS

CNTs offer a great potential for the development of a new generation of MMCs. Until now, few works on the subject have been published, and only slight enhancement of mechanical, tribological, or electrical properties has been obtained. However, there is a trend toward an increase of the research effort to develop reliable processing methods to manage main issues such as nanotube dispersion in the metal matrix and matrix–nanotube interfacial strength. The cost effective processing of high quality CNTs combined with appropriate powder metallurgy techniques would offer a suitable route for the development of high-performance affordable composites. The major challenge for the future is to make this happen.

## ACKNOWLEDGMENTS

The author wishes to thank Dr. R. Schaller (EPFL Lausanne) and Dr. D. Tománek (Michigan State University) for fruitful discussions. The technical support of N. Schmidt, D. Zufferey, and S. Héritier is gratefully acknowledged. This work was supported by the Swiss Innovation Promotion Agency under CTI Contract No. 5990.3 TNS and by the University of Applied Sciences of Western Switzerland under HEVs Grant.

# Carbon Nanotubes: Electrochemical Modification

Kannan Balasubramanian

Marko Burghard

Klaus Kern

Max Planck Institut für Festkörperforschung, Stuttgart, Germany

## INTRODUCTION

Carbon nanotubes (CNTs) are important because of their outstanding structural, mechanical, and electronic properties,<sup>[1]</sup> and are finding applications in molecular electronics,<sup>[2]</sup> chemical sensors,<sup>[3,4]</sup> scanning probes,<sup>[5]</sup> special capillaries,<sup>[6]</sup> supercapacitors,<sup>[7]</sup> energy storage devices,<sup>[8]</sup> and electromechanical actuators.<sup>[9]</sup> CNTs are expected to exhibit superior electrochemical properties in comparison with other carbon materials that are widely used in electrochemical applications.<sup>[10]</sup> Because CNTs have length scales similar to those of biological molecules such as enzymes and proteins, they can act as effective biosensing electrodes.<sup>[11]</sup> Furthermore, potential applications such as Coulter counters,<sup>[12]</sup> bio-electrochemical sensors,<sup>[13]</sup> as well as electrochemical hydrogen<sup>[14]</sup> and lithium<sup>[8]</sup> storage have stimulated an increasing amount of research into the electrochemical properties of CNTs.

Chemical functionalization is developing to be an effective tool to broaden the application spectrum of CNTs.<sup>[15]</sup> Until now, functionalization of CNTs has been accomplished by three different approaches, namely, thermally activated chemistry, photochemical functionalization, and electrochemical modification (ECM). Among these, ECM offers the specific advantage that the energy level of a chosen nanotube can be selectively tuned, allowing one to functionalize the tubes in a controlled manner.

To devise novel ECM schemes, it is essential to investigate the electrochemical properties of CNTs, such as their charging and discharging behaviors in various media, electron transfer (ET) rates for different redox couples, etc. In the following entry, the electrochemical characteristics of various types of nanotube electrodes are first presented. Then various ECM methods reported until now are reviewed. The modification of bulk CNTs is detailed first, followed by the modification of individual nanotubes. Finally, various (electro)chemical applications of pristine and electrochemically modified CNTs are discussed.

## NANOTUBE ELECTRODES

### Bulk Electrodes

Bulk nanotube electrodes have been realized from single-walled nanotubes (SWNTs) and multiwalled nanotubes (MWNTs). The most common types of bulk CNT electrodes are:

- *Powder microelectrodes.* These are fabricated by filling CNT powder into a microcavity, which is in contact with a metal wire.<sup>[16]</sup>
- *Paste electrodes.* Here, SWNTs<sup>[17]</sup> or MWNTs<sup>[18]</sup> are dispersed in an organic liquid containing an appropriate binder. The first CNT paste electrodes were made by packing a composite mixture of MWNTs, mineral oil, water, and bromoform into a capillary.<sup>[13]</sup> Alternatively, the CNTs can be mixed with polymers such as Teflon<sup>[19]</sup> or Nafion<sup>[20]</sup> as binders to form composite electrodes.
- *Film electrodes.* Films of SWNTs and MWNTs have been deposited on glassy carbon (GC) or metal supports. Typically, the CNTs are cast from an aqueous dispersion with or without a surfactant,<sup>[21]</sup> or from a dispersion in *N,N*-dimethylformamide (DMF).<sup>[22]</sup>
- *Arrays of vertically aligned CNTs.* This type of electrode has been obtained via chemical coupling of end-functionalized SWNTs onto surface-modified gold electrodes.<sup>[23]</sup> Additionally, electrodes composed of closely spaced MWNTs, forming so-called multiwalled nanotube towers (MWNTTs),<sup>[24]</sup> have been synthesized by thermal chemical vapor deposition (CVD), with the thickness of the grown films reaching up to 100  $\mu\text{m}$ .
- *Paper electrodes.* The SWNT “bucky” paper (SWNTP) is prepared by vacuum filtration of a SWNT suspension through a membrane filter.<sup>[25]</sup> The electrode is composed of sheets of entangled SWNT bundles held together by van der Waals interaction and probably some adhesive impurities.
- *Microbundle electrodes.* These are made by attaching a single MWNT<sup>[26]</sup> bundle to the end of a metal wire.<sup>[26]</sup>

In general, the aforementioned CNT electrodes show a featureless cyclic voltammogram (CV), as distinguished from  $C_{60}$  films, which exhibit several pairs of discrete redox waves characteristic of individual redox molecules. The broad CV signal mainly results from the fact that the CNT electrodes comprise a mixture of semiconducting and metallic tubes, both existing in a distribution of diameters and chiralities. As a consequence, bulk CNT electrodes behave similarly to other carbon-related electrodes such as gas chromatographs (GCs) or highly oriented pyrolytic graphites (HOPGs), and are well suited to probe the redox behavior of small inorganic redox couples as well as organic compounds including larger biomolecules.

CNT bulk electrodes are characterized by a large capacitance, reflecting the high effective surface area of the nanotube material. In many cases, the electrolyte is capable of (partially) penetrating through the electrode because of the porosity of the latter. For example, the surface-specific capacitance of SWNTP electrodes has been found to be  $125 \mu\text{F}/\text{mm}^2$ , three to four orders of magnitude higher than that of conventional carbon electrodes.<sup>[24]</sup> MWNTs also exhibit a large capacitance<sup>[27]</sup> similar to their single-walled counterparts.

Electrodes made from as-prepared or purified CNTs often show faradaic peaks superimposed on the predominant capacitive charging background.<sup>[28]</sup> This behavior has been ascribed to redox reactions associated with functional groups (e.g., quinone or carboxylic functions) introduced by the purification process, or adsorbates.<sup>[22,29]</sup> The faradaic responses can be removed by annealing the CNTs at  $\sim 1000^\circ\text{C}$ , which eliminates impurities.<sup>[30]</sup> It is noteworthy that removal of surface-bonded oxides reduces, at the same time, the wetting capability of the electrodes toward aqueous solutions.

Electrodes composed of SWNTs or MWNTs have remarkably fast ET rates for various redox reactions. The ET kinetics of SWNTP electrodes has been studied by using the  $\text{Fe}(\text{CN})_6^{3-}/\text{Fe}(\text{CN})_6^{4-}$  couple,<sup>[24]</sup> which is a standard benchmark<sup>[10]</sup> for comparing the ET rates at different carbon electrodes. The corresponding CV of the SWNTP electrode exhibits forward and backward redox waves with a separation of 96 mV (Fig. 1), comparable with that obtained with other carbon electrodes. Faster kinetics has been observed for the same redox couple with the MWNT microbundle electrode.<sup>[26]</sup> In this case, the peak-to-peak separation of the redox waves has been found to be only 59 mV, indicative of an ideal, reversible, one-electron transfer that is purely Nernstian in nature.<sup>[31]</sup> This ET rate is higher than that obtained using any other carbon electrode, and is most likely related to the fact that in the bundle electrode, the nanotube ends represent a significant fraction of the CNT surface exposed to the

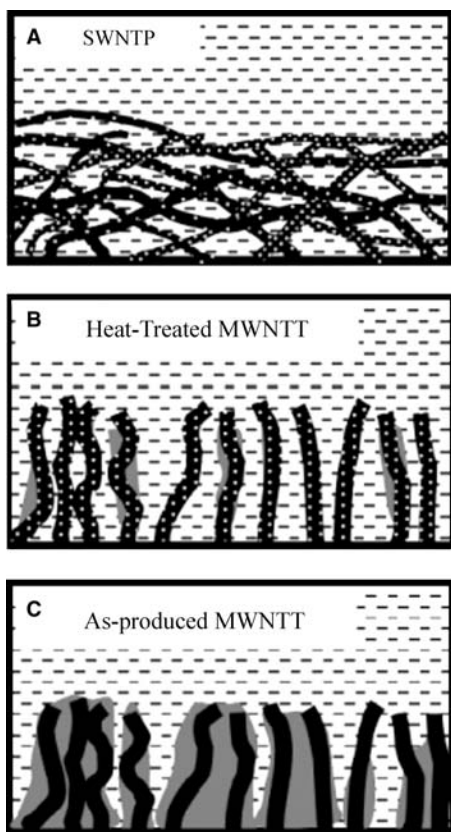

**Fig. 1** CV curves obtained with a SWNTP electrode (outer line) and a carbon paste electrode (inner line) in an aqueous solution of 5 mM  $\text{K}_4\text{Fe}(\text{CN})_6$  with 0.1 M KCl. The well-separated anodic and cathodic currents indicate a larger capacitance for the SWNTP. Arrows indicate pseudo-capacitive current arising probably because of oxides. *Source:* From Ref.<sup>[24]</sup>.

electrolyte. The tube ends can give fast charge transfer, similar to graphite edge planes. CNT electrodes show fast ET kinetics also with organic molecules. In an early study, it has been demonstrated that the oxidation/reduction of dopamine is more facile at MWNT electrodes compared with other carbon surfaces.<sup>[13]</sup> Based on this, facile ET was later also observed for other organic compounds, including ascorbic acid, uric acid, and the biologically relevant  $\beta$ -nicotinamide adenine dinucleotide (NADH; reduced form).<sup>[17–19]</sup>

A comparative study of the ET rates obtained with SWNTs (paper electrodes) and MWNTs (MWNTTs) has revealed an increasing separation between the redox peaks when moving from SWNTPs, through as-produced MWNTTs, to the heat-treated MWNTTs, signifying that the ET rate is maximum for the SWNTPs. Fig. 2 shows a schematic representation of these three types of CNT electrodes. The faster ET rate of the SWNTPs can be explained as resulting from the oxidative purification process, which introduces a large number of edge-plane-like defect sites in the sidewalls. A possible reason for the relatively fast electron transfer kinetics with the as-produced MWNTTs may be the presence of an amorphous coating on the sidewall of tubes, such that the electrochemically active surface consists mainly of tube ends.

### Single-Nanotube Electrode

Electrodes have been constructed also with single CNTs. An electrode consisting of a single MWNT attached to a sharpened platinum wire is shown in Fig. 3. The corresponding CVs of  $\text{Ru}(\text{NH}_3)_6^{3+}$  in aqueous solution show a sigmoidal response characteristic

**Fig. 2** Schematic representation of the various types of CNT electrodes in increasing order of effective capacitance. The dots represent defects on the CNT surface and the shaded areas covering the CNTs indicate amorphous carbon. *Source:* From Ref.<sup>[24]</sup>.

of steady-state radial diffusion.<sup>[32]</sup> Furthermore, the limiting current varies linearly with the depth of immersion. When the sidewalls of the nanoelectrode are insulated with a polymer layer, a constant limiting current originating exclusively from the unexposed bottom surface of the bundle is observed.

## ECM OF NANOTUBES

Electrochemistry is a versatile tool for modification of CNTs in a controlled and selective manner. ECM is normally performed potentiostatically or galvanostatically in a solution containing a molecular agent as precursor for an active species (e.g., a radical or radical ion) that will be formed through ET with the CNT electrode. Many organic radical species have a tendency to react with the precursor or to self-polymerize, resulting in a polymer coating on the tubes. Such a polymer deposition may or may not be accompanied by the formation of covalent bonds to the carbon framework of the nanotubes. In general, electrochemical deposition procedures, in addition to being simple,

**Fig. 3** Single-carbon nanotube electrode. (A) Schematic showing a partially insulated single MWNT electrode attached to a Pt tip through silver epoxy. TEM images of nanotubular electrodes showing (B) a 30- $\mu\text{m}$ -long electrode, (C) the tip of a  $\sim 100\text{-nm}$ -diameter uninsulated electrode, and (D) the tip of a  $\sim 22\text{-nm}$  electrode coated with a  $\sim 10\text{-nm}$ -thick insulation layer of polyphenol. The uninsulated electrodes show a limiting current proportional to their length of immersion in the solution, whereas the insulated electrodes display a constant limiting current arising from the bottommost uninsulated electroactive part. *Source:* From Ref.<sup>[32]</sup>.

clean, and efficient, also allow good control over the rate and extent of film deposition by the application of appropriate electrochemical conditions. Adjusting these conditions further enables one to tailor the chemical and physical properties of the resulting film. In the following, the covalent and non-covalent ECM of bulk CNT electrodes will be discussed first, followed by a description of ECM applied to single CNTs.

## Covalent Modification of CNTs in Bulk

Until now, covalent modification of CNTs has been successfully employed to attach organic (aromatic) residues, as well as oxygen (oxidation) and halogen atoms (halogenation). In these cases, the formation of covalent bonds has been concluded from changes in the optical absorption or Raman spectra of the tubes. As the chemical reactivity of CNTs increases with increasing curvature of their sidewalls,<sup>[15]</sup> small-diameter tubes have often been used for covalent functionalization. Especially the HiPco SWNT material was frequently chosen because it has a minimum diameter of 0.6 nm.<sup>[33]</sup> However, it should be noted that the chemical reactivity of CNTs is not fully explored, and there is some evidence that also larger-diameter tubes are sufficiently reactive, at least toward highly active species.<sup>[34]</sup>

Aromatic groups can be covalently linked to CNTs via reductive coupling of diazonium salts. The diazonium-based attachment of (substituted) phenyl rings to SWNT electrodes represents the first example of covalent ECM of CNTs.<sup>[35]</sup> Pronounced changes have been observed in the Raman spectra after modification, specifically an increase in the relative intensity of the disorder mode peak at ca.  $1290\text{ cm}^{-1}$  (also called the D-line), and a lowering of the intensity of the radial breathing mode. While the former change directly indicates an increased amount of  $\text{sp}^3$ -hybridized carbons, the latter signifies the disturbance in the carbon framework of the sidewalls. Chemical analysis of the modified products revealed that the extent of modification depends on the type of aryl diazonium salt. Functionalization degrees of up to 0.05 have been found, which corresponds to 1 in 20 carbon atoms bearing an aromatic residue. In the simplest scenario, the diazonium salt is reduced by accepting an electron from the CNT, followed by loss of nitrogen to form an aryl radical and covalent binding of this radical to the intact sidewall via addition to the partial double bonds. However, there are experimental indications that the preferred attachment sites are defects.<sup>[36]</sup> Once started at such an initiation site, the locally enhanced curvature would enhance the attachment of further radicals, thus enabling the reaction to spread along the tube. The aryl diazonium coupling is compatible with a range of different substituents on the aromatic ring. Hence, a proper choice of the substituent allows to control the surface properties of the modified tubes (e.g., to produce a polar, acidic surface with the aid of diazonium salts containing a carboxylic acid function).

Electrochemistry offers a viable route to CNT oxidation. The electrochemical oxidation of SWNT bundles has been investigated by *in situ* Raman spectroscopy under constant current flow.<sup>[37]</sup> In the initial stage, the Raman spectra reveal a continuing shift in the G-line frequency (Fig. 4) resulting from spontaneous and electrochemical charge transfer. On exceeding a critical doping level, irreversible formation of C–O bonds takes place, which is manifested in a decrease in the rate of the G-line frequency change.

Covalent attachment of chlorine or bromine atoms to CNTs has been achieved through anodic oxidation of the corresponding halide ions in an aqueous solution. In particular, bulk MWNT electrodes have been functionalized in this manner.<sup>[38]</sup> Every 1 in 23 carbon atoms has been found to be functionalized, which is relatively high considering the ratio of carbon atoms in the outermost shell to the inner ones. The modified MWNTs were found to be soluble in water or alcohol without adding a surfactant. This property points toward the simultaneous introduction of oxygen-containing functionalities such as hydroxyl or carboxylic groups.

**Fig. 4** Evolution of the SWNT G-line frequency  $\omega$ , its intensity  $I_p$ , and the cell potential  $V$  as a function of the electrochemical charge per unit (initial) electrode mass. The cell current was kept constant at  $10\ \mu\text{A}$ . The open triangles are measured during charging when  $V_{\text{SWNT vs. Pt}} < 0$  and the closed triangles during discharging when  $V_{\text{SWNT vs. Pt}} > 0$ . The irrecoverable change in the G-line frequency signified by the kink is interpreted as being caused by the irreversible formation of C–O bonds. *Source:* From Ref.<sup>[37]</sup>.

### Non-covalent Modification of CNTs in Bulk

The attachment of molecules onto the CNTs in a non-covalent manner is of interest for some applications because the carbon framework of the tubes remains intact; therefore their electronic properties are largely preserved. Non-covalent ECM has been utilized to coat CNTs with a polymer consisting of polypyrrole or polyaniline, which allows to combine the specific properties of CNTs and electrically conducting polymers (ECPs) in a novel composite material. Electropolymerization of monomers has been performed under various conditions. For instance, pyrrole was polymerized in an aqueous solution containing chemically oxidized CNTs at a potential between 0.7 and 1 V vs. saturated calomel electrode (SCE).<sup>[39]</sup> High-resolution scanning electron microscopy (SEM) images revealed the presence of CNTs incorporated within the polypyrrole matrix, and the formation of dense, high-quality composite films. Here, the CNTs with their negatively charged surface groups act as a conductive dopant. Careful inspections have suggested that there must be a polymer coating around the surface of most of the nanotubes, as is shown in Fig. 5. It is possible to control the thickness of the polymer coating on the tubes through the magnitude of the applied potential and the duration of electropolymerization. Formation of polyaniline layers on MWNTs has been accomplished via oxidative polymerization of aniline using a potential of  $\sim 0.8\text{ V}$  vs. SCE in dilute sulfuric acid.<sup>[40]</sup> The thickness of polyaniline films can be up to 10 times

**Fig. 5** High-resolution TEM image of two nanotubes coated with polypyrrole, showing the inner CNT framework and the outer amorphous polymer layer. The coating was performed by applying a potential of 0.8 V for 2 min onto a bare copper grid on a Pt wire in a degassed solution containing 0.2% CNTs and 0.5 M pyrrole. *Source:* From Ref.<sup>[39]</sup>.

higher than that formed on a Pt electrode after passing the same amount of charge, which can be traced back to the relatively large surface area of the CNT electrode.

An inorganic variant of non-covalent ECM is the electrodeposition of metals onto CNTs. Although metal-carbon bonds may be formed on evaporation of certain metals onto CNTs under ultrahigh vacuum (UHV) conditions,<sup>[41]</sup> the reduction of metal ions at the surface of adsorbate-covered tubes more likely results in physisorbed metal particles. Electrodeposition has been used to decorate purified MWNTs deposited onto HOPGs with metallic clusters of copper.<sup>[42]</sup> The clusters start forming at sites where the MWNT is in contact with the HOPG and continue to grow over time. Moreover, magnetic nanoparticles consisting of Ni, Fe, and Co have been electrodeposited from aqueous solutions onto carbon nanowalls as templates.<sup>[43]</sup> Carbon nanowalls are two-dimensional carbon nanosheets grown on Cu substrates using microwave plasma-enhanced CVD.<sup>[44]</sup> The shape and size of the deposited metal particles can be tailored by the detailed characteristics of the applied bipolar current density profile, which induces cycles of nanoparticle deposition and partial etching. A representative example of the deposited nanoparticles is shown in Fig. 6. On closer inspection, it was concluded that the clusters were deposited on the corners and edges of the nanowalls, as can be expected from the current intensity being higher at these positions.

### ECM of Single Nanotubes

Electrochemistry is particularly attractive for the chemical alteration of single molecular objects because

**Fig. 6** SEM images of magnetic nanoparticles electrodeposited onto carbon nanowalls. The scale bars are 1  $\mu\text{m}$  in (A) and (B), and 100 nm in (C) and (D). This sample was fabricated by applying a current density of 75  $\text{mA}/\text{cm}^2$  for 15 sec followed by a subsequent etch time of 3 sec at a current density of  $-25 \text{ mA}/\text{cm}^2$ . *Source:* From Ref.<sup>[43]</sup>.

the extent of modification can be controlled by the electrochemical potential.<sup>[45]</sup> This has been demonstrated by the attachment of substituted phenyl groups to appropriately contacted SWNTs, resulting in homogeneous coatings on the individual tubes.<sup>[36]</sup> For that purpose, single SWNTs/bundles are deposited on a Si/SiO<sub>2</sub> substrate and contacted with electrode lines on top. Both a covalent and a non-covalent coupling scheme have been developed for ECM at the single-tube level. The covalent modification scheme is based on reductive coupling of an aromatic diazonium salt (Fig. 7B), analogous to the modification of CNTs in the bulk,<sup>[35]</sup> whereas the noncovalent scheme involves oxidation of a substituted aromatic amine at anodic

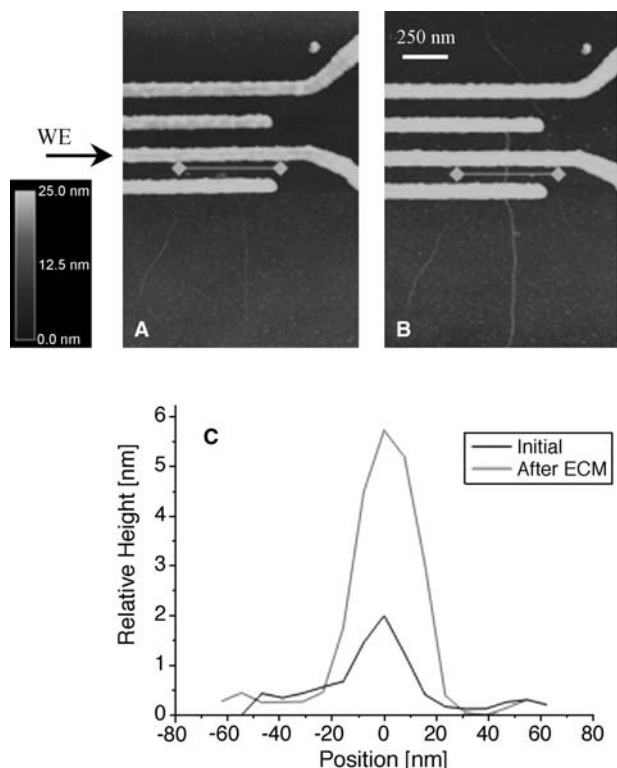

**Fig. 7** Reaction schemes for (A) oxidative ECM with 4-aminobenzylamine and (B) reductive ECM with an aryl diazonium salt. In the former case, the modified SWNT is covered by a polymeric layer of aminobenzyl groups without the formation of a chemical bond, whereas in the latter case, polyphenyl groups that are covalently attached to the nanotube are formed. *Source:* From Ref.<sup>[34]</sup>.

potentials (Fig. 7A). After both types of couplings, one observes a homogeneous coating on the nanotube originating from polymerization among the created radicals (or by reaction between the radicals and the attached molecules). The formation of electrodeposited layers is apparent from atomic force microscopy (AFM) images, as exemplified in Fig. 8A and B for an individual SWNT before and after ECM with 4-aminobenzylamine. This specific tube reveals a height increase of  $\sim 4$  nm, as seen from the line profiles in Fig. 8C. The thickness of such layers is found to increase with the time of ECM, the magnitude of the applied potential, as well as the concentration of the diazonium salt or amine. In practice, the thickness of the coated layers can be adjusted between  $\sim 2$  and  $\sim 15$  nm.

The respective covalent and non-covalent characters of the two coupling schemes have been concluded from a combined electrical transport and confocal Raman spectroscopic study of the coated SWNTs.<sup>[34]</sup> This study was performed separately with metallic and semiconducting pristine tubes. The diazonium coupling to

**Fig. 8** Oxidative electrochemical modification of individual SWNTs using 4-aminobenzylamine. (A) AFM image of a single SWNT/bundle contacted by four electrodes on top. (B) AFM image of the same sample after performing ECM on the electrode marked WE. (C) Topological line profiles along the lines marked in the AFM images. The modified SWNTs show a clear increase in height, which appears to be relatively homogeneous.

the metallic and semiconducting SWNTs resulted in an increase of both the resistance and the relative D-line intensity after ECM, which signifies the formation of chemical bonds between the polymer layer and the carbon framework of the nanotube. By contrast, only minor changes in the confocal Raman spectra were detected after oxidative amine coupling on metallic and semiconducting SWNTs. For this type of coupling, the electrical resistance of the metallic SWNTs remained unchanged, whereas that of the semiconducting SWNTs showed a moderate increase in resistance. This increase in resistance can be understood by the decreased p-doping level of the semiconducting tubes as a result of the electrons accepted during oxidation of the amine.

Until now, only one report on ECM of individual MWNTs has appeared, which involves their strong electrochemical oxidation. Single MWNTs coated with an amorphous carbon layer have been electrochemically etched in an aqueous electrolyte solution.<sup>[46]</sup> The onset potential for the anodic current was found to be 1.3 V vs. Ag/AgCl. At potentials higher than 1.7 V, MWNTs and the surrounding amorphous carbon layer begin to etch. Chronoamperometric measurements have revealed that the etching follows a kinetically controlled mechanism. Three different models have been proposed for the etching mechanism, as shown in Fig. 9. In the first model, etching starts from the amorphous carbon layer at the distal end (probably because of the creation of a high field) and proceeds to the proximal end. In a second scenario, the MWNT is

**Fig. 9** (A) Possible mechanisms for the electrochemical etching of MWNTs: (1) longitudinal etching from the distal end to the proximal end; (2) uniform etching in a radial direction; and (3) preferential etching at the air/electrolyte interface. (B) TEM image of the distal end of a partially etched MWNT. The arrow indicates the level of the electrolyte solution. *Source:* From Ref.<sup>[46]</sup>.

etched uniformly from the periphery toward the inner graphitic core. A third model involves the selective etching at the air/electrolyte solution interface, possibly because of the less probable occurrence of a defect at this interface. It was concluded from transmission electron microscopy (TEM) images of the etched MWNTs that the former two models are the predominant mechanisms that operate simultaneously, with the amorphous layer being etched more quickly than the graphitic core.

## ELECTROCHEMICAL APPLICATIONS OF CNTs

### (Bio)Electrochemical Sensors

CNT-based electrodes are very useful in the electrochemical study of biomolecules because of their electrocatalytic property, which is well documented for nicotinamide adenine dinucleotide (NADH) and biological amines.<sup>[17,19]</sup> Moreover, amperometric biosensors have been fabricated by incorporating enzymes such as glucose oxidase or alcohol dehydrogenase into a CNT matrix.<sup>[18–20]</sup> An illustrative example is provided by Fig. 10, where a glucose sensor is obtained by immobilizing glucose oxidase onto SWNTs deposited on a GC surface.<sup>[47]</sup>

**Fig. 10** Schematic showing the functioning of the SWNT-based glucose sensor. Glucose oxidase enzymes immobilized on the SWNT electrode turn over the solution-phase D-glucopyranose, and this redox signal is communicated to the underlying nanotube through ferrocene monocarboxylic acid acting as a diffusive mediator. *Source:* From Ref.<sup>[47]</sup>.

Their high aspect ratio and diameter in the nanometer range make CNTs particularly well suited for direct electrochemical communication with the redox site of a protein, without requiring any mediator. When properly arranged, a nanotube should have the capability to act as one-dimensional channel guiding electrons into the redox center. Direct ET has been achieved with various types of CNT electrodes for cytochrome *c*,<sup>[48]</sup> horseradish peroxidase,<sup>[16]</sup> glucose oxidase,<sup>[11]</sup> as well as myoglobin.<sup>[49]</sup> In some cases, an oxidative pretreatment introducing negatively charged surface groups on the CNTs was necessary to achieve the high ET rates. In a strategy to optimize the accessibility of the redox center, aligned CNT arrays have been fabricated using self-assembly techniques, followed by covalent attachment of microperoxidase to the tube ends.<sup>[50]</sup> For obtaining the best signal-to-background ratio, the CNT electrodes must be grown with a low density such that the intertube distance is in the same order of magnitude as the diffusion layer thickness.<sup>[24]</sup> Along this direction, a high-sensitivity neurotransmitter sensor,<sup>[51]</sup> where the reduced density has been achieved by a soft lithographic method, has recently been demonstrated.

ECM of CNT electrodes can be employed within the fabrication scheme of (bio)electrochemical sensors for various purposes. One example is the electrodeposition of polypyrrole onto vertically aligned MWNTs,<sup>[52]</sup> yielding a versatile composite system that allows one to exploit the sensing capabilities of inherently conductive polymers.<sup>[53]</sup>

### Batteries and Fuel Cells

CNTs have strong applicability in energy storage because of their excellent chemical stability, light mass, and large surface area. Electrochemical lithium insertion has been studied for both SWNT bundles<sup>[54]</sup> and MWNTs,<sup>[55]</sup> with respect to their application as anodes in rechargeable batteries. SWNTs whose ends were opened by chemical etching show storage capacity comparable with that of  $LiC_3$ , which is twice the value observed in intercalated graphite.<sup>[56]</sup> A major problem is the decrease in storage capacity with increasing number of cycles, caused by, for example, the formation of insoluble salt layers that block the CNT surface.<sup>[8]</sup>

Bulk CNT electrodes are also promising for applications in fuel cells. For example, electrocatalytic reduction of oxygen has been observed in MWNT electrodes,<sup>[57]</sup> and MWNTs covered with platinum particles proved useful as cathodes in direct methanol cells.<sup>[58]</sup> In the latter work, the particles were formed via thermal decomposition of a platinum salt. For this purpose, platinum electrodeposition could be an alternative option.

## Hydrogen Storage

Recent years have witnessed a strong interest in CNTs as high-performance hydrogen storage material. As the maximum values obtained for the storage capacity of molecular hydrogen showed low reproducibility,<sup>[59]</sup> research activities were partially shifted toward reversible electrochemical storage of hydrogen. In a pioneering experiment, electrodes made of pressed pellets containing SWNTs were studied.<sup>[14]</sup> Remarkably, the electrodes were able to deliver still 70% of the initial capacity after 100 charge/discharge cycles. The mechanism of electrochemical hydrogen storage is still under debate.<sup>[60]</sup> Several possibilities have been suggested, including covalent bonding<sup>[61]</sup> and physisorption of molecular hydrogen.<sup>[62]</sup>

ECM has proven to be a useful tool to open the ends of CNTs, which can be exploited to improve the hydrogen storage capacity. It has been observed that electrochemical oxidation at high anodic potentials occurs preferentially at the end regions of MWNTs.<sup>[63]</sup> The open ends created in such a manner allow hydrogen to invade the hollow spaces of the MWNTs during the cathodic reduction.

## Actuators

Various applications in robotics, optical fiber switches, prosthetic devices, sonar projectors, and microscopic pumps rely on the direct conversion of electrical to mechanical energy through a material response. Recently, a bimorph cantilever actuator has been constructed by attaching two sheets of SWNT to the two sides of a Scotch double-stick tape.<sup>[9]</sup> On application of a potential across the two strips of the actuator immersed in an electrolyte, the tape showed deflection because of double-layer charging and change in the carbon/carbon bond length within the rolled graphene sheets.

## CONCLUSION

Because of their good electrical conductivity, nanoscopic size, and high aspect ratio, CNTs have turned out to be excellent candidates for electrochemical applications. CNT electrodes have been found to display significantly superior characteristics in comparison with other carbon materials. Further improvements in the fabrication of single-nanotube electrodes would represent an important step toward the development of nanoscale probes useful in biophysics and neurochemistry. The ECM methods developed to date for bulk CNT electrodes and individual CNTs have broadened the application spectrum of CNTs.

Covalent functionalization of bulk and individual CNTs has been successfully utilized to produce soluble nanotubes, and is also promising for the creation of molecular-scale electronic devices such as diodes or single-electron transistors by the local attachment of appropriate functional groups. However, non-covalent ECM allows researchers to tailor the surface properties of the tubes without disturbing their electrical properties. Both approaches will be of importance in the future for the controlled design and fabrication of novel (bio)electrochemical sensors, composite materials, actuators, batteries, and fuel cells.

## INTRODUCTION

Carbon nanotubes are currently of great interest in both fundamental and applied sciences.<sup>[1–10]</sup> Potential applications for these tubular nanostructures include use in nanoelectronics,<sup>[1–4]</sup> hydrogen storage,<sup>[5,6]</sup> and battery<sup>[7,8]</sup> and field-emitting display<sup>[9,10]</sup> technologies. We and others have shown that carbon nanotubes can be prepared via the template method<sup>[11–13]</sup> by chemical vapor deposition (CVD) of carbon along the pore walls of nanoporous alumina membranes.<sup>[8,14–17]</sup> These membranes have cylindrical pores with monodisperse diameters, and a corresponding cylindrical nanotube is deposited within each pore. Carbon nanotubes with outside diameters as small as 20 nm have been prepared via this method.<sup>[14]</sup> Using an alternative template material and method, Joo et al.<sup>[7]</sup> have prepared carbon nanotubes with outside diameters of 9 nm.

At a recent workshop, it was suggested that carbon nanotubes might be used as chemically selective filters.<sup>[18]</sup> This membrane separations application requires alignment of the tubes<sup>[10,19–21]</sup> into a defect-free, mechanically strong membrane, where each tube spans the complete thickness of the membrane and the tube mouths are open at the faces of the membrane. Although Sun and Crooks<sup>[22]</sup> have recently developed an elegant procedure for doing this with a single carbon nanotube, template synthesis inherently provides nanotube-containing membranes of this type, with up to  $10^{11}$  nanotubes  $\text{cm}^{-2}$  of membrane surface area.<sup>[13]</sup> Having large numbers of nanotubes per square centimeter of membrane area is essential to enhancing flux across the membrane—a critical issue in membrane separation processes. These highly porous carbon nanotube membranes (CNMs) have monodisperse pore dimensions, which can be controlled by template synthesis. Template-prepared CNMs have a number of advantageous properties such as versatile surface chemistry and good electrochemical properties, which make them an interesting membrane material.

Flux can also be enhanced by augmenting diffusive transport across the membrane with electrophoresis, or pressure-driven or electroosmotic flow (EOF). Sun and Crooks<sup>[22]</sup> demonstrated diffusive, pressure-driven, and electrophoretic transport of colloidal particles across their single CNMs. To our knowledge, we have performed the only investigation of EOF in CNMs.<sup>[15,23]</sup> Electroosmotic flow was driven across template-prepared CNMs by allowing the membrane to separate two electrolyte solutions and by using an electrode in each solution to pass a constant ionic current through the nanotubes. According to Bath et al.<sup>[24,25]</sup> EOF was investigated by measuring the flux of a probe molecule across the membrane. The as-synthesized CNMs have anionic surface charge and, as a result, EOF is in the direction of cation migration across the membrane. Electroosmotic flow in the direction of diffusion enhances permeant flux, whereas EOF in the opposite direction of diffusion lowers flux. Measurements of the rate of EOF as a function of applied transmembrane current provided the zeta ( $\zeta$ ) potential. The effect of pH on  $\zeta$  provided the  $\text{p}K_a$  for the surface acidic sites responsible for this anionic charge; the acidic site density was also determined. An electrochemical derivatization method was used to attach carboxylate groups to the nanotube walls;<sup>[26–28]</sup> this enhances the anionic surface charge density, resulting in a corresponding increase in the EOF rate. Electrochemical derivatization was also used to attach cationic ammonium sites to the nanotube walls to yield CNMs that show EOF in the opposite direction of the as-synthesized or carboxylated membranes.

## PREPARATION OF CARBON NANOTUBE MEMBRANES

Anodic alumina template membranes with different pore diameters are available commercially, or can be prepared in the laboratory.<sup>[8,15,29–31]</sup> The outside diameters of template-prepared carbon nanotubes

are defined by the pore diameter of the template membrane, whereas the length is determined by the template thickness. The CVD template method has been described previously.<sup>[8,15–17]</sup> Briefly, a heat-treated alumina template membrane was placed vertically in the CVD reactor and heated to the desired temperature, 650–950°C, under argon flow. When the temperature stabilized, the Ar flow was terminated and, simultaneously, a 20-sccm flow of ethylene gas mixture was initiated. Under these conditions, ethylene pyrolyzes to yield carbon nanotubes on the pore walls, as well as thin carbon films on both faces of the membrane. After deposition was completed, the Ar flow was resumed, the ethylene flow was terminated, the furnace was turned off, and the CNM was allowed to cool to room temperature.

Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) were used to image the carbon nanotubes prepared within the pores of the alumina template membrane. This was accomplished by first dissolving away the alumina by immersion (for 12 hr) in 49% hydrofluoric acid. Hydrofluoric acid was removed by pipette, leaving the liberated nanotubes (connected together by the carbon surface films; Fig. 1), which were rinsed with methanol and then sonicated in methanol for 20 min. For imaging, the resulting suspension was pipetted onto the appropriate sample holder and the methanol was allowed

**Fig. 1** A CNM synthesized within a 200-nm Anodisc template at 670°C for 5.5 hr. (A) A SEM image of a CNM cross section at the unbranched face after removal of the alumina template. (B) A TEM image montage of individual carbon nanotubes removed from a CNM.

to evaporate. For SEM imaging, gold was sputtered onto the sample to improve electrical conductivity.

Figs. 1–3 show SEM and TEM images of nanotubes from three different CNMs after dissolution of the alumina template. The CNMs were prepared using templates with differing pore morphologies and at different CVD conditions. Fig. 1A shows a SEM image of a CNM, such as those used in the EOF studies.<sup>[15,23]</sup> This membrane was synthesized in a commercially available Whatman Anodisc 200-nm filtration membrane. Carbon was deposited at 670°C for 5.5 hr. At these conditions, carbon deposition was very slow and resulted in nanotube walls of highly uniform 40 nm thickness (Fig. 1B). Although it is not evident from these images, this carbon surface film does not block the mouths of the nanotubes. The outside diameter of the nanotubes (~300 nm) is larger than the 200-nm nominal pore diameter of the template. Our SEM and TEM images indicate that this is because the pores are, in fact, larger than the nominal diameter for most of the thickness of the membrane, but branch at one face of the membrane into smaller (diameter ~200 nm) pores. This branching can be seen in the TEM image shown in Fig. 1B. Branching undoubtedly results from the voltage reduction technique used during the final step of the electrochemical process used to prepare these alumina membranes.<sup>[29]</sup>

Fig. 2 shows images of a CNM synthesized within a Whatman Anodisc 20-nm filtration membrane.<sup>[16]</sup> Like the 200-nm Anodisc, this template has large pores (diameters of ~300 nm) along ~99% of their length, but branch into many much smaller nanotubes (diameter ~20 nm) at the branched face of the membrane. Chemical vapor deposition was performed at 900°C for 0.5 hr, which resulted in a much more rapid rate of carbon deposition. At this higher temperature, deposition tends to be a diffusion-controlled process and occurs more rapidly at the face of the template as opposed to the interior of the small pores. The substantial surface film on the branched-face is seen in Fig. 2A. This results in a CNM that acts as an electrochemical actuator when  $\text{Li}^+$  is intercalated into and deintercalated out of the carbon nanostructures.<sup>[16]</sup>

Carbon nanotubes have also been prepared in laboratory-grown anodic aluminum oxide membranes for a variety of purposes.<sup>[31–35]</sup> The CNM shown in Fig. 3A was grown in a highly ordered template of 30  $\mu\text{m}$  thickness and an 80-nm pore diameter. These pores are extremely straight and do not branch at either face of the membrane. Chemical vapor deposition was performed for 2 hr at 670°C, resulting in nanotubes with highly monodisperse dimensions. From TEM images of individual nanotubes (Fig. 3B), the CNM was determined to have a 60-nm pore diameter with nanotube walls of very uniform thickness. Carbon nanotube membranes such as these can be

**Fig. 2** A CNM synthesized within a 20-nm Anodisc template at 900°C for 0.5 hr. (A) A SEM image of a CNM cross section at the branched face after removal of the alumina template. (B) A TEM image of individual branched carbon nanotubes removed from a CNM.

prepared with larger or smaller pore dimensions and could be utilized for size-based separations.

### TRANSPORT PROPERTIES OF CARBON NANOTUBE MEMBRANES

After synthesis, CNMs to be used in transport studies were stored in air for at least 24 hr prior to use. This results in oxidation of the carbon surfaces to yield acidic surface sites on the nanotube walls.<sup>[36–38]</sup> Carbon nanotube membranes treated in this way are referred to as “as-synthesized” membranes. The CNMs were mounted in a supporting assembly<sup>[15]</sup> and placed in a simple U-tube permeation cell.<sup>[39]</sup> The permeation half-cells were filled with 25 ml of pH = 7.2

**Fig. 3** A CNM synthesized within a highly ordered, anodic alumina template at 670°C for 2 hr. (A) A SEM image of a CNM cross section after removal of the alumina template. (B) A TEM image of an individual carbon nanotube removed from a CNM.

phosphate buffer of 0.01 M ionic strength. The feed half-cell was 4.82 mM in the small, electrically neutral, chromophoric probe phenol.

According to Bath et al.<sup>[24,25]</sup> the rate of EOF was determined by monitoring the transport of the probe molecule across the membrane and into the permeate half-cell. A constant current, passed through the CNM, was responsible for the EOF in the membrane. The following sign convention was employed: For a positive applied current, the anode was in the feed half-cell and the cathode was in the permeate half-cell. In this case, cations migrated from feed to permeate, and anions migrated from permeate to feed. A negative applied current had the opposite configuration (i.e., cathode in the feed half-cell and anode in the permeate half-cell). The current values are reported here as the current density, defined as the applied current divided by the total pore area of the membrane.

**Fig. 4** Micromoles of phenol transported vs. time at various values of applied current density (see text for current density values).

Fig. 4 shows a plot of micromoles of phenol transported across the CNM at various values of applied current density. This plot consists of five linear segments, and the slope of each segment is the flux of phenol ( $N_J$ ) at that applied current density (Table 1). The first linear segment in Fig. 4 (0–8.5 min) was obtained with no applied current, and the flux in this case is simply the diffusive flux of phenol  $N_{diff}$  from the feed across the membrane and into the permeate. The second linear segment (9–14.5 min) was obtained with an applied current density  $J_{app} = -7.2 \text{ mA cm}^{-2}$ . The flux of phenol across the membrane was observed to decrease, indicating EOF in the opposite direction of the diffusive flux (EOF from permeate solution to feed solution). This is confirmed by data in the third linear segment (15–20.5 min), which were obtained with  $J_{app} = +7.2 \text{ mA cm}^{-2}$ ; now the net flux is higher than the diffusive flux (Table 1), indicating EOF in the direction of diffusive transport. The final two linear segments were obtained at higher positive and negative applied current densities, and further enhancement and diminution, respectively, in the flux is observed.

**Table 1** Effect of applied current density on the flux, enhancement factor, and electroosmotic velocity in the carbon nanotube membrane

$J_{app}$ [mA cm <sup>-2</sup> ]	Flux [nmol (min cm <sup>2</sup> ) <sup>-1</sup> ] <sup>a</sup>	$E$	$v_{eo}$ [μm sec <sup>-1</sup> ]
-10.1	25.8	0.280	-35.0
-7.2	39.3	0.426	-24.5
0.0	92.1	1.000	0.0
+7.2	187.1	2.030	26.3
+10.1	237.9	2.581	37.6

<sup>a</sup>The geometric area of the membrane (0.713 cm<sup>2</sup>) was used.

## CALCULATION OF THE ELECTROOSMOTIC FLOW VELOCITY

In the presence of the applied transmembrane current, the steady-state flux of permeant across a membrane is described by the Nernst–Planck equation:<sup>[40]</sup>

$$N_J = -D[\partial C(x)/\partial x] - zF(RT)^{-1}DC[\partial\phi(x)/\partial x] \pm Cv_{eo} \quad (1)$$

where  $D$ ,  $C$ , and  $z$  are the diffusion coefficient, concentration, and charge of the permeate molecule, respectively;  $\partial C(x)/\partial x$  is the concentration gradient in the  $x$  direction across the membrane;  $\partial\phi(x)/\partial x$  is the potential gradient in the electrolyte within the nanotubes; and  $v_{eo}$  is the electroosmotic velocity. The three terms in Eq. (1) describe the diffusive, migrational, and EOF convective transport processes, respectively. Because phenol is a neutral molecule at the pH used here, Eq. (1) simplifies to:

$$N_J = -D[\partial C(x)/\partial x] + Cv_{eo} \quad (2)$$

When  $J_{app} = 0$ , only the first term in Eq. (2) is operative and the flux is the diffusive flux  $N_{diff}$ .

The experimental flux data in Table 1 can be used to calculate a parameter called the enhancement factor  $E$ , which can then be used to calculate the electroosmotic velocity.<sup>[40]</sup>  $E$  is given by:

$$E = N_J/N_{diff} \quad (3)$$

(i.e., the ratio of the flux in the presence of an applied current to the flux at  $J_{app} = 0$ ).  $E$  values for the data in Fig. 4 are presented in Table 1. When a positive current is applied,  $E$  is greater than unity, indicating, again, EOF in the direction of the diffusional flux. Analogous results were obtained by Bath et al.<sup>[24]</sup> for Nafion membranes, where EOF is because of the polymer's fixed sulfonate sites. This indicates that as would be expected for air-treated carbon, the pore walls on the carbon nanotubes have fixed negatively charged sites.<sup>[36–38]</sup>

Following Srinivasan and Higuchi,<sup>[40]</sup> the Peclet number ( $Pe$ ) can be calculated from  $E$  via:

$$E = Pe/(1 - (\exp(-Pe))) \quad (4)$$

$Pe$  can then be used to calculate  $v_{eo}$  using:<sup>[40]</sup>

$$v_{eo} = PeD/l \quad (5)$$

where  $l$  is the thickness of the membrane. Because the inside diameter of the carbon nanotubes (~120 nm) is ~500 times larger than the diameter of phenol, hindered diffusion<sup>[41]</sup> does not occur in these tubes, and

the bulk solution diffusion coefficient can be used in Eq. (5). This and the membrane thickness (0.006 cm) give the  $v_{eo}$  data shown in the last column of Table 1. As would be expected, current densities of the same magnitude but opposite sign give  $v_{eo}$  values of approximately the same magnitude but opposite sign.

### EFFECT OF APPLIED CURRENT DENSITY ON ELECTROOSMOTIC FLOW

Phenol transport data such as those shown in Fig. 4 were obtained for 16 different  $J_{app}$  values between +19.3 and  $-19.3 \text{ mA cm}^{-2}$ . Fig. 5A shows the corresponding flux vs.  $J_{app}$  data. As would be expected from the above results, the flux increases with  $J_{app}$  for positive currents, indicating the increasing importance of EOF to the transport of permeate across the membrane. At sufficiently negative  $J_{app}$  values, the net flux asymptotically approaches zero. In this case, EOF from the permeate half-cell to the feed half-cell negates the diffusive flux from feed to permeate.<sup>[24]</sup>

The Helmholtz–Smoluchowski equation<sup>[42]</sup> describes the relationship between electroosmotic velocity and

Fig. 5 (A) Plot of phenol flux vs. applied current density. (B) Plot of EOF vs. applied current density.

linear electric field gradient ( $E(x)$ ) [ $\text{V cm}^{-1}$ ] across the membrane:

$$v_{eo} = -\varepsilon\zeta E(x)/\eta \quad (6)$$

where  $\varepsilon$  and  $\eta$  are the permittivity and viscosity of the solution within the nanotubes, respectively; and  $\zeta$  is the zeta potential of the tube walls. Substituting the product of the applied current density and the resistivity of the electrolyte within the nanotubes  $\rho$ , the  $E(x)$  in Eq. (6) gives:

$$v_{eo} = -\varepsilon\zeta J_{app}\rho/\eta \quad (7)$$

which shows that  $v_{eo}$  is linearly related to the applied current density. Eqs. (4) and (5) were used to calculate  $v_{eo}$  from the flux data in Fig. 5A. Fig. 5B shows a plot of  $v_{eo}$  vs. current density; in agreement with Eq. (7), a linear relationship is obtained. (Some deviation is observed at the highest negative  $J_{app}$  values. This is because the flux is nearly zero at such large negative  $J_{app}$  values, making the error in the measurement large.)

According to Eq. (7), the slope of the  $v_{eo}$  vs.  $J_{app}$  plot in Fig. 5B is  $-\varepsilon\zeta\rho/\eta$ . Using the known values for the permittivity and viscosity of water ( $6.95 \times 10^{-10} \text{ C}^2 \text{ J}^{-1} \text{ m}^{-1}$  and 0.890 cP, respectively)<sup>[43]</sup> and the measured resistivity of the electrolyte (2.23 kΩ cm), the slope can be used to calculate the zeta potential for the CNM. A value of  $\zeta = -17.3 \text{ mV}$  was obtained from these data. Bismarck and Springer<sup>[37]</sup> obtained similar zeta potential values for carbon fibers, and Garcia et al.<sup>[38]</sup> obtained somewhat larger zeta potential values ( $\sim -45 \text{ mV}$ ) after grinding such carbon fibers.

It should be noted that Eqs. (6) and (7) are based on the assumption that the thickness of the double layer at the pore wall is much smaller than the pore radius. Because the double layer at this electrolyte concentration is less than 3 nm in thickness,<sup>[42]</sup> this is clearly a valid assumption. Finally, for this reason and because the measured zeta potential is relatively low, deviations because of surface conductance, or changes in permittivity and viscosity within the nanotubes are negligible.<sup>[44,45]</sup> Thus it is reasonable to use the resistivity, permittivity, and viscosity of the bulk solution in the zeta potential calculation.

### EFFECT OF IONIC STRENGTH ON ELECTROOSMOTIC FLOW

Phenol transport data were obtained at applied current densities of +19.7 and  $-19.7 \text{ mA cm}^{-2}$  in solutions with ionic strength varying from 0.01 to 0.50 M (Fig. 6). The pH of the electrolyte was maintained at 7.2. Transport data for the case  $J_{app} = 0$  were also

**Fig. 6** Plots of EOF vs. the ionic strength of the permeate and feed solutions. Applied current densities were ( $\blacktriangle$ )  $-19.7 \text{ mA cm}^{-2}$  and ( $\bullet$ )  $+19.7 \text{ mA cm}^{-2}$ .

obtained over this electrolyte concentration range. No change in the diffusional flux was observed ( $< 3\%$  relative standard deviation), indicating that the diffusion coefficient for phenol does not vary with electrolyte concentration over this concentration range. Fig. 6 shows plots of  $v_{eo}$  vs. ionic strength obtained from the transport data. The general trend—that the absolute value of  $v_{eo}$  decreases with increasing ionic strength—is expected.

Returning to Eq. (7), we see that  $v_{eo}$  is directly proportional to the zeta potential, which is related to the Debye length  $\kappa^{-1}$  (the effective thickness of the electrical double layer) by:<sup>[46]</sup>

$$\zeta = 2kT/ze \sinh^{-1}(\sigma\kappa^{-1}ze/(2\epsilon kT)) \quad (8)$$

where  $k$  is the Boltzmann constant,  $T$  is the temperature,  $e$  is the elementary charge, and  $\sigma$  is the surface charge density at the plane of shear between the nanotube wall and the electrolyte. For the zeta potential and Debye length ranges investigated here, Eq. (8) simplifies to:

$$\zeta = \sigma\kappa^{-1}/\epsilon \quad (9)$$

For a symmetrical electrolyte,  $\kappa^{-1}$  is related to the concentration of the electrolyte via:<sup>[42]</sup>

$$\kappa^{-1} = 9.61 \times 10^{-9}(z^2c)^{-1/2} \quad (10)$$

Eq. (10) shows that the double-layer thickness decreases with increasing ionic strength of the electrolyte, which means that the zeta potential decreases with increasing ionic strength [Eq. (9)]. This, in turn, causes  $|v_{eo}|$  to decrease with increasing ionic strength [Eq. (7)], which is the experimentally observed trend in Fig. 6.

A second factor contributes to the observed decrease in  $|v_{eo}|$  with increasing ionic strength. Eq. (7)

shows that  $v_{eo}$  is also proportional to the resistivity of the electrolyte  $\rho$ , which, of course, is inversely proportional to the number of charge-carrying ions in the solution. Hence  $\rho$  decreases with increasing ionic strength of the electrolyte, and Eq. (7) predicts that this would also contribute to the observed decrease in  $v_{eo}$  with increasing ionic strength (Fig. (6)).

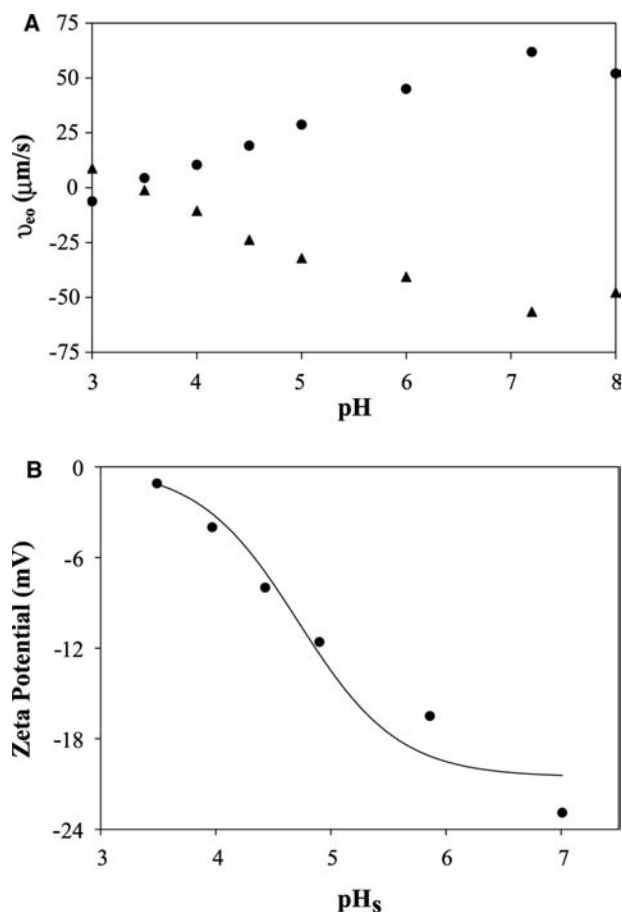

If it is assumed that  $\kappa^{-1}$  decreases with ionic strength ( $\mu$ ) as  $\kappa^{-1} \propto \mu^{-1/2}$  [Eq. (10)] and that  $\rho$  decreases with  $\mu$  as  $\rho \propto \mu^{-1}$ , we would predict that  $v_{eo}$  would decrease with  $\mu$  via  $v_{eo} \propto \mu^{-3/2}$ . The experimental data (Fig. 6) were fitted to the relationships  $v_{eo} \propto \mu^{-0.9}$  ( $R^2 = 0.993$ ) for the positive current density and  $v_{eo} \propto -\mu^{-1.0}$  ( $R^2 = 0.997$ ) for the negative current density. Hence the experimental fall-off of  $v_{eo}$  with increasing  $\mu$  is less than the predicted value.

Another factor needs to be considered. As shown in Eq. (9), the zeta potential is also directly proportional to the charge density. The charge density can be divided into two general categories: covalently bound charge and adsorbed charge. We discuss the effect of the quantity of covalently bound charge on  $v_{eo}$  in “Effect of Solution pH on Electroosmotic Flow.” It is possible that over the very large ionic strength range investigated in Fig. 6, there is a significant change in the quantity of adsorbed charge from the electrolyte. Adsorbed charge would primarily come from the anions of the electrolyte, and this adsorbed negative charge would increase with increasing  $\mu$ . This would cause both the zeta potential and  $v_{eo}$  to increase with increasing  $\mu$ . Because this is the trend opposite to the  $\kappa^{-1} \propto \mu^{-1/2}$  and  $\rho \propto \mu^{-1}$  dependencies discussed above, this would make the net decrease in  $v_{eo}$  with increasing  $\mu$  less extreme than the predicted  $\mu^{-3/2}$  dependence, and this is what is observed experimentally.

Finally, at the highest ionic strength used in Fig. 6, both the negative and positive electroosmotic velocities decrease nearly to zero. This shows that the effect of double-layer compression on the zeta potential (which causes  $v_{eo}$  to decrease with increasing ionic strength) dominates any effect of increasing adsorbed negative charge at high ionic strengths.

## EFFECT OF SOLUTION pH ON ELECTROOSMOTIC FLOW

Phenol transport data were obtained at applied current densities of positive and negative  $24.9 \text{ mA cm}^{-2}$  from solutions that were  $10 \text{ mM}$  in NaCl and  $0.5 \text{ mM}$  in phosphate, with the pH adjusted to values between 3 and 8. The NaCl served to maintain the ionic strength at a constant value. The  $v_{eo}$  vs. solution pH data are shown in Fig. 7A. In general, the expected trend for surface acidic sites is observed (i.e.,  $v_{eo}$  is high at high pH values, where the sites are deprotonated, and goes

**Fig. 7** (A) Plots of EOF vs. pH. Applied current densities were ( $\blacktriangle$ )  $-24.9 \text{ mA cm}^{-2}$  and ( $\bullet$ )  $+24.9 \text{ mA cm}^{-2}$ . (B) Plot of zeta potential of the CNM vs. surface pH [Eq. (11)]. The points are the experimental data and the curve is the best fit to Eq. (13).

to zero at lower pH values, where the sites are protonated). However, there are two features of the data in Fig. 7A that are unexpected.

First, although  $v_{eo}$  goes to zero at  $\text{pH} \sim 3.5$ , at lower pH, the flow resumes again, but in the opposite direction. This indicates that positive sites are introduced by protonation of some very weakly basic surface functional groups. Such protonatable carbon sites have been known for some time and have been attributed to two chemical features of the carbon:<sup>[47]</sup> pyrone-like structures and basal plane sites that act as Lewis bases. These protonatable carbon sites have also been observed in zeta potential measurements of carbon fibers.<sup>[37,38]</sup> The presence of these sites makes the EOF characteristics of the carbon nanotubes quite interesting because the direction of EOF can be switched by controlling the pH of the contacting solution phase.

The second unexpected feature of the data in Fig. 7A is that  $|v_{eo}|$  at  $\text{pH} = 8.0$  is lower than at  $\text{pH} = 7.2$ .

Although it is tempting to attribute this to experimental error, it was observed at all current densities studied and with both positive and negative currents. This is unexpected because the fraction of the deprotonated form of a monoprotic weak acid ( $\alpha_1$ ) goes to a maximum ( $\alpha_1 = 1$ ) at some high pH and does not change at higher pH values. Hence the plots of  $v_{eo}$  vs. pH would be expected to become flat at high pH. The unexpected decrease in  $|v_{eo}|$  suggests that anionic surface charge density decreases from  $\text{pH} = 7.2$  to  $\text{pH} = 8.0$ . As discussed above, it is possible that adsorbed phosphate contributes to the surface charge on the carbon nanotubes. Perhaps at  $\text{pH} = 8.0$ , adsorbed  $\text{HPO}_4^{2-}$  is displaced by  $\text{OH}^-$ , resulting in a net decrease in the negative surface charge density.

The data in Fig. 7A can be used to determine both the number density and  $\text{pK}_a$  of the surface acidic sites on the CNMs.<sup>[46]</sup> The Boltzmann equation is first used to calculate the surface hydronium ion concentration ( $[\text{H}^+]_s$ ) from the bulk solution hydronium ion concentration ( $[\text{H}^+]_o$ ):

$$[\text{H}^+]_s = [\text{H}^+]_o \exp(-e\zeta/2kT) \quad (11)$$

The requisite zeta potential values at each pH are obtained as before from the  $v_{eo}$  data (Fig. 7A). Following Jimbo, Tanioka, and Minoura<sup>[46]</sup> the surface charge density is related to the number density of acidic sites ( $N_a$ ) and the surface  $\text{pK}_a$  via:

$$\sigma = -[(eN_a)/(1 + 10^{\text{pK}_a - \text{pH}_s})] \quad (12)$$

Eq. (9) can be solved for  $\sigma$  and set equal to Eq. (12). Solving for the zeta potential gives:

$$\zeta = -[(eN_a)/(1 + 10^{\text{pK}_a - \text{pH}_s})](\kappa^{-1}/\epsilon) \quad (13)$$

Fig. 7B shows a plot of  $\zeta$  vs.  $\text{pH}_s$  obtained from the data in Fig. 7A, omitting the highest and lowest pH values where unusual effects (vide supra) were observed. The points are the experimental data, and the curve is the result of a nonlinear least squares regression fit of Eq. (13) to the experimental data using the surface  $\text{pK}_a$  and  $N_a$  as adjustable parameters. The best fit ( $R^2 = 0.95$ ) was obtained for  $\text{pK}_a = 4.7$  and  $N_a = 0.03$  acidic sites  $\text{nm}^{-2}$ .

The surface  $\text{pK}_a$  value obtained is typical of that for an alkyl carboxylic acid (e.g., acetic acid) dissolved in aqueous solution. However, it is often the case that  $\text{pK}_a$  values for surface-bound species differ from those obtained when the corresponding molecule is dissolved in an aqueous solution. For example, the  $\text{pK}_a$  values for *p*-aminobenzoic acid (PABA)<sup>[28]</sup> and 4-carboxyphenyl<sup>[48]</sup> immobilized on glassy carbon electrode surfaces were measured to be 3.0 and 2.8, respectively. These values are significantly different

from the  $pK_a$  values for the same molecules dissolved in aqueous solution (PABA = 4.6 and benzoic acid = 4.2). For this reason, although the most likely assignment for the surface acidic sites is carboxylic acid, we cannot unambiguously make this assignment at this time. A less likely alternative would be to posit a surface phenolic site whose surface  $pK_a$  has been dramatically shifted from the typical solution value. One potential source for discrepancies between surface and free solution  $pK_a$  values is electrostatic interactions between the surface-bound sites. The site density of  $0.03 \text{ nm}^{-2}$  indicates that the sites are, on average, 3 nm apart.<sup>[49]</sup> This is comparable to the double-layer thickness at the ionic strength used to obtain the data in Fig. 7. Hence electrostatic interactions between surface acidic sites should not be significant.

### EFFECT OF ELECTROCHEMICAL DERIVATIZATION ON ELECTROOSMOTIC FLOW

An interesting advantage of the CNMs is that they are electronically conductive and thus can be used as electrodes in electrochemical experiments.<sup>[8,16,17]</sup> This has allowed us to electrochemically derivatize the carbon nanotube walls to augment or change the fixed surface charge.<sup>[15,23]</sup> The derivatization method entails the electrooxidation of a primary amine to a cation radical at the carbon nanotube walls. This results in the formation of a C–N bond, thus covalently attaching the amine to the tube walls.

Fig. 8 shows a plot of  $v_{eo}$  vs. applied current density for an as-synthesized CNM and for membranes that had been electrochemically derivatized with either 2-(4-aminophenyl)ethylamine (APEA) or PABA.<sup>[28]</sup> The pH = 7.2 buffer used was such that the

**Fig. 8** Plots of electroosmotic velocity vs. applied current density for (▲) PABA-derivatized membrane, (■) as-synthesized membrane, and (●) APEA-derivatized membrane.

carboxylic acid was deprotonated and the amine was protonated. Considering the as-synthesized membrane first, we see the expected (Table 1) change from positive EOF at the positive applied current, to zero flow at no applied current, to negative EOF at negative applied current. The measured slope of the line corresponds to  $\zeta = -20.8 \text{ mV}$ . The same trend is observed for the PABA-derivatized membrane, but the slope of the  $v_{eo}$  vs. applied current density line is steeper and corresponds to  $\zeta = -30.6 \text{ mV}$ . This indicates that there is greater negative surface charge density after the attachment of PABA, which was the anticipated result.

For the APEA-derivatized membrane, positive EOF is observed at negative applied currents and negative EOF is observed at positive applied currents (Fig. 8). This indicates that the zeta potential, and thus surface charge, are now positive, again the anticipated result. The zeta potential for the APEA-derivatized membrane was determined to be  $+13.2 \text{ mV}$ . However, note that the magnitude of the zeta potential for the APEA-derivatized membrane is not as great as for either the underivatized or PABA-derivatized membranes. Although this might be because of a lower surface charge density for the APEA-derivatized membrane, other factors contributing to zeta potential [Eq. (8)] must also be considered. For the as-synthesized and PABA-derivatized membranes, the solution side of the double layer contains monovalent  $\text{Na}^+$  ions. In contrast, for the APEA-derivatized membrane, the double layer contains a mixture of monovalent  $\text{H}_2\text{PO}_4^-$  and divalent  $\text{HPO}_4^{2-}$  ions. The presence of the divalent ions (which are electrostatically preferred over the monovalent) will compress the double layer relative to the case where only monovalent ions are present.<sup>[50]</sup> As a result, at any surface charge density value, the double layer will be thinner when divalent ions are present. This will cause the zeta potential to be lower and  $v_{eo}$  to be smaller than in the monovalent case. This factor undoubtedly contributes to the smaller slope for the APEA-derivatized membrane (Fig. 8).

### CONCLUSION

Template synthesis is a highly flexible method for preparation of CNMs that can be used for a variety of purposes. For instance, EOF can be driven across template-prepared CNMs, and the rate and direction of flow can be controlled by changing the magnitude and the sign of the transmembrane current. The direction of EOF can also be switched by varying the pH of the contacting solution phase, and all of the pH-induced changes in EOF are reversible. This means, for example, that returning a membrane that had been exposed to pH = 3.5 buffer, where no EOF is

observed (Fig. 7A), to pH = 7.2 buffer restored the flow. Electrochemical derivatization methods can be used to attach specific surface functional groups to the carbon nanotubes and this provides another route for adjusting the rate and direction of EOF.

There is a third possible way to affect the rate and direction of EOF in such membranes. We have shown with gold nanotube membranes that the sign and magnitude of the excess surface charge can be controlled potentiostatically by simply applying a potential to the membrane in an electrolyte solution.<sup>[51]</sup> When negative potentials are applied, the nanotubes have excess negative (electron) surface charge, and when positive potentials are applied, the nanotubes have excess positive surface charge. This ability to control excess surface charge potentiostatically is unique to membranes that are electronically conductive, as are Au and CNMs. We are currently investigating whether this simple potentiostatic charging method can be used to control EOF in the CNMs.

## ACKNOWLEDGMENTS

Aspects of this work were supported by the National Science Foundation and the Office of Naval Research. The authors acknowledge valuable discussions with Prof. Henry White and Prof. Richard McCreery. Thanks are offered to Dr. David Mitchell for SEM analysis and Lacramioara Trofin for preparation of anodic alumina templates.

## INTRODUCTION

The discovery of carbon nanotubes (CNTs) in the early 1990s has stimulated intensive research to characterize their structure and properties. The outstanding electronic and mechanical properties suggest that CNTs may find application in electronic devices, composite materials, energy storage, field emission, biology, medicine, and chemical sensors. Most of these applications take advantage of the structure and physical properties of CNTs, such as high mechanical strength, excellent thermal and electric conductivity, high aspect ratio, and the hollow cavity. Chemical functionalization has been employed to tailor the properties of CNTs and to enhance the ability to manipulate CNTs.

CNTs contain only conjugated carbon atoms and therefore they are chemically inert, and this is reflected by their properties such as insolubility in all solvents and low chemical reactivity. The inert nature of CNTs limits the available identification and characterization tools, and hinders the manipulation and application of carbon nanotubes. Chemical functionalization of CNTs is a useful tool for addressing these problems, and functionalized CNTs have found broad application, including composite materials, sensors, and biomaterials. In the present entry we review the structure and properties of CNTs, but in the main we focus on the chemistry of carbon nanotubes including previous work and recent development.

## STRUCTURE AND PROPERTIES OF CARBON NANOTUBES

CNTs can be classified as single-walled carbon nanotubes (SWNTs) and multiwalled carbon nanotubes

(MWNTs). The structure of an individual SWNT can be regarded as a two-dimensional (2-D) graphene sheet cut at various angles with respect to the hexagonal lattice that has been wrapped up into a seamless cylinder, which is capped by fullerene hemispheres at both ends (Fig. 1). MWNTs are composed of concentric cylinders placed around a common central hollow, with spacing between the layers close to that of the interlayer distance in graphite ( $\sim 0.34$  nm).

CNTs can be metallic or semiconducting, depending on their diameter and chirality. “Armchair” tubes have energy bands that cross the Fermi level and are therefore metallic. “Chiral” and “zigzag” nanotubes are expected to be metallic when  $n - m = 3l$  (where  $l$  is an integer) or semiconducting with an energy gap of order  $\sim 1$  eV when  $n - m \neq 3l$ .  $n$  and  $m$  are integers of the vector equation  $\mathbf{R} = n\mathbf{a}_1 + m\mathbf{a}_2$ , where  $\mathbf{a}_1$  and  $\mathbf{a}_2$  are the unit cell vectors of a graphene sheet. Fig. 2 shows the electronic density of states (DOS) of a metallic and a semiconducting SWNT close to Fermi level. For the metallic SWNT, there is a finite value of the DOS at the Fermi level. On the other hand, a complete gap between the spikes close to Fermi level can be found in the semiconducting SWNT. The energy separation between each pair of peaks represents the band gap of SWNTs. By using simple tight-binding (STB) theory, in which the electronic band structure is assumed to arise from a pure p-orbital at each conjugated carbon atom, the low-energy band gap transitions take a simple analytical form:  $S_{11} = 2a\beta/d$ ,  $S_{22} = 4a\beta/d$ ,  $M_{11} = 6a\beta/d$ , where  $a$  is the carbon-carbon bond length (0.142 nm),  $\beta$  is the transfer or resonance integral between the p- and  $\pi$ -orbitals ( $\beta = 2.9$  eV), and  $d$  is the diameter (nm) of the particular semiconducting or metallic SWNT.  $S_{11}$  and  $S_{22}$  are the first and second pairs of singularities in the

Fig. 1 Structure of the single-walled carbon nanotube.

DOS of semiconducting SWNTs, respectively.  $M_{11}$  corresponds to the transition between the first pair of singularities in the DOS of metallic SWNTs.<sup>[1-3]</sup> The characteristic interband electronic transitions provide the spectroscopic signature of the SWNTs in the near-IR (NIR)/VIS spectral region (Fig. 2). As most SWNT preparations are a mixture of metallic and semiconducting SWNTs, the interband transitions arising from both species are visible.

Besides these unique electronic properties, CNTs exhibit excellent mechanical and thermal properties. CNTs exhibit the highest Young's modulus and tensile strength of all known materials. The Young's modulus for an individual (10, 10) SWNT is  $\sim 0.64$  TPa<sup>[4]</sup> and up to 1.47 TPa for a 15-SWNT rope,<sup>[5]</sup> which is much higher than that of conventional carbon fibers which have values in the range of 200–800 GPa.<sup>[6]</sup> Young's modulus of MWNTs was reported to be 1–2 TPa,<sup>[7]</sup> and the bending strength of individual MWNTs reaches 28.5 GPa.<sup>[8]</sup> The measured thermal conductivity of an individual MWNT ( $\sim 3000$  W/m<sup>2</sup>K) is larger than that of natural diamond and the basal plane of graphite (both 2000 W/m<sup>2</sup>K).

## CHEMISTRY OF CARBON NANOTUBES

The covalent chemistry of CNTs may be classified into two categories.<sup>[9]</sup> The first involves functionalization at

the ends or at defect sites of the CNTs, where there exists the possibility to add to the carbon nanotube at a  $\sigma$ -bonded site, without attacking the  $\pi$ -system; this type of chemistry usually involves reaction at a previously introduced carboxylic acid group. These carboxylic acid groups are usually generated by nitric acid treatment and can be used as precursors in functionalizations such as amidation and esterification.<sup>[10,11]</sup> The second type of covalent chemistry involves sidewall functionalization in which the carbon-carbon double bonds on the sidewall of CNTs react. Such reactions include fluorination,<sup>[12]</sup> carbene<sup>[9,11,13,14]</sup> or nitrene addition, Birch reduction,<sup>[9,15]</sup> 1,3-dipolar addition,<sup>[16]</sup> and reactions with radicals.<sup>[17-19]</sup>

## Purity Evaluation of SWNTs

In current preparations, a large amount of impurities, such as metal catalysts, amorphous carbon, and carbon nanoparticles, are generated during SWNT production. In order to develop a rigorous macromolecular science of CNTs it is necessary to work with materials of the same high level of purity that is found in the pharmaceutical, electronics, and polymer industries. An obvious first step is the development of quality control and quality assurance criteria for the bulk purity of CNTs. Recently, a method was reported to quantitatively evaluate the carbonaceous purity of electric arc produced as-prepared SWNT soot by using solution-phase near-IR spectroscopy (NIR), in which the purity of a SWNT sample (X-SWNT) was evaluated against a reference sample (R-SWNT) by using the region of the second interband transition ( $S_{22}$ ) for semiconducting SWNTs;<sup>[20-22]</sup> whereas the metal content is obtained by thermogravimetric analysis.<sup>[22]</sup> As illustrated in Fig. 3, AA(T, R-SWNT) and AA(T, S-SWNT) (areal absorbance) are obtained by integration

Fig. 2 Interband transition of arc-produced SWNTs near Fermi level.

Fig. 3 Purity evaluation of SWNTs.

of the NIR spectra between the spectral cutoffs of  $SCL = 7750$  and  $SCH = 11,750 \text{ cm}^{-1}$ , whereas  $AA(S, R-SWNT)$  and  $AA(S, S-SWNT)$  represent the area under the  $S_{22}$  absorption after baseline correction. In the example shown in Fig. 3, the carbonaceous relative purity of X-SWNT is then obtained as:

$$\begin{aligned} \text{Purity} &= [AA(S, S-SWNT) \div AA(T, S-SWNT)] \\ &\div [AA(S, R-SWNT) \div AA(T, R-SWNT)] \\ &= 0.058 \div 0.141 = 41\% \end{aligned}$$

This method is also applicable to the evaluation and optimization of SWNT purification procedures, and makes it possible to investigate the effects of purification treatment on SWNTs in a quantitative manner.<sup>[21,22]</sup>

### Reactivity of SWNTs

The strain in non-planar-conjugated organic molecules arises from two principal sources: pyramidalization of the conjugated carbon atoms, and  $\pi$ -orbital misalignment between adjacent pairs of conjugated atoms.<sup>[23–25]</sup> It is well known that the chemistry of the fullerenes is characterized by addition reactions.<sup>[26–29]</sup> The relatively high reactivity of  $C_{60}$  results from the conversion of trigonal carbon atoms ( $sp^2$ -hybridized) to tetrahedral carbon atoms ( $sp^3$ -hybridized). This serves to release the tremendous strain present in the spheroidal geometry, because the pyramidalization angle  $\theta_p$ , which is related

to the curvature at a conjugated carbon atom, of  $C_{60}$  ( $\theta_p = 11.64^\circ$ ) is actually closer to the ideal tetrahedral angle ( $\theta_p = 19.47^\circ$ ) than to the planar geometry required for trigonal hybridization ( $\theta_p = 0$ ).<sup>[25,30]</sup> Fig. 4 shows the pyramidalization angle of  $sp^2$ - and  $sp^3$ -hybridized carbon atoms. As a result of the spheroidal geometry there is no  $\pi$ -orbital misalignment in  $C_{60}$ .

From the standpoint of chemistry, carbon nanotubes can be divided into two regions: the end caps and the sidewall. The origins of the strain in the end caps and the sidewall of CNTs are somewhat different. The end cap of a CNT can be regarded as a hemispherical fullerene, and the carbon-carbon bonds in this region of the carbon nanotube therefore experience

Fig. 4 Pyramidalization angle ( $\theta_p$ ) of  $sp^2$  (left)- and  $sp^3$  (right)-hybridized carbon.

**Fig. 5** The  $\pi$ -orbital misalignment angles ( $\phi$ ) along the C1–C4 in the (5, 5) SWNT and fullerene.

a similar degree of strain due to pyramidalization to that of the equivalent fullerene. However, as the curvature in the sidewall of a CNT is much less than that in a fullerene of equivalent diameter, the carbon–carbon bonds in the sidewall of a carbon nanotube are much less reactive than those in the end cap.<sup>[9,31]</sup> In the fullerenes, pyramidalization is essentially the only source of strain because the  $\pi$ -orbital alignment is almost perfect because of the quasi-spheroidal geometry.<sup>[30,31]</sup>

In the case of the armchair CNT shown in Fig. 5, there are two types of carbon–carbon bonds in the sidewall: one is parallel to the circumference plane (which is perpendicular to the axis of the CNT), whereas the other lies at an angle to the circumference plane. As may be seen in Fig. 5, the first bond is reminiscent of the situation in the fullerenes with perfect alignment of the lobes of the  $\pi$ -orbitals, whereas the second bonding geometry requires a twist of the  $\pi$ -bond.<sup>[9,31]</sup> In the latter case, the angle between the lobes of the  $\pi$ -orbitals of the adjacent carbon atoms [ $\pi$ -orbital misalignment angle ( $\phi$ )] will differ from zero and this is a source of strain in the carbon nanotubes that is almost totally absent in the fullerenes. This strain due to orbital misalignment leads to a differentiation between the bonds in the CNTs that may be reflected in their relative reactivity.

In the foregoing discussion we have adopted the  $\pi$ -orbital axis vector (POAV) analysis, which was successful in the analysis of the electronic structure and chemistry of the fullerenes,<sup>[25]</sup> and applied it to the CNTs. This analysis relies on the local geometry of the structures; however, the CNTs possess an extended electronic structure and this leads to the development of energy bands, which in the case of the metallic SWNTs produces a finite DOS at the Fermi level;<sup>[13,32]</sup> the semiconducting SWNTs, of course, have an energy gap at the Fermi level. Thus there should be a marked difference in the reactivity of metallic and semiconducting SWNTs in chemical reactions that are initiated by electron donation or electron transfer processes.<sup>[9,19]</sup>

## Covalent Functionalization

### Oxidation of Carbon nanotubes

Oxidative processes were among the first chemical reactions to be applied to CNTs,<sup>[33]</sup> mainly for the purposes of purification and catalyst removal. Heating of CNTs in air at 700°C for 10 min leads to the opening of the hemispherical end caps of CNTs and demonstrated the different reactivities of the bonds in CNTs (end cap vs. sidewall). The controlled annealing of SWNTs in O<sub>2</sub> is an effective method of purification.<sup>[21]</sup> Other gas-phase oxidation methods including the use of H<sub>2</sub>S + O<sub>2</sub><sup>[34]</sup> and O<sub>3</sub><sup>[35]</sup> have also been reported. Liquid-phase oxidation processes, such as treatment with HNO<sub>3</sub>,<sup>[22,36–40]</sup> HNO<sub>3</sub> + H<sub>2</sub>SO<sub>4</sub>,<sup>[10,40]</sup> H<sub>2</sub>SO<sub>4</sub> + KMnO<sub>4</sub>,<sup>[41]</sup> and KMnO<sub>4</sub>,<sup>[40]</sup> have been widely used in the processing of CNTs. These oxidants can remove the end caps of CNTs and introduce functional groups, such as –COOH, –OH, –C–O, at the dangling bonds.<sup>[40,42]</sup> Among these functionalities, the carboxylic acid group is of great importance as it has been employed in a large number of CNT functionalization reactions. After nitric acid treatment of SWNTs, the concentration of carboxylic acid groups is about 1–3 at.% based on acid–base titration.<sup>[43]</sup>

### End functionalization

As the carbon atoms at the ends have larger curvature than carbon atoms in the sidewall, they can be oxidized more easily than the other carbon atoms. The end (and defect) functionalization of the CNTs has important ramifications:

1. End functionalization does not destroy the extended  $\pi$ -network, thereby retaining the unaltered electronic and mechanical properties of the CNTs.

Fig. 6 Schematic representation of end functionalization of SWNTs.

- End functionalization can dramatically change the chemical and physical properties of CNTs, enhance their solubility, and facilitate the manipulation of CNTs.

The carboxylic acid groups that terminate the ends and defect sites of SWNTs act as chemical precursors for the functionalization chemistry (Fig. 6). The first chemical synthesis of soluble SWNTs was reported in 1998.<sup>[11]</sup> The functionalization methodology was based on the amidation of SWNTs with a long-chain amine [octadecylamine (ODA)]. Acid-treated SWNTs were first reacted with thionyl chloride to form an acyl chloride intermediate.<sup>[10]</sup> Then the acyl chloride intermediate was heated with ODA at 90°C to 100°C for 96 hr. The resulting amide form of SWNTs was soluble in many common organic solvents, including chloroform, dichloromethane, aromatic solvents (benzene, toluene, chlorobenzene), and CS<sub>2</sub>. The solubility of the s-SWNTs in 1,2-dichlorobenzene and CS<sub>2</sub> is higher than 1 mg/mL. This important finding not only provides a new method for obtaining well-characterized highly purified SWNT materials by separating soluble SWNTs from insoluble impurities,<sup>[44,45]</sup> but also opened the door for the study of SWNT chemistry in the organic solution phase. Various solution spectroscopy can be applied to characterize the dissolved SWNTs.<sup>[11,46,47]</sup>

Based on the same method, other amines, such as 4-dodecyl-aniline,<sup>[46]</sup> glucosamine<sup>[48]</sup> and amine-rich polymers, dendra, and proteins,<sup>[49–52]</sup> have been used to functionalize SWNTs. The methodology of these reactions is based on amidation via acyl chloride intermediate or the 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDAC)- or 1,3-dicyclohexylcarbodiimide (DCC)-activated reaction. The poly(propionylethylenimine-co-ethylenimine (PPEI-EI)-<sup>[51]</sup> and bovine serum albumin (BSA)-functionalized SWNTs<sup>[52]</sup> were quite soluble in water as well as organic solvents. Sonication during the

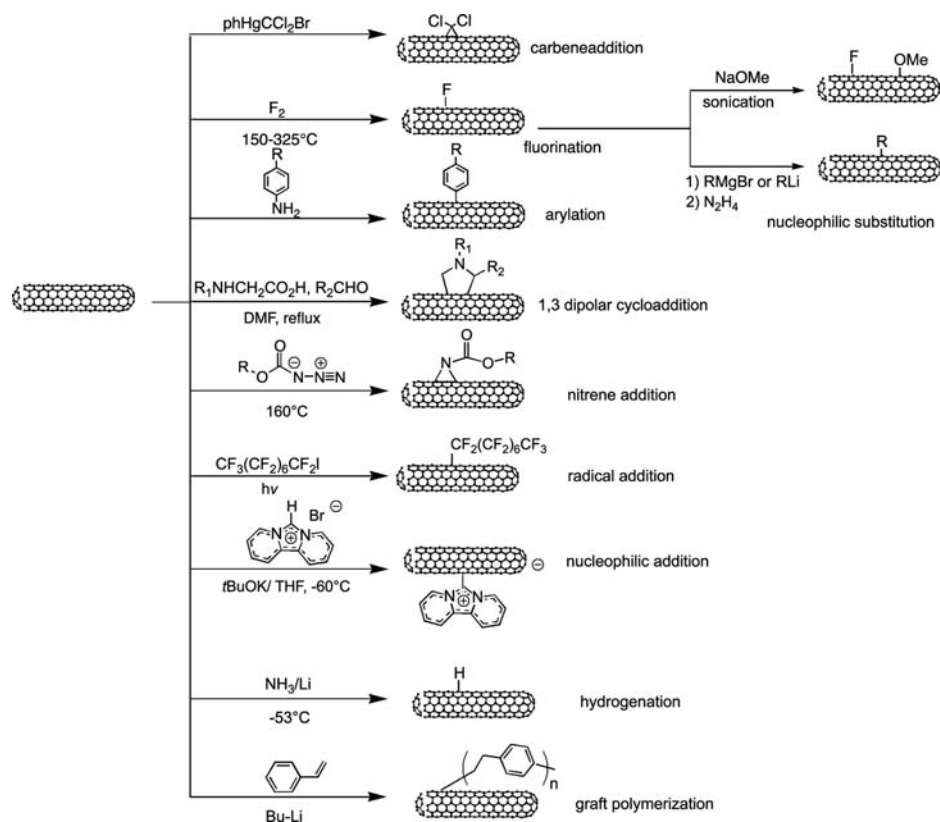

reaction can promote EDAC-activated amidation.<sup>[51]</sup> The ring closure of SWNTs by reaction between the –COOH and –OH at their ends has also been reported.<sup>[53]</sup>

Solution-phase mid-IR spectroscopy had been used to estimate the ratio of the carbon atoms in the SWNT backbone to the carbon atoms in the end-groups and at defect sites of the ODA-functionalized soluble SWNTs.<sup>[47]</sup> By measuring the intensity of  $\nu_{(C-H)}$  stretching vibrations that originate from the ODA alkyl chains and comparing with an external standard, the fractional amount of the alkyl chains in the soluble SWNTs samples can be determined. A quantitative C<sup>13</sup> NMR study of ODA functionalized MWNTs has also been used to discuss the relationship between the content of ODA and the solubility of the CNTs.<sup>[54]</sup>

### Sidewall functionalization

As the carbon–carbon bonds in the sidewall of the CNTs are of lower reactivity than the bonds in fullerenes, reagents with high chemical reactivity have been involved in the sidewall functionalization of CNTs (Fig. 7). Such reagents include carbenes,<sup>[9,11,13]</sup> fluorine,<sup>[12]</sup> aryl radicals,<sup>[17,18,55]</sup> and azomethine ylides.<sup>[16]</sup> Several methods for the metal reduction of SWNTs have also been reported,<sup>[9,15]</sup> and SWNTs with alkyl substituents were obtained by treating the fluorinated SWNTs with nucleophilic reagents such as alkyllithium and alkyl magnesium bromides.<sup>[56,57]</sup>

Once the sidewall functionalization of SWNTs had been accomplished, the properties of the SWNTs change dramatically. The carbon atoms on the sidewalls of SWNTs that react with functional groups are converted from sp<sup>2</sup> into sp<sup>3</sup> hybridization. The saturation of the  $\pi$ -network leads to a significant change in the electronic band structure of SWNTs that can be monitored by optical spectroscopy.<sup>[11,13,14,17,18,55]</sup> The presence of sp<sup>3</sup>-hybridized carbon atoms in the SWNT framework can be detected by Raman spectroscopy<sup>[12,14,17,18,55,58,59]</sup>

**Fig. 7** Schematic representation of sidewall functionalization of SWNTs.

and is reflected by an increase in the relative intensity of the disorder mode of the SWNTs after sidewall functionalization. The solubility of sidewall-functionalized SWNTs in organic solvents or water is usually improved by the addition of different functional groups.

Phenyl(bromodichloromethyl)-mercury has been used to add dichlorocarbene to both soluble and insoluble SWNTs (Fig. 8).<sup>[9,11,13,14]</sup> The degree of dichlorocarbene functionalization of soluble HiPco SWNTs can be as high as 23%, which is sufficient to almost completely eliminate all vestiges of the interband transitions in the SWNTs. The transitions at the Fermi level in the metallic SWNTs that appear in the far-infrared (FIR) region of the spectrum (Fig. 9) show a dramatic decrease of intensity on dichlorocarbene functionalization, which indicates that the dichlorocarbene addition significantly perturbs the conjugated  $\pi$ -network and

converts a metal into semiconductor. On the other hand, the reaction of the SWNTs with oxidants causes an increase in the intensity of absorption at the Fermi level that was observable in the FIR due to hole doping of the semiconducting SWNTs.<sup>[13,32]</sup> Therefore the FIR region of the spectrum allows a clear differentiation between covalent and the ionic chemistry of SWNTs.<sup>[14]</sup>

The fluorination of SWNTs can produce a high degree of functionalization (up to the composition  $C_2F$ ) by using elemental fluorine at temperatures from 150°C to 600°C.<sup>[12]</sup> FT-IR spectra confirmed that the fluorine was covalently bonded to the carbon on the sidewall ( $\nu_{C-F}$  at 1220–1250  $\text{cm}^{-1}$ ). TEM images of these highly functionalized SWNTs showed that the nanotubes were significantly degraded. The electrical conductivity of the functionalized SWNTs (resistance

**Fig. 8** Schematic representation of dichlorocarbene addition to soluble SWNTs.

**Fig. 9** Absorption spectra of films of soluble SWNTs functionalized with dichlorocarbene (right). The curves are labeled with the degree of functionality. Spectra are normalized to the value of the absorption at the  $\pi$ -plasmon peak at  $37,000\text{ cm}^{-1}$ .

$>20\text{ M}\Omega$ ) is greatly decreased in comparison with the pristine SWNTs (resistance  $10\text{--}15\text{ }\Omega$ ), which indicates a disruption of the conjugated  $\pi$  network. Hydrazine was used to defluorinate the SWNTs.

When the temperature of fluorination was  $400^\circ\text{C}$  or higher, most of the SWNT structure was destroyed. This was confirmed by Raman spectroscopy that showed that the radial ( $186\text{ cm}^{-1}$ ) and tangential ( $1580\text{ cm}^{-1}$ ) modes decreased, whereas the disorder mode ( $1340\text{ cm}^{-1}$ ) increased.

The fluorinated SWNTs are soluble in alcohols after ultrasonication.<sup>[58]</sup> Nucleophilic reagents such as alkyl-lithium and alkyl magnesium bromides have been used to convert fluorinated SWNTs to alkylated SWNTs.<sup>[56]</sup> The alkylated SWNTs, such as hexyl-SWNTs, were soluble in THF and methylene chloride. Pristine SWNTs could be recovered from hexyl-SWNTs by heating in air at  $250^\circ\text{C}$  for 1 hr. The weight loss of these derivatized tubes was about 35%, corresponding to the attachment of a hexyl group to 1 in every 10 sidewall carbon atoms.

Aryl diazonium salts are known to react with olefins<sup>[60]</sup> and have been used for the sidewall functionalization of SWNTs.<sup>[17,18]</sup> A series of aryl radicals have been generated by electrochemical reduction of aryl diazonium salts to derivatize SWNTs. The estimated degree of aryl radical functionalization was as high as 1 out of every 20 carbons in the SWNTs. Such

high functionalization significantly improved the solubility of the SWNTs in organic solvents (THF, DMF, chloroform). The Raman spectra showed a significant increase in the disorder mode of the SWNTs at  $1290\text{ cm}^{-1}$ , and a complete loss of structure in the solution-phase absorption spectra was observed. The functional groups can be removed by heating at  $500^\circ\text{C}$  in argon, restoring the pristine SWNTs. In a solvent-free sidewall functionalization of SWNTs, the SWNTs were mixed with 4-substituted aniline and vigorously stirred at  $60^\circ\text{C}$  in the presence of isoamyl nitrite or sodium nitrite.<sup>[55]</sup> The isoamyl nitrite or sodium nitrite converted the aniline into diazonium salts which then reacted with SWNTs. The products showed a significant loss of the fine structure of interband transitions in the NIR-VIS region of the spectrum and a strong increase in the disorder mode in the Raman spectra. The aryldiazonium salts have also been used to react with individual SDS-coated SWNTs in aqueous solution to form aryl functionalized SWNTs.<sup>[61]</sup> 4-(10-hydroxydecyl)benzoate-SWNTs have been produced by the same method and used to make composite materials with polystyrene.<sup>[59]</sup>

Sidewall functionalization of SWNTs by using aryldiazonium salts shows high chemoselectivity with metallic SWNTs vs. the semiconducting SWNTs.<sup>[19]</sup> The high selectivity is reflected in the optical spectra of the SWNTs that show a different degree of functionalization in the metallic and semiconducting SWNTs. The absorption intensity of the electronic interband transitions of the metallic SWNTs decreased with increasing degree of functionalization, whereas the absorption intensity of semiconducting SWNTs was unaffected. The result was confirmed by Raman spectroscopy on a sample with 22.4 groups attached per 1000 carbon atoms, in which all of the metallic modes had disappeared but the semiconductor modes remained. The reaction was explained in terms of the formation of a charge-transfer salt involving the aryldiazonium salt at the SWNT surface. Because the metallic SWNTs are superior electron donors they react preferentially with the diazonium salts.

The 1,3-dipolar cycloaddition reaction of azomethine ylides is another important method used in sidewall functionalization of SWNTs.<sup>[16]</sup> This 1,3-dipolar cycloaddition has been widely applied to the organic modification of fullerenes.<sup>[62,63]</sup> The 1,3-dipolar cycloaddition of azomethine ylides to SWNTs has been accomplished by using aldehyde and a N-substituted glycine derivative. The glycine derivative has a long ether chain to enhance the solubility of SWNTs in organic solvents such as chloroform, methylenechloride, acetone, alcohol, and even water. The degree of functionalization was estimated to be 1 in 95 SWNT carbon atoms. The NIR spectra of these pyrrolidine

functionalized SWNTs showed some loss of the electronic properties of the parent SWNTs. The pyrrolidine-functionalized SWNTs associated in bundles with diameters of 100 nm. The authors found that the pyrene-modified tubes formed more compact bundles than other functionalized SWNTs.

Recently, SWNTs were functionalized with polystyrene via an in situ polymerization.<sup>[64]</sup> First, the SWNTs were treated with *sec*-butyllithium to form carbanions. When styrene monomer was added, both free *sec*-butyllithium and the SWNT carbanions initiated polymerization, resulting in an intimately mixed composite system. The loading of SWNTs in the graft polymer was about 0.05 wt.%. The composite was soluble in organic solvents such as dimethylformamide, chloroform, and tetrahydrofuran.

### Noncovalent Functionalization

The advantage of noncovalent functionalization is that it does not destroy the conjugation in the CNTs. One strategy for non-covalent functionalization is based on the usage of an amphiphilic molecule or polymer to interact with CNTs via its hydrophobic part, whereas the hydrophilic part of this molecule can enhance the solubility of CNTs or react with other molecules. Another method is the ionic interaction of SWNTs, which leads to the formation of acid–base salts or charge-transfer complexes. For example, the acid form of SWNTs was heated with melted octadecylamine to form an SWNT-carboxylate zwitterion.<sup>[65]</sup> Such a form of SWNTs is soluble (>0.5 mg/mL) in tetrahydrofuran and 1,2-dichlorobenzene. Generally, a 0.1 mg/mL solution is stable for more than 10 days and is visually non-scattering. The majority of the SWNT ropes were exfoliated into small ropes (2–5 nm in diameter) and individual SWNTs with length of several micrometers during the dissolution process.

Non-covalent functionalization of SWNTs has been achieved by using small molecules such as 1-pyrenebutanoic acid succinimidyl ester.<sup>[65]</sup> This amphiphilic molecule can attach to the surface of SWNTs by  $\pi$ – $\pi$  interaction with the pyrene moiety, while the hydrophilic ester of this molecule enhances the solubility of SWNTs, and this approach has been used in protein immobilization, including the study of ferritin, streptavidin, and biotin–PEO–amine. These bioactive molecules have been attached to the surface of SWNTs via a nucleophilic substitution of *N*-hydroxysuccinimide by using the amine group on the proteins to form an amide.

Molecules of high molecular weight can wrap themselves around the surfaces of SWNTs. Polymers, including polyvinyl pyrrolidone (PVP) and polystyrene sulfonate (PSS),<sup>[66]</sup> poly(phenylacetylene) (PPA),<sup>[67]</sup>

poly(metaphenylenevinylene) (PmPV),<sup>[68]</sup> poly(aryleneethynylene)s (PPE),<sup>[69]</sup> poly-anisidine (POAS),<sup>[70]</sup> amylose,<sup>[71]</sup> amphiphilic copolymer poly(styrene)-block-poly(acrylic acid),<sup>[72]</sup> and natural polymer,<sup>[73]</sup> have been used to wrap or encapsulate CNTs.

The interaction between the CNTs and the polymer hosts usually originates from the van der Waals interaction between the surface of the CNTs and the hydrophobic part of the host polymer. The mechanism of these polymer-wrapping methods depends on both the interaction between SWNTs and polymers, and the structure of the polymers. A thermodynamically driven model for wrapping SWNTs has been suggested, wherein the polymer disrupted both the hydrophobic interface with water and nanotube–nanotube interactions in the CNT aggregates.<sup>[66]</sup> AFM investigation revealed that the individual PVP–SWNT displayed a uniform diameter along its length, which indicates that the polymers were uniformly wrapped along the surface of the SWNTs rather than being randomly attached. A helical wrapping model was used to explain the solubilization of SWNTs at the molecular level. In another case, a straight, rigid polymer, poly(aryleneethynylene)s (PPE), has been used to interact with SWNTs.<sup>[69]</sup> Because the polymer is short and rigid, it attached to the surface of SWNTs in a non-wrapping form parallel to the nanotube axis.

### APPLICATIONS OF CHEMICALLY FUNCTIONALIZED CARBON NANOTUBES

The functionalized CNTs can have higher solubility or differing molecular affinity or electronic response and this allows for more effective use of their outstanding electronic and mechanical properties. It is already clear that the CNTs will find applications in electronics, sensors, composite materials, biology, and medicine.

The strength and high aspect ratio of CNTs are particularly valuable in the design of probe tips for scanning probe microscopy,<sup>[74–76]</sup> electrochemistry,<sup>[77]</sup> and biological analysis.<sup>[78,79]</sup> In 1998, a nanometer-size probe was made with covalently modified MWNTs.<sup>[75]</sup> Using carbodiimide chemistry, carboxyl groups at the tip ends coupled with different amines to form amide-linked groups. By employing the characteristic properties of these amide groups, this chemically modified MWNT probe could be used for titrating acid and base groups, to image patterned samples based on molecular interactions, and for measuring the binding force between single protein–ligand pairs. Individual semiconducting SWNT-based chemical sensors are reliable for the detection of small amounts of gases such as NH<sub>3</sub> and NO<sub>2</sub>.<sup>[80]</sup> The mechanism of this sensor action is based on charge transfer between the

SWNTs and NO<sub>2</sub> or NH<sub>3</sub>. Exposure to the gases affected the electronic properties of the SWNTs and led to a change in the conductivity. It was observed that the conductance of the SWNT sample dramatically increased in NO<sub>2</sub> and decreased in NH<sub>3</sub>.

Because of their 1-D structure and excellent mechanical properties, CNTs are the ideal reinforcing fibers for composite materials. By the addition of CNTs, the strength, elasticity, toughness, durability, and conductivity of the composite material can be improved. The major challenge in using CNTs for composite materials lies in achieving a homogeneous dispersion of CNTs throughout the matrix without destroying their integrity, and an enhanced interfacial bonding with the matrix. Functionalized CNTs show great potentials in this field and CNT composite materials are under active investigation. Conducting polymers such as polypyrrole (PPy) has been used to grow composite films with MWNTs by electrochemistry,<sup>[81]</sup> a SWNT/PmPV composite has been used in making organic light-emitting diodes,<sup>[82]</sup> poly(*p*-phenylene benzobisoxazole) (PBO) has been applied to produce PBO/SWNT fibers.<sup>[83]</sup>

Recently, there has been intense interest in exploring the novel properties of CNTs and especially SWNTs for biological applications. The 1-D structure of SWNTs makes them an ideal candidate for the development of a new generation of biodevices. Because SWNTs are molecular wires with every carbon atom exposed on the surface, SWNTs are promising candidate for the development of extremely sensitive biosensors. Because of their small dimensions SWNTs can be easily introduced into cells with little or no disturbance of the cell function. Additionally, the outstanding electronic properties of SWNTs will allow biological events to be addressed electronically. The progress in understanding the interactions between CNTs and biomolecules has stimulated extensive research on the fabrication of bio-nanodevices and especially biosensors. SWNT devices have shown high sensitivity in the detection of redox enzymes,<sup>[84–86]</sup> DNA,<sup>[87]</sup> and proteins.<sup>[88]</sup>

Yet the interactions of biomolecules with SWNTs are poorly understood. Early studies have focused on the non-specific interactions between proteins and CNTs arising from the hydrophobic nature of the nanotube walls. It has been demonstrated that streptavidin and HupR form highly ordered helical structures upon adsorption on MWNTs.<sup>[89]</sup> Non-specific binding on SWNTs has been shown to be a general phenomenon with a wide range of proteins, including streptavidin, avidin, bovine serum albumin, glucosidase, staphylococcal protein A, and human IgG.<sup>[65,84,89–91]</sup> These non-specific interactions could be explored for the controlled organization of SWNTS into useful architectures. It has been shown that specifically designed amphiphilic  $\alpha$ -helical peptides wrap and solubilize nanotubes, enabling controlled assembly of peptide-wrapped

nanotubes into macromolecular structures.<sup>[92]</sup> The importance of the non-specific interactions between SWNTs and biomolecules has been recently demonstrated in a study on the separation of metallic from semiconducting nanotubes by DNA-assisted dispersion in aqueous solution.<sup>[93]</sup> It has been suggested that the highly efficient mechanism for dispersion of individual SWNTs in solution involves  $\pi$ -stacking interactions between the nanotube walls and the DNA-bases, resulting in helical wrapping of the nanotubes, complemented by hydrophilic interactions between the sugar-phosphate groups in the backbone of DNA and water molecules, rendering the hybrid structure soluble in water. Strategies to prevent the nonspecific binding of proteins to SWNTs by immobilization of PEG in the presence of surfactant have also been developed.<sup>[90]</sup>

As the biocompatibility and biorecognition properties are key issues regarding biological applications of SWNTs, recent research focuses on the functionalization of SWNTs. Both covalent and noncovalent functionalization with proteins, enzymes, and DNA has been explored. The non-covalent approach involves  $\pi$ -stacking of 1-pyrenebutanoic acid succinimidyl ester onto the sidewalls of SWNTs.<sup>[65]</sup> This technique has enabled the immobilization of a wide range of biomolecules on the sidewalls of SWNTs including ferritin, streptavidin, and biotin-PEO-amine.<sup>[65]</sup> The immobilization is robust and its application has been demonstrated in biosensors based on glucose oxidase-functionalized SWNTs.<sup>[91]</sup>

An alternative approach to tethering biological molecules to SWNTs in a controlled manner is covalent functionalization. Covalent functionalization provides better integrity, stability, and reproducibility of the fabricated devices. Typically, covalent binding of proteins and enzymes utilizes the diimide-activated amidation of carboxylic acid-functionalized carbon nanotubes as schematically illustrated in Fig. 10 (paths a and b).<sup>[52,94–96]</sup> For covalent attachment of DNA, amine-terminated SWNTs are cross-linked with succinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC) to produce maleimide groups further reacted with thiol-terminated DNA (path c).<sup>[97]</sup>

A method for functionalization of SWNTs with *N*-protected amino acids based on the 1,3-dipolar cycloaddition reaction to the external walls of SWNTs has also been reported.<sup>[98]</sup>

While in most cases the functionalization is essential to impart biorecognition properties to SWNTs, it should be noted that antifullerene IgG monoclonal antibody<sup>[99]</sup> and several peptides have been shown to bind specifically to SWNTs.<sup>[100]</sup>

The ultimate goal of this work is the utilization of the CNTs in medicine leading to the development of a broad-based effort in nanomedicine which offers the promise of conquering disease at the level at which

Fig. 10 Schematic representation of functionalized SWNTs in biological application.

it occurs—the molecular level. Thus it is important to begin to investigate the interaction of CNTs with live cells. The first efforts in this direction explored the use of CNTs as the substratum for neuron growth.<sup>[101]</sup>

## CONCLUSION

The chemistry of CNTs has made enormous strides, and it is clear that this subject will drive the applications of carbon nanotubes. In order to further refine the chemically functionalized CNTs, it is important to begin the chemistry with high quality materials. Functionalization of individual CNT, and particularly CNTs of defined length, diameter, and chirality, is the next step that will lead to the control of CNT-based materials and devices at the molecular level.

## INTRODUCTION

Carbon nanotubes, single or multiwalled, have been the object of a large amount of studies since their discovery in the last decade of the 20th century. Those studies revealed the nature of this material, its chemical structure, and many of its physical and chemical properties. Almost immediately after its discovery, a major technological application was envisioned as potential medium to store hydrogen, and other gases employed as fuel. Despite the large amount of work performed in this area, there is no agreement in many basic questions concerning the gas storage capacity of this material. Here we review the work performed in the area of gas adsorption on carbon nanotubes. Those studies aimed to determine the adsorption capacity of different gases, to characterize the structure of the material through the adsorption of nitrogen, to explore the molecular sieving properties of nanotubes, and to test models involving matter in quasi one-dimension or in confined spaces.

## GAS PHYSISORPTION

Gas physisorption is mostly employed to characterize the surface structure of carbon nanotubes.<sup>[1–11]</sup> Stan et al.<sup>[12]</sup> analyzed the conditions required for a given gas to be adsorbed in carbon nanotubes or their bundles; their results confirm the intuitive expectation that small molecules can be adsorbed within both the interstitial channels and the tubes. It has been demonstrated<sup>[13]</sup> that the entry ports of single-walled carbon nanotubes (SWNT) are blocked with functional groups (quinone, carboxylic, etc.) that can be eliminated through a thermal activation at moderate temperatures; Fig. 1 is a schematic representation of an open-ended SWNT containing carboxylic acid groups at the entry ports of the nanotube. Heating in vacuum above 600 K removes these blocking groups.<sup>[13]</sup>

Other researchers claimed that certain adsorbates can penetrate the tubes producing a radial deformation.<sup>[14,15]</sup>

In opposition to those results, Froudakis<sup>[16]</sup> performed theoretical calculations that showed that no chemisorption and no penetration can occur, and that radial deformation is found upon adsorption of certain adsorbates. Other authors<sup>[17]</sup> claimed to have demonstrated that chemisorption can occur on the outer wall when the energy of the incident H atom is between 96 and 289 kJ/mol. They estimated that the energy required to penetrate through a hexagon of the wall is 1350 kJ/mol. Another conclusion is that the hole on the wall, produced by the atom passing through it, can be healed after relaxation.

Eswaramoorthy, Sen and Rao<sup>[18]</sup> detected a marked hysteresis in N<sub>2</sub> adsorption isotherms on SWNT that the authors assigned to capillary condensation in the intertubular space. In the same study, benzene cross-sectional area was estimated to be between 0.3 and 0.4 nm<sup>2</sup>.

Migone et al.<sup>[19,20]</sup> reported experimental results on adsorption of Xe, methane, and Ne on samples of closed-ended SWNT. Using classical techniques, the authors calculated the adsorption energies of those gases. The obtained values are 21.4 kJ/mol for CH<sub>4</sub>, 27.2 kJ/mol for Xe, and 5 kJ/mol for Ne. All these values are ca. 70% larger than the corresponding values obtained for adsorption on the basal plane of graphite. These authors also indicated that, if physisorption is the prevailing adsorption mechanism for H<sub>2</sub>, and, if geometric factors are determinant, this gas cannot occupy the interstitial channels of SWNT bundles as its dynamic molecular diameter is 0.29 nm. Xe adsorption has also been studied using computer simulations,<sup>[21]</sup> and the main conclusion is that the interaction potential between a Xe atom and the SWNT walls can be well represented by the same potential for a flat graphite surface. Some controversy exists with respect to the possibility of Xe to be adsorbed in the interstitial sites of a bundle of nanotubes. According to Muris et al.<sup>[22]</sup> Xe, as well as CF<sub>4</sub> and SF<sub>6</sub>, can only be adsorbed on the outer part of the bundle. Xe binding energy has been also estimated using thermal desorption spectroscopy<sup>[23]</sup> and

**Fig. 1** Schematic representation of an open-ended SWNT containing carboxylic acid groups at the entry ports of the nanotube.

the obtained value is 27% higher than the corresponding value for highly oriented pyrolytic graphite (HOPG) in agreement with other experimental techniques. If the same comparison is made for oxygen,<sup>[24]</sup> the value obtained for SWNT (18.5 kJ/mol) is ca. 55% larger than the corresponding one for HOPG (12 kJ/mol).

N<sub>2</sub>, Ar, H<sub>2</sub>, and D<sub>2</sub> isosteric heats of adsorption experimentally determined have been recently reported.<sup>[25]</sup> The heat profiles correspond to a heterogeneous surface, and the obtained values were 15 kJ/mol for nitrogen and argon, 9 kJ/mol for deuterium, and 7 kJ/mol for hydrogen. N<sub>2</sub> value is somehow low compared to other reported experimental and theoretical values that put it closer to 17–18 kJ/mol.<sup>[26,27]</sup>

Carbon nonohorns are another form of nanotubes that are capped with a cone instead of half fullerene molecule. The adsorption potential on these tubes has been analyzed in detail by Murata et al.<sup>[28]</sup> Xe adsorbed on single-walled carbon nanohorns (SWNH) in a “dahlia flower” arrangement<sup>[29]</sup> has a smaller (20%) binding energy compared to the value obtained for SWNT.

Nitrogen physisorption in carbon nanotubes has been studied mainly to characterize the porous texture of the samples.<sup>[30]</sup> Grand Canonical Monte Carlo (GCMC) computer simulations have been employed in a pioneering paper dealing with nitrogen and argon adsorption on carbon nanotubes.<sup>[31]</sup> The authors found that both gases were strongly adsorbed in a 1.02-nm SWNT at 77 K. They also showed that the adsorption isotherms were of Type I in IUPAC

**Fig. 2** Ar adsorption isotherms in a semiinfinite carbon nanotube at 77 K. Source: Adapted from Ref.<sup>[31]</sup>.

classification system. In the cases where hysteresis was found, the isotherms were of Type IV in IUPAC classification. Thus Fig. 2 shows simulated adsorption–desorption isotherms for argon at 77 K on a 4.78-nm double buckytube, either semiinfinite, or open. The hysteresis loop covers a broader pressure range for the semiinfinite model.

Other computer simulations performed on bundles of SWNT in a square array<sup>[32,33]</sup> showed some qualitative agreement between experiments and simulations. Other conclusions derived from the simulations are that adsorption is dominated by geometric factors, and that the interstitial spaces make a significant contribution to the total adsorption capacity. Other authors<sup>[34]</sup> found that the quadrupole moment of nitrogen has a little effect on the adsorption in SWNT; nevertheless, it has been proved that the opposite is true.<sup>[35,36]</sup>

First-principles calculations of the adsorption of NO<sub>2</sub>, O<sub>2</sub>, NH<sub>3</sub>, N<sub>2</sub>, CO<sub>2</sub>, CH<sub>4</sub>, H<sub>2</sub>O, H<sub>2</sub>, and Ar have been reported,<sup>[37]</sup> nevertheless, a poor agreement between the calculations and other theoretical estimates and experiments (see, e.g., the Ar case<sup>[38]</sup> and previously cited data on methane adsorption) is obtained for the adsorption energies. In the case of oxygen, the disagreement between theoretical calculations is more pronounced (compare the two previous cited papers with Ref.<sup>[39]</sup>). Oxygen adsorption on carbon nanotubes and graphite has been studied using density functional theory (DFT) calculations by Giannozzi, Car, and Scoles.<sup>[40]</sup> These authors report the formation of a weak bond between oxygen and the wall of a nanotube or a graphene layer of graphite, which is characteristic of physisorption. This bond does not involve any charge transfer between the molecule and the solid. The authors also point out the inability of current approximation functionals to correctly deal with dispersion forces. Nevertheless,

other studies<sup>[41]</sup> indicate that the curvature of the walls of SWNT exerts a large influence on the adsorption potential.<sup>[21,40]</sup>

Methane adsorption on carbon nanotubes has been studied in detail by Migone et al.<sup>[42–44]</sup> Along these studies, the authors found that hysteresis in the adsorption isotherms is present only when the tubes are open-ended and that the filling of nanotubes is controlled by the wetting characteristics of the adsorbate–nanotube system. Liquid methane completely wets the tubes whereas an incomplete wetting is found for solid methane. The isosteric heat of adsorption was determined (21.4 kJ/mol), which is 76% larger than the corresponding value for graphite. This increment in the adsorption energy with respect to graphite agrees with what was found for other gases. Other authors<sup>[45]</sup> studied methane adsorption, and they concluded that density functional theory (DFT) is a good method, provided that the interaction potential is described by a well-defined analytical function; otherwise, GCMC is a better method. They also showed that adsorption in the interstices formed by the tubes in the bundle is significant.

Using DFT, Tanaka et al.<sup>[46]</sup> showed that methane adsorption is enhanced through CH<sub>4</sub>–CH<sub>4</sub> interactions between molecules inside and outside the tube. As an illustration, Fig. 3 shows excess methane adsorption isotherms on the internal and external surfaces of an isolated tube of reduced diameter (= 4.2 at 303 K). Both endohedral and exohedral adsorptions are enhanced by fluid–fluid interactions across the carbon wall. Butane physisorption on multiwalled carbon nanotubes (MWNT) has been studied at room temperature,<sup>[47]</sup> and it was found that most of the butane is adsorbed on the external surface of the tubes.

**Fig. 3** Excess adsorption isotherms of methane at 303 K on carbon nanotubes. Open symbols indicate that the gas–gas interactions across carbon walls are not taken into account, while filled symbols include these interactions. *Source:* Adapted from Ref.<sup>[46]</sup>.

Moreover, no hysteresis was observed between adsorption and desorption experiments.

Ethane adsorption on SWNT bundles forming a square array has been investigated using GCMC computer simulations.<sup>[48]</sup> The authors found that the adsorbed phase inside the tubes is quite disordered. Nevertheless, their conclusions should be revised in view of certain assumptions done in the simulation model.

The adsorption of several types of alkylamine on SWNT induced large changes in the electrical conductance of semiconducting nanotubes.<sup>[49]</sup> The phenomenon is reversible, and it took, according to the authors, 12 hr to restore the initial characteristics of the studied samples. Decane adsorbed in SWNT has been shown<sup>[50]</sup> to be in a fluid state that is highly inhomogeneous and anisotropic. Molecular dynamics computer simulations have been performed to explore the behavior of SWNT toward the adsorption of gaseous mixtures.<sup>[51]</sup> The main and obvious conclusion is that the efficiency in the separation of molecules decreases as the tube diameter increases.

## GAS STORAGE CAPACITY OF CARBON NANOTUBES

Before a massive use of hydrogen in fuel cells is achieved, it is necessary to be able to store it safely and efficiently.<sup>[52]</sup> The U.S. Department of Energy (DOE) has elaborated an energy plan that includes hydrogen as a potential source provided a weight efficiency of 6.5 weight percentage (wt.%) and volumetric density of 62 kg H<sub>2</sub>/m<sup>3</sup> are achieved at ambient temperature. Carbon nanotubes are fascinating objects that could be employed for gas storage, particularly hydrogen.<sup>[53,54]</sup> Hirscher et al.<sup>[55]</sup> summarized the available experimental data on hydrogen sorption capacity in carbon nanotubes. They conclude that none of the promising experiments on H<sub>2</sub> uptake could be repeated by an independent group. The authors also provided evidence for a small reversible hydrogen uptake for SWNT and for the need of opening or cutting of the tubes as a prerequisite for high storage capacity. Fig. 4 compares thermal desorption spectra of deuterium in high vacuum for SWNT, graphite nanofibers, and graphite ball-milled under D<sub>2</sub> atmosphere. However, the D<sub>2</sub> release from SWNT not submitted to ball milling was practically negligible.

Several authors have studied the influence of synthesis and purification methods of carbon nanotubes upon H<sub>2</sub> sorption capacity.<sup>[56–64]</sup> The influence of the structure (packing) of the bundles has also been investigated.<sup>[65,66]</sup>

Wang and Johnson<sup>[67]</sup> performed computer simulations, classical and quantum path integral, of hydrogen

**Fig. 4** Thermal desorption rate of  $D_2$  from SWNT, graphite nanofibers (GNF), and ball-milled-graphite (graphite). *Source:* Adapted from Ref.<sup>[55]</sup>.

adsorption in SWNT and carbon slit pores. Among their conclusions, the most relevant are: quantum effects are important in hydrogen adsorption in the interstices even at room temperature; a reasonable agreement exists between their simulations and experimental data; and the adsorption capacity of carbon slit pores is larger than that of the SWNT bundles. They also concluded that none of the materials studied in their work were able to approach DOE's target for hydrogen storage capacity. Gu and Gao<sup>[68]</sup> arrived to almost the same conclusions using the same computational methods; they also found that DOE's requirements could be achieved at ca. 18 K. Nevertheless, Darkrim and Levesque<sup>[69]</sup> found using computer simulations a gravimetric density storage equal to ca. 11 wt.% at 77 K. This value leads the authors to conjecture that SWNT could be employed for hydrogen storage systems. Recently, Hou et al.<sup>[70]</sup> reported a storage capacity of 6.3 wt.% and 31.6 kg/m<sup>3</sup> at room temperature. This unconfirmed result shows an acceptable gravimetric hydrogen uptake but the volumetric efficiency is still 50% of DOE's target.

Hydrogen adsorption has also been studied using Raman spectroscopy,<sup>[71]</sup> which showed no indication of chemisorption but physisorption on multiple sites of the SWNT ropes at 85 K and up to 8 atm. Hydrogen adsorption produces the separation of the individual SWNT at ca. 40 bar and 80 K because of a small cohesive energy between the tubes, 0.48 kJ/mol.<sup>[72]</sup> Single-walled carbon nanohorns have also been investigated to determine their hydrogen uptake capacity at supercritical conditions.<sup>[73]</sup>

From the experimental point of view, the studies on hydrogen storage in carbon nanotubes indicate that this material is not suitable from DOE's criteria, at least for the structures already known. Nevertheless,

there is a controversy when the problem is analyzed with theoretical tools. There are several computer simulation studies predicting a good sorption capacity;<sup>[74–76]</sup> moreover, other studies claim to have partially accomplished with DOE's requirements.<sup>[77]</sup> On the other side, there are several studies indicating that carbon nanotubes are not suitable according to DOE's criteria.<sup>[78–81]</sup>

## MATTER IN CONFINED SPACES

Stan and Cole<sup>[82]</sup> published one of the pioneering works on the theory of adsorption in carbon nanotubes. In that paper, the authors found that carbon nanotubes provide a physical realization of a quasi 1-D system for both classical and quantum gases. This subject is reprised in more detail by Calbi et al.<sup>[83–86]</sup> where the authors analyzed a very rich collection of phases found for the adsorbate. Grand Canonical Monte Carlo simulation results have been reported for the adsorption of Ar and Kr on SWNT bundles.<sup>[87]</sup> The calculated isotherms revealed phase transitions associated with the formation of quasi 1-D lines of atoms on the grooves between two nanotubes; as an illustration, Fig. 5 shows calculated adsorption isotherms of Ar at several temperatures. The quasi 1-D character of <sup>4</sup>He adsorbed inside carbon nanotubes has been explored by several authors.<sup>[88,89]</sup> Equations of state have been derived for H<sub>2</sub> and D<sub>2</sub> in pure 1-D geometry.<sup>[90,91]</sup> The obtained equation of state predicts a liquid H<sub>2</sub> phase inside a (5,5) carbon nanotube. To study transport properties of fluids in confined spaces, carbon nanotubes can be employed as they constitute a model system with real existence.<sup>[92]</sup>

Quantum molecular sieving effects have been studied<sup>[93,94]</sup> by comparing computer simulations with the

**Fig. 5** Simulated Ar adsorption isotherms over a wide temperature range. *Source:* Adapted from Ref.<sup>[87]</sup>.

predictions of a simple model. The studied systems included  $H_2-T_2$ ;  $^3He-^4He$ ;  $CH_4-CD_4$ ; and  $H_2-HD$ .

Ayappa<sup>[95,96]</sup> reported a quite complete study on binary mixtures adsorbed in carbon nanotubes. The author studied equimolar binary Lennard–Jones gas mixtures using Grand Canonical Monte Carlo simulations. He found that for mixtures of species with different sizes, the energetically favored species is adsorbed at high temperatures. However, at moderate and lower temperatures and intermediate nanotube diameter, a complete exclusion of the larger species is observed. If both species are of similar size, the most favored energetically is adsorbed at all temperatures. Hydrogen and CO mixtures have been studied by Gu et al.<sup>[97]</sup> The authors showed that CO is adsorbed inside the tubes and  $H_2$  is kept outside the tubes. At higher pressure, the situation is reversed because  $H_2$ , being smaller than CO, can be easily packed inside the tube.

Transport and diffusion of gases in carbon nanotubes have been studied by several authors.<sup>[98–100]</sup>

## GAS CHEMISORPTION ON CARBON NANOTUBES

The work carried out in this area mainly concerns the behavior of carbon nanotubes as field emitters and the mechanism of field emission.<sup>[101]</sup> The first paper<sup>[102]</sup> to be commented on reported an increment in the field emission current as a result of the presence of unknown chemisorbed species on the surface of carbon nanotubes. A recent study<sup>[103]</sup> using density functional calculation concluded that all the molecules studied, except nitrogen, dissociate and then chemisorb. The Fermi levels are moved toward the valence bands for the adsorption of oxygen, hydrogen, and water. Nitrogen does not change the Fermi level position. Their main conclusion was that water enhances the field emission current whereas oxygen adsorption decreases it. The increasing field emission properties of carbon nanotubes as a result of oxygen adsorption have also been investigated.<sup>[104]</sup> Using first-principles calculations, the authors found that all the analyzed configurations produce an enhancement of the emission current. Similar results have been reported by Grujicic, Cao, and Gersten<sup>[105]</sup> including that the effect increases with the magnitude of the dipole moment of linear adsorbates. This phenomenon is illustrated in Fig. 6, where the decrease in ionization potential (and concomitant increase in field emission) shows a complex relationship with the dipolar moment, which suggests the additional contribution of other factors.

According to density functional calculations,<sup>[106]</sup> carbon nanotubes can survive adsorption and desorption

**Fig. 6** Nanotube ionization potential as a function of the magnitude of the dipole moment of linear-single-molecule adsorbates. *Source:* Adapted from Ref.<sup>[105]</sup>.

of chemisorbed oxygen provided a precise control on the annealing temperature is exerted.

Hydrogen dissociation and chemisorption on carbon nanotubes has been investigated using different approaches and theoretical tools. The obtained results predict dissociation and then chemisorption of the H atoms.<sup>[107–109]</sup> There are several studies that confirm the dissociative adsorption of hydrogen on SWNT and that the energy barrier is very high, even when the nanotubes are doped with Li.<sup>[110]</sup> The DFT theory was employed to study  $H_2$  interaction with SWNT and the calculations indicate that when the molecule has enough kinetic energy, it can be dissociated on the surface and the resulting atoms chemisorbed to two nearest-neighbor carbon atoms.<sup>[111]</sup> Finally, another reported DFT study concluded that  $H_2$  cannot be adsorbed on the inner wall of any nanotube included in the study.<sup>[112]</sup>

## CONCLUSION

Carbon nanotubes and other tubular forms of carbon are investigated since their discovery a decade ago. Although the structures of these new forms of carbon are well known, their properties are not fully disclosed. One of the most important aspects of carbon nanotubes is related to its potential use as hydrogen storage devices. Unfortunately, there is no agreement between experiments and theory. Several factors contribute to this disagreement. From the experimental point of view, there are still problems in the postproduction purification of nanotubes. Depending on the method employed, different adsorption capacities are obtained and the final materials are still quite irreproducible.

From the theoretical point of view, two main research lines can be found: computer simulations

using Monte Carlo or Molecular Dynamics method, and quantum mechanics calculations. The most reliable computer simulations predict that DOE's requirements could not be achieved by carbon nanotubes. On the other hand, other theoretical calculations are in disagreement between themselves. Several authors predict high adsorption capacities using methods that are questioned in their ability to model dispersion forces, while other authors predict no adsorption at all. There is no agreement in several theoretical aspects such as the effect of wall curvature on the adsorption potential.

There is agreement in several aspects. Hydrogen dissociation on the wall of carbon nanotubes has a large activation energy. When dealing with gas mixtures, carbon nanotubes exhibit molecular sieving properties. The dependence of selectivity on temperature is well known. The radial deformation of carbon nanotubes upon adsorption of certain molecules has been predicted by several authors using different methods. Carbon nanotubes can resist mild oxidation processes provided the annealing temperature is carefully controlled. The penetration of hydrogen atoms in the tubes is possible if the atoms have enough kinetic energy. The hole produced can be healed by relaxation.

It is accepted, from the theoretical point of view, that SWNT can be considered as a physical realization of many model systems.

## INTRODUCTION

This entry shows the mechanisms of hydrogen sorption in carbon nanotubes. The research topic was inconclusive and controversial, but fabrication of precise measuring system and high-purity single-walled carbon nanotubes made it possible to obtain fully reproducible results of hydrogen physisorption.

## OVERVIEW

Since its discovery in 1991,<sup>[1]</sup> carbon nanotubes have attracted much expectation to store hydrogen because they have cylindrical structures and hollow spaces inside of their sidewalls. Novel carbonaceous materials for hydrogen storage are strongly needed for fuel cell (FC) devices because conventional hydrogen storage materials are too heavy for compact FC devices and, on the other hand, carbon is light, stable, and abundant. Fig. 1 shows the comparison of hydrogen amount in various adsorbent. One can see that when 5 wt.% of hydrogen storage in nanotubes can be realized the Department of Energy (DOE) target is almost achieved. Compared with the other adsorbent, such as alloys, carbon can store much hydrogen in the energy density per weight.

The pioneering work by Dillon et al.<sup>[2]</sup> on the possibility of 5–10 wt.% storage in single-walled carbon nanotubes (SWNTs)<sup>[3]</sup> at room temperature aroused interest toward SWNTs and other carbonaceous materials in this research field.<sup>[4–7]</sup> However, it was very difficult to fabricate apparatus for precise measurements because the leakage problem of high-pressure hydrogen was serious, and much attention should have been paid for the measurement of the change of introduced hydrogen pressure because in some cases temperature

dependence of hydrogen pressure (before equilibrium) was believed to be the evidence of hydrogen sorption. In addition, the lack of understanding in sorption prevented to obtain reliable results (for instance, the origin of abnormally high value of sorption cannot be fully explained). Thus further efforts were awaited for the establishment of fully reproducible and convincing data.<sup>[8–13]</sup> In particular, a question remained as to whether the adsorption site for hydrogen existed in carbon at moderate temperature. At present, about 7 wt.% of hydrogen desorption from nanographite at high temperature ( $\sim 700$  K)<sup>[14]</sup> and the storage of 8 wt.% of hydrogen in SWNTs at low temperature (80 K)<sup>[15]</sup> have so far been believed to be reliable.

This report is focusing on detailed analyses of hydrogen adsorption in carbon nanotube systems and its mechanisms. Hydrogen physisorption at room temperature was characterized by using SWNTs and C<sub>60</sub> encapsulated SWNTs (peapods), and the physisorption was achieved by fabricating and activating subnanometer-scale pores. Adsorption potential of the pores was estimated to be about  $-0.21$  eV and this large potential induced the physisorption.<sup>[16,17]</sup> Molecular dynamics of hydrogen adsorbed in the pores was also characterized by nuclear magnetic resonance (NMR) and the result suggested the hydrogen strongly interacts with the sidewalls of the SWNTs.<sup>[18]</sup> Future prospects and a guideline of material designing are summarized in the end of the report.

## EXPERIMENTS

Single-walled carbon nanotubes were synthesized by Nd:YAG laser ablation using Ni/Co catalysts. The metal/carbon target was heated to 1200°C in a furnace. The diameter of the SWNTs is typically 1.4 nm. For purification, carbon soot containing the SWNTs

**Fig. 1** Comparison of hydrogen adsorbent. DOE target means the target of the Department of Energy.

was refluxed in an aqueous solution of  $\text{H}_2\text{O}_2$  for 3 hr. After the removal of any amorphous carbon, the sample was treated with HCl overnight to eliminate the remaining catalytic metals. Thermogravimetric analysis of this product showed that the metal contents were decreased less than 3 wt.%. For further purification, the purified SWNTs were treated with aqueous NaOH.<sup>[16,19,20]</sup> Small particles of by-products in the  $\text{H}_2\text{O}_2$  purification, amorphous carbon, which covered a surface of the SWNTs and occupied intertube pores, were removed in this process by ultrasonication in the NaOH (pH = 10–11) for 2 hr. The effect of the NaOH treatment was checked by the change in Raman spectra. The intensity ratio of the G- to the D-band (G/D) changed from 50 to 90 after this treatment; this observation indicates that the amorphous carbon particles were removed and the SWNTs were cleaned. Transmission electron microscopy (TEM) measurements also verified the cleaning of the SWNTs. Fig. 2 shows that amorphous carbon particles coated the surface of the SWNTs before treatment, whereas they were removed and the sidewalls of the SWNTs were clearly seen after the treatment. It is concluded from these characterizations that NaOH treatment is effective for cleaning of the sidewalls and that the resulting SWNT bundles have minute intertube pores suitable for hydrogen adsorption.

A peapod is a new form of a SWNT-based material which has unique physical properties.<sup>[21–28]</sup> The inside of peapods is filled with  $\text{C}_{60}$  molecules (or other fullerenes and metallofullerenes) and peapods differ from SWNTs only in this structural point. This structural difference is suitable to examine the gas adsorption sites in SWNT-based materials. In this work peapods ( $\text{C}_{60}$ @SWNTs)

**Fig. 2** TEM photographs of purified SWNTs. (A) Before NaOH treatment, in which case many tube sidewalls were covered with amorphous carbon clusters. (B) After NaOH treatment, by which carbon clusters were removed and sidewalls were clearly seen.

were synthesized<sup>[23]</sup> from the same batch of SWNTs after NaOH treatment. The filling rate of  $\text{C}_{60}$ s in the SWNTs was estimated to be about 85%.<sup>[24]</sup> After washing the sample by toluene to remove unreacted  $\text{C}_{60}$  on the sidewalls,<sup>[23]</sup> the sample was heated in a vacuum for complete elimination of the toluene. The whole procedures for sample preparations are summarized in Fig. 3.

Hydrogen desorption was studied by a custom-made temperature-programmed-desorption (TPD) system, by which desorption of the gaseous species was measured as a function of temperature under about  $10^{-5}$  Pa.<sup>[2]</sup> A pretreatment condition of the samples was  $T = 873$  K,  $P = 10^{-4}$  Pa for 1 hr. The pretreatment of the sample is a critical procedure for the adsorption and desorption of hydrogen. The purity of hydrogen was 99.99999%. The applied pressure was 6 MPa and ca. 0.1 MPa at room temperature,

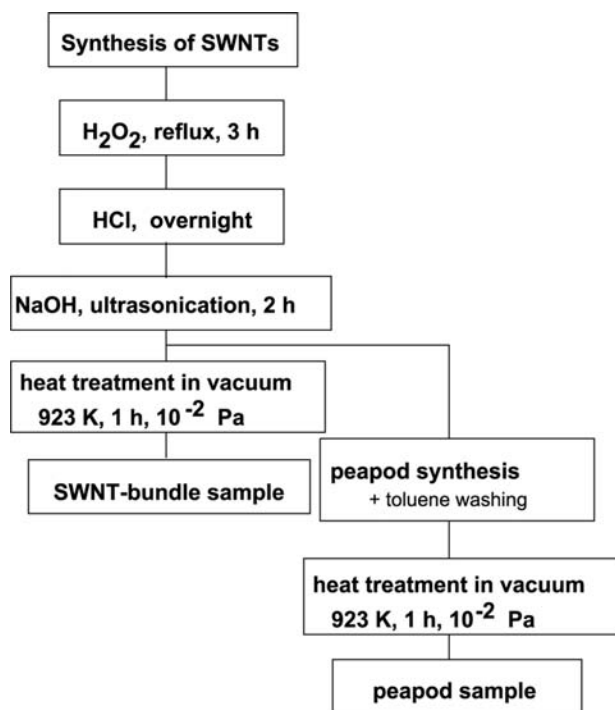

Fig. 3 Detailed procedures for a sample preparation.

and the pressure dependence of hydrogen desorption can be of help to distinguish whether hydrogen was extrinsically introduced or not.

Hydrogen adsorption capability was measured up to 9 MPa, and care was taken to eliminate the leakage of the system for precise measurements. The amount of the SWNTs was increased to about 1 g to suppress the error bar, and the volume of the applied hydrogen was evaluated with allowance for the temperature effect and by taking sufficient time to let hydrogen reach equilibrium.

A NMR study was carried out to obtain information about the molecular dynamics of the hydrogen trapped in the intertube pores, as in the case of  $H_2$  in a  $C_{60}$  solid.<sup>[29]</sup> We performed solid-state  $^1H$  magic angle spinning (MAS) NMR observation of the hydrogen at 293 K with a CMX-300 Infinity (Chemagnetics Co.; 298.99 MHz) after introducing hydrogen at 9 MPa for 5 days. The MAS was adopted at 3000 rpm because of the low intensity of the spectral pattern of the powder. The inversion recovery method was used for the determination of the spin-lattice relaxation time,  $T_1$ , with the application of a  $\pi/\tau/\pi/2$  pulse sequence. Therefore the  $T_1$  thus obtained under rotation is  $T_{1\rho}$ .

## RESULTS AND DISCUSSION

### Sorption Mechanisms

Before showing the experimental results, we discuss the mechanisms of adsorption. Physisorption and

chemisorption are possible mechanisms of hydrogen adsorption. In chemisorption, hydrogen is covalently bonded with host materials and desorption temperature is too high ( $>500$  K) for commercial use. In physisorption, the van der Waals force between hydrogen molecules and the host materials is a main force to stabilize hydrogen on the surface. The desorption temperature is generally near room temperature, and so physisorption is much more preferable for industrial applications. Thus we focus only on the physisorption of hydrogen in SWNTs.

Physisorption is controlled by a relation between chemical potential of gases,  $\mu$ , and adsorption potential of solids,  $\varepsilon$ . Coverage of adsorption sites,  $f$ , is determined by the Langmuir adsorption isotherm, typically

$$f = \frac{1}{1 + \exp\left(\frac{\varepsilon - \mu}{kT}\right)} \quad (1)$$

When  $\varepsilon = \mu$ , the coverage is equal to 0.5 and this means about 4 wt.% of hydrogen adsorption. The temperature and pressure dependence of the chemical potential of hydrogen gas,  $\mu$ , shown in Fig. 4, was calculated by the use of experimental values of enthalpy,  $H$ , entropy,  $S$ , taken from Ref.<sup>[30]</sup> and Eq. (2),

$$G = H - TS$$

$$\mu = \frac{\partial G}{\partial n} \quad (2)$$

where  $G$  is Gibbs free energy and  $n$  is the number of molecules. The adsorption potential of the inside and

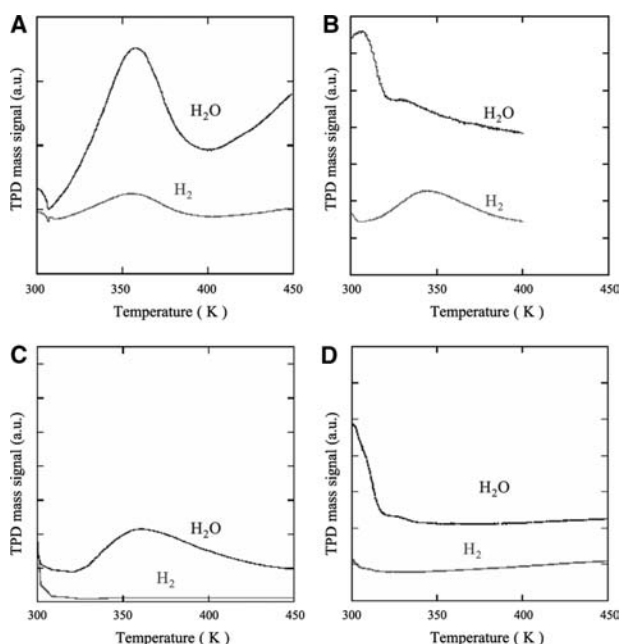

Fig. 4 Temperature dependence of the chemical potential of hydrogen,  $\mu$ . Open circles, crosses, and open squares represent  $\varepsilon$  at 0.1, 1, and 10 MPa, respectively.

outside of an individual SWNT has been estimated to be at most  $-0.09$  eV.<sup>[31]</sup> Thus one can see that hydrogen adsorption on the outer surface and the intratube pores can occur only at low temperature. According to Ye et al.,<sup>[15]</sup> hydrogen adsorption amount at 80 K is about 8 wt.%, the coverage  $f$  being nearly equal to 1. This value seems to be a reasonable estimate, because the chemical potential of hydrogen is small enough at such low temperature. On the contrary, one cannot expect hydrogen physisorption at room temperature unless the adsorption potential is significantly enhanced by the modification of adsorption pore structures. In our material systems, the intertube pores are small enough and one can expect that they have large adsorption potential, as mentioned in the following subsections.

### Experimental Evidence for Hydrogen Physisorption at Room Temperature

Results of temperature-programmed-desorption analyses

Fig. 5A–D shows TPD profiles of gas desorption from the SWNTs and the peapods after application of

**Fig. 5** TPD observations for hydrogen and water. (A) Desorption from the SWNTs after application of 6-MPa hydrogen. Both hydrogen and water were desorbed. (B) Desorption from the peapods after application of 6-MPa hydrogen. Only hydrogen was desorbed. (C) Desorption from the SWNTs after application of 0.1-MPa hydrogen. (D) Desorption from the peapods after application of 0.1-MPa hydrogen.

6 MPa and ca. 0.1 MPa of hydrogen. Hydrogen desorption was observed around 350 K from the SWNTs and the peapods which experienced only the application of high-pressure hydrogen. This fact suggests that hydrogen was introduced extrinsically and adsorbed at room temperature. Water desorption was observed only from the SWNTs, and the appearance of the peak was independent of the hydrogen pressure. These facts suggest that all sites in the peapods for water adsorption were fully occupied by  $C_{60}$  molecules so that no more spaces were available.

The similarity of the hydrogen desorption profiles obtained from the SWNTs to that from the peapods suggests that the hydrogen adsorption sites in these samples are essentially the same. Because  $C_{60}$ s are embedded inside the tubes, the inside of the tubes cannot contribute to hydrogen adsorption. Moreover, desorption temperature of about 350 K excludes the possibility of surface adsorption. Therefore the possible sites for hydrogen adsorption are the intertube sites in the bundles.

Fig. 6 shows a size comparison of the inter- and intratube pores in SWNT bundles. SWNTs form a triangular lattice, and the pore size can be estimated by taking the van der Waals radii of carbon atoms into account. Because the diameter of the SWNTs is 1.4 nm, the size of the intertube pores is about 0.2–0.3 nm, while the size of the intratube pores is about 1 nm. On the other hand, the size of water and hydrogen molecules is 0.39 and 0.24 nm, respectively. This comparison indicates that the intertube pores can adsorb hydrogen only when high-pressure hydrogen is applied, whereas they cannot store the water molecule because it is too large to penetrate into the intertube pore. Here the size and the adsorption potential of the intratube pore are 1 nm and  $-0.09$  eV, respectively. Because the size of the intertube pore is 0.2–0.3 nm, one can expect that the pores have larger adsorption potential, which allows hydrogen physisorption. In the next subsection, we discuss the mechanism of hydrogen adsorption.

### Adsorption mechanisms

To determine the adsorption mechanism, desorption energy analysis is a commonly used procedure. The relationship of the desorption energy,  $E_d$ , the heating rate,  $\beta$ , and the temperature at the desorption peak maximum,  $T_m$ , is represented as<sup>[32]</sup>

$$\frac{T_m^2}{\beta} = \frac{R}{E_d} \tau_0 \exp\left(\frac{E_d}{RT_m}\right) \quad (3)$$

where  $R$  is the gas constant and  $\tau_0$  can be interpreted as the mean lifetime of the gas molecules adsorbed

Fig. 6 Size comparison between the intra- and the intertube pores and hydrogen.

on a surface. The desorption energy is evaluated by changing the heating rate, as shown in Fig. 7. The estimated energy, 0.21 eV, clearly indicates that the adsorption mechanism is physisorption; if hydrogen were chemisorbed, the value should be about 10 times larger. In addition, when deuterium instead of hydrogen was introduced in the SWNTs, a similar desorption peak at 350 K was observed and the desorption energy was estimated to be about  $-0.20$  eV. From these experimental results, we can conclude that hydrogen (and deuterium) is *physisorbed at room temperature*. This is the first reliable report on hydrogen physisorption at room temperature by using well-purified SWNTs.

The estimated desorption energy can be regarded as the adsorption potential of the intertube pores when the surface of the pores is clean enough.<sup>[32]</sup> Eq. (4) shows the relation between the desorption energy,  $E_d$ ,

the activation energy for adsorption,  $E_a$ , and the heat of adsorption,  $q$ ,

$$E_d = E_a + q \quad (4)$$

When the surface is clean,  $E_a$  is nearly equal to zero and  $q$  is equal to the desorption energy. In this work, the surface of the SWNTs was rinsed by NaOH and it was clean enough. Thus the measure  $E_d$  can be regarded as the adsorption potential of the hydrogen adsorption sites,  $\epsilon$ . As a result, the adsorption potential of the intertube pores is about  $-0.21$  eV. This value is about 2.3 times larger than the calculated value of the intratube pores ( $-0.09$  eV), and the minute intertube pores (0.2–0.3 nm) surely have larger adsorption potential. Murata et al. calculated the adsorption potential of pores in nitrogen/single-walled carbon nanohorns (SWNHs) system.<sup>[33]</sup> Although the size of SWNH is 2 nm and the interaction between  $N_2$  and SWNHs was focused, the ratio between the adsorption potential of the inter- and intrananohorn is 1.8, and this has good accordance with our experimental result.

Hydrogen adsorption capability and validity of our model

Fig. 8 shows the hydrogen adsorption capability of the SWNTs. The amount of adsorbed hydrogen depends on the applied hydrogen pressure, and the storage of hydrogen at 9 MPa is about 0.3 wt.%. In this experimental scheme, hydrogen is adsorbed only in the intertube pores. The maximum amount of adsorbed hydrogen in the intertube pores is limited and estimated to be about 0.8 wt.%.<sup>[34]</sup> This means that the coverage of the pore is about 0.38 in our experiments. Fig. 9 shows a comparison of the adsorption potential of the intertube pores and the chemical potential of hydrogen. The coverage of the intertube pores at

Fig. 7 Kissinger's plot of  $\ln(T_m^2/\beta)$  against  $1/T_m$  with  $\beta$  varying from 0.017 to 0.17 K/sec.

**Fig. 8** Amount of adsorbed hydrogen (wt.%) against applied hydrogen pressure,  $P$ . The error bar is estimated to be 0.03% from the precision of the pressure gauge.

300 K and 10 MPa,  $f = 0.31$ , as estimated from the  $\mu$  value in Fig. 9 and the experimental  $\varepsilon$  value, is comparable with the measured value, 0.38. This similarity corroborates our experimental results and the Langmuir model used in this study. The corresponding coverage for the intratube pores,  $f = 0.0044$ , is smaller by two orders of magnitude, although the adsorption potential of the intertube pores is at most 2–3 times as large as that of the intratube pores. In other words, only a small difference in  $\varepsilon$  induces a major difference in  $f$ . Therefore fabrication of minute pores, with 0.2–0.3 nm in size and with large  $\varepsilon$ , is indeed a crucial

**Fig. 9** Comparison of the adsorption potential of the intertube pores and the chemical potential of hydrogen.

factor to achieve hydrogen physisorption at room temperature. This indicates the importance of fabricating “subnanometer-ordered” spaces.

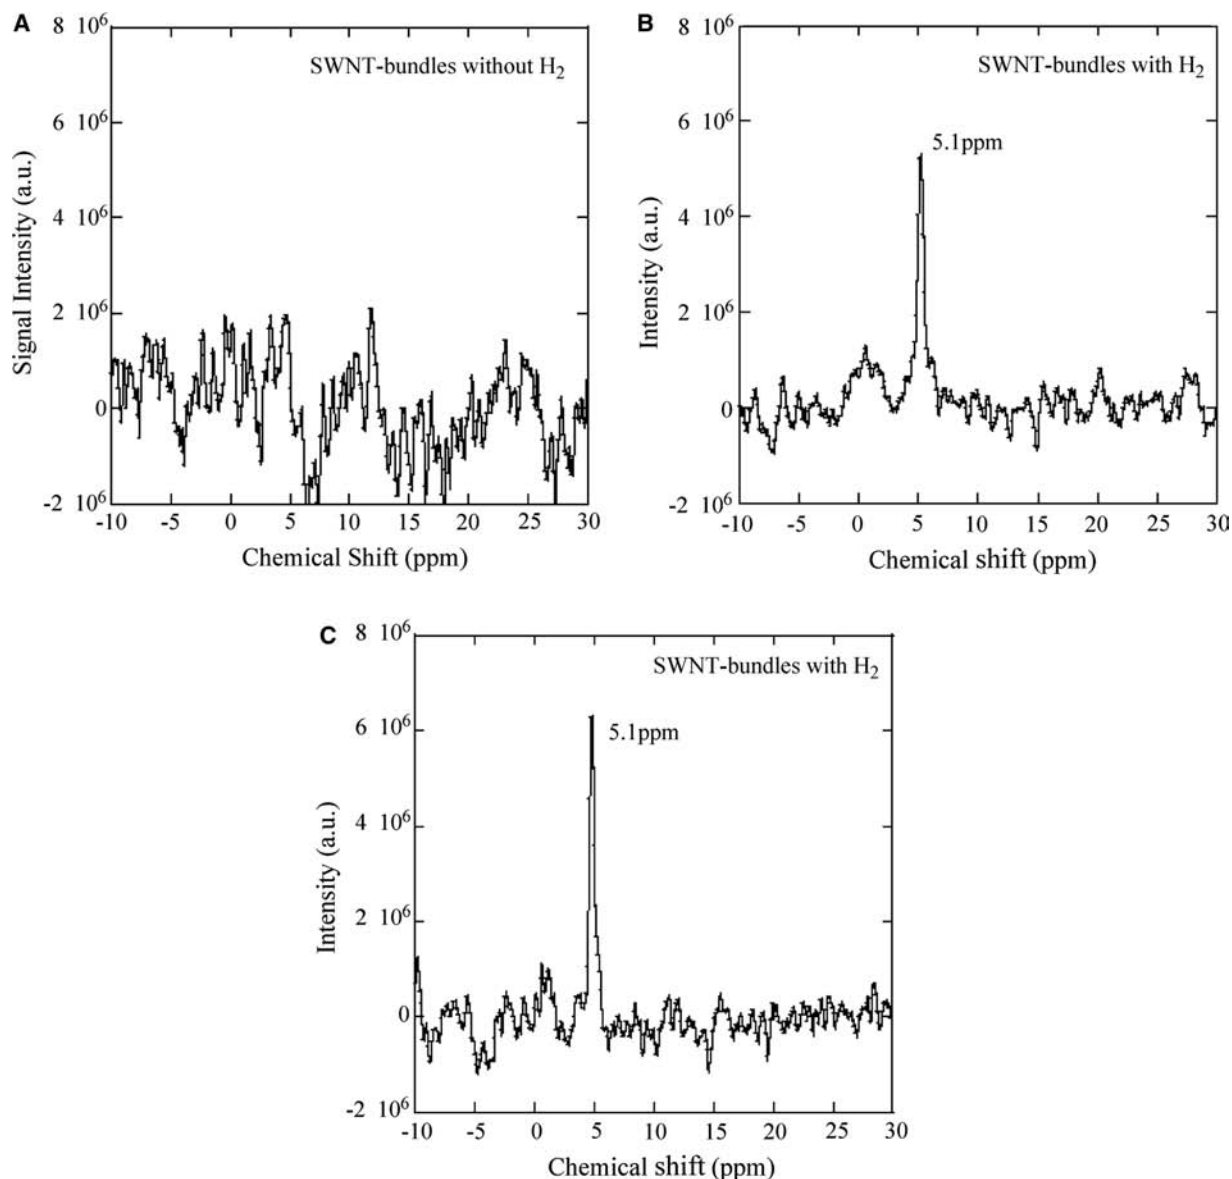

#### A NMR study on hydrogen trapped in SWNT bundles

In the previous subsections, physisorption of hydrogen in SWNTs was analyzed in detail. The next concern is the condition under which hydrogen exists in the pores. In this subsection, a NMR characterization of the adsorbed hydrogen in the intertube pores is discussed. A NMR study can give information about the molecular dynamics of hydrogen trapped in hollow spaces, for instance, an interstitial site in solid  $C_{60}$ .<sup>[29]</sup>

Fig. 10A and B shows the  $^1H$  MAS NMR spectra observed for the no- $H_2$ -adsorbed sample (sample A) and the  $H_2$ -adsorbed sample (sample B). A clear peak at 5.1 ppm was observed in sample B, although no peak was able to be seen in sample A. It is notable that the peak position is close to that for water molecules.<sup>[35]</sup> Actually, liquid water has a peak at 4.96 ppm at 296.3 K. To confirm whether the peak is attributable to hydrogen or water, sample B was exposed to  $SO_2$  gas mixed with the same volume of dry  $N_2$  gas for 3.5 hr. If the peak is attributed to the remaining water molecules in the sample, the water would easily interact with the  $SO_2$  gas and the peak would change or disappear. After 3.5 hr of exposure, no change in the peak position or shape was observed [Fig. 10C]. From this result and the fact that no peak was observed in sample A, it is concluded that the peak at 5.1 ppm is attributable to hydrogen molecules in the intertube pores. The value, 5.1 ppm, is comparable with the previously reported value of hydrogen molecules loaded in silica,  $4.8 \pm 0.2$  ppm.<sup>[36,37]</sup> In that work, hydrogen was loaded in the non-heat-treated silica at 1.09 MPa for 70 days. As discussed later, the relaxation time  $T_1$  in both cases is also very similar. The similarity also supports the validity of our experimental results.

Hydrogen is trapped in the intertube pores, as mentioned above. Judging from the size of the pores, hydrogen is trapped in the minute pores and it can interact strongly with the sidewalls of the SWNTs. The spin-lattice relaxation time,  $T_1$ , can be a good index of the strength of interaction in this case. Fig. 11A shows the inverse recovery of the NMR signals, and the time dependence of the normalized peak intensity is shown in Fig. 11B. In Fig. 11B, the difference between the initial and the final intensity is regarded to be  $M_0$ , and the difference between the initial and the time-dependent intensity at each measuring time is normalized by  $M_0$ . From this result,  $T_1$  is estimated to be about 0.1–0.2 sec.  $T_1$  of hydrogen molecules in a-Si and silica is about 0.45<sup>[38]</sup> and 1 sec,<sup>[36]</sup> respectively. In both cases, hydrogen

**Fig. 10** NMR signals of hydrogen in SWNTs bundles. (A) Sample A (non-adsorbed). (B) Sample B (adsorbed). (C) NMR signal from sample B after exposure to  $\text{SO}_2$  and  $\text{N}_2$  mixture for 3.5 hr.

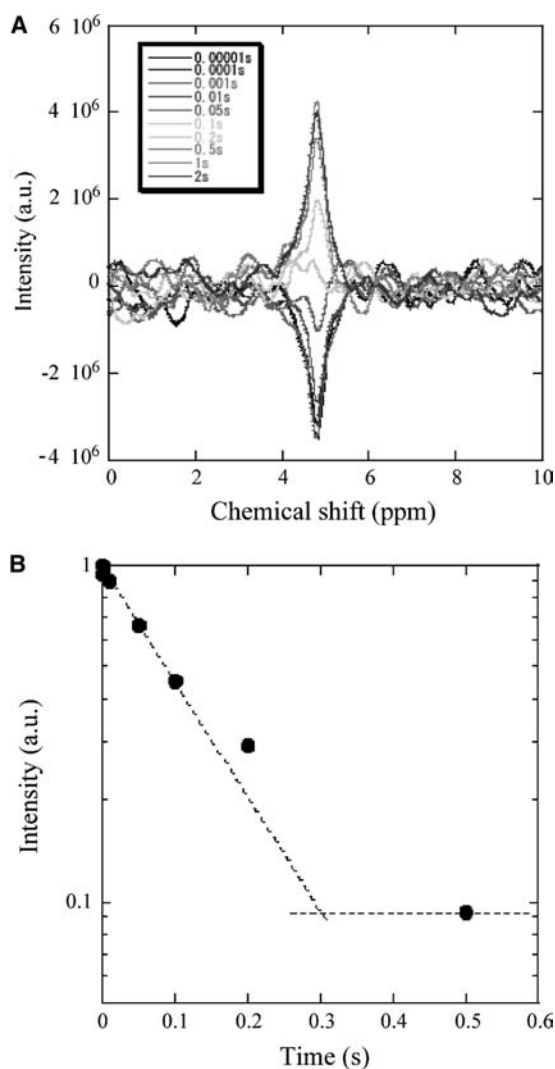

molecules exist in the minute space, for instance, interstitial sites. In our case also, hydrogen is trapped tightly in the minute spaces. Therefore the similarity of  $T_1$  in each case can be explained by the similarity of circumstances where hydrogen molecules exist.

## CONCLUSION

In this report the adsorption of hydrogen in SWNTs and its mechanisms were studied, and the first hydrogen physisorption at room temperature in the well-purified SWNTs and peapods was achieved by using NaOH-rinsed SWNTs. Hydrogen was adsorbed in the intertube pores of the SWNT bundles, because

the pores are 0.2–0.3 nm in size and therefore they have sufficiently large adsorption potential ( $-0.21$  eV) for the achievement of physisorption. This suggests the importance of subnanometer-ordered spaces. By  $^1\text{H}$  MAS NMR measurements, it was clarified that the adsorbed hydrogen strongly interacts with the side-walls of the SWNTs as the hydrogen does in silica and a-Si. Until this work, the research topic of hydrogen storage in SWNTs was not conclusive, but we believe that this work can be of help in understanding the fundamental mechanisms.

The most important point of hydrogen physisorption in SWNT systems is to fabricate and activate minute pores. At present, intratubes cannot be available because they are too large for hydrogen. However,

**Fig. 11** (A) The inverse recovery of the NMR signals in sample B. (B) The time dependence of the normalized peak intensity.

if one can succeed in synthesizing small-sized-materials encapsulated SWNTs, the intratube pores also become suitable spaces. Similarly, double-walled carbon nanotubes (DWNTs), SWNTs with very small diameter, seem to be promising candidates. “Nanotechnology” is becoming a key term in science now, but we would like to emphasize that “subnanotechnology” is also important in this field.

## ACKNOWLEDGMENT

The authors (M.S., M.A.) thank Mr. Y. Murakami for his TEM observation and Dr. Kajiura for providing Fig. 1.

# Carbon Nanotubes: Modeling of Hydrogen Chemisorption

Ronald C. Brown

Department of Chemistry, Mercyhurst College, Erie, Pennsylvania, U.S.A.

## INTRODUCTION

Among the potential storage materials for use in portable hydrogen-containing devices, carbon nanotubes have received a relatively large amount of attention. Their adsorptive properties and relatively light weight make carbon nanotubes ideal candidates for the development of efficient H<sub>2</sub>-powered vehicular fuel cells. Evidence for hydrogen adsorption levels large enough to be used in such devices was first reported by Dillon et al. in 1997.<sup>[1]</sup> Since that time, experiments attempting to reproduce these results and to optimize the levels of hydrogen adsorption<sup>[2–8]</sup> have been inconclusive as to the applicability of carbon nanotubes toward this technology. The difficulty in reproducing high adsorption levels has led to a number of computational studies concerning hydrogen interactions with carbon nanotubes. Many computational studies have attempted to model the process of hydrogen adsorption to nanotubes to quantify the relationship between environmental parameters and hydrogen uptake amounts. In an attempt to clarify the experimental results, adsorption models have been designed and simulations based on these models<sup>[9–19]</sup> have been performed. Yet the results of many of these simulations have not corresponded with the observed experimental levels of hydrogen adsorption. This has led to questions concerning both the validity of the experimental results and the physical reality of the models. A central uncertainty is the nature of the molecular-level mechanism through which adsorption occurs. To resolve this critical uncertainty, researchers turned to atomistic investigations of interactions between hydrogen and nanotube surfaces. Molecular dynamics simulations,<sup>[20]</sup> kinetic studies,<sup>[21]</sup> and first principles calculations<sup>[22–33]</sup> have all been performed recently in an attempt to elucidate more clearly the adsorption mechanism. Among the significant conclusions derived from the results of the atomistic studies are that the deformation of the carbon nanotubes should be considered during the adsorption process<sup>[20]</sup> and that localized, chemical bonds must be formed between adsorbed hydrogen and the nanotube walls<sup>[21,25]</sup> to explain the experimental findings. In

addition, the atomistic studies make it clear that the energetics of potential adsorption mechanisms strongly depend on the nanotube geometry. The purpose of this article is to review the current understanding of the adsorption process and to establish the necessity for a further understanding of the adsorption mechanism. The dependence of hydrogen adsorption on the geometry of the nanotubes will be demonstrated. Because of the atomistic nature of the adsorption process, first principles calculations should play a vital role in resolving uncertainties regarding the applicability of carbon nanotubes to hydrogen storage.

## BACKGROUND

### Nanotube Structure and Hydrogen Adsorption Results

An atomistic description of hydrogen adsorption mechanisms to carbon nanotubes requires a clear understanding of tube geometry. Although the synthesis of both multiwalled and single-walled nanotubes (MWNTs and SWNTs, respectively) has been achieved, the high levels of hydrogen adsorption have been primarily observed with SWNTs. The structure of an SWNT can be described as a graphene sheet cylindrically wrapped about an axis. The cylindrical tubes that result are of varying radii and lengths, and are typically enclosed at both ends by fullerene-like structures.<sup>[34]</sup> Similar to the structure of a graphene sheet, the surface of a nanotube is composed of interlocking sp<sup>2</sup> carbon atoms. The central feature that geometrically distinguishes the type of SWNT is the location of the tube axis in relation to the original graphene sheet. The orientations of a perpendicular pair of tube axes relative to a graphene sheet are shown in Fig. 1. The tubes resulting from these axis orientations, termed zigzag and armchair nanotubes, are geometrical extremes and have been the subjects of most computational studies. The accepted convention for the geometrical classification of SWNTs is an indexing system composed of two integers,  $(n_1, n_2)$ , derived from the coefficients of the Bravais lattice

Fig. 1 Zigzag and armchair tube axis orientations.

vectors.<sup>[34]</sup> The geometries of zigzag tubes yield  $n_2 = 0$ , whereas armchair tube geometries yield  $n_1 = n_2$ . As a result, zigzag tubes have indices in the form  $(n,0)$  and armchair tubes have indices of  $(n,n)$ . Examples of several cross-sectional models for zigzag and armchair nanotubes are shown in Figs. 2 and 3, respectively. It is significant to note that the bulk properties of the tubes are strongly dependent on tube geometry. However, for most of the adsorption investigations described in this article, the primary differences between armchair and zigzag tubes are attributed to variations in the local geometry at the adsorption site. In addition to the axis orientation, the radii of the tubes influence the local environment of the carbon atoms. The radii of the tubes increase with increasing  $n$  values—a trend clearly seen in Figs. 2 and 3. If the C–C bond length is represented by  $d$ , the radii of curvatures for zigzag and armchair tubes can be determined by using  $r = (\sqrt{3}dn/2\pi)$ , and  $r = (3dn/2\pi)$ , respectively.

The potential use of carbon nanotubes in hydrogen storage devices has been the subject of a number of recent reviews.<sup>[35–38]</sup> The Department of Energy (DOE) has determined that, in order for nanotubes to be considered as a material for use in such devices, they must have the ability to adsorb a minimum of 6.5 wt.% hydrogen.<sup>[35]</sup> In 1997, Dillon et al.<sup>[1]</sup> reported results suggesting a range of hydrogen adsorption by carbon nanotubes between 5.0 and 10.0 wt.%. Subsequent investigations have sought to confirm these

Fig. 2 Cross-sectional models of zigzag nanotubes.

Fig. 3 Cross-sectional models of armchair nanotubes.

findings and to optimize the environmental parameters leading to hydrogen adsorption. Since the study by Dillon et al., other researchers<sup>[2–7]</sup> have reported adsorption levels near or above the DOE minimum under a variety of conditions. However, the positive results have been controversial because experiments at room temperature<sup>[8]</sup> have not produced adsorption levels as high as those initially reported by Dillon et al. Because of the disparate results, the validity of the positive findings was questioned. Proponents of nanotube utilization countered with the argument that the high sensitivity of adsorption levels to experimental conditions make reproducibility difficult. The controversy has led to the design of computational models, in which parameters can easily be varied to determine both the optimal conditions for adsorption and the viability of the process.

### Models for Hydrogen Adsorption

In addition to the goals stated above, simulation models could presumably be used to determine the optimal nanotube geometries for hydrogen adsorption. Both the nanotube geometries described in the previous section and the arrangement of the tubes can be easily varied in adsorption models. Indeed, the determination of hydrogen storage feasibility and the optimization of geometrical variables are codependent goals. A simulation model producing hydrogen adsorption levels at or above the DOE threshold would strongly support the use of nanotubes in hydrogen fuel cells. Thus far, however, many of the simulation models have not reproduced the required DOE levels of adsorption.<sup>[9–14]</sup> Other models have given hydrogen adsorption amounts at or above the DOE levels at low temperatures or high pressures.<sup>[16–19]</sup> This discord with experimental observations has led to suggestions that the hydrogen adsorption mechanisms considered are insufficient. Most of the initial simulation models considered the adsorption of hydrogen through the process of physical adsorption—or physisorption. Physisorption describes the adhesion of an adsorbate  $H_2$  molecule via dispersion forces to the nanotubes. Adsorption models have used a variety of potentials to describe these van der Waals interactions between the carbon atoms and hydrogen. Researchers who

Fig. 4 Endohedral hydrogen physisorption.

believe that physisorption is insufficient have pointed to chemical adsorption—or chemisorption—as another possible mechanism to consider.<sup>[9,20,35]</sup> Chemisorption involves the formation of a direct chemical bond between a hydrogen atom and a carbon atom on the nanotube surface. An additional complicating issue that simulation models must address is whether the hydrogen storage process is most efficient inside the tubes or in the interstitial spaces between tubes. Hypothetical examples of these two possibilities, termed endohedral and exohedral adsorption, are shown in Figs. 4 and 5, respectively. If a significant amount of endohedral adsorption is necessary to realize the DOE levels, mechanisms must exist both for inserting and extracting hydrogen from the interior of the tubes.

In a series of grand canonical Monte Carlo simulations, Johnson and coworkers<sup>[12–14]</sup> modeled the exohedral and endohedral physisorption of hydrogen molecules in arrays of carbon nanotubes. They found that the DOE target could be approached only at a temperature that is too low for use in vehicular fuel cells.<sup>[13]</sup> Similar results were found with other models that use physisorption mechanisms to simulate adsorption of hydrogen to arrays of nanotubes<sup>[10,11]</sup> The DOE levels of adsorption were met or exceeded in several Monte Carlo physisorption simulations, yet these occurred only at low temperatures or at high pressures.<sup>[16,18,19]</sup> Taken together, the results of the modeling studies

Fig. 5 Exohedral hydrogen physisorption.

support the assertion that the uptake of hydrogen by nanotubes through physisorption alone is insufficient to account for the experimental observations. A Monte Carlo simulation by Cracknell<sup>[9]</sup> used, in addition to a physisorption mechanism, a hypothetical chemisorption mechanism. It was found that chemisorption was necessary if the experimental results of Dillon et al. were to be approached. In addition to the need to address a chemisorption mechanism, Cheng and coworkers<sup>[20]</sup> have suggested that the lower levels of adsorption observed in models could also be attributable to the neglect of nanotube deformation. They found evidence for partial reconstruction of the nanotubes on adsorption of hydrogen and have suggested that this may increase the favorability of the interaction between the tubes and hydrogen. It is evident that the phenomena that may facilitate a more realistic modeling of hydrogen adsorption, chemisorption, and nanotube deformation are processes occurring locally at an adsorption site. The study of localized processes at the nanotube surface can be undertaken by using first principles calculations. For this reason, atomistic investigations that use first principles calculations to more clearly understand the hydrogen adsorption are of primary importance.

## FIRST PRINCIPLES INVESTIGATIONS OF HYDROGEN ADSORPTION

### Computational Strategies

First principles calculations are ideal for studying localized events such as hydrogen chemisorption to a nanotube or the deformation of a nanotube surface site. A critical step in the implementation of any such study is the design of the nanotube model. Ideally, cross-sectional models such as those in Figs. 1 and 2 could be used to study local phenomena occurring either exo- or endohedrally. Unfortunately, levels of ab initio theory such as configuration interaction (CI) calculations, which provide a rigorously defined degree of accuracy, are intractable with all but the smallest nanotube models. This problem has been circumvented in studies using density functional theory (DFT) calculations. Because DFT is an efficient and generally reliable means of calculating energies for relatively large systems, it has been extensively used with nanotubes. Researchers have used DFT in conjunction with classical potentials,<sup>[31]</sup> with plane-wave pseudopotentials<sup>[22,23,29,30]</sup> and with a tight-binding method.<sup>[24–26]</sup> If relatively small clusters of atoms are used to model nanotubes, CI calculations give a more rigorously reliable energy for local phenomena. However, the accuracy of the results may be compromised because of errors associated with the cluster size. The size of

Fig. 6 Small cluster models for nanotubes.

cluster models that can be used with these methods do not allow for a complete cross section for most nanotubes (Fig. 6). Studies have been performed<sup>[27,39]</sup> using small clusters and terminating the boundary carbons with hydrogen. Because the terminating hydrogen atoms do not allow for the continuation of the  $sp^2$  network, significant errors may be introduced if the boundaries are in close proximity to the adsorption site. Care must be taken to either minimize or to account for these errors. Bauschlicher<sup>[27,28]</sup> and Froudakis<sup>[32]</sup> have used a mix quantum mechanics and molecular mechanics (QM/MM) method. Specifically, they used an ONIOM approach, which treats a relatively large nanotube model with molecular mechanics and an embedded smaller model with more accurate *ab initio* calculations. Another study of small clusters using CI calculations is an energetic comparison, as opposed to an absolute determination, of adsorption energies.<sup>[39]</sup> In this study, it was assumed that the errors introduced by cluster size were equally present in all models and would effectively cancel for the comparison. The computational strategy used for extended systems such as nanotubes largely depends on the goals of the study and the process under investigation.

### Physisorption Studies

Many of the simulation models discussed in the “Background” section use potentials to describe the physisorption of  $H_2$  molecules to carbon nanotubes.<sup>[9–18]</sup> In large part, the parameters for these potentials have been developed using hydrogen–carbon interactions in systems other than nanotubes. A potentially more accurate description of hydrogen–nanotube interactions could be developed. However, as dispersion interactions are relatively weak and are highly delocalized compared to a chemical bond, accurate physisorption binding energies are difficult to determine using first principles calculations. A few successful studies have been performed. Using DFT, Arellano and coworkers<sup>[29]</sup> studied the binding energy of a physisorbed hydrogen molecule to (5,5) and (6,6) armchair tubes. They were able to detect loosely bound endo- and exohedral configurations. Despite the presence of these loosely bound states, they found that if enough energy were present to allow for an  $H_2$  to approach the nanotube, the hydrogen molecule would

dissociate and chemisorb to the wall, possibly leading to the decomposition of the nanotube structure.

Cheng and coworkers<sup>[20]</sup> suggested that the neglect of nanotube deformation in simulation models could explain the discrepancies between models and experimental results. Li and coworkers<sup>[30]</sup> studied the degree to which tube deformation plays a role in the physisorption of  $H_2$  to a (7,7) nanotube. Using a DFT plane wave pseudopotential approach, they calculated physisorption energies with allowance for the full relaxation of both the hydrogen molecule and all nanotube carbon atoms. They found that the allowance for tube deformation does not significantly increase the physisorption binding energy at room temperature. In addition, no evidence for an increased stability of physisorbed  $H_2$  on nanotubes as compared to a graphene sheet was found. Even with an allowance for tube deformation, this study suggests that physisorption alone is too weak to explain the observed experimental levels of hydrogen adsorption. For this reason, mechanisms of hydrogen adsorption that involve chemisorption are now the principal focus. Because chemisorption is a highly localized process, first principles calculations constitute a critical method in these investigations.

### Chemisorption Studies

Results from both first principles calculations and modeling studies suggest that room temperature hydrogen adsorption at or above the DOE limit can only be accounted for by a mechanism that includes chemisorption to some degree. Early adsorption models did not consider chemisorption for several reasons. The complexity of a chemisorption model is greater as a result of the number of steps that are necessarily involved. The energy of chemisorption, or binding energy, for atomic hydrogen exhibits a significant dependence on the local geometry of the adsorption site. Thus if chemisorption is to be modeled, an accounting of individual chemisorption site geometries must be established. If endohedral adsorption processes are to be considered, a mechanism for incorporating chemisorbed hydrogen into the interior of the tube must be determined. Because of the variation of local chemisorption geometries that warrant consideration, a detailed chemisorption model would need to address the local environment of adsorption—in other words, the model must be atomistic in nature. This dependence on local environment necessitates the use of first principles calculations in which local model geometries can be easily controlled.

The most direct approach in a chemisorption study is the computation of the binding energy for a single hydrogen atom chemisorbed to a nanotube model.

Such an approach is identical to the calculation of the C–H bond energy on the surface of a nanotube. A typical strategy is to compute the energies of a nanotube cluster model with and without a single chemisorbed hydrogen atom. If  $E(\text{cluster-H})$  represents the energy of the cluster model with a chemisorbed hydrogen,  $E(\text{cluster})$  is the energy of the “clean” cluster, and  $E(\text{H})$  is the energy of a lone hydrogen atom, then the binding energy,  $E_b$ , can be determined using the formula below.

$$E_b = [E(\text{cluster}) + E(\text{H})] - E(\text{cluster-H})$$

Several recent investigations have used first principles calculations to determine hydrogen chemisorption energies. In Bauschlicher’s ONIOM study,<sup>[27]</sup> the innermost layer was treated at the B3LYP/4-31G level of theory. The binding energy of hydrogen to a (10,0) tube was found to be 20.9 kcal mol<sup>-1</sup>. In addition, the barrier to hydrogen migration on the tube was found to be larger than the binding energy itself. Using a DFT plane wave pseudopotential method, Gülseren and coworkers<sup>[22]</sup> investigated the binding energy of hydrogen to a series of zigzag(*n*,0) tubes. Allowing full relaxation, they found that the binding energies on zigzag tubes decrease with increasing radius. They attributed this difference to the increased sp<sup>3</sup> character of a C–H bond formed at a “sharp site” of a nanotube. Smaller tubes, because of the larger degree of curvature, will have sites that more readily fit this description. Another recent study<sup>[39]</sup> determined chemisorption energies to smaller clusters by using CI calculations at the QCISD(T)/6-31G(d,p) level. The QCISD(T) method uses quadratic configuration interaction calculations including single and double substitutions with a triples correction. This study modeled both zigzag and armchair nanotubes to compare the adsorption energies as a function of tube geometry. A trend with respect to tube radius similar to that reported by Gülseren and coworkers was found. The higher degree of curvature, and hence sp<sup>3</sup> character, present in the models for smaller tubes (Fig. 7) offers an explanation for this trend. Yet it was also found that, for a single adsorption event, hydrogen chemisorption to an armchair site is slightly more favorable than chemisorption to a zigzag site of similar radius. It is precisely these dependencies of chemisorption

Fig. 7 Curvature of possible hydrogen chemisorption sites.

energetics on localized site geometry that must be considered in an atomistic chemisorption model.

However, in order for any model to accurately consider the necessary levels of adsorption, the dependency of the chemisorption process on hydrogen coverage must also be determined. The degree of coverage is significant because, if the DOE limit were to be achieved through chemisorption of hydrogen alone, 83% of the carbon atoms in a nanotube must have a chemisorbed hydrogen. Furthermore, because of the changes in localized geometries upon adsorption, it is expected that the hydrogen chemisorption energy will depend on surface coverage. The different chemisorption environments are evident in Fig. 8, which shows two cross sections of a (8,0) nanotube; one with a single hydrogen atom chemisorbed and one at full hydrogen coverage. Froudakis<sup>[32]</sup> has shown, using QM/MM calculations on a (4,4) armchair tube, that there is a significant increase in tube volume upon hydrogen chemisorption. The evidence for tube deformation upon adsorption coupled with the observed variance in chemisorption energy with tube geometry suggests that a dependence of chemisorption energy with hydrogen coverage exists. This dependence was studied by Bauschlicher<sup>[28]</sup> using the ONIOM approach. It was found that binding energies increase for the first several chemisorbed hydrogen atoms on a (10,0) zigzag tube, but decrease from 57.3 to 38.6 kcal mol<sup>-1</sup> as hydrogen coverage increases from 50% to 100%. Similar results were found by Li et al.,<sup>[30]</sup> who studied the fully relaxed (7,7) armchair tube with DFT. In addition, they found strong evidence for tube reconstruction at full hydrogen coverage. At full hydrogen coverage on a (7,7) nanotube, the most stable structure was a reconstructed tube with 50% of the hydrogen chemisorbed endohedrally and 50% of the hydrogen chemisorbed exohedrally. Compared to the separated nanotube and hydrogen molecules, the structure was found to be stable by 8.3 kcal mol<sup>-1</sup> per H atom. A range of armchair and zigzag nanotube models at full hydrogen coverage were also studied

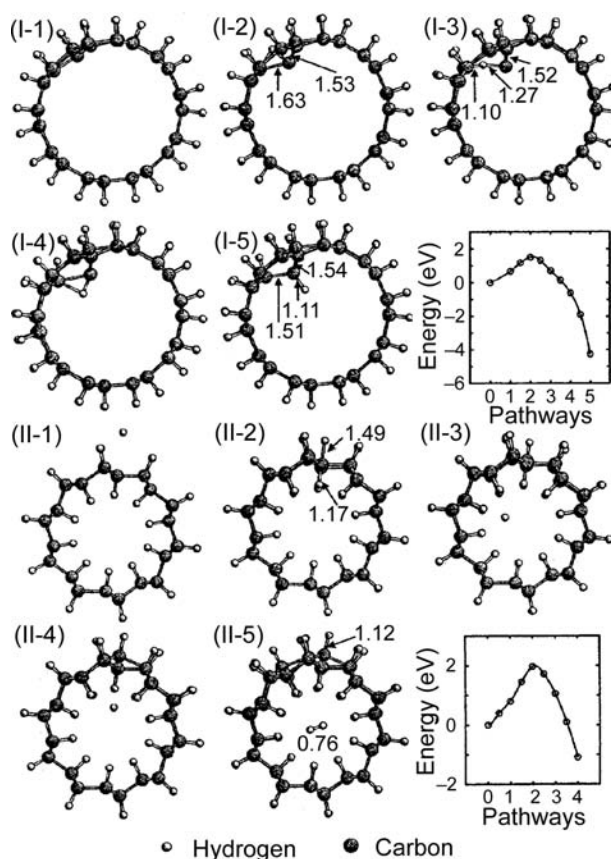

Fig. 8 Single H-atom chemisorption and full hydrogen coverage.

by Yildirim, Gülseren, and Ciraci.<sup>[23]</sup> using the DFT plane wave pseudopotential method. Binding energies as a function of nanotube geometry were determined. Interestingly, at full coverage, the binding energy of chemisorbed H atoms to zigzag tubes was found to be lower by  $0.69 \text{ kcal mol}^{-1}$ . This effect is in sharp contrast to the one found in the single-hydrogen-atom chemisorption study previously described. This suggests that, as the hydrogen coverage on armchair tubes increases, the binding energy declines in relation to zigzag tubes.

### From Hydrogen Adsorption to Hydrogen Storage

The apparent decline of hydrogen binding energies above 50% coverage<sup>[28]</sup> suggests that additional mechanisms may be necessary to account for the achievement of the DOE minimum. It is possible that a combination of chemisorption and physisorption mechanisms must be considered to achieve the required levels. Lee and coworkers<sup>[24–26]</sup> proposed a mechanism that converts exohedrally chemisorbed hydrogen on a tube into endohedrally physisorbed hydrogen molecules. They used a tight-binding DFT approach to initially investigate a process for converting a full exohedral covered (10,10) tube into a stable structure similar to that found by Li et al.<sup>[30]</sup> This structure has 50% of the hydrogen chemisorbed exohedrally and 50% chemisorbed endohedrally. Lee and coworkers<sup>[25]</sup> have termed the conversion process the “flip-in” mechanism and found an activation barrier of  $34.8 \text{ kcal mol}^{-1}$ . Following the flip-in mechanism, they propose a “kick-in” mechanism that provides a pathway for endohedrally chemisorbed hydrogens to recombine as hydrogen molecules in the interior of the tube. The kick-in mechanism was found to have an activation barrier of  $45.5 \text{ kcal mol}^{-1}$ . Their flip-in and kick-in mechanisms are shown in Fig. 9. With these mechanisms, Lee and coworkers have shown that a maximum hydrogen storage capability of 14 wt.% is possible with the (10,10) tube. In addition to suggesting a pathway for exceeding the DOE thresholds, such mechanisms also provide a viable description of a hydrogen insertion process. Further study on these and similar mechanisms is necessary to determine their dependencies on the geometries, sizes, and spatial arrangements of carbon nanotubes. If a complete mechanistic picture is established, atomistic models for the hydrogen adsorption process can be developed. From such models, the dependencies of nanotube adsorptive properties on geometry and arrangement can be determined, and a better understanding of the experimental parameters necessary to optimize the process could ultimately be gained.

**Fig. 9** Proposed mechanisms of Lee and coworkers. *Source:* Reprinted with permission from reference<sup>[25]</sup>. © 2001 American Chemical Society.

Even if a mechanism for hydrogen adsorption and storage can be established, a concomitant mechanism for hydrogen abstraction from the tube must also be developed. It was estimated by Li et al.<sup>[30]</sup> that to achieve hydrogen desorption from their fully hydrogenated structure, temperatures above 600 K would be required. Such temperatures would be prohibitive for use in vehicular fuel cells. In addition, any storage mechanisms involving hydrogen chemisorption will require an efficient means of dissociating molecular hydrogen ( $\text{H}_2$ ) into atomic hydrogen. Despite such barriers, it is clear that first principles calculations constitute a flexible and reliable method for examining adsorption and storage mechanisms that occur at localized nanotube sites. There are several significant issues that must be addressed by future computational studies. If the levels of hydrogen adsorption observed by Dillon et al. are to be accurately modeled, some degree of chemisorption must be considered. The dependence of this chemisorption process on the local geometry of the adsorption site could be further developed. For example, the finding that hydrogen chemisorption occurs most favorably to nanotube surfaces with high degrees of curvature<sup>[22]</sup> suggests that chemisorption

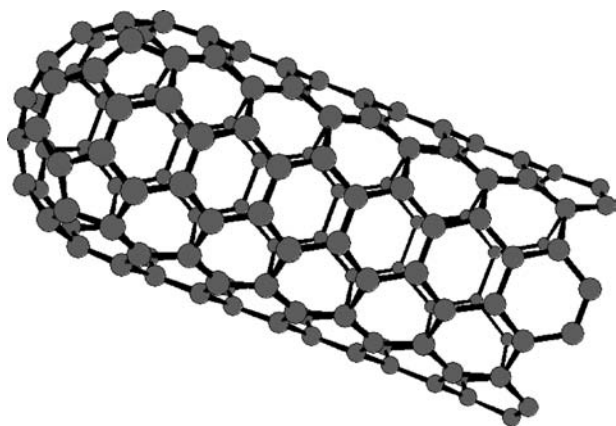

Fig. 10 The cap at the end of a nanotube.

of hydrogen on the capped end of a nanotube (Fig. 10) may occur more readily. Combined with mechanisms similar to those developed by Lee and coworkers,<sup>[25]</sup> the chemisorption to a tube end or reconstructed nanotube site may lead to more favorable storage pathways. In addition, the deformation of the nanotubes should be considered in any study or model that is developed. To achieve these goals, models with increased atomistic design that consider variable environments for each carbon atom need to be developed.

## CONCLUSION

If an adsorption model is to be developed that matches experimental findings, several critical aspects of hydrogen adsorption to carbon nanotubes must be considered. First, mechanisms involving some degree of chemisorption are necessary to explain the high levels of hydrogen adsorption observed experimentally. While some degree of chemisorption is necessary, the lower binding energies at high hydrogen coverages suggest that it is unlikely that chemisorption is the exclusive mechanism for achieving the necessary levels outlined by the DOE. Secondly, the role that nanotube deformation may play in the hydrogen adsorption process is not clear. Models that do not include any tube deformation do not achieve the levels of adsorption that have been observed experimentally. To address localized chemisorption and tube deformation, future studies must involve a deeper understanding of mechanisms that occur at the nanotube surface. First principles calculations can play a key role in clarifying the energetics of the mechanistic steps. As soon as mechanisms for adsorption and storage can be established, models that are atomistic in approach can be used to help predict the dependency of adsorption levels upon nanotube geometry and spatial arrangement. Such atomistic models could potentially

determine the ultimate applicability of carbon nanotubes toward hydrogen storage and serve to optimize any such utilization.

## INTRODUCTION

The interaction between light and solids gives rise to many optical properties in solid-state systems that can be observed by a variety of experimental techniques such as photo absorption and emission, infrared absorption, Raman scattering, photoelectron and Auger spectroscopy, and ultraviolet and X-ray photoelectron spectroscopy. Especially in one-dimensional (1-D) solids, such as carbon nanotubes,<sup>[1–3]</sup> much useful information on the optical properties can be obtained by exploiting low-dimensional effects, such as the direction of the polarization of the light relative to the nanotube axis, the resonance between the laser excitation energy and a singularity in the joint density of states, and the variety of crystal structures of nanotubes stemming from their chirality. Thus, by rotating the orientation angle of the nanotube relative to the incident and scattered light polarization directions, by changing the laser excitation energies, or by selecting different geometries for the nanotubes, we can systematically investigate the optical properties for many different types of carbon nanotubes in a consistent way. Especially fruitful has been the study of the resonance Raman spectra from only one nanotube by using micro-Raman measurements of a nanotube on a Si/SiO<sub>2</sub> substrate. Because of the large amount of detailed information

that can be obtained from this technique, micro-Raman spectroscopy is considered to be a standard nanotechnique for probing the optical properties of a nanotube in a quick, nondestructive way at room temperature and atmospheric pressure.

Since the reported observation of carbon nanotubes in 1991, high-resolution transmission electron microscopy (HRTEM) and scanning probe microscopy [SPM, such as scanning tunneling microscopy/spectroscopy (STM/STS), atomic force microscopy (AFM), Kelvin force microscopy (KFM), magnetic force microscopy (MFM), and so on] have provided definitive tools for observing tiny samples on nanometer length scales. However, for single-wall carbon nanotubes (SWNTs), the high quality required of the measurement instruments and of the personnel to observe structure at the atomic level restricts the number of instruments and researchers who can make such measurements.

The finding of so many new phenomena and concepts in the nanotube field in the past decade reminds us of the good old times of the adventurers on sailing ships who ventured out to find the new world. In the next decade, nanotube research will enter a new period in which nanotube samples are easily obtained, in which many nanotube-based industrial technologies and applications will be developed, and in which fundamental physics and chemistry discoveries will

continue to be made, but more and more the research will be stimulated by the needs of the applications and by the availability of new measurement tools. In this sense, a standard technique to characterize nanotubes is highly desirable. Here it is proposed that resonance Raman spectroscopy should fill this role.

## OVERVIEW

One unique feature of a SWNT is the fact that the electronic structure is either metallic or semiconducting, depending only on the chirality of the nanotube and not on the impurities that it contains.<sup>[1]</sup> Here the chirality of a SWNT denotes the spiral geometries of a nanotube structure, which is specified by two integers ( $n$ ,  $m$ ) as discussed below. Thus, the interaction of the conduction electrons in the metallic nanotube with light can be investigated, e.g., by comparing the Raman spectra of metallic nanotubes with that of semiconducting nanotubes that have no doping with noncarbon atoms. Thus, carbon nanotubes provide an ideal material for understanding the physical properties of a low-dimensional solid. Another important fact about nanotubes is that the diameter of a nanotube is much smaller than the wavelength of light, but the length of the nanotube is usually comparable to or greater than the optical wavelength. Thus microscopic and macroscopic views of nanotubes can coexist within a single nanotube, and it is expected that these unique properties will lead to new optical applications in the future.

Among the various optical techniques, resonance Raman spectroscopy of nanotubes has been investigated in depth during the last few years. The resonance Raman effect is a strong enhancement ( $\sim 10^3$ ) of the Raman intensity when a real optical absorption takes place in the excitation process. The resonance condition for each nanotube is very sharp in energy, known as van Hove singularities, with a width of less than 10 meV. Because the resonant energies of each ( $n$ ,  $m$ ) nanotube are different from one another, the energies of the van Hove singularities can be used for identification (something like a fingerprint) of the nanotube atomic structure. Thus, van Hove singularity is a key word to understand optical properties of nanotubes. We can select a particular ( $n$ ,  $m$ ) SWNT for investigation by selecting the appropriate laser energy  $E_{\text{laser}}$ , or we can investigate metallic or semiconducting nanotubes separately by selecting  $E_{\text{laser}}$ , even for samples consisting of SWNT bundles containing a mixture of metallic and semiconducting SWNTs. Recently, using a chemical vapor deposition (CVD) growth technique for preparing isolated SWNTs on a Si/SiO<sub>2</sub> substrate, we have observed resonance Raman spectroscopy from one nanotube. Compared with the

spectra from SWNT bundle samples, single nanotube spectroscopy gives much more definitive information on the electronic and phonon properties of SWNTs.

In this entry, we first discuss the singular nature of the electronic energy states and then discuss optical absorption and the resonance Raman spectra. Finally, we present the double resonance theory of Raman nanotubes, which is necessary for describing the experimentally observed dispersive phonon modes in SWNTs.

## VAN HOVE SINGULARITIES

A single-wall carbon nanotube is a graphene (honeycomb) sheet rolled up into a cylinder. In Fig. 1, we show the cylindrical structures of SWNTs. Each end of the nanotube is terminated by a hemisphere of fullerene containing six pentagonal carbon rings. Because it is considered that nanotubes grow with a cap, the cap structure is essential for generating different kinds of geometries for nanotubes. The relative positions of the pentagonal rings with respect to one another is almost arbitrary except for the requirement that two pentagonal rings do not touch each other (isolated pentagon rule), thus giving rise to many possible geometries for generating nanotube structures. Among the various nanotube structures, there are only two kinds of nanotubes that have mirror symmetry along the nanotube axis, namely, the armchair and zigzag nanotubes, as shown in Fig. 1A and B, respectively. The names armchair and zigzag are taken from the shape of the edge cuts shown on the right side of

**Fig. 1** Single-wall carbon nanotubes. The ends of nanotubes are capped by fullerene hemispheres. (A) Armchair nanotube, (B) zigzag nanotube, and (C) chiral nanotube.

**Fig. 2** The unrolled honeycomb lattice of a nanotube. OA is the equator of the nanotube and OB corresponds to the translation vector of this 1-D material. By connecting OB to AB', we can make a seamless cylindrical shape. OAB'B is a unit cell of the nanotube. The figure corresponds to the (4,2) chiral nanotube and there are  $N = 28$  hexagons in the unit cell.

**Fig. 1.** All other nanotubes (Fig. 1C) exhibit axial chirality and are called chiral nanotubes.

The geometry of a nanotube is uniquely expressed by two integers,  $(n, m)$ . In Fig. 2, the rectangle OAB'B is shown, and by connecting OB to AB', we can make the cylindrical shape of the nanotube. In this case, the vector OA (hereafter we call OA the chiral vector) corresponds to the equator of the nanotube. OA can be expressed by a linear combination of the two unit vectors,  $\mathbf{a}_1$  and  $\mathbf{a}_2$ , of the honeycomb lattice, so that

$$OA = n\mathbf{a}_1 + m\mathbf{a}_2 \equiv (n, m) \quad (1)$$

The length of OA divided by  $\pi$  gives the diameter of the nanotube,  $d_t$ . Two lattice vectors OB and AB', which are perpendicular to OA, correspond to the translational vector  $\mathbf{T}$  in the 1-D lattice of the nanotube, and  $\mathbf{T}$  is a function of  $n$  and  $m$ , as shown in Table 1. The rectangle OAB'B denotes the unit cell of the nanotube containing  $N$  hexagons and  $2N$  carbon atoms, where  $N$  is expressed by

$$N = \frac{2(n^2 + m^2 + nm)}{d_R} \quad (2)$$

The integer  $d_R$  is the common multiple divisor of  $(2n+m)$  and  $(2m+n)$ . Further details of the mathematics describing these variables are given in Table 1 and are further explained in Ref.<sup>[1]</sup>. (This introductory textbook of nanotube can be cited for the "Introduction" and "van Hove Singularity" sections.)

The valence electrons of  $sp^2$  carbons, such as graphite and nanotubes, consist of  $\pi$  ( $2p$ ) electrons. Because a carbon atom in a nanotube has one  $\pi$  electron (and because there are  $2N$  carbon atoms in the nanotube unit cell),  $2N$  1-D electronic  $\pi$  bands are obtained for a SWNT by applying periodic boundary conditions around the circumferential direction OA. Such a treatment for the electronic structure is called "zone folding." Along the direction OA, the wave vectors ( $2\pi/\text{wavelength}$ ), which are perpendicular to the nanotube axis direction  $\mathbf{k}_\perp$ , are discrete and are given by the condition:

$$\mathbf{C}_h \cdot \mathbf{k}_\perp^p = 2\pi p, \quad (p = 1, \dots, N) \quad (3)$$

Thus, one obtains  $N$  inequivalent  $\mathbf{k}_\perp^p = 2\pi p/|\mathbf{C}_h| = 2p/d_t$  discrete wave vectors for bonding and antibonding  $\pi$  bands and the 1-D wave vectors  $\mathbf{k}_\parallel$ , parallel to the nanotube axis, are continuous ( $-\pi/T \leq \mathbf{k}_\parallel \leq \pi/T$ ) for an infinitely long SWNT.

One-dimensional energy dispersion relations for a nanotube  $E_{1-D}(p, \mathbf{k}_\parallel)$  are obtained by cutting the 2-D energy dispersion relations of graphite  $E_{2-D}(k)$  along the  $\mathbf{k}_\parallel$  direction with wave vectors  $\mathbf{k}_\perp^p$  placed at equal distances of  $2/d_t$  with a length of  $2\pi/T$ ,

$$E_{1-D}(p, \mathbf{k}_\parallel) = E_{2-D}(\mathbf{k}_\perp^p + \mathbf{k}_\parallel) \quad (4)$$

where, by a tight binding calculation,  $E_{2-D}(k)$  is given by:

$$E_{g2-D}(k_x, k_y) = \pm\gamma_0 \left\{ 1 + 4 \cos\left(\frac{\sqrt{3}k_x a}{2}\right) \cos\left(\frac{k_y a}{2}\right) + 4 \cos^2\left(\frac{k_y a}{2}\right) \right\}^{1/2} \quad (5)$$

in which the coordinates of  $k_x$  and  $k_y$  are given in Table 1. The plus and minus signs in Eq. (5) correspond to unoccupied (antibonding) and occupied (bonding)  $\pi$  energy bands, respectively.  $\gamma_0 > 0$  is the tight-binding nearest-neighbor overlap energy parameter. When we plot the  $E_{g2-D}$  in the hexagonal 2-D Brillouin zone (BZ) (Fig. 3), the bonding and antibonding energy dispersion relations touch each other at the hexagonal corners, the  $K$  and  $K'$  points of the 2-D Brillouin zone. Because of the periodicity of  $E_{g2-D}(k_x, k_y)$  in  $k$  space, the  $K$  and  $K'$  points are inequivalent to each other. The asymmetry between the shapes of the bonding and antibonding  $\pi$  bands comes not directly from Eq. (5) but from the higher-order correction to the tight-binding parameters known as the overlap parameter  $s$ . In the following discussion, however, for simplicity, we use  $s = 0$ .

**Table 1** Parameters for carbon nanotubes

Symbol	Name	Formula	Value
$a$	Length of unit vector	$a = \sqrt{3}a_{C-C} = 2.49\text{\AA}$	$a_{C-C} = 1.44\text{\AA}$
$\mathbf{a}_1, \mathbf{a}_2$	Unit vectors	$\left(\frac{\sqrt{3}}{2}, \frac{1}{2}\right)a, \left(\frac{\sqrt{3}}{2}, -\frac{1}{2}\right)a$	$x, y$ coordinates
$\mathbf{b}_1, \mathbf{b}_2$	Reciprocal lattice vectors	$\left(\frac{1}{\sqrt{3}}, 1\right)\frac{2\pi}{a}, \left(\frac{1}{\sqrt{3}}, -1\right)\frac{2\pi}{a}$	$k_x, k_y$ coordinates
$\mathbf{C}_h$	Chiral vector	$\mathbf{C}_h = n\mathbf{a}_1 + m\mathbf{a}_2 \equiv (n, m)$	$(0 \leq  m  \leq n)$
$L$	Length of $\mathbf{C}_h$	$L =  \mathbf{C}_h  = a\sqrt{n^2 + m^2 + nm}$	
$d_t$	Diameter	$d_t = L/\pi$	
$\theta$	Chiral angle	$\sin \theta = \frac{\sqrt{3}m}{2\sqrt{n^2 + m^2 + nm}}$ $\cos \theta = \frac{2n + m}{2\sqrt{n^2 + m^2 + nm}}$	$0 \leq  \theta  \leq \pi/6$ $\tan \theta = \frac{\sqrt{3}m}{2n + m}$
$d$	$\text{gcd}(n, m)^a$		
$d_R$	$\text{gcd}(2n + m, 2m + n)^a$	$d_R = \begin{cases} d & \text{if } (n - m) \text{ is not multiple of } 3d \\ 3d & \text{if } (n - m) \text{ is multiple of } 3d \end{cases}$	
$\mathbf{T}$	Translation vector	$\mathbf{T} = t_1\mathbf{a}_1 + t_2\mathbf{a}_2 \equiv (t_1, t_2)$	$\text{gcd}(t_1, t_2) = 1^a$
		$t_1 = \frac{2m + n}{d_R}, t_2 = -\frac{2n + m}{d_R}$	
$T$	Length of $\mathbf{T}$	$T =  \mathbf{T}  = \frac{\sqrt{3}L}{d_R}$	
$N$	Number of hexagons in the nanotube unit cell	$N = \frac{2(n^2 + m^2 + nm)}{d_R}$	

$n, m, t_1, t_2, p,$  and  $q$  are integers and  $d, d_R, N,$  and  $M$  are integer functions of these integers.

<sup>a</sup> $\text{gcd}(n, m)$  denotes the greatest common divisor of the two integers  $n$  and  $m$ .

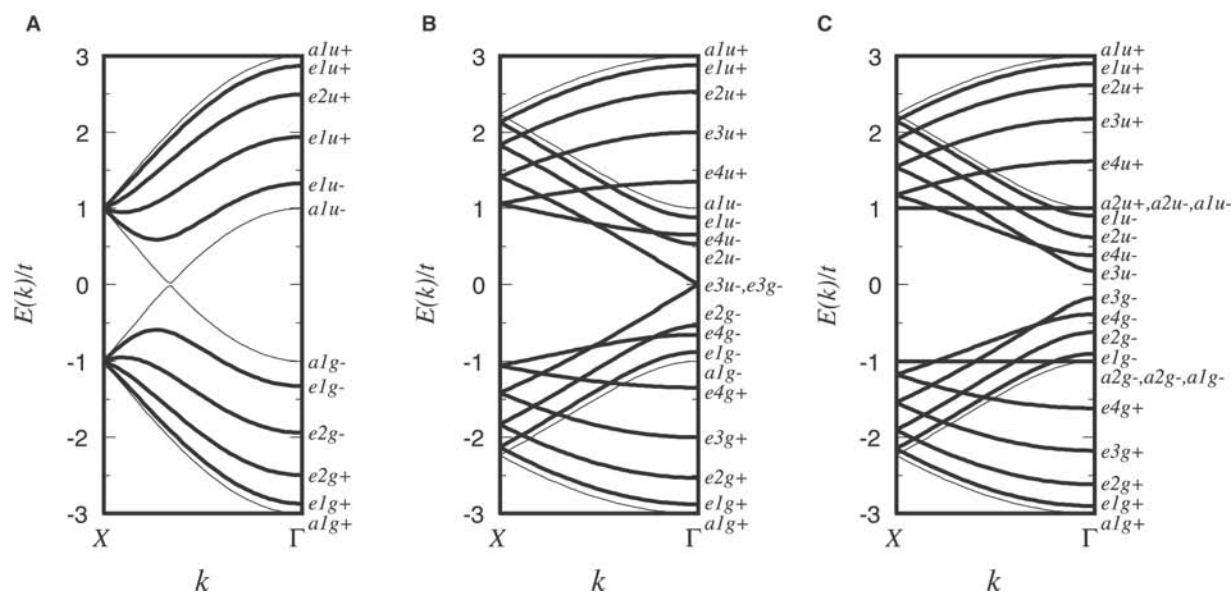

Cutting these 2-D energy dispersion relations by equidistant lines parallel to the nanotube axis (hereafter we call these lines ‘‘cutting lines’’) corresponds to obtaining the 1-D energy dispersion of nanotubes,

**Fig. 3** The energy dispersion relations for 2-D graphite are shown throughout the whole region of the Brillouin zone. The inset shows the energy dispersion along the high symmetry lines.

as shown in Fig. 4. In this formulation the Fermi energy is located at  $E(\mathbf{k})/t =$ , and thus depending on whether there are energy bands that cross the Fermi energy or not, the nanotube is either metallic or semiconducting, respectively. The condition to get either metallic or semiconducting nanotubes is whether the cutting lines cross the  $K$  or  $K'$  points where the bonding and antibonding  $\pi$  bands of 2-D graphite touch each other (Fig. 3).

In Fig. 5, we show by solid lines the electronic density of states (DOS) for (A) (10,0) and (B) (9,0) zigzag nanotubes. Dotted lines denote the DOS for 2-D graphite for comparison. For metallic nanotubes, the density of states at the Fermi energy is constant as a function of energy, while there is an energy gap for semiconducting nanotubes. The value of the density of states for metallic SWNTs at the Fermi energy,  $D(E_F)$  is  $8/\sqrt{3}\pi a \gamma_0$  in units of states per unit length along the nanotube axis per electron volt, which is independent of diameter. If  $D(E_F)$  is given by per gram per electron volt, the  $D(E_F)$  is relatively large for small-diameter nanotubes. The many spikes in the DOS for

**Fig. 4** The energy dispersion relations for carbon nanotubes. (A) (5,5) Armchair, (B) (9,0) zigzag, (C) (10,0) zigzag nanotubes. Bold and thin lines are doubly or singly degenerate energy bands, respectively. The Fermi energy is located at  $E(k)/t = 0$ . (5,5) and (9,0) are metallic nanotubes while (10,0) is semiconducting.

nanotubes correspond to the energy positions of the minima (or maxima) of the energy dispersion curves of Fig. 4. Each spike exhibits a singularity of  $1/\sqrt{E - E_0}$  (where  $E_0$  is the energy extremum) that is characteristic of 1-D materials and is known as a van Hove singularity.

The energy position of the van Hove singularity near the Fermi energy is determined by how the cutting lines are oriented near the  $K$  point of the 2-D BZ. In Fig. 6, we show the cutting lines around the  $K$  point for (A) metallic and (B) semiconducting nanotubes. In the case of metallic nanotubes, the central cutting line just goes through the  $K$  point, and the two nearest cutting lines are located at the same distance of  $\mathbf{K}_2$  from the  $K$  point. The corresponding energy dispersions for the central line and for the two neighboring lines are, respectively, metallic linear energy dispersions, and are the first subbands (Fig. 4A), which give the van Hove singularities nearest to the Fermi energy. An important fact about the energy dispersion of 2-D graphite around the  $K$  point is that the energy dispersion of Eq. (4) is linear in  $k$ , when we measure  $k$  from the  $K$  point, i.e.,

$$E(k) = \pm \frac{\sqrt{3}\gamma_0}{2} |k| \quad (6)$$

Within the linear approximation of the energy dispersion, the equienergy contour of 2-D graphite is a circle around the  $K$  point (Fig. 7). Thus, only the distance of the two neighboring cutting lines from the  $K$  point is

essential for determining the energy position of a van Hove singularity. Because the separation between two cutting lines,  $\mathbf{K}_2$ , is inversely proportional to the diameter of the nanotube,  $d_t$ , the van Hove singular energies relative to the Fermi energy are inversely proportional to  $d_t$ , too.

In the case of a semiconducting nanotube, on the other hand, the  $K$  point is always located at a position one-third of the distance between the two lines as shown in Fig. 6B. Thus, the first and the second van Hove singular energies from the Fermi energy correspond to the 1-D energy dispersion for the nearest and the second nearest cutting lines, respectively, whose energies are one-third and two-thirds of the smallest energy separation of the van Hove singularity of metallic nanotubes with a similar diameter.

The linear energy approximation, however, does not work well for  $k$  points far from the  $K$  point. In this case, the equienergy contours deform with a deformation that increases with increasing  $k$ , and eventually become a triangle that connects three  $M$  points around the  $K$  point (Fig. 7) when we consider the periodicity of the electron dispersion relations in  $k$  space. This effect is known as the trigonal warping effect of the energy dispersion. When the trigonal warping effect is included, the direction of the cutting lines, which depends on the chiral angle of the nanotube (or simply on its chirality), is essential to determine the precise positions of the van Hove energies. For example, the two neighboring cutting lines in the metallic nanotube in Fig. 6A are not equivalent to each other, which gives

**Fig. 5** Electronic density of states for the (A) (10,0) semiconducting zigzag nanotube, (B) (9,0) metallic zigzag nanotube. Dotted lines denote the density of states for 2-D graphite.

rise to a splitting of the van Hove peaks in the DOS. This splitting of van Hove peaks is a maximum for zigzag nanotubes and monotonically decreases to zero for armchair nanotubes for which the two neighboring cutting lines are equivalent to each other. For both metallic and semiconducting nanotubes, the trigonal warping effect appears as a modification of the energy position of the van Hove singularities that depends on chirality. This value of the splitting of the van Hove singularities (0.1 eV at most) is large enough to be easily detected by the energy accuracy of resonance Raman spectroscopy (10 meV). It is therefore possible to specify the  $(n, m)$  values for SWNTs from a detailed analysis of the resonance Raman spectra of each SWNT using a tunable laser.

**OPTICAL ABSORPTION**

Optical absorption of an electron occurs “vertically” at a  $k$  point of the Brillouin zone from an occupied

**Fig. 6** Cutting lines around the  $K$  point in the Brillouin zone for (A) metallic and (B) semiconducting nanotubes.

to an unoccupied energy band. An optical transition from an occupied 2p to an unoccupied 2p atomic orbital in the same carbon atom is forbidden. However, the transition from the 2p orbital of one atom to the 2p orbital of another atom (mainly a nearest

**Fig. 7** Equienergy contours for the electronic  $\pi$  bands of 2-D graphite.

neighbor atom) is possible, which makes  $\pi$  to  $\pi^*$  transitions possible in graphite and carbon nanotubes.

First-order time-dependent perturbation theory gives the following formula for the absorption probability per unit time  $W(\mathbf{k})$  for an electron with wave vector  $\mathbf{k}$ ,

$$W(\mathbf{k}) = \frac{4e^2\hbar^4 I}{\tau\epsilon m^2 c^3 E_{\text{laser}}^2} |\mathbf{P} \cdot \langle \Psi^c(\mathbf{k}) | \nabla | \Psi^v(\mathbf{k}) \rangle|^2 \times \frac{\sin^2[E_c(\mathbf{k}) - E_v(\mathbf{k}) - E_{\text{laser}}](\tau/2\hbar)}{[E_c(\mathbf{k}) - E_v(\mathbf{k}) - E_{\text{laser}}]^2} \quad (7)$$

where  $\Psi^c$  and  $\Psi^v$  ( $E_c$  and  $E_v$ ) are the wave functions (energies) of the valence and conduction bands, respectively,  $\mathbf{P}$  is the polarization vector of light, and  $E_{\text{laser}}$ ,  $I$ ,  $\epsilon$ ,  $m$ , and  $\tau$  are the incident laser energy and intensity, dielectric constant, mass of the electron, and the time used for taking the average, respectively. The value of  $\tau = \Delta x/c = 2\pi/\Delta\omega$  is determined by the uncertainty relation and the width of the incident laser frequency  $\Delta\omega$ . Typical values of  $\tau$  for  $\Delta\omega = 10\text{ cm}^{-1}$  correspond to 0.5 psec. If we take a sufficiently large value for  $\tau$ , the function  $\sin^2 X/X^2$   $\{X = [E_c(\mathbf{k}) - E_v(\mathbf{k}) - E_{\text{laser}}]\tau/2\hbar\}$  appearing in the second line of Eq. (7), becomes the delta function  $\delta[E_c(\mathbf{k}) - E_v(\mathbf{k}) - E_{\text{laser}}]$ , and Eq. (7) is known as Fermi's golden rule.  $\Psi_c$  and  $\Psi_v$  can be written as a sum of the two Bloch functions consisting of the two carbon atoms, A and B in the graphite unit cell,  $\Phi_j(\mathbf{k}, \mathbf{r})$ , ( $j = A, B$ )

$$\Psi^i(\mathbf{k}, \mathbf{r}) = \sum_{j=A,B} C_j^i(\mathbf{k}) \Phi_j(\mathbf{k}, \mathbf{r}), \quad (i = c, v) \quad (8)$$

where  $C_j^i(\mathbf{k})$  is the coefficient of the Bloch functions that is obtained by solving the 2-D Hamiltonian and overlap matrices ( $H$  and  $S$ ) for 2-D graphite.

In the case of graphite, simple zone folding of the energy bands gives the wavefunction of the nanotube in which  $\Psi^i(\mathbf{k}, \mathbf{r})$  of graphite is changed to  $\Psi_p^i(\mathbf{k}_{\parallel}, \mathbf{r})$  for the nanotubes, where the subband index  $p$  and the 1-D wave vectors  $\mathbf{k}_{\perp}$  and  $\mathbf{k}_{\parallel}$  are given by Eqs. (3) and (4).

The dipole selection rule is given by group theory applied to the  $\Gamma$  point (zone center) of the Brillouin zone, because each eigenfunction belongs to an irreducible representation of the space group. This rule can be extended smoothly to lower symmetry  $k$  points, even though there is no longer strict selection rule for the lower symmetry  $k$  points. The optical intensity can be directly obtained by calculating the dipole matrix element, as shown in Eq. (7). When the light polarization is parallel to the nanotube axis, the optical transition occurs between valence and conduction subbands that come from the same cutting line. When the

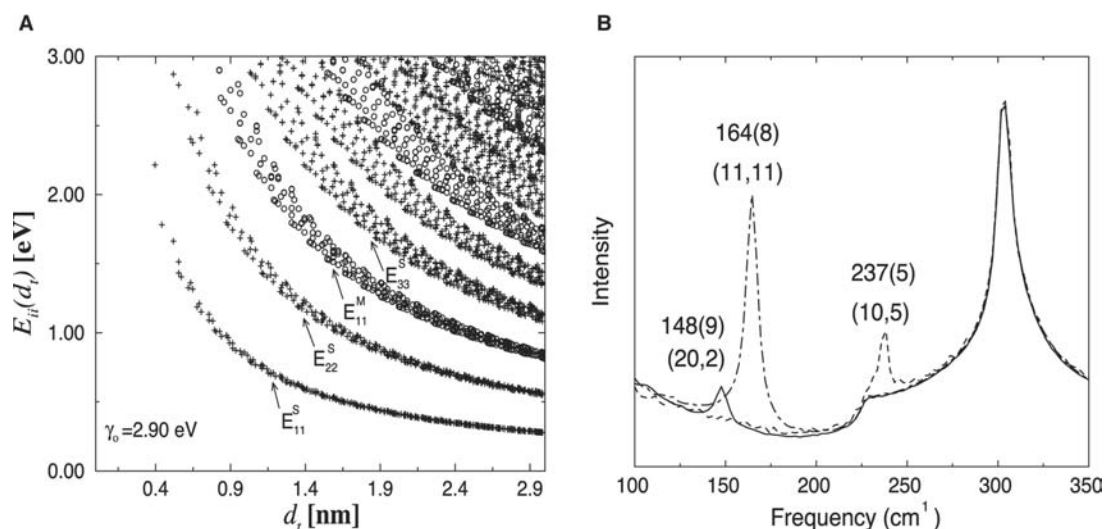

light polarization is perpendicular to the nanotube axis, the optical transition occurs between the two subbands that belong to nearest neighbor cutting lines in the 2-D Brillouin zone.

Hereafter we mainly consider the case of light polarization parallel to the nanotube axis, because the optical absorption for perpendicular polarization is relatively much weaker. The reason why the perpendicular polarization is weak is that 1) the nanotubes have a high aspect ratio of nanotube diameter to length, 2) the van Hove singular  $k$  points are not the same for the valence and conduction energy subbands for different cutting lines, and 3) there is a strong screening effect of the electric field perpendicular to the nanotube axis [depolarization effect, see H. Ajiki and T. Ando, Physica 201 (1994) 349]. Especially for isolated single nanotube spectroscopy, no Raman signals are observed for light polarization perpendicular to the nanotube axis.

In Fig. 8A the energy separations  $E_{ii}$  between the  $i$ th valence and the  $i$ th conduction band van Hove singular energies, which are dipole allowed for parallel light polarization, are plotted as a function of the nanotube diameter,  $d_t$ . Here the subband label  $i$  is counted from the subband closest to the Fermi energy. Each point of this figure corresponds to van Hove singularities for a different  $(n, m)$  nanotube. For a given tube diameter, we can obtain optical transitions for the first and the second van Hove singularities in the joint density of states (JDOS) for semiconducting nanotubes,  $E_{11}^S$ ,  $E_{22}^S$  when we increase the laser energy. The next band in Fig. 8A is for metallic nanotubes  $E_{11}^M$ , followed by  $E_{33}^S$  for semiconducting nanotubes. For a given laser energy, we can find possible diameter regions of nanotubes that have an optical transition between two van Hove singularities. In this sense, the excitation laser light selects the diameter of a nanotube within a mixed sample containing nanotubes with a diameter distribution.

In Fig. 8B, typical Raman signals at the single nanotube level are shown for 3 different  $(n, m)$  SWNTs at three different locations on the sample obtained by illuminating an individual SWNT with a 1- $\mu\text{m}$ -diameter laser light spot on a Si/SiO<sub>2</sub> substrate. The Raman feature at around 300 and 225  $\text{cm}^{-1}$  come from the nonresonant Si substrate. Although the number of carbon atoms is much smaller than the number of Si atoms (Si/C  $\sim 10^6$ ), the Raman signal of one nanotube is comparable to that of Si. This is because the Raman signal in the nanotube comes from a resonance effect in which the resonant signal is enhanced by more than  $10^3$  times relative to the nonresonant signal. This enhancement factor can be observed by changing the laser excitation energy on the same light spot. Because a SWNT is too small to see with an optical microscope, the signal from a resonant SWNT is obtained by

**Fig. 8** (A) Energy separations  $E_{ii}$  between valence and conduction band van Hove singularities are plotted as a function of nanotube diameter. (B) Raman spectra (radial breathing mode) from three different  $(n, m)$  isolated single-wall nanotubes.

putting many light spots on the Si/SiO<sub>2</sub> substrate that has previously been scanned by an AFM probe to determine the location of the SWNTs in the sample.

The three spectra correspond to the radial breathing mode (RBM) of a SWNT in which the carbon atoms of the nanotube are vibrating in the radial direction. The RBM frequency  $\omega_{\text{RBM}}$  for an isolated SWNT is inversely proportional to the tube diameter and is independent of chirality:

$$\omega_{\text{RBM}} = \alpha/d_t \quad (9)$$

The  $(n, m)$  assignment is done by fitting two empirical theoretical parameters,  $\gamma_0$  in Eq. (5) and  $\alpha$  in Eq. (9), to reproduce many RBM frequencies observed in the experiment. The values of the parameters that were obtained for isolated SWNT sample on a Si/SiO<sub>2</sub> substrate are  $\gamma_0 = 2.89 \text{ eV}$  and  $\alpha = 248 \text{ cm}^{-1} \text{ nm}$ . These parameters work well to three effective digits for a laser excitation energy  $E_{\text{laser}} = 1.58 \text{ eV}$  and in the nanotube diameter range  $1 < d_t < 2 \text{ nm}$  for isolated SWNTs on a Si/SiO<sub>2</sub> substrate. In other cases, a few possible  $(n, m)$  identifications are possible. Then, using the same two parameters, more accurate Raman techniques, such as the Stokes/anti-Stokes intensity ratio or a tunable laser approach, are necessary (see Ref.<sup>[4]</sup> for details. This is a review entry on Raman spectroscopy in single-carbon nanotubes and “Resonant Raman Process” and is relevant to this entry). However, the accuracy of the  $(n, m)$  assignments might decrease in the following situations: 1) for SWNT diameters smaller than 1 nm, where we expect departures to occur from the calculation of  $E_{ii}$  described above, 2) for thick SWNT bundles in which we expect nanotube–nanotube interactions, and 3) for higher

excitation energies ( $E_{\text{laser}} > 3 \text{ eV}$ ) where  $\sigma$ -band contributions become more important.

In Fig. 9, we show the optical absorption spectra of SWNT bundles synthesized using the laser ablation method and four different catalysts. In the laser ablation method, the pulsed YAG laser hits a graphite rod containing the indicated catalysts in a furnace kept at about 1200°C with an Ar gas flow, and the smoke emerging from the rod and containing the SWNT bundles is transported by Ar gas flow out of the furnace. By controlling the temperature of the furnace and the selection of catalysts, a narrow diameter distribution of nanotubes is obtained. Although there are SWNTs with many different chiralities mixed in the SWNT bundle sample, we can see three peaks in the optical absorption in Fig. 9, where each peak corresponds to either  $E_{11}^S$ ,  $E_{22}^S$ , or  $E_{11}^M$ . By comparing the energies where the peaks in Fig. 9 occur with the results of Fig. 8A, we can estimate the diameter distribution produced by each catalyst and these estimates are confirmed by the RBM spectra shown in the inset of Fig. 9.

When such a bundle of SWNTs is doped with an alkali metal, a charge transfer of electrons occurs from the alkali metal donor ions to the nanotube or from the nanotube to acceptor ions. In the case of donor ions, the unoccupied states of the pristine sample become occupied with electrons starting from the lowest available conduction band energies. This causes a disappearance of the optical absorption peaks starting from the lower-energy side as the doping concentration increases, because of a lack of unoccupied excited states to allow optical transitions to occur. An electrochemical doping or a field effect transistor (FET) type doping method would be good for observing this

**Fig. 9** Optical absorption spectra are taken for single-wall nanotubes synthesized using four different catalysts, each yielding a different diameter distribution, namely, NiY (1.24–1.58 nm), NiCo (1.06–1.45 nm), Ni (1.06–1.45 nm), and RhPd (0.68–1.00 nm). Peaks at 0.55 and 0.9 eV are due to absorption by the quartz substrate. The inset shows the corresponding RBM modes of Raman spectroscopy obtained using 488-nm laser excitation with the same four catalysts, and the tube diameters corresponding to RBM peaks are given for two catalysts. *Source:* From H. Kataura et al. *Synthetic Metals* 103 (1999) 2555.

phenomenon since the Fermi energy can be modified by changing the gate voltage. Although direct optical absorption measurements of one nanotube will be very difficult because there is no special enhancement mechanism available such as resonance Raman spectroscopy, a combination of optical absorption with resonance Raman spectroscopy should make it possible to observe the Fermi energy shift associated with donor or acceptor doping.

Optical emission or fluorescence signals from a nanotube are not easy to observe, because most SWNT samples contain bundles of nanotubes in which one of three nanotubes are metallic. In a metallic nanotube, the electron–hole recombination occurs non-radiatively along the metallic energy dispersion. Furthermore, optical or direct coupling between nanotubes in the bundle suppresses fluorescence in semiconducting nanotubes, but if a semiconducting nanotube is isolated from other nanotubes, it is then possible to

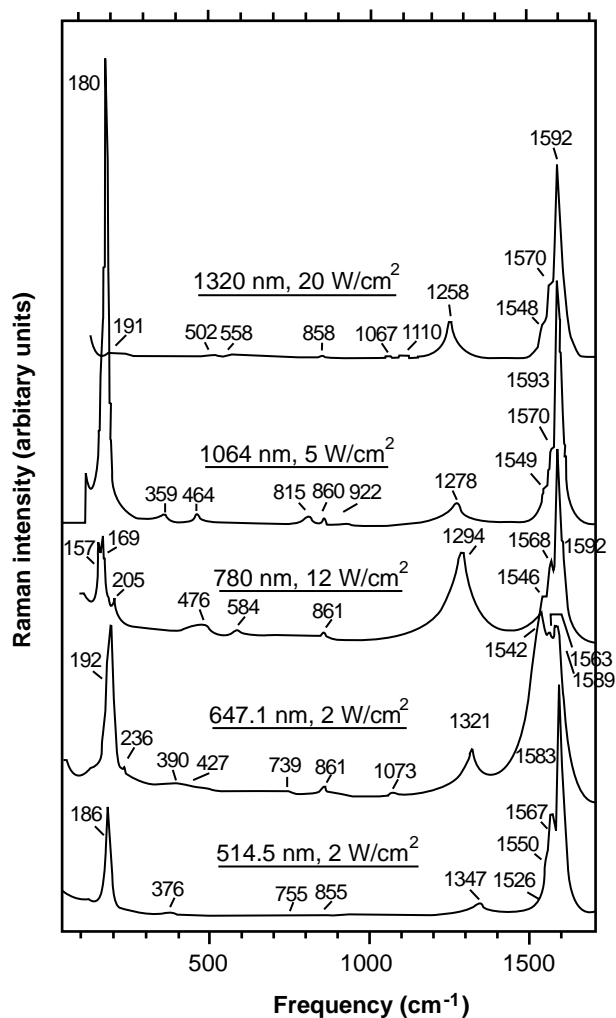

measure the fluorescence. Such spectra have been obtained for nanotubes separated from one another in a zeolite or when covered by a micelle (soap) structure [see Z. M. Li et al. *Phys. Rev. Lett.* 87 (2001) 127401 and M. J. O’Connell et al. *Science* 297 (2002) 593]. The fluorescence of nanotubes occurs at the real energy gap  $E_{11}^S$  of semiconducting nanotubes and provides a good probe of excitonic effects in SWNTs. If high spatial resolution greater than the average distance between two nanotubes is available, we can assign  $(n, m)$  values from the fluorescence measurement.

## Resonance Raman Process

One of the most powerful optical measurements for carbon nanotubes is resonance Raman spectroscopy. The resonance enhancement effect which is caused by a real optical absorption or emission process makes it possible to observe a signal from even one nanotube, as shown in Fig. 8B. Recently much progress in Raman spectroscopy has been made, and therefore it is not possible to explain the many important advances in detail (see Ref.<sup>[4]</sup>) within the available space of this review. The present summary therefore only provides an overview of Raman spectroscopy of carbon nanotubes, and only a few essential points that are important for analyzing the many features of the observed resonance Raman spectra of SWNTs are discussed (Fig. 10).

In carbon nanotubes, the Raman spectra show a variety of features associated with first-order processes, as well as combination or overtone modes up to  $3200\text{ cm}^{-1}$ . The characteristic mode that is not observed in other  $\text{sp}^2$  carbons, but is observed only in nanotube samples, is the radial breathing mode (RBM). The RBM frequency appears from  $100$  to  $550\text{ cm}^{-1}$ , depending on the SWNT diameter, ranging from  $2.5$  to  $0.4\text{ nm}$ , respectively. To check if a sample contains any nanotubes, the RBM spectra provides an easy way to do just that. It is further noted that if no RBM spectra are observed, this does not always mean that there are no SWNTs in the sample, because we can imagine the case that the resonance condition for a given diameter distribution of SWNTs might be far from the available laser excitation energy. In some cases, because of the large noise signal from the Rayleigh (elastically) scattered light, the RBM signal cannot be resolved in the noisy Rayleigh background signal. Use of a notch filter is a simple way to avoid this problem, but use of a notch filter in practice limits observations to  $\omega_{\text{RBM}} > 100\text{ cm}^{-1}$ .

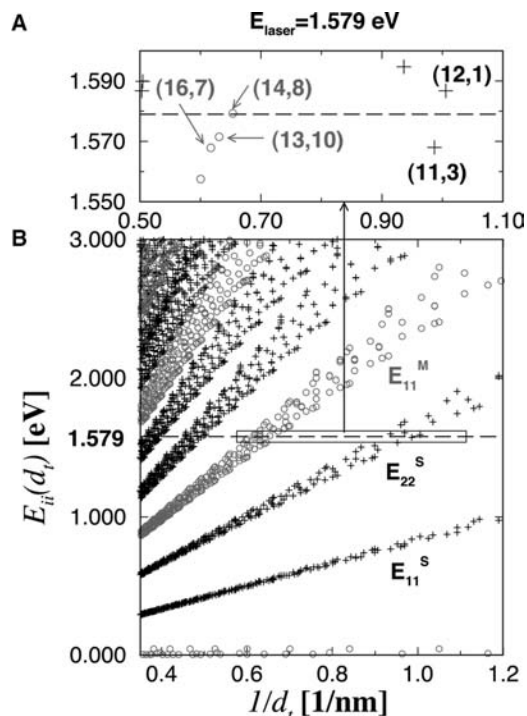

In Fig. 11B we plot  $E_{ii}$  as a function of inverse tube diameter  $1/d_t$ . Circles and crosses correspond, respectively, to metallic and semiconducting  $(n, m)$  tubes. For a laser energy of  $1.579\text{ eV}$ , only a few metallic

**Fig. 10** Room-temperature Raman spectra for purified single-wall carbon nanotube bundles excited at five different laser frequencies, showing RBM modes around  $200\text{ cm}^{-1}$ ,  $G$  band ( $\sim 1590\text{ cm}^{-1}$ ), and  $D$  band ( $1250\text{--}1350\text{ cm}^{-1}$ ). We can also see some weak features in the intermediate frequency region around  $800\text{ cm}^{-1}$ . *Source:* From A. M. Rao et al. *Science* 275 (1997) 187.

and semiconducting  $(n, m)$  tubes with  $E_{11}^M$  and  $E_{22}^S$  van Hove singularities satisfy the resonance condition, as seen in Fig. 11A. Since the RBM frequency can be measured to the accuracy of  $1\text{ cm}^{-1}$  out of  $100\text{--}200\text{ cm}^{-1}$ , the difference between the peak frequencies of different  $(n, m)$  tubes are easily distinguished.

The second important Raman feature is the  $G$ -band mode that appears near  $1590\text{ cm}^{-1}$  in SWNTs. This mode is the Raman-active mode of  $sp^2$  carbons (graphite), and thus many graphitic materials show this spectral feature. What is special in nanotubes is that the  $G$  band mainly splits into two peaks, denoted by  $G^+$  and  $G^-$ , and this is because of the properties of the six (or three) phonon modes that are active for chiral (or achiral) nanotubes around this phonon

**Fig. 11** Van Hove singular energies in the JDOS,  $E_{ii}$  as a function of  $1/d_t$  are shown in (B) where circles and crosses correspond, respectively, to metallic and semiconducting  $(n, m)$  chirality tubes. For  $1.579\text{-eV}$  laser excitation, expansion of the rectangular section in (B) is shown in (A). The resonance condition satisfies only a limited number of  $(n, m)$  tubes whose RBM frequencies can almost always be distinguished from one another.

frequency region. Among Raman-active modes, two  $A$  (or  $A_{1g}$ ) modes are considered to be the strongest and account for the two peaks,  $G^+$  and  $G^-$ . Regarding the other four Raman-active modes, two have  $E_1$  and two have  $E_2$  symmetries (or two Raman-active modes  $E_{1g}$  or  $E_{2g}$  for achiral tubes), and the  $E_1$  and  $E_2$  modes are relatively weak. The presence of the  $E_1$  and  $E_2$  modes are mainly seen from the Lorentzian decompositions of the line shape of the observed spectra using polarized light when carrying out polarization studies. The frequency difference between the two  $G$  band spectral features,  $G^+ - G^-$ , is inversely proportional to  $d_t^2$ , which comes from the curvature effect that is responsible for the splitting of the degenerate in-plane optic phonon modes,  $E_{2g}$ , of 2-D graphite at the  $\Gamma$  point.

Around  $1250\text{--}1350\text{ cm}^{-1}$ , defect-induced Raman modes, called the  $D$  band, appear only for defect-rich  $sp^2$  carbons. The appearance of a  $D$  band in nanotubes means that a nanotube (or a non-SWNT carbon impurity in the sample) has many defects. The nanotubes synthesized by CVD are known to be defective relative to other nanotubes. The  $D$ -band mode is

**Fig. 12** (A) First-order Raman processes that are resonant with (a1) the incident and (a2) the scattered laser light. Solid and open dots denote resonance and nonresonance scattering processes, respectively. Crossed lines show the linear energy dispersion of 2-D graphite around the  $K$  point. (B) Second-order Raman processes that are resonant with (b1, b2) the incident laser light, and with (b3, b4) the scattered laser light. The solid scattered vectors and dashed scattered vectors with wave vector  $\mathbf{q}$ , respectively, denote inelastic and elastic scattering processes.

known as a dispersive phonon mode in which the D-band frequency increases by  $53\text{ cm}^{-1}$  with a  $1\text{ eV}$  increase in the laser excitation energy. The physical origin of this very large dispersiveness has been recently explained by double resonance Raman theory<sup>[5]</sup> in which the photon-absorbed electron is scattered twice before final recombination. Although this process is a second-order light-scattering process, the intensity is comparable to that of the first-order resonance process when two of the three intermediate states are in resonance with the real electronic states.

In Fig. 12, inequivalent (A) first-order and (B) second-order Raman processes are shown. The crossed lines for each figure denote the electronic energy states of graphite around the  $K$  points in the Brillouin zone about which the optical transition occurs. The upper figures are for the incident resonance condition for laser light in which the laser excitation is at almost the same energy as the energy required for optical absorption. The lower figures are for the scattered resonance condition, in which the scattered electron energy,  $(E_{\text{laser}} - E_{\text{phonon}})$ , is almost the same as the optical emission energy. Both resonance conditions give a similar Raman intensity, but the resonance laser energy differs in the two cases by the phonon energy. More precisely, the laser energy for the scattered resonance energy is higher by  $E_{\text{phonon}}$  than that for the incident resonance energy in a Stokes scattering process, which creates a phonon. Note that for all Raman-active phonon modes, the incident resonance condition gives the same resonance laser energy, whereas the scattered resonance condition gives different laser energies, depending on the energy of phonons. Thus,

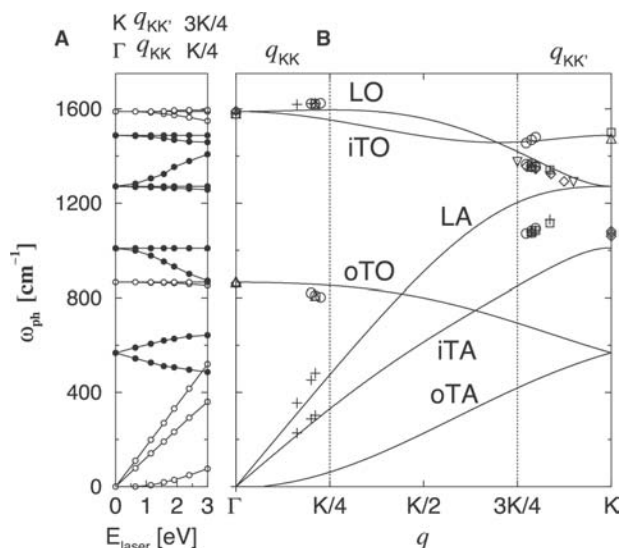

by observing more than one Raman spectral feature for the same tube or not, respectively, we know whether the observed resonance Raman process is with an incident photon or with a scattered photon.

In the first-order process, in order to recombine an electron and a hole at the original  $k$  point, the phonon wave vector  $\mathbf{q}$  should be sufficiently small. This is why we see in most solid-state textbooks that the Raman spectra of solids can be observed only for zone-center ( $\mathbf{q} = 0$ ) Raman-active phonon modes. In the second-order double resonance process, it is clear from Fig. 12 that the phonon wave vector  $\mathbf{q}$  is not zero. Furthermore, when the laser energy increases, the electron  $k$  vector moves further from the  $K$  point to satisfy the requirements for optical absorption, and thus the corresponding  $\mathbf{q}$  vectors become longer. Here we use the requirement of the double resonance process that the intermediate  $k + q$  states should be unoccupied electronic states, too. This is the reason why the dispersive phonon modes change their Raman frequencies when the laser excitation energy is changed, since the phonon wave vector  $\mathbf{q}$  that satisfies the double resonance Raman condition changes when the excitation laser energy changes.

In 2-D graphite, there are two inequivalent corners of the Brillouin zone,  $K$  and  $K'$ , as shown in Fig. 7. In the electron scattering by phonons or impurities (elastic scattering), there are two possibilities. One is an intravalley scattering process in which an electron scatters within the same region of the  $K$  (or  $K'$ ) point. The other is intervalley scattering in which an electron is scattered from the  $K$  to the  $K'$  region (or  $K'$  to  $K$ ). The corresponding phonon  $\mathbf{q}$  vectors for intravalley and intervalley scattering are phonons around the  $\Gamma$  and  $K$  points, respectively. Thus, we try to find the phonon dispersion point around either the  $\Gamma$  or  $K$  points that satisfies the double resonance condition.

In Fig. 13A the phonon  $\mathbf{q}$  vectors for the double resonance condition are shown as a function of  $E_{\text{laser}}$  (bottom axis) and of the  $\mathbf{q}$  vector along  $\Gamma-K$  (top axis). Solid and open circles correspond to phonon modes around the  $K$  and  $\Gamma$  points, respectively. In Fig. 13B are collected the many experimental Raman signals that have been observed in many disordered graphitic materials for many years, and these are here plotted in the Brillouin zone of 2-D graphite. By specifying either  $\Gamma$  or  $K$  point phonons, all of the experimental points could be assigned to one of the phonon energy dispersion relations (six solid lines), thus providing clear evidence that double resonance theory can work well for the dispersive phonon modes of 2-D graphite. The resulting dispersion relations show how resonance Raman scattering can be used to obtain phonon dispersion relations experimentally based on double resonance theory.

**Fig. 13** (A) Calculated Raman frequencies for the double resonance condition as a function of  $E_{\text{laser}}$  (bottom axis) and  $q$  vector along  $\Gamma$ -K (top axis). Solid and open circles correspond to phonon modes around the K and  $\Gamma$  points, respectively. (B) The six graphite phonon dispersion curves (lines) and experimental Raman observations (symbols) are placed according to double resonance theory.

All second-order phonon processes shown here are one-phonon emission processes. Thus, one of the two scattering processes shown in Fig. 12B should not be a phonon-scattering process. We consider that the nonphonon scattering process is an elastic electron scattering caused by an impurity or a defect in which electronic states with momentum  $k$  are mixed with each other. This is the reason why the dispersive phonon modes appear in a frequency region lower than  $1600\text{ cm}^{-1}$  only for defective carbon materials. If the two scattering processes are both phonon-scattering processes, we do not need the defect scattering process, and thus strong dispersive overtone phonon modes appear. An example of a two-phonon process is the  $G'$  band appearing around  $2700\text{ cm}^{-1}$  with its large dispersion of  $106\text{ cm}^{-1}/\text{eV}$ .

## CONCLUSION

In summary, the optical properties of carbon nanotubes shows rich spectra because of low-dimensional physics phenomena, such as van Hove singularities in the density of states. The resonance Raman spectra, in particular, provide a powerful tool for observing individual nanotubes in the sample, and especially for specifying  $(n, m)$  values of individual nanotubes. Double resonance theory explains the dispersive Raman phonon modes, and can be used to provide information about the dispersion relations for submicron-sized samples, too small for study by neutron scattering techniques.

## INTRODUCTION

Graphite exhibits a three-dimensional (3-D) stacking ordering of large graphene layers (where an individual carbon layer in the honeycomb graphite lattice is called a graphene layer) of planar hexagonal networks of carbon atoms based on  $sp^2$  bonding. In contrast, carbons consist of *randomly stacked* defective and relatively small graphene sheets, which are termed turbostratic carbons (T-carbons). Furthermore, carbon nanotubes are seamless cylindrical forms of such graphene layers of nanometer-size diameter, consisting of single- or concentric multilayers.<sup>[1–3]</sup> The diameter of the central hollow core is basically of fullerene size (around 1 nm), and the minimum size diameter that has been observed is 0.4 nm.<sup>[4]</sup> These carbon nanotubes are strongly related to 3-D-graphite or T-carbon when considering their large curvature (see Fig. 1). The nanotube curvature introduces some  $sp^3$  bonding into the  $sp^2$  planar bonding of the graphene sheet. Numerous unusual properties of carbon nanotubes arise from the  $sp^2$  graphene layers by imposing additional quantum confinement and topological constraints in the circumferential direction of the nanotubes. In this entry, carbon nanotubes are first reviewed in terms of their relevance to typical carbon and graphite materials and then are connected with other fibrous forms of carbon and graphite.

## BASIC CONCEPTS FROM FIBERS TO NANOTUBES

As carbon nanotubes might be the ultimate 1D form of carbon, their structure and properties are

closely related to those of other forms of carbon, especially to crystalline 3-D-graphite, T-carbons, and to their constituent 2D layers. Therefore several forms of conventional carbon materials should be mentioned in terms of their similarities and differences relative to a carbon nanotube. Especially, a direct comparison should be made between typical 1D materials of carbon and graphite (carbon fibers), because the carbon fiber acts as a bridge between carbon nanotubes and conventional bulky carbon materials.

Carbon fibers were developed in the early 1960s and have given many breakthroughs to carbon science because of their unique fibrous morphology.<sup>[5,6]</sup> Therefore it is necessary to compare the structure and properties of carbon nanotubes with conventional carbon fibers exhibiting diameters around 10  $\mu\text{m}$ . Furthermore, there are also very important materials that can be related to both carbon nanotubes and carbon fibers. These are called the vapor-grown carbon fibers (VGCFs) synthesized directly by the catalytically assisted pyrolysis of hydrocarbons.<sup>[7–10]</sup> Vapor-grown carbon fibers have diameters ranging from 1 nm to 10  $\mu\text{m}$ , the thinner ones corresponding to carbon nanotubes and the thicker ones are similar to carbon fibers. It has been reported that the central core of a VGCF consists of a carbon nanotube.<sup>[11]</sup> Through precise control of the synthesis conditions, it is possible to produce carbon nanotubes and carbon fibers on a large scale. Both materials have been industrialized for different practical applications.<sup>[12]</sup> Therefore the structures of carbon nanotubes and carbon fibers as well as VGCFs, in which the latter connects both typical materials, are strongly emphasized in this account.

**Fig. 1** Schematic diagram of an individual carbon layer in the honeycomb graphite lattice called a graphene layer, and how it can be rolled to form a carbon nanotube.

We will also show the similarities and differences of these 1D carbon materials.

## BONDING NATURE OF CARBON ATOMS

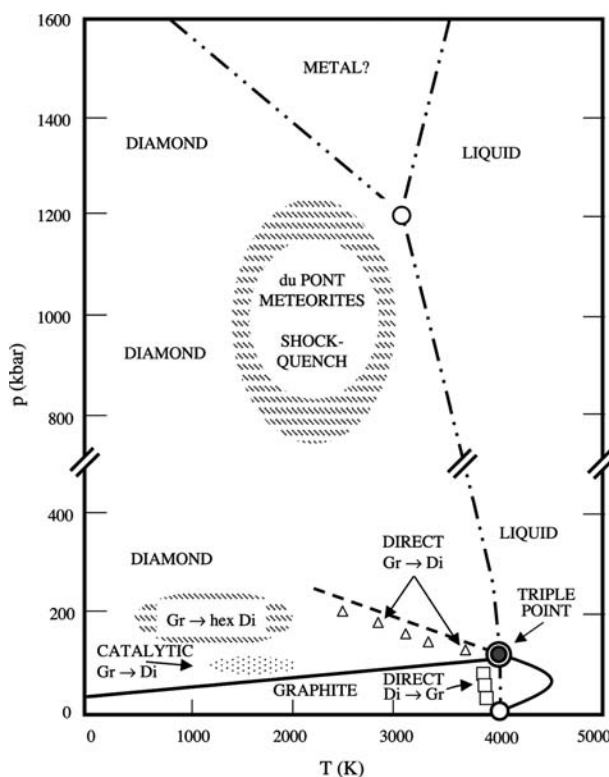

Carbon is the sixth element in the periodic table and has the lowest atomic number of any of the elements in column IV. Each carbon atom has six electrons which occupy  $1s^2$ ,  $2s^2$ , and  $2p^2$  atomic orbitals. The  $1s^2$  orbital contains two strongly bound core electrons. Four more weakly bound electrons occupy the  $2s^2 2p^2$  valence orbitals. In the crystalline phase, the valence electrons give rise to  $2s$ ,  $2p_x$ ,  $2p_y$ , and  $2p_z$  orbitals, which are important in forming covalent bonds within carbon materials. Because the energy difference between the upper  $2p$  energy levels and the lower  $2s$  level in carbon is small compared to the binding energy of the chemical bonds, the electronic wave functions for these four electrons can readily mix with each other, thereby changing the occupation of the  $2s$  and three  $2p$  atomic orbitals, so as to enhance the binding energy of a C atom with its neighboring atoms. The general mixing of  $2s$  and  $2p$  atomic orbitals is called hybridization, whereas the mixing of a single  $2s$  electron with one, two, or three  $2p$  electrons is called  $sp^n$  hybridization with  $n = 1, 2, 3$ .<sup>[13,14]</sup>

Thus three possible hybridizations occur in carbon:  $sp$ ,  $sp^2$ , and  $sp^3$ , while other group IV elements, such as Si and Ge, exhibit primarily  $sp^3$  hybridization. Carbon differs from Si and Ge because carbon has no inner atomic orbitals, except for the spherical  $1s$  orbitals, and the absence of nearby inner orbitals facilitates hybridizations involving only valence  $s$  and  $p$  orbitals for carbon. The various bonding states are connected with certain structural arrangements, so that  $sp$  bonding gives rise to a chain structure such as carbynes,  $sp^2$

bonding to planar structures such as graphene, and  $sp^3$  bonding to a tetrahedral structure such as diamond.

The carbon phase diagram (see Fig. 2) guided the historical synthesis of diamond in 1960 and has continued to inspire interest in novel forms of carbon, as they are discovered.<sup>[15,16]</sup> While  $sp^2$  bonded graphite is the ground-state phase of carbon under ambient conditions, at higher temperatures and pressures,  $sp^3$  bonded cubic diamond is stable. Other regions of the phase diagram show stability ranges for hexagonal diamond, hexagonal carbynes,<sup>[17,18]</sup> and liquid carbon.<sup>[19]</sup> The triple point of the graphite–diamond–liquid phase is located at 123 kbar and 4100 K. It is expected that a variety of novel  $\pi$ -electron carbon bulk phases still remain to be discovered and explored.

A carbon nanotube is a graphene sheet appropriately rolled into a cylinder of nanometer-size diameter.<sup>[2,3,20–23]</sup> The curvature of the nanotubes admixes a small amount of  $sp^3$  bonding so that the force constant (bonding) in the circumferential

**Fig. 2** The phase diagram of carbon.<sup>[15]</sup> The diamond (Di) and graphite (Gr) phases are emphasized in this figure. Other phases shown in the diagram include hexagonal diamond and a high-temperature–high-pressure phase, denoted in the diagram by du Pont, meteorites, and shock-quench, which has not been studied in much detail and may be related to carbynes. Liquid carbon, which has been studied at low pressures and high temperatures, and an unexplored high-pressure phase, which may be metallic, are also indicated on the figure.

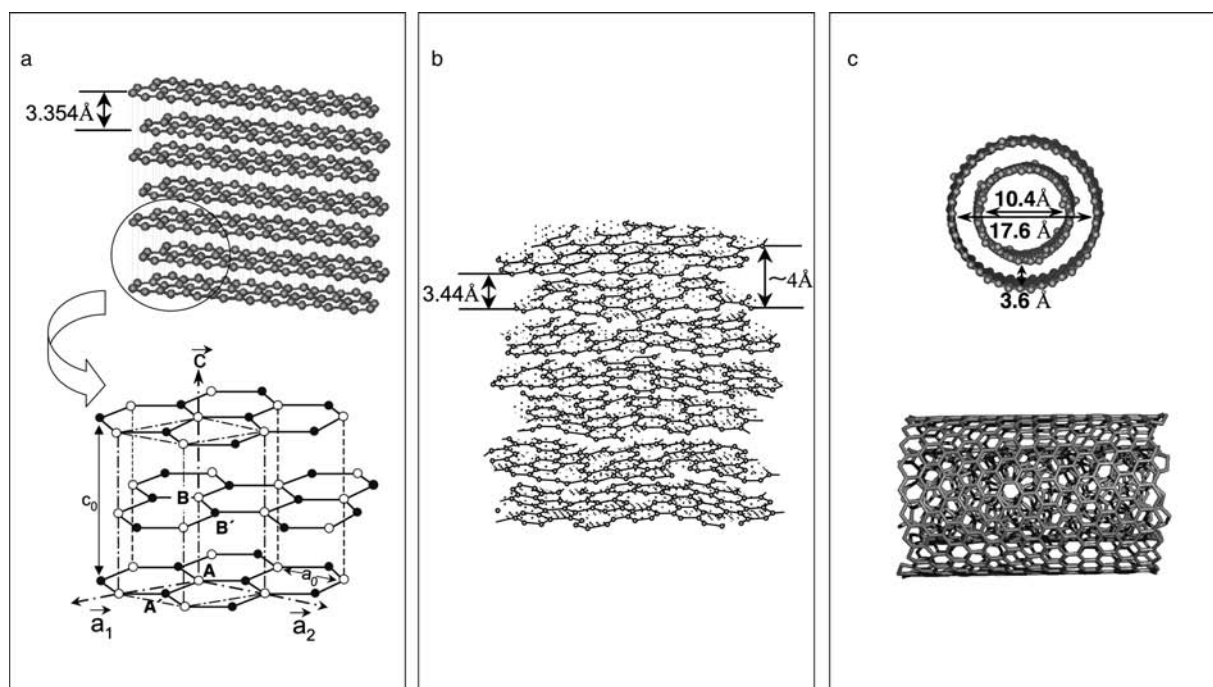

direction is slightly weaker than along the nanotube axis. Because the single-wall carbon nanotube (SWNT) is only one atom thick and has a small number of atoms around its circumference, only a few wave vectors are needed to describe the periodicity of the nanotubes. These constraints lead to quantum confinement of the wavefunctions in the radial and circumferential directions, with plane wave motion occurring only along the nanotube axis, corresponding to a large number or closely spaced allowed wave vectors. Thus although carbon nanotubes are related to a 2D graphene sheet, the tube curvature and the quantum confinement in the circumferential direction lead to a host of 1D properties that are different from those of a graphene sheet. As nanotubes can be rolled from a graphene sheet in many ways, there are numerous possible orientations of the hexagons on the nanotubes, although the basic shape of the carbon nanotube wall is a cylinder, where the two indices ( $n$ ,  $m$ ) that fully identify each carbon nanotube are specified.<sup>[2,3,23]</sup> The rolling of a single graphene layer, which is a honeycomb network of carbon atoms, to form a carbon nanotube is well reviewed in many review papers and books.<sup>[2,3,20–23]</sup> Carbon nanotubes ( $n$ ,  $m$ ) can be either metallic ( $n-m = 3q$ ,  $q = 0, 1, 2, \dots$ ) or semiconducting ( $n-m = 3q \pm 1$ ,  $q = 0, 1, 2, \dots$ ), and likewise the individual constituents of multiwall nanotubes or single-wall nanotube bundles can be metallic or

semiconducting.<sup>[2,3,21]</sup> These remarkable electronic properties follow from the electronic structure of 2D graphite under the constraints of quantum confinement in the circumferential direction.<sup>[2]</sup>

## GRAPHITES AND DISORDERED CARBONS

The ideal crystal structure of graphite (Fig. 3A) consists of layers in which the carbon atoms are arranged in an open honeycomb network, such that the A and B atoms on consecutive layers are on top of one another, but the A' atoms in one plane are over the hexagon centers of the adjacent layers, and similarly for the B' atoms.<sup>[24]</sup> This gives rise to an ABAB planar stacking arrangement (called Bernal stacking) shown in Fig. 3A, with an in-plane nearest neighbor distance  $a_{C-C}$  of 1.421 Å, an in-plane lattice constant  $a_o$  of 2.456 Å, a  $c$ -axis lattice constant  $c_o$  of 6.708 Å, and an interplanar distance of 3.354 Å. This structure is consistent with the  $D_{6h}^4$  ( $P6^3/mmc$ ) space group and has four atoms per unit cell.

Another ordered graphite phase is rhombohedral graphite with ABC stacking of the graphene sheets; it has  $a_o = 2.456$  Å (same as for Bernal-stacked hexagonal graphite),  $c_o = 3(3.438) = 10.044$  Å, and space group  $D_3^7$  ( $R32$ ).<sup>[24]</sup> When describing the ABC stacking of graphene sheets in the hexagonal structure, it is

**Fig. 3** Schematic diagrams exhibiting (a) a 3-D graphite lattice (b) a turbostratic structure,<sup>[24]</sup> and (c) a schematic structural model of the outer two layers for a multiwall carbon nanotube.<sup>[33]</sup> The inset in (a) depicts the A and B carbon sites denoted by open circles and the A' and B' sites by black circles. The in-plane lattice constant is denoted by  $a_o$ , and the vectors of the unit cell in the direction  $a_1$ ,  $a_2$ , and  $c$  are indicated. The nearest-neighbor carbon distance  $a_{C-C}$  in graphite is 1.421 Å.

**Table 1** Cohesive energy per carbon atom for various carbon-related structures

Structure	Cohesive energy (meV/atom)	Ref.
3-D graphite	20.0	[25–27]
Rhombohedral graphite	19.9	[27]
2D graphene sheet	10.3	[25–27]
Carbon nanotube (based on C <sub>60</sub> )	9.76	[25]

necessary to consider six atoms per unit cell, but if the rhombohedral description is used, only two atoms per unit cell are needed. Because the total energy for rhombohedral graphite differs only slightly from that of the more stable Bernal ABAB stacking (Table 1), graphite crystals tend to have stacking faults where ABC rhombohedral stacking is found admixed with the AB Bernal stacking for the ideal graphite crystal. Most of graphite crystals and natural graphite follow the hexagonal system, but, sometimes, natural graphite and artificial graphite heat-treated at high temperatures have been observed to include several percent of the rhombohedral system. Also, mechanical grinding and ball milling increase the rhombohedral component.

Stacking disorder tends to have little effect on the in-plane lattice constant largely because the in-plane C–C bond is very strong and the nearest-neighbor C–C spacing is very small. As has already been mentioned elsewhere, the C–C spacing in fullerenes and carbon nanotubes is very close to  $a_{C-C}$ . Disorder does, however, have a significant effect on the interplanar spacing, because of the weak interplanar bonding based on the van der Waals force. One consequence of the small value of  $a_{C-C}$  and the large value of the interplanar  $c$ -axis separation is that impurity species are unlikely to enter the in-plane lattice sites substitutionally, but rather impurities tend to occupy some interstitial positions between the layer planes as to form intercalation compounds.

Weak disorder results in stacking faults (meaning departure from the ABAB stacking order) and gives rise to a small increase in the interlayer distance. This increase is modest when ABC stacking faults are occasionally introduced. Greater disorder is introduced when the stacking become random or uncorrelated and departs from AB or ABC stacking. The greater the stacking disorder the greater the interlayer distance, until random stacking occurs. When the interlayer spacing reaches a value of about 3.44 Å, the stacking of the individual graphene layers becomes uncorrelated. The resulting 2D honeycomb structure of uncorrelated graphene layers is called turbostratic carbon (see Fig. 3b).<sup>[24]</sup>

In both structures, the bonding force between adjacent carbon hexagonal networks is the van der Waals force. The degree of 3-D ordering or the stacking fidelity is defined in terms of the degree of graphitization ( $g$ ) as a function of the interlayer spacing ( $d_{002}$ ), by the following equation,<sup>[28]</sup> where  $g$  is the probability to preserve 3-D stacking.

$$d_{002} = 3.354g + 3.44(1 - g) \quad (1)$$

For interlayer spacings larger than 3.44 Å, the probability of 3-D stacking is 0, and  $d_{002} = 3.354$  Å gives perfect 3-D graphite ordering with  $g = 1$ . Between  $g = 0 - 1$ , various forms of carbon materials exist as a function of heat treatment temperatures. For carbonaceous materials exhibiting a  $g$  value in the range between 0.5 and 1 when heat-treated up to 3000°C, these pristine carbons are called graphitizing or soft carbons.<sup>[29,30]</sup> In contrast, carbonaceous materials with lower  $g$  values, exhibiting a high resistance for graphitization, are so-called nongraphitizing or hard carbons.<sup>[29,30]</sup> These graphitization behaviors are strongly dependent on the microstructure of carbonaceous materials, where highly oriented small carbon networks (the smallest called a basic structural unit) generally determine the graphitizability. The chemical and physical properties, such as the electrical resistivity and mechanical strength, are largely affected by the graphitizing nature of a carbon. Therefore structural control of the pristine material, namely, the starting organic material, is very important for designing the desired performance of carbons and graphite.<sup>[31,32]</sup>

The electronic structure of turbostratic graphite, a zero-gap semiconductor, is qualitatively different from that of ideal graphite, a semimetal with a small band overlap (0.04 eV). As the crystalline disorder is further increased and the in-plane ordering in the graphene sheets is reduced, the interlayer spacing also continues to increase. Such disorder further modifies the electronic properties of the ideal 2D graphite and introduces an effective energy gap.

Multiwall carbon nanotubes (MWNTs) relate closely to the layer stacking of graphite, insofar as the interlayer spacing is found to vary from 3.4 to 3.6 Å between adjacent cylinders, possibly due to glide defects (see Fig. 3c).<sup>[33]</sup> Magnetoresistance measurements provide a highly sensitive measure of the degree of 3-D crystalline order using the following equation.

$$\Delta\rho/\rho_0 = [\rho(B) - \rho(0)]/\rho(0) \quad (2)$$

where  $\rho(B)$  and  $\rho(0)$  are the electrical resistivity with and without a magnetic field  $B$ , respectively. As shown in Fig. 4,<sup>[12,34–36]</sup> highly oriented pyrolytic graphite with the highest degree of structural perfection shows

large positive transverse magnetoresistance, with smaller values of positive  $\Delta\rho/\rho_0$  [mesophase-pitch-based carbon fibers (MPCFs) at 3000°C] corresponding to more disordered graphite. As more disorder is introduced, the 3-D ordering disappears and the fibers assume 2D or turbostratic ordering, where there is no interlayer site correlation between adjacent graphene planes. The magnetoresistance for the turbostratic carbon is characteristically negative, with the magnitude of the negative magnetoresistance decreasing as the disorder increases. For the case of VGCFs heat treated at 2000°C<sup>[35]</sup> and multiwall carbon nanotubes,<sup>[36]</sup> the negative magnetoresistance strongly suggests that the stacking infidelity of the shells is quite similar to that of turbostratic graphite regarding their electronic properties along the tube axis (see the dotted curve in Fig. 4). The curvature of the coaxial layers, however, excludes the possibility of the AB or ABC stacking of the graphene layers, and in this sense, the stacking of layers in a MWNT is equivalent to turbostratic stacking (see Fig. 3c). As some interlayer site correlation between carbon atoms exists in nanotubes, especially regarding the direction of the nanotube axis, the interlayer stacking is not completely turbostratic. Also, for small-diameter carbon nanotubes, there is

**Fig. 4** Comparative study of transverse magnetoresistance at low temperature (as indicated in parenthesis) for highly oriented pyrolytic graphite (the dot-dashed curve),<sup>[34]</sup> typical mesophase-pitch-based carbon fibers heat treated at different temperatures (the solid curves),<sup>[13]</sup> vapor-grown carbon fibers (the dashed curve),<sup>[35]</sup> and multiwall carbon nanotubes (the dotted curve).<sup>[36]</sup> Vapor-grown carbon fibers exhibit a similar magnetoresistance behavior to that of multiwall carbon nanotubes.

a limited number of possible nanotube diameters, and these depend also on the nanotube chirality, so that it is not in general possible to find a nested set of nanotubes which all have the same chirality and also show a close packing of cylindrical shells. Thus the electronic properties of multiwall carbon nanotubes have some differences and some similarities when compared with T-carbons.

In order to describe the electronic and phonon dispersion relations of 3-D graphite, the Brillouin zone (see Fig. 5) is used.<sup>[3,13]</sup> As the in-plane nearest-neighbor distance in real space is much smaller than the interplanar separation, the Brillouin zone for graphite has a small length in reciprocal space along  $k_z$ . As the interplanar correlation becomes less and less important, as in the case of turbostratic 2D graphene layers, the Brillouin zone is reduced to a sheet. The special point *K* at the Brillouin zone corner in 2D graphite is the location of the Fermi level, and of the symmetry-imposed degeneracy of the conduction and valence bands,<sup>[37]</sup> making 2D graphite a zero band gap semiconductor. The band structure model for graphite near the Fermi energy ( $E_F$ ) focuses on the electronic dispersion relations in the vicinity of the *HKH* and *H'K'H'* edges of the Brillouin zone.

## MULTI- AND SINGLE-WALL CARBON NANOTUBES

Carbon nanotubes can be visualized as rolled sheets of graphene that are sometimes capped (by a fullerene-like hemisphere) on each end. They can be single-walled with diameters as small as about 0.4 nm, or multiwalled (2 to 30 concentric tubes positioned within one another) with outer diameters ranging from 5 to 100 nm. The constituent shells of MWNTs can possess many different helical structures, and variations in the radii and helical structures have been predicted to affect the nanotube's electronic transport, which can vary from metallic to semiconducting.<sup>[2,3]</sup> As shown

**Fig. 5** Graphite Brillouin zone showing several high-symmetry points and a schematic version of the graphite electron and hole Fermi surfaces located along the *HKH* and *H'K'H'* axes. Source: From Refs.<sup>[3,13]</sup>

**Fig. 6** Band gap as a function of nanotube radius calculated using an empirical tight-binding Hamiltonian. *Source:* From Ref.<sup>[38]</sup>.

in Fig. 6, the band gap estimated by an empirical tight-binding method as a function of nanotube radius suggests that as the nanotube's diameter gets larger, thus decreasing the pronounced curvature of a graphene layer, the value of the band gap corresponds to that of graphene sheet.<sup>[38]</sup> Three typical structures of SWNT have been proposed (Fig. 7), and their structures have been confirmed by scanning tunneling microscopy (STM) and electron diffraction

studies.<sup>[3,39,40]</sup> If the  $C_{60}$  molecule is bisected normal to a fivefold axis, the cap for an "armchair" nanotube is formed, and if the  $C_{60}$  molecule is bisected normal to a threefold axis, the cap for a "zigzag" nanotube is formed. In addition to the armchair and zigzag nanotubes, a large number of chiral carbon nanotubes can be formed with a screw axis along the axis of the nanotube, which is terminated by a variety of "hemispherical"-like caps.

On the other hand, in MWNTs, no graphitic 3-D stacking is established, although an individual shell of the multilayers consists of perfect graphene sheets. Also, each tube has different and independent chirality, which might contribute to a larger inter-shell spacing than is found in graphite. These characteristic structures of SWNTs and MWNTs indicate that they are unique 1D materials with fascinating electronic and mechanical properties.

## FIBROUS FORMS OF CARBON AND GRAPHITE

Carbon fibers represent an important class of graphite-related materials that are closely related to carbon nanotubes, with regard to structure and properties. Carbon fibers have been studied scientifically since the late 1950s and fabricated industrially since 1963. They are now becoming a technologically and commercially important material in the aerospace, construction, sports, electronic device, and automobile industries. The global carbon fiber

**Fig. 7** Three typical structural models for SWNTs, where the nanotubes are related to rolling a graphene sheet into a cylinder.<sup>[2,3]</sup> Fullerene caps for the armchair and zigzag tubes are also indicated.

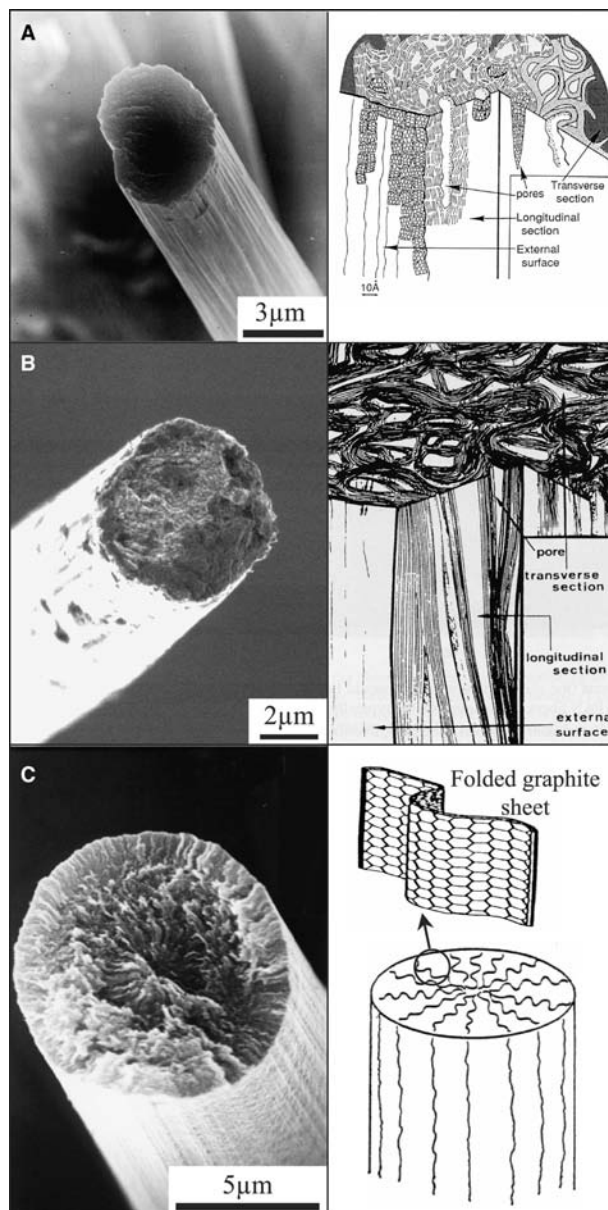

market has now grown to about 12,500 tons/year of product, after 40 years of continuous R&D work.<sup>[41]</sup> Carbon fibers are defined as a filamentary form of carbon with an aspect ratio (length/diameter) greater than 100. Probably, the earliest documented carbon fibers are the bamboo-char filaments made by Edison for use in the first incandescent light bulb in 1880. With time, carbon fibers were replaced by the more robust tungsten filaments in light bulb applications, and, consequently, carbon fiber R&D vanished at that early time. But in the late 1950s, carbon fibers once again became important because of the aggressive demand from aerospace technology for the fabrication of lightweight, strong composite materials, in which carbon fibers are used as a reinforcement agent in conjunction with plastics, metals, ceramics, and bulk carbons. The specific strength (strength/weight) and specific modulus (stiffness/weight) of carbon fiber-reinforced composites demonstrate their importance

**Fig. 8** Model for graphite whiskers grown by the DC arc-discharge of graphite electrodes.<sup>[42]</sup> Whiskers were reported to have the carpet-rolling structure of graphite sheets and to have high mechanical strength and modulus along the fiber axis, similar to the ideal values of a graphene sheet.

as engineering materials, because of the high performance of their carbon fiber constituents.

Because the temperature and pressure necessary to prepare a carbon fiber from the liquid phase is at the triple point ( $T = 4100\text{ K}$ ,  $p = 123\text{ kbar}$ , see Fig. 2), it would be almost impossible to prepare carbon fibers from the melt under industrial processing conditions. Carbon fibers are therefore prepared from organic precursors. This preparation is generally done in three steps, including stabilization of a precursor fiber in air (at  $\sim 300^\circ\text{C}$ ), carbonization at  $\sim 1100^\circ\text{C}$ ,

**Fig. 9** SEM micrographs of three types of carbon fibers and their corresponding structural models: (A) a high-strength PAN-based fiber, (B) a high-modulus PAN-based fiber, and (C) MPCF.<sup>[43,44]</sup> On the right-hand side of each fiber type, a schematic diagram of the fiber structure is shown.

and subsequent graphitization (above 2500°C). Fibers undergoing only the first two steps are commonly called “carbon fibers,” while fibers undergoing all three steps are called “graphite fibers.” Carbon fibers are generally used for their high strength, while graphite fibers are used for their high modulus.

Historically, Bacon’s graphite whisker (see Fig. 8) has demonstrated the highest mechanical properties of a carbon fiber (with regard to both strength and modulus), comparable to the ideal value for a graphite network.<sup>[42]</sup> Graphitic whiskers were grown under conditions near the triple point of graphite. Then, the structural model was proposed, in which the layers consisting of graphene sheets are wound around the axis as in rolling up a carpet. These whiskers were used as the performance target in the early stages of

carbon fiber technology, although they have never been produced on a large scale.

### Synthesis and Properties of Carbon Fibers

SEM photographs together with schematic structural models are shown in Fig. 9 for typical carbon fibers: a high-strength polyacrylonitrile (PAN)-based fiber (Fig. 9A), a high-modulus PAN-based fiber (Fig. 9B), and a MPCF (Fig. 9C).<sup>[43,44]</sup> The PAN-based fibers consist of small  $sp^2$ -carbon structural units preferentially aligned with the carbon hexagonal segments parallel to the fiber axis. This orientation is responsible for the high tensile strength of PAN-based carbon fibers.<sup>[45]</sup> By varying the processing conditions (e.g., oxidation conditions, choice of precursor material,

**Fig. 10** (A) The mechanical properties of various kinds of carbon and graphite fibers<sup>[13,32]</sup> and (B) a direct comparison of the mechanical properties for high strength and high modulus fibers, where low modulus fiber droops under its own weight, but the high modulus fibers do not.

and especially by increasing the heat treatment temperature) of PAN fibers, a better alignment of the graphene layers can be achieved (see the structural model of Fig. 9B), thus leading to stiffer, higher-modulus PAN fibers, but with lower strength.<sup>[44]</sup> Polyacrylonitrile-based fibers are one of the typical hard carbons. MPCFs consist of well-aligned graphitic layers arranged nearly parallel to the fiber axis, and this high degree of preferred orientation is responsible for their high modulus or stiffness as well as their relatively high graphitizability. The structures described above give rise to different physical properties, although each type of fiber features carbon hexagonal networks, possessing the strongest covalent bonds in nature (C–C bonds). These strong interatomic bonds lie in sheets essentially parallel to the fiber axis and are responsible for the high mechanical performance of these carbon fibers.

Referring to Fig. 10A we see that PAN-based fibers have high strength and MPCFs have high modulus, while VGCFs provide mainly ultra-high modulus materials.<sup>[13,32]</sup> In this figure we also observe isotropic pitch-based (general grade) fibers, exhibiting much lower modulus and strength, but widely used in composites with cement matrix for construction because of their low cost and chemical stability. Fig. 10B demonstrates a direct indication of the differences in the mechanical properties of various carbon fibers, from low modulus-high strength to high modulus-low

strength fibers from the lower left to the upper right in the photograph, where a yarn containing 500 fibers was initially placed in a horizontal position. These fibers are combined with other materials in order to design suitable mechanical properties and the fibers are used as a filler for various advanced composite materials. In order to get high performance in carbon and graphite fibers, it is very important to control the microstructure by selecting the appropriate organic precursor as well as the processing conditions.

### Vapor-Grown Carbon Fibers

Vapor-grown carbon fibers have a very special structure such as annular-rings (see Fig. 11A) and are synthesized by a somewhat different formation process than that used to produce PAN-based and MPCFs. In particular, VGCFs are not prepared from a fibrous precursor, but rather from hydrocarbon gas, using a catalytic growth process outlined in Fig. 11B.<sup>[7–10,43,46]</sup> Ultra-fine transition metal particles, such as iron particles with a diameter of less than 10 nm, are dispersed on a ceramic substrate, and a hydrocarbon, such as benzene diluted with hydrogen gas, is introduced at temperatures of about 1100°C. Hydrocarbon decomposition takes place on the catalytic particle, leading to a continuous carbon uptake by the catalytic particle and a continuous output by the particle of well-organized tubular filaments of

**Fig. 11** (A) SEM image of vapor-grown carbon fibers (VGCFs),<sup>[43]</sup> (B) suggested growth mechanism of VGCFs using ultra-fine catalytic metal particles,<sup>[7]</sup> (C) very early stage of fiber growth in which the catalytic-particle is still active for promoting elongation growth. The primary fiber thus formed acts as a core for vapor-grown fibers.<sup>[43]</sup> (D) The fiber is obtained through a thickening process, such as the pyrolytic deposition of carbon layers on the primary thin fibers.<sup>[43]</sup> The encapsulated catalytic particle can be seen at the tip of the hollow core.

hexagonal  $sp^2$ -carbon. The rapid growth rate of several tens of  $\mu\text{m}/\text{min}$ , which is  $10^6$  times faster than that observed for the growth of common metal whiskers,<sup>[42]</sup> allows the production of commercially viable quantities of VGCFs. Evidence in support of this growth model is the presence of catalytic particles at the tips of the resulting VGCFs (Fig. 11C).<sup>[43]</sup> The primary thin hollow fiber is first formed by the catalytic process (with a diameter of less than several nanometers), and the fiber is then thickened by a successive chemical vapor deposition (CVD) process, corresponding to the deposition

**Fig. 12** (A) A vertical-type fiber synthesis system for the floating reactant method in which benzene vapor containing an organic-metallic compound such as ferrocene is introduced into a vertical-type reactor by hydrogen gas. The fibers grow while the catalytic particles are floating in the growth region of the reactor<sup>[13,43]</sup> and (B) VGCFs, obtained under controlled growth conditions, exhibit relatively homogeneous diameter along the fiber length and also high purity.

of pyrolytic carbon layers on the primary tubular core (Fig. 11D).

Such a high growth rate of the primary core fiber provides the possibility of employing a 3-D growth process involving a floating catalyst in a reaction chamber without the presence of a solid substrate (see Fig. 12A). In this process, the nanometer-sized catalytic particles of metal can float (or be suspended) for a specified time in the hot zone of the reaction chamber in order to produce thin (100 nm homogeneous diameter) VGCFs of several hundred microns in length.<sup>[13,43]</sup> The resulting VGCFs sample shown in Fig. 12B consists of straight fibers with high purity, implying that the individual fibers experienced uniform reaction conditions as they passed through the reactor.<sup>[43]</sup> By proper choice of growth conditions, large quantities of high purity VGCFs can be obtained continuously. Furthermore, the fiber diameter can be varied through control of the residence time of

**Fig. 13** (A) Carbon nanotube exposed at the breakage edge of a vapor-grown carbon fiber as grown (A) and heat-treated at  $3000^\circ\text{C}$  (B). The sample is fractured by pulverization and the core diameter is  $\sim 50 \text{ \AA}$ . (B) These photos suggest a structural discontinuity between the nanotube core of the fiber and the CVD-deposited carbon layers. The images show the strong mechanical properties of the nanotube core, which maintains its form after breakage of the periphery. Source: From Ref.<sup>[11]</sup>.

**Fig. 14** (A) Co-existence of a VGCF and a single-wall carbon nanotube (with a diameter of about 20 nm) obtained by the pyrolysis of benzene.<sup>[50]</sup> The deposition of a partial carbon layer on a carbon nanotube during the thickening process is observed. (B) Carbon nanotube (obtained by benzene decomposition) and subsequently heat treated at 2800°C, yielding the same structure as nanotubes prepared by the arc method. *Source:* From Ref.<sup>[50]</sup>.

the fiber in the reaction zone and of the pressure of the hydrocarbon feed stock. This basic process could be used for the large-scale production of carbon nanotubes by a CVD process based on the catalytic growth.<sup>[10,13,43,47–49]</sup>

In Fig. 13A, we observe the broken edge of a thick VGCF. At the center of the annular ring structure, we can clearly observe an extruded carbon nanotube (with a diameter of ~5 nm), which serves as a template for growing the thicker carbon fiber.<sup>[11]</sup> This tubular core implies a discontinuity in the structure between the core and the thickened periphery of the carbon fiber. Such a discontinuity in structure is retained even after heat treatment at temperatures as high as 3000°C. This graphitization process introduces a fully developed graphite structure in the peripheral region of a VGCF exhibiting a polygonal shape (see Fig. 13B). Fig. 14A shows the early stage of fiber growth of a thin tubule corresponding to a SWNT, which has both a bare region and a region partially coated with pyrolytically deposited carbon.<sup>[50]</sup> Sometimes it is possible to observe an isolated carbon nanotube without a pyrolytic carbon coat at the early stage of formation (Fig. 14B). This type of nanotube can be produced

by the same process as VGCFs by carefully controlling the vapor pressure of the hydrocarbon and using a much smaller size of catalytic particle.<sup>[50]</sup>

The CVD synthesis method has been considered as a promising method for the large-scale production of SWNTs and also MWNTs, especially using a floating reactant technique.<sup>[10,13,43,47–49]</sup> In terms of the manufacturing process, this process has been shown to be more controllable and cost efficient as compared with the arc discharge or laser vaporization methods. Fig. 15A and B exhibits a double-wall carbon nanotube and a four-wall carbon nanotube produced by a catalytic CVD method.<sup>[12,49,51]</sup> For the fabrication of a carbon nanotube transistor,<sup>[52]</sup> this synthesis technique appears to be highly efficient because of the reproducibility and low cost when compared to other routes.<sup>[53,54]</sup>

Exceptional mechanical properties of carbon nanotubes are expected, when few structural defects are present. The TEM image (Fig. 16A) and a theoretical simulated image (Fig. 16B) demonstrate that carbon nanotubes have nearly ideal mechanical properties because nanotubes do not break even after twisting, bending, or flattening. This particular behavior does

**Fig. 15** (A) Double-wall carbon nanotube and (B) a four-wall carbon nanotube produced by a catalytic CVD method.

**Fig. 16** (A) HRTEM image of a distorted single-wall carbon nanotube and (B) a computer-simulated model. *Source:* From Ref.<sup>[50]</sup>.

not occur in carbon fibers, because they are brittle and more fragile.<sup>[50]</sup>

### INTERCALATION AND DOPING BY FOREIGN MOLECULES OR ATOMS

Because of the weak van der Waals interlayer forces associated with the  $sp^2$  bonding in graphite, graphite intercalation compounds (GICs) may be formed by the insertion of layers of guest species between the layers of a graphite host material,<sup>[55,56]</sup> as shown in Fig. 17A and B. The guest species may be either atomic or molecular. In the so-called donor GICs, electrons are transferred from the donor intercalate species (such as a layer of the alkali metal potassium) into the

graphite layers, thereby raising the Fermi level in the graphitic electronic states, and increasing the mobile electron concentration by two or three orders of magnitude, while leaving the intercalate layers positively charged. Conversely, for acceptor GICs, electrons are transferred to the intercalate species (which is usually molecular, such as  $Br_2$ ) from the graphite layers, thereby lowering the Fermi level in the graphitic electronic states and creating an equal number of positively charged hole states in the graphitic  $\pi$ -band. The enhanced electrical conduction in GICs (whether they are donors or acceptors) occurs predominantly in the graphene layers and as a result of the charge transfer between the intercalate and host layers. The electrical conductivity between adjacent graphene layers is very poor. It is noteworthy that among the GICs, Li-based

**Fig. 17** (A,B) Schematic model for a Li graphite intercalation compound showing the stacking of graphite layers (networks of hexagons on a sheet) and of intercalate (e.g., lithium) layers, (C) TEM image of an individual rope consisting of single-walled nanotubes aligned along the axis,<sup>[57]</sup> (D) a simulated image of a potassium-intercalated single-walled carbon nanotube rope superlattice. *Source:* From Ref.<sup>[58]</sup>.

GICs are widely used as anode materials in commercialized Li-ion secondary batteries for cell phones, personal computers, and electric vehicle batteries.<sup>[31]</sup>

Basic concepts similar to those occurring in GICs have been applied to carbon nanotubes in terms of the variation in structures, modification of electronic properties, and functionalities through the intercalation process. Namely, the bonding force between SWNT bundles or ropes (see Fig. 17C) is governed by the weak van der Waals force,<sup>[57]</sup> so that foreign species, such as atoms or molecules, can be intercalated in the van der Waals gaps, similar to graphite. Donor species, such as alkali metal atoms, can be easily intercalated into the trigonal lattice of nanotube ropes (see Fig. 17D),<sup>[58]</sup> while acceptor intercalation has proved more difficult. This result indicates the lack of 3-D structural fidelity within these nanotube ropes as it is found in 3-D bulk graphite.

Not only interstitial but also substitutional doping of foreign atoms into the carbon network of graphene sheets has also been studied widely for altering their electronic and structural properties for potential applications, such as high-temperature oxidation protection for carbon/carbon composites and as an anode material for Li-ion batteries, because, for instance, boron-doping introduces an electron acceptor level.<sup>[59]</sup> Fig. 18A shows an STM image of a 3-D surface plot and a sectional analysis of highly oriented pyrolytic graphite doped with boron.<sup>[60]</sup> Each bright area consists of boron atoms, with the highest electron density located at the center of six surrounding sites, and with medium electron density corresponding to carbon atoms. Also, the electron density distribution of a substitutional boron atom and of the surrounding six carbon atoms clearly appears in the 3-D surface plot (Fig. 18A inset). The substitutional boron atom

**Fig. 18** (A) STM image of a three-dimensional surface plot and a section analysis for boron-doped highly oriented pyrolytic graphite<sup>[60]</sup> and (B) schematic model of the top view and the side view of a boron-doped graphene sheet based on the measured dimensions of B-C<sub>1</sub> and C<sub>1</sub>-C<sub>1</sub>. *Source:* From Ref.<sup>[60]</sup>.

**Fig. 19** (A) STM image of the surface of a 20-nm  $CN_x$  nanotube and (B) suggested structural model for a  $CN_x$  tube. Source: From Ref.<sup>[61]</sup>.

exhibits the highest electron density in the center. Also, the substitution of boron should slightly deform the flatness of the basal plane (Fig. 18B). By restricting the measured bond length between the B–C atoms obtained from Fig. 18A, the optimized structure of a graphene sheet has been simulated. An improper torsion angle (B at the apex) is calculated to be  $164^\circ$  as shown in Fig. 18B, while the original plane is almost flat with an angle of  $179^\circ$ . For the case of multiwall carbon nanotubes, a comprehensive study of the effect of nitrogen doping was carried out using STM.<sup>[61]</sup> Fig. 19A shows an STM image of a nitrogen-doped carbon nanotube, exhibiting both distortion and holes. The suggested structure of a  $CN_x$  nanotube is shown in Fig. 19B. This type of hole might be due to pyridine-like and highly coordinated nitrogen atoms replacing carbon atoms. Substitutional doping into carbon nanotubes thus provides a useful method to modify the electronic and mechanical properties and enlarge the functionality of carbon nanotubes even further.

## CONCLUSION

It has been demonstrated that carbon nanotubes, consisting of graphene tubes of nanometer-size diameter, are different from conventional carbon and graphite materials, even from carbon fibers consisting of oriented planar graphene sheets. The structure of VGCFs exhibiting a carbon nanotube core can relate to both carbon nanotubes and fibers (Fig. 20).<sup>[62]</sup> The diameters range from 1 nm for nanotubes to  $10^4$  nm for carbon fibers, and VGCFs are located between the two. Bulk effects that are based on the Bernal stacking of planar graphene sheets disappear with decreasing diameter, and new quantum effects based on the thin nanotube morphology appear in the range of nanotube diameters corresponding to those of single- and multiwall carbon nanotubes. The special characteristics of carbon nanotubes in this diameter range can expand carbon science and provide new opportunities for developing innovative and exciting applications in the nanotechnology field.

# Carbon Nanotubes for Storage of Energy: Supercapacitors

**Elzbieta Frackowiak**

*Institute of Chemistry and Technical Electrochemistry,  
Poznan University of Technology, Poznan, Poland*

## **Abstract**

Carbon nanotubes (CNTs) due to their excellent conducting and mechanical properties play a useful role of electrode material in supercapacitors. Pure nanotubes (multi-walled as well as single-walled) supply moderate capacitance values because of their well developed mesoporosity but very limited microporosity. Microporosity of CNTs, hence, capacitance can be enhanced by functionalization and activation of CNTs (KOH treatment at high temperatures). On the other hand, CNTs are a perfect component of composites with electrically conducting polymers (ECP) and transition metal oxides, e.g.  $\text{MnO}_2$ . The three-dimensional network of the nanotubular composite enables an easy penetration of ions, in turn, a good performance of capacitor. Another interesting capacitor material could be obtained by carbonization of various carbon precursors, e.g. polymers, in the presence of nanotubes. In this case, attractive C/C composites have been prepared. Especially, peculiar properties have been found if the carbon precursor was rich in nitrogen (polyacrylonitrile, melamine). The presence of nitrogen in the capacitor material was responsible for pseudocapacitance effects. Nanotubular composites with pseudocapacitive materials offer a great progress in supercapacitor development.

## **INTRODUCTION**

Carbon nanotubes (CNTs), because of their exceptional physicochemical properties, have been used for energy storage devices such as supercapacitors. Especially, conducting and microtextural properties of CNTs are noteworthy for this electrochemical application. The presence of more or less continuous graphitic layers, cylindrically rolled, together with a tight entanglement of nanotubes supply a conducting and well-accessible carbon network with a moderate surface area (ca.  $100\text{--}400\text{ m}^2/\text{g}$ ). Because the performance of electrochemical capacitors is connected with the accumulation of charges in the electrode/electrolyte interface, such a material in the form of an easily available web is of great interest. However, for supercapacitor application, apart from small mesopores, which are perfect for ion transportation, easily accessible micropores are required for the accumulation of ions in the electrical double layer (EDL). Ultramicropores with diameter below 1 nm are especially adapted for efficient charging of EDL because they well match with dimensions of ions. Generally, as a capacitor electrode material, a highly developed specific surface area carbons are used. Carbon nanotubes can be used as electrode material but the capacitance values will be very moderate because CNTs are mesoporous with negligible microporosity. The values of capacitance strictly depend on nanotube microtexture. The more defected the outer walls of CNTs, the higher the capacitance values. The presence of a thin amorphous carbon layer on the CNT walls can supply better conditions for charge accumulation. Additionally, catalytic

impurities of nanotubes remaining from the production process could be a source of redox reactions giving pseudocapacitance effects. Hence, CNTs directly used as the electrode material has a limited interest; on the other hand, they can serve as a perfect additive or support of active material in composite electrodes.

Generally, from the literature data, a high discrepancy of capacitance for pure CNTs is found because the values strongly depend on CNTs' preparation method, purification, or modification process. Some research has been devoted to elucidate the effect of microtexture on capacitance properties. Enhancement of CNTs' capacitance has been achieved by an increase in their surface area. A few fold increase of capacitance has been obtained by KOH activation at  $800^\circ\text{C}$  because of the development of microporosity while preserving the mesoporous character. This interesting phenomenon can be explained by the insertion or intercalation of potassium in the walls of nanotubes at  $800^\circ\text{C}$  and the subsequent formation of micropores. Consequently, the opening of nanotube tips was also observed that could be profitable for charge accumulation. Higher values of capacitance can also be obtained if CNTs are used as a conducting component or support in the composite electrode. In this case, conducting polymers or redox species are mainly responsible for the capacitance values (giving the so-called pseudocapacitance). Generally, a synergy effect is obtained between the components of the supercapacitor electrode. A nanocomposite gives better results than its components alone.

Carbon nanotubes can also be used as a frame for carbon obtained from different polymeric precursors.

In this case, the nanotube skeleton is very profitable to prevent shrinkage during the carbonization process and to allow a simultaneous autoactivation of carbon by the evolving gases and consequently an interesting CNT/carbon composite is obtained for supercapacitor application.

## UNIQUE CHARACTERISTICS OF CNTs

The discovery of CNTs by Iijima in 1991<sup>[1]</sup> has generated great interest in carbon materials and nanotechnology. Carbon nanotubes have exceptional electrical, mechanical, thermal, optical, and textural properties, which are attractive for various potential applications ranging from nanoelectronics to biomedical devices.<sup>[2]</sup> Their unique characteristics result from the helical or fishbone arrangement of the graphitic layers, the presence of a central canal, as well as entanglement or bundle formation. The areas of nanotube interest include composites, field emitters, electronic devices (nanotransistor, one-dimensional quantum wire), gas adsorption, catalyst support, templating, sensors, and others. However, the scope for using CNTs in practical applications has been limited by a moderate-scale production and their high cost. One of the most promising uses of CNTs seems to be energy storage device, i.e., supercapacitor, where CNTs could be used as an electrode component, which allows a nanoscale dispersion of active material on such three-dimensional well-conducting skeleton.

## SUPERCAPACITOR PERFORMANCE

An electrochemical capacitor (supercapacitor) is a very attractive energy source due to its high power, i.e., fast delivery of energy and long-term durability.<sup>[3–8]</sup> It is

built from a positive electrode with electron deficiency, whereas the second one is negative with electron excess (Fig. 1). In such a simple model, capacitor consists of two polarizable electrodes, a separator and the electrolytic solution. A pure electrostatic attraction between ions and the charged surface of an electrode takes place. Figure 1 shows a reversible charging/discharging of supercapacitor. The amount of electrical energy  $W$  accumulated in such a capacitor is proportional to capacitance  $C$  and voltage  $U$ .

$$W = 1/2CU^2 \quad (1)$$

The operating voltage of the capacitor is determined by the decomposition potential of electrolyte. The electrical energy of the capacitor can be significantly enhanced by the selection of an aprotic electrolytic solution where the decomposition potential of the electrolyte varies from 3 to 5 V. The performance of an electrochemical capacitor is based on the charge accumulation in the EDL, without the Faradaic reactions that take part in typical accumulators. The stored energy is based on the separation of charged species across the electrode/solution interface. As far as a pure electrostatic attraction of ions is involved, the electrode capacitance  $C$  is proportional to the electrode/electrolyte interface (to the electrode surface) according to the following equation.

$$C = S\epsilon/d \quad (2)$$

The capacitance is also proportional to the relative permittivity of the solution  $\epsilon$ , and reciprocally dependent on the thickness  $d$  of the EDL. It is noteworthy that the overall capacitance  $C$  is determined by the series connection of two electrodes  $C_1$  and  $C_2$ ; hence, in the case of a capacitor built from two electrodes with different surfaces, the component of smaller capacitance will contribute more to the total value

Fig. 1 Charging/discharging of electrochemical capacitor.

due to reciprocal dependence.

$$1/C = 1/C_1 + 1/C_2 \quad (3)$$

The capacitance unit is a farad (F), which is the charge accumulated in the defined range of voltage (coulomb per volt). The specific capacitance can be related to the electrode mass (F/g), to the electrode volume (F/cm<sup>3</sup>), or the electrode surface (F/cm<sup>2</sup>).

Values of capacitance are strictly determined by the porosity of electrode material. It is well known that micropores (with a diameter less than 2 nm) play an essential adsorption role in the formation of the EDL, whereas mesopores (diameter from 2 to 50 nm) are responsible for the adsorption of ions and for their quick transportation to the bulk of the electrode material. Obviously, taking into account size of ions, only the smallest mesopores could play some useful role.

The enhancement of capacitance values can be realized through a redox pseudocapacitive mechanism by the simultaneous combination of two kinds of energy storage, i.e., an electrostatic attraction of ions together with Faradaic reactions. Large charge-storage capabilities obtained through this process have been observed in the case of conducting polymers and transition metal oxides. The transfer of counter ions between the electrolyte and the bulk of the electrode material proceeds as a response to the electron transfer processes associated with oxidation and reduction of the material. In this case, the capacitor is named ultra- or supercapacitor.

## NANOTUBES AS SUPERCAPACITOR ELECTRODES

Carbon nanotubes, either aligned or randomly entangled, present interesting capacitance properties and have been widely used for supercapacitor application.<sup>[7–29]</sup> Both arrangements supply an open network of mesopores due to the entanglement, presence of central canal, or mutual interconnections. Even if the capacitance values are very moderate, such a good accessibility of the electrode/electrolyte interface of the nanotubular material facilitates the charging of the EDL and allows very high dynamics of charge propagation, typical for good performance of a supercapacitor. Both types of CNTs, i.e., single and multi-walled, will be considered for this application.

### Single-Walled Nanotubes as Electrode Materials

Single-walled nanotubes (SWNTs) have been tested as electrode materials for electrochemical

capacitors.<sup>[8,13–16]</sup> The bucky paper from nanotubes (Rice University, USA) allowed one to get self-standing electrodes that can be directly used for the capacitor assembly. They supply a value of 40 F/g in the alkaline 6 M KOH solution.<sup>[13]</sup> After their annealing at 1650°C, the capacitance diminishes to 18 F/g because of a better arrangement of the tubes in the bundles that decreases microporosity.

Raw materials containing 30% of SWNTs have also been used for the preparation of supercapacitor electrodes after mixing with poly(vinylidene chloride) (PVDC) and pyrolysis of the mixture at 1000°C. The authors attribute the high capacitance value of 180 F/g measured in 7.5 M KOH to the SWNT material.<sup>[14]</sup> However, in reality the carbonization of PVDC at 1000°C produces microporous carbon, and as a consequence the high capacitance values are due to the carbon obtained from the polymeric binder but not to SWNTs.

The electric double layer capacitance of highly pure SWNTs (HiPco™) was carefully studied in organic medium, i.e., 1 M LiClO<sub>4</sub> in propylene carbonate.<sup>[15]</sup> The gravimetric capacitance of SWNTs is around 45 F/g and does not diminish with the increase in current density from 10 to 160 mA/g. The specific capacitance per unit surface area was compared for SWNTs and for activated carbon fibers (ACFs). The authors found higher values of 10 μF/cm<sup>2</sup> for SWNTs and only 5.5 μF/cm<sup>2</sup> for ACFs due to ion sieving in the case of highly microporous ACFs. The open mesoporous network of SWNTs is profitable for a quick charge propagation, especially when an organic medium is used as electrolytic solution.

Some research was devoted to modification of SWNTs by chromium oxide.<sup>[16]</sup> The capacitance values increased two times and the electrode material was characterized by very good charge propagation.

After careful analysis of literature data, it is clear that pure single-walled nanotubes without catalyst impurities and without any modification cannot supply higher values than ca. 45 F/g due to their limited surface area and negligible microporosity. Similar moderate capacitance values (20–40 F/g) for SWNTs have been found as well in aqueous and non-aqueous solutions by electrochemical investigation.<sup>[30]</sup>

### Multi-Walled Nanotubes for Capacitor Application

Multi-walled carbon nanotubes (MWNTs) as a typical mesoporous material were carefully investigated for supercapacitor applications in the form of electrodes or electrode component.<sup>[7–13,17–24]</sup> The specific surface area of different nanotubes varied from 120 to 450 m<sup>2</sup>/g. Generally, the values of capacitance for

nanotubes widely range from 5 to 80 F/g. Higher values of 110 F/g have been also found<sup>[9]</sup> when the catalytically grown nanotubes were chemically modified by nitric acid treatment (10% of the carbon atoms on the surface were bound to oxygen). Such functionalized MWNTs were self-adhesive and could easily form very thin freestanding mat. A good frequency response is mentioned by the authors for this material (100 F/g was withdrawn at 1 Hz). However, the stability of supercapacitor performance during subsequent cycles was not investigated. On the other hand, values of 15–25 F/cm<sup>3</sup> that give ca. 20 F/g have been measured for MWNTs in the same solution, i.e., 38% H<sub>2</sub>SO<sub>4</sub>.<sup>[10]</sup>

The high discrepancy in the capacitance values of various MWNTs can be easily explained by their different microtextures and composition. Typically, the smaller capacitance values were observed with CNTs of low surface area. For example, purified nanotubes obtained by the decomposition of acetylene at 600°C using the in situ catalyst formed from the solid solution Co<sub>x</sub>Mg<sub>(1-x)</sub>O,<sup>[31]</sup> with a specific surface area of 220 m<sup>2</sup>/g, supplied only 15 F/g. Figure 2 shows an entangled network of these nanotubes and Fig. 3 presents a detailed transmission electron microscopy (TEM) image of a few representatives. The high purity of these nanotubes, quite regular walls, and a lack of any disordered carbon are responsible for limited capacitance properties. A completely different nanotubular product is obtained from the decomposition of acetylene at 700°C using a silica support for the cobalt catalyst.<sup>[7]</sup> It is striking that a value of 80 F/g could be reached for such catalytic nanotubes, which possess a moderate surface area of only 430 m<sup>2</sup>/g. In this case, a thin layer of pyrolytic carbon on the nanotubes with a number of surface defects gives the high values of capacitance. Generally, the more defective the walls and the better developed the surface area of the nanotubes, the higher

the values of capacitance. On the other hand, nanotubes with perfect walls and a high degree of graphitization provided limited capacitance values from 5 to 20 F/g.<sup>[8,17]</sup> From a careful analysis of the results, it seems that the values of capacitance and amount of micropores, even if quite limited, are well correlated.

For the pure nanotubular materials, it is clear that capacitance can be improved in two ways: development of microporosity and surface functionality by chemical activation.

### Modification of MWNTs by Functionalization and Chemical Activation

Carbon nanotubes can be easily modified by hot nitric acid treatment, which introduces oxygenated surface groups. Voltammetry characteristic of capacitor built from oxidized nanotubes is shown in Fig. 4. Capacitance increased up to 135 F/g through functionalization of CNTs by concentrated nitric acid at 80°C for 1 hr.<sup>[7,8,11]</sup> However, owing to the irreversible character of redox reactions of some surface groups, e.g. carboxylic, the pseudocapacitance effect can diminish with cycling. On the other hand, the redox couple of quinone–hydroquinone is reversible and stable.

The great increase in capacitance visible as a well-defined hump at ca. 0.2 V has been attributed to the following quinone–hydroquinone redox reactions<sup>[7,8,11]</sup>

In the case of CNTs directly grown on a graphite foil,<sup>[9]</sup> to improve the electrical contact between the substrate and nanotubes, the authors introduced functional groups on the nanotube surface by a special exposure of the material to air. Finally, capacitance

**Fig. 2** SEM image of nanotubes obtained by the decomposition of acetylene at 600°C using the in situ formed catalyst from a Co<sub>x</sub>Mg<sub>(1-x)</sub>O solid solution.

**Fig. 3** TEM image of nanotubes prepared using the Co<sub>x</sub>Mg<sub>(1-x)</sub>O solid solution.

**Fig. 4** Voltammetry characteristics (10 mV/s) of a supercapacitor built from multiwalled CNTs modified by hot nitric acid. Electrolyte: 6 M KOH. *Source:* Reprinted with permission from Ref.<sup>[11]</sup>.

results reached values of 115 F/g due to the presence of oxygen in nanotubular material. Stability of pseudocapacitance during cycling has not been investigated by authors.

Chemical KOH activation is another very attractive method to develop microporosity of nanotubes.<sup>[17,19,20,32]</sup> In some cases, the specific surface area increases four times and the values of capacitance increase from 15 to 90 F/g.<sup>[17,19]</sup> The nanotubes are opened and micropores are formed because of the various possible reactions. The insertion or intercalation of free potassium between

the graphitic-type layers of nanotubes plays an extremely important role in the formation of microporosity. The process starts preferentially from the tips, the separation of the graphene layers is also observed on the walls of nanotubes. KOH attack can also proceed in the central canal of nanotubes. The final effect of activation can be easily demonstrated by the increase in nitrogen adsorbed in the first part of the adsorption/desorption isotherm at 77 K.<sup>[19]</sup> The IV type isotherm with a hysteresis loop presented in Fig. 5 confirms a wide distribution of pores due to highly defected walls, cracks, and surface irregularities, but a still preserved mesoporous character for the activated nanotubes. Because of activation, the micropore volume increases from ca. 0.1 to 0.4 cm<sup>3</sup>/g. The specific surface area of these nanotubes increased from 220 to 880 m<sup>2</sup>/g giving a significant enhancement in capacitance values from 15 to 90 F/g in 6 M KOH, whereas reaching 85 F/g in 1 M H<sub>2</sub>SO<sub>4</sub> and 65 F/g in organic medium.<sup>[17,19]</sup> Voltammetry characteristics for a supercapacitor built from activated nanotubes present a regular square shape that proves high dynamics of charge propagation for such an activated nanotubular material with developed microporosity. The values of time constant ( $RC$ ), where  $R$  is the resistance and  $C$  is the capacitance, estimated from impedance measurements vary from 0.1 to 1 s. The smaller the values of time constant, the quicker the charge propagation in the capacitor.

It has been found that the optimal KOH/C ratio for the activation process is 4:1, whereas the higher ratio 5:1 gives total destruction of the nanotubes into a microporous carbon.<sup>[32]</sup>

**Fig. 5** Nitrogen adsorption/desorption at 77 K for nanotubes prepared using the  $\text{Co}_x\text{Mg}_{(1-x)}\text{O}$  solid solution: (A) before KOH activation, (B) after KOH activation. *Source:* Reprinted from Ref.<sup>[19]</sup>.

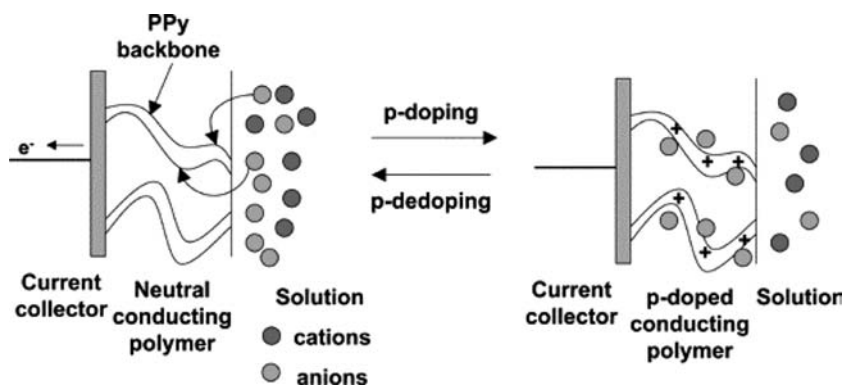

Fig. 6 Doping/dedoping process of polypyrrole.

Development of microporosity has been also realized by activation and ammoxidation process. In this case, apart from microporosity, nanotubular material was enriched in heteroatoms such as oxygen and nitrogen.<sup>[33]</sup> Some research was also devoted to modification of nanotubes by air oxidation and various chemical oxidations<sup>[34]</sup> as well as electrochemical treatment.<sup>[35]</sup>

As a conclusion, a well-performed KOH activation, controlled oxidation, or ammoxidation seems to be an attractive method for the development of nanotube microporosity, compared with CO<sub>2</sub> activation, which removes the outer graphitic layers by a gasification process without penetrating into the walls. The oxidative treatment also affects hydrophilicity and conductivity of nanotubes.<sup>[36]</sup>

## NANOTUBES AND CONDUCTING POLYMERS COMPOSITES

The specific capacitance of nanotubular carbon materials can be increased by pseudocapacitance effects. It can be realized through the preparation of novel CNT-conducting polymer composites.<sup>[8,13,21–25,37–50]</sup> Such a modification supplies, apart from the electrostatic attraction of ions, also stable Faradaic reactions (pseudocapacitance).

One of the most interesting aspects of conducting polymers is the coupling of an electron transfer reaction and of the counterion exchange during the electrochemical oxidation and reduction of the polymer. In the case of polypyrrole (PPy), this is schematically represented in Fig. 6 and described by the following reaction:

Polypyrrole has been especially selected for its high conductivity, stability in the oxidized form, and ability to be electrochemically switched between the conducting and isolating states. Polypyrrole supplies a high specific capacitance because of its high doping level;

however, it is valid only for thin films that have limited practical application. Generally, the thicker layers of PPy undergo shrinkage and swelling that is the cause of film degradation and conductivity loss. Such aggravation with cycling is also observed with other electrically conducting polymers (ECPs).

The combination of the two components, i.e., nanotubes and ECP, allows one to overcome this problem and to efficiently use the mesoporous nanotubular network as a perfect support for the highly conducting polymer. It is the most effective solution, which has been proposed to improve the mechanical and electrochemical properties of electrodes based on ECPs.<sup>[8,13,21–25,40–50]</sup> Swelling and shrinkage of ECPs does not occur during doping/dedoping of ECP material with nanotubes, because they adapt to volumetric changes and protect electrode from mechanical degradation. Hence, fading of the electrochemical performance is not observed during cycling if the suitable operating voltage range of capacitor is selected.

For the preparation of CNT composites with ECPs, the chemical or electrochemical polymerization of the monomer, e.g., pyrrole, aniline, 3,4-ethylenedioxythiophene on the nanotubular materials

Fig. 7 SEM image of a MWNT (15%)/PEDOT (85%) composite.

**Fig. 8** Voltammetry charge/discharge of a supercapacitor built from the MWNT/PPy composite at 5 mV/s scan rate. Mass of each electrode: 8.6 mg. *Source:* Reprinted from Ref.<sup>[45]</sup>.

was applied.<sup>[21–25,37–50]</sup> The SEM micrograph (Fig. 7) shows a quite uniform polymer coating of a nanotube material by PEDOT chemically deposited. Such composite was characterized by a good performance and cyclability with a wider voltage range than other ECP.<sup>[41,43]</sup>

A lot of research was devoted especially to PPy nanocomposites. Coating with a thin layer of polypyrrole has been achieved on MWNTs,<sup>[21,44]</sup> well-aligned MWNTs,<sup>[38,39]</sup> and SWNTs.<sup>[25]</sup> When MWNTs are oxidized, their surface is covered with oxygen-containing groups, which can be used as anionic dopants of a PPy film electrodeposited on the MWNTs.<sup>[22]</sup> These films are notably less brittle and more adhesive to the electrode than those formed using an aqueous electrolyte as a source of counter ion.

The electrochemical behavior of ECP/CNT composites has been studied either in two- or three-electrode cells. A comparison of the redox performance of PPy films on aligned MWNTs and on flat Ti and Pt

surfaces shows a noticeable improvement for the case of the composites with MWNTs owing to the high accessible surface area of the CNTs in the aligned arrays.<sup>[39]</sup> The authors present only the values of capacitance per surface that give limited information about the possibility of practical application of this material in a real capacitor. In contrast, the results found with SWNT/PPy nanocomposites<sup>[25]</sup> are probably of limited application because: 1) the nickel foam used as current collector supplies an additional capacity in the alkaline solution used for the study; 2) PPy degrades quickly in alkaline solution. For the electrochemically obtained MWNTs/PPy composite where the layer of PPy was about 5 nm, the values of capacitance in acidic medium reach ca. 170 F/g with a good cyclic performance (over 2000 cycles) at current load of 350 mA/g.<sup>[21]</sup>

From a careful analysis of results, it seems that a non-homogeneous layer of ECP deposited chemically can supply even higher values of capacitance.

**Fig. 9** Galvanostatic charge/discharge of a supercapacitor built from the MWNT/PPy composite. Current:  $I = 2$  mA. Mass of each electrode: 8.6 mg. *Source:* Reprinted from Ref.<sup>[45]</sup>.

**Fig. 10** Specific capacitance of electrode based on PPy/MWNT composite vs cycle number during galvanostatic charge–discharge of supercapacitor using 1 M  $\text{H}_2\text{SO}_4$  as electrolyte.

Polypyrrole obtained by a chemical method<sup>[37,40,45]</sup> was more porous and less compact; hence, the diffusion of ions could proceed more easily. For a composite containing only 20 wt.% of MWNTs (prepared by decomposition of acetylene on the solid solution  $\text{Co}_x\text{Mg}_{(1-x)}\text{O}$ ), a good distribution of PPy was obtained and high energy could be extracted from the conducting PPy. In this case, the values of capacitance reach 200 F/g with long-term durability if a limited range of capacitor voltage (0.6 V) is selected.<sup>[45]</sup> It is noteworthy that both components alone, i.e., bulk PPy and pure nanotubes, supply at the same current load (200–400 mA/g) very low capacitance values (below 20 F/g). Figure 8 shows the charge/discharge characteristics of such a supercapacitor built from the nanotube/PPy nanocomposite in 1 M  $\text{H}_2\text{SO}_4$  using voltammetry technique at 5 mV/s scan rate. Figure 9 presents a galvanostatic cycling of the same capacitor with 2 mA current load (the mass of each electrode is 8.6 mg).

It has been shown that the values of capacitance for the composites with polyaniline (PANI) and PPy strongly depend on the cell construction.<sup>[45]</sup> With chemically deposited ECPs, extremely high values of specific capacitance can be found—from 250 to 1100 F/g—using a three-electrode cell, whereas smaller values of 190 F/g for MWNTs/PPy and 360 F/g for MWNTs/PANI have been measured in a two-electrode cell. It highlights the fact that only two-electrode cells allow the materials performance to be well estimated in electrochemical capacitors. The applied voltage was found to be the key factor influencing the specific capacitance of ECPs-based nanocomposites. Generally, it cannot exceed 0.6–0.8 V due to oxygen evolution in the positive range of potentials and switching to an insulating state in the negative values.<sup>[45]</sup> The effect of selection of appropriate voltage range is shown in Fig. 10 for MWNT/PPy composite and in Fig. 11 for PANI/MWNT composite. Good capacitor cyclability was reached only with a narrow operating voltage range.

It is observed (Fig. 11) that capacitance values only slightly diminish after cycling but charge propagation is well preserved. At a frequency of 1 Hz, composites still supplied 100 F/g in both cases.

An interesting strategy was recently selected for the elaboration of nanotube/conducting polymer composites, using the electrochemical synthesis of PPy on well-aligned CNT electrodes.<sup>[38,39]</sup> The nanotubular material instead of a flat metallic surface accelerates the redox processes proceeding in PPy, demonstrating the high profitability of using this composite.

A careful analysis of the above-presented results shows that both types of nanotubes (MWNTs and SWNTs) are attractive components of composite electrodes with ECP. Such novel nanocomposite electrodes for supercapacitors combine the complementary

**Fig. 11** Dependence of capacitance vs. frequency for PANI/MWNT composite before and after 3000 cycles at current load of 300 mA/g. Voltage range of capacitor 0.6 V. Source: Reprinted from Ref.<sup>[40]</sup>.

unique properties of CNTs and conducting polymers owing to an efficient three-dimensional charge distribution and easily accessible electrode/electrolyte interface.

Comparing the results of the two coating techniques, the non-homogeneous PPy layer deposited chemically is more porous and less compact than that electrochemically deposited. Consequently, the diffusion of ions proceeds more easily, giving a better efficiency for charge storage.<sup>[45]</sup> It is noteworthy that ECP nanocomposites due to their limited operating voltage range are perfect material for hybrid application with two different electrodes.<sup>[40,43]</sup>

### NANOTUBES/METAL OXIDES COMPOSITES

Carbon nanotubes can also be a perfect support for cheap transition metal oxides of poor electrical conductivity, such as amorphous manganese oxide ( $\alpha\text{-MnO}_2 \cdot n\text{H}_2\text{O}$ ).<sup>[51–56]</sup> The  $\alpha\text{-MnO}_2$ /MWNT composite can be prepared by precipitation of  $\alpha\text{-MnO}_2$  from a  $\text{KMnO}_4 + \text{Mn}(\text{OAc})_2 \cdot 4\text{H}_2\text{O}$  mixture, which contains a predetermined amount of CNTs. Such composites can also be obtained by galvanostatic deposition of  $\text{MnO}_2$  on nanotubes by galvanostatic or potentiodynamic method. In both cases, a remarkable template effect of the entangled nanotubes framework is observed. Consequently, the composite electrodes have a good resiliency, and their porosity is high enough to favor the access of ions to the bulk of the active material. The  $\text{MnO}_2$ /MWNT composite has a capacitance of 140–160 F/g and can operate with good cyclability and high dynamic of charge propagation but in the narrow voltage range. The voltage window of  $\text{MnO}_2$ -based capacitors is limited to 0.6 V, because of the irreversible conversion of Mn(IV) to Mn(II) at the negative electrode and Mn(IV) to Mn(VII) at the positive one.<sup>[52,53]</sup> To circumvent this drawback, an asymmetric configuration has been proposed, where the positive electrode consists of  $\text{MnO}_2$  and the

negative is built from activated carbon.<sup>[43,51–53]</sup> When the  $\text{MnO}_2$ /MWNT composite is used as the positive electrode, the supercapacitor can be operated up to 2 V in aqueous medium with an extremely good cyclability.<sup>[51–53,56]</sup> Figure 12 presents galvanostatic characteristics of capacitor built from activated carbon as negative electrode and  $\text{MnO}_2$ /MWNTs nanocomposite as positive electrode. In this case, electrochemical method (galvanostatic) was used for  $\text{MnO}_2$  deposition. Composites contain 70% of nanotubes and 30% of manganese oxide (by weight). At current of 500 mA/g, the capacitance of 158 F/g was reached whereas for 1000 mA/g, it was 144 F/g.

Instead of  $\text{MnO}_2$ , different oxides have also been used for preparation of nanocomposites with nanotubes.<sup>[57–62]</sup> Some research was devoted to hydrous ruthenium oxide composite.<sup>[57–59]</sup> However, taking into account a high cost of Ru, the composite with manganese oxide seems to be more interesting.

An asymmetric or hybrid configuration, with two electrodes of different nature, e.g., conducting

**Fig. 13** Texture of C/C composite from PAN (70%)/MWNT (30%) blend.

**Fig. 14** Capacitance of C/C composite obtained by carbonization of PAN (70%)/MWNT (30%) blend.

polymer, transition metal oxide, and activated carbon<sup>[43,53,56,60]</sup> taking into account the optimal potential range of each electrode, is an excellent way to reach a wide operating voltage. The most promising material for use as a negative electrode is activated

carbon, whereas conducting polymers composites, e.g. PEDOT, PPy can easily operate as positive or negative electrode. The advantage of the asymmetric combination over the symmetric one is clearly proved. A significant increase in energy and power can easily be obtained especially owing to the extension of the supercapacitor voltage.

### CARBON/CARBON COMPOSITES BASED ON NANOTUBES

Nanotubes have also been extensively used for preparation of composites based on different polymers, such as polyacrylonitrile (PAN), polymerized blend of melamine with formaldehyde and others.<sup>[10,63–66]</sup> For example, a cheap C/C composite electrode for supercapacitor was prepared by pressing a CNTs/polyacrylonitrile blend, followed by one-step pyrolysis of the pellet under neutral atmosphere

**Fig. 15** TEM images of composites with a variable N content (A–D). Sample (A) stands for M + F, (B) for Nt + M + F, (C) for (Nt + 2M + F), (D) for Nt + 3M + F. *Source:* Reprinted from Ref.<sup>[64]</sup>.

**Table 1** Physicochemical and electrochemical characteristics of Nt composites rich in nitrogen. Capacitance was estimated at 5 A/g current load

Sample	N [wt.%]	$S_{\text{BET}}$ [ $\text{m}^2/\text{g}$ ]	$V_{\text{total}}$ [ $\text{cm}^3/\text{g}$ ]	$V_{\text{micro}}$ [ $\text{cm}^3/\text{g}$ ]	C [F/g]	C [ $\mu\text{F}/\text{cm}^2$ ]

(850°C). MWNTs used as a 30 wt% component improved the electrical conductivity and mechanical properties of electrode,<sup>[63]</sup> offering additional porosity of the composite. Polyacrylonitrile (PAN) was selected for obtaining an electrochemically active carbon matrix containing in-frame incorporated nitrogen, because of its high carbonization yield and high residual nitrogen content in the char. Although specific surface area of C/C composite was very low, e.g., 200  $\text{m}^2/\text{g}$ , it demonstrated high values of capacitance, up to 100 F/g. These remarkable values are due to the nanotexture of the composite (Fig. 13) and the pseudo-Faradaic properties of the in-frame incorporated nitrogen functionality.

Nanotubes not only play an essential role from the mechanical point of view, but also are very profitable for a good electronic conductivity of the electrodes. Such C/C composites prepared without any activation treatment are very promising for high volumetric energy density capacitors, where high apparent density carbon materials are requested. A good performance of composite in acidic medium at high current loads until 10 A/g is shown in Fig. 14.

A series of nitrogen-rich composites with a wide range of nitrogen content from 7.4 to 21.7 wt.% has been synthesized by carbonization of melamine (M)/formaldehyde (F) polymer blends in the presence

of carbon nanotubes (Nt) without any activation.<sup>[64]</sup> Carbonization was performed at 750°C for 1 hr under nitrogen flow. Texture of C/C composites enriched in nitrogen is shown in Fig. 15A–D. Sample M + F (Fig. 15A) does not contain nanotubes, whereas the proportion of melamine in polymer blend gradually increases being the highest for Nt + 3M + F. Good conducting and mechanical properties of MWNTs used for carbonization of a polymer blend allowed to prepare unique composites with a comparable texture (surface area of ca. 400  $\text{m}^2/\text{g}$ ) but variable nitrogen content. Pseudocapacitance effects related to the nitrogen presence in carbon composite, where nanotubes played the role of a three-dimensional conducting support, have been efficiently used in electrodes of supercapacitor. Useful effect of nitrogen has been already proved for different carbon materials rich in nitrogen.<sup>[67,68]</sup>

In the case of nanotubular composites from ex-melamine, the exceptionally good dynamic of charge was obtained especially for composite with ca. 12 wt% of N, i.e., Nt + 2M + F sample. The capacitance values of 160 F/g at 1 mHz frequency diminish only to 120 F/g at 1 Hz and remain equal to 55 F/g at 10 Hz that proves a good charge propagation.

Table 1 shows a detailed physicochemical data together with capacitance values taken at high current load of 5 A/g in 1 M sulfuric acid.

**Fig. 16** Capacitance values vs. current load for composites obtained by carbonization of melamine/formaldehyde polymer blend. Electrolyte: 1 M sulfuric acid.

Fig. 17 Scheme of possible redox reactions with pyridinic groups.

Nt + 2M + F composite could be loaded at extremely high current density of 50 A/g because mesoporous network allowed a pseudocapacitance effect of nitrogen to be efficiently used (Fig. 16).

The positive effect of nitrogen is connected with Faradaic reactions not only because of the presence of pyridinic groups (Fig. 17) but also because of the presence of quaternary nitrogen, which could be responsible for significant modification of the electronic states density. Obviously, effect of pyridinic groups will take part only in aqueous medium.

Exceptional capacitor behavior of composites can be explained by synergy effect of both components, i.e. nanotubes and carbon from melamine. During carbonization process, nanotubes play a perfect template role; they allow to evolve gases with a simultaneous slight autoactivation. Substitutional heteroatoms in the carbon network are a promising way to improve capacitor performance. Suitable amount of nitrogen without conductivity aggravation is able to not only enhance capacitance but also improve electrode wettability in aqueous medium. The beneficial effect on overall capacitance induced by nitrogen groups has also been proved by cycling. Obviously, only stable pseudocapacitance effects are demanded and they seem to be the future for the development of high-performance supercapacitors.

The role of nanotubes is effective for decreasing the resistance because they enhance both ionic and electronic conductivity in the electrode network. Because of their higher electronic conductivity than activated carbons, one interesting approach is to use them as a conductivity additive for activated carbons. For the CNTs themselves, the conductivity varies from a few S/cm up to 1000 S/cm, depending on the CNT types (single-walled, double-walled, multi-walled, ...).<sup>[69]</sup> Intensive research has been devoted to study effect of nanotubes as an electrode component with activated carbon.<sup>[70–74]</sup> The evolution of the equivalent series resistance was studied for a supercapacitor constructed using electrodes obtained by adding CNTs to a commercial activated carbon. A nanotube content of 15 wt% seems to be the percolation threshold of such a system.<sup>[70]</sup> A significant improvement of power and charge propagation was observed in all cases.

## CONCLUSION

Carbon nanotubes, because of their highly accessible surface area, low resistivity, and good stability in electrolytic solutions, offer potential possibilities as electrode components for supercapacitors. A high discrepancy of capacitance values for nanotubes, from 10 to 80 F/g, has been found because of their various microtextures. Both types of nanotubes (SWNTs as well as MWNTs) in the purified state, without amorphous carbon film on the walls and catalyst residues, supply rather moderate capacitance values below 40 F/g independent of the electrolytic solution. Even if the capacitance values are low, they could have some potential application when extremely high charge propagation is demanded, taking into account that they can be charged/discharged even at 1 V/s with a good performance.<sup>[75]</sup>

Surface modification of nanotubes by nitric acid or chemical KOH activation at 800°C enhance the capacitance values up to 135 F/g because of the introduction of functional groups on the surface and increase in microporosity, respectively.

On the other hand, CNTs, owing to their unique morphology, exceptional conducting, and mechanical properties, can be used directly as three-dimensional supports for active materials because the percolation with CNTs is very efficient. The open mesoporous network formed by the entanglement of nanotubes allows the ions to diffuse easily to the active surface of the composite components. The two latter properties are essential to lower the equivalent series resistance (ESR) and consequently increase the power of the device. Finally, since the nanotubular materials are characterized by a high resiliency, the composite electrodes can easily adapt to the volumetric changes during charge and discharge, which improves drastically the cycling performance. Hence, CNTs regardless of the type (MWNTs and SWNTs) are a perfect support for conducting polymers, redox species, microporous carbon, in various composites, giving excellent enhancement of capacitance values for the final product. Especially, high improvement of supercapacitor performance can be reached by coating of nanotubes with conducting polymers. The mesoporous

network of well-conducting nanotubes forms a frame for the polymer, which explains the synergy effect between the two components of the CNT/ECP composite electrodes, because of good access of ions from the electrolyte. Such composites seem to be especially adapted for operating in organic electrolytic solutions. However, operating voltage of ECP/CNT as well as oxide/CNT composites should be carefully selected. Hybrid configuration with two different electrode material is preferred.

It has been demonstrated that nanotubes also play a perfect role in carbon/carbon composite obtained by carbonization of polymeric blend. In this case, pseudocapacitance effects of nitrogen or oxygen present in the carbon network can be efficiently used.

In conclusion, composites incorporating a nanotubular backbone coated by an active phase with pseudo-capacitive properties represent an important breakthrough for developing a new generation of supercapacitors.

## INTRODUCTION

Supramolecular interactions are usually short-range (near contact) forces between the molecules, too weak to cause the intermolecular changes or bond formation between the particles. At the same time, their strength and range are sufficient to cause self-assembly of the molecular units or certain elastic deformations of these building blocks. Because of the weakness of supramolecular interactions, the resulting organization is sensitive to external conditions and ensures certain ease of transformations in response to external fields. Well known is a fascinating class of liquid crystals, whose “liquid” aspect is exactly a result of relatively small energy of intermolecular forces. Nanoparticles and especially nanotubes offer a kind of building blocks that can be efficiently glued by weak supramolecular forces in a self-assembly process. In case of nanotubes, because of their hollow structure and large aspect ratio, same forces or interaction between them can cause deformations of bending, torsion, flattening polygonization, etc. In turn, the degree of such deformation can enhance (like in case of partial polygonization of nanotubes in the array bundles) supramolecular attraction or decrease it under other circumstances. Supramolecular behavior of nanotubes is therefore intrinsically coupled with their own mechanical properties which we will discuss in some detail.

Unique mechanical properties of carbon nanotubes indirectly lead to unusual role of the forces *between* them. These *supramolecular* interactions are normally weak and, for most molecular species, are easily overcome by thermal agitation. However, they turn out to be significant in case of nanotubes, building up very strong attractive potentials over the extensive aligned contacts ( $\sim 0.5$  eV/nm). The general aspects and issues of supramolecular mechanics are discussed, including an overview of the mechanical properties of nanotubes, especially linear elastic parameters and their relation with persistence length, non-linear elastic instabilities, and buckling. Furthermore, inelastic relaxation, yield strength, and fracture mechanisms, including their

kinetic theory, are also discussed. A discussion of theoretical and computational studies is supplemented by brief summaries of experimental results for the entire range of the deformation amplitudes. Atomistic scenarios of “strong” supramolecular interactions, when polymerization and coalescence welding occur, are also discussed because of their significance in potential applications.

## OVERVIEW

Nanomechanics is generally distinguished from the well-established dynamics of molecules in that it relies on the heuristics and methods of mechanical engineering and structural mechanics. It deals with objects of distinct shape and function: rods, beams, shells, plates, membranes, etc. At the same time, because of the small length scale, nanomechanics also relies on physics of interatomic and molecular forces, quantum chemistry, solid state theory, and statistical thermodynamics. With these come a variety of numerical and computational methods (molecular dynamics, Monte Carlo simulations, classical empirical interatomic potentials, tight-binding approximation, density functional theory, etc.). This cross-disciplinary aspect makes this area both complex and exciting for research and education.

Among the numerous subjects of nanomechanics research (tips, contact junctions, pores, whiskers, etc.), carbon nanotubes (CNTs)<sup>[1]</sup> have earned a spotlight (see Ref.<sup>[2]</sup> for a popular review). Their atomically precise structure, elongated and hollow, an effective absence of a surface (which is no different than the bulk, at least for the single-walled cylinders, SWNTs), and superlative covalent bond strength are among the traits that put CNTs in the focus of nanomechanics. Discussion of numerous other objects as well as details of the multiscale methods involved in nanomechanics (for example, see recent monograph)<sup>[3]</sup> is far beyond the scope of this article.

It is noteworthy that the term *resilient* has been first applied not to nanotubes, but to smaller fullerene

**Fig. 1** Simulations of the axial and radial deformation of nanotubes. (A) Axial deformation resulting from the crossing of two (10,10) nanotubes. cages, in the study of high-energy collisions of  $C_{60}$ ,  $C_{70}$ , and  $C_{84}$  bouncing from a solid wall of H-terminated diamond. The absence of any fragmentation or other irreversible atomic rearrangement in the rebounding cages was somewhat surprising and indicated the ability of fullerenes to sustain great elastic distortion. The very same property of resilience becomes more significant in case of carbon nanotubes because their elongated shape, with the aspect ratio close to a thousand, makes the mechanical properties especially interesting and important because of potential structural applications. An accurate simulation (with realistic interatomic and van der Waals forces) in Fig. 1<sup>[4]</sup> vividly illustrates the appeal of CNTs as a nanomechanical object: well-defined cylindrical shape, compliance to external forces, and an expected type of response qualitatively analogous to a common macroscopic behavior places these objects between molecular chemical physics, elasticity theory, and mechanical engineering.

The utility of nanotubes as elements in nanoscale devices or composite materials remains a powerful motivation for the research in this area. While the feasibility of the practical realization of these applications is currently unknown, another incentive comes from the fundamental materials physics. There is an interesting duality in the nanotubes. Carbon nanotubes

possess simultaneously molecular size and morphology as well as sufficient translational symmetry to perform as very small (nano-) crystals with well-defined primitive cell, surface, possibility of transport, etc. Moreover, in many respects, they can be studied as well defined as engineering structures and many properties can be discussed in traditional terms of moduli, stiffness or compliance, or geometric size and shape. The mesoscopic dimensions (a nanometer diameter) combined with the regular, almost translation-invariant morphology along the micrometer lengths (unlike other polymers, usually coiled) make nanotubes a unique and attractive object of study.

In the following, “Linear Elastic Properties” discusses theoretical *linear elasticity* and results for the elastic moduli, compared wherever possible with the experimental data. In “Van der Waals Interactions,” the weak supramolecular interactions are quantified in the form of *van der Waals* force potential, and the large-scale mechanical deformations of nanotubes caused by their attraction to each other are outlined. The *non-linear elastic* behavior, buckling instabilities, and shell model are presented in “Supramolecular Morphology Changes Within Elastic Shell Model,” with mentioning of experimental evidence parallel to theoretical results. *Yield and failure* mechanisms in tensile load are presented in “Failure and Relaxation Mechanisms,” with the emphasis on the combined dislocation theory and computational approach. More recent results of *kinetic theory* of fracture and strength evaluation in application to CNTs are briefly presented in “Kinetic Approach to Strength-Failure Evaluation”; fast molecular tension tests are recalled in the context of kinetic theory. “Coalescence of Nanotubes as a Reversed Failure” presents some of the more recent result on CNT *coalescence welding*, a process essentially reverse to fracture. In “Tensegrity at Supramolecular Scale,” we also briefly discuss the concept of *tensegrity* and how it might be implemented in nanoscale by combining mechanically stiff and flexible supramolecular units. Throughout the discussions, we do not attempt to provide a comprehensive review of broad activities in the field. Broader or a more comprehensive discussion can be found in other relatively recent reviews by the author.<sup>[2,5]</sup>

## LINEAR ELASTIC PROPERTIES

Numerous theoretical calculations are dedicated to linear elastic properties when displacements (strain) are proportional to forces (stress). We recently revisited<sup>[6]</sup> this issue to compare within the same method the elasticity of three different materials: pure carbon (C), boron nitride (BN), and fluorinated carbon ( $C_2F$ ). Because of obvious uncertainty in definition of

a nanotube “cross section,” the results should be represented by the values of in-plane stiffness,  $C$  ( $\text{J}/\text{m}^2$ ). The values computed with Gaussian-based density functional theory are  $C = 345, 271,$  and  $328 \text{ N}/\text{m}$  for C, BN, and  $\text{C}_2\text{F}$ , respectively. These values in ab initio calculations are almost independent of nanotube diameter and chirality [consistent with the isotropic elasticity of a hexagonal two-dimensional (2-D) lattice], somewhat in contrast to previous reports based on tight binding or classical empirical approximations. Notably, substantial fluorination causes almost no change in the in-plane stiffness because the bonding involves mainly  $\pi$ -system while the stiffness is largely a result of in-plane  $\sigma$ -system. For “material” property assessments, the values of bulk moduli (based on a graphite-type 0.34-nm spacing of layers) yield 1029, 810, and 979 GPa—all very high. Knowing the elastic shell parameter  $C$  immediately leads to accurate calculation of a nanotube beam-bending stiffness  $K$  (proportional to the cube of diameter,  $\sim d^3$ ) as discussed later in “Van der Waals Interactions” and “Coalescence of Nanotubes as a Reversed Failure.” It also allowed us to compute vibration frequencies of the tubules, e.g., symmetric breathing mode frequency,  $f \sim 1/d$ ,<sup>[6]</sup> detectable in Raman spectroscopy.

An unexpected feature discovered in the course of that study<sup>[6]</sup> is the localized strain induced by the attachment of fluorine. This shifts the energy minimum of the  $\text{C}_2\text{F}$  shell lattice from an “unstrained” sheet toward the highly curved polygonal cylinders (for  $\text{C}_2\text{F}$  composition of a near square shape, Fig. 2). Equilibrium free angle is  $\sim 72^\circ$ .

Theoretical values agree reasonably well with experimental values of the Young’s modulus. It was first estimated<sup>[7]</sup> by measuring freestanding room-temperature vibrations in a transmission electron microscope (TEM). The motion of a vibrating cantilever is governed by the known fourth-order wave equation,  $y_{\text{tttt}} = -(YI/\rho A)y_{\text{xxxx}}$ , where  $A$  is the cross-sectional area and  $\rho$  is the density of the rod material. For a clamped rod, the boundary conditions are such that

**Fig. 2** Geometries of the polygonal fluorinated carbon tubes: (A) square  $\text{F}_4$ -(10,10) and (B) pentagonal  $\text{F}_5$ -(10,10). Source: From Ref.<sup>[6]</sup>.

the function and its first derivative are zero at the origin and the second and third derivative are zero at the end of the rod. Thermal nanotube vibrations are essentially elastic, relaxed phonons in equilibrium with the environment; therefore the amplitude of vibration changes stochastically with time. The amplitude of those oscillations was defined by means of careful TEM observations of a number of CNTs and yields the values of moduli within a range near 1 TPa.

Another way to probe the mechanical properties of nanotubes is to use the tip of an atomic force microscope (AFM) to bend an anchored CNT while simultaneously recording the force exerted by the tube as a function of the displacement from its equilibrium position.<sup>[8]</sup> Obtained values also vary from sample to sample but generally are close to  $Y = 1 \text{ TPa}$ . Similar values have been obtained in Ref.<sup>[9]</sup> with yet another accurate technique based on a resonant electrostatic deflection of a multiwall carbon nanotube under an external a.c. field. The detected decrease in stiffness must be related to the emergence of a different bending mode for the nanotube. In fact, this corresponds to a wavelike distortion buckling of the inner side of the CNT. Non-linear behavior is discussed in more detail in the next section. Although experimental data on elastic modulus are not very uniform, it corresponds to the values of in-plane rigidity  $C = 340\text{--}440 \text{ N}/\text{m}$  to the values  $Y = 1.0\text{--}1.3 \text{ GPa}$  for multiwall tubules and to  $Y = 4C/d = (1.36\text{--}1.76) \text{ TPa nm}/d$  for SWNTs of diameter  $d$ .

## VAN DER WAALS INTERACTIONS

Supramolecular interactions between the SWNTs are mainly because of van der Waals forces (VdW), except special situations when local charge or covalently bonded functional group introduce additional electrostatic fields. van der Waals forces play also an important role in the interaction of the nanotubes with the substrata. The different shells of a MWNT (multiwall nanotube) interact primarily by van der Waals forces; single-wall tubes form ropes for the same reason.

An interesting manifestation of van der Waals interactions involves the self-interaction between two segments of the same single-wall CNT to produce a closed ring (loop).<sup>[10]</sup> Single-walled nanotube rings were first observed in trace amounts in the products of laser ablation of graphite and assigned a toroidal structure. More recently, rings of SWNTs were synthesized with large yields ( $\sim 50\%$ ) from straight nanotube segments. These rings were shown to be loops and not tori.<sup>[10]</sup> The synthesis involves the irradiation of raw SWNTs in a sulfuric acid–hydrogen peroxide solution by ultrasound. This treatment both etches the CNTs,

shortening their length to about 3–4  $\mu\text{m}$ , and induces ring formation.

Fundamentally, van der Waals attraction between the CNT is a result of dispersion forces, i.e., electrostatic dipole-to-dipole interaction (which gives  $V \sim 1/r^3$  dependence of potential energy), and because the dipoles are mutually induced excited states, this actually yields nonzero effect only in the second-order perturbation theory, an always negative shift in potential energy  $U^{(2)} \sim -V^2 \sim -1/r^6$ .

For nanotubes and other carbon-cage structures, the van der Waals energy can be obtained from a universal graphitic potential<sup>[11]</sup> and for (10,10) tubes is

$$U(s) = -0.9516 \text{ eV/nm} (5/3)[(1 + 0.291s)^{-4} - (2/5)(1 + 0.291s)^{-10}] \quad (1)$$

Equilibrium point  $s = 0$  corresponds to intercenter distance 1.67 nm that is wall-to-wall distance 0.315 nm, with the potential well depth about 0.95 eV/nm. This value is equivalent to energy of 0.04 eV per each pair of C-atoms facing across the van der Waals spacing, or near 0.9 kcal/mol (e.g., of inserted spacer group that would push the nanotubes off the energy-minimum position). Although significant, this attraction energy decays fast with the nanotube separation: to the half of the value at only 1 Å from equilibrium and almost vanishes at 3–5 Å, as Fig. 3 shows.

The formation of coils by CNTs is particularly intriguing. While coils of biomolecules and polymers are well-known structures, they are stabilized by a number of interactions that include hydrogen bonds and ionic interactions. On the other hand, the formation of nanotube coils is surprising given the high flexural rigidity ( $K = \text{Young's modulus times areal moment}$

**Fig. 3** van der Waals energy per unit length is shown as function of displacement from equilibrium. From top down, three lines correspond to the tube deflecting from a contact with one, a pair, or a triplet of others; shallow plot corresponds to deflection in tangential direction *Source*: From Ref.<sup>[12]</sup>.

of inertia) of CNTs and the fact that CNT coils can only be stabilized by van der Waals forces. However, estimates based on continuum mechanics show that, in fact, it is easy to compensate for the strain energy induced by the coiling process through the strong adhesion between tube segments in the coil. Details of this analysis can be found in the original reports<sup>[10]</sup> or in our recent review.<sup>[5]</sup> Here we will outline briefly a different and more common situation where the competition of elastic energy and the intertubular linkage is important. Following our recent work,<sup>[12]</sup> we will discuss the connection between the nanomechanics of CNTs and their *random* curling in a suspension or a raw synthesized material of bucky paper.

Single-walled nanotubes are often compared with polymer chains as having very high rigidity and therefore large persistence length. To quantify this argument, we note that a defectless CNT has almost no static flexing, although 5/7 defects, for example, introduce small kink angle 5–15° and could cause some static curvature, but their energies are high and concentration is usually negligible. Only dynamic elastic flexibility should be considered. If  $\mathbf{u}(s)$  is a unit direction vector tangent to the CNT at contour length point  $s$ , and the bending stiffness is  $K$ , then statistical probability of certain shape  $\mathbf{u}(s)$  is

$$P[\mathbf{u}(s)] = \exp[-1/2(K/k_bT) \int (\partial\mathbf{u}/\partial s)^2 ds] = \exp[-(1/2)L \int (\partial\mathbf{u}/\partial s)^2 ds] \quad (2)$$

Here persistence length is  $L = (K/k_bT)$ . For a (10,10) SWNT of radius  $R = 0.7 \text{ nm}$  and the effective wall thickness  $h = 0.09 \text{ nm}$  (see “[Linear Elastic Properties](#)” and “[van Der Waals Interactions](#)”), the bending stiffness is very close to  $K = \pi CR^3$  ( $C = 345 \text{ N/m}$  is the in-plane stiffness, based on ab initio calculations). Persistence length at room temperature therefore is  $L_1[(10,10), 293 \text{ K}] \sim 0.1 \text{ mm}$ , in the macroscopic range much greater than for most polymer molecules. The result can be generalized for a single SWNT of radius  $R$ ,

$$L_1 = (30K/T)(R/0.7 \text{ nm})^3 \text{ mm} \quad (3)$$

or  $N$  times more for a bundle of  $N$  tubes (assuming additive stiffness for the case of weak lateral cohesion of the constituent SWNTs). For example, for a smallest close packed bundle of seven (one surrounded by six neighbors), this yields  $L_7 = 1 \text{ mm}$ . Such incoherent bundle and a solid-coherent bundle with perfect lateral adhesion provide the lower and upper limits for the persistence length,  $NL_1 < L_N < N^2L_1$ . Remarkably, these calculations show that the true thermodynamic persistence length of small CNT bundles or even an individual

**Fig. 4** Raw-produced SWNTs often form ropes–bundles entangled bent into a rubbery structure called “bucky paper.” The length scale of bends is much smaller than the persistence length for the constituent filaments. Shown here is such material produced by HiPco (high pressure CO) synthesis method *Source:* From O’Connell et al., *Chem. Phys. Lett.*, 342, 265, 2001.

SWNT is in the macroscopic range from a fraction of a millimeter and greater. This means that highly curved structures often observed in bucky-paper mats (Fig. 4) are attributed not to thermodynamic fluctuations, but rather to residual mechanical forces preventing these coils from unfolding. Elastic energy of a typical micron size ( $r \sim 1 \mu\text{m}$ ) curl-arc is much greater than thermal,  $U_{\text{curl}} \sim k_b T(L/r)^2 \gg k_b T$ .<sup>[12]</sup> At the same time, a force required to maintain this shape  $F_{\text{curl}} \sim K/r^2 = N \text{ pN}$ , several piconewtons, where  $N$  is the number of SWNTs in each bundle. This is much less than a force per single chemical bond ( $\sim 1 \text{ nN}$ ), and therefore any occasional lateral bonding between the tubules can be sufficient to prevent them from disentanglement.

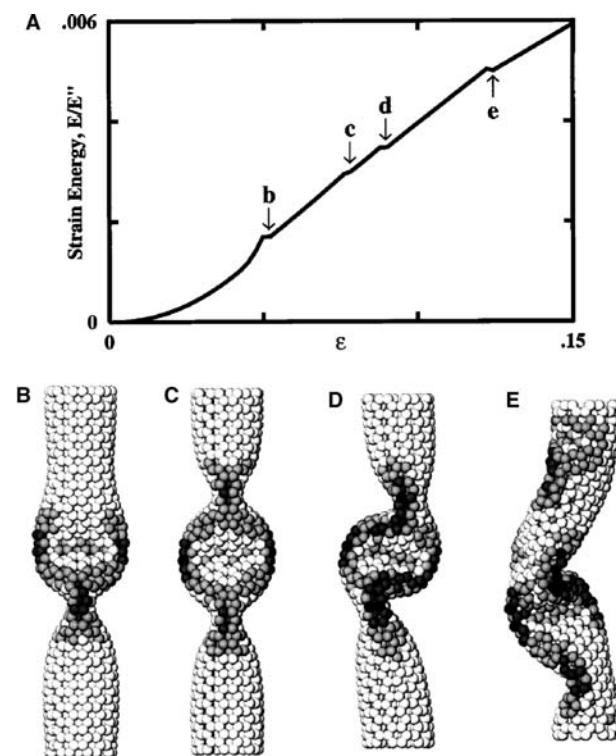

### SUPRAMOLECULAR MORPHOLOGY CHANGES WITHIN ELASTIC SHELL MODEL

Almost any molecular structure can sustain very large deformations, compared with the range common in macroscopic mechanics. A less obvious property of CNTs is that the specific features of large non-linear strain can be understood and predicted in terms of continuum theories. One of the outstanding features of nanotubes is their hollow structure, built of atoms densely packed along a closed surface that defines the overall shape. This also manifests itself in dynamic properties of molecules, resembling so much the macroscopic objects of continuum elasticity known as *shells*. Macroscopic shells and rods have long been of interest: the first study dates back to Euler, who discovered the elastic instability. A rod subject to longitudinal compression remains straight but shortens

by some fraction  $\varepsilon$ , proportional to the force, until a critical value (the Euler force) is reached. It then becomes unstable and buckles sideways at  $\varepsilon > \varepsilon_{\text{cr}}$ , while the force almost does not vary. For hollow tubules, there is also a possibility of local buckling in addition to buckling as a whole. Therefore more than one bifurcation can be observed, thus causing an overall non-linear response to the large deforming forces (note that local mechanics of the constituent shells may well still remain within the elastic domain).

In nanomechanics, the theory of shells was first applied in our early analysis of buckling and since then serves a useful guide.<sup>[13–16]</sup> Its relevance for a covalent-bonded system of only a few atoms in diameter was far from being obvious. Molecular dynamics simulations seem better suited for objects that are small.

Fig. 5 shows a simulated nanotube exposed to *axial compression*. The atomic interaction was modeled by the Tersoff–Brenner potential, which reproduces the

**Fig. 5** Simulation of a (7,7) nanotube exposed to axial compression,  $L = 6 \text{ nm}$ . The strain energy (A) displays four singularities corresponding to shape changes. At  $\varepsilon_c = 0.05$ , the cylinder buckles into the pattern (B), displaying two identical flattenings—“fins” perpendicular to each other. Further increase of  $\varepsilon$  enhances this pattern gradually until at  $\varepsilon_2 = 0.076$ , the tube switches to a three-fin pattern (C), which still possesses a straight axis. In a buckling sideways at  $\varepsilon_3 = 0.09$ , the flattenings serve as hinges, and only a plane of symmetry is preserved (D). At  $\varepsilon_4 = 0.13$ , an entirely squashed asymmetric configuration forms (E). *Source:* From Ref.<sup>[13]</sup>.

lattice constants and binding energies of graphite and diamond. The end atoms were shifted along the axis by small steps and the whole tube was relaxed by conjugate-gradient method while keeping the ends constrained. At small strains, the total energy (Fig. 5A) grows as  $E(\varepsilon) = (1/2)E''\varepsilon^2$ . The presence of four singularities at higher strains was quite a striking feature and the patterns (b)–(e) illustrate the corresponding morphological changes. The shading indicates strain energy per atom, equally spaced from below 0.5 eV (brightest) to above 1.5 eV (darkest). The sequence of singularities in  $E(\varepsilon)$  corresponds to a loss of molecular symmetry from  $D_{\infty h}$  to  $S_4$ ,  $D_{2h}$ ,  $C_{2h}$ , and  $C_1$ . This evolution of the molecular structure can be put in the framework of continuum elasticity.

The intrinsic symmetry of a graphite sheet is hexagonal, and the elastic properties of 2-D hexagonal structure are isotropic. A curved sheet can also be approximated by a uniform shell with only two elastic parameters: flexural rigidity  $D$  and its in-plane stiffness  $C$ . The energy of a shell is given by a surface integral of the quadratic form of local deformation,

$$E = \frac{1}{2} \int \int \{ D[(\kappa_x + \kappa_y)^2 - 2(1 - \nu)(\kappa_x\kappa_y - \kappa_{xy}^2)] + \frac{C}{(1 - \nu^2)} [(\varepsilon_x + \varepsilon_y)^2 - 2(1 - \nu)(\varepsilon_x\varepsilon_y - \varepsilon_{xy}^2)] \} dS \quad (4)$$

where  $\kappa$  is the curvature variation,  $\varepsilon$  is the in-plane strain, and  $x$  and  $y$  are local coordinates. To adapt this formalism to a graphitic tubule, the values of  $D$  and  $C$  can be identified by comparison with the detailed ab initio and semiempirical studies of nanotube energetics at small strains. Indeed, the second derivative of total energy with respect to axial strain corresponds to the in-plane rigidity  $C$  (cf. “Linear Elastic Properties”). Similarly, the strain energy as a function of tube diameter  $d$  corresponds to  $2D/d^2$  in Eq. (4). Using recent ab initio calculations,<sup>[6]</sup> one obtains  $C = 56 \text{ eV/atom} = 340 \text{ J/m}^2$  and  $D = 1.46 \text{ eV}$ . The Poisson ratio  $\nu = 0.15$  was extracted from a reduction of the diameter of a tube stretched in simulations. A similar value is obtained from experimental elastic constants of single crystal graphite. One can make a further step toward a more tangible picture of a tube as having wall thickness  $h$  and Young modulus  $Y_s$ . Using the standard relations  $D = Yh^3/12(1 - \nu^2)$  and  $C = Y_s h$ , one finds  $Y_s = 3.9 \text{ TPa}$  and  $h = 0.089 \text{ nm}$ . With these parameters, linear stability analysis allows one to assess the nanotube behavior under strain.

To illustrate the efficiency of the shell model, consider briefly the case of imposed axial compression. A trial perturbation of a cylinder has a form of Fourier harmonics, with  $M$  azimuthal lobes and  $N$  halfwaves

**Fig. 6** The critical strain levels for a continuous, 1-nm-wide shell tube as a function of its scaled length  $L/N$ . A buckling pattern  $(M, N)$  is defined by the number of halfwaves  $2M$  and  $N$  in  $y$  and  $x$  directions, respectively, e.g., a  $(4, 4)$ -pattern is shown in the inset. The effective moduli and thickness are fit to graphene. Source: From Ref.<sup>[13]</sup>.

along the tube (Fig. 6 inset), i.e., sines and cosines of arguments  $2My/d$  and  $N\pi x/L$ . At a critical level of the imposed strain,  $\varepsilon_c(M, N)$ , the energy variation (4.1) vanishes for this shape disturbance. The cylinder becomes unstable and lowers its energy by assuming an  $(M, N)$  pattern. For tubes of  $d = 1 \text{ nm}$  with the shell parameters identified above, the critical strain is shown in Fig. 6. According to these plots, for a tube with  $L > 10 \text{ nm}$ , the bifurcation is first attained for  $M = 1, N = 1$ . The tube preserves its circular cross section and buckles sideways as a whole; the critical strain is close to that for a simple rod,

$$\varepsilon_c = 1/2(\pi d/L)^2 \quad (5)$$

or four times less for a tube with hinged (unclamped) ends. For a shorter tube, the situation is different. The lowest critical strain occurs for  $M = 2$  (and  $N \geq 1$ , see Fig. 6), with a few separated flattenings in directions perpendicular to each other, while the axis remains straight. For such a local buckling, in contrast to (4.2), the critical strain depends little on length and estimates to  $\varepsilon_c = 4\sqrt{D/C}d^{-1} = (2/\sqrt{3})(1 - \nu^2)^{-1/2}hd^{-1}$  in the so-called Lorenz limit. For a nanotube, one finds

$$\varepsilon_c = 0.1 \text{ nm}/d \quad (6)$$

Specifically, for the 1-nm-wide tube of length  $L = 6 \text{ nm}$ , the lowest critical strains occur for  $M = 2$  and  $N = 2$  or  $3$  (Fig. 6). This is in accord with the two- and three-fin patterns seen in Fig. 5B and C. Higher singularities cannot be quantified by the linear analysis, but they look like a sideways beam buckling, which at this stage becomes a non-uniform object.

Axially compressed tubes of greater length and/or tubes simulated with hinged ends (equivalent to a

doubled length) first buckle sideways as a whole at a strain consistent with (5). After that, the compression at the ends results in bending and a local buckling inward. This illustrates the importance of the “beam-bending” mode, the softest for a long molecule and most likely to attain significant amplitudes because of either thermal vibrations or environmental forces. In simulations of *bending*, a torque rather than force is applied at the ends and the bending angle  $\theta$  increases stepwise. While a notch in the energy plot can be mistaken for numerical noise, its derivative  $dE/d\theta$  drops significantly. This unambiguously shows an increase in tube compliance—a signature of a buckling event. In bending, only one side of a tube is compressed and thus can buckle. Assuming that it buckles when its local strain,  $\varepsilon = \kappa d/2$ , where  $\kappa$  is the local curvature, is close to that in axial compression, Eq. (6), we estimate the critical curvature as

$$\kappa_c = 0.2 \text{ nm}/d^2 \quad (7)$$

In simulation of *torsion*, the increase of azimuthal angle  $\phi$  between the tube ends results in abrupt changes of energy and morphology.<sup>[13,14,17]</sup> In continuum model, the analysis based on Eq. 4 is similar to that outlined above, except that it involves skew harmonics of arguments such as  $N\pi x/L \pm 2My/d$ . For overall beam buckling ( $M = 1$ ),

$$\phi_c = 2(1 + \nu)\pi \quad (8)$$

and for the cylinder-helix flattening ( $M = 2$ ),

$$\phi_c = 0.06 \text{ nm}^{3/2}L/d^{5/2} \quad (9)$$

The latter should occur first for  $L < 140d^{5/2}$  nm, which is true for all tubes we simulated. However, in simulations, it occurs later than predicted by Eq. (9). The ends, kept circular in simulation, which is physically justifiable, by a presence of rigid caps on normally closed ends of a molecule, deter the thorough flattening necessary for the helix to form (unlike the local flattening in the case of an axial load).

Experimental evidence provides sufficient support to the notion of high resilience of SWNT. An early observation of noticeable flattening of the walls in a close contact of two MWNT has been attributed to van der Waals forces pressing the cylinders to each other.<sup>[18]</sup> Collapsed forms of the nanotube (“nanoribbons”), also caused by van der Waals attraction, have been observed in experiment, and their stability can be explained by the competition between the van der Waals and elastic energies.<sup>[19]</sup> Any additional torsional strain imposed on a tube in experimental environment also favors flattening<sup>[13,14]</sup> and facilitates the collapse. Graphically more striking evidence of resilience is

provided by bent structures,<sup>[20]</sup> as well as the more detailed observations that actually stimulated our research in nanomechanics.<sup>[21]</sup> An accurate measurement with the atomic force microscope (AFM) tip detects the “failure” of a multiwall tubule in bending,<sup>[8]</sup> which essentially represents non-linear buckling on the compressive side of the bent tube. The estimated measured local stress is 15–28 GPa, very close to the calculated value.<sup>[22,23]</sup> Buckling and ripple of the outermost layers in a dynamic resonant bending has been directly observed and is responsible for the apparent softening of MWNT of larger diameters.<sup>[5,24]</sup>

## FAILURE AND RELAXATION MECHANISMS

The important issue of ultimate tensile strength of CNTs is inherently related with the atomic relaxation in the lattice under high strain. This thermally activated process was first predicted to consist of a sequence of individual bond rotations in the approach based on dislocation theory.<sup>[22,25,26]</sup> Careful computer simulations demonstrate feasibility of this mechanism and allowed us to quantify important energy aspects.<sup>[27,28]</sup> It has been shown that in a crystal lattice such as the wall of a CNT, a yield to deformation must begin with a homogeneous nucleation of a slip by the shear stress present. The non-basal edge dislocations emerging in such slip have a well-defined core, a pentagon–heptagon pair, 5/7. Therefore the prime dipole is equivalent to the Stone–Wales (SW) defect. The nucleation of this prime dislocation dipole “unlocks” the nanotube for further relaxation: either brittle cleavage or a plastic flow. Remarkably, the latter corresponds to a motion of dislocations along the helical paths (glide “planes”) within the nanotube wall. This causes a stepwise (quantized) necking, when the domains of different chiral symmetry and therefore different electronic structure are formed, thus coupling the mechanical and electrical properties.<sup>[22,25,26]</sup> It has further been shown<sup>[22,23,25,28–30]</sup> that the energy of such nucleation explicitly depends on CNT helicity (chirality).

Below, we deduce starting with dislocation theory the atomistics of mechanical relaxation under extreme tension. Locally, the wall of a nanotube differs little from a single graphene sheet, a 2-D crystal of carbon. When a uniaxial tension  $\sigma$  (N/m—for the 2-D wall, it is convenient to use force per unit length of its circumference) is applied, it can be represented as a sum of expansion (locally isotropic within the wall) and a shear of a magnitude  $\sigma/2$  (directed at  $\pm 45^\circ$  with respect to tension). Generally, in a macroscopic crystal, the shear stress relaxes by a movement of *dislocations*, the edges of the atomic extraplanes. Burgers vector  $\mathbf{b}$  quantifies the mismatch in the lattice as a result of a

dislocation. Its glide requires only local atomic rearrangements and presents the easiest way for strain release, provided sufficient thermal agitation. In an initially *perfect* lattice such as the wall of a nanotube, a yield to a great axial tension begins with a homogeneous *nucleation* of a slip, when a dipole of dislocations [a tiny loop in three-dimensional (3-D) case] first has to form. The formation and further glide are driven by the reduction of the applied-stress energy, as characterized by the elastic Peach–Koehler force on a dislocation. The force component along  $\mathbf{b}$  is proportional to the shear in this direction and thus depends on the angle between the Burgers vector and the circumference of the tube,

$$f_b = -(1/2)\sigma|b|\sin 2\theta \quad (10)$$

The max  $|f_b|$  is attained on two  $\pm 45^\circ$  lines, which mark the directions of a slip in an isotropic material under tension.

The graphene wall of the nanotube is not isotropic; its hexagonal symmetry governs the three glide planes—the three lines of closest zigzag atomic packing, oriented at  $120^\circ$  to each other (corresponding to the  $\{10\bar{1}l\}$  set of planes in 3-D graphite). At non-zero shear, these directions are prone to slip. The corresponding *c*-axis edge dislocations involved in such slip are indeed known in graphite. The six possible Burgers vectors  $1/3a\langle 2\bar{1}10 \rangle$  have a magnitude  $b = a = 0.246$  nm (lattice constant), and the dislocation core is identified as a  $5/7$  pentagon–heptagon pair in the honeycomb lattice of hexagons. Therefore the primary nucleated dipole must have a  $5/7/7/5$  configuration (a  $5/7$  attached to an inverted  $7/5$  core). This configuration is obtained in the perfect lattice (or a nanotube wall) by a  $90^\circ$  rotation of a single C–C bond, well known in fullerene science as a Stone–Wales diatomic interchange. One is led to conclude that the SW transformation is equivalent to the smallest slip in a hexagonal lattice and must play a key role in the nanotube relaxation under external force.

The preferred glide is the closest to the maximum shear  $\pm 45^\circ$  lines and depends on how the graphene strip is rolled up into a cylinder. This depends on nanotube helicity specified by the chiral indices ( $c_1, c_2$ ) or a chiral angle  $\theta$  indicating how far the circumference departs from the leading zigzag motif  $\mathbf{a}_1$ . The max  $|f_b|$  is attained for the dislocations with  $\mathbf{b} = \pm(0,1)$  and their glide reduces the strain energy

$$E_g = -|f_b a| = -Ca^2/2 \sin(2\theta + 60)\varepsilon \quad (11)$$

per one displacement,  $a$ . Here  $\varepsilon$  is the applied strain and  $C = Yh = 342$  N/m can be derived from the Young's modulus of  $Y = 1020$  GPa and the interlayer spacing  $h = 0.335$  nm in graphite; one then obtains

$Ca^2/2 = 64.5$  eV. Eq. (11) allows one to compare different CNTs (assuming similar amount of preexisting dislocations): the more energetically favorable is the glide in a tube, the earlier it must yield to applied strain.

In a pristine nanotube molecule, the  $5/7$  dislocations have to first emerge as a dipole by a prime SW transformation. Topologically, the SW defect is equivalent to either one of the two dipoles, each formed by an  $\sim a/2$  slip. Applying Eq. 11 to each of the slips, one finds

$$E_{SW} = E_O - A\varepsilon - B\sin(2\theta + 30)\varepsilon \quad (12)$$

The first two terms, the zero-strain formation energy and possible isotropic dilation, do not depend on chiral symmetry. The symmetry-dependent third term, which can also be derived as a leading term in the Fourier series, describes the fact that SW rotation gains more energy in an armchair ( $\theta = 30^\circ$ ) CNT, making it thermodynamically the weakest and most inclined to SW nucleation of the dislocations, in contrast to the zigzag ( $\theta = 0$ ) where the nucleation is least favorable.

Consider for example a (*c,c*) armchair CNT as a typical representative (we will also see below that this armchair type can undergo a more general scenario of relaxation). The initial stress-induced SW rotation creates a geometry that can be viewed as either a dislocation dipole or a tiny crack along the equator. Once “unlocked,” the SW defect can ease further relaxation. At this stage, both brittle (dislocation pileup and crack extension) and plastic (separation of dislocations and their glide away from each other) routes are possible, the former usually at larger stress and the latter at higher temperatures.

Formally, both routes correspond to a further sequence of SW switches. The  $90^\circ$  rotation of the bonds at the “crack tip” (Fig. 7, left column) will result in a  $7/8/7$  flaw and then  $7/8/8/7$ , etc. This further strains the bonds—partitions between the larger polygons, leading eventually to their breakage, with the formation of greater openings such as  $7/14/7$ , etc. If the crack, represented by this sequence, surpasses the critical Griffith size, it cleaves the tubule.

In a more interesting distinct alternative, the SW rotation of another bond (Fig. 7, top row) divides the  $5/7$  and  $7/5$ , as they become two dislocation cores separated by a single row of hexagons. A next similar SW switch results in a double-row separated pair of the  $5/7$ 's and so on. This corresponds, at very high temperatures, to a plastic flow *inside* the nanotube molecule, when the  $5/7$  and  $7/5$  twins glide away from each other driven by the elastic forces, thus reducing the total strain energy [cf. Eq. (11)]. One remarkable feature of such glide is a result of mere cylindrical geometry: the glide

**Fig. 7** SW transformations of an equatorially oriented bond into a vertical position create a nucleus of relaxation (top left corner). It evolves further as either a crack—brittle fracture route, left column—or as a couple of dislocations gliding away along the spiral slip “plane” (plastic yield, top row). In both cases, only SW rotations are required as elementary steps. The stepwise change of the nanotube diameter reflects the change of chirality, bottom right image, causing the corresponding variations of electrical properties *Source*: From Ref.<sup>[25]</sup>.

“planes” in case of nanotubes are actually spirals, and the slow thermally activated Brownian walk of the dislocations proceeds along these well-defined trajectories. Similarly, their extraplanes are just the rows of atoms also curved into the helices.

A nanotube with a 5/7 defect in its wall loses axial symmetry and has a bent equilibrium shape; the calculations show<sup>[31]</sup> the junction angles  $<15^\circ$ . Interestingly then, an exposure of an even achiral nanotube to the axially symmetric tension generates two 5/7 dislocations, and when the tension is removed, the tube “freezes” in an asymmetric configuration, S-shaped or C-shaped, depending on the distance of glide, i.e., time of exposure. This seemingly “symmetry-violating” mechanical test is a truly nanoscale phenomenon. Of course, the symmetry is conserved statistically because many different shapes form under identical conditions.

When the dislocations sweep a noticeable distance, they leave behind a tube segment changed strictly following the topological rules of dislocation theory. By considering a planar development of the tube segment containing a 5/7, for the new chirality vector  $\mathbf{c}'$ , one finds

$$(\mathbf{c}'_1, \mathbf{c}'_2) = (\mathbf{c}_1, \mathbf{c}_2) - (\mathbf{b}_1, \mathbf{b}_2) \quad (13)$$

with the corresponding reduction of diameter,  $d$ . While the dislocations of the first dipole glide away, a generation of another dipole results, in further narrowing and proportional elongation under stress, thus forming a neck as shown above. The orientation of a generated dislocation dipole is determined every time by the Burgers vector closest to the lines of maximum shear ( $\pm 45^\circ$  cross at the endpoint of the current circumference vector  $\mathbf{c}$ ). The evolution of a  $(c,c)$  tube will be:  $(c,c) \rightarrow (c,c-1) \rightarrow (c,c-2) \rightarrow \dots (c,0) \rightarrow [(c-1,1)$  or  $(c,-1)] \rightarrow (c-1,0) \rightarrow [(c-2,1)$  or  $(c-1,-1)] \rightarrow (c-2,0) \rightarrow [(c-3,1)$  or  $(c-2,-1)] \rightarrow (c-3,0)$ , etc. It abandons the armchair  $(c,c)$  type entirely, but then oscillates in the vicinity of zigzag  $(c,0)$  kind, which appears a peculiar attractor. Correspondingly, the diameter for a (10,10) tube changes stepwise,  $d = 1.36, 1.29, 1.22, 1.16$  nm, etc., the local stress grows in proportion, and this quantized necking can be terminated by a cleave at late stages. Interestingly, such plastic flow is accompanied by the change of electronic structure of the emerging domains, governed by the vector  $(c_1, c_2)$ . The armchair tubes are metallic, and others are semiconducting with the different band gap values. The 5/7 pair separating two domains of different chirality has been discussed as a pure-carbon heterojunction, is argued to cause the current rectification detected in a nanotube nanodevice,<sup>[32]</sup> and can be used to modify, in a controlled way, the electronic structure of the tube. Here we see how this electronic heterogeneity can arise from a mechanical relaxation at high temperature: if the initial tube was armchair-metallic, the plastic dilation transforms it into a semiconducting type irreversibly.<sup>[25,26,33]</sup>

While the above analysis is based on atomic picture (structure and interactions), recent developments<sup>[34]</sup> offer an approach where the fracture nucleation can be described rather elegantly within non-linear continuum mechanics (based on classical interatomic forces for carbon). Whether this approach can describe change in chirality, temperature dependence, or temporal aspects of relaxation should yet be explored.

The dislocation theory allows one to expand the approach to other materials, and we have recently applied it to boron nitride (BN) nanotubes.<sup>[35,36]</sup> While the binding energy in BN is lower than in CNT, the formation of 5/7/7/5 defect can be more costly because of Coulomb repulsion between emerging BB and NN pairs (Fig. 8A) (bonding in BN is partially ionic with strong preference to chemical neighbor alternation in the lattice). Another dislocation pair 4/8/8/4 that preserves the alternation must be considered (Fig. 8B). It turns out that the quantitative results are sensitive to the level of theory accuracy. Tight binding approximation<sup>[37]</sup> underestimates the repulsion by almost 3 eV.<sup>[35,36]</sup> Ab initio DFT calculations show that 5/7/7/5 is metastable lowest energy

**Fig. 8** The geometries of (5,5) BN tubule with (A) 5/7/7/5 defect emerging at high tension and temperature and (B) 4/8/8/4 dislocation dipole. *Source:* From Ref.<sup>[35]</sup>.

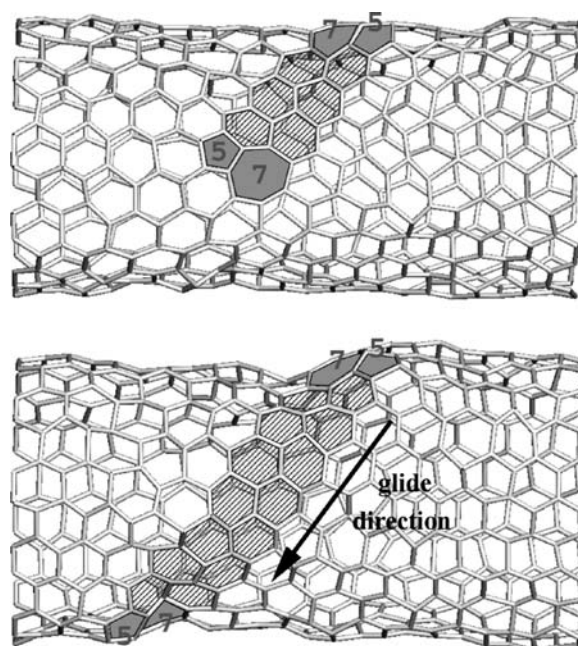

defect in BN, and its formation energy 5.5 eV is higher than 3.0 eV in carbon,<sup>[35,36]</sup> thus suggesting higher thermodynamic stability of BN under tensile load. Relaxation under compression is different as it involves skin-type buckling also investigated recently.<sup>[38]</sup>

### KINETIC APPROACH TO STRENGTH-FAILURE EVALUATION

Computer simulations have provided a compelling evidence of the mechanisms discussed above. By carefully tuning a *quasi-static* tension in the tubule and gradually elevating its temperature, with extensive periods of MD annealing, the first stages of the mechanical yield of CNT have been observed (Fig. 9).<sup>[27,28]</sup> In simulation of tensile load, the novel patterns in plasticity and breakage, just as described above, clearly emerge. At very *high strain* rate, the details of primary defects cannot be seen and they only begin to emerge at higher strain level, giving impression of exceedingly high breaking strain.<sup>[17]</sup>

Fracture, of course, is a *kinetic* process where time is an important parameter. Even a small tension, as any non-hydrostatic stress, makes material thermodynamically metastable and a generation of defects energetically favorable. Thus the important issue of strength remains beyond the defect formation energy and its reduction with the applied tension. Recently, we developed kinetic theory in application to CNT.<sup>[30,39]</sup> In this approach, we evaluate conditions (strain  $\varepsilon$ , temperature  $T$ ) when the probability  $P$  of defect formation becomes significant within laboratory test time  $\Delta t$ ,

$$P = \nu \Delta t N_B / 3 \sum_m \exp[-E_m(\varepsilon, \chi) / k_b T] \sim 1 \quad (14)$$

**Fig. 9**  $T = 3000$  K, strain 3%, plastic flow behavior (about 2.5 nsec). The shaded area indicates the migration path of the 5/7 edge dislocation. *Source:* From Ref.<sup>[28]</sup>.

Here  $\nu = k_b T / h$  is the usual attempt frequency and  $N_B$  is the number of bonds in the sample. Activation barrier  $E_m(\varepsilon, \chi)$  must be computed as a function of strain and chirality  $\chi$  of the tubule, and then the solution of this equation with respect to  $\varepsilon$  gives the breaking strain values. This approach involved substantial computational work in finding the saddle points and energies (Fig. 10A) for a variety of conditions and for several transition state modes (index  $m$  in the summation above). Obtained yield strain near 17% (Fig. 10B),<sup>[30,39]</sup> is in reasonable agreement with the series of experimental reports. We currently are implementing similar approach with ab initio level of saddle point barrier calculations.<sup>[40]</sup> Preliminary data show higher 8–9 eV barriers, but their reduction with tension is also faster.

Previously performed high strain rate simulations have shown temperature dependence of breaking strain,<sup>[14,17]</sup> consistent with the kinetic theory.<sup>[30]</sup> In a constant strain rate arrangement (when the ends of the sample are pulled from the equilibrium with certain rate), the rate equation is slightly modified to its integral form. However, the main contribution comes from the vicinity of the upper limit,

$$P = \nu N_B / 3 \int \sum_m \exp\{-E_m[\varepsilon(t), \chi] / k_b T\} dt \sim 1 \quad (15)$$

Simple analysis reveals certain invariant  $T \times \log(\nu \Delta t)$  of the time of failure and temperature (provided the constant strain). Detailed simulations could shed

**Fig. 10** Activation barrier values (here computed within classical multibody potential, (A) serve as input to the rate equation (14) and the calculation of the yield strain as a function of time (here from 1 msec to 1 year, (B), temperature (here 300 K), and chiral symmetry ( $\chi$ ). Source: From Ref.<sup>[30]</sup>.

additional light on this aspect (Cho et al., private communication, 2002). More significant finding reported recently<sup>[41]</sup> is that kinetic probability of SW bond rotation at room temperatures can be rather small and the actual mechanism of failure is a brittle cleave, through a sequence of “lattice-trapped” states corresponding to individual broken bonds, from one to two, three, etc.<sup>[41]</sup>

### COALESCENCE OF NANOTUBES AS A REVERSED FAILURE

Understanding the details of failure mechanism has led us recently<sup>[42–44]</sup> to investigate an opposite process, a coalescence of nanoscale clusters analogous to macroscopic sintering or welding. Fusion of smaller components into a larger whole is a ubiquitous process in condensed matter. In molecular scale, it corresponds to chemical synthesis, where exact rearrangement of atoms can be recognized. Coalescence or sintering of macroscopic parts is usually driven by the well-defined thermodynamic forces (frequently, surface energy reduction), but the atomic evolution path is redundant and its exact identification is irrelevant. Exploring a possibility of the two particles merging with atomic precision becomes compelling in nanometer scale, where one aspires to “arrange the atoms one by one.” Are the initial and final states connected by a feasible path of atomic movements, or separated by insurmountable barriers? Direct molecular dynamics (MD) investigation is usually hampered by energy landscape traps and beyond very few atomic steps needs to be augmented with additional analysis.

An example of very small particles is offered by fullerene cages and CNTs. Fusion of fullerenes has been previously reported and the lateral merging (diameter-doubling) of CNT has been observed and simulated.<sup>[45,46]</sup> In contrast, head-to-head coalescence of CNT segments remained unexplored and of

particular theoretical and practical interest: Is it permitted by rigorous topology rules to eliminate all the pentagons always present in the CNT ends and thus dissolve the caps completely? Can this occur through a series of well-defined elementary steps and what is overall energy change if the system evolves through the intermediate disordered states to the final purely hexagonal lattice of continuous tubule? If feasible, such “welding” can lead to increase of connectivity in CNT arrays in bundles/ropes and crystals and thus significantly improve the mechanical, thermal, and electrical properties of material. In addition, determining the atomistic steps of small-diameter tube coalescence (with the end caps identical to half-buckyball) can shed light on the underlying mechanism of condensed phase conversion or CNT synthesis from  $C_{60}$  components.

In Ref.<sup>[42]</sup> we have reported for the first time atomically precise routes for complete coalescence of generic fullerene cages: cap-to-cap CNT and  $C_{60}$  merging together to form defectless final structure. The entire process is reduced to sequence of Stone–Wales bond switches and therefore is likely the lowest energy path of transformation. Several other examples of merging follow immediately as special cases: coalescence of buckyballs in peapod, joining of the two (5,5) tubes as in Fig. 11, “welding” the (10,10) to (10,10) following Fig. 12, etc. The approach remains valid for arbitrary tubes with the important constraint of unavoidable grain boundary for the tubes of different chirality. The junction of  $(n,m)$  and  $(n',m')$  must contain  $5/7$  dislocations or their equivalent of  $(n - n', m - m')$  total Burgers vector.<sup>[25]</sup> The proposed mechanism<sup>[42–44]</sup> has important implications for nanotube material (crystals, ropes) processing and property enhancement, engineering of nanoscale junctions of various types, possible growth mechanisms with the  $C_{60}$  and other nanoparticles as feedstock. In the context of nanomechanics, an interesting feature of the late stages of coalescence is the annealing and annihilation of  $5/7$  pairs in a process

**Fig. 11** 2-D geodesic projection (left) and the actual 3-D structures (right) show the transformations from a pair of separate (5,5) tubes (A) to a single defect-free nanotube. Primary “polymerization” links form as two other bonds break (B, dashed lines). The  $\pi/2$  rotations of the links (the bonds subject to such SW flip are dotted) and the SW flips of the four other bonds in (C) produce a (5,0) neck (D). It widens by means of another 10 SW rotations, forming a perfect single (5,5) tubule (not shown). *Source:* From Ref.<sup>[42]</sup>.

exactly reverse to the formation and glide of these dislocation cores in the course of yield and failure under tension. On the other hand, although covalent bond flip represents intramolecular process, it is remarkable how it can lead to possibility of global supramolecular shape changes and reactions, from merging coalescence to interpenetration and encapsulation.

### TENSEGRITY AT SUPRAMOLECULAR SCALE

Usual supramolecular interactions possess the same generic properties as any other interatomic forces: weak but always present attraction at large distances (from tens of nanometers) results in a relatively shallow potential minimum at intermolecular vicinity of 0.2–0.5 nm spacing. Closer, it turns into a steep repulsive potential which, upon sufficient compression, can yield to a covalent bonding. Therefore supramolecular forces by themselves are unlikely to be able to support

**Fig. 12** 2-D projections (left) and the computed 3-D intermediate structures (right) in the coalescence of the two (10,10) nanotubes: separate caps (A) in a sequence similar to Fig. 8 develop a (5,5) junction (B), which then shortens (C) and widens into a (10,5) neck (D). Glide of the shaded 5/7 dislocations completes the annealing into a perfect (10,10) CNT (not shown). Due to the fifth-fold symmetry, only two cells are displayed. *Source:* From Ref.<sup>[42]</sup>.

low-density assembly of molecules and nanotubes in particular: they would form aligned bundles or at least relatively dense random mats. In this context, it became of interest recently to explore transferability of certain ideas of macroengineering and to connect rigid nanotubes by chemically attached polymer segments to keep them apart. This seems at a first glance counterintuitive—how adding *flexible* links can prevent rigid beams from lumping together? However, at the macroscopic scale, the idea goes back to Fuller,<sup>[47]</sup> who has proposed and patented *tensile-integrity structures*, hence the terms *tensegrity* in the literature. Tensegrity is a design principle that describes how network structures achieve shape stability. The main point is that a disconnected set of rigid beams can be tethered by sparse series of tensile threads (each perfectly bendable and unresponsive to any compression) in such a way that global structure

**Fig. 13** Molecular mechanics (relaxed with realistic interatomic force-field and weak van der Waals interaction) simulation of the simplest tensegrity structure c3t9 of carbon nanotube beams connected by covalently attached to the cap pentagons polyethylene chains *Source: From Ref.*<sup>[49]</sup>.

can become rigid, sustain compressive global load, and possess all-finite vibration eigenfrequencies. Such engineered structures can be found in architecture, furniture, entertainment, and aerospace applications (because of lightweight and “foldability”). In cell biology, cytoskeleton is also suggested to possess tensegrity properties.<sup>[48]</sup> Fig. 13 shows simplest simulated tensegrity unit (3 beams compression members connected by 9 chains tension members, c3t9 per Skelton’s nomenclature) composed of rigid carbon nanotubes tethered by polymer chains.<sup>[49]</sup> We have analyzed stability changes in such and several similar structures upon removal of one chain or adding a few extras.

## CONCLUSION

Mechanics of nanotubes has attracted keen interest since their discovery and over the past decade. Above, we have described several established facts and properties together with other, yet speculative aspects and possibilities. It may be useful to reiterate in conclusion some observations and notions of the field as discussed in this entry.

Because of qualitative differences, nanotube mechanics can be subdivided into *intramolecular*, involving bond rearrangements and atomic removal or insertion within the carbon lattice of the tube wall, and *supramolecular* mechanics of interactions *between* the tube molecules. As illustrated above, the latter can be a result of weak distant interactions via dispersion van der Waals forces, stronger direct electrostatic potentials, or by means of much stronger covalent linkage-tethering of nanotubes through intermediate functional groups or elongated chains (as in the example of tensegrity designs). While supramolecular interactions play central role in colloid chemistry, in

numerous biochemical processes, and have been broadly studied, in case of nanotubes, certain special aspects stand out. Great strength of carbon lattice makes it qualitatively different from most other molecules often involved in supramolecular processes: lowest activation barrier for intratube bond rearrangements is 7–9 eV high, which makes even covalent bonding with some other species or between the tubes relatively small supramolecular perturbation.

In contrast, the very same stiffness and “surface” smoothness of the tubes results in dramatic amplification or the traditionally weak dispersion forces. van der Waals interactions add up along the tube–tube contact and yield typically ~1 eV per each nanometer of length, i.e., many electron volts for a typical lateral contact. In turn, this makes solubility or even mechanical separation of nanotube bundles a very challenging task. These distinct features of supramolecular mechanics of nanotubes play critical role in their assembly in arrays-bundles of ropes, nematic crystals, or in their distribution in and coupling with solvents or matrix substances in composite materials.

# Carbon Nanotubes: Thermal Properties

J. Hone

Department of Mechanical Engineering, Columbia University, New York, New York, U.S.A.

## INTRODUCTION

As nanoscale graphitic structures, carbon nanotubes are of great interest not only for their electronic and mechanical properties, but also for their thermal properties. Because of their small size, quantum effects are important, and the low-temperature specific heat and thermal conductivity show direct evidence of 1-D quantization of the phonon bandstructure. Modeling of the low-temperature specific heat allows for determination of the on-tube phonon velocity, the splitting of phonon subbands on a single tube, and the interaction between neighboring tubes in a bundle. The thermal conductivity of nanotubes has been examined both theoretically and experimentally. Theoretical work predicts a room-temperature thermal conductivity that is larger than graphite or diamond. Measurements show a room-temperature thermal conductivity over 200 W/m K for bulk samples of single-walled nanotubes (SWNTs), and over 3000 W/m K for individual multi-walled nanotubes (MWNTs). Addition of nanotubes to epoxy resin can double the thermal conductivity for a loading of only 1%, showing that nanotube composite materials may be useful for thermal management applications.

The first part of this manuscript discusses theoretical and experimental work on the specific heat of nanotubes. The section “Specific Heat” provides an introduction to specific heat. In the section “Phonon Density of States,” the theoretically derived phonon density of states of nanotubes and nanotube bundles is compared to that of 2-D graphene and 3-D graphite. In “Theoretically Derived Specific Heat,” the measured specific heat of nanotubes is compared to theoretical models.

The second part of this manuscript reviews the thermal conductivity of nanotubes. The first section provides an introduction to thermal conductivity. The section “Thermal Conductivity: Theory” discusses theoretical treatments of the thermal conductivity. “Measured  $K(T)$  of SWNTs” reviews measurements of the thermal conductivity of single-walled nanotubes, and “Measured  $K(T)$  of MWNTs” reviews measurements of the thermal conductivity of multiwalled nanotubes. Finally, “Applications” describes thermal conductivity measurements of nanotube-based composites.

## Specific Heat

The specific heat  $C(T)$  of a material is a sensitive probe of the low-energy excitations. In 3-D graphite, 2-D graphene, and nanotubes, phonons are the dominant excitations, and the phonon specific heat  $C_{\text{ph}}$  dominates  $C(T)$  at most temperatures.  $C_{\text{ph}}$  depends on the phonon density of states  $\rho(\omega)$ , and can be obtained by integrating  $\rho(\omega)$  together with a temperature-dependent convolution factor accounting for the temperature-dependent occupation of each phonon state<sup>[1]</sup>

$$C_{\text{ph}} = \int k_{\text{B}} \left( \frac{\hbar\omega}{k_{\text{B}}T} \right)^2 \frac{e^{\left(\frac{\hbar\omega}{k_{\text{B}}T}\right)} \rho(\omega) d\omega}{\left( e^{\frac{\hbar\omega}{k_{\text{B}}T}} - 1 \right)^2} \quad (1)$$

At a given temperature  $T$ , the convolution factor decreases from a value of 1 at  $\omega = 0$  to a value of  $\sim 0.1$  at  $\hbar\omega = k_{\text{B}}T/6$ , so that phonons above this energy do not appreciably contribute to the specific heat. In general, Eq. (1) must be evaluated numerically.

At low temperatures,  $C_{\text{ph}}$  probes only the lowest energy phonons. These are the acoustic modes, whose dispersion can often be expressed as a power law,  $\rho(\omega) \propto \omega^{\alpha}$ . For a single such mode, Eq. (1) simplifies to

$$C_{\text{ph}} \propto T^{(d/\alpha)} \quad (2)$$

where  $d$  is the dimensionality of the system. For a linearly dispersing mode ( $\alpha = 1$ ), the specific heat is linear in  $T$  for a 1-D system, and shows the familiar Debye  $T^3$  behavior for a 3-D system.

## Phonon Density of States

The phonon bandstructure of isolated nanotubes has been calculated by Saito et al.<sup>[2,3]</sup> and by Sanchez-Portal et al.<sup>[4]</sup> From the bandstructure, it is straightforward to calculate the phonon density of states. Fig. 1 shows the phonon density of states of a (10,10) nanotube, compared to the density of states of a single 2-D sheet of graphene. When a graphene sheet is “rolled” into a nanotube, the 2-D

**Fig. 1** Phonon density of states of an isolated SWNT (solid line), compared to a 2-D graphene sheet. *Source:* From Ref.<sup>[2]</sup>.

bandstructure folds into a large number of 1-D subbands. For a (10,10) tube, for instance, the six phonon bands (three acoustic and three optical) of the graphene sheet become 66 separate 1-D subbands. A direct result of this folding is that the nanotube density of states has a number of sharp peaks as a result of 1-D van Hove singularities, which are absent in graphene and graphite. In spite of the presence of these singularities, the overall density of states is similar at high energies, so that the high-temperature specific heat should be roughly equal as well. This is to be expected: the high-energy phonons are more reflective of carbon-carbon bonding than the geometry of the graphene sheet.

At low energies, the geometry of the nanotube causes the phonon structure to substantially differ from that of the parent graphene sheet. Fig. 2 shows the theoretically derived low-energy phonon bandstructure of an isolated (10,10) nanotube. There are four acoustic modes (those with  $\omega \rightarrow 0$  as  $k \rightarrow 0$ ). All four have a linear dispersion,  $\omega = \nu k$ , near the zone center. The longitudinal (LA) mode has  $\nu = 24$  km/sec, the (doubly degenerate) transverse (TA) mode has  $\nu = 9$  km/sec, and the “twist” mode has  $\nu = 15$  km/sec. The first (doubly degenerate) optical mode enters at 2.7 meV.

The inset to Fig. 2 shows the nanotube phonon density of states (solid line) derived from the bandstructure shown. Only the four acoustic modes are present below 2.7 meV, producing a constant density of states. At the band edge of each optical mode, the density of states displays a van Hove singularity characteristic of 1-D dispersion, and increases stepwise. By comparison, 2-D graphene and 3-D graphite have very different low-energy phonon structure. The dot-dashed line shows the phonon density of states for an isolated

**Fig. 2** Low-energy phonon bandstructure of an isolated (10,10) SWNT. The inset shows the low-energy phonon density of states, compared to that of 2-D graphene and 3-D graphite.

graphene sheet.<sup>[3]</sup>  $\rho(\omega)$  is large and roughly constant at low energy, and does not extrapolate to zero at zero energy. This is because a graphene sheet has an out-of-plane acoustic mode (corresponding to a sheet-rolling motion) that is quadratic in energy. For a 2-D system, this corresponds to a constant  $\rho(\omega)$ . The phonon density of states for 3-D graphite, shown as the dashed line in the inset to Fig. 2, is significantly smaller than that of 2-D graphene, and approaches zero at  $k = 0$ . This is because interlayer coupling introduces dispersion in the  $z$  direction, and moves low-energy states upward in energy. The characteristic energy scale for this process is the Debye energy  $E_D^{\perp}$  of the interlayer modes, which is roughly 10 meV.

By analogy to the case of graphite, intertube interaction in bundles should depress the low-energy density of states in SWNT bundles. The characteristic energy for this process is the Debye energy of intertube modes. Because of the heterogeneous nature of nanotube bundles, it is difficult to calculate these modes theoretically. Mizel et al.<sup>[5]</sup> considered the case in which the coupling is graphite-like. By adjusting standard coupling constants for graphite for the case of tubular structures, they derived a bandstructure that has  $E_D^{\perp} \sim 5$  meV. However, because of issues of incommensurability between neighboring nanotubes, the true intertube coupling is likely to be weaker than this. Fig. 3 shows the 3-D dispersion of the nanotube acoustic modes calculated by Mizel et al.

**Fig. 3** Calculated low-energy phonon bandstructure of a SWNT bundle, for the case of graphite-like (“strong”) coupling. Source: From Ref.<sup>[5]</sup>.

### Theoretically Derived Specific Heat

For a given  $\rho(\omega)$ , it is straightforward to calculate  $C(T)$  using Eq. (1). The lines in Fig. 4 show the specific heat calculated from the known phonon bandstructure of graphene and graphite, from the predicted bandstructure of an isolated SWNT, and from the predicted

**Fig. 4** Calculated specific heat (lines) of graphene, isolated SWNTs, graphite, and strongly coupled SWNT bundles. The solid points represent the measured specific heat of a bulk sample of SWNTs. Source: From Ref.<sup>[7]</sup>.

bandstructure of a SWNT bundle in the case of graphite-like (“strong”) coupling. At temperatures above  $\sim 100$  K, the specific heat of all four materials is quite similar. However, at lower temperatures, the specific heats diverge substantially. The isolated graphene sheet displays the largest specific heat, which is roughly linear in  $T$  because of the 2-D quadratic sheet-rolling mode. The isolated nanotube specific heat is smaller, as a result of the absence of the rolling mode. At the lowest temperatures, the isolated nanotube  $C(T)$  is linear in  $T$ . The contribution of each acoustic mode to  $C(T)$  can be analytically expressed:<sup>[6]</sup>

$$C_{\text{ph}} = \frac{\pi k_{\text{B}}^2 T}{\hbar \nu \rho_{\text{m}}} \quad (3)$$

where  $\rho_{\text{m}}$  is the linear mass density. Above  $\sim 8$  K, the slope of  $C(T)$  increases, as the optical subbands begin to contribute. The linear behavior at low  $T$  is a direct signature of the 1-D quantized nature of the nanotube phonon bandstructure. Interlayer coupling (in graphite) and intertube coupling (in strongly coupled bundles) depresses the  $C(T)$  at low  $T$ . In real samples, the temperature at which the measured  $C(T)$  diverges from the single-tube curve provides measure of the actual intertube coupling.

### Electronic Specific Heat

A metallic SWNT is a one-dimensional metal with a constant density of states near the Fermi level. At low temperatures, it will have an electronic heat capacity that is linear in temperature, with a magnitude given by:<sup>[6]</sup>

$$C_{\text{el}} = \frac{4\pi k_{\text{B}}^2 T}{3\hbar \nu_{\text{F}} \rho_{\text{m}}} \quad (4)$$

where  $\nu_{\text{F}}$  is the Fermi velocity. Because there are four acoustic phonon modes, the ratio between the phonon and electron specific heat is

$$\frac{C_{\text{ph}}}{C_{\text{el}}} \approx \frac{\nu_{\text{F}}}{\nu_{\text{ph}}} \approx 100 \quad (5)$$

so that, as expected, the phonon contribution will dominate the electron contribution.

### Measured Specific Heat of SWNTs

The solid circles in Fig. 4 represent the measured specific heat of a bulk sample of highly purified single-walled nanotubes over the range 2–300 K.<sup>[7]</sup> The measured  $C(T)$  data agree with all of the theoretical curves

**Fig. 5** Measured specific heat of SWNTs at low temperature, fit with a simplified model. The fitting parameters are given in the text. *Source:* From Ref.<sup>[7]</sup>.

at high  $T$ , as is to be expected; this is a good confirmation that experimental errors such as sample contamination were not significant. At low  $T$ , the measured  $C(T)$  follows the predicted curve for isolated SWNTs over almost the entire temperature range, diverging below the single-tube curve only below  $\sim 5$  K. This surprising result indicates that the tube-tube coupling in real samples is substantially weaker than would be expected from a straightforward analogy to graphite.

Fig. 5 highlights the specific heat data at low temperature. The measured  $C(T)$  shows a linear temperature dependence from 2 to 8 K, with an upturn above 8 K. This behavior is a direct signature of the 1-D quantized nature of the SWNT phonon bandstructure, as discussed above. The lines in Fig. 5 represent the results of fitting the measured data to a simplified theory that takes into account intertube coupling. The low-energy phonon structure is simplified to include two phonon modes: a fourfold-degenerate acoustic mode with (high) on-tube Debye energy  $E_D$  and (low) transverse Debye energy  $E_D^\perp$ ; and a doubly degenerate optical subband with a band minimum at  $E_{\text{sub}}$ . The lines shown are obtained after varying all three parameters to obtain the best fit to the data. The dot-dashed line represents the contribution from the acoustic modes, with  $E_D = 92$  meV and  $E_D^\perp = 1.2$  meV. Its contribution is roughly cubic at low temperatures, then roughly linear above  $\sim 2$  K, corresponding to the saturation of the intertube modes. The dashed line represents the contribution from the optical mode, with  $E_{\text{sub}} = 4.1$  meV. This mode begins to contribute at  $\sim 7$  K, and the sum of the two contributions (solid line) fits the data well over

the entire range from 2–12 K, above which it can be expected that other optical subbands will begin to contribute.

The values for the fitting parameters in this model are directly related to the mechanical properties of nanotube bundles. The measured value of  $E_D$  (92 meV) agrees well with the value of 103 meV that can be derived from theory, confirming the high phonon velocity in the tubes, which is a direct result of their high Young's modulus and low density. On the other hand, the value of  $E_D^\perp$  is much weaker than would be expected from a simple analogy to graphite. This indicates that coupling between the tubes in bundles is very weak, an issue that will need to be carefully considered for applications such as high-strength composites. The measured value of  $E_{\text{sub}}$  (4.1 meV) is slightly larger than the theoretically derived value of 2.7 meV, which may be a result of mode stiffening due to radial tube-tube interaction. In fact, the measured value is in good agreement with theoretical calculations for nanotube bundles.<sup>[8]</sup> An unresolved issue is the seeming contradiction between the weak tube-tube coupling implied by the low transverse Debye energy, and the stiffening of the first optical mode. It may be that bundles are relatively well coupled radially, but are weak in shear. Detailed theoretical investigation of this matter is still needed.

## THERMAL CONDUCTIVITY

Because of the high thermal conductivity of diamond and graphite, it is interesting to examine whether nanotubes exhibit high thermal conductivity, a property that might complement their extraordinary electrical and mechanical properties. This property has been addressed theoretically for single tubes, experimentally for bulk samples of SWNTs, and experimentally for individual multiwalled nanotubes

In general, the thermal conductivity  $K$  is a tensor quality, but for this discussion, it is only important to consider the diagonal elements:

$$K_{zz} = \sum C \nu_z^2 \tau \quad (6)$$

where  $C$  is the specific heat, and  $\nu_z$  and  $\tau$  are the group velocity ( $\nu = d\omega/dk$ ) and relaxation time of a given phonon state. At low temperatures ( $T \ll \Theta_D$ ), the relaxation time is determined by scattering off of fixed impurities, defects, sample boundaries, etc. and is roughly constant. Therefore in ordinary materials, the low-temperature thermal conductivity has the same temperature dependence as the specific heat. However, in anisotropic materials, this relationship does not strictly hold. Because the contribution of each state is

weighted by the scattering time and the square of the velocity, the thermal conductivity preferentially samples states with high  $v$  and  $\tau$ . For instance, in graphite, the thermal conductivity parallel to the basal planes is only weakly dependent on the interlayer phonons. In SWNT bundles, it is likely that  $K(T)$  depends only on the on-tube phonons, rather than the intertube modes.

Thermal conductivity is of particular interest in low-dimensional systems. For a 1-D ballistic electronic channel, the electronic conductance is quantized, with a universal value of

$$G_0 = \frac{2e^2}{h} \quad (7)$$

Similarly, for a single ballistic 1-D channel, the thermal conductance is independent of materials parameters, and there exists a quantum of thermal conductance, which is linear in temperature.

$$G_{\text{th}} = \frac{\pi^2 k_B^2 T}{3h} \quad (8)$$

Conditions for observation of this quantum were first examined in detail by Rego and Kirczenow.<sup>[9]</sup> Using lithographically defined nanostructures, Schwab et al.<sup>[10]</sup> confirmed this value experimentally.

At high temperatures, three-phonon Umklapp scattering begins to limit the phonon relaxation time. Therefore the phonon thermal conductivity displays a peak and decreases with increasing temperature. Umklapp scattering requires production of a phonon beyond the Brillouin zone boundary; because of the high Debye temperature of diamond and graphite, the peak in the thermal conductivity of these materials is near 100 K, significantly higher than for most other materials. In less crystalline forms of graphite, such as carbon fibers, the peak in  $K(T)$  occurs at higher temperatures, because defect scattering remains dominant over Umklapp scattering to higher temperature.<sup>[11]</sup> In low-dimensional systems, it is difficult to conserve both energy and momentum for Umklapp processes,<sup>[12]</sup> and so it may be possible that Umklapp scattering is suppressed in nanotubes relative to 2-D or 3-D forms of carbon.

A measurement of  $K(T)$  yields the combined contribution of the electrons and phonons. However, a simultaneous measurement of the electrical conductivity  $\sigma$  provides a measure of the electron thermal conductivity  $K_e$  from the Wiedemann–Franz law<sup>[1]</sup>

$$\frac{K_e}{\sigma T} \approx L_0 = 2.45 \times 10^{-8} \text{ (V/K)}^2 \quad (9)$$

In this way, the phonon contribution can be deduced by subtracting the electronic contribution from the total measured thermal conductivity.

Fig. 6 Calculated thermal conductivity of an isolated SWNT, as a function of temperature. Source: From Ref.<sup>[13]</sup>.

### Thermal Conductivity: Theory

Berber et al.<sup>[13]</sup> have calculated the phonon thermal conductivity of isolated nanotubes. Fig. 6 shows the results of theoretical calculations of the phonon thermal conductivity of an isolated SWNT.  $K(T)$  peaks near 100 K, and then decreases with increasing temperature. The value of  $K$  at the peak (37,000 W/m K) is comparable to the highest thermal conductivity ever measured (41,000 W/m K for an isotopically pure diamond sample at 104 K). Even at room temperature, the thermal conductivity is quite high (6600 W/m K), exceeding the reported room-temperature thermal conductivity of isotopically pure diamond by almost a factor of 2.

Fig. 7 shows the calculated nanotube thermal conductivity compared to the calculated thermal conductivity of a single plane of graphene and that of 3-D graphite. In graphite, the interlayer interactions quench the thermal conductivity by nearly 1 order of magnitude. It is likely that the same process occurs in nanotube bundles. Thus it is significant that the

Fig. 7 Calculated nanotube thermal conductivity (solid line) compared to the thermal conductivity of a 2-D graphene sheet (dot-dashed line) and 3-D graphite (dotted line). Source: From Ref.<sup>[13]</sup>.

coupling between tubes in bundles is weaker than expected. It may be that this weak coupling, which is problematic for mechanical applications of nanotubes, is an advantage for thermal applications.

### Measured $K(T)$ of SWNTs

Fig. 8 shows the measured  $K(T)$  of a bulk sample of SWNTs.<sup>[14–16]</sup>  $K(T)$  increases with increasing temperature to 300 K; the decreasing slope at high temperature may indicate the onset of Umklapp scattering. It is difficult to ascertain the intrinsic thermal conductivity of an individual tube from these measurements, although they point strongly to a very high value. In disordered “mat” samples, the room-temperature thermal conductivity is  $\sim 35$  W/m K.<sup>[15]</sup> However, the nanotubes in such a sample are highly tangled, and the thermal path is considerably longer than the direct distance between points. This effect can be reduced by aligning the nanotubes; in samples where the nanotubes have been aligned by filtration in a magnetic field, the thermal conductivity is significantly higher, above 200 W/m K,<sup>[14]</sup> which is comparable to that of a good metal. Even in these samples, the thermal conductivity is likely to be limited by tube–tube junctions, so that the intrinsic single-tube thermal conductivity is certainly higher. Significantly, the temperature dependence of the thermal conductivity is roughly the same for both types of samples, suggesting that the measured  $K(T)$  reflects the intrinsic temperature dependence of the single-tube  $K(T)$ .

Using Eq. (7), it is possible to calculate the electronic contribution to the thermal conductivity. In all

**Fig. 8** Temperature-dependent thermal conductivity of a bulk sample of SWNTs which have been aligned by filtration in a high magnetic field. *Source:* From Ref.<sup>[14]</sup>.

**Fig. 9** Thermal conductivity divided by temperature for SWNT samples with different average diameters. The smaller-diameter tubes exhibit linear  $K(T)$  up to higher temperature, consistent with quantization effects. *Source:* From Ref.<sup>[16]</sup>.

samples, simultaneous measurement of the electrical and thermal conductivity shows that the electronic contribution to the thermal conductivity is only  $\sim 1\%$  of the total, so that phonons dominate  $K(T)$  at all temperatures.

At low temperature, SWNT samples exhibit a linear  $K(T)$ , strongly suggesting quantum effects. Because of the large number of nanotubes in a bulk sample, it is not possible to directly observe the thermal conductivity quantum measured by Schwab et al.<sup>[10]</sup> However, it is possible to measure the  $K(T)$  of SWNT samples with varying diameters: the phonon subband splitting is higher in smaller-diameter tubes, so that the linear  $K(T)$  behavior should extend to higher temperature. Fig. 9 shows the thermal conductivity divided by temperature,  $K/T$ , of two nanotube samples, one with average diameter 1.2 nm and the other with average diameter 1.4 nm.<sup>[16]</sup> In both samples,  $K/T$  approaches a constant value at low  $T$ , just as is expected for 1-D channels. At higher temperatures,  $K/T$  increases as more phonon modes contribute. In the 1.2-nm diameter sample, the upturn in  $K/T$  occurs  $\sim 5$  K higher than in the 1.4-nm diameter sample. This shift provides additional evidence that the low- $T$  linear behavior is true 1-D thermal conductivity. However, one unresolved issue is the different temperature ranges of the 1-D regime in heat capacity vs. thermal conductivity. For constant scattering time, the temperature ranges should be approximately identical. One possible explanation is that the phonons in the optical bands are much more strongly scattered, and so do not begin to contribute to the thermal conductivity until higher temperatures.

### Measured $K(T)$ of MWNTs

Because of the large diameter of MWNTs, the temperature scale for quantum effects should be quite small, and their thermal conductivity should be that of a 2-D system with linear acoustic phonons. The  $K(T)$  of such a 2-D sheet should follow a  $T^2$  temperature dependence. Graphite shows a temperature dependence closer to  $T^{2.3}$ , because of the effect of the quadratically dispersing out-of-plane mode.<sup>[17]</sup> As was discussed above, interlayer effects can be ignored when considering the thermal conductivity.

Yi et al.<sup>[18]</sup> have measured  $K(T)$  for bulk samples of MWNTs. They found a roughly  $T^2$  temperature dependence up to 100 K, as expected. The room-temperature thermal conductivity of these samples is only  $\sim 25$  W/m K, possibly as a result of the effects of tube-tube contacts, or also of the incomplete graphitization in their samples.

Recently, Kim et al.<sup>[19]</sup> have used a microfabricated structure (inset to Fig. 10) to directly measure the thermal conductivity of individual MWNTs. The data in Fig. 10 show the measured thermal conductivity of

one MWNT.  $K(T)$  increases as  $T^2$  up to  $\sim 100$  K, peaks near 300 K, and decreases above this temperature. Again, the quadratic temperature dependence is exactly what would be expected for large-diameter nanotubes that essentially act as 2-D sheets. The room-temperature value of  $K(T)$  is over 3000 W/m K.

### Applications

The high thermal conductivity of nanotubes may be useful for a number of thermal management applications, such as heat sinking of silicon processors, or to increase the thermal conductivity of plastics in such areas as housing for electric motors. Although many groups have studied nanotube-epoxy composite materials for their mechanical properties, their possible thermal properties have only recently attracted attention.

Biercuk et al.<sup>[20]</sup> have measured the thermal conductivity of epoxy resin loaded with SWNTs. Fig. 11 shows the enhancement in the thermal conductivity for loadings up to 1% SWNTs, and the enhancement

Fig. 10 Measured thermal conductivity of a single MWNT. Source: From Ref.<sup>[19]</sup>.

**Fig. 11** Enhancement of the thermal conductivity of epoxy resin as a function of loading by SWNTs and by carbon fibers. Source: From Ref.<sup>[20]</sup>.

for identical loadings of graphitic carbon fibers. Addition of 1% SWNTs doubles the thermal conductivity of the epoxy, while the same loading of carbon fibers provides only a  $\sim 40\%$  increase. This initial result is quite promising for the development of composites for thermal management.

## CONCLUSION

The thermal properties of carbon nanotubes are dominated by phonons. The measured specific heat of SWNTs closely matches calculations based on the phonon bandstructure of isolated nanotubes, and shows direct evidence of 1-D quantization of the phonon bandstructure. This shows that coupling between nanotubes in a bundle is relatively weak; detailed modeling permits direct measurement of the tube-tube coupling strength, as well as the low-energy phonon structure. Theoretical work predicts a room-temperature thermal conductivity of 6600 W/m K for individual nanotubes. Measurements show a room-temperature thermal conductivity over 200 W/m K for bulk samples of single-walled nanotubes, and over 3000 W/m K for individual multiwalled nanotubes. Addition of nanotubes to epoxy resin can double the thermal conductivity for a loading of only 1%, showing that nanotube composite materials may be useful for thermal management applications.

# Catalysis by Supported Gold Nanoclusters

D. Wayne Goodman

Department of Chemistry, Texas A&M University, College Station, Texas, U.S.A.

## INTRODUCTION

The physical and chemical properties of supported Au clusters are markedly sensitive to cluster size and morphology. To investigate the origin of the unique properties of nanosized Au clusters, model catalysts consisting of Au clusters of varying sizes have been prepared on single crystal TiO<sub>2</sub>(110) and ultrathin films of single crystalline TiO<sub>2</sub>, SiO<sub>2</sub>, and Al<sub>2</sub>O<sub>3</sub>. The morphology, electronic structure, and catalytic properties of these supported Au clusters have been investigated using an array of surface analytical techniques with particular emphasis to the unique properties of clusters <5.0 nm in size. These studies illustrate the novel and unique physical and chemical properties of nanosized supported metal clusters.

## BACKGROUND

Unique electronic and chemical properties are known to develop in solids when the dimensions of the solid reach the nanoscale.<sup>[1–3]</sup> These changes, which include discrete electronic structures, modified physical structures, and altered chemical reactivities, manifest themselves as new physical and chemical properties not observed in the “bulk” form of the material. Developing an understanding and ability to control the key features of nanoscale catalysts are daunting scientific challenges, yet could lead to the long-sought goals of optimum catalytic activities combined with highly specific selectivities.

It is well established that ultrasmall metal clusters on supports have catalytic properties distinct from those properties of large bulk-like particles, as illustrated by the selective oxidation of propylene to propylene oxide by gold,<sup>[4]</sup> alkene and arene hydrogenation catalysis,<sup>[5]</sup> and CO oxidation.<sup>[6–8]</sup> In these examples, the catalytic properties improve as the clusters become smaller. On the other hand, a reduction in size of the metal cluster can lead to less desirable catalytic properties as seen for ammonia synthesis on iron.<sup>[9]</sup> Various explanations have been offered to account for the unique properties of nanoscaled metal catalysts,<sup>[6–8]</sup> however, much remains to be understood. Clearly, experimental and theoretical studies will be

required to develop an in-depth understanding of the unique catalytic properties of limited dimensional solids.

The complexity of high surface area technical catalysts makes developing an atomic-level understanding an extremely challenging problem. Surface science studies offer atomic-level information regarding the details of catalytically relevant surfaces, but have traditionally focused on well-defined, single-crystal metal surfaces to address the relationship between reactivity and surface morphology. Single crystal studies, however, obviously do not address the size-dependent structural and electronic properties that are unique to metal nanoparticles. Toward the goal of understanding the properties of supported metal clusters, several groups have begun investigations of metal clusters supported on planar oxide surfaces.<sup>[10–14]</sup> Our group, in particular, has focused extensively on the unique properties of supported gold clusters for selective oxidation reactions.<sup>[15]</sup>

Our approach to studying supported metal clusters has been to combine ultrahigh vacuum (UHV) surface analytical methods with an elevated pressure reactor system shown schematically in Fig. 1. The design has been described in detail.<sup>[14,16]</sup> This arrangement allows pressures to 1 bar in the high-pressure cell without significantly altering the vacuum integrity of the UHV chamber. This arrangement facilitates the acquisition of kinetic data at elevated pressures using a conventional gas chromatograph. Polarization modulation infrared reflection absorption spectroscopy (PM-IRAS) is available as a probe of surface species present under reaction conditions.<sup>[13]</sup>

The oxide surfaces used as supports in these studies were either a TiO<sub>2</sub>(110) single crystal (Commercial Crystal Laboratories) or single crystalline TiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, or SiO<sub>2</sub> thin films synthesized on a refractory metal substrate. Thin film TiO<sub>2</sub> was deposited onto a Mo(110) single crystal.<sup>[17]</sup> Similarly, the SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub> supports were epitaxially grown as thin films deposited onto Mo(110)<sup>[18–20]</sup> and Re(0001)<sup>[21–23]</sup> substrates, respectively. Details of the sample mounting, cleaning, etc. can be found elsewhere.<sup>[14]</sup>

The Au doser was constructed by wrapping high-purity Au wire (99.99%) around 0.010-diameter tungsten filaments (H&R Cross), which were then

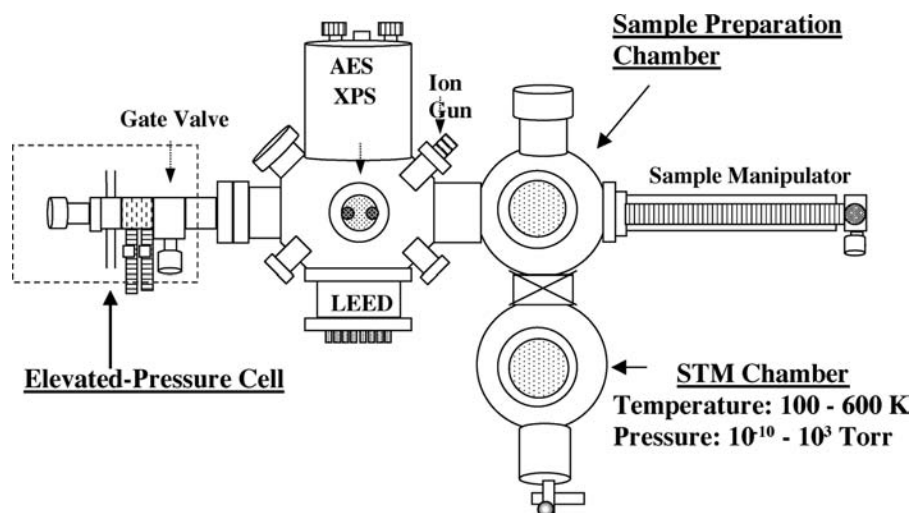

Fig. 1 Schematic of the combined surface analytical chamber with an elevated pressure reactor.

resistively heated in vacuum by passing current through the filament wires. The Au wire wrapping was melted and thoroughly outgassed to remove impurities prior to use. The Au flux was calibrated via integrating the Au temperature-programmed desorption peak area from a Re(0001) substrate<sup>[15]</sup> and also using the metal-to-substrate Auger intensity “break” to denote the first monolayer equivalent (ML).<sup>[24]</sup>

This entry focuses on our recent studies on these model catalysts to understand the special properties that nanosized clusters exhibit with respect to a variety of catalytic reactions.

## MODEL CATALYSTS: RESULTS AND DISCUSSION

### Synthesis

The synthesis of a typical model catalyst used in these studies is shown schematically in Fig. 2. The procedure

begins with a refractory metal substrate, such as Mo, Ta, or Re, that has been cleaned by standard procedures and verified clean with surface analytical techniques. The structure of the substrate is chosen specifically to match the particular oxide film to be grown since crystal orientation and the nature of the interface or critical parameters in obtaining a high-quality film. A thin metal oxide film, typically 1–10 nm thick, is then deposited onto the metal substrate by vapor deposition of the parent metal in an O<sub>2</sub> environment. Thin films of SiO<sub>2</sub>,<sup>[18–20]</sup> Al<sub>2</sub>O<sub>3</sub>,<sup>[21–23]</sup> Ti<sub>x</sub>O<sub>y</sub>,<sup>[17,25]</sup> MgO,<sup>[26–29]</sup> NiO,<sup>[30–33]</sup> and Fe<sub>x</sub>O<sub>y</sub>,<sup>[34]</sup> have been prepared using this methodology. Finally, metal clusters are formed on the oxide thin film by vapor depositing the metal of choice. By the judicious control of the metal deposition parameters, metal clusters of varying size can be routinely achieved.<sup>[14]</sup> A variety of oxide/metal systems have been synthesized in our laboratories including Cu/SiO<sub>2</sub>,<sup>[35,36]</sup> Pd/SiO<sub>2</sub>,<sup>[37]</sup> Ni/SiO<sub>2</sub>,<sup>[38]</sup> Pd/Al<sub>2</sub>O<sub>3</sub>,<sup>[39–41]</sup> Cu/Al<sub>2</sub>O<sub>3</sub>,<sup>[23,39]</sup> Au/Al<sub>2</sub>O<sub>3</sub>,<sup>[39]</sup> Ni/Al<sub>2</sub>O<sub>3</sub>,<sup>[42]</sup> Au/TiO<sub>2</sub>,<sup>[43]</sup> and Pd/MgO.<sup>[43]</sup>

## Characterization

Scanning tunneling microscopy (STM) is an indispensable technique for characterizing planar surfaces with sufficient conductivity. Fig. 3A shows a CCT-STM micrograph of 0.25 ML Au deposited onto a single crystal  $\text{TiO}_2(110)$ .<sup>[8,15]</sup> The deposition was performed at 300 K followed by an anneal of the  $\text{TiO}_2$  surface to 850 K. Three-dimensional (3-D) Au clusters have average diameters of  $\sim 2.6$  and  $\sim 0.7$  nm height (corresponding to 2–3 atoms thick) and preferentially nucleate on step edges. Quasi-two-dimensional (2-D) clusters are characterized by heights of 1–2 atomic layers.<sup>[44]</sup> An enlarged STM micrograph ( $150 \times 150 \text{ nm}^2$ ) of a Au-covered (1.0 ML)  $\text{TiO}_2(110)$  surface is shown in Fig. 3B. Hemispherical clusters with a narrow size distribution grow preferentially along the step edges with clusters on the flat terraces evident as well. At a Au coverage of 1.0 ML, more than 60% of the substrate is still metal-free and separated by mono-atomic steps, consistent with 3-D clustering or a Volmer–Weber (VW) growth mode.

Cluster size and density were studied as a function of metal coverage. With increasing Au coverage, the average cluster size (diameter) increases from 2.0 nm for 0.10 ML Au to 5.4 nm for 4.0 ML Au. However, the cluster density rapidly increases upon deposition of 0.10 ML Au, while the cluster density remains essentially constant at higher Au coverages ( $>1.0$  ML). With an increase in the Au coverage from 0.10 to 0.25 ML, the cluster density increases by  $\sim 30\%$ , with a further increase of  $\sim 50\%$  from 0.25 to 1.0 ML Au. The cluster density reaches a maximum at  $\sim 2.0$  ML where  $\sim 70\%$  of the substrate surface is covered by Au clusters. At higher Au coverages, the cluster density declines because of cluster coalescence and agglomeration. Approximately 60% of the nucleating sites are populated at a coverage of 0.25 ML.<sup>[45]</sup>

The cluster size, in contrast to cluster density, increases continuously with Au coverage. Increasing the Au deposition from 0.10 to 2.0 ML increases the cluster size from 2.0 to 4.5 nm. A rapid increase in Au cluster size occurs for very low Au coverages (below 0.10 ML). Higher Au coverages correlate with a limited cluster growth. It is noteworthy that the increase in cluster volume is not proportional to the increase in cluster size. For example, a 22% increase in the average cluster diameter, from 3.7 (1.0) to 4.5 nm (2.0 ML), corresponds to an 80% increase in the average cluster volume. This correlation between Au coverage and Au cluster diameter demonstrates that vacuum deposition can produce a specific size range and shape of Au clusters for model catalyst studies.<sup>[45]</sup>

## Catalytic Properties

A correlation has been observed between the Au cluster size and the catalytic activity for the partial oxidation of CO on  $\text{Au}/\text{TiO}_2(110)-(1 \times 1)$ . Fig. 4A shows a plot of the activity for CO oxidation [expressed as (product molecules)  $\times$  (total Au atoms on surface sites) $^{-1} \text{sec}^{-1}$  or turnover frequency (TOF)] at 350 K as a function of the size of Au clusters supported on a  $\text{TiO}_2(110)-(1 \times 1)$  substrate.<sup>[8,46]</sup> The CO and  $\text{O}_2$  (1:5 mixture of  $\text{CO}:\text{O}_2$ ) reaction was carried out over  $\text{Au}/\text{TiO}_2$  catalysts at 40-Torr total pressure.<sup>[8,46,47]</sup> A thin film of  $\text{TiO}_2$  epitaxially grown on a  $\text{Mo}(100)$  substrate<sup>[17]</sup> onto which Au clusters were deposited was used for the reaction kinetics measurements carried out in the reactor portion of Fig. 1. Scanning tunneling microscopy measurements of Au deposited onto a  $\text{TiO}_2(110)-(1 \times 1)$  single crystal were carried out in parallel with the kinetic measurements. The product ( $\text{CO}_2$ ) was extracted from the reactor with a vacuum syringe, compressed and analyzed with a

**Fig. 3** (A) A CCT-STM image of a 0.25 ML Au deposited onto  $\text{TiO}_2(110)-(1 \times 1)$  prepared just prior to a  $\text{CO}:\text{O}_2$  reaction. The sample had been annealed to 850 K for 2 min. (B) General morphology of Au clusters on the  $\text{TiO}_2(110)$  surface (2.0 V, 2.0 nA). The evaporation rate was  $0.083 \text{ ML min}^{-1}$  and the Au coverage was 1.0 ML.

**Fig. 4** (A) The activity for CO oxidation at 350 K as a function of Au cluster size supported on  $\text{TiO}_2(110)-(1 \times 1)$ . A 1:5  $\text{CO}:\text{O}_2$  mixture was used at a total pressure of 40 Torr. Activity is expressed as  $(\text{product molecules}) \times (\text{total Au atoms})^{-1} \text{sec}^{-1}$ . (B) Histogram of the distribution of cluster sizes and morphologies.

GC. For each point in Fig. 4A, a particular Au cluster size was prepared then subjected to the  $\text{CO}_2:\text{O}_2$  reaction. The cluster sizes of the Au particles and coverage of the surface sites obtained from parallel STM imaging experiments were used to calculate the TOF. The activity of the  $\text{Au}/\text{TiO}_2$  catalysts exhibits a maximum TOF at an average Au cluster diameter of  $\sim 3.5$  nm and decreases with an increase in diameter.

Fig. 4B is a histogram that shows the distribution of Au clusters with sizes ranging from 2.0 to 4.0 nm that are specifically two atoms thick (with diameters between 2.5 and 3.0 nm). The close correspondence between the maximum in the histogram and the maximum in the reactivity data is strongly suggestive that 2-atom-thick Au structures are optimally active for CO oxidation.<sup>[8]</sup>

Fig. 5 shows a plot of the scanning tunneling spectroscopy (STS) band gaps measured over the cluster size regime used for the  $\text{CO}:\text{O}_2$  reactions of Fig. 4A. There is a clear correlation between the onset of

**Fig. 5** Cluster band gaps measured by STS as a function of Au cluster size supported on  $\text{TiO}_2(110)-(1 \times 1)$ . The band gaps were obtained while the corresponding topographic scan was acquired on various Au coverages ranging from 0.2 to 4.0 ML. ●: Two-dimensional (2-D) clusters; ◆: 3-D clusters, 2-atom layers in height; ▲: 3-D clusters, 3-atom layers or greater in height.

catalytic activity and the observed metal-to-non-metal transition in the supported Au clusters. The average Au cluster size where non-metallic properties become apparent is 3.5 nm in diameter and 1.0 nm in height, corresponding to approximately 300 atoms per cluster. The square data in Fig. 5 are for those clusters two layers thick ranging in size from 2.0 to 4.0 nm in diameter and are those clusters which exhibit optimum catalytic activity for the CO oxidation reaction. The STS-measured band gaps of this group of clusters range from 0.2 to 0.6 V. These results demonstrate that electronic properties as a function of cluster size play a crucial role in defining the catalytic reactivity of small clusters.<sup>[8,46]</sup>

### Adsorbate Binding Energies

Thermodynamic data regarding the adsorption of CO on  $\text{Au}/\text{TiO}_2$  catalysts with varying Au cluster sizes have been acquired with TPD using the well-known Redhead method<sup>[48]</sup> and with IRAS using the Clausius–Clapeyron relationship.<sup>[49,50]</sup> Results for these measurements are displayed in Fig. 6. CO adsorption on Au clusters larger than  $\sim 4.0$  nm behaves as bulk Au. However, as the clusters become smaller, the heat of CO adsorption increases from  $12 \text{ kcal mol}^{-1}$  to a maximum of  $19 \text{ kcal mol}^{-1}$  for clusters  $\sim 3.0$  nm in diameter.<sup>[51]</sup> Both sets of data in Fig. 6 suggest a marked increase in the adsorption energy with a decrease in cluster size; however, the results derived using the Clausius–Clapeyron relationship show a maximum that correlates remarkably close to the maximum observed in the reactivity measurements of Fig. 4A. A similar increase in the binding energy of  $\text{O}_2$  with a decrease in the Au cluster size on  $\text{TiO}_2$  has been observed recently.<sup>[52]</sup> In any case, clearly, the

Fig. 6 CO heats of adsorption as a function of Au cluster size on a  $\text{TiO}_2(110)$  support.

effects of cluster size on the adsorption properties of Au clusters are significant and likely a key to the altered catalytic properties displayed by ultrasmall Au clusters.

### Electronic Properties

Fig. 7A shows the core level binding energies (BE) for the Au  $4f_{7/2}$  core level as a function of Au cluster coverage on a  $\text{TiO}_2(110)$  surface.<sup>[15]</sup> A +0.8-eV BE shift is evident for small clusters (0.02 ML, ~2-nm diameter) with a gradual shift to the bulk value of Au  $4f_{7/2} = 84.0 \text{ eV}$ <sup>[53]</sup> with increasing cluster size (6 ML Au coverage, ~5-nm diameter). This increase in the BE with a decrease in cluster size is consistent with an earlier XPS study by Mason<sup>[54]</sup> where the relative BE shifts of Au clusters (of varying sizes) supported on  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$  were shown to depend upon the relative abilities of the substrate to screen

the outgoing photoelectrons (final state effects). However, a comparison of the relative core level BE shifts of the Au/ $\text{TiO}_2$  with the Au/ $\text{SiO}_2$  shows that the BE shift for Au/ $\text{SiO}_2$  is significantly larger (+1.6 eV) than that for Au/ $\text{TiO}_2$  (+0.8 eV) in the transition from large to small cluster sizes. Differences in the magnitudes of these Au cluster core level BE shifts are believed to result from the relative strengths of the interaction of Au with the two metal oxide supports. Recent theoretical calculations<sup>[55]</sup> predict an initial state *reduction* in the BE of 1.1–1.5 eV for the  $4f_{7/2}$  core levels of Au on  $\text{TiO}_2$ . As shown in Fig. 7B, this relatively large initial state contribution to the core level shift of Au/ $\text{TiO}_2$  relative to Au/ $\text{SiO}_2$  is sufficient to account for the 0.8-eV difference observed for the total BE shifts measured for these two oxide supports. Fig. 8 shows the total density of states (TDOS) calculated for bulk Au compared with Au adsorbed on  $\text{TiO}_2$ .<sup>[55]</sup> For adsorbed Au, the Au  $d$  bands are much closer to  $E_f$  because of the charge polarization in the

Fig. 7 (A) XPS binding energies of the Au  $4f_{7/2}$  core level as a function of Au cluster coverage (ranging from 0.02 ML—bulk) on  $\text{TiO}_2(110)$ . (B) XPS binding energies for Au clusters on  $\text{TiO}_2$  compared with Au clusters on  $\text{SiO}_2$ . The histogram takes into account the initial and final contributions to the observed overall BE shifts for Au on the two supports.

**Fig. 8** The total density of states (TDOS) of Au/TiO<sub>2</sub>(110) in the top panel and the local density of states for Au on TiO<sub>2</sub>(110) compared with Au in bulk Au(001).

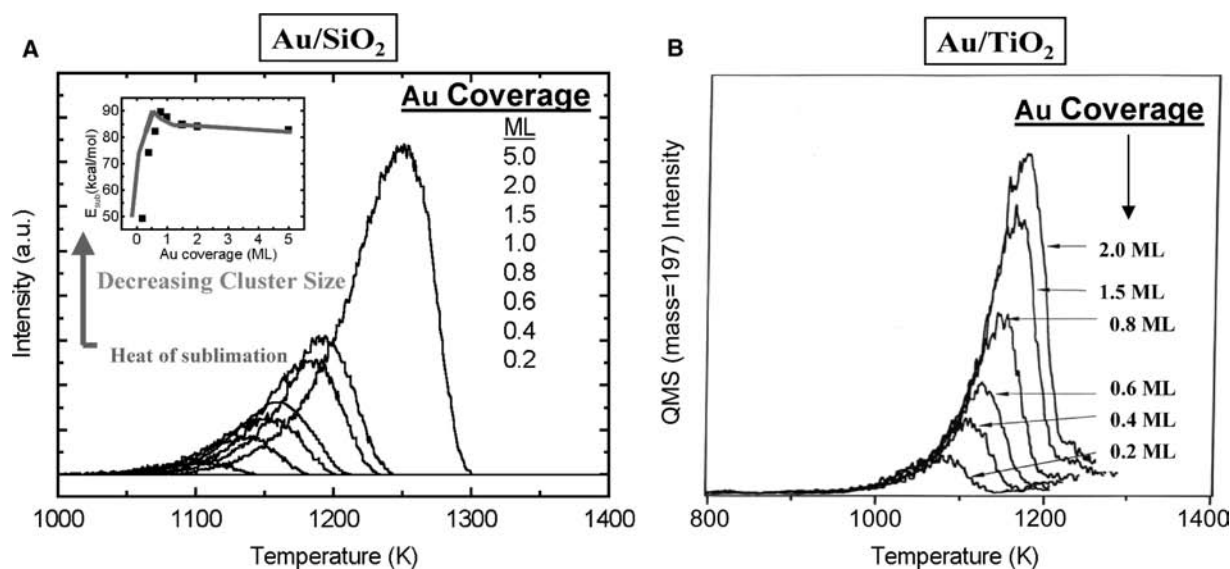

interfacial region and a subsequent increase of the potential in the adlayer. Such a large energy shift of the Au 5*d* band toward the  $E_f$ , as discussed by Hammer and Norskov,<sup>[56]</sup> should strongly alter the surface chemical properties of Au/TiO<sub>2</sub> from those of a clean bulk Au surface.

### Cluster Sublimation Energies

Temperature-programmed desorption (TPD) is a useful tool for obtaining detailed information on adsorbate-surface bonding and on adsorbate-adsorbate interactions, desorption kinetics, and determining binding energies of metals adsorbed onto surfaces. Temperature-programmed desorption binding energy determinations also allow for comparative estimations of admetal cluster size on different oxide supports. In a

series of TPD spectra acquired for Au on SiO<sub>2</sub>, a marked decrease in the Au cluster binding energies, denoted by the peak temperature maximum ( $T_m$ ) in the TPD of the clusters, is observed.<sup>[15]</sup> Fig. 9A shows a family of TPD spectra taken of the Au clusters deposited onto a SiO<sub>2</sub> thin film. The leading edge of the TPD peak maxima shifts to higher temperatures as the Au coverage increases. The inset shows a plot of the sublimation energy ( $E_{\text{sub}}$ ) as a function of Au coverage, determined using the leading edge analysis.<sup>[57]</sup> At 0.2 ML, the  $E_{\text{sub}}$  at  $\sim 50$  kcal mol<sup>-1</sup> increases rapidly (with increasing Au coverage) to the bulk value at  $\sim 90$  kcal mol<sup>-1</sup> at 5.0 ML. The decrease in  $E_{\text{sub}}$  can be explained by the fact that an atom at the edge of a small cluster has fewer nearest neighbors than larger ones and hence desorbs more easily because of decreased surface tension.

The interaction of Au with TiO<sub>2</sub>(001) has also been determined using the same approach. The results are shown in Fig. 9B. In this case, however, only a single desorption feature is observed with a common leading edge for all Au coverages. Using the leading edge analysis, the Au binding energy on TiO<sub>2</sub>(001) is found to be 50 kcal mol<sup>-1</sup>, considerably smaller than the Au bulk sublimation energy of 90 kcal mol<sup>-1</sup>. This dramatic decrease of the sublimation energies *at all cluster sizes*, from the smallest to the largest, is clearly related to the strong interaction between the Au clusters and the TiO<sub>2</sub> support. This strong interaction leads to a greater degree of wetting of the TiO<sub>2</sub> by Au compared with Au/SiO<sub>2</sub>, and thus the lower sublimation energies found for the clusters may arise because of the preferential evaporation of Au at the

**Fig. 9** A set of TPD spectra of Au ( $m/e = 197$ ) on a 2.5-nm-thick SiO<sub>2</sub> thin film on Mo(110) at Au cluster coverages ranging from 0.2 to 5.0 ML. The inset shows a plot of  $E_{\text{sub}}$  determined from leading edge analysis.

**Fig. 10** The activity for CO conversion as a function of reaction time at 300 K on a model Au/TiO<sub>2</sub>(001) catalyst. The initial average Au cluster size was 2.4 nm.

periphery of the clusters. In any case, this contrast of behavior regarding the sublimation of Au from SiO<sub>2</sub> and TiO<sub>2</sub> highlights the role of the support in altering the properties of ultrasmall clusters of Au.

### Catalyst Deactivation and Cluster Sintering

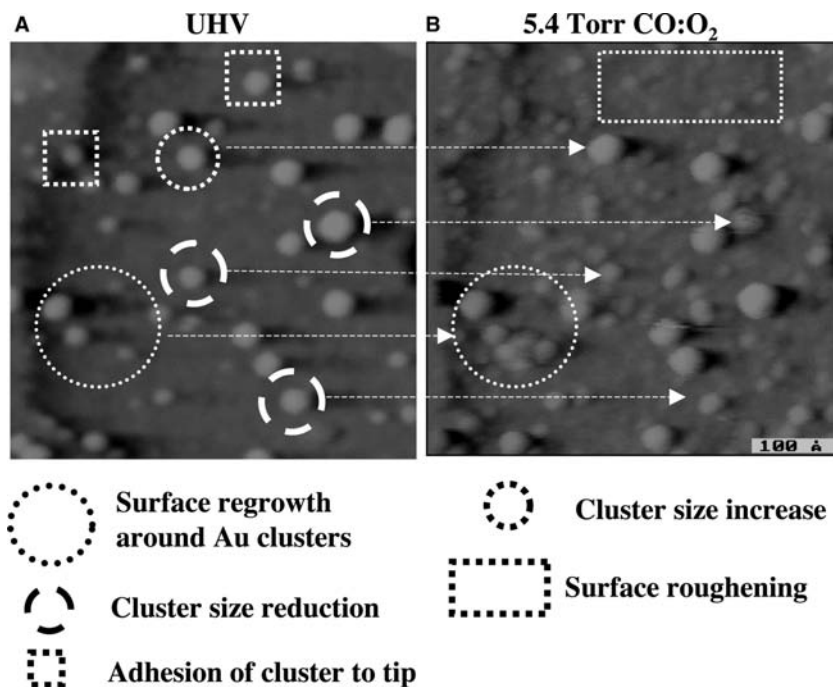

The presence of reactant gases at realistic conditions can affect the admetal's ability to wet the surface and

thereby alter particle size and distribution. For example, although the TiO<sub>2</sub>-supported Au catalysts exhibit a high activity for the low-temperature CO oxidation, the catalysts are often rapidly deactivated.<sup>[46]</sup> This is illustrated by Fig. 10, where the CO conversion is plotted as a function of reaction time for CO oxidation at 300 K on a catalyst prepared by depositing 0.25 ML Au on TiO<sub>2</sub>. The model Au/TiO<sub>2</sub> catalyst, which exhibits a high initial activity, deactivates after a CO:O<sub>2</sub> (1:5) reaction of ~120 min at 40 Torr. The deactivation is a result of the agglomeration of the Au clusters induced by interaction of O<sub>2</sub> with the Au clusters.<sup>[58,59]</sup>

In Fig. 11, a selected area is shown in (A) for UHV conditions and in (B) for 665 Pa of a CO:O<sub>2</sub> (1:5) reaction mixture.<sup>[59]</sup> There are noteworthy parallels between the instability of the small Au clusters, their catalytic activity, and the change in their catalytic activity with time. Au clusters of approximately 3 nm are optimum as CO oxidation catalysts. Clearly, reaction-induced sintering of these small clusters is a mechanism for the loss of activity with time.

### CONCLUSION

Model catalyst systems combined with surface-sensitive methods constitute a valuable methodology for probing the electronic and morphological structure of supported metal clusters. From detailed STM/STS studies combined with other surface analytical techniques, a physical basis for understanding the enhanced

**Fig. 11** A 50 × 50 nm<sup>2</sup> image of the same area taken at 450 K: (A) under ultrahigh vacuum conditions; (B) during exposure to a reaction mixture consisting of a 665 Pa CO:O<sub>2</sub> mixture.

catalytic activities of nanosized, dispersed metal clusters is developing. The results summarized in this entry show a close correlation among cluster size, morphology, electronic properties, and catalytic activity. The use of model catalysts prepared with metal clusters supported on thin oxide films has been essential for the development of these new insights into the special electronic and chemical properties that govern the unique catalytic chemistry of nanosized metal clusters. Future studies toward a more in-depth understanding of nanostructured supported clusters will undoubtedly lead to the design and the development of practical catalysts.

## INTRODUCTION

In recent years, X-ray absorption fine structure (XAFS) spectroscopy has become a routine method for determining the coordination environment and local structure of metallic nanoparticles. Because of the penetrating power of high-energy X-rays, XAFS data may be obtained under realistic operating conditions. In this entry, we provide a short overview of XAFS spectroscopy and some features that make it attractive for characterization of nanoparticles. We also give several examples of how XAFS has been applied to problems in catalysis. Special emphasis will be given to highlighting XAFS data taken on supported catalytic nanoparticles under realistic preparation, pretreatment, reaction, and deactivation conditions.

## INTRODUCTION TO EXTENDED X-RAY ABSORPTION FINE-STRUCTURE SPECTROSCOPY—THEORY AND TECHNIQUE

The interaction of X-rays with matter can be described by the attenuation of an X-ray beam as it penetrates through a sample. The absorption coefficient,  $\mu$ , is defined by

$$\frac{dI(x)}{dx} = -\mu I \quad (1)$$

where  $I$  is the incident X-ray intensity in some homogeneous region and  $x$  is a position in the region. The solution of Eq. (1) is the familiar exponential relation

$$I = I_0 e^{-\mu(E)x} \quad (2)$$

where  $I_0$  is the incident intensity and  $\mu(E)$  is written as a function of the incident photon energy,  $E$ , as the absorption coefficient is energy-dependent.

While there are multiple processes that contribute to the attenuation of photons, in the X-ray energy range up to 40 keV, the dominant process is photoelectric absorption; the other processes are scattering by electrons and nuclei and, at much higher energies, pair production. At X-ray energies, as the energy of the incident photons is increased through an atomic energy level, a new excitation channel becomes available and there is an increase in the absorption of photons. This increase is not a sharp-step increase, but has a structure that can be interpreted.

The region from slightly below the absorption-edge energy,  $E_0$ , up to as much as 2000 eV higher is the X-ray absorption fine-structure region (Fig. 1). The edge energy,  $E_0$ , primarily depends on the atomic species and the electron shell that is excited, but also, to a small degree, on the chemical environment. Absorption by a particular element may be measured by scanning an appropriate energy range. Using this feature of the absorption of X-rays, we can probe individual elements in a sample to the exclusion of all others. The X-ray absorption near-edge structure (XANES) region can provide information on the chemical and electronic states of the absorbing atoms.<sup>[1]</sup> Edge shifts of a couple electron volts reflect changes in the oxidation state of the absorbing element; an increasing edge energy typically corresponds to a higher oxidation state.

To describe the extended X-ray absorption fine-structure (EXAFS) region, we consider that the absorption of an X-ray photon excites a photoelectron wave, which propagates from the excited atom and scatters off of the surrounding atoms. It is the interference of the backscattered photoelectron wave function with the initial outgoing wave function at the site of the absorbing atom that modulates the absorption coefficient and produces the EXAFS. Thus the fine-structure oscillations can provide information about the number, type, and distance of neighboring atoms

**Fig. 1** Plot of the absorption coefficient,  $\mu x = \ln(I_0/I)$ , vs. incident X-ray energy for the Cu K-edge of a Cu foil sample. The edge energy,  $E_0$ , as well as the XANES and EXAFS regions are denoted on the plot.

to the absorbing atom. These oscillations have a relatively high frequency in  $E$  while the other attenuation modes are relatively slowly varying over the energy range. Only the oscillatory part of the absorption coefficient is of interest as a structural probe. The EXAFS is then defined as

$$\chi(E) = \frac{\mu(E) - \mu_0(E)}{\mu_0(E)} \quad (3)$$

where  $\mu_0(E)$  is the slowly varying background absorption (or attenuation) from an isolated absorbing atom and other processes. It can be shown that the EXAFS oscillations are periodic in terms of  $k$  (the electron wave number) and the equation is frequently written as

$$\chi(k) = \frac{\mu(k) - \mu_0(k)}{\mu_0(k)} \quad (4)$$

where  $E$  has been transformed to  $k$  as

$$k = \left( \frac{2m_e}{\hbar^2} (E - E_0) \right)^{\frac{1}{2}} \quad (5)$$

The equation describing EXAFS can be written as

$$\chi(k) = \sum_i \frac{N_i S_0^2}{2kR_i^2} |f_i(k, \pi)| \times \sin[2kR_i + \delta_i(k) - \pi] e^{-2k^2\sigma_i^2} \quad (6)$$

where  $N_i$  is the number of  $i$ -type atoms at a distance  $R_i$ ,  $S_0^2$  is the amplitude reduction factor,  $f_i(k, \pi)$  is the back-scattering amplitude function,  $\delta_i(k)$  is the phase shift, and  $\sigma_i^2$  is the EXAFS Debye–Waller factor. Because  $f_i$

is unique to a particular atom, one is able to distinguish different types of neighboring atoms based on the shape of  $\chi(k)$ . Many good books and articles that explain EXAFS in much greater detail have been written.<sup>[2–7]</sup>

The Debye–Waller factor introduced in the exponential at the end of the equation deals with the fact that the X-ray absorption event takes a snapshot of the local environment and the thermal motion of the atoms will cause them to be separated by different distances at different times. Because of the  $kR_i$  term in the sine function, the signal will get smeared out at higher  $k$  because of the relative motion of the atoms. This term is a first approximation and can also include static structural disorder. Thermal vibration and static structural disorder become very important, especially in the case of small particles having a large fraction of surface atoms.

Because all atoms of a particular element will exhibit increased absorption at the absorption-edge energy, EXAFS is typically a bulk measurement technique. However, in the case of very small particles, such as in most active catalysts, the surface atoms contribute a significant fraction to the overall signal. In these cases, EXAFS can be used to probe surface interactions. Also, as a result of the bulk averaging intrinsic in an EXAFS measurement, it is difficult to interpret the data in an individual measurement if there are even two phases present that contain significant quantities of the probed element. Obtaining useful information when three phases are present is nearly impossible because all scattering paths interfere. However, if many measurements are made as the sample is changing in some way (e.g., temperature-programmed reduction), it may become possible to identify the unique contribution of individual phases in a mixed-phase system using factor analysis.<sup>[8]</sup>

## Synchrotrons and Capabilities

The proliferation of synchrotron X-ray sources means that it is easier than ever to find a facility to do high-quality X-ray absorption spectroscopy research. In the last decade, three large new sources have been built for generating high-energy X-rays: the European Synchrotron Radiation Facility (ESRF, Grenoble, France), the Advanced Photon Source (APS, Argonne, Illinois, USA), and the Super Photon Ring (SPring-8, Hyogo, Japan). Several other smaller facilities with more modest, but nonetheless comparable, capabilities have also been built.<sup>[9]</sup> These newer, third-generation sources have been specifically optimized for insertion device beamlines. Other older synchrotron facilities, such as the Stanford Synchrotron Radiation Laboratory (SSRL, Stanford, California, USA) are upgrading their storage rings to take advantage of insertion devices and other advances in accelerator technology.

Insertion devices, which are large arrays of magnets, generate a high-brightness beam with a typical size of about  $1 \times 2$  mm (unfocused) at 60-m distance from the source at a third-generation source, compared to a large fan of radiation, 2 mm by several centimeters (more accurately, several milliradians), generated by bending magnet sources. The multiple magnets of an insertion device, first of all, increase the source power proportional to the number of magnets. Also, when the magnets are arranged in a periodic array, they can concentrate the emitted power into intense spikes in the energy spectrum.<sup>[10]</sup> Because the electron-beam deflection is much smaller in an insertion device compared to a bending magnet, the beam has very low divergence, rather than that of a broad fan. An undulator (a type of insertion device) beamline at the APS with a Si(111) double-crystal monochromator can generate  $\sim 10^{13}$  photons/sec in a  $1 \times 2$ -mm beam at 10 keV. With a second-generation bending magnet source, a typical intensity would be  $\sim 10^{11}$  photons/sec in an unfocused  $1 \times 10$ -mm beam.

### New Source Capabilities

The availability of higher-power X-ray sources means that experiments can be performed in much less time, opening up new classes of experiments. A simple transmission EXAFS measurement made on a second-generation bending magnet beamline may take up to an hour. A similar measurement on an undulator beamline at the APS can be made as fast as several seconds. At these rates, it becomes practical to monitor reactions in situ, as the measurement time is comparable to the timescale of the bulk properties of catalytic reactions. In situ measurements are strongly preferred for studying catalytic systems in many cases because there can be large differences between the state of the sample under reaction conditions and the state at room temperature or atmospheric pressure.

Instead of using the higher flux for faster measurements, one may attempt previously impractical measurements, such as measuring the XAFS of lower active catalyst concentrations or dilute alloying elements. More exotic experiments may also be considered, such as combining fluorescence spectrometry with XAFS, which may provide even higher site specificity.<sup>[11–15]</sup>

### INTRODUCTION TO HETEROGENEOUS CATALYSTS

Much of the productivity improvements in the chemical industry within the last century could not have occurred without the help of catalysts. Catalytic materials provide improvements in reaction rate and

product selectivity by lowering the activation energy by which chemical reactions occur. A wide variety of chemical substances show catalytic activity, but most industrial processes employ heterogeneous catalysts that are comprised of metal, metal oxide, or metal sulfide nanosize particles on porous, high-surface-area supports.

Heterogeneous catalysts are typically prepared by impregnating a support with a solution containing a metal compound, followed by thermal treatment or calcination to remove water and convert the metal salt to a supported phase that is readily transformed into the active phase under reaction conditions. Alternatively, metals can be added to the support by deposition of volatile species from the gas phase, addition of organometallic species, mixing of solid phases, ionic exchange, or numerous other methods. In some cases, pretreatment of the catalyst with reactive gases is performed to achieve the desired formation and dispersion of an active phase that cannot be obtained directly by impregnation and calcination. For example, pretreatment of supported metal oxides by  $H_2$  or  $H_2S$  gives reduced metal or metal sulfide particles.

While catalytic materials are theoretically not altered or consumed during the course of reaction, both reversible and irreversible changes inevitably occur. These can include the adsorption and desorption of reactant and product species, the transformation of the catalyst species to a new phase, the poisoning of the catalyst surface by trace contaminants in the reaction mixture, sintering and agglomeration of the dispersed active phase into large particles, and the blocking of active sites by the formation of carbonaceous deposits, called coke. Understanding the deactivation mechanisms can be used to design more rugged and stable catalysts. Alternatively, the catalysts may be regenerated, typically by oxidizing and rereducing the catalyst to restore the active phase.

Of interest to most catalyst researchers is the structure of the active site, especially under reaction conditions. While there are a number of instrumental methods used to characterize the active site in nanoparticles, many of these methods require idealized materials or conditions such as thin films, ultrahigh vacuum, low temperature, etc. This is in contrast with typical operating conditions requiring reaction pressures from atmospheric up to several hundred atmospheres and temperatures up to 700°C. Data obtained under ambient conditions may significantly differ from those obtained under realistic operating conditions. However, XAFS can be used to determine the average local electronic and structural environment of a catalytic metal site under realistic conditions, thus overcoming both the pressure and materials gap. As a result, the use of XAFS as a key method for nanoparticle characterization of heterogeneous catalysts has

**Fig. 2** Publication rate from 1991 to 2001 that includes characterization of heterogeneous catalytic nanoparticles by XANES and EXAFS spectroscopy.

considerably grown in the last decade (Fig. 2). Several excellent reviews describe EXAFS in the context of catalyst characterization.<sup>[1,16–25]</sup> The increase in the use of XAFS in catalysis is in part also a result of the increased availability of synchrotrons, improved data quality, and improvements in both hardware and software for data analysis.

While more catalysis researchers are using XAFS characterization, there is still a push for the development of in situ data collection methods to observe catalysts under reaction conditions. As one must allow X-ray access to the sample and detect X-rays from inside the sample chamber, reactor design can be quite involved. Any material that intercepts the X-ray beam, including the sample in transmission XAFS, must be somewhat transparent at the X-ray energy being used. There are a limited number of materials that are nearly transparent to X-rays, are non-reactive, and have high mechanical strength. Transmission measurements are relatively simple because only a small window is needed for X-ray entrance and exit. Catalyst samples are typically mounted as self-supporting wafers to reduce the detrimental absorption from a support. Several of these specially designed reactors are described in the open literature.<sup>[26–36]</sup>

## CATALYST PREPARATION

Although there are many methods for the preparation of supported catalysts, catalytic nanoparticles are most often prepared by dissolution of metal compounds in a suitable solvent and contacting with a high-surface-area support. Subsequently, the solvent is dried and the metal salts may be thermally treated,

reduced, oxidized, or sulfided. There are numerous examples in the catalytic literature where the choice of metal compound and methods of deposition and pretreatment greatly affect the final-phase composition or particle size and, thus, the catalytic performance. The reasons for these differences for compositionally equivalent materials are often unclear. In addition, many catalysts include metallic and nonmetallic promoters, which significantly alter their activity, selectivity, or stability. The degree of interaction of the promoter with the active component is often determined by the choice of metal compounds and pretreatment steps during the synthesis. Extended X-ray absorption fine-structure (EXAFS) spectroscopy has been increasingly applied to the study of catalyst preparations, providing structural details and insights often not readily available from other spectroscopic techniques.

## Addition of Metals to the Support

For economic reasons, most commercial heterogeneous catalysts are prepared from readily available inorganic metal salts soluble in water. The steps of catalyst impregnation can be explained by the speciation of the metal salts in aqueous solution and by the electric double-layer theory of solid oxides.<sup>[37–39]</sup> For example, with the increased sensitivity of the new generation of synchrotrons, the speciation of  $\text{H}_2\text{PtCl}_6$  (chloroplatinic acid, or CPA) in water, which is used to prepare very small metallic Pt particles on alumina, has been investigated by EXAFS.<sup>[37]</sup> Determination of the number of chloride and oxygen ligands of dilute CPA solutions at pHs typically used to prepare highly dispersed catalysts indicates that the solution chemistry is more complex than generally assumed. At a pH of about 2.5, there is rapid exchange of approximately three chloride ligands by water. For solutions at a higher pH, the number of Cl ligands decreases, while addition of HCl decreases the pH and increases the Cl concentration, leading to an increase in Cl coordination, reversibly giving  $\text{PtCl}_6^{2-}$ . Therefore specific Pt species depends on the pH as well as the CPA and  $\text{Cl}^-$  concentrations.

Catalyst supports significantly alter the pH of the impregnating solution because of the buffering effect of the oxide, determined by its point of zero charge (PZC). The effect of the support on the Coulombic interaction between the oxide surface and the aqueous metal species is twofold. First, there is a shift in the solution pH, which may alter the solution metal species, and, second, the adsorbed species appears to behave as if it is in the liquid phase at the pH of the adsorption plane.<sup>[38]</sup> The aqueous speciation of  $\text{AuCl}_4^-$  is strongly dependent on the solution pH, as shown in Fig. 3.

**Fig. 3** Effect of pH on the Au–Cl coordination number for  $\text{NaAuCl}_4$  in aqueous solution and adsorbed on alumina. Solid square: 200-ppm  $\text{AuCl}_4^-$ ; open square: 200-ppm  $\text{AuCl}_4^-$  plus 50 times molar excess of  $\text{Cl}^-$ ; solid circle: 500-ppm  $\text{AuCl}_4^-$ ; solid triangle: 200-ppm  $\text{AuCl}_4^-$  adsorbed on alumina at the solution pH; open triangle: 200-ppm  $\text{AuCl}_4^-$  adsorbed on alumina at the calculated pH of the alumina surface. The sum of the Au–Cl and Au–O coordination numbers is 4. Source: From Ref.<sup>[39]</sup>.

Below about a pH of 4, the solution species have four Cl ligands at a distance of 0.280 nm. As the pH increases to about 7, the average number of Cl ligands linearly decreases, being replaced by hydroxyl ligands at a distance of 0.203 nm. At pHs above about 7, all Au–Cl ligands are replaced by hydroxyl ligands, giving  $\text{Au}(\text{OH})_4^-$  in aqueous solution. Adsorption of Au onto alumina (PZC = 8.0) (solid triangles in Fig. 3) results in a decrease in the number of Cl ligands compared to aqueous solutions at the same pH. The Au–Cl coordination of adsorbed Au species follows the trend for the pH calculated at the surface of the support rather than the pH in the bulk solution (open triangles in Fig. 3). These results suggest that the composition of the adsorbed species is determined by the oxide properties of the support and that alumina is more basic than the aqueous solutions used to prepare the catalysts. Similar results have been obtained for  $\text{Na}_2\text{PtCl}_4$  and  $\text{Na}_2\text{PdCl}_4$  on alumina, CPA on carbons with different PZC, and  $\text{Pt}(\text{NH}_3)_4(\text{NO}_3)$  on silica.<sup>[39]</sup>

When the metals are added to supports that do not favor a strong Coulombic attraction, the subsequent treatments often lead to much larger particles. The effect of the method of metals addition on the size of the nanoparticles is demonstrated for Ni on silica.<sup>[40]</sup> Silica has a PZC of about 3; thus it is strongly deprotonated at pHs greater than about 8. Under these conditions, cationic metal salts are strongly adsorbed. Incipient wetness impregnation of an aqueous solution at nickel nitrate (pH of 4–5) leads to a weak interaction with the support and the formation of large NiO particles. The Ni–O and Ni–Ni coordination numbers (CNs) and bond distances are similar to those for bulk NiO after calcination in air at 500°C. By contrast, the

Ni–O and Ni–Ni CNs for impregnation of cationic ethylenediamine Ni(II) complexes at a pH of 12, i.e., a deprotonated silica surface, indicate surface-stabilized Ni that gives significantly smaller nickel oxide particles upon calcination.

The effect of metal loading and support composition on the adsorbed and reduced species has been investigated for chromium on silica, alumina, and silica–alumina with various alumina contents.<sup>[41]</sup> The hydrated adsorbed species differ on the different supports. For example, with incipient wetness impregnation of  $\text{CrO}_3$  at a 4% Cr loading on silica, the first shell Cr–O CN is near 4 at a distance of 0.158 nm, while on alumina and silica–alumina, the CN is near 6 at a distance of 0.165 nm. Calcination lowers the Cr–O CNs with little change in the bond distances. The lower the isoelectric point of the support and the higher the chromium loading, the greater the fraction of surface polychromates. In addition, upon reduction, the XANES spectra indicate that all catalysts contain both Cr(II) and Cr(III). However, the fraction of Cr(II) increases in the order silica > silica–alumina > alumina. Furthermore, at low loading, the Cr(II) species on silica are highly coordinatively unsaturated and correlate with high catalytic activity for ethylene polymerization. This example demonstrates that both the support and the metal loading can affect the phase composition and particle size, giving widely varying activities for catalysts of similar metal composition.

Three-way catalysts (TWC) are widely used to treat gasoline vehicle emissions (hydrocarbon, CO, and  $\text{NO}_x$ ). The method of Pt and Rh addition onto cerium-oxide-promoted alumina greatly affects the performance.<sup>[42]</sup> Coimpregnation of Pt and Rh displays low activity for propane oxidation (due principally to Pt) after calcination at 900°C. The Pt EXAFS spectrum indicates the formation of large metallic particles (bond distance 0.277 nm) with total CN (Pt–Pt and Pt–Rh) near 12. In addition, by comparison of the Pt–Rh EXAFS coordination number (CN) to the bulk composition, it is concluded that the particles are a PtRh alloy with high surface Rh content. Sequential deposition and reduction of Pt gives metallic Pt and reduced Ce. Subsequent Rh addition selectively deposited on the partially reduced Ce gives a catalyst with much higher activity. After calcination at 900°C, the large metallic particles are again formed; however, there is little alloy formation. Extended X-ray absorption fine structure spectroscopy is one of the few techniques whereby alloy formation, phase segregation, composition, and structure can be determined in bimetallic nanoparticles.

Catalytic nanoparticles can also be prepared from organometallic and metal carbonyl compounds dissolved in organic solvent.<sup>[43]</sup> Generally, with organometallic compounds, some of the ligands react with the support

hydroxyl groups to give attached metal species. Supported nanoparticles have been prepared from  $\pi$ -allyl compounds of Rh, Ni, Pd, and Pt. Reaction of the support hydroxyl groups leads to the loss of 1–2 ligands and the formation of a M–O coordination. The degree of reaction can often be determined by EXAFS. Reduction in hydrogen of the adsorbed Rh allyl species on silica leads to formation of 1.3-nm Rh particles; the Rh–Rh CN was 5.0 at a distance of 0.264 nm. From the EXAFS of the adsorbed species, the Rh–Rh CN (3.0) and bond distance (0.270 nm), and Rh–C (0.184 nm) and Rh–O (oxygen atom from the CO ligand) bond distances (0.293 nm) could be determined. Multimetallic carbonyl clusters have also been used to prepare nanoclusters having narrow particle size distributions. For example, EXAFS analysis of the Ir–Ir CN and bond distance of  $\text{Ir}_4(\text{CO})_{12}$  adsorbed onto  $\text{MgO}^{[44]}$  and  $\text{TiO}_2^{[45]}$  from pentane is consistent with formation of an  $[\text{H}(\text{Ir}_4(\text{CO})_{11})]^-$  complex. When the adsorbed complex is thermally decarbonylated at 300°C in He, an Ir–Ir coordination is found at a distance of 0.267 nm with a CN of 3.0, suggesting the formation of four-atom Ir nanoparticles. In addition, with these very small particles, two distances from the metal atom to the oxygen ions of support were resolved in the EXAFS spectrum at 0.219 and 0.268 nm. When the adsorbed Ir complex was decomposed in  $\text{H}_2$  at the same temperature, larger particles were formed (CN = 6.7). For Ir nanoparticles, the  $\text{H}_2$  and CO chemisorption capacities sharply decreased as the particle size decreased. As a result, accurate information on the particle size could only be determined from the EXAFS Rh–Rh coordination numbers. Similar catalysts with narrow particle size distributions have been prepared and characterized by EXAFS for  $\text{Rh}_6(\text{CO})_{16}$  on  $\text{TiO}_2^{[46]}$  and  $[\text{HOS}_3(\text{CO})_{11}]^-$  on NaY zeolite.<sup>[47]</sup>

The choice of metal salt and pretreatment conditions often affect the nanoparticle composition, and thus the catalytic performance. Alumina-supported Mo and W sulfide catalysts are widely used in petroleum refining for removing S and N heteroatoms. However, to meet future more stringent emissions regulations, more active and selective catalysts must be developed. Vapor deposition of  $\text{Mo}(\text{CO})_6$  into NaY zeolite followed by sulfidation at 400°C leads to very small or highly disordered, fully sulfided Mo particles, which possess high catalytic activity.<sup>[48]</sup> The Mo–S and Mo–Mo bond distances are consistent with that of  $\text{MoS}_2$ , and from the Mo–Mo coordination number of about 1, these are proposed to be dimeric Mo species. Oxidation of  $\text{Mo}(\text{CO})_6$  at 100°C produced Mo-oxide dimers with a Mo–Mo coordination number of 0.8, which upon sulfiding also gave  $\text{MoS}_2$  dimers. Catalysts with a similar Mo content but are prepared by aqueous impregnation of ammonium heptamolybdate formed tetrahedrally coordinated Mo–O species in the calcined catalysts, as determined from the

XANES spectra; however, these particles could not be fully sulfided at 400°C. These materials displayed much lower activity than those prepared from  $\text{Mo}(\text{CO})_6$ , which was ascribed to the incomplete formation of a sulfided Mo phase and lower dispersion.

### Catalyst Pretreatment

Once the metals are deposited on the support, the catalyst is usually treated prior to reaction, to produce the active state of the catalyst or, at least, to produce a phase that readily transforms into the active catalyst under reaction conditions. Typical pretreatment conditions are to increase the temperature in air (or inert gas) followed by reduction of the metals in hydrogen, oxidation in air, or sulfiding with  $\text{H}_2\text{S}$ . The catalyst's activity is often greatly affected by the pretreatment conditions. For many catalysts, the changes that occur during pretreatment and the reasons for the dramatic changes in activity are not well understood. The EXAFS technique is being increasingly applied to this phase in the development of catalyst preparations.

Reduction of noble metal catalysts, e.g., Pt, Rh, Ir, etc., by hydrogen gives metallic nanoparticles. For particles less than about 2.0 nm, a large fraction of the atoms are in contact with the support and the structure of the metal–support interface can be resolved in the EXAFS spectrum of the metal.<sup>[49]</sup> Because the energy dependence of the backscattering amplitudes of M–O<sub>support</sub> and M–M paths are different, the two overlapping contributions can be resolved. Deconvolution of the two EXAFS contributions is accomplished by fitting the M–M shell with a high-*k* weighting of the data. This contribution can be then subtracted from the data and the difference spectrum is fit with a low-*k* weighting, allowing determination of the M–O shell.<sup>[50,51]</sup> Analysis of the EXAFS spectra indicates that the distance of the metal atoms in small particles to the support oxide surface is dependent on the reduction temperature. For example, for Pt on  $\text{Al}_2\text{O}_3$  catalysts reduced at high temperature, i.e., ca. 450°C, the distance of the Pt atoms to the support is about 0.220 nm, which is approximately the sum of the covalent radii of metallic Pt and oxide ions.<sup>[52]</sup> However, low-temperature reduction, e.g., 300°C, gives a Pt-support distance of 0.270 nm. This long distance has been interpreted as resulting from atomic hydrogen being inserted between the metal particles and the support. The hydrogen atoms are not observed in the normal EXAFS spectrum because the hydrogen backscattering amplitude is small. Similar M–O<sub>support</sub> distances have been reported for several other supported noble metal catalysts.<sup>[49,53,54]</sup>

The effect of reduction temperature on particle morphology for Pt supported on  $\alpha$ -alumina single

crystals has been studied by polarized total reflection fluorescence spectroscopy.<sup>[55]</sup> By analysis of the EXAFS spectra at different angles to the incident beam, it is possible to obtain three-dimensional structural information. For Pt reduced at low temperature (110°C), the ratio of the Pt–Pt coordination numbers with the sample placed parallel and perpendicular to the beam is 0.5. Model calculations indicate that under these conditions, a single layer of Pt atoms is in contact with the support. Upon high-temperature (400°C) reduction, spherical Pt particles are formed. The application of angle-dependent EXAFS to nanoparticles supported on single crystals provides structural information on particle morphology not generally available by standard EXAFS analysis with nanoparticles on amorphous supports.

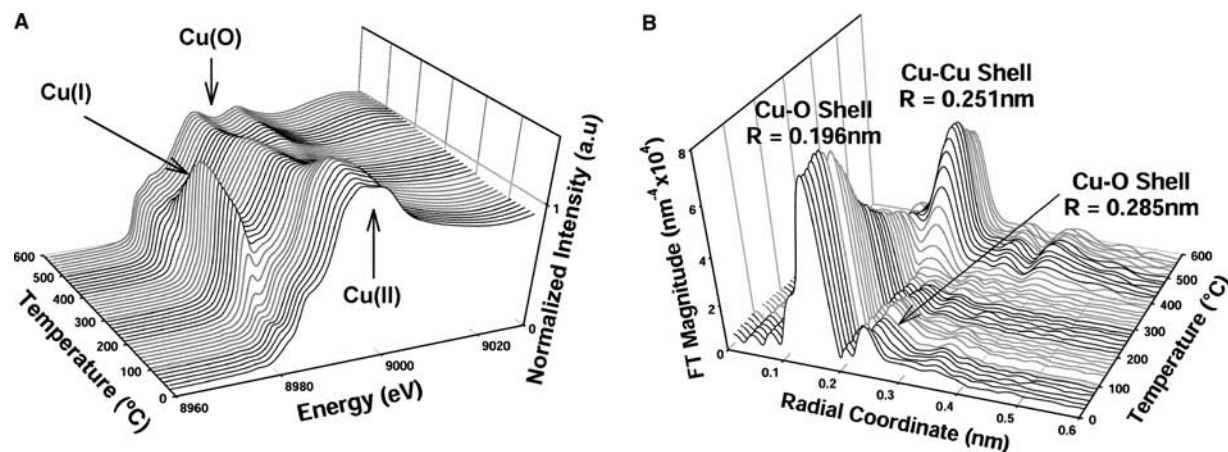

### Temperature-Programmed Pretreatments

For many years, thermal and mass-spectroscopic, temperature-programmed pretreatment methods have been used to characterize catalytic nanoparticles. In the last few years, two methods for rapid data acquisition have made it possible to collect high-quality, time-resolved EXAFS spectra for determination of the structural transformations that accompany these changes. Dispersive EXAFS uses a bent crystal monochromator to simultaneously expose the sample to all X-ray energies. The trajectory of the X-rays depends on the energy, and the transmitted flux is detected with a multielement photodiode detector. Depending on the sample concentration, a spectrum can be obtained from a fraction of a second to minutes.<sup>[56,57]</sup> Alternatively, by continuously scanning the monochromator, one can collect a quick EXAFS spectrum within a

few seconds to minutes. This latter technique can be used with a more conventional beamline design and detectors. For both techniques, kinetic EXAFS data can be collected for processes such as reduction, poisoning, phase change, sintering, etc. that occur on the timescale of minutes to hours.<sup>[58]</sup>

Copper-exchanged ZSM-5 zeolite is catalytically active for the reduction and disproportionation of nitrogen oxides (NO<sub>x</sub>) to N<sub>2</sub>. In addition, there are several possible oxidation states [Cu(0), Cu(I), and Cu(II)] that could be catalytically active. Analysis of the Cu XANES spectra can be used to determine the amounts of each oxidation state, as a result of the significant differences between the XANES features of each state, particularly the pre-edge peak of Cu(I). High-resolution *in situ* XANES and EXAFS were used to follow the temperature-programmed reduction of Cu-ZSM-5 in hydrogen (Fig. 4).<sup>[59]</sup> Using principal component analysis, the stepwise transformation of Cu(II) to Cu(I) to Cu(0) was apparent from the XANES spectra. In addition, as a result of the highly resolved Cu(I) pre-edge feature, two Cu(I) species were detected, differing in their coordination geometry. The reduction steps were also observable in the EXAFS spectra. At high temperature, the formation of Cu–Cu metallic bonds indicates that reduced Cu particles are formed, which are undesirable for good catalytic activity.

Cu/ZnO catalysts are commercially used for synthesis of methanol at high pressure from CO plus H<sub>2</sub>. At low pressure, Cu also decomposes methanol and is being investigated for production of hydrogen for automotive fuel cell applications. The active catalyst is synthesized by precipitation of a mixed CuO/ZnO phase followed by reduction and reaction. The evolution of the catalytic precursors was followed during temperature-programmed reduction by XANES and

**Fig. 4** Changes in Cu K-edge XANES and EXAFS spectra of Cu-ZSM-5 during temperature-programmed reduction in hydrogen. (A) Plot of XANES edges during the reduction process, showing the strong Cu(I) pre-edge feature ca. 8980 eV that was observed due to a high energy-resolution beamline. (B) The Fourier transform of the EXAFS spectra during the reduction process, along with some of the major features fitted during analysis. *Source:* From Ref.<sup>[59]</sup>.

EXAFS spectroscopy.<sup>[60]</sup> With decreasing amounts of CuO, the onset of reduction decreased from 200°C to 170°C and the Cu (metallic) crystallite size decreased from 21.0 to 4.0 nm. From the XANES spectra, the reduction was observed to proceed from Cu(II) to Cu(I) to Cu(0). Addition of O<sub>2</sub> during reforming led to a mixture of Cu(II) and Cu(I) and loss of catalytic activity. The catalyst compositions and methods of preparation and pretreatment that led to small metallic Cu nanoparticles gave high catalytic activity.

The effect of pretreatment conditions on the nanoparticle size has also been studied by temperature-programmed reduction of Pt(NH<sub>3</sub>)<sub>4</sub><sup>2+</sup> supported on silica.<sup>[61]</sup> Direct reduction in H<sub>2</sub> rapidly occurs at 150–200°C with the formation of moderately small Pt particles, based on a Pt–Pt CN of 8.0 and a hydrogen chemisorption (H/Pt) ratio of 0.89. During H<sub>2</sub> reduction, there is a sharp decrease in the white-line intensity, loss of Pt–N bonds, and the formation of Pt–Pt bonds. H<sub>2</sub> reduction at 400°C leads to larger Pt particles with a CN of 9.5. Thermal treatment in inert gas leads to autoreduction of the Pt(NH<sub>3</sub>)<sub>4</sub><sup>2+</sup> in multiple steps. At about 200°C, there is a loss of Pt–N ligands and a small decrease in the white-line intensity. The white-line intensity continues to decrease until about 300°C, after which the reduction is complete, with a final Pt–Pt CN of 7.8 and H/Pt ratio of 1.09. Thermal treatment at higher temperature did not lead to further growth of the nanoparticles. Calcination of Pt(NH<sub>3</sub>)<sub>4</sub><sup>2+</sup> leads to a gradual change in the white-line intensity over a temperature range from about 150°C to 325°C and a decrease in the Pt–N CN from 5.3 to 4.0. No Pt–Pt bonds are formed in the presence of O<sub>2</sub>. It was concluded that the key to making small metallic particles with uniform particle size distributions involves stable immobile surface species. Clearly, both the phase and particle size of the Pt nanoparticles are influenced by the gas composition and temperature of the pretreatment.

Molybdenum oxide is a key component in many selective oxidation catalysts and is known to form a number of well-defined suboxides whose average valence is between +6 and +4. A combination of the XANES spectra and X-ray diffraction (XRD) analysis was used to study the isothermal and temperature-programmed reduction kinetics of MoO<sub>3</sub>.<sup>[62]</sup> Below 425°C, MoO<sub>3</sub> is reduced to MoO<sub>2</sub> in a single step without the formation of intermediates. At higher temperatures, Mo metal and Mo<sub>4</sub>O<sub>11</sub> were formed in parallel. The average oxidation state was determined from the XANES spectra, while the crystallite size was determined from the XRD. Under the reaction conditions for propene oxidation, Mo<sub>4</sub>O<sub>11</sub> is not formed; thus it is not the catalytic species. In addition, because no other molybdenum oxide phases were observed, it was proposed that oxygen deficiencies on MoO<sub>2</sub> are the catalytic centers.

During pretreatment of NiMo hydrotreating catalysts, it is essential to fully sulfide the metals, produce small particles, and maximize the interaction between Ni and Mo. Temperature-programmed sulfidation of Mo indicates that sulfide formation is a complex series of steps.<sup>[63,64]</sup> Below about 100°C, Mo remains fully oxidized with a Mo–Mo bond and several Mo–O distances. From 100°C to 225°C, there is a loss of the Mo–Mo bond and the longest Mo–O distance, accompanied by the formation of Mo–S bonds. The Mo–Mo distance of 0.28 nm in the initial sulfided species is similar in structure to MoS<sub>3</sub>. In this temperature range, it is likely that Mo=O bonds are unreactive. The transformation of the remaining Mo–O bonds continues up to about 350°C, when the formation of MoS<sub>2</sub> is complete. Because EXAFS is element-specific, the sulfiding of Ni and Mo can be independently studied. For Ni, little sulfiding occurs below about 50°C, but is complete by 140°C. Addition of chelating ligands during preparation retards the onset of Ni sulfidation, but has little effect on Mo. Therefore chelating ligands were added during catalyst synthesis to retard the sulfiding of Ni, which maximizes the interaction of Ni with Mo, leading to higher activity.

## STRUCTURAL CHARACTERIZATION DURING REACTION

While EXAFS has become a standard technique for structural characterization of catalytic nanoparticles, the increased sensitivity of modern synchrotrons and improved analysis methods (software and theoretical standards) has provided an ever-increasing level of detail and understanding of the reactivity of the active site and catalyst promoters. To maximize the data quality and reduce the structural and thermal disorder, EXAFS analysis is often conducted on samples directly after pretreatment or reaction at low temperature. Generally, it is assumed that the structure of the active phase at low temperature is equivalent to that under reaction conditions. For many analytical methods, characterization is not generally possible under realistic reaction conditions, i.e., high temperature, pressure, and flow of reactants. However, with high-energy X-rays, it is possible to conduct EXAFS experiments under these conditions. In several instances, the results of structural analysis under reaction conditions significantly differ from that obtained at lower temperature and pressure and in the absence of a reactant.

### Characterization of the Catalytically Active Site

The structure of CoMoS<sub>2</sub> on alumina hydrotreating catalysts has been extensively studied, and there is

general agreement that the active phase consists of small MoS<sub>2</sub> particles promoted by isolated Co atoms bridge-bonded at the edges of the particles. However, EXAFS analysis of these catalysts under reaction conditions has recently provided further insight about the site of catalytic activity.<sup>[65]</sup> For example, during the reaction with organo-Se compounds at low temperature, ca. 200°C, Se exclusively replaces the terminal Co–S bond. This study is particularly interesting because the EXAFS spectra of the reactant molecule (Se) as well as the catalyst (Co and Mo) were obtained to determine the location of the Se in the catalyst during catalytic conversion. At higher reaction temperatures, e.g., 400°C, Se also replaces the bridging S between Co and Mo. Therefore the active site consists of two types of S sites, which differ in structure and activity.

Similar conclusions about the identity of the reactive Co–S bonds were suggested from a study of the adsorption of O<sub>2</sub> at room temperature and 100°C on CoMoS<sub>2</sub> supported on alumina.<sup>[66]</sup> Adsorption of O<sub>2</sub> leads to the selective replacement of the terminal Co–S bonds. Inspection of the spectra indicates a small change; however, direct analysis of the contribution due to the Co–O bond was not possible as it overlapped with the very large Co–S peak in the EXAFS spectrum (Fig. 5A). However, by analysis of the difference spectrum, i.e., the difference of the EXAFS spectrum of CoMoS<sub>2</sub> before and after O<sub>2</sub> chemisorption, it was possible to fit the peak due to Co–O at about 0.14 nm (Fig. 5B, not phase shift corrected). In addition, in the fit of the difference spectrum, there was a peak due to the loss of one Co–S at a distance of 0.225 nm. This reactive terminal Co–S has a slightly longer distance than the less-reactive, bridge-bonded Co–S (0.218 nm).

Pt, Pd, and Rh are used as catalysts for a large number of industrially important reduction and oxidation reactions. It is well known that when supported on certain materials, reduction of these metals at high temperature leads to a suppression of the H<sub>2</sub> and CO chemisorption capacities. This strong metal-support-interaction (SMSI) effect occurs most often for titania, ceria, and other partially reducible oxide supports. The nature of the SMSI effect has been investigated by EXAFS for Pt on cerium oxide.<sup>[67]</sup> While there was no evidence for the formation of a PtCe alloy, sintering, or decoration of the Pt particles by cerium oxide at any reduction temperature, there were significant differences in both of the Pt L<sub>III</sub> and L<sub>II</sub> edges in the presence and absence of hydrogen. There were additional changes for the catalyst reduced at low (200°C) and high temperature (500°C). Several factors contribute to the difference in the adsorption edges in the presence and absence of hydrogen. At the L<sub>II</sub> edge, the difference is primarily because of the scattering of chemisorbed hydrogen. The scattering from hydrogen occurs only at low photoionization energy; thus it is not observed in the normal EXAFS region. Differences in the Pt–H EXAFS for high- and low-temperature reduction indicate that there is a change in the mode of hydrogen chemisorption as evidenced by changes in the Pt–H bond distances. The changes in chemisorption capacity were thought to be due to electronic changes in the nanoparticles resulting from an interaction with the oxidized and partially reduced support at low and high temperature, respectively.

The effect of chemisorbed hydrogen on the L<sub>II</sub> and L<sub>III</sub> adsorption edges of Pt has been investigated in more detail for Pt on alumina.<sup>[68]</sup> Standard volumetric hydrogen chemisorption experiments indicate that

**Fig. 5** Room temperature Co-edge EXAFS of CoMoS<sub>2</sub> on alumina catalyst. (A) Magnitude of the Fourier transform ( $k^2$ -weighted,  $\Delta r = 2.8$ – $11.0$ ). Solid line: catalyst sulfided at 400°C; dotted line: adsorption of O<sub>2</sub> at room temperature on freshly sulfided catalyst. (B) Fourier transform (FT) of the difference spectrum between the CoMo sulfide catalyst with adsorbed O<sub>2</sub> and freshly sulfided catalyst. Solid line: magnitude of FT; dotted line: imaginary part of FT. *Source:* From Ref.<sup>[66]</sup>.

there are two types of adsorbed hydrogen that differ by their desorption temperature. Weakly chemisorbed hydrogen can be desorbed under vacuum at room temperature, while strongly chemisorbed hydrogen is desorbed at about 100°C. The Pt–H bond distances, fit using theoretical references, were 0.189 and 0.194 nm for strongly and weakly chemisorbed hydrogen, respectively. The Pt–H EXAFS spectra indicate that both weakly and strongly adsorbed hydrogen are dissociatively adsorbed.

It is well known that the interaction of a second metal with a metallic supported catalyst results in important changes in the adsorptive properties and catalytic performance. EXAFS spectroscopy is one of the most effective characterization techniques for establishing the formation of bimetallic particles. Addition of Sn as a promoter to Pt/alumina naphtha reforming catalysts significantly reduces the amount of carbon deposits, extending the time between regenerations. Analysis of the EXAFS spectrum for the reduced, bimetallic PtSn catalysts is complex because of an unusual interference between PtSn and Pt particles that coexist on the catalyst.<sup>[69]</sup> In the Fourier transform, two peaks are observed at about 0.215 and 0.275 nm. The shorter distance has previously been proposed to be due to oxidized or chlorided Pt. However, from the XANES spectrum, the white-line intensity precludes the possibility of oxidized Pt. The spectrum was successfully modeled by assuming that there were two types of nanoparticles, Pt and a PtSn alloy. The fraction of metal Pt in each particle was also determined from the experimental coordination numbers. From a multiple shell model fit, the Pt–Pt bond distance in the pure Pt fraction was 0.274 nm, which is similar to the bond distance in other Pt nanoparticles. However, the Pt–Pt distance in the PtSn alloy was significantly shorter (0.263 nm). The Pt–Sn distance was also 0.265 nm.

Bimetallic catalysts are also commonly used to minimize the effects of poisoning; however, the added complexity often makes identification of the active site more difficult.<sup>[70,71]</sup> For example, EXAFS analysis of bimetallic Pt and Pd indicates that alloys are formed.<sup>[72]</sup> As the ratio of Pd increases, the Pt–Pt bond distance in the bimetallic particle decreases from 0.274 nm in pure Pt particles to 0.270 nm in particles with a 3:1 Pd-to-Pt ratio. At the same time, there is little change in the Pd–Pd bond distance at about 0.275 nm. However, for pure Pd catalysts, the Pd–Pd bond distance is increased (0.281 nm), likely because of the formation of Pd hydride. Furthermore, modeling the metal coordination numbers indicates that the nanoparticles are surface-enriched in Pd with a core of Pt. Although much detail about the nanostructure can be obtained by EXAFS, it is unclear whether the enhanced catalytic activity and sulfur tolerance of

the catalysts are because of the stabilization of a metallic surface layer that does not form hydrides, because of a change in the Pd–Pd or Pt–Pd bond distance, or because of a fundamental change in the reactivity of the metals in the bimetallic particles.

### X-Ray Absorption Fine-Structure Spectroscopy under Reaction Conditions (High Temperature and Pressure)

Pd is known to readily form stable palladium hydrides and carbides. While metallic Pd is a highly active hydrogenation catalyst, palladium hydride is inactive. Similarly, palladium carbide leads to a loss in H<sub>2</sub> adsorption capacity and a loss of catalytic activity compared to metallic Pd. The EXAFS spectra obtained for reduced Pd on carbon or alumina exposed to H<sub>2</sub> at 100°C show an increase in the Pd–Pd distance of 2.5%, from 0.275 to 0.282 nm, indicating the formation of palladium hydride.<sup>[73]</sup> The amount of hydrogen dissolved in the Pd metal was approximately half of that in bulk palladium hydride. In 3.5% H<sub>2</sub> and above about 150°C, the palladium hydride decomposed to metallic Pd. Treatment of the Pd nanoparticles in 1% ethylene at 150°C lead to an expansion of the Pd–Pd distance of about 1.2%, which is consistent with the formation of palladium carbide. This study demonstrates that characterization of the catalyst at low temperature may not be equivalent to that of the catalyst under reaction conditions. At reaction conditions, metallic Pd or palladium hydride may be present, depending on the temperature and hydrogen partial pressure. In addition, palladium carbides may be formed quickly or after longer reaction times. It is likely that the structure of the catalyst at steady state is different from that after pretreatment.

For many catalysts, there is an initial period just after the catalyst is brought on-line where the activity rapidly changes. During this period, the pretreated catalyst is converted to its steady state activity and structure. Recently, a new catalyst containing both Mo and acidic zeolites such as H-ZSM-5 has been reported for the non-oxidative conversion of methane to benzene.<sup>[74,75]</sup> Mo is added as ammonium heptamolybdate, followed by calcination or thermal activation at temperatures up to 700°C. Heating the ammonium heptamolybdate indicates a spreading of the Mo oxide species, likely into the pores of the zeolite. Structural characterization suggests that the oxidized Mo species are similar to Mo<sub>2</sub>O<sub>7</sub><sup>2-</sup>, with a Mo–O coordination number of 4 at distances from 0.169 to 0.184 nm and a Mo–Mo coordination number of 1 at a distance of 0.370 nm. However, under reaction conditions (e.g., conversion of methane to benzene at 700°C), the molybdenum oxide is converted to isolated molybdenum

carbide particles within the zeolite pores. The Mo–Mo and Mo–C coordination numbers were 0.1 and 3.2, respectively. The Mo–C bond distance of 0.209 nm is consistent with molybdenum carbides, and is significantly longer than that for molybdenum oxides. The EXAFS and XANES spectra clearly indicate that the active catalytic phase is formed by reaction of methane at high temperature.

Rh supported on alumina, vanadia, and other supports is highly active for conversion of synthesis gas (CO plus H<sub>2</sub>) to methanol. Addition of RhCl<sub>3</sub>·xH<sub>2</sub>O to Al<sub>2</sub>O<sub>3</sub> followed by reduction at 400°C gives 1.0-nm metallic nanoparticles, or particles with about 10 Rh atoms per particle.<sup>[76]</sup> These catalysts produce methanol, higher alcohols, and hydrocarbons at pressures from 5 to 30 bar using a 1:1 H<sub>2</sub>-to-CO syngas ratio at 250°C. Analysis by EXAFS of the Rh particles exposed to CO at room temperature indicates that the small metallic particles are converted to Rh(CO)<sub>2</sub>Cl<sub>2</sub>. By contrast, at 250°C and 1 bar of syngas, the Rh particles are present as small metallic particles, and thus are responsible for the catalytic activity.

The low-temperature dissociation of small Rh particles in the presence of CO also appears to require the presence of Cl.<sup>[77]</sup> When similar Rh nanoparticles were prepared from rhodium nitrate, the metal particles were stable in CO. Thus not only can the reaction conditions, gases, temperature, pressure, etc. influence the phase present on the catalyst, but the presence of other trace elements, such as Cl, can also have a dramatic effect on the structure. Even in the absence of Cl, EXAFS has shown that small metallic Ru<sup>[78]</sup> and Pt<sup>[79]</sup> particles may be converted into metal carbonyl clusters at low temperature, while large metallic particles only chemisorb CO.

Catalytic-transition metal nanoparticles with multiple stable oxidations are among the most structurally complex materials; they are difficult to characterize. The factors affecting catalytic activity and selectivity are often poorly understood. In addition, the number of active sites often changes depending on the reaction temperature and gas composition. Under realistic reaction conditions, EXAFS and XANES spectra often provide the most reliable insight into the active state of the working catalyst. Propane can be partially oxidized over Ag, Cd, and Fe molybdenum phosphates to propylene and acrolein.<sup>[80]</sup> Analysis of the XANES spectra of AgMo<sub>3</sub>P<sub>2</sub>O<sub>14</sub>, at reaction temperatures between 300°C and 460°C (propane/O<sub>2</sub>/N<sub>2</sub> of 60:20:20), indicate that the average oxidation state of Mo decreases from 5.66 in the pretreated catalyst to 5.25. For CdMo<sub>3</sub>P<sub>2</sub>O<sub>14</sub>, the Mo oxidation state increases under reaction conditions; however, the average oxidation state is very similar to that in silver molybdenum phosphate, i.e., 5.25. Although the

reaction environment results in a change in the average oxidation state, there is little change in the Mo–O and Mo–Mo coordination numbers or bond distances. Incorporation of Fe, even in small amounts, leads to a loss of catalytic activity. In all Fe-containing cadmium molybdenum phosphate catalysts, only Mo(V) ions are present. It is concluded that selective partial oxidation catalysts require both Mo(V) and Mo(VI) ions in about a 2:1 ratio. Propane is thought to be activated on the Mo(V) ion and then react with the oxygen ion located on the Mo(VI) site, which is regenerated by oxygen.

An EXAFS study of a rhodium-on-alumina catalyst for partial oxidation of methane to produce syngas demonstrates that the structure of the catalyst under reaction conditions can be very different from that of the used catalyst at low temperature.<sup>[81]</sup> Reduction of Rh<sub>4</sub>(CO)<sub>12</sub> on alumina at 500°C leads to 6.0-nm Rh particles, as indicated by a Rh–Rh CN of 10.3 at 0.269 nm. At temperatures below the ignition temperature of about 330°C, the large metallic particles are oxidized. The resulting structure is similar to that of the metal particles in O<sub>2</sub> at the same temperature. Above 330°C in 6%CH<sub>4</sub>/3%O<sub>2</sub>/He, the partial oxidation of methane was accompanied by reduction of oxidized Rh particles with the formation of smaller metallic particles. Upon cooling to room temperature in the reaction mixture, large metallic Rh particles are again formed. In this study, the reaction products were simultaneously monitored with the EXAFS data collection; thus the state of the active surface could be clearly identified and was only present under the reaction conditions.

Pt and Rh three-way autoexhaust catalysts also undergo changes in structure with the composition of the reaction gases.<sup>[82,83]</sup> During the catalytic cycle, the gas composition alternates between reducing and oxidizing. Exposure of the pretreated catalyst, which contained fully oxidized Pt and Rh, to a reducing gas mixture at 250°C led to the partial reduction of Pt (6.8 Pt–Pt at 0.272 nm and 1.3 Pt–O at 0.199 nm), but Rh remained fully oxidized (6.5 Rh–O at 0.203 nm). At 350°C, Pt was fully reduced (11.0 Pt–Pt and 1.0 Pt–Rh at 0.265 nm), while Rh was partially reduced (6.5 Rh–Rh at 0.270 nm, Rh–Pt at 0.266 nm, 2.7 Rh–O at 0.199 nm, and 1.1 Rh–O at 0.219 nm). Analysis of both the Pt and Rh edges indicates the partial formation of bimetallic particles at 350°C. Under oxidizing conditions, Pt is difficult to oxidize and remains largely reduced, while Rh is readily oxidized. However, oxidation of Rh did not affect the oxidation activity of Pt.

Ion-exchange of H-ZSM-5 with an aqueous-ammonia solution of Cu(NH<sub>3</sub>)<sub>4</sub><sup>2+</sup> leads to incorporation of an amount of Cu in excess of the ion-exchange capacity, which is active for the decomposition of NO into

$N_2+O_2$ .<sup>[84,85]</sup> After calcination at 500°C, the XANES spectrum indicates that Cu(II) is present with a Cu–O coordination number of 3.7. By contrast, pretreatment in He at 500°C leads to the autoreduction of about 70% of the Cu(II) to Cu(I). In the presence of  $O_2$ , Cu(I) is readily oxidized to Cu(II). Under steady state reaction conditions of NO decomposition, the XANES spectra indicate that about 25% of the Cu/ZSM-5 is reduced to Cu(I). The catalytic activity is strongly influenced by the temperature and correlated with the amount of Cu(I) present in the catalyst. Thus the number of catalytic sites depends on the reaction temperature and  $O_2$  concentration, which is dependent on the NO conversion.

Cu(I) was also identified as the active species in Cu/ZSM-5 during reduction of  $NO_x$  by CO.<sup>[86]</sup> As previously observed,<sup>[84,85]</sup> pretreatment of the catalyst in He leads to the autoreduction of about 70% of the divalent Cu to Cu(I). Under the reducing reaction conditions, one CO molecule chemisorbs on each Cu(I) site at a Cu–C bond distance of 0.189 nm. However, with increasing temperature, the surface CO coverage decreases. Therefore two factors determine the catalytic activity. The rate increases with increasing temperature because of the activation energy, but decreases at higher temperature because of the lower CO surface coverage. Therefore the number of catalytic sites and activities are a strong function of the reaction temperature and CO concentration.

A catalytically active copper species that is selective for partial oxidation of methanol to formaldehyde has been determined by a new surface-sensitive, in situ X-ray absorption technique. In situ, time-resolved EXAFS analysis at the Cu K-edge of polycrystalline and reduced supported Cu catalysts indicates that at temperatures from 300°C to 400°C and in a flow of air–methanol (1:2 ratio), the metal phase does not change, i.e., no copper oxides were detected.<sup>[87]</sup> By contrast, exposure of the catalysts to air results in the loss of the Cu–Cu peak at about 0.22 nm (not phase-corrected) and the simultaneous formation of the Cu–O peak at 0.19 nm due to bulk  $Cu_2O$ . The transformation of metallic copper to  $Cu_2O$  occurs in about 5 min at 400°C.  $Cu_2O$  is further converted to CuO after an additional 10 min in air at 400°C. X-ray absorption near-edge spectroscopy analysis of these catalysts at the O K-edge or Cu  $L_{III,II}$  edge are normally performed in ultrahigh vacuum.<sup>[36,88]</sup> However, under vacuum, metallic copper is primarily converted to  $Cu_2O$ , which is active for total oxidation of methanol to  $CO_2$ . On the other hand, XANES analysis of the Cu  $L_{III,II}$  edges at 400°C and 0.1 mbar of methanol–air indicates no oxidation of the metallic Cu, results that are in agreement with that obtained in situ at the Cu K edge. However, at the O K-edge, the XANES spectrum is different from those of bulk copper oxides, suggesting that the catalytically active site corresponds to metallic

Cu with a surface film of atomic oxygen. This copper suboxide phase could only be observed at the reaction temperature and under pressure. The XANES spectra obtained after cooling to room temperature were characteristic of that for  $Cu_2O$ . Similar evidence for a catalytic silver suboxide phase has also been reported from the surface-sensitive in situ XANES spectra.<sup>[88]</sup>

While the nature of the nanoparticle surface in oxidation catalysts is often strongly influenced by the reaction conditions, structural changes in metallic nanoparticles may also occur under reducing conditions. In small metal particles, the motion of the surface atoms is more anharmonic than that of the bulk atoms. Therefore as the size of the particles gets smaller, the fraction of surface atoms increases and the EXAFS pair distribution function gets increasingly asymmetric.<sup>[89]</sup> For a Cu/ZnO/ $Al_2O_3$  methanol synthesis catalyst, as the reacting gas composition ( $CO$ ,  $CO_2$ ,  $H_2$ , and  $H_2O$ ) changes, the catalytic activity also changes. In addition, under similar reaction conditions, there are changes in the Cu–Cu coordination number from about 6.8 to 9.5. By analysis of the non-Gaussian pair distribution function, it was concluded that the metallic Cu particles are spherical in the presence of water, while the particles are disk-like under dry conditions. Because of the differences in particle morphology, the number of active sites is not the same under the different gas compositions. Correcting the kinetic rates by the number of surface atoms gave nearly identical turnover rates. Failure to account for the non-Gaussian pair distribution in the EXAFS analysis of small metal particles leads to an underestimation of the particle size from the coordination numbers.<sup>[90]</sup>

## CATALYST DEACTIVATION AND REGENERATION

Ideally, catalysts do not change or participate in the reactions they catalyze. However, nearly every catalyst suffers some form of deactivation that must be accounted for in the design of a commercial process. For metallic nanoparticles, sintering and poisoning of the surface are the primary modes of deactivation. In addition, for many catalysts, carbon deposition, or coking, of the surface blocks active sites and lowers the activity. For some catalysts, deactivation may be reversible and the active state may be regenerated by additional treatment, typically through high-temperature oxidation and rereduction. However, for other catalysts, deactivation may be irreversible, motivating researchers to modify the catalyst composition to minimize these deleterious effects. Analysis by the EXAFS and XANES methods are often informative in understanding the structural changes

that accompany deactivation and have led to development of improved regeneration procedures or deactivation-resistant catalysts.

### Deactivation by Poisoning

Trace levels of sulfur in the reaction stream can easily and irreversibly poison the activity of metallic platinum catalysts. After an initial reduction, Pt supported on  $\text{Al}_2\text{O}_3$  was found to exist mostly as metallic nanosize Pt particles.<sup>[91,92]</sup> Upon exposure to  $\text{H}_2\text{S}$  at  $450^\circ\text{C}$ , the platinum particles were disrupted, and only Pt–S coordination (CN = 2.8) was observed. Although some metallic character was present after high-temperature reduction in  $\text{H}_2$ , the Pt–S coordination remained largely unchanged, indicating the irreversibility of the sulfur poisoning. However, when Pt was alloyed with Re, the Pt–S CN was 2.0 after  $\text{H}_2\text{S}$  treatment, and further decreased to 1.0 after rereduction. In addition, there was only minimal change in the metallic coordinations of Pt–Pt and Pt–Re. Alloy formation with Re and other metals helps to stabilize the metallic Pt phase and minimizes the amount of surface-adsorbed S.

Sulfur poisoning of Pt can also accelerate the formation of coke on the metallic particles. Pt nanoparticles on both alkaline and acidic LTL (Linde Type L) zeolite are active for the hydrogenolysis and isomerization of neopentane. Sulfur poisoning blocks active sites and leads to a loss of about 90–95% of the S-free activity.<sup>[93]</sup> With poisoned catalysts, Pt–S bonds are formed on the surface of each particle. While the sulfur coverage was found to be only slightly higher on alkaline-supported Pt nanoparticles, coke deactivation was very rapid, whereas on acidic supports deactivation was low. It is suggested the higher S surface coverage of Pt in alkaline LTL leads to nearly isolated sites, which rapidly deposit coke.

Platinum is also the active component in many fuel cells, and is easily poisoned by trace quantities of CO in the  $\text{H}_2$  fuel. Cyclic voltammetry studies of a Pt/C electrode exposed to  $\text{CO}$ <sup>[94]</sup> were carried out using in situ EXAFS analysis. CO readily adsorbed on the small metallic Pt particles with nearly full surface coverage blocking the adsorption of  $\text{H}_2$ , thus altering the effectiveness of the electrode. CO can be oxidized at higher oxidation potential and before the irreversible oxidation of Pt. The addition of a second electro-negative metal can beneficially alter the absorption properties of CO on Pt and minimize the effect of CO poisoning. The effect of CO poisoning on the performance of two Pt–Ru/C fuel cell electrodes was dependent on the composition of the nanoparticles.<sup>[95]</sup> For one electrode wherein the Pt and Ru were present as separate phases, as elucidated by EXAFS, there was

no significant advantage of the second metal. However, for the electrode with small Pt–Ru alloy clusters, there was a significant improvement in the electrochemical performance in the presence of low concentrations of CO, emphasizing the importance of nanostructure on catalytic performance.

### Deactivation by Sintering

Many metals are prone to sintering at high reaction temperatures. Several previous examples showed the sintering of metal particles under calcination or other pretreatment steps, but very few studies have actually looked at the sintering of a catalyst during the course of reaction. The deactivation of Cu/ZnO during the reaction of NO and CO was monitored with EXAFS and XANES analysis with time on stream.<sup>[96]</sup> Initially, the activity of the catalyst at  $250^\circ\text{C}$  quickly dropped, but continued to slowly decline after about 2 hr. The analysis showed that the surface initially consists of a highly dispersed Cu(II) phase interacting with the support. After an hour, the Cu was still highly dispersed, but had been reduced to a Cu(I), based on the change in pre-edge XANES features and Cu–O coordination distance. After 5 hr, the Cu–O coordination had changed, and new Cu–Cu coordination was observed that was consistent with the formation of small Cu particles. These particles continued to grow slightly with additional time on stream, which was indicative of sintering. However, upon high-temperature treatment in  $\text{O}_2$  or NO, the catalyst was regenerated to the original Cu(II) structure. The reversible reduction and sintering of the isolated copper species was determined to be the primary cause of deactivation.

### Deactivation by Coking

Platinum catalysts used for a variety of hydrocarbon conversions are easily coked. As with poisoning, alloy formation can improve coke resistance. In situ EXAFS data were collected for Pt/ $\text{Al}_2\text{O}_3$ , Pt–Re/ $\text{Al}_2\text{O}_3$ , and Pt–Sn/ $\text{Al}_2\text{O}_3$  during hydrogen reduction and heptane conversion.<sup>[97]</sup> For Pt/ $\text{Al}_2\text{O}_3$ , the reduced Pt existed primarily as small metallic clusters with Pt–Pt coordination of 5.0. During heptane conversion at  $500^\circ\text{C}$ , the Pt–Pt coordination dropped to 4.4 and a significant Pt–C contribution was observed, which was attributed to the formation of coke. On the other hand, the reduced Pt–Re/ $\text{Al}_2\text{O}_3$  system was primarily composed of small Pt–Re alloy particles. Under identical reaction conditions, these nanoparticles did not undergo any structural changes nor indicate the formation of Pt–C bonds. Similar observations were made with the Pt–Sn catalysts. The addition of Re or Sn to Pt appears to lower the adsorption strength of the hydrocarbon

species that eventually leads to coke formation. A similar analysis was also made for Ni/C and Au–Ni/C catalysts used for steam reforming.<sup>[98]</sup> While Ni alone is quickly deactivated as a result of graphite formation, addition of Au and formation of an alloy showed no appreciable deactivation due to the formation of graphite. For Ni, the formation of graphite is thought to require several adjacent Ni atoms. In the alloy, inactive Au atoms isolate surface Ni atoms.

### Regeneration and Deactivation/Regeneration Cycles

While long-term investigations of the effects of regeneration and cyclic operations with EXAFS are impractical, the state of the catalytic metals under similar conditions can be simulated. For example, Pt/Al<sub>2</sub>O<sub>3</sub> and Pt–Sn/Al<sub>2</sub>O<sub>3</sub> catalysts were treated to several redox cycles while being monitored by in situ EXAFS.<sup>[97]</sup> The fresh Pt/Al<sub>2</sub>O<sub>3</sub> prior to any reduction shows a Pt–O coordination of 6.0, indicating isolated Pt species on the support. After two and four redox cycles, the Pt–O coordination dropped to 4.0 and 3.0, respectively. Moreover, increasing Pt–Pt coordination (after rereduction) was observed, suggesting that repeated cycling caused the Pt particles to sinter. Alternatively, Pt–Sn showed no change in the Pt–O coordination of 6.0 after four cycles, suggesting that Sn was stabilizing the isolated Pt species during regeneration treatment and would help to maintain the catalyst's activity for many more regeneration cycles.

### FUTURE PROSPECTS

In addition to the standard structural and electronic information currently extracted from the EXAFS and XANES spectra, it is likely that future developments will provide more detailed structural information including three-dimensional geometric data on nanoparticle morphology and how the morphology changes upon chemisorption of reactants. In general, the large single-scattering contributions in the EXAFS spectra are used for determination of local structure. However, multiple scattering contributions can provide information about the bond angle of the scattering pair. Small changes in the multiple scattering contributions to the Fourier transform were shown to correlate with changes in the tetrahedral geometry of the zincate ion, i.e., Zn(OH)<sub>4</sub><sup>1-</sup>, in an alkaline battery as a result of hydrogen bonding with the cation.<sup>[99]</sup> While, currently, multiple scattering peaks are seldom analyzed, development of reliable methods for interpreting these peaks could provide crucial information about small

changes in the geometry of the active site and the resulting changes upon interaction with adsorbates.

Good progress has also already been made with respect to the geometry of nanoparticles supported on single crystals.<sup>[55,100–106]</sup> For example, analysis of the fluorescence spectra at different orientations of the X-ray beam relative to the support surface has shown that when Mo(CO)<sub>6</sub> on TiO<sub>2</sub> is reduced, the orientation of the metallic Mo–Mo bonds is parallel to the (001) direction.<sup>[106]</sup> On the other hand, calcination of ammonium heptamolybdate on TiO<sub>2</sub> gives molybdenum oxide dimers with Mo–Mo bonds perpendicular to the (001) direction. The effect of the support on the orientation of the nanoparticles to the surface and its effect on catalytic activity are poorly understood, and detailed characterization of particle morphology may provide new insights into the influence of the support on the function of catalysts.

Because chemical transformations occur at the surface of nanoparticles and small changes in the energy of the valence orbitals of these reaction centers can have a significant effect on the catalytic performance, techniques that can provide a better understanding of these properties are also likely to be developed in the coming years. Recently, two new XAFS techniques, which demonstrate that electronic changes parallel changes in catalytic performance, have been applied to metallic Pt nanoparticles on heterogeneous catalysts. Adsorption of hydrogen leads to the formation of a Pt–H bond and an empty antibonding orbital near the Fermi level. Taking the double difference in the Pt L<sub>III</sub> and L<sub>II</sub> edges in the presence and absence of chemisorbed hydrogen can isolate this shape resonance in the near-edge region of the spectrum.<sup>[107–115]</sup> Fitting the shape resonance with a Fano line shape indicates that the energy of the Pt–H antibonding orbital shifts to lower ionization potential as the alkalinity of the support increases, which is consistent with data obtained from more established techniques, like X-ray photoelectron spectroscopy and infrared spectroscopy of adsorbed CO.<sup>[110,111,113]</sup> Shape resonance analysis has also been applied to the Pt electrodes for fuel cell applications in H<sub>2</sub>SO<sub>4</sub> and HClO<sub>4</sub> to determine the surface species with different applied voltage. From 0 to 0.54 V, Pt–H bonds dominate the surface, while at higher voltages, Pt–O species are present.<sup>[114,115]</sup>

A second XAFS technique provides information on important electronic changes in metallic particles resulting from alloy formation, the metal–support interaction, or changes in applied voltage on electrodes. This atomic XAFS, or AXAFS, can be obtained from scattered photoelectrons involving the electrons at the periphery of the absorbing atom<sup>[116–121]</sup> and can be observed in the low R peaks (<0.15 nm) in the Fourier transform. Changes in the Pt potential experienced by the charge on the oxygen ions from

the support result in a shift in the intensity and position of the XAFS peak.<sup>[108,120,121]</sup> It is expected that further development of these latter two techniques will be applied to other elements and used in a number of other applications related to properties of nanoparticles in catalysis and electrocatalysis.

## CONCLUSION

The rapid increase in the number of XAFS papers applied to the characterization of heterogeneous supported catalytic nanoparticles is a testament to the increasing availability of synchrotrons, improved data quality, and user-friendly software. The number and availability of new synchrotrons is expected to continue to increase within the next 10 years. In addition, data quality continues to improve and data acquisition time continues to decrease. Spectra that once took several hours to collect can now be obtained within a few minutes. At the same time, commercial software is now readily available for data analysis and calculation of theoretical standards.

In some cases, XAFS may be the only technique available to obtain structural information on heterogeneous catalyst systems, while the newer in situ techniques have proven to be extremely useful at examining catalysts under typical working conditions (T, P, SV, etc.) and are providing unprecedented looks at the mechanisms of catalytic reactions. These tools will provide stronger links between catalyst testing at pilot plant stage and the fundamental of the catalysts. This should lead to a much greater fundamental understanding of nanophase catalysts as well as improved catalyst activity and selectivity.

# Catalysts by Nanoscale Design

Chaitanya Kumar Narula

*Physical Chemistry of Materials, Materials Science and Technology Division,  
Oak Ridge National Laboratory, Oak Ridge, Tennessee, U.S.A.*

## Abstract

The development of new catalytic materials is still dominated by trial-and-error methods. Although it has been successful, the empirical development of catalytic materials is time-consuming and expensive with no guarantee of success. In our laboratories, we are developing a comprehensive “catalysts by design” approach which involves state-of-the-art first principle density functional theory calculations, experimental design of catalyst sites, and sub-Ångström resolution imaging with an aberration-corrected electron microscope to characterize the microstructure. In this entry, we focus on supported platinum cluster catalyst systems, which are one of the most important industrial catalysts and attempt to demonstrate the feasibility of the “catalyst by design” concept.

## INTRODUCTION

Supported metal clusters have been synthesized and extensively studied over the last several decades, and their best-known application is in emission treatment system for transportation vehicles.<sup>[1–3]</sup> Other nanotechnology applications include fuel cells, sensors, and catalysts for chemical processes.<sup>[4–7]</sup> Generally, metal clusters are deposited on a high surface area substrate employing metal salts solution and subsequent decomposition at a slow rate to obtain a relatively uniform distribution of particles. The control on the particle size and distribution is necessary to obtain an efficient catalyst, since smaller particle size translates into a larger number of catalyst sites for the desired catalyst loading. Unfortunately, despite extensive efforts to define relationships between surface morphology, particle size and shape, and catalytic activity, the understanding of catalytic mechanisms is often lacking. The nature of bonding between support and metal clusters has been indirectly inferred but is approximate. It is in part due to the difficulty in preparing supported monodispersed catalyst particles of small size. The small size is highly desirable to increase the catalyst surface because the active part of a catalyst is its surface where low-coordinated atoms reside.<sup>[8]</sup> Thus, increasing the centers that are responsible for catalysis can lead to a decreased use of precious metals that are generally the catalysts of choice for heterogeneous catalysis. New synthetic approaches have made it possible to synthesize small clusters from a variety of techniques allowing supported clusters of Re, Os, Rh, Ir, Pt, and Au to be synthesized.<sup>[9–18]</sup> Under operating conditions, the particles start to grow in size resulting in a reduced number of catalyst sites.<sup>[19–23]</sup> Thus, the catalysts are designed to function over a desired period of time.

The development of new catalytic materials is still dominated by trial-and-error methods. Although it has been successful, the empirical development of catalytic materials is time-consuming and expensive with no guarantee of success. Theoretical studies have generally been carried out on gas-phase isolated atoms and have not provided insights into practical catalyst systems. Now, the advances in computation methods make it possible to model and understand experimentally simple but theoretically complex systems, thereby bridging the gap between theory and experiments. Thus, it is now possible to establish a “catalysts by design” protocol that combines the power of theoretical modeling and experiments (see Fig. 1). The essential component of this approach is that the catalysts are iteratively examined by both theoretical and experimental methods. This approach involves state-of-the-art first principle density functional theory calculations, experimental design of catalyst sites, and sub-Ångström resolution imaging with an aberration-corrected electron microscope to characterize the microstructure. A comprehensive approach, employing this protocol, is being developed in our laboratories; components of this approach are beginning to appear in the literature. For examples, theoretical models of supported gold catalyst have been studied to understand the factors that are important in catalysis such as the roles of undercoordinated sites, particle-support interface, altered oxidation state, and quantum size effects.<sup>[24–27]</sup>

In this entry, we will focus on supported platinum cluster catalyst systems that have been examined by both theory and experiments and we will attempt to demonstrate the feasibility of the “catalyst by design” concept. We selected alumina-supported platinum catalyst because it is one of the most important industrial catalysts and is utilized in a large variety of processes.<sup>[28–36]</sup>

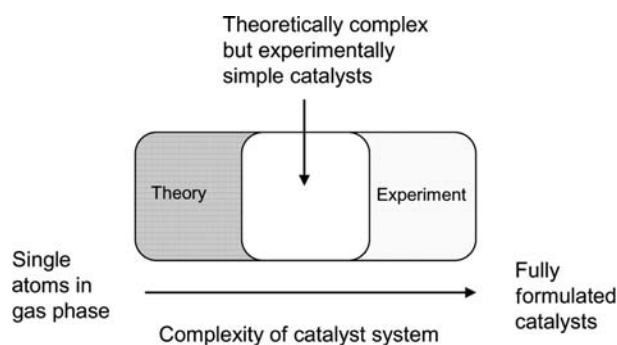

Fig. 1 “Catalyst by design” concept.

## STRUCTURE OF SUPPORTED PLATINUM NANOCLUSTERS

The first automotive catalyst was platinum supported on  $\gamma$ -alumina and designed to oxidize CO and hydrocarbons in the emission stream.<sup>[1]</sup> Since then, several advanced versions of automotive catalysts have been deployed but supported Pt clusters remain an integral component of the catalysts. The synthetic approach is quite simple and involves coating  $\gamma$ -alumina with platinum salts dissolved in water using incipient wetness or suspension methods. Subsequent pyrolysis leads to Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> powders that are generally degreened under reducing environment.

The nanostructure of freshly prepared catalyst has been a subject of speculation. In fact, nanoparticles of platinum were invisible when examined by X-ray techniques or high-resolution electron microscopes. Chemical activity and X-ray absorption studies had suggested the presence of isolated atoms, which was confirmed in 1996 by the first direct imaging of the atomic configuration of ultradispersed Pt particles.<sup>[37]</sup> Individual atoms, two atoms, triangular trimers, and

larger clusters of Pt atoms were observed in this entry. Since such electron microscopes are available only at a handful of laboratories even today, most of the characterization of supported Pt clusters is still carried out employing dark field images obtained from a variety of electron microscopes that can provide Å-resolution images. A typical high-angle annular dark-field image of 2% Pt/ $\gamma$ -alumina, recorded in our laboratory, by scanning transmission electron microscopy showed an average diameter of 0.9 nm and a size range from 0.6 to 1.4 nm for Pt particles (Fig. 2). A similar result was reported in the literature previously by Kang et al.<sup>[38]</sup> where a distribution of Pt centered at 0.9 nm was observed. The clusters were determined to be hemispherical in shape with  $\sim 90\%$  containing  $12 \pm 5$  atoms and the rest containing  $35 \pm 7$  atoms. The small clusters (individual atoms, 2-atom, or 3-atom) were not observed in this study. The EXAFS study of this sample showed average first shell coordination number to be  $5.5 \pm 0.2$ , which is consistent with a 15-atom hemispherical Pt cluster. Authors also noted an unexpected  $\sim 3\%$  Pt–Pt bond distance contraction from the bulk value in these hydrogen-treated catalysts, which was dependent on temperature.<sup>[38]</sup>

Previous experimentally observed Pt–Pt bond distances for a Pt trimer by electron microscopy are  $2.7 \pm 0.2$ ,  $3.2 \pm 0.2$ , and  $3.4 \pm 0.2$  Å.<sup>[37]</sup> Density functional theoretical calculation of a model with five layers of  $\gamma$ -alumina exposing the 110C face and a Pt-trimer occupying two oxygen and one aluminum vacancies show Pt–Pt bond distances to be 2.59, 2.65, and 2.73 Å.<sup>[39]</sup> The calculated distances are typical of Pt–Pt bond distances but do not agree with observed values. The calculated bond distances of Pt atom clusters on oxygen-terminated  $\gamma$ -alumina were found to be 2.6, 2.6, and 3.6 Å, which are also outside the error limits of observed distances. The authors conclude that if a Pt-trimer structure is capped with –OH, the computed

Fig. 2 High-angle annular dark-field image of 2% Pt/ $\gamma$ -alumina (left) and Pt particles size distribution (right). Source: From Ref.<sup>[50]</sup>; Reprinted with permission from SAE paper #2007-01-1018 © 2007 SAE International.

distances are 2.6, 3.1, and 3.6 Å, which are in good agreement with their experimentally observed values.

One needs to be careful about these models because they employ an overly simplified version of  $\gamma$ -alumina models. There is still disagreement on the structure of  $\gamma$ -alumina. Traditionally,  $\gamma$ -alumina is described as having a defective spinel structure derived from  $\text{MgAl}_2\text{O}_4$ .<sup>[40–42]</sup> The cubic unit cell of the structure is an fcc sublattice of oxygen with 96 (64 tetrahedral and 32 octahedral) interstices between oxygen ions and cation vacancies at tetrahedral 8a positions. Literature reports differ on the distribution of cation vacancies.<sup>[42–45]</sup> Experimental studies have also not been able to resolve this issue, but a recent density functional theoretical (DFT) study favors cation vacancies in energetically preferred octahedral sites.<sup>[42]</sup> The presence of hydroxyl groups further complicates the structure of  $\gamma$ -alumina. Although it is generally accepted that hydroxyl groups are present on the surface, there is disagreement on the presence of hydrogen in the bulk structure. There is some experimental evidence for the presence of hydrogen in the bulk structure, but theoretical models suggest that hydrogen spinel is thermodynamically unstable<sup>[42]</sup> and will decompose into anhydrous defect spinel and boehmite. A recent DFT study combined with Rietveld refinement analysis on different spinel and non-spinel structures show that spinel-based models represent structural features of  $\gamma$ -alumina better than non-spinel models and are able to reproduce synchrotron X-ray powder diffraction patterns.<sup>[46]</sup>

Density functional theoretical studies of gas-phase Pt clusters and Pt supported on  $\alpha$ -alumina provide useful information that is helpful in explaining the experimental observations. Gas-phase studies show that 2-, 3-atom Pt clusters are two-dimensional while 4-atom and larger Pt clusters have three-dimensional shape.<sup>[47,48]</sup> The calculated bond distances of small

clusters are shown in Fig. 3. The atomization energy of these clusters increases with cluster size, i.e. atoms are held together more strongly as the cluster size increases. Clusters with 13-atoms are generally considered important because 13-atom clusters form high symmetry icosahedral and cuboctahedral structures according to geometric shell models. Density functional theoretical calculations of 13-atom Pt clusters show that a stacked triangular structure and a square structure combined with a tetrahedron have the lowest energy.<sup>[49]</sup>

The sample, 2% Pt/ $\gamma$ -alumina, shown in Fig. 2, was also examined via aberration-corrected electron microscope (ACEM) in scanning transmission electron microscopy (STEM) in scanning transmission electron microscopy (STEM) mode. The high-angle annular dark-field (HA-ADF) images of this catalyst obtained on an ACEM in STEM mode show that there are isolated atoms, 2–3 atom clusters, and several 10–20 atom clusters of Pt (Fig. 4).<sup>[50]</sup> The directly measured Pt–Pt bond distances are 2.35, 2.54, 2.7, and 3.2 Å for 2-atom clusters. Theoretical bond distance for Pt–Pt dimer in the gas phase is 2.34 Å. While it appears that one of the observed bond distance matches closely with the calculated one for gas-phase Pt–Pt dimers, it is not a good comparison because gas-phase dimers do not include substrate interactions. Theoretical models of oxides of Pt nanoclusters suggest them to be two-dimensional in the gas phase (Fig. 5). The calculated Pt–Pt bond distance for a  $\text{Pt}_2\text{O}_4$  cluster is 2.77 Å and although it matches the observed value, we are reluctant to assign  $\text{Pt}_2\text{O}_4$  structure to Pt-dimers primarily

**Fig. 5** Gas-phase Pt and  $\text{Pt}_x\text{O}_{2x}$  dimers and trimers. *Source:* From Ref.<sup>[47]</sup>; Reprinted with permission from *J. Phys. Chem. B*, **2006**, *110*, 5839–5846 © 2006 American Chemical Society.

due to the two-dimensionality of the calculated structure. None of the large clusters exhibit two-dimensional structures. A better comparison is with Pt dimers supported on  $\alpha$ -alumina where they occupy two adjacent  $\text{Al}_T\text{-Al}_T$  sites and exhibit bond distance of 2.723 Å.<sup>[51]</sup> This study also suggests that a Pt–Pt dimer undergoes dissociative adsorption on two adjacent  $\text{O}_{3h}$  sites with each Pt atom occupying an  $\text{O}_{3h}$  site. This would probably explain the larger bond distance of 3.2 Å observed for Pt dimers.

The calculated Pt–Pt bond distances for gas-phase Pt trimers are 2.5 Å and do not match with observed bond distances of 2.3 and 2.8 Å perhaps owing to substrate interactions. These observed values are also different from previously reported values of  $2.7 \pm 0.2$  Å,  $3.2 \pm 0.2$  Å, and  $3.4 \pm 0.2$  Å. This calculated value for a gas-phase trimer is also different from the calculated value described previously for  $\gamma$ -alumina supported Pt trimers. Interestingly, the calculated Pt–Pt bond distances of  $\text{Pt}_3\text{O}_6$  clusters are 2.75 Å, which is close to our observed value, but the observed structure of Pt trimers is different from the two-dimensional gas-phase structure of  $\text{Pt}_3\text{O}_6$ . The calculated Pt–Pt distances of Pt trimer supported on  $\alpha$ -alumina are a better match with our observed values. In the theoretical model, Pt-trimer orients itself parallel to the (0001) surface forming an equilateral triangle with each Pt atom occupying an  $\text{O}_{3h}$  site. In this model, the Pt–Pt bond distance is 2.696 Å (see Fig. 6).

Thus, there is still a need for theoretical study of Pt supported on  $\gamma$ -alumina since simplified models do not adequately explain the observed structures of Pt nanoclusters.

### OXIDATION OF CARBON MONOXIDE ON SUPPORTED PLATINUM NANOCLUSTERS ( $\text{Pt}/\gamma\text{-Al}_2\text{O}_3$ )

Oxidation of carbon monoxide (CO) on 2%  $\text{Pt}/\gamma\text{-Al}_2\text{O}_3$  with 10–20 atom clusters of Pt initiates at 180°C and completes at 210°C (Fig. 7).<sup>[52]</sup> After two cycles of testing and cooling the catalyst to 25°C and retesting, no change in the quantitative conversion temperatures is observed in the third cycle. The nanostructural analysis of the recovered sample suggested some growth in particle size but we could not rule out sample-to-sample variation. It is important to note that change in CO-oxidation activity between fresh and successive cycles of supported Pt catalyst has been observed previously.<sup>[53]</sup> A study of 19 catalyst samples showed “light-off,” on average, at 207°C, just below isokinetic temperature of  $216 \pm 15.3^\circ\text{C}$ . The mean activation energy was  $85.7 \pm 16.9 \text{ kJ mol}^{-1}$ .

The particle size effect on CO oxidation has been observed previously too. The reaction rates for unit amounts of catalyst with platinum dispersions of 0.63, 0.29, and 0.2 were similar but turnover frequency (Fig. 8) increased with increasing particle size.<sup>[53]</sup> Thus, the catalytic activity per surface platinum atom increased with increasing particle size. Zafirris and Gorte<sup>[54]</sup> reported that the turnover frequency of a catalyst with a particle size of 14 nm was 10-fold greater than that of a catalyst with a particle size of

**Fig. 7** Complete conversion of CO to CO<sub>2</sub> as a function of temperature with sampling after 15 min at the given temperature. The dotted lines are results for 2% Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (ca. 1 nm Pt), the solid lines are results of 2% Pt/ $\theta$ -Al<sub>2</sub>O<sub>3</sub> (ca. 1 nm Pt), and the dashed lines are results for the 2% Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> annealed at 650°C (ca. 12 nm Pt). *Source:* From Ref.<sup>[52]</sup>.

1.7 nm. This probably is due to increased fraction of planar sites when compared with low-coordination sites such as edges and corners.<sup>[55]</sup> Interestingly, the temperature required to achieve 50% CO conversion increased with a decrease in dispersion, i.e. a catalyst with a dispersion of 0.83 showed  $T_{50}$  of 217°C while the catalyst with a dispersion of 0.03 showed  $T_{50}$  of 299°C.

Theoretical studies on the adsorption of O, O<sub>2</sub>, CO, CO<sub>2</sub>, NO, and NO<sub>2</sub> on Pt nanoclusters show that the adsorption of these species is highly size-dependent and substantially stronger than that on the bulk Pt surface (Fig. 9).<sup>[50]</sup> As a result, the energy profiles of CO and NO oxidation on Pt<sub>x</sub> nanoclusters also differ from that on Pt bulk-surface.

Carbon monoxide oxidation on the bulk Pt surface is exothermic along the reaction path. But, the enhanced adsorption of CO leads to a minimum in

energy when CO adsorbs on the clusters (Fig. 10). Theoretical studies also show that NO adsorbs strongly on clusters indicating that the ability of the Pt nanoclusters to catalyze CO and NO oxidation may be inhibited by the strongly adsorbed CO and NO. Furthermore, strongly adsorbed O atom diminishes the energetic driving force for Pt<sub>x</sub>-O + NO(g) → NO<sub>2</sub>(g) due to smaller enthalpy of the overall reaction NO(g) + 1/2O<sub>2</sub>(g) → NO<sub>2</sub>(g) and makes the Pt<sub>x</sub> clusters inefficient oxidizers for NO oxidation. On the other hand, the adsorption of O, CO, and NO on the Pt<sub>x</sub>O<sub>x</sub> and Pt<sub>x</sub>O<sub>2x</sub> clusters is weaker when compared with Pt clusters. This suggests that CO and NO oxidation may be more favorable on the small oxidized Pt clusters than on the metallic clusters. Thus, theoretical models of CO interaction with gas phase Pt nanoclusters provide a rationale

for explaining the experimentally observed CO oxidation behavior on supported Pt clusters.

### NANOSTRUCTURAL CHANGES IN SUPPORTED PLATINUM NANOCLUSTERS

The nanostructural analysis of the recovered sample suggested some growth in particle size. To determine if the particle size growth indeed occurs and is not due to sample-to-sample variation, we carried out CO-oxidation studies employing the ex situ reactor available at Oak Ridge National Laboratory. The ex situ reactor is specially designed to expose catalyst samples on a TEM grid to various operating conditions. This enables monitoring of structural changes in selected areas by electron microscopy after every

experiment. For CO oxidation experiments, the fresh sample was exposed to the following conditions: (1) quantitative CO oxidation conditions at 210°C, (2) quantitative CO oxidation at 210°C and then temperature raised to 450°C for two cycles, and (3) quantitative CO oxidation at 210°C and then temperature raised to 450°C for three cycles. As expected, the fresh sample showed isolated Pt atoms and 10–20 atom Pt clusters (Fig. 11A). Atomic resolution imaging of the sample after two cycles of quantitative CO oxidation at 210°C and then raising the temperature to 450°C shows that the Pt cluster/particles have sintered significantly, although a few clusters of ~1 nm size could still be seen (Fig. 11C). After three cycles of quantitative CO conversion and then raising temperature to 450°C, the number of larger Pt clusters/particles increased and the larger Pt particles exhibited well-ordered structures. For example, a bcc Pt<sub>3</sub>O<sub>4</sub> particle looking down the (120) lattice plane can be seen in Fig. 11D. It is important to note that isolated Pt atoms, dimers, trimers, and 10–20 atom clusters were still present in samples; they do not appear in the micrograph shown in Fig. 11D since they are out of focus at this resolution.

Recent studies on platinum nanoclusters of 7–10 atoms, supported on Al<sub>2</sub>O<sub>3</sub>/SiO<sub>2</sub>/Si(100), have been carried out employing grazing incidence small-angle X-ray scattering technique.<sup>[56]</sup> The results show that these clusters are unusually stable at 400°C under vacuum or hydrogen. Our results, on the other hand, clearly showed instability of Pt nanoclusters under CO oxidation conditions. Thus, a study of stability under hydrogen or vacuum is not a good indicator of catalyst stability under operating conditions.

Theoretical studies point to three pathways for nanocluster growth—triangular packing of subnanoclusters is energetically favored and as Pt cluster size

**Fig. 10** The reaction energy profiles for CO +  $\frac{1}{2}$ O<sub>2</sub> → CO<sub>2</sub> and NO +  $\frac{1}{2}$ O<sub>2</sub> → NO<sub>2</sub> on Pt<sub>x</sub> ( $x = 1-5$  and 10). The profiles on the bulk Pt surface (represented by the Pt(111) surface) are included. *Source:* From Ref.<sup>[50]</sup>; Reprinted with permission from SAE paper #2007-01-1018 © 2007 SAE International.

**Fig. 11** ACEM HAADF-STEM images of the exact same sample area of fresh 2% Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (A), after quantitative CO oxidation at 210°C (B), after 2- (C), and 3-cycles of quantitative CO-conversion at 450°C (D). The second row shows the area at higher magnification for each stage, respectively. Circles and squares are located at the same place on each image to allow monitoring of Pt growth at each stage of testing. *Source:* From Ref.<sup>[52]</sup>.

approaches 19-atoms, triangular clusters transform to icosahedral clusters. Further increase in Pt cluster to 38-atoms results in transition of fcc-like clusters.<sup>[48]</sup> A recent combined EXAFS and DFT study of platinum supported on carbon suggests that a 37-atom Pt cluster already has a bulk like average Pt–Pt bond and fcc (111)-stacked cuboctahedral geometry.<sup>[57]</sup> Thus, theoretical models and experimental evidence suggests that platinum clusters, after agglomerating to 38 atoms, attain the structure of bulk metal.

### IMPACT OF Pt PARTICLE SIZE—Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> PARTICLES

Previous studies have demonstrated the impact of Pt particles size on CO oxidation activity<sup>[16–18]</sup> and the Pt particles of less than 5 nm have been shown to either

exhibit decreased activity or no strong size dependence. We sintered 2% Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> sample at 650°C for 5 hr to obtain Pt particles size distribution of more than 5 nm. Electron microscopy studies of our thermally treated sample showed  $\sim$ 12 nm Pt particles. The CO-oxidation on this catalyst starts at  $\sim$ 240°C and becomes quantitative at  $\sim$ 250°C in the first two cycles. Third cycle of CO oxidation starts at  $\sim$ 230°C (Fig. 8). Transmission electron Microscopy analysis of fresh samples, samples after exposure to CO-oxidation initiation conditions, and after three cycles of quantitative CO-conversion showed a slight particle size growth and could be attributed to sample-to-sample variation based on a subsequent ex situ reactor study, which clearly ruled out particle size growth under these reaction conditions (Fig. 12).

Thus, the behavior of large particles is quite different from nanoparticles where 1, 2, 3, 10–20 atom clusters in fresh samples rapidly sintered under our

**Fig. 12** HAADF-STEM images of the exact same sample area: Fresh 2% Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> and after Initiation testing, two-cycles and three-cycles of quantitative CO oxidation (left to right, respectively). *Source:* From Ref.<sup>[52]</sup>.

experimental conditions. Our study suggests that catalyst particles become stable as they increase in size. The TEM analysis suggests that these crystalline Pt particles are most probably oxidized on the surface. The structure of surface oxide is under determination.

### IMPACT OF SUBSTRATE MORPHOLOGY—Pt/ $\theta$ -Al<sub>2</sub>O<sub>3</sub> NANOCCLUSERS

In principle, any experimentally observed difference in the catalytic activity of Pt/ $\theta$ -Al<sub>2</sub>O<sub>3</sub> when compared with Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> can be attributed to substrate morphology change and changes in Pt nanoclusters—substrate interaction provided Pt nanocluster distribution is identical for both catalysts. In practice, it is difficult to obtain and stabilize identical Pt nanocluster distribution on two different substrates. We followed an experimental protocol identical to that previously used to impregnate  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> in an attempt to obtain almost identical Pt nanocluster distribution on  $\theta$ -Al<sub>2</sub>O<sub>3</sub>. The average Pt particle size was 0.9 nm (range 0.6–1.3 nm) as observed in STEM images of fresh 2% Pt/ $\theta$ -Al<sub>2</sub>O<sub>3</sub> catalyst. This particle size distribution is almost identical to that seen for a fresh catalyst sample of Pt supported on  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>. Interestingly, the CO oxidation reaction on 2% Pt/ $\theta$ -Al<sub>2</sub>O<sub>3</sub> catalyst also initiates around 170–180°C with ~5% conversion (Fig. 8). The catalyst sample, collected after stopping the reaction at this stage, also exhibits Pt particle size growth. Scanning transmission electron microscopy analysis shows that the average Pt size is 1.8 nm with the clusters/particles ranging in size from 0.6 to 4.0 nm. Thus, platinum nanoclusters dispersed on  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> and  $\theta$ -Al<sub>2</sub>O<sub>3</sub> exhibit almost identical nanostructural changes under CO oxidation initiation conditions.

In another experiment, the CO oxidation reaction was allowed to attain quantitative conversion over 2% Pt/ $\theta$ -Al<sub>2</sub>O<sub>3</sub> catalyst and then the reaction was stopped and reactor was cooled. A catalyst sample was collected after three cycles of quantitative CO conversion and cooling. An average Pt size of 2.0 nm that ranges from 0.7 to 5.1 nm was observed in STEM images of multiple areas of catalyst sample. This nanostructural observation is also comparable with that observed for 2% Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> under CO oxidation conditions. There is no difference in CO oxidation activity of both catalysts under our experimental conditions.

While there is still disagreement on the structure of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>,  $\theta$ -Al<sub>2</sub>O<sub>3</sub> has a well-ordered crystal lattice making it possible to examine it by theoretical models. We have initiated theoretical studies of Pt/ $\theta$ -Al<sub>2</sub>O<sub>3</sub> catalyst and its CO oxidation behavior to explain the nanostructural differences from Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> system. Experimentally observed similarities in Pt/ $\theta$ -Al<sub>2</sub>O<sub>3</sub> and

Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> suggest that the local environment of Pt clusters must be identical in both catalysts. It is important to point out that Pt–Pt bond strengthening has been suggested to govern the reaction behavior of co-adsorbed species on Pt/TiO<sub>2</sub> nanoclusters caused by strong adsorption of O<sub>2</sub> at low-coordination sites of Pt.<sup>[58]</sup> Assuming that this model also applies to Pt/Al<sub>2</sub>O<sub>3</sub> systems, the degree of Pt–Pt bond strengthening must be very similar in Pt/ $\theta$ -Al<sub>2</sub>O<sub>3</sub> and Pt/ $\gamma$ -Al<sub>2</sub>O<sub>3</sub> catalysts.

### CONCLUSIONS

Advances in computation methods, experimental techniques, and instrumentation make it possible to model and understand experimentally simple but theoretically complex systems. The platinum–alumina system described in this entry clearly shows that it is possible to synthesize subnanoclusters of platinum supported on alumina. It is also possible to directly observe the clusters and monitor changes that occur under operating conditions. Density functional theoretical models suggest structures and reactivity of clusters that match the experimental observations.

Even for an experimentally simple system such as platinum–alumina, extensive theoretical modeling was found to be necessary to provide insights into the nanostructures. It is still necessary to use experimental observations as inputs to carry out theoretical models of this system to better understand substrate interactions.

In our studies, theoretical modeling of CO oxidation reaction was able to forecast that platinum nanoclusters in gas phase were less catalytically active for CO oxidation than oxidized Pt nanoclusters. Theoretical studies on various supported clusters also point to stable structures for Pt dimers and trimers. This is the first step towards “catalyst by design” approach. The ability to examine a complex system will indeed make this approach highly valuable in the design of catalysts.

## INTRODUCTION

In heterogeneous catalysis, adsorption and reaction processes usually occur on supported metal nanoparticles. To study such processes experimentally, a variety of surface science techniques came into use in the last decades of the 20th century. Along with the appearance of high-precision techniques for surface characterization, considerable progress in the manufacturing of model catalysts with well-defined properties such as particle size, shape, and separation has been achieved. For example, modern electron beam lithography makes it possible to fabricate equidistant particles on the scale down to  $\sim 10$  nm. Despite this progress, the cognitive potential of the experimental studies in this field is still limited because the measurements are usually indirect and the information derived demands quantitative processing and interpretation. This can be done only with the use of mathematical models. Successful interpretation of the results requires constructing mathematical models providing accurate descriptions of the systems under consideration. Application of conventional mean-field models is often limited here because of the peculiarities of the reaction performance on the nanometer scale, including the inherent heterogeneity of metal crystallites as well as spontaneous and adsorbate-induced changes of the shape and degree of dispersion of supported catalysts. Under such circumstances, the use of stochastic simulations based, e.g., on the Monte Carlo (MC) technique, is almost inevitable. This entry focuses on theoretical studies (simulations) of catalytic reaction kinetics on active supported nanoparticles. Our goal is to describe the main achievements of the corresponding theoretical works.

## SPECIFICS OF CATALYTIC REACTIONS ON NANOMETER-SIZED PARTICLES

It is well known that the overwhelming majority of real commercial catalysts consists of particles of nanometer

size (1–100 nm) deposited on a porous support with a high surface area. Recently, the synthesis of such systems made great strides toward manufacturing of well-characterized particles with regular structure on the nanometer scale.<sup>[1,2]</sup> Use of these model catalysts provides a bridge between fundamental studies of single-crystal reactivities and applied studies of high-surface-area catalyst activities. These objects attract attention from both applied and theoretical points of view because their properties differ significantly from those of similar systems with large dimensions. Particularly, the surface morphology of supported nanoparticles is not fixed and can appreciably change during reaction. This phenomenon of “building of the catalytic surface to the reaction condition” confirms G. K. Boreskov’s thesis about the mutual interaction between the catalyst and the surrounding reaction medium. At the same time, the specific catalytic activity (the rate per surface metal atom or per adsorption site) can substantially depend on the size of the active particle.<sup>[3]</sup>

The turnover rate of catalytic reactions often depends on the diameter of the particle,  $d$ , indicating that the relationship between the reaction kinetics on nanoparticles and those measured on single-crystal surfaces is not straightforward. This structure gap between the kinetics may have different origins, as indicated schematically in Fig. 1. The geometric shape, exposed crystal planes, etc. of nanometer-size crystallites depend in general on their size, properties of the support (including the metal–support interaction), temperature, and the method of fabrication. For clusters or very small metal particles with  $d < 4$  nm the electron structure is significantly different from that of bulk metals and their catalytic activities are also different. This factor may be crucial to understanding the catalytic activity of such small particles. The metal–support interaction may modify the catalytic properties, and this effect may be important for particles up to  $d \sim 4$  nm. For crystallites with  $4 < d < 10$  nm, the role of edges is usually believed to be appreciable. For  $d > 10$  nm, the particles are electronically

**Fig. 1** Electronic and kinetic effects as ingredients of the structure gap in heterogeneous catalysis. *Source:* From Ref.<sup>[4]</sup> with permission from Elsevier.

identical to bulk metal but may still exhibit remarkably different kinetics compared to single crystals. In this case, reactions may occur primarily on facets although the edges may of course be important as well. From the theoretical point of view, the latter size range is especially interesting because on this scale there is hope of understanding the special features of the size-dependent reaction kinetics based on kinetic data obtained for single-crystal surfaces. In particular, the kinetics on facets are expected to be the same (for a given coverage) as for the corresponding single-crystal faces, and the influence of facet boundaries may be inferred from those steps on single crystals.

The main reasons why kinetic phenomena do not occur on single crystals as opposed to supported catalysts are as follows:<sup>[5]</sup> 1) the different catalytic activities on different facets of a small supported crystalline particle become coupled in a strongly nonlinear (synergistic) fashion because of diffusion occurring over facet boundaries; 2) equilibrium-shape changes of small particles, caused by adsorbates, induce changes in catalytic behavior; 3) different kinetic rate constants at the facet boundaries of a supported particle compared to those for the perfect facets give rise to new kinetics; and 4) spillover by diffusion of reactants between the particle

and its support also create new kinetics. These peculiarities of the supported nanosystems dictate the special requirements to theoretical models aimed at the simulation of catalytic properties of nanometer-scale particles.

Factors (1)–(4) mentioned above are expected to be especially important for *rapid bistable* reactions (“rapid” means that the surface reaction steps between intermediates are fast compared to adsorption) because in this case the reaction regimes on different facets of a catalyst may be very different and the adsorbed overlayer is often far from adsorption–desorption equilibrium. The most interesting feature of rapid reactions is the existence of kinetic phase transitions (for a review, see Ref.<sup>[6]</sup>). An analysis of rapid reactions on the nanometer scale almost inevitably requires the use of MC simulations.

### POSSIBLE APPROACHES TO SIMULATIONS

In modeling catalytic supported systems, two lines of investigation should be conventionally marked out: modeling of the fabrication process of the supported system itself (e.g., Refs.<sup>[7,8]</sup>) and modeling of physico-chemical processes in particular supported systems. Both these directions are now rapidly progressing. We shall pay our attention to the latter and will not consider modeling the processes of nanoparticle manufacturing. The theoretical study of supported catalysts is a rather complicated problem, and an analysis of reaction performance on the small particles almost inevitably requires use of atomic-scale computer simulations taking into account the intrinsic heterogeneity of nanoparticles.

There are three main classes of atomic-scale computer techniques: molecular dynamics, Monte Carlo algorithms based on Metropolis-like procedures, and the so-called kinetic (or dynamic) Monte Carlo. Despite the potential power of molecular dynamics, the use of this technique for analysis of physico-chemical processes over supported particles is rather limited because of the short length and time scales typical for this approach<sup>[9]</sup> The most effective tool for simulation of the spatiotemporal dynamics of adsorbed species on real catalytic surfaces, whose structure and properties can change under the influence of the reaction, are now the stochastic methods based on the Monte Carlo technique permitting one to obtain qualitatively new results. The Monte Carlo method<sup>[10,11]</sup> considers the dynamics of the processes occurring on the catalytic surface as a random Markovian chain of elementary events (adsorption, reaction, diffusion, local surface reconstruction, etc.) on the active sites of the catalysts, represented as the cells of a lattice with predetermined rigid or dynamically

changed structure. An obvious disadvantage of stochastic methods is the large body of calculations involved, whereas their main advantage is the possibility of precise control over the local environment and state of each active site on the surface of the catalyst. Another attractive advantage of the Monte Carlo technique is the possibility of including in the simulation all relevant physical and chemical processes (specifically those that can hardly be described analytically) with the corresponding characteristic rate constants obtained from experimental data or from molecular dynamics simulations. Active use of the Monte Carlo technique for simulation of heterogeneous catalytic reaction kinetics (see, e.g., Refs.<sup>[6,12]</sup>) started after the pioneering and nowadays classical paper.<sup>[13]</sup>

At present, the theoretical study of adsorption and reaction processes over supported catalysts is at its very beginning. A comprehensive and careful review of simulations of the reaction kinetics on supported nanoparticles has been published recently by Zhdanov and Kasemo.<sup>[5]</sup> Adapting the key points of that review, we also discuss the results of more recent studies.

Details of simulations of reaction kinetics on supported nanometer catalyst particles depend on the particle structure, reaction mechanism, and ratio between the rates of elementary reaction steps (such as adsorption, desorption, reaction steps, and surface diffusion). Thereupon, one more shortcoming of the kinetic Monte Carlo algorithms should be mentioned—it is difficult to take into account real ratios between the rates of adsorption, reaction, and diffusion. Let us consider the  $2A + B_2 = 2AB$  reaction mimicking CO oxidation on such catalysts as Pt, Rh, and Pd (this reaction is often used in simulations to compare reaction performance on the flat homogeneous surfaces of single crystals and small supported particles). It occurs via the standard Langmuir–Hinshelwood (LH) mechanism,

As stated in Refs.<sup>[5,14]</sup>, the following relationships should be fulfilled between the rate constants for diffusion jumps of A and B particles to nearest-neighbor vacant sites and for the reaction between two nearest-neighbor reactants: the rate of A diffusion is usually *rapid* compared to the LH step, whereas the rate constant for the LH step might be higher, close to, or lower than that for B diffusion.

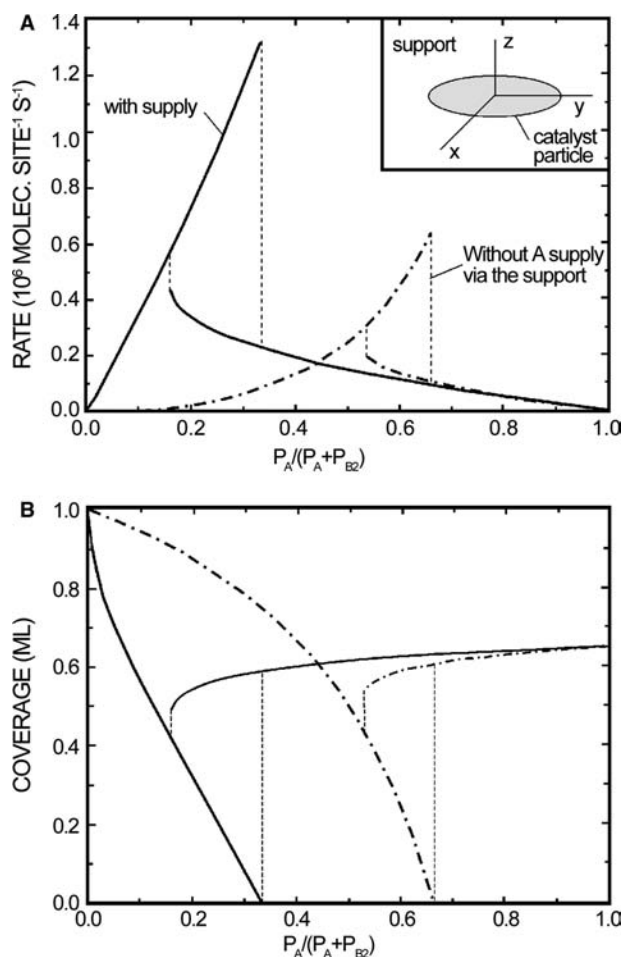

In some Monte Carlo simulations presented below,<sup>[4–6,14,20–22,24–28]</sup> adsorbed A particle diffusion is always considered to be fast compared to the LH step; the latter is in turn much faster than adsorption

(a special MC algorithm had been designed especially for this case). On the other hand, B particles are assumed to be immobile. This practically important limit ( $k_{\text{dif}}^B \ll k_r \ll k_{\text{dif}}^A$ ) is far from the mean-field (MF) approximation and from the case when the LH step is considered to be instantaneous<sup>[13]</sup> (the latter assumption is widely used in MC simulations of reaction kinetics on single-crystal surfaces, but often does not correspond to reality).

## REACTANT SUPPLY VIA THE SUPPORT (SPILLOVER)

A factor of both fundamental and practical importance in catalysis, which might change the reaction kinetics on supported systems,<sup>[5]</sup> is the possibility of adsorption of reactants on the support followed by diffusion to the catalyst and vice versa. The early models<sup>[15,16]</sup> focused primarily on reactant adsorption, desorption, and diffusion along the support toward catalytic particles, which were assumed to be widely separated (no interference of the diffusion zones)<sup>[15]</sup> or regularly distributed with overlapping diffusion zones.<sup>[16]</sup> The reaction kinetics on the catalyst in those studies has, however, not been analyzed explicitly. CO oxidation reaction on metal particles has been simulated<sup>[17]</sup> by combining CO adsorption, desorption, and diffusion on the support with the reaction steps on the catalyst. Diffusion jumps from the support to the metal were considered rapid and irreversible.

In Ref.<sup>[14]</sup> this effect was analyzed on the example of CO oxidation reaction occurring via LH mechanism (1) by solving the MF equations for the reaction kinetics on the catalyst particle self-consistently with the diffusion equation describing the net flux of A particles from the support to the catalysts. (We do not consider hereinafter the detailed formulation of the problems under consideration and the peculiarities of used algorithms; these can be found in cited papers.) The model used includes circularly shaped catalyst particles regularly distributed on the support. Typical results obtained in the limit when the A diffusion zones around different catalytic particles are not overlapping (i.e., the particles are sufficiently far apart) are shown in Fig. 2 together with the results corresponding to the case when there is no A supply via the support. Because of the A supply from the support, the position of the maximum reaction rate shifted to a lower value of the  $P_A/(P_A + P_{B_2})$  ratio. This intuitively expected result could be expressed in terms of an increased “effective pressure” of the reactant(s) supplied to the catalyst via adsorption on the support and diffusion to the catalyst. Note also that with the action of the support to trap reactant particles, a much higher (by a factor of two) maximum rate becomes possible,

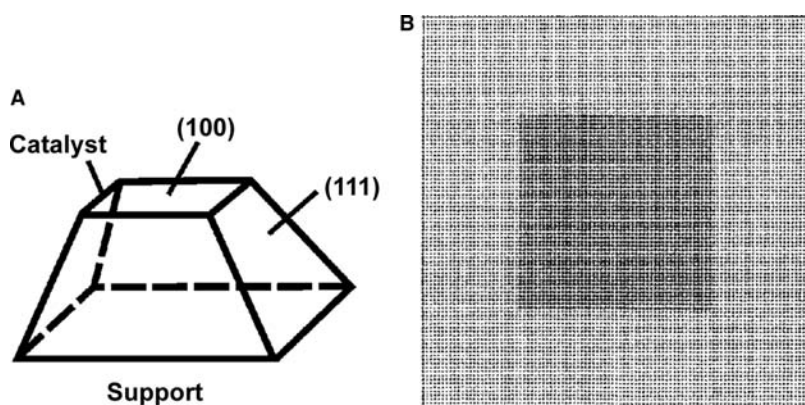

**Fig. 2** (A) Reaction rate and (B) reactant coverages for the rapid  $2A + B_2 \rightarrow 2AB$  reaction under steady-state conditions. The solid and dashed lines show, respectively, the kinetics with and without A supply via the support. The inset on panel (A) exhibits the model used in calculations. *Source:* From Ref.<sup>[21]</sup> with permission from Elsevier.

compared with an inert support. Similar effects were revealed by MC simulation<sup>[18]</sup> considering the same LH reaction mechanism, but with irreversible A adsorption. Another aspect of the spillover phenomena

has been studied by scanning tunneling microscopy (STM) and the corresponding Monte Carlo simulation.<sup>[19]</sup> It has been shown that Pd nanoparticles enhance the rate of reoxidation of a substoichiometric  $TiO_2(110)$  surface. The authors propose that  $O_2$  dissociatively adsorbs on Pd and then spills over onto the support, where  $Ti^{n+}$  interstitial ions in the bulk crystal lattice react with the spillover oxygen at the surface, preferentially growing  $TiO_2$  around and over the particles. The kinetic Monte Carlo model used, in which mobile species spills over from the metal particle and performs a random walk until it reaches a step edge where it may react to form  $TiO_2$ , is in good agreement with STM images.

### INTERPLAY OF KINETICS ON DIFFERENT ADJACENT FACETS

During catalytic reactions on nanometer-size crystallites, adjacent crystal facets can communicate with each other by reactant diffusion. The effect of this factor on the reaction kinetics has been simulated<sup>[5,20]</sup> by using the same  $2A + B_2 \rightarrow 2AB$  catalytic reaction (steps 1–3 with irreversible A adsorption) on the catalyst particle shaped into a truncated pyramid (Fig. 3), with top and bottom (100) faces and (111) side faces, with the largest (100) facet attached to the substrate. In kinetic simulations<sup>[20]</sup> the pyramidal particle was represented by a  $100 \times 100$  square lattice, where the central  $50 \times 50$  array of sites mimics the top (100)-(1  $\times$  1) facet, and the periphery corresponds to the side (111) facets. In the framework of this model, one can use different values of the  $B_2$  (and/or A) sticking coefficient for adsorption on the top (central) and side (peripheral) facets. The A and/or B binding energies and the LH reaction rate constants for the different facets may be different as well. Many other effects can also be easily incorporated into the model, but even the simplest case, when the central part and the periphery of the lattice differ only in the sticking

**Fig. 3** (A) Typical shape of the supported metal particle. (B) 2-D  $100 \times 100$  lattice mimicking a particle. The central  $50 \times 50$  part of the lattice represents the top (100) facet. The periphery models the side (111) facet. *Source:* From Ref.<sup>[20]</sup> with permission from Elsevier.

coefficients for  $B_2$  adsorption (differing by a factor 10), can provide the unexpected results. Usually, it is assumed that the geometry of the nanoparticle surface area introduces no additional complications. Small particles exposing different crystal faces are then simply regarded as presenting a superposition of the contributions from different structural elements. This statement is illustrated in Fig. 4A where the total reaction rate for a finite catalyst particle is given simply by a superposition of the rates corresponding to two infinite faces (without communication between the facets). However, if there is diffusion-mediated coupling of the reaction on the different crystal planes, distinctly new kinetics appear (Fig. 4B), compared to those for the infinite surfaces, and completely different compared to that predicted by using the conventional superposition prescription. Specifically, a single new reaction window appears, which is very different from those on either facet. Compared to the isolated facets, the communicating facets provide new channels for A particles. The central facet, which in isolation can resist self-poisoning by A particles up to high values of  $p$  (here  $p$  is the governing parameter defined as the ratio

of the A impingement rate to the total impingement rate), will in a communicating system receive an additional supply of A particles from the adjacent peripheral area, which is less resistant to A poisoning because the  $B_2$  sticking coefficient is 10 times smaller there. This latter net flow of A particles from the peripheral to the central area facilitates A poisoning of the central facet at high values of  $p$  and simultaneously prevents A poisoning from occurring on the peripheral area at relatively low values of  $p$ . Addition to the considered model of the effect of the edge sites (i.e., the sites located on the boundaries between the central and peripheral facets) on the reaction rate makes the resulting global kinetics even more complicated.<sup>[21]</sup> The contribution of the edge sites to the reaction rate is significant if the  $B_2$  sticking coefficient for adsorption on these sites is much higher compared to that on the facet sites. The most important result of these studies is that it has been explicitly shown that the kinetics on nanometer-sized particles exposing different crystalline facets can be dramatically different from the mere superposition of the kinetics on the individual facets because of the combined effect of the difference in the sticking coefficients and the diffusion transport of reactants over the facet boundaries.

**Fig. 4** Modeling the influence of adsorbate diffusion on the overall kinetics of reaction on a nanoparticle exposing two different kinds of planes (Fig. 3): (A) without diffusion; (B) with rapid diffusion across the facet boundaries. ## ADSORBATE-INDUCED RESHAPING OF CRYSTALLITES

Crystallite shape transformations, due to adsorbed reactants, may affect the steady-state kinetics of catalytic reactions. In particular, adsorbates can change the surface energy situation of a crystallite participating in a catalytic reaction, so that it transforms into a new shape with new kinetic conditions. To study such transformations, MC simulations of the  $A + B_2 = 2AB$  reaction kinetics combined with the use of the Wulff rule has been used.<sup>[22]</sup>

The equilibrium geometric shape of small, clean particles is determined by the Wulff rule, stating that the shape is a consequence of minimizing the total surface free energy. Specifically, the rule states that the geometric distance from a common center to a particular facet is proportional to its surface tension. In the case of adsorption, the standard derivations of the Wulff rule holds as well if there is an adsorption-desorption equilibrium. The only difference is that the properly defined surface tension becomes dependent on adsorbate coverages. In this case, the clean surface shape may no longer minimize the surface energy. A shape transformation then occurs (unless it is kinetically hindered), including changes in the relative areas of exposed facets, or even removal and/or creation of new facets. In open, chemically reactive systems, application of the Wulff rule with

coverage-dependent surface tension can also often be justified, but not always. Anyway, this rule is a reasonable starting point for the analysis even far from equilibrium. The conventional Wulff rule is strictly applicable for rather large particles because it neglects, e.g., edge and corner energies, which may be important at smaller sizes. Despite this shortcoming, the Wulff rule is usually robust at least for  $d > 10$  nm. Often the Wulff rule works reasonably well even for smaller particles.<sup>[5]</sup>

In simulations,<sup>[22]</sup> in the absence of adsorbates, the equilibrium shape was assumed to be a truncated pyramid with the (111) and (100) faces, similar to Fig. 3. During the reaction, the particle shape and reaction kinetics were calculated self-consistently by assuming a linear dependence of the surface tension of the (100) facet on B coverage (shape transformations were considered to occur instantaneously when they were energetically favorable). If this dependence is sufficiently strong, the pyramid-shaped catalyst particles become unstable with respect to reconfiguration to the parallelepiped shape with (100) facets. Such reconfiguration results in shifting the reaction window to higher values of  $p$  (Fig. 5). If the adsorbate-induced transition from one shape to another is energetically impossible, the adsorbate-induced changes in the relative areas of different facets may still take place and influence the reaction kinetics. An interesting example illustrating this case has recently been given in Ref.<sup>[23]</sup>. The kinetics of methanol synthesis on nanometer-size Cu particles supported by ZnO has been analyzed. The generalized surface tension for the substrate-particle interface was assumed to be dependent on the reduction potential of the gas phase. The latter resulted in the dependence of the areas of the (111), (100), and (110) facets on the gas-phase concentrations [such changes were observed by using extended X-ray absorption fine structure (EXAFS)]. This dynamic microkinetic model is able to describe the change in particle morphology (i.e., the number of active sites and the exposed facets) with change in feed gas composition as well as the reaction rate over the three basal Cu surface planes. The total reaction rate, represented as a sum of the reaction rates on different facets, was strongly affected by the changes in particle morphology.

Thus, it has been shown that adsorbate-induced reshaping of nanometer-sized catalyst particles may result in dramatic changes in the steady-state reaction kinetics. Experimental search for such changes is of course not always easy, because the transitions from one catalyst structure to another might be slow especially at mild conditions, e.g., at  $T \sim 500$  K. Physically, it is clear that the transition time strongly depends on the crystallite size, temperature, and reaction conditions.

**Fig. 5** Reaction rate as a function of the ratio of the A impingement rate to the total impingement rate  $p$ : (A) superposition of the reaction rates corresponding to two infinite facets; (B) kinetics for the crystallite with communicating facets and fixed facet areas; (C) kinetics obtained by taking into account B-induced changes in the shape of the crystal particle. Along the line  $\alpha\beta$ , the catalyst is shaped as a parallelepiped (the point  $\beta$  corresponds to reconfiguration of the catalyst shape from a parallelepiped to a pyramid). ## OSCILLATIONS AND CHAOS

In the previous section the effect of adsorbate-induced 3-D reshaping of catalyst crystallites on the reaction kinetics was considered. In this section, the opposite case—when there are no changes in the global shape of a crystallite but there is adsorbate-induced surface restructuring of one of the crystallite facets—will be treated.<sup>[5,24–26]</sup> This restructuring in interplay with purely chemical reaction steps may cause kinetic oscillations in catalytic reactions. Classic examples are CO oxidation reactions over Pt(100) and Pt(110) single crystals. For example, Pt(100) undergoes the reversible adsorbate-induced surface structure reconstruction

[Pt(100): hex  $\leftrightarrow$   $1 \times 1$ ] depending on adsorbate coverage. The lifting of the hex  $\leftrightarrow$   $1 \times 1$  reconstruction is accompanied by an increase in the oxygen sticking coefficient from  $\approx 0.001$  (hex) to  $\approx 0.3$  ( $1 \times 1$ ) thus inducing a transition from a catalytic inactive state into an active state with high sticking coefficient for oxygen. The competition of the O<sub>2</sub> and CO adsorption in combination with the processes of the surface structure transition hex  $\leftrightarrow$   $1 \times 1$  is a driving force for self-oscillations. It has been shown<sup>[21,24–26]</sup> that such oscillations (and chaotic behavior) are distinctly different on the supported nanometer-sized catalyst particles, compared with extended crystals, mainly because of diffusion communication between facets.

In the models constructed for CO oxidation reaction over Pt(100),<sup>[21,24–27]</sup> adsorbate-induced surface restructuring, treated as a first-order phase transition, occurs only on the central (100) facet. That means that the active centers of the central facet could exist in two different states: active  $Z_{1 \times 1}$  and inactive  $Z_{\text{hex}}$ . The reaction under consideration is run via the conventional LH mechanism (CO = A, O<sub>2</sub> = B<sub>2</sub>). The peripheral (111) facets are considered to be stable (no adsorbate-induced restructuring, i.e., no oscillations). Physically, it is clear that here the interplay of the reaction kinetics on different facets may weaken or even suppress oscillations on the central facet. The simulations show, however, that the amplitude of oscillations may still be large and, in addition, may exhibit qualitatively new features.<sup>[5,24]</sup>

For example, one of the conceptually simplest cases had been considered<sup>[5,24]</sup> when 1) A adsorption, desorption, and diffusion are realized on the peripheral facets with the same MC rules as on the perfect central facet and 2) B<sub>2</sub> adsorption on the peripheral facets is negligible (because of low sticking probability). In this case, the main role of the peripheral facets is to provide an additional supply of A particles to the central face via adsorption and surface diffusion. This supply shifts the oscillation window to lower  $p_A$  values and results in a strongly nonuniform phase distribution on the central facet. In particular, the facet is restructured primarily near the boundaries. In this case, the conditions for oscillations on different regions of the central facet are quite different. This results in a wide distribution of oscillation frequencies. In addition, the kinetics becomes very sensitive with respect to small fluctuations in adsorbate coverages. These special features taken as a whole result in chaotic oscillations. Such chaos, connected with the interplay of the reaction kinetics on adjacent (100) and (111) facets, seems to be inherent for reactions on nanometer-size particles and can hardly be observed in reactions on single-crystal surfaces.

The role of edges mimicked as the rows of sites located on the boundaries between the central (100)

and peripheral (111) facets was considered in Ref.<sup>[21]</sup>. It was shown that for rapid oscillating catalytic reactions the effect of edge sites on the reaction rate can be considerable if the B<sub>2</sub> sticking coefficient for these sites is much higher than for facets. With regard to the diffusion and reaction steps, they have to be slowed down toward that of the rate-limiting adsorption step to cause significant effect in the global kinetics. The influence of other factors (e.g., of higher A-binding energy on edge sites or higher reactivity of edge sites) on the reaction kinetics was demonstrated to be minor.<sup>[5,21]</sup>

The algorithm constructed on the rules of statistical physics<sup>[21,24–27]</sup> makes it possible to take into account substrate–substrate, substrate–adsorbate, and adsorbate–adsorbate lateral interactions. The MC algorithm combines kinetic Monte Carlo procedures for the calculation of probabilities of elementary steps (1)–(3) of the LH mechanism, and Metropolis rules for attempts of surface restructuring and A<sub>ads</sub> particle diffusion; that is, the latter events, as well as A<sub>ads</sub> desorption, depend on local environment of the lattice sites and their respective states. It has been shown,<sup>[27]</sup> using the restricted set of lateral interactions (e.g., the nn A–A and A–B interactions have not been used), that the model predicts the formation of well-developed restructured islands with a size of 5–10 nm (phase separation), in agreement with experimental data.

The dependence of oscillation features on the size of nanoparticles was studied in Ref.<sup>[26]</sup>. The facet size was varied from  $50 \times 50$  to  $5 \times 5$ . With decreasing size, oscillations become less regular. More or less regular oscillations accompanied by formation of CO islands are found for sizes down to  $15 \times 15$ . This means that for observation of such oscillations the particle diameter should be above  $\sim 4$  nm. These findings are in agreement with available experimental data.

An alternative version for the oscillatory behavior of catalytic reaction, such as the formation of subsurface oxygen, has been considered in Ref.<sup>[28]</sup>. The model includes the conventional LH mechanism (1) and the stages of subsurface oxygen formation and removal. The analysis focused on such aspects as CO supply via the support, the role of this supply in synchronization of oscillations on adjacent catalyst particles, and cooperative effects in the subsurface oxygen formation. It was shown<sup>[28]</sup> that 1) CO supply via the support shifts the oscillatory windows to lower CO pressures, as was shown above,<sup>[14]</sup> and may also result in nonuniform oxide distribution on the catalyst particle; 2) with physically reasonable model parameters, synchronization of oscillations on the adjacent catalyst particles due to the CO supply via the support seems to be unlikely; 3) heterogeneous nucleation and cooperative effects in the subsurface oxygen formation may worsen oscillations. In combination with CO adsorption via

precursor states, oscillations may, however, be well developed.<sup>[28]</sup>

The results presented in this section illustrate that catalytic reactions occurring on a single nanometer-size particle may exhibit oscillatory regimes.<sup>[5]</sup> Oscillations may be more or less regular or chaotic. On the macroscopic scale, observation of such oscillations may be hampered if synchronization of oscillations on different particles is not effective. Practically, synchronization is expected to occur via the gas phase (see, e.g., Ref.<sup>[29]</sup>.) or, in exothermic reactions, due to thermal conductivity via the support. Simulations describing the latter aspect of the reaction kinetics on nanometer-size particles are just beginning and not numerous. One of the first studies in this field<sup>[30]</sup> uses the Monte Carlo method for simulation of CO oxidation over nonisothermal supported catalysts. The reaction proceeded via LH mechanism (1) on square  $L \times L$  crystallites ( $L = 5\text{--}100$ ); the total number of islands ( $n = 1\text{--}20$ ) was distributed on the grid mimicking the support. The reaction kinetics on the crystallites were simulated by using the MC technique in combination with the conventional partial differential energy balance to describe the heat transfer over the support. Two general conclusions drawn in Ref.<sup>[30]</sup> are of interest: 1) Oscillatory behavior of reaction (1) was not observed even in the case of nonisothermal surfaces. 2) To reproduce oscillations, the LH mechanism was complemented by subsurface oxygen formation and removal, as in Ref.<sup>[29]</sup>. The latter made it possible to obtain oscillations and changes in oscillatory behavior with temperature and the  $O_2/CO$  ratio. The simulations also show that thermal communications among active particles affect the shape of global oscillations: regular, irregular, and chaotic oscillations were observed depending on crystallite size, activity, and distribution of the particles on the support.

## REACTION SELECTIVITY AND PARTICLE SIZE

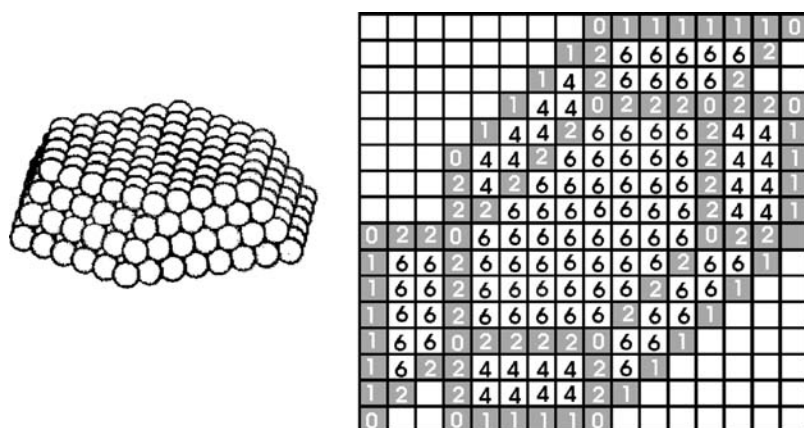

The relatively simple model reaction occurring via the LH mechanism (steps 1–3) represents a wide class of important real catalytic reactions occurring via a few elementary steps and resulting in the formation of a single product. Simulations have in fact been very much focused on catalytic reactions belonging to this class.<sup>[5]</sup> The world of real catalytic reactions is, of course, much wider and richer. Very often, real catalytic reactions involve complex polyatomic molecules, occur via a large number of steps, and result in the (parallel) formation of several products. Increasing the selectivity of catalytic reactions toward desirable products is often the main goal of applied catalytic chemistry. For this reason, understanding the factors influencing selectivity of catalytic reactions is an

important and challenging problem. The following reaction, mimicking hydrocarbon hydrogenation, has been considered<sup>[31]</sup> to occur on 2-D islands located on a  $128 \times 128$  square lattice with periodic boundary conditions:

- 1)  $(A_n)_{\text{gas}} \rightarrow (A_n)_{\text{ads}}$
- 2)  $B_{\text{gas}} \rightarrow B_{\text{ads}}$
- 3)  $2(A_n)_{\text{ads}} \rightarrow C_{\text{gas}}$
- 4)  $(A_n)_{\text{ads}} + B_{\text{ads}} \rightarrow D_{\text{gas}}$
- 5)  $2B_{\text{ads}} \rightarrow E_{\text{gas}}$

Both regular islands, consisting of a simple rectangular pattern, and irregular islands, generated by a Voronoi tessellation of the lattice, have been used to represent the catalyst surface. In the latter case, the lattice is divided into a set of polygons constructed by using randomly distributed Poisson points as the polygon centroids. Each polygon is then randomly given an identity, either as an active catalytic region or as an inactive region of the support material. By assigning a greater number fraction of the polygons as active regions, the average size of such regions increases because of coalescence of the individual polygons into larger single islands and vice versa. The goal of the simulations<sup>[31]</sup> was to determine the extent to which simple geometrical parameters, such as the average size of catalyst particles and the spatial distribution of active sites, determine the selectivity of complex catalytic reactions. The simulations<sup>[31]</sup> showed that the total reaction rate  $W_{\text{tot}} = \sum W_i$  and selectivity  $S_i = W_i/W_{\text{tot}}$  toward different products for regular islands are nearly the same as those for irregular islands; that is, the reaction under consideration is insensitive with respect to the island structure. In contrast, the dependence of the reaction rate and selectivity on the average island size is rather strong. On the nanometer scale, the total reaction rate decreases with the decline of the average island size. The C and D selectivities decrease as well. On the other hand, the E selectivity increases with decreasing average island size. All these findings are rationalized by noting that small islands inhibit adsorption of larger molecules and so favor reactions in which smaller molecules are reactants.

If reactant diffusion is incorporated in simulations, the results become quantitatively, but not qualitatively, different (this has actually been demonstrated in Ref.<sup>[32]</sup>). In particular, the influence of hydrogen spillover on the rate of hydrogenation reaction was shown to be negligible. The main qualitative conclusion in Refs.<sup>[31,32]</sup> that the influence of the catalyst particle size on the reaction activity and selectivity becomes significant below a particle size of approximately 10–20 nm is

**Fig. 6** Crystallite size model and lattice representation. 0: corner site; 1: base site; 2: edge site; 4: site on (100) plane with four nearest neighbors (NN); 6: site on (111) plane with six NN. *Source:* From Ref.<sup>[35]</sup> with permission from Elsevier.

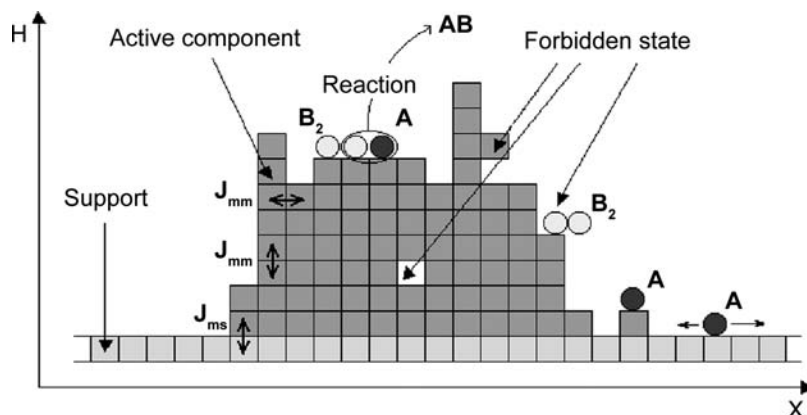

expected to be robust.<sup>[5]</sup> This conclusion is in agreement with experimental observations for a range of hydrocarbon reactions over supported catalysts.<sup>[3]</sup>

## REACTION KINETICS AND PARTICLE SURFACE MORPHOLOGY

As inferred from the experimental data, the influence of the various surface defects appearing under the action of the reaction media, as well as the change of the shape and size of deposited particles, can significantly determine the catalyst performance. For example, it was shown recently that in some cases, nanoparticles undergo reversible adsorbate-induced shape changes ( $\text{H}_2 + \text{H}_2\text{O}$  and  $\text{CO} + \text{H}_2$  over Cu/ZnO system studied by in situ transmission electron microscopy,<sup>[33]</sup>) and even disintegrate into atoms (effects of CO and NO adsorption on the morphological changes of Rh/TiO<sub>2</sub> studied by scanning tunneling microscopy<sup>[34]</sup>). For better understanding of the reaction kinetics, one should take into account these processes and the inherent heterogeneity of supported particles.

In the bulk of the theoretical studies cited above (except Refs.<sup>[22,23]</sup>), the change of surface morphology

was not taken into account; that is, the specificity of active centers, their state, and coordination (configuration) are defined by introducing the proper lateral interactions. The attempt to distinguish the active centers according to their coordination on the surface was undertaken in Ref.<sup>[35]</sup> where the influence of crystallite size on the activity of a supported catalyst for the LH reaction mechanism (steps 1–3) has been investigated. The active surface was modeled (following the model proposed in Ref.<sup>[36]</sup>) as a set of particles, each one represented as the top projection of a truncated hexagonal pyramid on a flat support surface (Fig. 6). Catalytic centers with different configuration (edges, corners, etc.) have differing activity with respect to the elementary reaction steps. These activities were calculated as a product of specific process rates for adsorption, desorption, and reaction and of some additional weight coefficients, which account for enhancement or reduction of these rates on each type of center. The ratio between the number of different active centers depends, of course, on the size of the crystallites (the relative concentration of surface defects increase with decreasing particle size). The important result of simulations<sup>[35]</sup> is that the structural features affect the production rate in ways that depend

**Fig. 7** Scheme of the supported catalytic particle model: cross cut of the Kossel crystal. *Source:* From Ref.<sup>[18]</sup> by permission of The Royal Society of Chemistry on behalf of the PCCP Owner Societies.

**Fig. 8** The initial (A) and equilibrium (b–d) shapes of the metal particles simulated at different temperatures: (B) –500 K, (C) –900 K, (D) –1100 K. The size of the initial particle is  $21 \times 21 \times 10$  atoms.  $J_{mm} = -10$  kJ/mol,  $J_{ms} = -2.5$  kJ/mol. on which of the elementary steps in the reaction mechanism is altered by the presence of different types of sites. In other words, there is no universal trend on the effect of particle size, but rather it is an integral effect that depends on the importance of the interaction of these structural features and the reactants.<sup>[35]</sup>

Recently,<sup>[18,37]</sup> a statistical lattice model has been proposed that imitates the physicochemical processes that proceed on the supported particle. To simulate the active metal particle, the finite Kossel crystal<sup>[38]</sup> located on the inert support was chosen (Fig. 7). The surface morphology of the particle is defined by distribution of heights of the metal atom columns. The metal atoms attract the nearest neighbors and the atoms of the support. The change of morphology is caused by thermal diffusion of the surface atoms. To model diffusion of metal atoms on the metal and support surfaces, the Metropolis algorithm has been used. (Similar algorithm was used in Ref.<sup>[39]</sup> for the modeling of catalyst sintering behavior.) As a result, the equilibrium shapes of the particle were observed depending on the temperature and the relative ratio of metal–metal and metal–support interaction energies  $J_{mm}$  and  $J_{ms}$  (Fig. 8). Although this model is two-dimensional, it allows one to model adsorption, diffusion, and reaction events on the dynamically changed surface of the particle to take into account various lateral metal–adsorbate and adsorbate–adsorbate interactions. It was shown<sup>[18]</sup> that the reaction kinetics on such particles can be qualitatively and quantitatively different from those corresponding to the flat surface only because of the change of the shape and surface morphology of nanoparticles and spillover phenomena. The simulations show that if the adsorbate–metal

interaction energies become comparable with the metal–metal ones the nanoparticle undergoes reversible adsorbate-induced reshaping,<sup>[37]</sup> and that the particle size determines the degree of reshaping as in experiments.<sup>[33]</sup> The proposed approach offers new routes to model catalytic reactions closer to reality (see also 3-D models of supported nanoparticles published recently<sup>[40]</sup>).

## CONCLUSION

The most important message from the simulations reviewed is that *the kinetics of catalytic reactions occurring on nanometer-sized metal particles, exposing different crystalline facets, can be dramatically different from the mere superposition of the kinetics of the individual facets.*<sup>[5]</sup> This finding has far-reaching consequences both for the interpretation of kinetic data from supported and nanofabricated catalysts and for the design of catalysts. In particular, one should, in analysis of experimental data, consider the special kinetics *inherently* associated with nanoparticles before more complex explanations are tried, such as size-related electron-structure effects, support-related effects, special active sites, etc. With respect to catalyst design, the kinetics on supported catalysts may be manipulated by influencing the relative amounts of different facets, the size of the nanoparticles, and the adsorption properties of the support. Modeling of heterogeneous catalytic processes over supported nanoparticles demands the construction of new statistical lattice models describing in detail the fcc or bcc nanometer-sized metal crystallites and kinetic MC models for elementary steps of particular catalytic reactions. The mutual influence of the reaction media on the particles shape and surface structure, and vice versa, of nanoparticle characteristics on the reaction kinetics is one of the fundamental problems in heterogeneous catalysis. The simulations are expected to be strengthened by using the parameters provided by ab initio quantum mechanical calculations. Such a combined approach will be a powerful complementary tool to high-resolution kinetic experiments.<sup>[41]</sup>

# Ceramic Nanocomposites: Self-Diagnostic Ability of Catastrophic Damage

Pavol Šajgalík  
Zoltán Lenčič

*Institute of Inorganic Chemistry, Slovak Academy of Sciences,  
Bratislava, Slovakia*

## INTRODUCTION

Ceramic nanocomposites are widely used as engineering materials owing to their excellent mechanical properties. In the last decade ceramic nanocomposites found new uses as a different kind of sensor. In this entry, examples of the preparation of electroconductive ceramic nanocomposites are shown together with their utilization as self-monitoring sensors for crack initiation and propagation. Four different methods for synthesis of nanocomposite ceramics are presented, and their effects on the structure of nanocomposites are compared. The self-diagnostic ability of graded and layered ceramic nanocomposites was not accompanied by any sizable deterioration of mechanical properties.

## BACKGROUND

In modern material science there is a trend toward more flexibility and an increased interest in “smart” and “adaptive” materials. These are generally structural composite materials with constituents, which include functions, such as conductivity, sensing/activating properties, health monitoring abilities, thermal-load dissipation, tailorable thermal expansion, environmental protection, etc., as an inherent part of their design and application. This multifunctionality applies to the new scientific and engineering approaches required for the development of these new ceramic materials. The latest achievements in ceramic nanotechnology offer solutions for these market demands. On the other hand, ceramic materials generally exhibit brittleness with relatively low reliability. A fundamental approach to improve reliability is the design of ceramic materials with high fracture toughness and strength. Promising results have been achieved for ceramic nanocomposites exhibiting such properties.<sup>[1,2]</sup> Unfortunately, brittleness remains an intrinsic character of ceramic materials, and it is difficult to overcome this problem completely in ceramics for practical use. Accordingly, the development of

screening techniques and methods for damage detection and fracture forecasting are important to ensure the reliability of structural ceramics.<sup>[3]</sup> Incorporation of real-time damage sensors into ceramic materials can assist in lifetime predictions of complex structures. Until now, the most common applied sensor for detection of defect initializing strain was a gauge method. However, this is not practical for the determination of maximum strain applied after the load has been removed. The other nondestructive methods using x-ray, ultrasonic, and acoustic emission demand large-scale equipment and their applications in the practical use of ceramic parts are limited.

In the beginning of the 1990s, Yanagida proposed a new method of fracture forecasting by electrical measurements.<sup>[4]</sup> This self-diagnosis mechanism as an intelligent function in ceramic materials is based on the observation that there is a correlation between the increase of electrical resistivity and crack propagation. The majority of works are focused on forecasting the fatal fracture in carbon- or SiC-fiber reinforced plastics and ceramic composites by measuring electrical resistance.<sup>[3,5,6]</sup> The change in electrical resistance occurs with a change in connectivity of C or SiC fibers/whiskers in the composites. A similar approach can be applied also for ceramic composites with spherical micro-/nanoelectroconductive particles.

Although it is promising to fabricate ceramic composites with such a self-diagnosis mechanism, available conductive ceramic systems are limited and it seems difficult to maintain the mechanical properties at a level equivalent to those of the structural ceramics already used. In addition, because engineering ceramics usually show a small strain prior to fracturing, it is necessary that the electrical resistance change induced by the strain be large. Such behavior is observed near the percolation threshold of conductive phase, when the resistivity can vary by several orders of magnitude. Depending on the size and distribution of electroconductive ceramic particles, the percolation threshold varies from 8 to 30 vol%.

There are several processing routes for the introduction of electroconductive phase. Conductive ceramic

nanostructures are produced using molecular beam epitaxy, organometallic vapor phase epitaxy, top-down lithography, etc. These composites include, among others, sensors, actuators, or even miniaturized systems comprising sensing, processing, and/or actuating functions. These systems can sense, control, and activate on the micro-/nanoscale and function individually or in arrays to generate effects on the macroscale.<sup>[7]</sup> However, all the above-mentioned processing routes of nanoceramics are rather expensive and the size of the products is limited. The market demands multifunctional materials with acceptable production costs and shape flexibility. Examples of relatively low-cost processing of structural ceramics with  $\text{Si}_3\text{N}_4$  or  $\text{Al}_2\text{O}_3$  matrix and electroconductive carbon, SiC, or TiN are shown in this work. Four different methods have been used for in situ preparation of nanosized electroconductive phases: 1) addition of an organometallic precursor to commercial  $\text{Si}_3\text{N}_4$  powder as a source of nanoinclusions; 2) carbothermal reduction of ultrafine  $\text{SiO}_2$  with carbon black to SiC and C; 3) pyrolysis of organometallic Si/N/C precursors with SiC,  $\text{Si}_3\text{N}_4$ , and C products; and 4) preparation of conductive TiN by exchange reaction between titanium butoxide or fine  $\text{TiO}_2$  and AlN.

The structure of shown nanocomposites varies from homogenous bulk  $\text{Si}_3\text{N}_4/\text{SiC}$  or  $\text{Al}_2\text{O}_3/\text{SiC}$  ceramics, through organometallic polymer-derived functionally graded materials (FGM) on the base of  $\text{Si}_3\text{N}_4/\text{SiC}$  with controlled electroconductive C content to layered  $\text{Si}_3\text{N}_4/\text{TiN}$  composites prepared by tape casting. The two later ceramic nanocomposites showed self-diagnostic ability without sizeable degradation of mechanical properties.

### $\text{Si}_3\text{N}_4/\text{SiC}$ NANO-/MICROCOMPOSITES

Silicon nitride-based ceramics is a promising material for a wide variety of applications. The diapason of applications is very broad, from cast industry—where these materials are used as a new generation of refractories—to the high-tech applications in the automotive and space industry. The main requirement for application of this ceramics is an increased reliability at room temperature as well as at high temperature. An example of a material that fulfills such requirements is the  $\text{Si}_3\text{N}_4/\text{SiC}$  nanocomposite (SNC).

Samples were prepared by mixing  $\text{Si}_3\text{N}_4$  matrix powder (Ube E-10, Japan) with 5 wt%  $\text{Y}_2\text{O}_3$  (H.C. Starck, Germany) sintering additive and 20 wt% pyrolyzed polysilazane-based precursor (NCP 200, Japan) in isopropanol. The detailed processing route of the reference materials is already described elsewhere.<sup>[8]</sup>

Samples were hot-pressed under nitrogen atmosphere and mechanical pressure of 30 MPa at 1750°C

for 2 hr. The hot-pressed samples were cut to bars of  $3 \times 4 \times 45$  mm and polished to 1  $\mu\text{m}$  final finish. The creep tests in bending (20/40 inner/outer span) were performed in air from 1200°C to 1400°C, with the step of 50°C. The stepwise-loading regime was applied at each temperature. The creep experiment started with a load of 50 MPa for 24 hr, then 100 MPa for the next 24 hr, and 150 MPa for the last 24 hr to speed up the collection of data.

These nano-/microcomposites consist of the major crystalline silicon nitride phase and the minor silicon carbide phase. The larger matrix  $\text{Si}_3\text{N}_4$  grains have an elongated shape with a mean diameter below 1  $\mu\text{m}$  and lengths up to 15  $\mu\text{m}$ . SiC nano-/microparticles are randomly distributed along the grain boundaries (inter-SiC grains; diameter 300–600 nm) as well as within the  $\text{Si}_3\text{N}_4$  micrograins (intra-SiC grains, diameter 5–100 nm) as shown in Fig. 1.

The distribution of inter- and intra-SiC grains within the  $\text{Si}_3\text{N}_4$  matrix is shown in Fig. 2. The larger grains were found at the grain boundaries (inter-SiC grains), while the finer SiC were determined within the  $\text{Si}_3\text{N}_4$  host grains (intra-SiC grains). The number of intra- vs. inter-SiC grains was estimated from transmission electron microscopy micrographs and a ratio of 80 vs. 20 was determined.

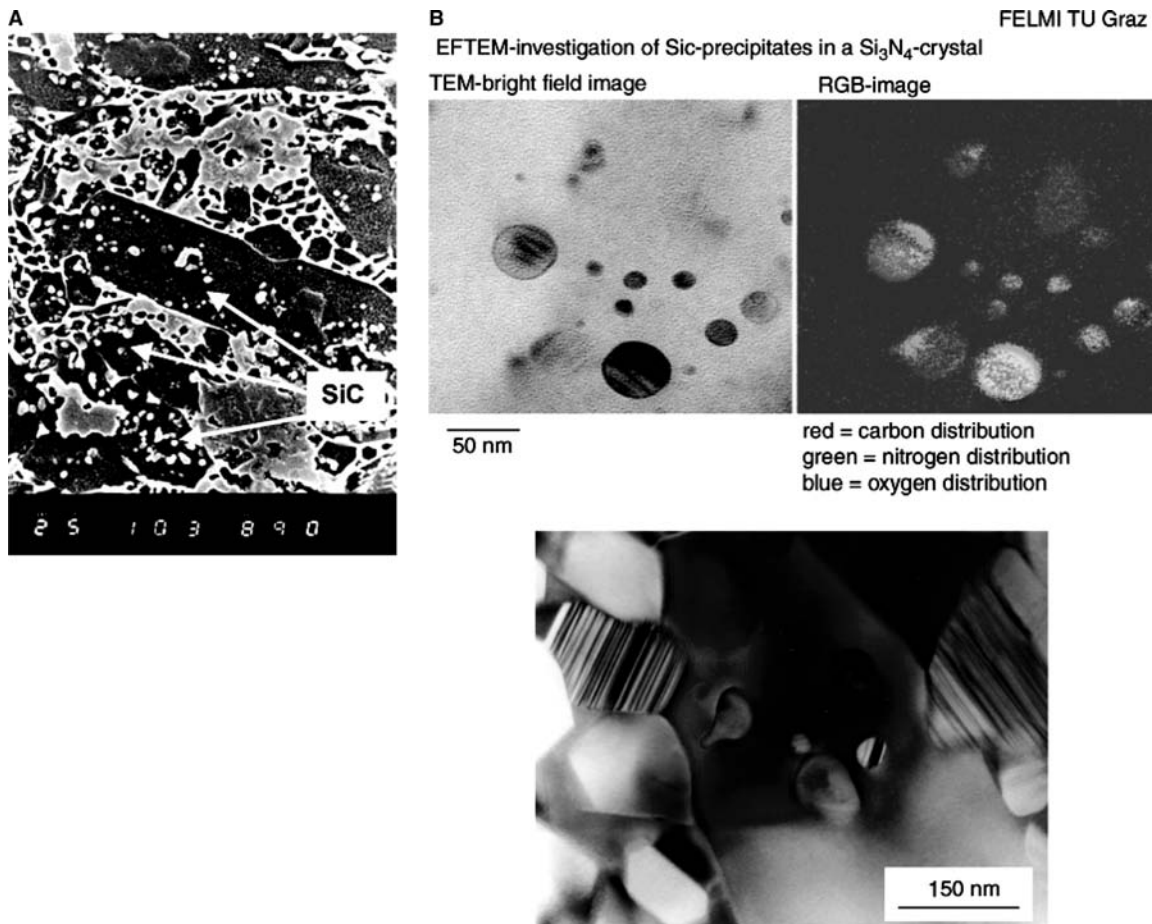

### Room Temperature Properties

The room temperature properties of the  $\text{Si}_3\text{N}_4/\text{SiC}$  composite (sample SNC) and of the reference  $\text{Si}_3\text{N}_4$  materials (sample SN) are listed in Table 1.

The distinctly higher Weibull modulus of SNC confirms the homogeneity of this composite. The homogeneity of the SNC microstructure is reached by the pinning effect of randomly distributed SiC nanograins, which hinder the abnormal grain growth of  $\text{Si}_3\text{N}_4$ . The length of  $\beta\text{-Si}_3\text{N}_4$  grains was below 15  $\mu\text{m}$ . This effect has already been presented elsewhere, and it is a general feature of SNCs.<sup>[9]</sup>

The fracture toughness of SN sample (7.4  $\text{MPa m}^{1/2}$ ) is slightly higher compared to SNC (6.9  $\text{MPa m}^{1/2}$ ). Lower fracture toughness of nano-/microcomposite material compared to the relative monolithic material is attributed to the more equiaxed microstructure of  $\text{Si}_3\text{N}_4$  matrix and the low number of intra-SiC grains, only 20% (see Fig. 2). However, the intrainclusions of the second phase with a similar (but not the same) ratio of thermal expansion coefficients as in the present case should have a positive effect on the fracture toughness of the two-phase composite.<sup>[10]</sup>

The amount of SiC phase within the microstructure also plays an important role because of SiC influence on the grain growth and simultaneously on residual internal stresses. The optimum amount of SiC

**Fig. 1** (A) SEM image of the Si<sub>3</sub>N<sub>4</sub>/SiC micro-/nanocomposite; white dots are SiC inclusions. (B) TEM image of the SiC nanoinclusions within the Si<sub>3</sub>N<sub>4</sub> grains. *Source:* From Ref.<sup>[29]</sup>.

nanograins for room temperature properties is in the range of 5–10 wt%.<sup>[11]</sup> The amount of SiC nanograins present in the SNC nano-/microcomposite is only 2.7 wt%, i.e., much lower than the indicated optimum

**Fig. 2** SiC particle size distribution within the Si<sub>3</sub>N<sub>4</sub> matrix. *Source:* From Ref.<sup>[14]</sup>.

of 5–10 wt%. The fact that the present composite has excellent room temperature properties at such low levels of SiC phase indicates the potential for further increase in the fraction of SiC. Moreover, depending on the content of SiC and the remaining free-carbon content, the electrical conductivity of the nanocomposite can be varied.

### High-Temperature Properties

The SNC has almost one order of magnitude higher creep resistance compared to the reference SN material (Fig. 3). The difference is smaller at higher temperatures. The apparent activation energy of SNC at stress load 100 MPa is 566 kJ/mol; for the reference material SN it is only 289 kJ/mol. A more detailed analysis showed that cavitation was the controlling mechanism at lower temperatures, while at higher temperatures diffusion creep dominated. Frequent cavitation was observed in sample SN after creep test; on the other hand, sample SNC was almost free of cavities.

**Table 1** Room temperature mechanical properties of  $\text{Si}_3\text{N}_4$ -based materials

Sample	$K_{IC}$ ( $\text{MPa m}^{1/2}$ )	Strength (MPa)	Weibull modulus
SN	7.4	990	7
SNC	6.9	1203	19

Abbreviations: SN, reference  $\text{Si}_3\text{N}_4$  material; SNC,  $\text{Si}_3\text{N}_4/\text{SiC}$  micro/nanocomposite.

The improvement of the creep resistance is usually attributed to the distribution of the fine SiC nanograins along the grain boundaries.<sup>[12]</sup> A recent publication of Rendtel et al. shows that there exists an optimum of SiC nanograins content, which lies within the range of 10–15 wt%.<sup>[13]</sup> The amorphous SiCN powder added in the amount of 20 wt% to the starting mixture yields only 5.5 wt% of SiC present in the SNC nano-/microcomposite. The reason for the improved creep resistance is an excess of the carbon in SiCN amorphous powder, which reduces the residual glassy phase on the grain boundaries and/or changes its chemistry and increases the viscosity of the glassy phase.<sup>[14,15]</sup>

### $\text{Al}_2\text{O}_3/\text{SiC}$ Nanocomposites

A similar approach has been used for the preparation of alumina-based nanocomposites.<sup>[16]</sup> Nanosized alumina powder (Taimicron TM DAR, particle size 150 nm) was used as a matrix with 5 wt%  $\text{CaO} \cdot 5\text{SiO}_2$  sintering additive. An organic granulation additive (Dolapix ET85) was used as a source of carbon. The SiC inclusions were prepared by in situ reactions between  $\text{SiO}_2$  sintering additive and carbon. Samples

**Fig. 3** Comparison of the creep resistance of  $\text{Si}_3\text{N}_4$  material (SNY) and  $\text{Si}_3\text{N}_4/\text{SiC}$  nanocomposite prepared from  $\text{Si}_3\text{N}_4$  and pyrolyzed polysilazane mixture (SNY20). Source: From Ref.<sup>[8]</sup>.

**Fig. 4** SEM of  $\text{Al}_2\text{O}_3/\text{SiC}$  nanocomposite; upside arrows indicate intergranular SiC inclusions and downside arrows indicate intra-SiC inclusions.

were densified by hot-pressing at 1450°C in argon and 30 MPa mechanical load.

The results showed that  $\text{Al}_2\text{O}_3/\text{SiC}/\text{C}$  nanocomposites could be prepared by in situ pyrolysis of organic additives. The mean grain size of the alumina matrix was finer compared with the carbon-free reference samples (Fig. 4). The remaining free carbon did not impair the mechanical properties. The hardness of densified materials increased from 20.3 to 23.2 GPa because of the presence of in situ formed SiC nanoinclusions and reduction of grain boundary glassy phase. This is a promising method for nonexpensive in situ preparation of  $\text{Al}_2\text{O}_3\text{-SiC}$  nanocomposites.

### Low-Cost SNCs

Silicon nitride–silicon carbide nanocomposite has been prepared by an in situ method that utilizes the formation of SiC nanograins by carbothermal reduction of  $\text{SiO}_2$  in the temperature range 1450–1630°C, prior to the final sintering process.<sup>[17,18]</sup> The developed  $\text{SiO}_2 + \text{C}$ -derived nanocomposite consists of a silicon nitride matrix with an average  $\text{Si}_3\text{N}_4$  matrix grain diameter of approximately 200 nm with inter- and intragranular SiC inclusions with sizes of approximately 150 and 40 nm, respectively. No pores, clusters of grains/phases were identified in the microstructure of the nanocomposite. However, there were small areas of free carbon with the maximum size of several micrometers. The mean value of room temperature four-point bending strength is 670 MPa with a Weibull modulus of 7.5 and indentation fracture toughness of  $7.4 \text{ MPa m}^{1/2}$ . The Vickers hardness was  $\text{HV1} = 28.1 \text{ GPa}$ . The creep behavior was investigated in bending at temperatures

**Fig. 5** Comparison of the creep rate of  $\text{Si}_3\text{N}_4$  material (5SNY) and  $\text{Si}_3\text{N}_4/\text{SiC}$  nanocomposite prepared from  $\text{Si}_3\text{N}_4$  and  $\text{SiO}_2 + \text{C}$  mixture (SNYC2b). Source: From Ref.<sup>[19]</sup>.

from 1200°C to 1450°C under stresses ranking from 50 to 150 MPa in air. The creep resistance of the nanocomposite was significantly higher compared to the creep resistance of the monolithic  $\text{Si}_3\text{N}_4$  (Fig. 5). This improvement was achieved by the incorporation of intergranular SiC nanoparticles into the  $\text{Si}_3\text{N}_4$  matrix.

The cutting performance of the ceramic cutting inserts prepared from this low-cost SNC shows a three times longer lifetime compared to the commercially available  $\text{Si}_3\text{N}_4$ -based cutting inserts.<sup>[19]</sup>

### MULTIFUNCTIONAL Si-C-N BULK CERAMIC NANOCOMPOSITES PREPARED BY PYROLYTIC CONVERSION OF POLYHYDRIDOMETHYLSILAZANE

Formation of ceramics from polymer precursors is desirable because the processing is done at lower temperatures and with simpler procedures than conventional processes of sintering ceramic powders. Although the preceramic polymers offer many advantages over conventional coating techniques, the large shrinkage that occurs on conversion from polymer to ceramic remains a processing problem. This shrinkage can exceed 50% and causes warping or cracking in a coating or bulk material. The two main methods for elimination of this effect are employing compatible fillers (either active or passive) into the polymer, or using a preceramic precursor with high ceramic yield. On pyrolysis, the active filler reacts with the surrounding matrix or a reactive atmosphere and expands, thereby compensating for the shrinkage of the polymer. Concerning the latter method, preceramic precursors with ceramic yield higher than 85% became recently available. In both methods two steps are applied,

**Fig. 6** The results of thermal mechanical analysis characteristic for different states of cross-linking of polysilazane NCP200. Sample CA3531 is optimally cross-linked. Source: From Ref.<sup>[24]</sup>.

cross-linking of a liquid precursor into a rigid polymer followed by pyrolysis of the polymer into a monolithic SiCN ceramic. These steps must be optimized for each precursor. An example of optimal cross-linking conditions of NCP200 polyhydridomethylsilazane is shown in Fig. 6.<sup>[20]</sup>

The composition of polyorganosilazane precursor and, consequently, the final ratio of  $\text{Si}_3\text{N}_4/\text{SiC}$  can be modified. Pyrolysis in argon results in an amorphous product with composition  $\text{Si}_1\text{C}_{0.58}\text{N}_{0.90}$ , while carbon-free specimens with compositions close to that of stoichiometric  $\text{Si}_3\text{N}_4$  were prepared by heat treatment in ammonia ( $\text{NH}_3$ ) atmosphere.<sup>[21–23]</sup> In our earlier work it was shown that by heat treatment of polysilazane in mixed Ar/ $\text{NH}_3$  atmosphere with different volume ratio or ammonia, the carbon content could be adjusted in a wide range.<sup>[24]</sup> The optimal annealing temperature for adjustment of carbon content in amorphous Si-C-N ceramics was found between 500°C and 550°C. Higher annealing temperatures within this interval and longer dwell periods at the respective temperatures resulted in lower carbon content in the product of pyrolysis. The increase of the volume ratio of  $\text{NH}_3$  in reactive atmosphere from 10 to 50 vol% resulted in faster carbon removal from the specimens. Dwell periods at intermediate temperature in argon promoted the formation of Si-C bonds, and produced specimens with higher carbon content. Optimization of the pyrolysis conditions up to 1100°C yielded crack-free amorphous bulk specimens with carbon contents in the range of 0.3–16.2 wt%. After crystallization of such stoichiometric tough amorphous intermediates,  $\text{Si}_3\text{N}_4$ -SiC micro-nanocomposites with different volume fractions of SiC nanoparticles could be obtained.

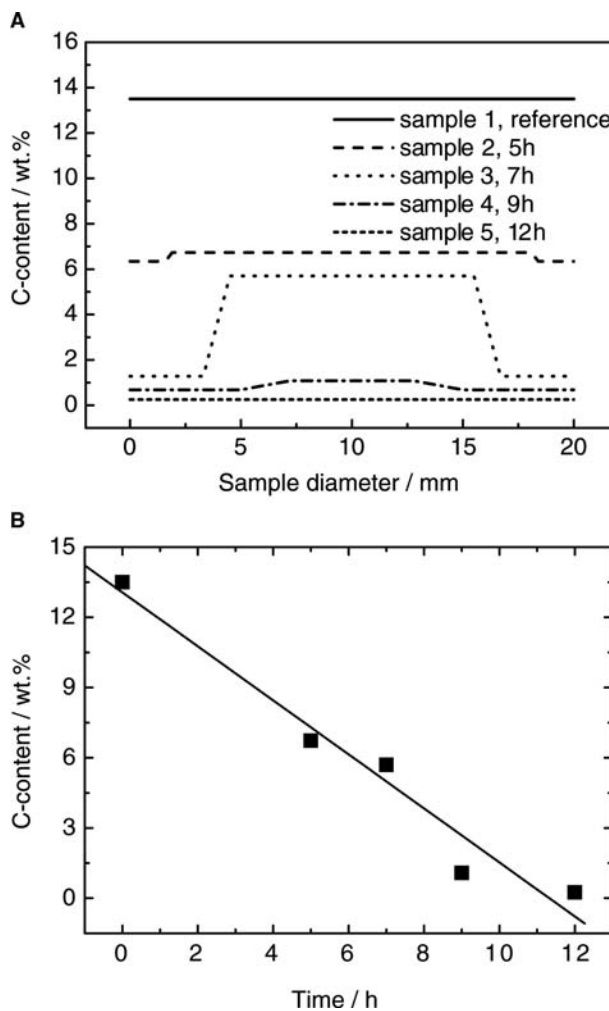

**Fig. 7** Optical micrograph of polymer-derived nanocomposite annealed in (A) combined Ar and Ar + NH<sub>3</sub> atmosphere; (B) NH<sub>3</sub>; (C) Ar + 10% NH<sub>3</sub>; and (D) Ar.

In addition, the Si–C–N stoichiometry can also be tailored in the cross section of amorphous ceramics.<sup>[25]</sup> Graded carbon content was achieved by changing the conditions of reactive heat treatment (temperature, holding time, Ar/NH<sub>3</sub> ratio, and gas flow rate) of polycarbosilazane polymer during processing (Fig. 7). Topochemical carbon analysis of a reference sample with homogenous carbon distribution and of samples heat-treated for 5, 7, 9, and 12 hr in the reactive atmosphere (Ar + 10 vol% NH<sub>3</sub>) at 525°C are shown in Fig. 8A. A core-shell carbon distribution is evident. The time dependence of the carbon content in the core of a specimen under the same conditions is shown in Fig. 8B. Depending on the carbon content, the electrical conductivity of Si–N–C materials also varies. Fig. 9 illustrates the differences in DC-conductivity of two amorphous Si/C/N ceramics with approximately 0.5 and 13.53 wt% C-content.<sup>[26]</sup> Lowering the C-content from 13.5 to 0.5 wt% by ammonia treatment decreases the DC-conductivity over the whole measured temperature range by approximately four orders of magnitude.

The relative simplicity of preparation of specimens with different concentrations of carbon in the surface layer and in the core opens the possibility for easy preparation of FGM with respect to their electrical properties.<sup>[27]</sup> Fig. 10 highlights the range of DC-conductivity

**Fig. 8** (A) Topochemical analysis of a reference sample and samples heat-treated 5, 7, 9, and 12 hr in the reactive atmosphere (Ar + 10 vol% NH<sub>3</sub>) at 525°C. (B) Time dependence of the carbon content in the core of a specimen pyrolyzed at 525°C. Source: From Ref.<sup>[25]</sup>.

that can be covered by polysilazane-derived samples through reactive ammonia treatment, nonreactively pyrolyzed samples in argon, and also subsequent aging at elevated temperatures (between 1100°C and 1450°C). This opens the opportunity for the preparation of novel high-temperature resistant electrical conductors mechanically reinforced by insulator the Si<sub>3</sub>N<sub>4</sub> surface layer.

#### LAYERED CERAMIC NANOCOMPOSITES WITH SELF-DIAGNOSTIC ABILITY

Designing ceramic composites with laminated structure has gained increasing attention, because these materials show improved mechanical properties (due to decreased sensitivity to defects) and display a

**Fig. 9** Variation of DC-conductivity of amorphous Si/C/N ceramic body with temperature and carbon content. Source: From Ref.<sup>[25]</sup>.

balanced combination of other engineering properties (like thermal and electrical conductivity, oxidation and wear resistance, etc.). Nature has many objects with laminated or graded structures. An example is the nacre of abalone shell: a natural multifunctional

nanolaminated ceramic-polymer composite material with good mechanical properties and the ability to repair itself.<sup>[28]</sup>

Inspired by the nature, a similar design of layered materials was used for the preparation of composites with multifunctional properties. Ceramic laminates based on  $\text{Si}_3\text{N}_4$  with different TiN content (from 0 to 33 vol%) were prepared by tape casting and hot-pressing.<sup>[29,30]</sup> TiN was prepared by in situ reaction of titanium butoxide or fine grade rutile ( $\text{TiO}_2$ ) with AlN according to the following reaction:

TiN derived from titanium butoxide had an average diameter of 100 nm, while the size of particles obtained from rutile was several micrometers (Fig. 11).

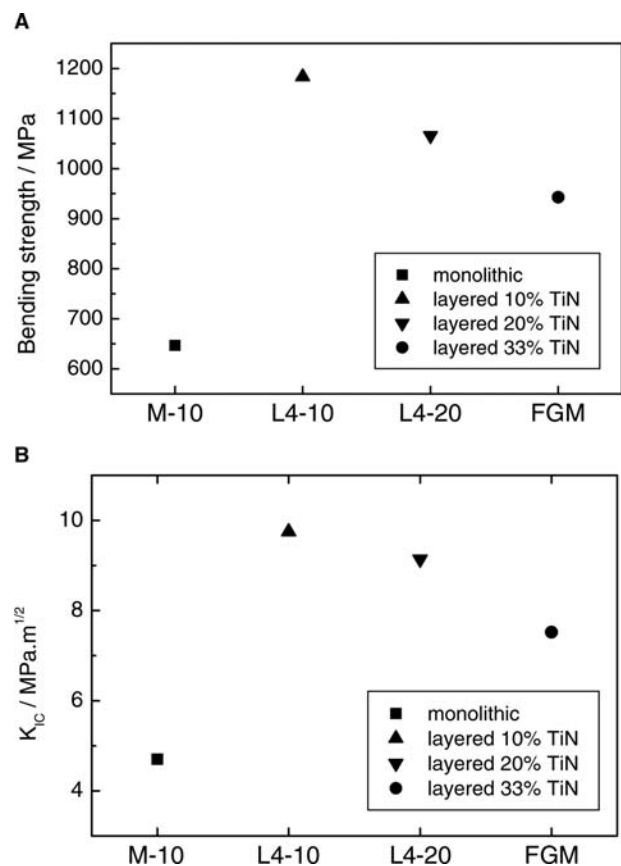

During the design of the layer sequence special attention was paid to the minimization of residual stresses in the layered composite, and the TiN content was gradually increased from 0 to 3, 8, 10, 15, 20, 25, and 33 vol%.<sup>[31]</sup> The bending strength normal to the layers and the fracture toughness of materials are shown in Figs. 12A and 12B. Both properties are markedly higher for the layered L4-10 material in comparison to the monolithic M-10 sample ( $\text{Si}_3\text{N}_4$  with 10 vol% TiN). The high increase of fracture toughness can be explained by the laminated structure, by strong alignment of elongated  $\beta\text{-Si}_3\text{N}_4$  particles, and by reasonable thermal expansion mismatch between  $\text{Si}_3\text{N}_4$  and  $\text{Si}_3\text{N}_4 + \text{TiN}$  layers.

**Fig. 10** DC-conductivities [ $\sigma_{\text{dc}}, (\Omega\text{cm})^{-1}$ ] of various materials at 20°C.

**Fig. 11** Scanning electron micrograph of the interface between seeded  $\text{Si}_3\text{N}_4$  layer and  $\text{Si}_3\text{N}_4 + 10 \text{ vol}\% \text{ TiN}$  layer. Source: From Ref.<sup>[29]</sup>.

**Fig. 12** (A) Three-point bending strength of the monolithic and layered samples. (B) Fracture toughness (SEVNB) of monolithic and layered samples. Source: From Ref.<sup>[29]</sup>.

**Table 2** Electrical resistivity  $\rho$  of monolithic (M-10) and layered samples

Sample	TiN (vol%)	$\rho_x$ ( $\Omega \text{ cm}$ )	$\rho_y$ ( $\Omega \text{ cm}$ )
M-10	10	$5.10^6$	$5 \times 10^6$
L4-10	10	$8.10^7$	$2 \times 10^{12}$
L4-20	20	$6.10^{-2}$	$5 \times 10^{11}$
FGM	33	$4.10^{-4}$	$8 \times 10^{10}$

The higher strength of the layered composites compared to the monolithic M-10 sample is caused by the presence of strong  $\text{Si}_3\text{N}_4$  layers. However, on increasing the TiN content to 33 vol%, the strength of the layered samples decreases because of higher residual stresses.

The anisotropic electrical conductivity was measured for the layered L4-20 and FGM samples in parallel ( $x$ ) and perpendicular ( $y$ ) direction to the layers (Table 2). In the parallel direction, the presence of electroconductive TiN caused an increase in conductivity. On the other hand, the electrical conductivity decreased in the direction perpendicular to the layer alignment because of the presence of insulating  $\text{Si}_3\text{N}_4$  layers. Very good conductivity was obtained for the layered material with 33 vol% TiN.

The listed results show that a remarkable improvement in strength and fracture toughness was achieved for the layered ceramic materials. Nevertheless, the possibility for catastrophic failure of ceramic components hinders their wider application in the industry. Fracture prediction in engineering ceramics is a promising method to increase the reliability and practical application of ceramic materials. One of the possible methods for forecasting the fracture is the measurement of electrical resistivity of the conductive layer based on the fact that, generally, the resistivity increases with cracks generation.

For this reason, electroconductive self-monitoring layer was joined to the layered composite (Fig. 13). The monitoring layer contained a threshold volume fraction of conductive phase, 19 vol% TiN.<sup>[32]</sup> The testing bars were positioned on the four-point bend test holder and the piezo-electric displacement transducer stepwise increased the programmed load. The load was released at a certain level, and the bar reloaded again. The results of electrical resistivity measurements under tensile load are shown in Fig. 14. The increase in electrical resistivity can be explained by the formation of microcracks in the conductive layer, which were also observed by SEM. The change of electrical resistance was of the order of  $0.1 \Omega \text{ cm}$  and can be recorded with the available measuring devices. The output of the measuring device can be simply recorded, and if the derivative of the electrical resistance by load is equal to zero ( $d\rho/dF = 0$ ), it means that the probability of

Fig. 13 Schematic of the electrical conductivity measurement on the self-diagnostic layered material.

crack formation increased to a serious level. In practical use, it indicates that the ceramic component should be replaced.

The above results demonstrate that the ceramic materials with electroconductive nano-inclusions can be used as a simple and useful tool for the crack formation and failure of brittle ceramic materials.

## CONCLUSIONS

Silicon nitride or alumina-based ceramic nanocomposites with electroconductive carbon, SiC, or TiN inclusions can be used for the preparation of self-monitoring sensors with an ability to detect crack initiation and crack propagation. Four different methods of nanocomposite synthesis have been compared:

Fig. 14 Change of electrical resistivity after cyclic loading/unloading of self-diagnostic layered sample. Increasing resistivity indicates crack formation.

1) adding an organometallic precursor to commercial  $\text{Si}_3\text{N}_4$  powder as a source of nano-inclusions; 2) carbothermal reduction of ultrafine  $\text{SiO}_2$  with carbon black to SiC and C nano-inclusions; 3) pyrolysis of organometallic Si/N/C precursors with fine SiC,  $\text{Si}_3\text{N}_4$ , and C products; and 4) preparing conductive TiN by exchange reaction between titanium butoxide or fine  $\text{TiO}_2$  and AlN.

Depending on the preparation method, the structure of nanocomposites varies from homogenous bulk  $\text{Si}_3\text{N}_4/\text{SiC}$  or  $\text{Al}_2\text{O}_3/\text{SiC}$  ceramics, through organometallic polymer-derived functionally graded  $\text{Si}_3\text{N}_4/\text{SiC}$ -based materials to layered  $\text{Si}_3\text{N}_4/\text{TiN}$  composites prepared by tape casting. The graded and layered ceramic nanocomposites showed self-diagnostic ability without a sizeable degradation of mechanical properties.

## INTRODUCTION

Nanomaterials, studied extensively during the past two decades, represent a class of materials with at least one relevant dimension on the length scale of a few to a few hundred nanometers.<sup>[1–17]</sup> In this size regime, properties of nanomaterials become strongly dependent on factors such as surface characteristics, shape, and size due to the quantum confinement effect.<sup>[1,6,7,18]</sup> It is, in principle, possible to adjust the properties such as the color and redox potentials of nanomaterials by changing the particle size or shape, without any change of chemical composition. Nanomaterials become increasingly important in applications such as transistors,<sup>[19]</sup> light emitting diodes,<sup>[20,21]</sup> sensors,<sup>[22]</sup> solar cells,<sup>[23]</sup> and lasers.<sup>[24]</sup>

Compared with the static properties such as optical absorption and emission, dynamic properties of charge carrier in nanomaterials are relatively less understood. Considerable progress has been made in the study and understanding of charge carrier dynamics recently.<sup>[3–5,11,13–17,24–31]</sup> Most studies have focused on issues such as charge carriers trapping, carrier interaction, recombination, and their dependence on particle size, shape, surface characteristics. Studies of dynamic properties provide complementary information to static studies and help to gain a better fundamental understanding of the charge carrier behavior in nanomaterials.

Several powerful time-resolved laser techniques have been employed to investigate charge carrier dynamics, including transient absorption, transient bleach, and time-resolved fluorescence. In a transient absorption measurement, samples are first excited with an ultrafast laser pulse. A second laser pulse, delayed with respect to the first (excitation) pulse, is used to detect the population of charge carriers in excited states.<sup>[32]</sup> Transient bleach has been used to monitor the population of ground states in a similar pump–probe setup.<sup>[33,34]</sup> The excited-state population has also been monitored by time-resolved fluorescence combined with a fluorescence up-conversion method<sup>[35]</sup> or stimulated emission.<sup>[36]</sup>

This entry reviews the recent advances in the studies of charge carrier dynamics and optical properties of

semiconductor and metal nanoparticles (NPs). It starts with a general picture of photoexcited electron relaxation in semiconductor NPs. Specific nanoparticle systems are then discussed in some detail, including CdS, CdSe, CdTe, PbS, Cu<sub>2</sub>S, Ag<sub>2</sub>S, GaAs, InP, Mn<sup>2+</sup>-doped ZnS, Mn<sup>2+</sup>-doped ZnSe, TiO<sub>2</sub>, Fe<sub>2</sub>O<sub>3</sub>, AgI, AgBr, MoS<sub>2</sub>, PbI<sub>2</sub>, BiI<sub>3</sub>, and Si. The dynamic properties of metal NPs are then illustrated with examples such as Ag and Au NPs. Possible dependence of charge carrier dynamics on parameters such as size, shape, and surface characteristics is discussed with appropriate examples. A summary is given at the end of the entry.

## CHARGE CARRIER DYNAMICS IN SEMICONDUCTOR NANOPARTICLES

### General Picture of Charge Carrier Dynamics in Semiconductor Nanoparticles

A general scheme of charge carrier relaxation in semiconductor NPs can be illustrated in Fig. 1. Upon photoexcitation, an electron is generated in the conduction band (CB) and a hole in the valence band (VB). The hot electron then relaxes to the bottom of the CB and hole to the top of the VB. Because of Coulombic attraction, an exciton is formed from the electron and hole. The exciton can decay radiatively or non-radiatively through electron–hole recombination. If there are no states within the bandgap, as in single crystal semiconductors, the recombination will be mainly radiative, producing bandedge emission, and the lifetime should be on the order of nanoseconds for direct bandgap semiconductors. However, if states exist within the bandgap because of defects or surface dangling bonds, as in semiconductor NPs, photoexcited charge carriers can be trapped in these states on time scales faster than radiative recombination.

Trapping time constants have been reported for different semiconductor NPs. For example, a trapping time of about 100 fsec has been suggested for CdS NPs.<sup>[32,37]</sup> For CdSe NPs, a trapping time of 0.5–8 psec has been reported.<sup>[38]</sup> A much longer trapping time of

**Fig. 1** Schematic illustration of charge carrier relaxation in semiconductor NPs and the pump–probe scheme for monitoring the carrier dynamics. The long solid line with upward arrow indicates excitation and the short solid lines with upward arrows indicate the probe of the conduction band, shallow and deep trap states, and valence band, respectively. The curved lines with downward arrows indicate different relaxation processes: (1) electronic relaxation within the conduction band, (2) trapping into shallow trap (ST) and deep trap (DT) states and further trapping from ST to DP, (3) bandedge electron–hole recombination, (4) trapped electron–hole recombination, and (5) exciton–exciton annihilation. *Source:* From Fig. 4 of Ref. [11].

30 psec has been suggested for CdS NPs based on measurements of trap state emission<sup>[39,40]</sup> and the study of electron acceptor such as viologen derivatives on particle surface.<sup>[41]</sup> The variation of trapping time may be due to the difference in samples, experimental conditions, and/or different data interpretations. However, it is reasonable to conclude that the time constants for trapping in semiconductor NPs are on the order of a few hundred femtoseconds to a few tens of picoseconds, depending on the nature of the NPs or quality of sample.

The trapped carriers can further recombine radiatively or non-radiatively. The radiative decay will produce trap state emission that is red shifted with respect to bandedge emission. Trap states in NPs have lifetimes from a few tens of picoseconds to nanoseconds or longer, depending on the nature of trap states.

At high excitation intensities, nonlinear processes come into play. For example, exciton–exciton annihilation could take place when there is a high density of excitons within a small volume of sample at a given time. This can happen for both bulk and nanoparticle semiconductors. For nanoparticles, interestingly, this

has been observed only when trap states are saturated and accumulation of excitons becomes possible. Exciton–exciton annihilation is a non-radiative process and occurs on the time scale of a few picoseconds or longer depending on the exciton concentration. Auger recombination, another non-radiative, non-linear decay pathway, becomes significant at very high excitation intensity as well and ionization is involved in this process. Experimentally, it is often difficult to distinguish between exciton–exciton annihilation and Auger recombination.

The general picture described above will be illustrated next with specific nanoparticle systems.

### Metal Chalcogenide Semiconductor Nanoparticles

Metal chalcogenide semiconductor NPs such as CdS and CdSe have been the most extensively studied systems. Earlier picosecond studies on charge carrier dynamics observed a strong transient bleach feature near the excitonic absorption region.<sup>[42–48]</sup> The peak of the bleach was found to shift with time and attributed to increased screening by charge carriers for the particles.<sup>[49]</sup> Also, a red shift of the transient absorption features was observed in CdSe, which was explained as a result of the formation of biexciton.<sup>[50,51]</sup> Later, femtosecond studies found that the transient bleach decay follows a double exponential decay with the fast component increasing with excitation intensity faster than the slower component.<sup>[33]</sup>

A similar excitation intensity dependence of the transient absorption signals was observed for CdS NPs.<sup>[32,52]</sup> The decay profiles feature a fast 2–3-psec and a slow 50-psec decay component. As shown in Fig. 2, the amplitude of the fast component increases faster than the slower component with increasing excitation intensity. The fast decay component was initially assigned to nongeminate electron–hole recombination at high excitation intensities.<sup>[32]</sup> More detailed investigations on both CdS and CdTe NPs were subsequently carried out using both transient absorption and time-resolved fluorescence.<sup>[53]</sup> The bandedge fluorescence was found to be power dependent as well. The power-dependent fast component was then assigned to exciton–exciton annihilation, as suggested previously.<sup>[54]</sup> The slower decays were attributed to trapping and the recombination of trapped carriers. It was concluded that the transient absorption signals observed have contributions from both bandedge electrons (excitons) and trapped electrons. At early times, the excitons have significant contributions, especially at high excitation intensities. The contribution from trapped electrons becomes more important and eventually the signal is basically all from trapped

**Fig. 2** Excitation intensity-dependent photoinduced electron relaxation dynamics of CdS NPs probed at 780 nm, following excitation at 390 nm. The fast decay component increases nonlinearly with excitation intensity and is absent at low intensity. *Source:* From Fig. 5 of Ref.<sup>[11]</sup>.

charge carriers on long time scales. This is believed to be true for many other colloidal semiconductor nanoparticles.<sup>[28,55–58]</sup>

Recently, femtosecond fluorescence up-conversion spectroscopy has been used to study the charge carrier dynamics in CdSe nanocrystals.<sup>[59]</sup> Both the rise time and decay of bandedge emission show a direct correlation to the size of nanocrystal and the rise time is dependent on excitation intensity. The long-lived bandedge emission was assigned to the slow relaxation of “dark exciton” from triplet states to ground state, which is consistent with other studies.<sup>[60,61]</sup> The deep trap emission was attributed to ultrafast relaxation of a surface selenium dangling bond electron to the valence band where it recombines radiatively with the initially photogenerated hole; and this process attenuates the bandedge emission within 2–6 psec.

A recent study of the emission lifetimes on nanosecond time scale of surface passivated and unpassivated CdS nanoparticles showed that the passivated samples have a lower excitation threshold for observing exciton–exciton annihilation.<sup>[62]</sup> In surface passivated samples, the density of trap states is expected to be lower due to more effective capping. It is therefore easier to observe the saturation of trap states. The observation supports the model of exciton–exciton annihilation upon trap state saturation at high excitation intensities. Excitation intensity dependence has also been observed in the ultrafast transient absorption signals of CdTe NPs.<sup>[63]</sup> In addition, the fluorescence of thiol-capped CdTe NPs has been measured using

nanosecond laser spectroscopy.<sup>[64]</sup> The amplitude of fluorescence signal has been found to decrease unexpectedly with increasing excitation intensity at high excitation intensities. This unusual excitation intensity dependence was explained by nonlinear exciton–exciton annihilation or Auger photoionization. The results indicate that CdTe NPs show strong nonlinear optical properties due to strong quantum confinement effect than other II–VI semiconductor NPs.

It is interesting to note that very different time constants have been reported for the fast excitation-intensity-dependent component. Zhang et al. have observed 1–4 psec in both CdS colloid and glass, Zn<sub>0.5</sub>Cd<sub>0.5</sub>S colloids, and trioctylphosphine oxide (TOPO)-capped CdS colloids in toluene. The time constant for the fast excitation-intensity-dependent component of the bleach has been found to decrease from 1.3 to 0.8 psec with increasing power.<sup>[33]</sup> Using time-resolved photoluminescence, exciton recombination times in CdS<sub>0.081</sub>Se<sub>0.919</sub> glass decrease from 4 nsec to hundreds of picoseconds with increasing laser intensity.<sup>[54]</sup> A power-dependent decay on the time scale of 1–3 nsec has been observed in the measurements of emission lifetimes for surface passivated CdS NPs.<sup>[62]</sup> For the 2.3-nm CdSe colloids, time constant decreases from 510 to 10 psec for decays from one to four electron–hole pair.<sup>[12]</sup> The different time constants are possibly due to the difference in excitation intensities. Under low excitation intensities when there is on average one or less electron–hole pair (exciton) created per particle, linear processes such as trapping and subsequent recombination from the trapped states dominate the relaxation process of charge carrier in nanoparticles. With increasing excitation intensity, more excitons can be generated in one particle, higher-order processes such as exciton–exciton annihilation and Auger recombination become more important. It can be envisioned that the higher-order process becomes more significant at higher excitation intensities and the decay time constant would vary accordingly. Therefore the different nonlinear decay constants reported could be a reflection of the different excitation intensities used.

The variation of time constants can also be due to differences in particle size, embedding environment (solvent or glass), and experimental techniques used. It was found that the fast decay time constant changes from 363 to 6 psec when the radius of CdSe NPs was reduced from 4.1 to 1.2 nm.<sup>[12]</sup> Compared with colloidal solutions, semiconductor NPs embedded in glass usually have reduced lifetimes because of photoionization and greatly enhanced Auger interaction in ionized particles.<sup>[65–67]</sup> Time-resolved fluorescence measurements are often more sensitive than transient absorption, as fluorescence is a zero-background measurement and absorption is not. This leads to lower *S/N* ratio for

transient absorption data and thereby larger uncertainties in the time constant measured. Also, as the non-linear component decreases in amplitude quickly with decreasing excitation intensities, the uncertainty becomes larger in the time constant from data fitting.

Effects of shape on charge carrier dynamics have also been investigated by several groups. Earlier attempt showed that ultrafast dynamic profiles of PbS nanoparticles were not dependent on the shape of particles.<sup>[58]</sup> This shape independence has been attributed to the dominance of surface properties on the electronic relaxation. If density of surface trap states is high and dynamics are dominated by the surface trap states, the effect of shape may not be observed. Other attempts to study the shape effect compared nanorods with nanoparticles. For example, CdSe nanorods of different aspect ratios have been synthesized.<sup>[68,69]</sup> Nanorods exhibit linearly polarized emission along long axis.<sup>[70]</sup> Static absorption and emission spectra showed that the bandgap of nanorods depends mainly on the width and only slightly affected by the length.<sup>[71]</sup> Femtosecond transient bleach spectroscopy was used to compare the dynamics of CdSe nanorods with that of nanodots.<sup>[72]</sup> It was found that higher energy excitons relax faster in nanorods than in nanodots, but lower energy excitons decay slower in nanorods than in nanodots. It was suggested that the faster decay of higher energy excitons is due to the higher density of exciton states at higher energy in the nanorods caused by the decrease in symmetry and the splitting of degeneracy. However, no detailed explanation has been offered for the slower decay in nanorods for lower energy excitons.

In another comparison of nanorods vs. quantum dots, elongated NPs were found to have increased optical gain lifetime and lower gain threshold.<sup>[73]</sup> The improved optical gain performances of nanorods have been attributed to increased absorption cross sections, stronger quantum confinement, and weaker interference from excited state absorption. Very recently, comparison of CdS nanorods and nanoparticles has been performed in our lab using ultrafast transient absorption.<sup>[74]</sup> A fast decay component appears to be faster in nanorods than spherical particles. The slow decay components remain unaffected by the shape of particle.

It is clear from the above studies that there is no consensus on the dependence of dynamic properties on particle shape. This could be because there are competitive factors that influence the shape dependence. On one hand, nanorods have larger volume per rod/particle if the diameter of the cross section of the nanorods is the same or similar to that of spherical nanoparticles. In the meantime, nanorods have enhanced local field factor.<sup>[75]</sup> As the absorption cross section is linearly proportional to the volume and local

field factor,<sup>[75]</sup> the increased volume and local field factor should lead to a larger absorption cross section and thereby shorter radiative exciton lifetime for nanorods.

On the other hand, quantum confinement effect is weaker in nanorods,<sup>[76,77]</sup> because the three-dimensional confinement in quantum dots becomes two-dimensional in nanorods. One may expect that lifetimes in nanorods to be longer than that in NPs given the reduced quantum confinement. Also, for the same number of excitons per nanoparticle or nanorod, the effective exciton (charge carrier) density is lower for nanorods because of their larger volume. The exciton lifetimes in nanorods should be longer than in NPs as the reduced effective carrier density decreases the probability of fast nonlinear processes such as exciton–exciton annihilation.

However, because nanorods have larger volume than NPs with the same diameter/width, the number of particles/rods per volume would be smaller for nanorods than in NPs if the samples have the same optical density. Given the same excitation intensity, rod samples will have more excitons per rod and thereby shorter lifetimes, as nonlinear processes such as Auger recombination or exciton–exciton annihilation have relatively short lifetimes that are inversely proportional to exciton population.

Density of states (DOS) is another factor to consider. Theoretical studies show that elongation of particles to rods can cause the splitting of degenerated states and change the distribution of the electronic states. This could increase or decrease the exciton lifetime, depending on the state distribution. On average, a higher DOS is expected for nanorods than for nanoparticles if the nanorods have a larger volume. This should generally lead to a shorter exciton lifetime in nanorods due to better exciton and phonon spectral overlap. In the meantime, elongation can also introduce new surface states that could shorten the exciton lifetime in nanorods.<sup>[70,78,79]</sup> Overall, all the factors, including quantum confinement effect, local field factor, charge carrier density, distribution of states, and DOS, are dependent on the aspect ratio of the nanorod. The exciton lifetime in nanorods could be longer or shorter than that in spherical particles, depending on the aspect ratio and how the various factors change with the aspect ratio.

Other metal chalcogenide semiconductor NPs include  $\text{Cu}_x\text{S}$  and  $\text{Ag}_2\text{S}$ . Copper sulfides can have various stoichiometries between  $\text{Cu}_2\text{S}$  and  $\text{CuS}$ , and the variations in structure and valence result in some unique properties.<sup>[80–90]</sup> In a study of  $\text{CuS}$  NPs, an IR band was found to disappear after the reduction of  $\text{CuS}$  to  $\text{Cu}_2\text{S}$  and was attributed to the presence of  $\text{Cu(II)}$ .<sup>[80,81]</sup> The IR band was attributed to a middle-gap, electron donor state but the model appears to have some inconsistencies.<sup>[91]</sup> Both  $\text{Cu}_2\text{S}$  and  $\text{CuS}$

NPs have been studied using femtosecond transient absorption spectroscopy.<sup>[91]</sup> They were found to exhibit different dynamic behavior with competing transient absorption and bleach features as well as power dependence attributed to trap state saturation. Based on a simple kinetic model developed, an alternative explanation for the middle-gap state has been proposed. The state was suggested to be electron-acceptor state or unoccupied and the IR band corresponds to a transition from the valence band to this state.<sup>[91]</sup> Similarly, in the dynamics study of cystine and glutathione capped Ag<sub>2</sub>S NPs, it was found that the signal has contributions from both transient absorption and transient bleach and the transient absorption becomes more dominant over bleach with increasing excitation intensity.<sup>[92]</sup> The observed excitation intensity dependence was attributed to saturation of shallow trap states at high excitation intensities.

### III–V Semiconductor Nanoparticles

Most dynamic studies of III–VI semiconductor NPs have focused on charge carrier cooling in the CB or VB. Carrier cooling is extremely important for many device applications such as transistors, lasers, and photocathodes.<sup>[14]</sup> A fundamental question is how electron cooling may be different in NPs from that in bulk materials. Electron cooling time has been found to be slower in NPs than in bulk for a series of self-assembled III–V semiconductor nanoparticles. Mukai et al. reported the electron cooling time in self-assembled InGaAs NPs ranging from 10 psec to 1 nsec using time-resolved photoluminescence measurements.<sup>[93–95]</sup> Slow cooling (~1 nsec) was found for strain-induced GaAs NPs.<sup>[96]</sup> In another study under condition of high injection, a lifetime of 500 psec for excited electronic states was observed for self-assembled InAs/GaAs NPs.<sup>[97]</sup> The hole cooling time was reported to be 400 psec for InAs/GaAs NPs.<sup>[98,99]</sup> Heitz et al. also reported a 40-psec hole relaxation time for stacked layer of InAs NPs deposited on GaAs.<sup>[100]</sup>

The above slow relaxation times for electron and hole cooling were all reported for self-assembled NPs. The studies for carrier cooling in colloidal III–V semiconductor NPs are rare because of the difficulties in synthesis. The best results to date have been obtained for InP NPs.<sup>[101–103]</sup> The charge carrier relaxations in colloidal InP quantum dots have been found to be dependent on excitation intensity,<sup>[104]</sup> particle size, and surface chemistry.<sup>[105]</sup> With increasing excitation intensity, efficiency of charge carrier relaxation to bandedge states is reduced. It was also found that the 1P to 1S relaxation rate increases with decreasing size of quantum dots.<sup>[105]</sup> The relaxation rate of chemically injected electrons was found out to be

slower than that of photoexcited excitons by approximately an order of magnitude.

### Doped II–VI Semiconductor Nanoparticles

Among all the doped II–VI semiconductor NPs, Mn<sup>2+</sup>-doped ZnS has been the most extensively studied because of its interesting magnetic<sup>[106–110]</sup> and electron-optical properties.<sup>[111–115]</sup> In 1994, Bhargava et al. reported for the first time that Mn<sup>2+</sup>-doped ZnS has high luminescence efficiency accompanied by significantly shortened lifetime (~20 nsec).<sup>[111]</sup> The spin-forbidden transition of Mn<sup>2+</sup> <sup>4</sup>T<sub>1</sub> to <sup>6</sup>A<sub>1</sub> in bulk ZnS has a lifetime of about 1.8 msec. The shortened lifetime was explained by the strong interaction of Mn<sup>2+</sup> d electronic states with the sp electronic states of ZnS. However, a subsequent study found that the Mn<sup>2+</sup> emission in Mn<sup>2+</sup>-doped ZnS NPs is the same as that in bulk.<sup>[116]</sup> This has been confirmed by other studies recently.<sup>[117–119]</sup> The fast nanosecond decay observed was apparently due to trap state emission from the ZnS NPs.

Mn<sup>2+</sup>-doped ZnSe is another interesting doped semiconductor NPs system. Photoluminescence measurements of Mn<sup>2+</sup>-doped ZnSe showed distinct ZnSe bandedge emission at 440 nm and Mn<sup>2+</sup> emission at 560 nm.<sup>[120]</sup> The lifetime of Mn<sup>2+</sup> emission (in hundreds of microseconds) was reported to be an order of magnitude smaller than that of the bulk (msec). The shortened lifetime has been attributed to stronger spin-orbit coupling between Mn<sup>2+</sup> and Se<sup>2-</sup> than Mn<sup>2+</sup> and S<sup>2-</sup>. It was also found that Mn<sup>2+</sup> emission decreases from 290 to 190 μsec when the concentration of Mn<sup>2+</sup> increases from 0.2% to 0.9% because of the exchange interaction between Mn<sup>2+</sup> pairs. However, the presence of Mn<sup>2+</sup> defect sites and their effect on the luminescence were not fully addressed.

The optical and surface structure properties of Mn<sup>2+</sup>-doped ZnSe NPs have recently been investigated using UV–visible absorption, fluorescence, electron spin resonance (ESR), and X-ray absorption fine structure (XAFS) techniques.<sup>[121]</sup> It was found that the amount of ZnS bandedge, trap states, and Mn<sup>2+</sup> <sup>4</sup>T<sub>1</sub> to <sup>6</sup>A<sub>1</sub> emission was dependent on the amount of Mn<sup>2+</sup> present. The ESR and EXAFS data indicated the presence of two different Mn<sup>2+</sup> sites. One is the Mn<sup>2+</sup>-substituted Zn<sup>2+</sup> lattice site and the other is the surface Mn<sup>2+</sup> site. EXAFS data suggested that the core of NPs resembles that of bulk ZnSe, and the surface of the particle has a higher concentration of metal atoms. It was then proposed that surface Mn<sup>2+</sup> possessed an octahedral geometry due to significant OH<sup>-</sup>/O<sup>2-</sup> coordination and the interior Mn<sup>2+</sup> occupied the Zn<sup>2+</sup> tetrahedral site. It was also suggested that surface Mn<sup>2+</sup> quenched the ZnSe bandedge

emission and promoted the ZnSe trap state emission but gave no  $\text{Mn}^{2+}$  emission.  $\text{Mn}^{2+}$   ${}^4\text{T}_1$  to  ${}^6\text{A}_1$  emission increased with  $\text{Mn}^{2+}$  present in the reaction solution because of the interior  $\text{Mn}^{2+}$  that occupied the  $\text{Zn}^{2+}$  lattice site, but the overall fluorescence quantum yield went down.

## Metal Oxide Nanoparticles

Metal oxide NPs such as  $\text{TiO}_2$ ,  $\text{ZnO}$ , and  $\text{Fe}_2\text{O}_3$  have found applications in various fields such as catalysis, paint pigment, and solar cells. Among them,  $\text{TiO}_2$  NPs received the most attention because of its stability, availability, and its application in solar energy conversion.<sup>[122]</sup> Charge carrier dynamics have been studied for  $\text{TiO}_2$  NPs alone and in conjunction with dye sensitization. For  $\text{TiO}_2$  NPs alone, the electrons excited by a 310 nm light were found to decay following second-order kinetics with a recombination rate of  $1.8 \times 10^{-10} \text{ cm}^3/\text{sec}$ .<sup>[123]</sup> Trapping of electrons was suggested to occur on the time scale of 180 fsec.<sup>[37]</sup>

Dye sensitization of  $\text{TiO}_2$  has been extensively studied as  $\text{TiO}_2$  alone does not absorb visible light. Dye sensitization helps to extend the absorption into the visible region. In dye sensitization, visible light is absorbed and creates electrons in the excited states of dye molecules. Electrons are then injected from the excited states of dye molecules to the conduction band of  $\text{TiO}_2$  NPs. A Ru dye with the best performance showed light-to-electricity conversion efficiency as high as 10%.<sup>[122,124]</sup> This high efficiency has stimulated considerable interest in the study of charge carrier injection and relaxation processes in dye-sensitized NPs. It has been found that the forward electron transfer rate is generally very fast. For example, electron injection rate was found to be around 200 fsec for coumarin dye on  $\text{TiO}_2$ <sup>[125]</sup> and less than 50 fsec for the Ru ( $\text{N}_3$ ) dye on  $\text{TiO}_2$ .<sup>[126,127]</sup> However, there are some questions about the possible degradation of the dye used.<sup>[126,128]</sup> A slower electron injection time (20 psec) was reported based on a picosecond infrared study.<sup>[129]</sup> Cherepy et al. have studied the charge carrier dynamics of anthocyanin dye on  $\text{TiO}_2$  NPs and an electron injection rate of  $\sim 100$  fsec has been determined.<sup>[130]</sup> Compared with forward electron injection, the rate of back electron injection has been found to be much slower, on the time scales from 10 psec to  $\mu\text{sec}$ , depending on the nature of dyes<sup>[130,131]</sup> and the methods used to synthesize  $\text{TiO}_2$  NPs.<sup>[131]</sup>

In a recent review of electron injection dynamics from a ruthenium dye to  $\text{TiO}_2$  nanocrystalline thin films, the effects of parameters such as absorbate redox potential, pH of solution, solvent, and excitation wavelength have been studied using a tunable femtosecond infrared spectrometer.<sup>[16]</sup> The injection kinetics

typically features an ultrafast ( $< 100$  fsec) component and a slower component. The fast component showed no noticeable variation within the 200-fsec time resolution of the measurements. For the slow component, the amplitude increased and the relaxation rate decreased with increasing pH of the solution. A two-state injection model was developed, with the fast decay component attributed to injection from a non-thermalized excited state and the slow component attributed to injection from the thermalized excited state.

Iron oxide ( $\text{Fe}_2\text{O}_3$ ) NPs have been used as pigments, photocatalysts, electrodes, and high-density recording media.<sup>[132–135]</sup> Photoexcited electron dynamics of  $\gamma$ - and  $\alpha$ - $\text{Fe}_2\text{O}_3$  have been performed using femtosecond laser spectroscopy.<sup>[55]</sup> It has been determined that  $\gamma$ - $\text{Fe}_2\text{O}_3$  NPs are spherical and paramagnetic and  $\alpha$ - $\text{Fe}_2\text{O}_3$  NPs are spindle-shape and diamagnetic. Despite the significant differences in shape and magnetic properties, both  $\gamma$ - and  $\alpha$ - $\text{Fe}_2\text{O}_3$  NPs show similar ultrafast electronic relaxation that seems to be dominated by non-radiative processes, possibly because of the high density of trap states or simply strong coupling between trap states. The ultrafast relaxation is consistent with weak luminescence of the NPs and low photocurrent efficiency of typical  $\text{Fe}_2\text{O}_3$  electrodes, as the rapid electron–hole recombination is unfavorable for charge transport in photocurrent generation.

## Silicon Nanoparticles

Bulk silicon (Si) is an indirect band gap semiconductor with a band gap of 1.1 eV and a very weak luminescence. The discovery of visible luminescence from porous silicon<sup>[136]</sup> has stimulated great interest in Si NPs because luminescence silicon is highly desirable for optoelectronics applications. Various techniques have been used to produce luminescent Si NPs, including electrochemical etching,<sup>[136]</sup> sputtering,<sup>[137–139]</sup> ion implantation,<sup>[140–142]</sup> and plasma-enhanced chemical vapor deposition.<sup>[143,144]</sup> The mechanism of the luminescence from Si NPs has been extensively studied but remains somewhat controversial. One explanation for the observed luminescence is quantum confinement.<sup>[136,145]</sup> Another explanation is surface effect<sup>[146]</sup> that attributes the luminescence to localized states on the Si surface<sup>[147,148]</sup> or at the Si/ $\text{SiO}_2$  interface.<sup>[149–152]</sup>

A few studies have been reported on the dynamics of Si NPs. In a transient absorption study, ion-implanted Si NPs showed two photoinduced absorption features.<sup>[153]</sup> One is the short-lived high-energy band and it was attributed to quantized states in Si NPs. The other one is the low-energy band due to Si/ $\text{SiO}_2$  interfaces states. In another recent study of porous silicon using infrared photoinduced absorption spectroscopy, intraband transitions between

sublevels in the conduction and valence bands were observed, which supports the model of quantum confinement.<sup>[154]</sup> Also, additional features in the photoinduced absorption spectrum were found and correlated with the Si=O vibrational modes, indicating a strong coupling between bulk excitonic states and surface states in Si NPs. These studies seem to suggest that both quantum confinement and surface effect contribute to the emission process in Si nanoparticles.

### Layered Semiconductor Nanoparticles

Layered semiconductors have unique crystal structures composed of extended, thin layers with weak van der Waals interaction in between layers. There are only a few studies on the dynamic properties of layered semiconductor NPs. Using picosecond transient absorption spectroscopy, it was found that charge carrier relaxation in MoS<sub>2</sub> NPs was dominated by trap states.<sup>[155]</sup> Femtosecond transient absorption spectroscopy has been used to study the dynamics in PbI<sub>2</sub><sup>[56]</sup> and BiI<sub>3</sub><sup>[156]</sup> NPs. The electronic relaxation dynamics in PbI<sub>2</sub> and BiI<sub>3</sub> are both found to be sensitive to solvent and insensitive to particle size. Interestingly, oscillations at early times with a period changing with solvent but not with particle size have been observed. The strong surface (solvent) dependence and size independence indicate that either the relaxation is dominated by surface characteristics that do not change significantly with size or quantum confinement is not significant in the size regime studied.<sup>[157,158]</sup>

### Silver Halide Nanoparticles

Interest in the dynamics of silver halide NPs has been partly due to their application in photography. The ultrafast charge carrier dynamics in AgI and proposed “core/shell” structures of AgI/Ag<sub>2</sub>S and AgBr/Ag<sub>2</sub>S have been studied.<sup>[57]</sup> Dynamic profiles of AgI NPs showed a fast 2.5-psec decay component and a slow component (>0.5 nsec). The fast decay was attributed to trapping and nonradiative electron–hole recombination dominated by a high density of trap states. The slow decay was assigned to the reaction of deep-trapped electrons with silver cations to form silver atom, which is the basis for latent image formation in photography. The slow decay is consistent with early nanosecond study.<sup>[159]</sup> Comparison between two “core/shell” systems, AgI/Ag<sub>2</sub>S and AgBr/Ag<sub>2</sub>S, revealed a new 4-psec rise component with AgBr/Ag<sub>2</sub>S. It was taken as an indication of electron transfer from Ag<sub>2</sub>S to AgBr initially. However, a similar dynamics was observed later in pure Ag<sub>2</sub>S NPs. The rise is more likely due to transient bleach as there is

noticeably ground-state absorption at the probe wavelength.<sup>[92]</sup>

## CHARGE CARRIER DYNAMICS OF METAL NANOPARTICLES

Metal NPs have long been of interest because of their applications in areas such as optical waveguides,<sup>[160]</sup> catalysis,<sup>[161]</sup> sensors,<sup>[162]</sup> and in surface-enhanced Raman scattering (SERS).<sup>[163,164]</sup> Metal NPs such as silver and gold have some unique optical properties, typified by a strong absorption band in the visible, termed as surface plasmon absorption. Mie theory,<sup>[165–168]</sup> which is essentially the solution of Maxwell’s equation for the scattering of light off a small charged sphere in a dielectric medium, can be used to quite accurately describe the surface plasmon absorption of most metal NPs.

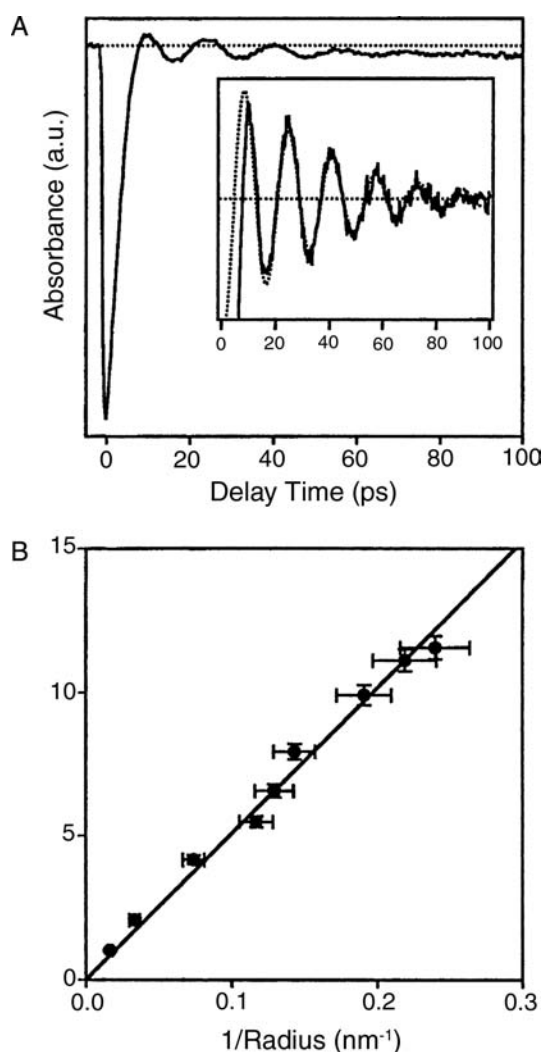

Charge carrier dynamics of metal NPs has received considerable attention recently. Hot electron relaxation in metals occurs on ultrafast timescales because of strong electron–phonon interaction. One of the important issues in the dynamics of metal NPs is whether the relaxation is dependent on the particle size or not. Theoretically, electron and phonon spectral overlap is expected to decrease with decreasing size, leading to weaker electron–phonon interaction. Early electronic relaxation measurements by Smith et al. suggested a possible size dependence of the electronic relaxation in the 1–40-nm range.<sup>[169]</sup> However, Hodak et al. and El-Sayed et al. found no size dependence of the relaxation down to the size of 2.5 nm recently.<sup>[29,170,171]</sup> The relaxation time in Au NPs was reported to be the same as that of bulk gold (~1 psec). Excitation intensity dependence of the relaxation time could be the reason for the discrepancy. It is likely that the excitation intensities used in earlier work are much higher than those used in later measurements. Another possible explanation for the difference is surface and/or solvent environment, which was found to affect electronic relaxation of Au NPs.<sup>[172–174]</sup> It seems consistent that electron–phonon coupling constant is the same for Au NPs as for bulk, at least for particles down to 2 nm in diameter.<sup>[175]</sup>

However, when the particle size is smaller than 1 nm, the electronic relaxation time seems to become significantly longer than that of bulk. An earlier study of Au<sub>13</sub> and Au<sub>55</sub> found that the electron lifetime becomes significantly longer for Au<sub>13</sub> nanoclusters than for Au<sub>55</sub> or larger nanoparticles, indicating bulk to molecule transitions in the size regimes of 55 and 13 Au atoms.<sup>[169]</sup> A recent study of Au<sub>28</sub> clusters found biexponential decays with a subpicosecond and a nanosecond component.<sup>[176]</sup> The fast component was attributed to relaxation from a higher lying excited state

to lower electronic states, and the longer nanosecond component was assigned to the radiative lifetime of the Au<sub>28</sub> clusters.<sup>[177]</sup> More recently, studies of electronic relaxation in Au<sub>11</sub> clusters revealed a similar long-lived component (~1 nsec).<sup>[178]</sup> The longer lifetime again suggests that for very small metal clusters, particles are becoming molecule-like in nature and the electron–phonon interaction becomes weaker, similar to that found for Au<sub>13</sub>.<sup>[169]</sup>

Another interesting issue concerning metal NPs is the oscillations recently observed in the electronic relaxation dynamics of Au and bimetallic core/shell particles.<sup>[175,179–182]</sup> As shown in Fig. 3A, femtosecond transient absorption data for Au particles probed at 550 nm following 400-nm pulse excitation show clearly

**Fig. 3** (A) Transient absorption data for 60-nm-diameter Au particles recorded with 400-nm pump and 550-nm probe pulses. Modulations due to the coherently excited breathing motion can be clearly seen. (B) Plot of the measured frequencies vs.  $1/R$  for different Au samples. A straight line fit to the data is also shown. *Source:* From Fig. 6 of Ref.<sup>[175]</sup>.

modulations with a period of about 16 psec. The frequency of the oscillation was found to increase linearly with decreasing particle size [Fig. 3B]. The oscillations have been attributed to a coherent excitation of the radial breathing vibrational modes of the particles. Photoexcited electrons can transfer their energy into the lattice, heating up the particle and causing a rapid expansion. The expansion and distraction of particle volume over time cause the electron density of particle to change and periodic shift of the surface plasmon absorption band, manifesting itself as a modulation in the transient absorption signal.

Similar oscillation has been observed more recently in silver ellipsoids,<sup>[183]</sup> Au nanorods,<sup>[184]</sup> and strongly coupled Au aggregates.<sup>[185]</sup> Time-resolved laser spectroscopy has been used to investigate Au nanorods with aspect ratio from 2 to 5.<sup>[184]</sup> Coherent excitation of the acoustic vibrational modes in Au nanorods results in the oscillation of transient absorption signals. The period of the oscillation has been found to be  $2L/c_t$ , where  $L$  is the length of the rod and  $c_t$  is the transverse speed of sound in bulk gold. This is different from the results of silver ellipsoids, where the period is determined to be  $2d/c_l$ , where  $d$  is the length or width of the ellipsoid, and  $c_l$  is the longitudinal speed of sound in silver.<sup>[183]</sup> The discrepancy has been explained by the different natures of the vibrational motion and elastic properties.<sup>[184]</sup>

Aggregates of metal NPs are fundamentally interesting as they can be used to study interparticle interactions. The interaction between particles can be roughly divided into three regimes: weak, moderate, and strong. In weakly or moderately interacting systems such as DNA-linked Au NPs<sup>[186,187]</sup> and superlattice structures of Au NPs,<sup>[188]</sup> the transverse plasmon band shift noticeably to the red. In strongly interacting systems such as Au nanoparticle aggregates, a whole new absorption band, termed extended plasmon band (EPB), appears near 700–950 nm in addition to the transverse surface plasmon band (~520 nm).<sup>[189,190]</sup> The EPB is similar to the longitudinal plasmon absorption in nanorods and its appearance is a signature of strong interaction between nanoparticles. In a recent dynamic study of strongly interacting Au aggregates, the electronic relaxation time appeared to be similar to those of isolated particles and bulk.<sup>[185]</sup> Surprisingly, periodic oscillations and probe wavelength dependence of the oscillation period were observed in the dynamic profiles of Au nanoparticle aggregates. The oscillations have been attributed to the coherent excitation of vibration of the aggregates. The dependence of oscillation period on probe wavelength indicates that the broad EPB in static absorption spectrum is inhomogeneously broadened because of different aggregate sizes, supported by a spectral hole burning experiment. Interestingly, the

observed oscillation period is longer than that predicted based on an elastic sphere model. A possible explanation is that the vibrational motion in aggregates is “softer” than that of isolated hard spherical particles. This study shows that transient absorption measurements can provide information on size distribution and vibrational frequencies of metal nanoparticle aggregates or similar systems.

## CONCLUSION

In summary, charge carrier dynamics of nanomaterials have been studied with powerful time-resolved laser techniques to provide important information complementary to static or equilibrium studies. The recent progress in synthesizing high-quality nanomaterials samples has made it possible to start to explore some of the most fundamental issues concerning the effects of size, shape, structure, and surface on charge carrier dynamics. Further research is clearly needed to better control these parameters in order to achieve a more complete understanding of the dynamic properties of charge carriers in nanomaterials.

## INTRODUCTION

What is nanoscale? Albert Einstein's doctoral research, using experimental data on the diffusion of sugar in water, showed that each single sugar molecule measures about a nanometer in diameter, a billionth of a meter. One nanometer is the approximate width of 10 hydrogen atoms laid side by side. It is one thousandth the length of a typical bacterium ( $\sim 1\ \mu\text{m}$ ,  $10^{-6}\ \text{m}$ ), one millionth the size of a pin head, one billionth the length of Michael Jordan's well-muscled legs ( $\sim 1\ \text{m}$ ). While the exact definition of "nanotechnology" is somewhat imprecise, the term generally implies devices or structures with at least two characteristic dimensions in the range of 1–100 nm. Along with biomedical research and defense—fighting cancer and building missile shields—nanotechnology has become a visible and energized discipline in science and technology. It spans fields from condensed matter physics, engineering, molecular biology to large swath of chemistry<sup>[1,2]</sup> (Fig. 1). Key themes within this area include 1) the ability to understand, and ultimately to control, important properties of materials and structures at the nanometer scale; and 2) improved understanding of how nanostructured elements interact with the external environment.

In contrast to the relatively recent recognition of nanotechnology as a field, charge transfer has been known for decades.<sup>[3,4]</sup> It is a very important process in chemistry, biology, and physics in semiconductor devices and in electronics. Our respiration, photosynthesis, many biological processes, and thin films of tunnel-diode involve electron or charge transfer, in some cases even at a large distance.<sup>[5]</sup> In both respiration and photosynthesis, the primary action of the energy source (combustion of substrate by oxygen in respiration and absorption of light by chlorophyll or bacteriochlorophyll in photosynthesis) is to move charges or

electrons, a long distance, in an electron-transport chain.<sup>[6,7]</sup> Charge transfer in photosynthetic reaction centers<sup>[8]</sup> and in protein–protein electron-transfer complexes such as hemoglobin<sup>[9]</sup> can even occur at liquid helium temperature. The measurement of electrical currents,  $I$ , tunneling through insulating layers, as in the invention of Esaki tunnel-diode, is a classic example of charge transfer in semiconductor devices.<sup>[10]</sup> In this entry, results about charge transfer at the nanoscale from the electrostatic surface potential (ESP) measurements of self-assembled monolayers (SAMs) are presented. A brief overview of current theoretical understanding including our ongoing calculations is included.

## AN OVERVIEW OF MOLECULAR ELECTRONICS

The quest for miniaturization of semiconductor devices has created a tremendous interest in nanomaterials in recent years.<sup>[11,12]</sup> Nanoscale structures have now become essential parts of integrated circuit (IC) technologies for providing faster computer chips. Decades before computers pervaded our workplaces and homes, Gordon Moore, cofounder of Intel Corporation, observed that the number of transistors per unit area in an IC chip was doubling approximately every 18 months. This relationship, widely known as Moore's Law,<sup>[13]</sup> has held for over 30 years. It drives much of the technology development and is responsible for the continuous increase in computer speeds, memory capacities, and capabilities of components based on ICs. In the first international conference on nanomanufacturing at MIT in April 2003, Intel showed their progress toward 100-nm computer chips. However, there is a limit to the top-down approach, a concern shared by the researchers in semiconductor industry.<sup>[14]</sup>

**Fig. 1** An overview of micro- and nanoscale.

The gap between the top-down approach and the size of an individual molecule (Fig. 1) may be best realized using a bottom-up approach. Nanotechnology with direct impact on commercial application of nanoscale systems will depend on their assembly with predefined geometry either in solution or on a solid support. Interesting new phenomena such as single-electron charging effects<sup>[15]</sup> and conductance quantization<sup>[16]</sup> have already been discovered. As decreasing the size of microfabricated components becomes increasingly difficult, it is possible that molecular electronic approaches can play a significant role in electronics. As molecules with sizes in the range of 1–3 nm have been shown to have interesting functionality when integrated into device structures, this approach should provide inherent scalability to the nanoscale (Fig. 2).

Aviram and Ratner originally proposed in 1974 that molecules could replace computer-chip components and a single molecule with a donor-spacer-acceptor would behave as a diode when placed between two

electrodes.<sup>[17]</sup> This has now been extended to electronics using hybrid molecular and monomolecular devices and has been reviewed recently by Aviram and his colleagues at IBM.<sup>[18]</sup> More significantly in the past 5 years, nanoscale devices ranging from simple switches and wires to more complex transistors and circuits have been unveiled. Let us review briefly what is inside an IC and a few major accomplishments in the past 5 years.

An IC chip, the heart of a computer, is made of silicon, a semiconductor material. A stamp-size chip can hold billions of components, primarily the transistors that allow a computer to process instructions, perform calculations, and manage data flow. The transistor is a switch that controls and generates electrical signals using three terminals: the source, gate, and drain. More sophisticated functions can be performed using multiple transistors.<sup>[19]</sup> In computational circuits such as microprocessors, the transistors are typically interconnected to form logic gates, which represent and manipulate data using a binary system often designated as “1” and “0.” The binary system, or rather the patterns and sequences of 1 (“on”) or 0 (“off”) can be interpreted as numbers. Generally, the state (“1” or “0”) of a given logic gate is determined by the voltage state at the output of that gate. The state of a logic gate switches in a specified response to its inputs, based on the configuration of wires that interconnect the gates within the IC. The switching signals consist of voltages, and associated electronic charge/current, flowing through the wires leading into the logic gate. Within an IC, bits of information can also be stored in memory cells, where a bit is typically represented by a quantity of electronic charge or a voltage state.<sup>[19]</sup>

Typically, the wires in ICs are made from metals, which are good electrical conductors. In the past decade, individual molecules have been shown to conduct electricity; the Aviram-Ratner mechanism, slightly

modified, has been confirmed both in macroscopic and nanoscopic conductivity measurements.<sup>[20]</sup> Simulations have shown that gold nanowires can be stretched to one-atom thickness. Phaedon Avouris at IBM designed a “NOT” gate (similar to the part of a computer’s logic circuitry) with nanotubes.<sup>[21,22]</sup> A nanotube covering gold electrodes formed two p-type transistors: one covered with an insulator and the other was exposed to chemical processes, converting it to n-type.

As with a typical transistor in IC, containing three terminals: the source, gate, and drain, conductive tripod-shaped molecules have been attached to three terminals to form a transistor. Charles Lieber and his group at Harvard University have designed a nanoscale memory device using crisscrossed nanotubes as both wires and, at their junctions, switches.<sup>[23,24]</sup> The tubes that touch are “on” and that do not are “off” and they can hold that state indefinitely. Cees Dekker, of Delft University, unveiled a transistor that worked at room temperature using a semiconductor carbon nanotube, an electrode, and a substrate.<sup>[25]</sup> In contrast, Mark Reed at Yale and James Tour at Rice have designed organic molecules that serve as conductors. When a voltage is applied and varied to the molecule containing a para-nitro aniline moiety (aromatic species), it functions as a switch.<sup>[26]</sup>

The Yale–Rice team followed the bottom-up approach to assemble the system on a gold surface using chemical self-assembly which relies on ordered and functional structure formed by dipping a Au-substrate into a solution containing the aromatic thiol. This is the basis of a common bottom-up approach for making nanoscale devices based on self-assembled monolayers (SAMs). The SAMs of organic thiols have been widely studied and they have been reviewed in recent literature.<sup>[27,28]</sup>

The current–voltage measurement of SAMs is one of the most active area of research because of its role in molecular electronics and other sensing applications.

The resistance or conductance of molecules bonded to an Au electrode has been measured using scanning probe techniques by different groups.<sup>[29–34]</sup> For example, in the case of insulating SAMs of dodecanethiol (DDT), octadecylthiol (ODT), and resorcinarene C10 tetrasulfide (RC10TS) on Au(111), the electrical conductivity of the monolayers, measured using scanning tunneling microscopy (STM), is observed to depend both on the monolayer thickness and on the nature of the Au/S bond. Leakage current densities across 1.4-nm DDT and 2.0-nm RC10TS on Au indicate superior insulating properties of the latter at high voltages. The SiO<sub>2</sub> layers with comparable leakage current densities were calculated to have a thickness of 1.0 and 1.5 nm, respectively. These data strongly suggest that organic SAMs are capable of providing necessary insulation for the efficient operation of molecular or nanoscale electronic circuits.<sup>[35]</sup>

A close coupling between theoretical modeling<sup>[36]</sup> and experimental measurements is necessary to provide useful insights into the conductance spectra of organic molecules interfaced with semiconductor and metal surfaces. This can be exemplified by the work of the teams led by Datta and Reifenger of Purdue University.<sup>[34,37,38]</sup> The basic picture for molecular conduction is fairly straightforward in principle. Consider a molecule of phenyl dithiol sandwiched between two gold electrodes as shown in Fig. 3. The molecular energy levels consist of a set of occupied levels separated by a gap from a set of unoccupied levels (Fig. 3B). At equilibrium, the Fermi energy ( $E_f$ ) is typically located somewhere in the gap between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO). When a bias is applied, the Fermi energy in the right contact ( $\mu_2$ ) floats up by  $eV_d$  relative to the left contact ( $\mu_1$ ), i.e.,  $\mu_2 - \mu_1 = eV_d$ . The low bias conductance is determined by tunneling near the Fermi energy. The conductance of the molecule increases dramatically when the bias is large enough that one or more of the molecular energy

**Fig. 3** (A) Phenyl dithiol (1,4-benzenedithiol) sandwiched between two gold electrodes. (B) Schematic diagram showing molecular energy levels and electrochemical potentials of the contacts.

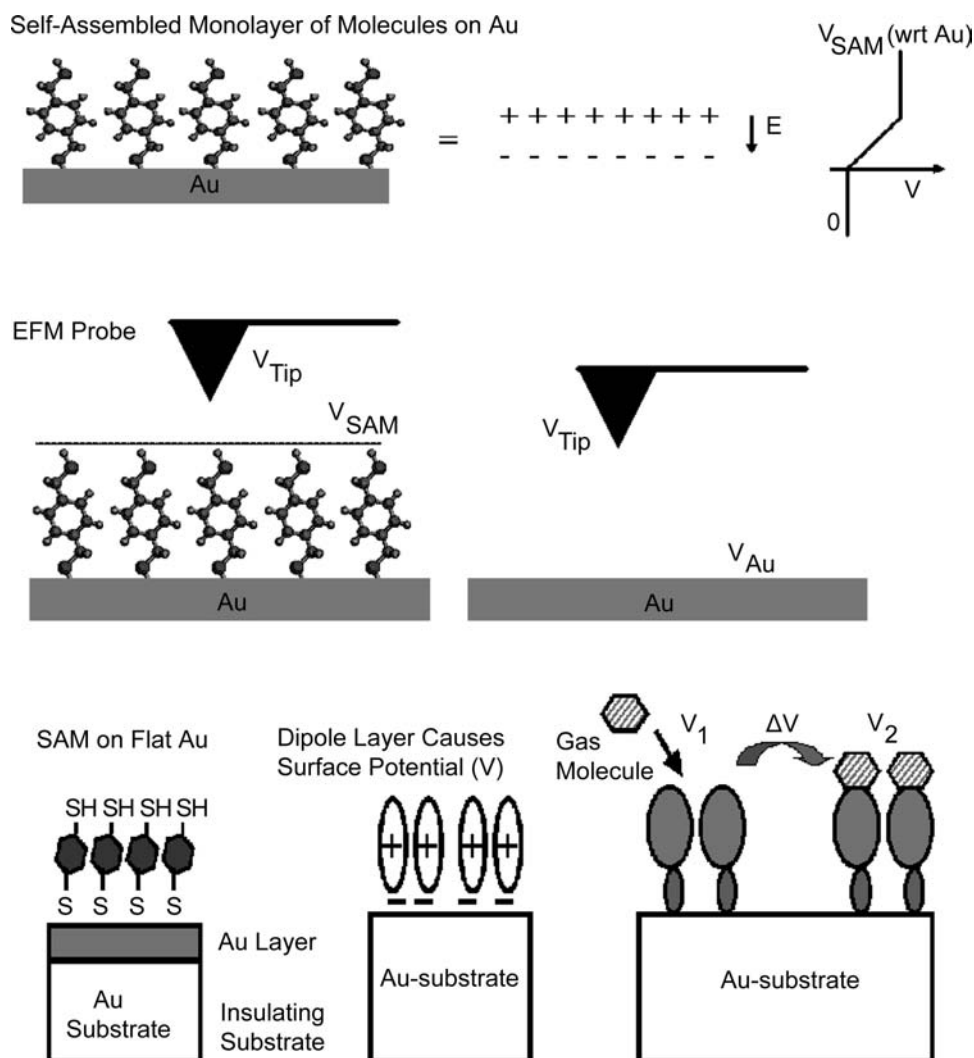

levels lie between  $\mu_1$  and  $\mu_2$ . This basic picture has been extended into a quantitative model using the standard methods of quantum chemistry.<sup>[38]</sup>

## ELECTROSTATIC SURFACE POTENTIAL

Although significant progress has been made in different areas of nanotechnology, a proper understanding of charge transfer at the metal–molecule interface is still lacking. In contrast to  $I$ – $V$  studies, the electrostatic surface potential of SAMs—due to the presence of dipoles on a surface—has not been explored that much. As shown in Fig. 4, ESP arises from the dipoles created by the chemisorbed aromatic thiol on Au (Fig. 4). Now the question arises, why is this important? First of all, the measurement of ESP

gives an insight into the electronic properties of SAMs. Secondly, such measurements provide a diagnostic feature for the molecule and better models for  $I$ – $V$  measurements. Furthermore, a knowledge of ESP can help build a potential chemical field-effect transistor (FET) for nanoelectronic devices. The origin of the measured potential is intimately related to orientation and bonding as well as the molecule itself. Thus ESP measurement is of fundamental interest and has potential applications for chemical and biochemical sensors (Fig. 4 bottom).

What follows next is a description of ESP measurements and experimental results derived from our collaborative efforts as well as that of other groups. A brief overview of current theoretical understanding of ESP measurements including our ongoing calculations is included.

**Fig. 4** Top: Self-assembled monolayers of xylyldithiol chemisorbed on gold; the opposite charge dipoles produce electrostatic surface potential (ESP). Middle: The ESP measured with or without the molecule chemisorbed on the surface using electrostatic force microscopy (EFM). Bottom: A schematic view of potential chemical sensors based on electrostatic surface potential measurements of a SAM of an organometallic compound before and after it is exposed to a gas.

## ESP Measurements

Although several techniques exist for measuring the surface potential of monolayers, the most widely used method is the vibrating Kelvin probe developed initially to measure the contact-potential differences (CPDs) between two conducting materials.<sup>[39,40]</sup> When two metals are electrically connected, electrons flow immediately from one metal to the other until an equilibrium is established, i.e., when both metals reach the same electrochemical potential. The potentials outside the metals are no longer strictly constant due to these slight surface charges, creating a potential drop from one metal to another, which is described as the local CPD between these two metals (Fig. 5). The CPD for clean metal surfaces is the difference in work functions (defined by removal of an electron from the surface to vacuum) of the two materials. The work function is modified as the surface is coated with SAMs of different dipole moments (Fig. 5). However, as the work function of the tip is the same for both measurements, the surface potential of the SAM-coated Au can be referenced to the bare Au substrate (Fig. 4).

A commercial AFM can be modified as the Kelvin probe to enable surface potential measurements (Fig. 6). Two conductors are arranged as a parallel plate capacitor with a small spacing (nanometer scale), and the resultant CPD (as shown above in Fig. 5), in a simple sense, can be defined as  $V_{\text{CPD}} = -(\phi_1 - \phi_2)/e$ , where  $\phi_1$  and  $\phi_2$  are the work functions of the conductors that include the adsorbed layers. A periodic vibration between the two plates at a frequency  $\omega$  gives an alternating current (a.c.) with the same frequency  $\omega$

when the two plates have different work functions.<sup>[39]</sup>

$$I(t) = (V_{\text{bias}} + V_{\text{CPD}})\omega\Delta C \cos \omega t$$

The zero point of a.c. can be detected when the additional bias voltage is applied between the two plates until the electric field between them disappears, i.e.,  $V_{\text{CPD}} = -V_{\text{bias}}$ . The spatial resolution of CPD in electrostatic force microscopy (EFM) can be improved using a Kelvin probe tip and has been called Kelvin probe force microscope (KFM) by Wickramasinghe and coworkers.<sup>[40]</sup>

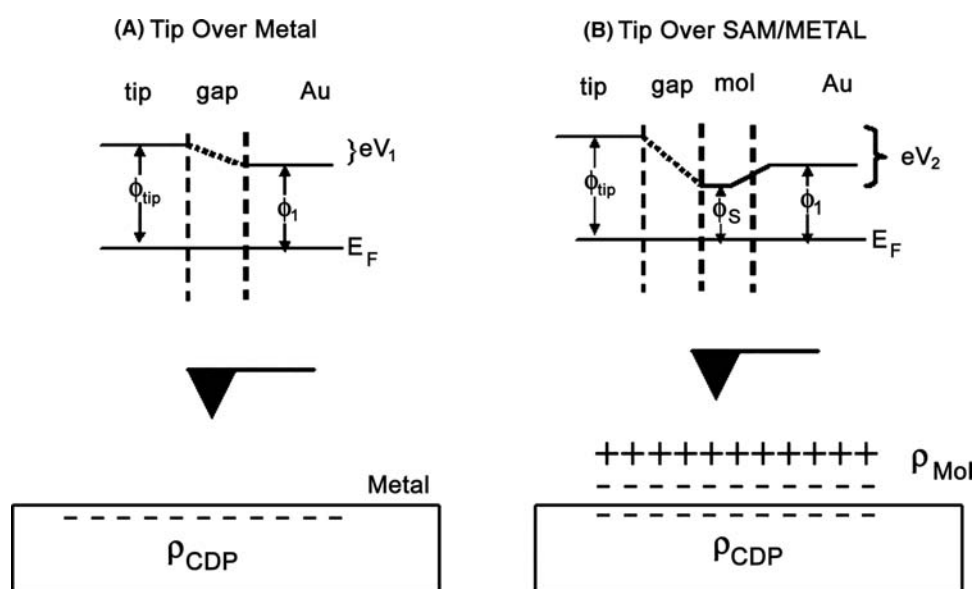

The electrostatic surface potential ( $V_s$ ) measurement is based on the standard noncontact force detection technique described elsewhere.<sup>[41,42]</sup> In short, the tip is held at a fixed distance of approximately 100 nm above the sample using a noncontact topographic feedback system as shown in Fig. 6. This system controls the separation by monitoring and maintaining a specific mechanical vibration of the cantilever ( $\omega_r$ ) near its resonance frequency.

The electrostatic force on a conducting tip held close to a conducting surface is given by  $F = -(1/2)V_s^2 (dc/dZ)$ ; where  $V_s$  or  $V_{\text{SAM}}$  is ESP.

The ESP for a SAM, relative to that of a bare metal surface, is defined as:

$$V_{\text{SAM}} = \frac{N_{\text{mol}}}{2K\epsilon_0} \vec{p}\hat{n} \quad (1)$$

where  $N_{\text{mol}}$  is the local density of molecules in the SAM (assuming uniform coverage),  $\vec{p}$  is the dipole moment of the adsorbed molecule,  $\hat{n}$  is a unit vector normal to the

**Fig. 5** The contact potential difference (CPD) due to difference in work functions resulting from the AFM tip over metal and the metal coated with the self-assembled monolayer of a molecule.

Fig. 8 A reflectance absorption infrared spectrum of tetramethylxylyldithiol chemisorbed on Au.

A typical RAIR spectrum of an aromatic thiol, with thickness of 0.8 nm, used to form a charge-transfer (CT) complex (see “[Surface Potential Measurements of a CT Complex](#)”) is shown in Fig. 8 (see Ref.<sup>[42]</sup>).

### Electrostatic Surface Potential Results

Evans and Ulman first studied the ESPs of SAMs of alkanethiols on gold surfaces using a macroscopic Kelvin probe.<sup>[43]</sup> As the probe diameter was on the order of a few millimeters, the surface potential produced by a large number of molecules ( $\sim 10^{13}$ ) was measured. These measurements indicated a dependence of the ESP on the number of  $\text{CH}_2$  groups that formed the backbone of the alkanethiols. A change of  $\sim 10$  mV per  $\text{CH}_2$  group was observed. Thus while the ESP of dodecanethiol (DDT) was  $\sim 520$  mV, that of octadecylthiol (ODT) was measured to be  $\sim 580$  mV.

In these studies, Evans and Ulman modeled SAMs as a two-dimensional ensemble of dipoles with length  $l$ , where  $l$  is approximately the length of the molecule (Fig. 7). A layer of negative charge resides very close to the Au substrate, while the positive charge is thought to lie at the tail of the molecule, approximately a distance  $l$  above the gold surface. The orientation of the dipole moment is inferred from the positive slope in the surface potential as the chain length is increased. This suggests that increase in ESP is directly related to the change in distance between the two charged sheets. In molecular terms, this implies that the effective  $\text{R}^+-\text{S}^-$  dipole (where  $\text{R} = \text{C}_n\text{H}_{2n+1}$ ) must be larger than the  $\text{Au}^+-\text{S}^-$  dipole and this is reasonable as the  $\text{Au}^+$  can be screened within a very short distance by the electrons within the metal, whereas this cannot be applicable for the monolayer (see “[Negative Surface Potential](#)”).

Recently, Lü et al. used a KFM to measure the surface potential of alkanethiol SAMs transferred to a gold substrate using microcontact printing techniques.<sup>[44]</sup> The lateral resolution in this case was  $\sim 50$  nm. As in the case of Evans and Ulman, a dependence of surface potential on the chain length is observed ( $\sim 14$  mV per  $\text{CH}_2$  unit). These measurements were made with respect to a  $-\text{COOH}$ -terminated thiol SAM, making it difficult to estimate the absolute value of the potential produced by the molecules themselves. However, these studies clearly established a strong dependence in the polarity and magnitude of the ESP on the number of  $\text{CH}_2$  groups present in an alkanethiol molecule.

The ESP measurements of alkanethiols using a modified AFM or EFM at Purdue have yielded much lower values than that reported by Evans and Ulman. An average surface potential of  $100 \pm 20$  mV for DDT SAMs and  $230 \pm 30$  mV for ODT SAMs (Fig. 9) are observed. Although the ESP measurements of alkanethiols by Evans and Ulman, Lü et al., and that measured by the Purdue group are somewhat different from each other, they may still be compared on a qualitative sense as shown in Fig. 10.

The large difference between the surface potential measured by the Purdue group and those reported by Evans and Ulman may arise due to different standards. As the electrostatic force is a long-range interaction, the cantilever as well as the tip contributes to the electrostatic force. It is estimated that SAM interrogated by the EFM technique is roughly given by a circular region with a diameter of  $\sim 40$   $\mu\text{m}$ , a dimension determined roughly by the triangular region of the cantilever supporting the tip. Thus due to the uncertainties of the absolute values of the surface potential, it is more relevant to discuss only the relative changes between alkanethiols with different chain

**Fig. 9** The electrostatic surface potentials of dodecanethiol (DDT) and octadecylthiol (ODT) chemisorbed on Au.

lengths. The relative dependence of ESP on chain length is in agreement with that reported by Lü et al.<sup>[44]</sup>

There are other factors that may explain the observed difference in ESP values. Evans and Ulman did reference their measurements to polycrystalline Au.<sup>[43]</sup> If the S–Au bonding is affected by the orientation of the surface Au atoms, then it is possible that the charge associated with S–Au bond also depends on the orientation of the surface Au atoms. Thus the charge associated with the S–Au bond can cause an offset in the magnitude of the surface potential. Further investigation is necessary to know the effect of the orientation of the Au atoms on surface potential.

The ESP measurements are further complicated by contamination of the surface. The preparation of the Au surface can affect the packing density as well as the orientation of the molecule. A “bare” Au substrate has been considered as a control sample in our measurements. Zehner et al. have shown in their studies that the ESP value varies with time using hexadecanethiol (HDT) SAM as a reference.<sup>[45]</sup> In our studies also, we have observed the ESPs of DDT and ODT SAMs decrease slightly with time.<sup>[41]</sup> This may indicate that SAM organizes further with time and this is consistent with structural changes observed over time by Barrena et al.<sup>[46]</sup> Similarly, Saito et al. have used a monolayer of octadecyltrimethoxysilane (ODS) and have shown how the electrostatic potential depends on the surface coverage of the monolayer.<sup>[47]</sup> Thus how exactly different factors such as the substrate and packing of SAMs affect surface potential may need to be addressed further.

#### Effect of Solvent on ESP Measurements

To our knowledge, this aspect has not been reported in the literature. We have examined the surface potential of SAMs of ODT prepared from different solvents such as ethanol, dichloromethane, and acetonitrile. The solvents used for SAM formation do not form a chemical bond with Au as they are removed by evaporation. Thus it is unlikely that the solvents themselves can form a close-packed monolayer. This is corroborated by IR spectroscopic investigations of Gericke, Simon-Kutscher, and Huehnerfuss<sup>[48]</sup> which provide no evidence of solvent molecules embedded in the monolayer. Our ESP measurements yield an average surface potential of  $200 \pm 50$  mV for ODT SAMs (prepared from different solvents) with respect to bare Au(111), thus showing no significant effect of solvent on surface potential measurements.

**Fig. 10** The electrostatic surface potentials of alkanethiols measured at Purdue and elsewhere. Source: From Ref.<sup>[41]</sup>.

## ESP Measurements of Symmetric and Nonsymmetric Aromatic Thiols

The structure of the molecule may play a significant role and we investigated this by ESP studies of symmetric and nonsymmetric aromatic molecules shown in Fig. 11. The SAMs of these molecules were characterized using RAIR and ellipsometry<sup>[41,42]</sup> and the RAIR spectrum of a typical sample such as tetramethyl-xylyldithiol (TMXYL) is shown in Fig. 8 (above). The molecules with a symmetric structure, xylyldithiol (XYL) and TMXYL, show a small surface potential with respect to Au ( $\sim +50$  and  $\sim +16$  mV). The non-symmetric molecules show significantly higher potential: benzyl mercaptan, which is equivalent to replacing one of the  $\text{CH}_2\text{SH}$  groups of XYL with a hydrogen atom yields an average surface potential that is  $> +200$  mV with respect to gold. Similarly, the replacement of one  $\text{CH}_2\text{SH}$  group with  $-\text{CH}_3$  in PMBM results in a large surface potential with respect to bare Au(111) (Fig. 11) substrate.

The difference in surface potential (Fig. 11) may be explained on the basis of the structures considering the absence of symmetry or lower symmetry in benzyl mercaptan (BM) and pentamethylbenzyl mercaptan (PMBM). In both XYL and TMXYL, there is a symmetry present in the structures. So the expected dipole moment of these systems before attachment to the Au surface will be low or negligible. However, it is not obvious what happens to the dipole moment of the system when the hydrogen is replaced by gold and attached to only one side of the molecule. Experimental results seem to suggest that the Au–S and H–S dipoles, in some sense, cancel each other; but preliminary theoretical calculations suggest that this may not be the case; attachment of three, six, and seven

Au clusters does produce significant dipole moments for the symmetric molecule (see “[Theoretical Modeling of the Surface Potential of SAMs](#)”). Overall, these measurements suggest that the molecular structure plays a significant role in the charge transfer between S and Au.

## Negative Surface Potential

The molecular structure and attachment of  $\text{sp}^2$ -hybridized carbon to sulfur bound to Au can have a profound effect on the charge transfer or on the ESP measurements of the SAMs of phenyl, biphenyl, and triphenyl thiols (Fig. 12). The ESP of mono-phenyl thiol becomes negative with respect to bare Au ( $-0.38$  V) and increases further for biphenyl,  $-0.76$ , and levels off for the triphenyl species at  $-0.72$  V (Table 1). The surface potential produced by these thiols can be estimated using the formula described in Eq. (1) (Fig. 7). The angle of inclination can be estimated using the RAIRS data and with respect to normal they are  $0^\circ$ ,  $31.79^\circ$ , and  $36.13^\circ$ , respectively. Both the calculations from isolated molecule (unpublished) and ESP data show a significant shift in ESP when an additional phenyl ring is attached to phenyl thiol and it levels off with three phenyl rings.<sup>[49]</sup>

It is interesting to compare the observed ESP results of phenylthiols with other aromatic thiols and alkanethiols. From a chemical standpoint, the bonding of sulfur to gold produces polarization:  $[\text{Au}]^+-\text{SR}$ . SR. In contrast to the situation in aliphatic thiols or benzyl mercaptan with a  $\text{CH}_2$  group attached to S that is bonded to Au, the negative charge on the sulfur of phenyl thiols becomes relatively large as it can be delocalized through several conjugated structures.

**Fig. 11** The electrostatic surface potentials of symmetric and nonsymmetric aromatic thiols chemisorbed on Au.

MPT, monophenylthiol; BPT, bi-phenylthiol; TPT, tri-phenylthiol

**Fig. 12** The electrostatic surface potentials of mono-, di-, and tri-phenyl thiols.

Hence a negative surface potential is observed (see below).

Negative surface potential has also been measured for SAMs of helix peptides. Miura et al.<sup>[50]</sup> have prepared SAMs of two peptides with different molecular length, LipoA16B and LipoA24B (Fig. 13; notice that LipoA24B, figure on the right, is much longer), and observed a few hundred millivolts negative surface potential. These peptide SAMs with N-terminal attached to sulfur, that is connected to gold, show tilt angles of the helix axis from the surface normal to be 36° and 30°, respectively, by FTIR-RAIR spectroscopy. The large dipole moment of the helices directs toward the surface, with a negatively charged surface of the SAM exposed outside (Fig. 13). The molecular arrangement is important for the evaluation of the effect of the large dipole moment of the helices because the alkyl-thiol SAMs, described above, produce a positive surface potential. Clearly, the large dipole moment of the helices exceeds over the effect of Au<sup>+</sup>–S<sup>–</sup> to yield the observed negative surface potential of the peptides. Further, the surface potential of LipoA24B (tetracosapeptide) is much larger than LipoA16B (hexadecapeptide) and is consistent with the view that it originates from the dipoles aligned toward the surface. The calculated dipole moments, using MOPAC, are 55 D for the hexadecapeptide and 83 D for the tetracosapeptide and consistent with the observed experimental results. These results further emphasize that in contrast to physically adsorbed species, where the effect of individual dipoles on the

**Table 1** The electrostatic surface potentials of mono-, di-, and tri-phenyl thiols (Fig. 12)

Phenylthiols	ESP, V
Monophenyl thiol	$-0.38 \pm 0.04$
Biphenylthiol	$-0.76 \pm 0.04$
Triphenylthiol	$-0.72 \pm 0.02$

surface potential is approximately evaluated only by considering the mutual depolarization of a set of dipoles, the dipole moment or ESP of a chemisorbed adsorbance cannot be predicted easily.<sup>[51]</sup>

### Surface Potential Measurements of a Charge Transfer (CT) Complex

The interplay between positive and negative ESP can be controlled by chemistry alone. A CT complex SAM can be formed by reacting a strong electron acceptor such as tetracyanoethylene (TCNE) with a SAM of TMXYL which is an electron donor<sup>[42]</sup> (Fig. 14). It has been shown previously that molecular conduction is greatly influenced by the location of the equilibrium Fermi level within the HOMO–LUMO gap (Fig. 15).<sup>[34,37,38]</sup> Thus mixing of the orbitals or rather the energy levels can produce a significant surface potential of the SAM. As shown in Table 2, the surface potential of TMXYL is close to that of bare Au(111) because of the molecule's symmetric structure. However, complexation to yield a CT complex of TMXYL–TCNE produces a negative surface potential which is due to the accumulation of negative charge on the surface of the complex as observed for the peptides above. As TCNE is a strong  $\pi$ -electron acceptor, a significant amount of electron density is withdrawn from TMXYL, the donor molecule, and is redistributed over the complex. This can be confirmed by the removal of TCNE using tetrathifulvelene (a strong donor), which returns the surface potential to the value before the reaction of TMXYL with TCNE.

### Theoretical Modeling of the Surface Potential of SAMs

Although we have measured the surface potential of several SAMs, there is no quantitative understanding of these measurements at present. As a first step for the SAMs on gold, we have used a quantum chemistry software, Hyperchem Pro 6 software<sup>[41]</sup> (parameters for the ab initio calculations; basis set STO-3G, Fletcher–Reeves geometry optimization). These initial calculations determine the dipole moment of alkanethiol molecules without their attachment to the Au(111) atoms. The dipole moments from these calculations for DDT, HDT (hexadecanethiol, CH<sub>3</sub>(CH<sub>2</sub>)<sub>15</sub>SH), and ODT are 0.67, 0.72, and 0.74 D, respectively (1 D = 3.336 × 10<sup>–30</sup> C m).

Now using the Eq. (1) above and typical parameters such as a packing density of 4.46 × 10<sup>18</sup> molecules/m<sup>2</sup>,<sup>[52]</sup> and a molecular tilt of 30°,<sup>[53]</sup> and a dielectric constant of ~2.5,<sup>[43]</sup> the model potentials for DDT, HDT, and ODT are calculated to be +450, +480, and +500 mV, respectively (Fig. 10). The magnitude of the calculated potentials is close to the data

**Fig. 13** The electrostatic surface potentials of N-terminal peptides with different lengths chemisorbed on Au; the one on the right is longer than that of the left peptide. *Source:* Adapted from Ref.<sup>[50]</sup>.

**Fig. 14** A molecular doping experiment to produce a charge-transfer (CT) complex of tetramethyl-xylyldithiol (TMXYL) and tetracyanoethylene (TCNE); orientation of TMXYL changes before and after its reaction with TCNE and after removal of TCNE from the complex. *Source:* From Ref.<sup>[42]</sup>.

published by Evans and Ulman,<sup>[43]</sup> which may suggest that EFM measurement is probably an indicator of how well the SAM is organized when it is bound to a metallic surface.

It is possible to calculate the dipole moments of DDT and ODT from the surface potentials measured by the Purdue group. Using the same parameters, the dipole moments are estimated to be 0.17 and 0.39 D, respectively. These are smaller than the calculated values. Furthermore, the dependence of the dipole moments on the number of CH<sub>2</sub> groups present in the molecule is different by a factor of three between the calculated and measured values.

Similar difference between experimental and theoretical results has been observed by Taylor for the surface potential of monolayers both at the air–water interface and deposited onto solid supports.<sup>[51]</sup> The ESP calculated for an un-ionized stearic acid monolayer,  $\Delta V_{\text{Head}} + \Delta V_{\text{Tail}} = 727 \text{ mV}$ , is almost twice the experimental value of  $390 \pm 10 \text{ mV}$ . Such a discrepancy, however, is not surprising as the model ignored 1) possible hydration effects on the head group; 2) imaging effects in the subphase; and 3) reorientation of water molecules. A significant negative contribution from these sources would reduce the discrepancy between the experimental and theoretical results.

In order to establish the measured surface potential on a firm ground and especially those of the aromatic systems adsorbed on gold, we have done quantum chemistry calculations using the supercomputer

**Fig. 15** The HOMO–LUMO diagram of an isolated metal and an isolated molecule.

facilities at La Tech. As a starting point, we have considered benzenethiol and benzenedithiol molecules adsorbed on Au surfaces.<sup>a</sup>

Quantum chemistry can provide orientation and dipole moment, two important factors, which can be used to determine the ESP described in Eq. (1). First, it is necessary to optimize the geometry of the molecule adsorbed on the metal surface of interest to a reasonable approximation, and then calculate its dipole moment in that configuration. The orientation of the molecule can be experimentally verified using RAIR spectroscopy.

The gold surfaces are modeled by a single layer of 3 and 6 gold atoms and clusters of 4, 7, 10, and 13 gold atoms, all of which have (111) lattice. Figure 16 shows the structure of the benzenedithiol molecule adsorbed on a typical cluster of gold atoms using a mixed basis set.<sup>[54]</sup> The smallest unit of the gold surface (111) consists of a cluster of three gold atoms, which can be denoted as Au<sub>3</sub> hereafter. The preferred bonding site of the S atom in the interaction of thiols with (111) gold surfaces<sup>[55]</sup> is a hexagonal close-packing (hcp) hollow site; however, it cannot be adequately represented by the Au<sub>3</sub> unit. It requires the presence of a fourth gold atom below the plane of the triangle, denoted as

Au<sub>4</sub> in Fig. 16. Larger gold clusters consisting of 6, 7, 10, and 13 gold atoms, denoted as Au<sub>6</sub>, Au<sub>7</sub>, Au<sub>10</sub>, and Au<sub>13</sub>, respectively, were also considered to determine the influence of additional layers of metal atoms. The Au<sub>13</sub> cluster has been designated as a “magic number” cluster by Larsson et al., where an octahedral cluster has been shown to have the lowest energy from Density Functional Theory (DFT) calculations.<sup>[56]</sup> It should be mentioned, in this context, that recently a 20-atom cluster, Au<sub>20</sub>, has been found to have exceptional stability and a large band gap,<sup>[57]</sup> but this cluster lacks the symmetry of the clusters studied here.

The results of our ongoing calculations show that both symmetric and nonsymmetric molecules bonded to Au<sub>n</sub> clusters have significant dipole moments.<sup>[54]</sup> In general, the symmetric molecules tend to have smaller dipole moments, which is qualitatively consistent with experimental observations. However, the calculations indicate that the origins of these dipole moments may have less to do with the Au–S bonds rather than the charge distribution in the rest of the molecule. A careful analysis of the charges is currently underway. These comments further underscore the fact that a fundamental theoretical understanding of the mechanisms by which SAMs develop ESPs on gold is still lacking.

### Organosilane SAMs

In contrast to the SAMs on Au, the experimental surface potentials of organosilane SAMs agree very well with the calculated values acquired by KFM. In the ab initio molecular calculations of surface

**Table 2** The electrostatic surface potentials ( $V_{SAM}$ ) of TMXYL and the charge-transfer complex TMXYL–TCNE on Au(111) (Fig. 14)

Species	ESP, mV
TMXYL (upright)	20 ± 70
TMXYL–TCNE	–140 ± 25
TMXYL (flat)	30 ± 60

<sup>a</sup>The quantum chemistry calculations for this work are all done with the Gaussian98 package of programs, using density functional theory and the details will be published elsewhere (Ref.<sup>[54]</sup>). The popular B3LYP functional is used for all calculations. Different basis sets are used for different atoms: the LanL2DZ basis set, which consists of a double zeta basis along with the Los Alamos relativistic effective core potential, is used for the gold atoms, the 6–31G(*d*) basis for the carbon and sulfur, and the 4–31G(*d*) for the H atoms. Most of the previous studies have used basis sets such as the LanL2DZ for all the atoms in the system. The use of the *n*–31G(*d*) family of basis sets on the nonmetal atoms yields a much lower variational energy compared to a calculation in which LanL2DZ is used for all the atoms. The additional flexibility of the basis set and the presence of the extra *d*-functions to describe polarization effects allow for a more accurate description of the molecular structure, charge density distribution, and, therefore, of the dipole moment. Our objective has been to use the largest basis set possible while keeping the calculations to a manageable size.

**Fig. 16** The optimized geometry of a phenyldithiol molecule attached to four-atom gold cluster.

potentials of organosilane SAMs, Saito et al. used  $\text{H}_3\text{C}(\text{CH}_2)_{15}\text{CH}_3$  for *n*-octadecyltrimethoxysilane (ODS),  $\text{F}_3\text{C}(\text{CF}_2)_7\text{CH}_2\text{CH}_3$  for heptadecafluoro-1,1,2,2-tetrahydro-decyl-1-trimethoxysilane (FAS), and  $\text{H}_2\text{N}(\text{CH}_2)_6\text{NH}(\text{CH}_2)_2\text{CH}_3$  for *n*-(6-aminoethyl)aminopropyltrimethoxysilane (AHAPS) as models.<sup>[47]</sup> The structures of ODS-, FAS-, and AHAPS molecules were gauche and antiforms, respectively. The ODS, FAS, and AHAPS molecules have net dipole moments of 0.03, 2.38, and 0.57 D, respectively. If these alkyls stand normal to the substrate, the dipole moment would be zero according to Eq. (1). In reality, these molecules are tilted on the surface and the calculated ESP values match well with the values acquired by KFM. These results perhaps indicate that molecule–semiconductor interface behaves differently from that of metal–molecule heterostructure.

## CONCLUSION

Nanoscale charge transfer studies at the interface of metal–molecule heterostructures are very important to provide a better understanding of useful nanostructures. Research from different laboratories suggests that building SAMs on a surface can bridge the gap between the top-down approach and the size of individual molecules. The electrostatic surface potential studies of SAMs are limited in contrast to their *I–V* measurements. The Kelvin probe measurements using a modified AFM can produce reliable ESP results. Although the absolute values of ESP may differ

because of substrate preparation, contamination, etc., the qualitative values of the alkanethiols compare well among different groups; the ESP values increase with the increase in chain length. The solvents used to prepare the SAMs do not appear to have any major effect on the measured values. However, the structure, especially symmetry, plays a significant role on the ESP values of aromatic thiols; while the ESP of xylyldithiol and tetramethyl–xylyldithiol are quite low, their non-symmetric counterparts such as benzyl mercaptan and pentamethylbenzylthiol produce a significant positive surface potential. The molecular structure and the attachment of  $\text{sp}^2$ -hybridized carbon of phenyl thiol to Au(111) can have a profound effect on ESP as its sign is reversed and becomes more negative with the addition of the second aromatic ring. This, however, levels off for triphenyl thiols.

A negative surface potential, i.e., nanoscale charge transfer in the opposite direction, has also been observed in helical peptides. Furthermore, chemistry alone through the formation of a CT complex of tetramethyl–xylylthiol (TMXYL) with tetracyano-ethylene (TCNE) can reverse the sign and magnitude of ESP.

Theoretical calculations, to understand charge transfer in Au/S heterostructures using Hyperchem Pro 6 and Gaussian 98, seem to predict the trend, but not the magnitudes of dipole moments or ESP of the molecules. Further, in contrast to the observed experimental results, our initial calculations show that both symmetric and non-symmetric molecules bonded to Au clusters have significant dipole moments. Thus the use of 4, 6, or 13 gold atoms to represent the gold surface may not be adequate to compare the calculated ESPs with the experimental results. Although the ab initio calculations of organosilane SAMs by Saito et al. match quite well with the experimental results, extensive theoretical studies will be necessary to have a better understanding of the ESP measurements of organothiol SAMs on gold.

## ACKNOWLEDGMENTS

We thank Professors Ron Reifenberger and Supriyo Datta, and Drs. Steve Howell, Bala Kasibhatla and Helen McNally for experimental results and some of the theoretical discussions presented here. We are very grateful to Professor Bala Ramachandran and Mr. Devendra Patel for the quantum chemistry calculations done using the supercomputing facilities at La tech. We also thank Professor Purna Das, Dr. Avik Ghosh, Dr. Prashant Damle, and Mr. Titas Rakshit for useful discussions. D.K. would like to thank Dr. S. Howell for some of the Figures and Mr. D. Patel and Mr. R. Aithal for their help with the manuscript and Louisiana Tech for its support to write this entry.

# Charge Transport in Multilayer Nanostructures

Daniel M. Schaadt

*Department of Electrical and Computer Engineering, University of California–San Diego,  
La Jolla, California, U.S.A.*

## INTRODUCTION

The demand to increase device speeds and to obtain higher data storage densities leads to decreased device sizes and new device design proposals, of which some were based on multilayer or granular metal/insulator structures, which consist of metallic nanoclusters embedded within an insulating matrix. The design and optimization of devices incorporating these materials require a detailed understanding of the relevant nanoscale electrical transport properties, which can be investigated by scanning probe techniques. This entry reviews recent studies of the nanoscale charge transport properties of multilayer or granular metal/insulator structures, and the application of the results of these studies in a novel magnetic field sensor design based on the combination of charge storage and tunnel-magnetoresistance in magnetic discontinuous magnetic multilayer structures is discussed briefly. In particular, charge deposition into Co nanoclusters embedded in a SiO<sub>2</sub> matrix and the decay of the charge as a function of time are discussed. Local charge deposition into and removal from Co nanoclusters was achieved by applying a voltage pulse to a conductive probe tip in a scanning probe microscope. Electrostatic force microscopy (EFM) was used to image charged areas, to determine quantitatively the amount of stored charge, and to characterize charge transport within the Co layer and into the Si substrate. Measurements of decay times for positive and negative charge as a function of nominal Co layer film thickness are presented, and the dynamics of the charge decay for positively and negatively charged nanoclusters is analyzed as a consequence of Coulomb-blockade effects at room temperature considering a detailed model for charge transport within the Co layer as well as from charge Co nanoclusters into the Si substrate.

## BACKGROUND

### Nanoscale Multilayer Structures

Structures consisting of metallic nanoparticles embedded in an insulating matrix have attracted increasing attention over the past decade because of their new

or unusual physical properties and the resulting possible use in various fields and applications such as non-volatile high density data storage. For instance, the possibility to store electrical charge with long retention times<sup>[1,2]</sup> in these materials might be used to build non-volatile floating gate memory devices,<sup>[3]</sup> or spin-polarized tunneling between ferromagnetic metal nanoparticles embedded in a non-magnetic insulator<sup>[4–8]</sup> can be used in magnetic sensors such as read head for hard disks.<sup>[9]</sup> These materials are generally easy to fabricate by co-sputtering of the metal and the oxide and they are very stable both chemically and electrically.<sup>[10]</sup>

### Investigations of nanoscale charge transport properties

The use of granular or discontinuous metal/insulator materials in non-volatile memory applications or in magnetic field sensors requires a detailed understanding of the charge transport between the metal nanoclusters, which can be measured on a large scale using standard electrodes.<sup>[11]</sup> However, the reduction of device sizes due to the requirements of increased speed and higher data storage density increases the need to complement large area measurements with investigations of the charge transport properties on the nanoscale, especially in the case of memory applications where charge retention times and decay mechanism are of importance. In recent years, scanning probe microscopes<sup>[12]</sup> (SPM) have been employed to characterize the properties of locally deposited charge and its decay over time. It was demonstrated that electrical charges can be stored locally in nitride-oxide-semiconductor structures,<sup>[13,14]</sup> insulator films,<sup>[15,16]</sup> nanocrystals,<sup>[2,17–20]</sup> or quantum dots.<sup>[21,22]</sup> Charge storage in these studies was achieved by applying a bias voltage pulse between the SPM probe tip and the sample. The deposited charge was typically characterized by EFM. Further, studies to investigate charge retention times and decay mechanisms were conducted.<sup>[2,23–25]</sup> These studies have led to improvements in and better understanding of the measurement techniques,<sup>[26,27]</sup> have helped to illuminate the charge decay mechanisms in discontinuous Co/SiO<sub>2</sub> multilayer structures,<sup>[23]</sup> and have resulted in a novel magnetic

field sensor design based on the combination of charge storage and tunnel-magnetoresistance in magnetic discontinuous multilayer structures.<sup>[28,29]</sup>

Combination of charge storage and tunnel-magnetoresistance in multilayer structures: a new magnetic field sensor

The possibility to store electrical charges with long retention times in a tunnel-magnetoresistive film allows the design of a novel magnetic field sensor design. In this device design, a granular tunnel-magnetoresistive (TMR)  $\text{Co}_x(\text{SiO}_2)_{1-x}$  thin film is placed between two oxide layers within the gate of a p-channel Si metal-oxide-semiconductor-field-effect transistor (MOSFET). Two contacts are placed on the TMR film outside the gate structure. The basic concept is, however, applicable to any field-effect transistor as well as other granular TMR materials, which show the possibility of charge storage in the metal clusters. If fixed voltage  $V_{\text{MR}}$  is applied across the contacts to TMR film, a current  $I_{\text{MR}}$  flows through the TMR film and leads to charge  $Q$  build-up within the Co nanoclusters. This charge in turn yields a shift in the threshold voltage of the transistor.  $I_{\text{MR}}$  changes with changing externally applied magnetic field due to spin-dependent tunneling of charge between the Co nanoclusters. Therefore the total charge  $Q$  within the gate and thus the transistor threshold voltage  $V_{\text{T}}$  are magnetic field dependent. In the prototype device described in Refs.<sup>[28]</sup> and <sup>[29]</sup>, a maximum threshold voltage shift of approximately 50 mV is reached when the external magnetic field was changed from 0 Oe to the saturation field of about 6 kOe. This results in an absolute change in the transistor saturation current of approximately 30  $\mu\text{A}$ , a factor of 500 larger than the corresponding change in  $I_{\text{MR}}$ , which is about 60 nA. The absolute change in transistor subthreshold current is about 200 nA, corresponding to a relative change of about 20%. Compared to the relative change in  $I_{\text{MR}}$  of about 5%, this is an amplification in sensitivity of a factor of four. This demonstrates that the nanoscale charge transport properties of multilayer structures consisting of (magnetic) metal nanoclusters embedded in an insulating matrix can be used in sensor devices with increased performance and are therefore worth investigating in detail.

## NANOSCALE CHARGE TRANSPORT EXPERIMENTS

### Experimental Procedure

#### Sample structure and preparation

Samples were prepared by alternating sputtering from two separate targets onto a heavily doped n-type Si

**Fig. 1** Plan-view transmission electron micrographs of Co/SiO<sub>2</sub> with varying nominal Co film thickness  $d_{\text{Co}}$  ranging from 1.4 to 2.0 nm. The light speckled contrast corresponds to amorphous SiO<sub>2</sub> and the dark contrast to crystalline Co. As  $d_{\text{Co}}$  increases, the Co particles become more connected.

(100) substrate covered with a native oxide layer of about  $\sim 2.5$  nm thickness. The Co was d.c. sputtered and the SiO<sub>2</sub> was rf sputtered. Deposition was performed at room temperature with 2 mTorr Ar pressure. The base pressure in the sputtering system was  $\sim 10^{-7}$  Torr. The nominal deposited film structures were SiO<sub>2</sub>(3 nm)/Co(1.0–2.0 nm)/SiO<sub>2</sub>(3 nm) as determined from the deposition times and rates (0.9–1.3 nm/min for the Co and 2.0–3.0 nm/min for the SiO<sub>2</sub>), which were calibrated by low-angle X-ray reflection. Transmission electron microscopy (TEM) studies<sup>[7,10,30]</sup> have shown that, when deposited on SiO<sub>2</sub>, the Co layer is discontinuous with formation of Co nanoclusters, as shown in Fig. 1. The nanoscale structure of the Co layer depends sensitively on the nominal Co film thickness and consists of isolated spherical Co nanoclusters for films with a nominal thickness of approximately less than 1.4 nm and of a chain-like arrangement of spherical Co nanoclusters to tubes of Co for nominal thicker films.<sup>[7,10,30]</sup>

#### Charge deposition and imaging of deposited charge

Scanning probe studies were performed at room temperature under ambient conditions using a Digital Instruments MultiMode<sup>™</sup> Scanning Probe Microscope<sup>a</sup> with a heavily doped p<sup>+</sup>-Si tip. Sample charging was achieved during TappingMode<sup>™</sup> operation<sup>[9]</sup> by holding the tip at the center of the scan area for 10 sec with a bias voltage  $V_{\text{ch}}$  applied to the tip and the sample grounded, as shown in Fig. 2.

EFM was used to image charged regions and to estimate the total stored charge. EFM images were

<sup>a</sup>MultiMode, TappingMode and LiftMode are trademarks of Digital Instruments, Santa Barbara, CA.

**Fig. 2** Schematic diagram showing the charging of Co clusters embedded in the Co/SiO<sub>2</sub> layer. The Si substrate is grounded and a bias voltage  $V_{ch}$  is applied to the probe tip, which is tapping on the surface. This causes current to flow from the tip into the Co clusters and from the Co clusters into the Si substrate as well as into neighboring clusters. Charge is initially deposited directly under the tip and spreads out to neighboring clusters.

obtained using LiftMode.<sup>a</sup> First, a scan line of the topography is recorded using TappingMode. Then the probe tip is lifted about 20 nm above the surface and an imaging bias  $V_{EFM}$  is applied. Finally, the probe tip is scanned at the fixed tip-sample distance with VEFM applied by retracing the previously recorded topography scan. During this second scan, the probe tip reacts to long-range forces such as electrostatic interactions between the deposited charge in the sample and its image charge in the probe tip.

The contrast observed in the EFM image may be used to calculate the total stored charge  $Q$ . An exact calculation of the deposited charge can be complicated because of the complex arrangement of image charges in the probe tip and the sample.<sup>[27]</sup> Possible artifacts in the topography scan due to electrostatic forces between the image and these charges can lead to an incorrectly measured topography and can cause difficulties separating EFM contrast from topography. However, if the deposited charge is small, its influence on the topography scan is minimal and might not lead to these artifacts. Further, if the tip-sample separation is large enough and the deposited charge small, the EFM response becomes symmetric with respect to imaging bias  $V_{EFM}$ .<sup>[27]</sup> It is easy to check if these conditions are met by imaging the topography after charge has been deposited and by recording the EFM signal for opposite imaging voltages. Assuming that no artifacts are visible before and after charging in the topography and the EFM signal is symmetric with respect to  $V_{EFM}$ , a simple approach can be used to estimate the deposited charge. Specifically, the shift  $\Delta f$  in the resonant frequency of the cantilever is related to the force gradient  $F' \equiv dF/dz$  by the expression.<sup>[31]</sup>

$$\Delta f = -f_0 F'(z_0)/(2k) \quad (1)$$

where  $z_0 = 20$  nm is the lift height during EFM imaging,  $f_0 = 232$  kHz the cantilever resonant frequency, and  $k$  the cantilever spring constant, which was calculated from the lever geometry to be  $90 \pm 10$  N/m. The force  $F(z)$  arises from Coulomb interactions of the stored charge, its image charges in the tip and Si substrate, and the induced charges due to the voltage  $V_{EFM}$  applied during imaging. From an electrostatic analysis of the tip-sample system modeled using a simple parallel-plate geometry, the force is found to be given by<sup>[21]</sup>

$$F(z) = \frac{1}{(z + (d_1 + d_2)/\epsilon_{SiO_2})^2} \times \left( -\frac{d_1^2 Q^2}{\epsilon_{SiO_2}^2 \epsilon_0 A} + \frac{2d_2 Q V_{EFM}}{\epsilon_{SiO_2}} + \frac{\epsilon_0 A V_{EFM}^2}{2} \right) \quad (2)$$

where  $d_1$  and  $d_2$  are the thicknesses of the top and bottom oxide layer, respectively,  $\epsilon_{SiO_2}$  the relative dielectric constant of SiO<sub>2</sub>,  $z$  the tip-sample separation, and  $A$  the area of the charged region. If the deposited charge  $Q$  is small, the first term in the bracket in Eq. (2) is small. The third term in the bracket is independent of the stored charge and yields a constant background frequency shift at all points in the EFM image. Thus the final contrast observed is proportional to the stored charge  $Q$  and to  $V_{EFM}$ . Using the values for  $f_0$ ,  $k$ ,  $z$ ,  $d_1$ , and  $d_2$  given above, the total charge  $Q$  is then given by

$$Q = 18 \pm 2e/V \cdot \text{Hz} V_{EFM} \Delta f \quad (3)$$

As mentioned above and provided that  $Q$  is small, the EFM response  $\Delta f$  is symmetric with respect to  $V_{EFM}$ , which can be readily checked in control experiments.

## Results and Discussion

### Nanoscale charge storage

A series of topography and EFM images obtained with  $V_{\text{EFM}} = 1\text{ V}$  and  $V_{\text{EFM}} = -1\text{ V}$  before and after charging of a nominally 1.4-nm-thick Co layer with  $V_{\text{ch}} = -12\text{ V}$  for 10 sec are shown in Fig. 3. No image-charge artifacts are observed in the topography and EFM images before charging. After charging, charged areas are observed in the EFM images as peaks or dips with a symmetric resonant frequency shift of about 1 and  $-1\text{ Hz}$ , depending on the relative sign of the imaging voltages. No charge-induced artifacts are observed in the topography images after charge has been deposited, and measurements with  $V_{\text{EFM}} = 0\text{ V}$  are showing no contrast difference between charged and uncharged regions. Such a contrast difference would be expected if the amount of deposited charge is large enough to cause an attractive force between the deposited charge and its image charge in the tip.<sup>[27]</sup> The above observations suggest, however, that the amount of deposited charge  $Q$  is small and therefore the simplified approach to estimate  $Q$  from the EFM contrast, as described above, can be used.

No charging was observed in a control sample in which no Co layer was present, and it is therefore concluded that the deposited charge is stored in the Co layer. Little variation in sample charging was observed for charging times longer than 5 sec. Deposited charge can be erased by applying a voltage pulse of opposite sign.<sup>[23]</sup>

The charging of the Co/SiO<sub>2</sub> film is believed to occur in the following way: when the tip approaches the sample surface, charges tunnel from the tip through the top oxide layer into the Co clusters. At the same time, charges tunnel to neighboring uncharged Co clusters and through the thicker bottom oxide layer into the Si substrate. The currents that charge and discharge clusters are initially different because of the different oxide thicknesses of the top oxide layer and

the oxide layer between the Co clusters and the Si substrate. These currents equilibrate over time as a consequence of the adjustments in the electric fields across the oxide layers due to the charge build-up in the Co layer, in a manner analogous to the charging process in a floating-gate MOS structure. Once equilibrium is reached, the charge in the Co layer does not increase any further and its value is determined by the tip-sample capacitance.

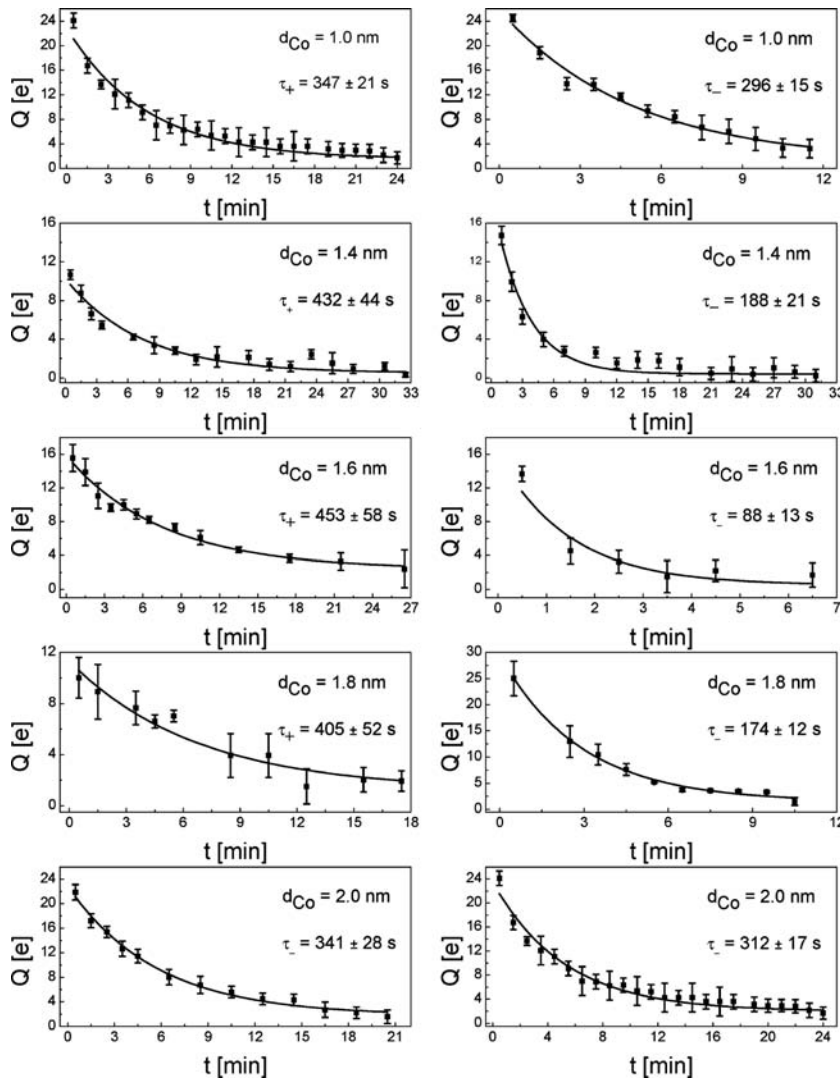

### Nanoscale charge transport

Previous measurements have shown that the deposited charge decays over time, with most of the stored charge tunneling into the Si substrate and some carrier transport also occurring between Co nanoclusters.<sup>[23]</sup> Decay times for positive and negative charges were measured and a strong dependence on the nanoscale Co film structure was observed. However, because of the difficulties in extracting the exact amount of charge as a function of time after charging, large error bars were observed in the decay times. To overcome the uncertainties and to confirm these measurements, additional measurements and analysis were performed. Fig. 4 shows the decay in charge for regions charged at 12 V and  $-12\text{ V}$  for various nominal Co layer film thicknesses. The charge decay appears exponential in all cases, but with different decay times  $\tau_+$  and  $\tau_-$  for positive and negative stored charge, respectively.

The difference in the decay times for positive and negative charging can be interpreted as a consequence of the Coulomb blockade energy  $E_0 = q^2/(2C_{\text{Co}})$  of a single Co cluster with capacitance  $C_{\text{Co}}$ . Assuming in a first approximation that charge decay occurs only between Co clusters and the Si substrate, this leads to a difference in barrier heights for escape of positive and negative charge, given, respectively, by  $\phi_+ = \phi_0 + E_0$  and  $\phi_- = \phi_0 - E_0$ , where  $\phi_0 = (\phi_{\text{Co}} + \chi_{\text{Si}} - 2\chi_{\text{SiO}_2})/2$  is the barrier height of the Co–SiO<sub>2</sub>–Si tunnel barrier,  $\phi_{\text{Co}}$  the Co workfunction,  $\chi_{\text{Si}}$  the Si electron affinity,  $\chi_{\text{SiO}_2}$  the SiO<sub>2</sub> electron

**Fig. 3** Topography (left) and EFM images (right) before charging using (A)  $V_{\text{EFM}} = 1\text{ V}$  and (B)  $V_{\text{EFM}} = -1\text{ V}$ , and after charging using (C)  $V_{\text{EFM}} = 1\text{ V}$  and (D)  $V_{\text{EFM}} = -1\text{ V}$ . Charge was deposited with  $V_{\text{ch}} = -12\text{ V}$  for 10 sec. The image sizes are 500 nm by 2  $\mu\text{m}$ . There are no image-charge-induced artifacts visible in the topography and EFM images before charging. After charging, the topography images show no artifacts due to the deposited charge, while the EFM images show a peak and dip with a height of about 1 and  $-1\text{ Hz}$ , respectively.

**Fig. 4** Decay of positive charge (left column) and negative charge (right column) for Co/SiO<sub>2</sub> films with nominal Co film thickness ranging from 1.0 to 2.0 nm. The retention times  $\tau_+$  and  $\tau_-$ , obtained by first-order exponential fits to the peak height for positive charge and the valley depth for negative charge in the EFM images, respectively, depend strongly on the nominal Co film thickness. The retention time  $\tau_+$  for positive charge is for all film thicknesses larger than the retention time  $\tau_-$  for negative charge.

affinity, and  $q$  the electron charge. As the dependence of the tunneling probability  $T$  on barrier height  $\phi$  and barrier thickness  $d$  is given approximately by  $T \propto \exp(-2d\sqrt{2mq\phi}/\hbar)$  and the retention is inversely proportional to  $T$ ,<sup>[2]</sup> the relation between the decay times is given approximately by

$$\frac{\tau_+}{\tau_-} \approx e^{\frac{2\sqrt{2m}}{\hbar}d_{SiO_2}(\sqrt{q\phi_0 + E_0} - \sqrt{q\phi_0 - E_0})} \approx 1 + \frac{2\sqrt{2m}}{\hbar} \frac{d_{SiO_2}}{\sqrt{q\phi_0}} E_0 \text{ for } E_0 \ll q\phi_0 \quad (4)$$

Solving Eq. (4) for the charging energy and using the measured values for  $\tau_+$  and  $\tau_-$  of the nominally 1.4-nm-thick Co layer, we obtain  $E_0 = 33 \pm 6$  meV. As seen in the TEM image shown in Fig. 1, the Co particles are roughly spherical with a radius of  $\sim 1.5$  nm and are roughly arranged in chains with typical lengths of 3–6 particles for a nominally 1.4-nm-thick Co film.

The charging energy of such nanoclusters is approximately  $31 \pm 10$  meV, which is in very good agreement with the value estimated from measured decay times. The Coulomb-blockade energy  $E_0$  depends strongly on the size and shape of the Co cluster, and it is observed that the retention times depend strongly on the nanoscale structure of the Co layer. Fig. 5 shows the retention times  $\tau_+$  for positive charge and  $\tau_-$  for negative charge as functions of the nominal Co film thickness. The results are comparable to the previously measured retention times but show smaller errors in the values.  $\tau_+$  first increases with increasing  $d_{Co}$ , reaching a maximum for  $d_{Co} = 1.6$  nm, and then decreases and approaches  $\tau_-$ . In contrast, the negative charge retention time  $\tau_-$  shows the opposite behavior, first decreasing with increasing  $d_{Co}$ , reaching a minimum for  $d_{Co} = 1.6$  nm, and then increasing with increasing  $d_{Co}$ . As expected from the above simplified model, the retention time for positive charge is larger than that for negative charge over the entire range of values of  $d_{Co}$ .

**Fig. 5** Retention times for  $\tau_+$  positive charge and  $\tau_-$  for negative charge and the ratio  $\tau_+/\tau_-$  plotted as functions of nominal Co film thickness  $d_{Co}$ .  $\tau_+$  first increases with increasing  $d_{Co}$ , reaching a maximum for  $d_{Co} = 1.6$  nm, and then decreases and approaches  $\tau_-$ . In contrast, the negative charge retention time  $\tau_-$  shows the opposite behavior, first decreasing with increasing  $d_{Co}$ , reaching a minimum for  $d_{Co} = 1.6$  nm, and then increasing with increasing  $d_{Co}$ .

and for  $d_{Co}$  larger than 1.6 nm the difference in retention times becomes smaller as  $d_{Co}$  increases, i.e., as the Coulomb blockade energy decreases. However, the decreasing difference in retention times with decreasing  $d_{Co}$  below 1.4 nm is not expected from the simplified model. This behavior of the retention times can be explained by a model including discharging from the Co nanoclusters into the Si substrate and charge decay within the Co layer. The total retention times  $\tau_+$  and  $\tau_-$  will then be given by

$$\frac{1}{\tau_{+,-}} = \frac{1}{\tau_{+,-}^{\text{in}}} + \frac{1}{\tau_{+,-}^{\text{out}}} \quad (5)$$

where  $\tau_+^{\text{in}}$  and  $\tau_-^{\text{in}}$  are the characteristic retention times for charge transport within the Co layer and  $\tau_+^{\text{out}}$  and  $\tau_-^{\text{out}}$  pertain to charge transport from the Co layer into the Si substrate. As the retention times depend strongly on the barrier width as well as the Coulomb-blockade energy, it is necessary to account for the nanoscale structure of the Co layer. It is known from TEM micrographs that the Co layer consists of isolated spherical clusters for a nominal layer thickness of about 1.4 nm and below, and of chainlike or tubelike arrangements of connected spherical particles for nominally thicker films.<sup>[7,10,30]</sup> As the Co clusters increase in size with increasing nominal thickness above 1.4 nm, the capacitance of these clusters increases and thus the Coulomb-blockade energy decreases. As the nominal film thickness decreases below about 1.4 nm, the

Co particles remain spherical and the spacing between the particles increases.<sup>[7,10,30]</sup> Thus the Coulomb-blockade energy remains fairly constant below nominal thicknesses of about 1.4 nm.

For discharging within the Co layer, the retention times are given by<sup>[23]</sup>

$$\tau_{+,-}^{\text{in}} \propto e^{\frac{2\sqrt{2m_{\text{SiO}_2}^{\text{h,e}}}}{h} d_{\text{sp}} \sqrt{q\phi_{\text{Co}} - q\chi_{\text{SiO}_2} \pm E_0}} \quad (6)$$

where  $d_{\text{sp}}$  is the spacing between the Co clusters, and  $m_{\text{SiO}_2}^{\text{h}}$  and  $m_{\text{SiO}_2}^{\text{e}}$  are the effective mass of holes and electrons in  $\text{SiO}_2$ , respectively.  $\tau_+^{\text{in}}$  and  $\tau_-^{\text{in}}$  increase exponentially with increasing  $d_{\text{sp}}$  as the nominal Co film thickness decreases below 1.4 nm, and approach each other as  $E_0$  decreases for Co films with nominal thickness above 1.4 nm. For small Coulomb-blockade energies  $E_0 \leq kT$ , where  $k$  is the Boltzmann constant, a hole will tunnel from the Co cluster into the conduction band of the Si substrate, and  $\tau_+^{\text{out}}$  is given by<sup>[23]</sup>

$$\tau_+^{\text{out}} \propto e^{\frac{2\sqrt{2q}}{h} \int_0^{d_{\text{SiO}_2}+W} \sqrt{m^{\text{h}} \phi(x)} dx} \approx e^{\frac{2\sqrt{2}}{h} \left( d_{\text{SiO}_2} \sqrt{m_{\text{SiO}_2}^{\text{h}} (q\phi_0 + E_0)} + \frac{\pi}{2} W \sqrt{qm_{\text{Si}}^{\text{h}} V_{\text{bi}}} \left( 1 + \frac{E_0}{qV_{\text{bi}}} \right) - W \sqrt{2m_{\text{Si}}^{\text{h}} E_0} \right)} \quad (7)$$

where the barrier height is given by  $\phi(x) = \phi_{\text{Co}} - \chi_{\text{SiO}_2} + E_0/q + (\chi_{\text{Si}} - \phi_{\text{Co}})x/d_{\text{SiO}_2}$  for  $0 \leq x \leq d_{\text{SiO}_2}$  and  $\phi(x) = V_{\text{bi}} + E_0/q - V_{\text{bi}}(x - d_{\text{SiO}_2})^2/W^2$  for  $d_{\text{SiO}_2} < x < d_{\text{SiO}_2} + W$ ,  $m_{\text{Si}}^{\text{h}}$  is the effective hole mass in Si,  $W = \sqrt{2\varepsilon_{\text{Si}} V_{\text{bi}} / (qN_{\text{C}})}$  is the depletion width,  $\varepsilon_{\text{Si}}$  is the Si permittivity,  $N_{\text{C}}$  the effective density of states in the Si conduction band, and  $V_{\text{bi}}$  the built-in potential. As the Coulomb-blockade energy increases with decreasing  $d_{\text{Co}}$ ,  $\tau_+^{\text{out}}$  increases.

For Coulomb-energies in the range  $kT < E_0 < E_{\text{g}} - qV_{\text{bi}} - kT$ , where  $E_{\text{g}}$  is the Si bandgap, no hole states exist on the semiconductor side. The tunneling probability becomes very small and thus the retention time  $\tau_+^{\text{out}}$  reaches a maximum value. According to Eq. (5), the total retention time  $\tau_+$  for positive charge will be limited by  $\tau_+^{\text{in}}$  in this regime.

Finally, for Coulomb energies  $E_0 \geq E_{\text{g}} - qV_{\text{bi}} - kT$ , tunneling of holes into the valence band is possible, and  $\tau_+^{\text{out}}$  is given by<sup>[23]</sup>

$$\tau_+^{\text{out}} \propto e^{\frac{2\sqrt{2m_{\text{SiO}_2}^{\text{h}}}}{h} d_{\text{SiO}_2} \sqrt{q\phi_0 + E_0 + (E_{\text{g}} - qV_{\text{bi}})/2}} \quad (8)$$

For tunneling from a negatively charged Co cluster into the Si substrate, the tunneling barrier width depends on the Coulomb-blockade energy  $E_0$  due to

**Fig. 6** Calculated retention times as functions of nominal Co film thickness. The computed curves follow the measured curves qualitatively but cannot reproduce the exact behavior because of uncertainties in the Coulomb blockade energies of the Co clusters and the detail band structure.

the band bending within the Si substrate layer.  $\tau_{-}^{\text{out}}$  is then given, in a manner analogous to that used to obtain Eq. (7), by<sup>[23]</sup>

$$\tau_{-}^{\text{out}} \propto e^{\frac{2\sqrt{2}}{\hbar} \left( d_{\text{SiO}_2} \sqrt{m_{\text{SiO}_2}^c (q\phi_0 - E_0)} + \frac{\pi}{2} W \sqrt{q m_{\text{Si}}^c V_{\text{bi}}} \left( 1 - \frac{E_0}{qV_{\text{bi}}} \right) \right)} \quad (9)$$

where  $m_{\text{Si}}^c$  is the effective electron mass in Si.

The expressions for  $\tau_{+,-}^{\text{in}}$ ,  $\tau_{+,-}^{\text{out}}$ , and  $\tau_{+,-}$  derived in Eqs. [5–9] may be used to analyze the dependence of  $\tau_{+,-}$  on  $d_{Co}$ . As exact values for the Coulomb-blockade energies and the spacing between Co clusters are unknown or difficult to extract from TEM images, the following values are assumed, which are believed to be physically reasonable. A value of 2.05 nm was assumed for  $d_{sp}$  for  $d_{Co} = 1.0$  nm, decreasing linearly to 2 nm for  $d_{Co} = 1.4$  nm and then remaining constant for  $d_{Co} > 1.4$  nm.  $E_0$  is assumed to decrease linearly from 0.11 to 0.01 eV for  $d_{Co}$  increasing from 1.0 to 2.0 nm. The computed dependence of  $\tau_+$  and  $\tau_-$  on  $d_{Co}$ , as shown in Fig. 6, qualitatively reproduces the experimentally observed dependence quite closely. However, discrepancies exist between the measured and simulated values because of the uncertainties in the estimation of values such as the Coulomb energies, barrier thicknesses, and barrier heights.

## CONCLUSION

The use of granular or discontinuous metal/insulator materials in memory or sensor devices requires a detailed understanding of the nanoscale charge transport, which can be investigated by scanning probe

techniques. Electrostatic force microscopy was used to demonstrate and characterize local charge deposition and transport in Co nanoclusters embedded in an insulating  $\text{SiO}_2$  matrix. Positive and negative charge can be deposited controllably and reproducibly in such nanoclusters, typically in quantities of  $\sim 5$ – $20$  electrons within areas 30–50 nm in radius. The charge decays over several minutes with part of it spreading out in the discontinuous Co film and the rest tunneling into the Si substrate. The charge retention times  $\tau_+$  for positive charge and  $\tau_-$  for negative charge as well as their ratio depend strongly on the nanoscale structure of the discontinuous metal cluster film. These results were interpreted as a consequence of Coulomb-blockade effects, and a detailed model considering charge transport within the Co layer as well as from the Co cluster into the Si substrate was used to explain the dependence of the retention times on the nanoscale Co/ $\text{SiO}_2$  film structure qualitatively. These studies have led to a novel magnetic field sensor design based on the combination of charge storage and tunnel-magnetoresistance of the Co/ $\text{SiO}_2$  film, which shows a significant improvement in magnetic field sensitivity as compared to the tunnel-magnetoresistance of the Co/ $\text{SiO}_2$  film alone. Incorporation of a granular metal/insulator magnetoresistive film into the gate of a field-effect transistor structure allows the magnetoresistive response to be converted to a shift in the threshold voltage of the transistor, resulting in a large amplification in sensitivity to an external magnetic field. In a prototype device based on a p-channel MOSFET, a threshold voltage shift of 50 mV upon application of a 6-kOe magnetic field was obtained at room temperature. This resulted in a fourfold amplification in relative current response, and an increase in absolute current response by a factor of 500 in the saturation regime, as compared to the response attainable in the magnetoresistive film alone.

## INTRODUCTION

### Detection of Chemical Warfare Agents in Water

Working with primary-source freshwater drinking samples from the Clinch and Tennessee Rivers, we have developed a tissue-based biosensor detection system that uses naturally occurring aquatic photosynthetic tissue as the sensing material for the detection of chemical antagonists in the water. Sensor readout is based on well-known principles of fluorescence induction by living photosynthetic tissue. The Clinch River is the main source of drinking water for Oak Ridge, TN, while the Tennessee River is a major source for the city of Knoxville. We have successfully detected algae in every sample that we examined and readily monitored changes in the characteristic fluorescence induction curves when the samples were exposed to potassium cyanide (KCN), methyl parathion (MPt), *N*(3,4-dichlorophenyl)-*N*,*N*-dimethylurea (DCMU), and paraquat. The percentage decreases in photochemical yields observed in Tennessee River samples after a 25-min exposure to KCN, MPt, and DCMU were  $21.89 \pm 0.76$ ,  $3.28 \pm 0.18$ , and  $14.77 \pm 1.81$ , respectively. For a site at the Clinch River, the percentage decreases were  $22.78 \pm 1.63$ ,  $8.32 \pm 0.21$ , and  $17.71 \pm 1.32$  (Table 1). For each percentage decrease, the probable error is the computed error based on standard error analysis.<sup>[44]</sup> The unique aspect of this approach to real-time water-quality monitoring is that unlike conventional sensing devices, this sensor material is external to the detecting instrument and is continuously refreshed. These biosensors may be used as continuous rapid-warning sentinels for the detection of chemical warfare (CW) agents in sunlight-exposed drinking water supplies.

### Detection of Chemical Warfare Agents in Air

Tissue biosensors based on immobilized whole cell photosynthetic microorganisms have been developed

for the detection of airborne CW agents and simulants. The sensor read-out is based on well-known principles of fluorescence induction by living photosynthetic tissue. Like the cyanobacteria and algae from which they were constructed, the sensors are reasonably robust and mobile. Commercially available handheld fluorometric detector systems were used to measure Photosystem II (PSII) photochemical efficiency of green algae and cyanobacteria entrapped on filter paper disks. Toxic agents flowing in the gas stream through the sensors can alter the characteristic fluorescence induction curves with resultant changes in photochemical yields. Tabun (GA), sarin (GB), mustard agent, tributylamine (TBA; a sarin stabilizer), and dibutylsulfide (DBS; a mustard agent analog) were tested. Upper threshold limits of detectability for GA, TBA, and DBS are reported. With additional research and development, these biosensors may find application in stand-off detection of chemical and perhaps biological warfare agents under real-world conditions.

## BACKGROUND

### Detection of Chemical Warfare Agents in Water

Algae and cyanobacteria are present in all surface waters that are exposed to sunlight. The unattached microscopic organisms that are found individually or in small clumps floating in rivers and lakes are composed of phytoplankton and zooplankton. Most of the phytoplankton is composed of algae.<sup>[1]</sup> Based on cell count, biomass, and photosynthetic carbon fixation, green microalgae are a major component of the phytoplankton population. Microalgae are ubiquitous and can grow year-round. Their small size and efficient uptake mechanisms enable them to utilize nutrients in low concentrations or in forms that are unsuitable for larger cells.<sup>[2]</sup>

**Table 1** Decrease in photochemical yields of naturally occurring algae in primary-source drinking waters from the Clinch and Tennessee rivers following exposure to toxic agents

	Sample site	Toxic agent [ $\Delta \pm$ probable error (%)] <sup>a</sup>		
		KCN	MPt	DCMU
1	Clark Center Recreation Park	22.78 $\pm$ 1.63	8.32 $\pm$ 0.21	17.71 $\pm$ 1.32
2	Melton Hill Hydroelectric Dam	29.85 $\pm$ 4.17	7.66 $\pm$ 0.90	23.45 $\pm$ 4.77
3	Oak Ridge Marina	25.88 $\pm$ 0.90	8.58 $\pm$ 0.27	12.81 $\pm$ 0.81
4	Tennessee River	21.89 $\pm$ 0.76	3.28 $\pm$ 0.18	14.77 $\pm$ 1.81

<sup>a</sup>For each agent,  $\Delta$  is defined as the decrease in photochemical yield following a 25-min exposure. It was computed by subtracting the value obtained for each toxic agent from its corresponding control. The entries for rows 1 and 4 correspond to the 25-min data points shown in Figs. 6 and 7. Similar plots (not shown) were obtained for the data in rows 2 and 3. The probable error is the computed error (the square root of the sum of the squares of the sample standard deviations of the toxin and control data) based on standard error analysis. Source: From Ref.<sup>[44]</sup>.

Source: From Ref.<sup>[3]</sup>.

The focus of the first part of this entry is the detection of toxic agents in sunlight-exposed primary-source drinking waters.<sup>[3]</sup> The agents used in this study were methyl parathion (MPt), potassium cyanide (KCN), Diuron (DCMU), and paraquat. MPt is an organophosphorus insecticide used to control soil-dwelling pests and a wide range of insects and mites that infest agricultural crops. It is a cholinesterase inhibitor that is structurally and functionally similar to the CW agents classified as nerve agents (including VX and GA). Severe exposure in humans and animals can lead to convulsions, unconsciousness, cardiac arrest, and death. Hydrogen cyanide has an odor characteristic of bitter almonds and is completely miscible in water. For these experiments, the water-soluble salt KCN was used. The cyanide ion is an extremely toxic and fast-acting poison. Food and drinking water are the main sources of cyanide exposure for individuals not subjected to occupational exposures.<sup>[4]</sup> Typical symptoms of cyanide poisoning are headache, nausea, weakness, palpitations, tremors, and breathlessness. In cases of severe poisoning, the nervous and respiratory systems are the first to fail. With high levels of exposure, death results from respiratory arrest. The U.S. Army has proposed field drinking water standards for cyanide of 2 and 6 mg/L, assuming a water consumption of 15 and 5 L/day, respectively.<sup>[5]</sup> Paraquat is a herbicide that is usually sold as paraquat dichloride. It is used as an inhibitor of weeds infesting seed crops and orchards, as a crop defoliant on cotton and potato vines, and as a harvest aid for soybeans. Because it possesses high solubility, paraquat may remain in water for several days following its use in aquatic weed control. Acute poisoning may cause respiratory distress and effects on the nervous system and kidneys. Death is usually due to progressive pulmonary fibrosis and epithelial proliferation in the lungs. DCMU (Diuron) is a substituted urea-based herbicide employed principally for the control of vegetation in noncrop areas, including irrigation and

drainage ditches. Diuron is a non-ionic compound with moderate water solubility. The U.S. Environmental Protection Agency has ranked Diuron fairly high (i.e., as a Priority B Chemical) with respect to potential for groundwater contamination. Diuron is of low acute toxicity.<sup>[4]</sup>

There is increased interest in the development of biosensors for the detection of pesticides in drinking water supplies. Merz and colleagues<sup>[6]</sup> isolated plant chloroplasts (pea seedlings or lettuce) and exposed them to herbicides of the triazine/phenylurea group, which accelerate an increase in PSII fluorescence induction. Frende and coinvestigators<sup>[7]</sup> reported the use of an optical biosensor that incorporated the green alga *Scenedesmus subspicatus* for the detection of herbicides in wastewater. The filter paper-immobilized algae covered with alginate did not lose significant fluorescence properties after 6 months of storage at 4°C. Rizzuto and colleagues<sup>[8]</sup> tested a biosensor consisting of PSII particles of the cyanobacterium *Synechococcus elongatus* for the detection of herbicides in three rivers in the Lazio region in Italy. By washing the sensor, they were able to reuse it for several assays after the removal of the toxic agent. Koblizek and associated researchers<sup>[9]</sup> used this type of biosensor and reported a detection limit of  $5 \times 10^{-10}$  M for Diuron, a lower limit that is comparable to that of the most sensitive enzyme-linked immunosorbent assay (ELISA). Pogacnik and Franko<sup>[10]</sup> used a photothermal sensor to determine organophosphate and carbamate pesticides in spiked drinking water and fruit juices. Pesticide detection in a single sample by the biosensor consisting of the enzyme acetylcholinesterase was performed within 15 min. Another approach for the determination of herbicides in river water samples is the application of immunosensors. Mallat and colleagues<sup>[11]</sup> reported the use of an optical immunosensor with fluorescently labeled antiparaquat antibodies. The fluorescence signal was indirectly related to the paraquat concentration in the sample.

Mallat et al. then used capillary zone electrophoresis with ultraviolet detection to validate the paraquat immunosensor response. Although the immunosensor achieved a lower paraquat detection limit of 0.06 µg/L in river water, the procedure was quite elaborate, requiring labeling of antiparaquat antibodies. Recently, fiberoptic biosensors with entrapped algae in membranes have been developed to monitor the effects of herbicides. Fiber optics provide a fast method to transmit a reproducible signal. The membranes are inexpensive to prepare and easy to handle. Campanella and associated researchers<sup>[12]</sup> reported the effect of triazinic herbicides on a biosensor containing the cyanobacterium *Spirulina subsalsa*. Naessens and colleagues<sup>[13]</sup> detected a response to atrazine, simazine, and Diuron using a *Chlorella vulgaris* biosensor.

There is an increased awareness of the possibility of attacks on metropolitan areas using chemical and biological warfare agents. Depending on the specific agent used, the low water solubilities of these agents may allow contaminants to persist for a long period of time, constituting in effect a time-release system that moves from insoluble agent to the aqueous environment. A large volume of the released agent may stay effective for years if the water is still or moving slowly. Factors that can accelerate hydrolysis of nerve agents are dilution, turbulence, high pH, and heat. Higher temperatures can enhance degradation of nerve agents by increasing their solubility in water. Also, the presence of certain ions in the salt content of seawater significantly increases the hydrolysis of specific nerve agents when compared with those in freshwater.<sup>[14]</sup> Application of entrapped cyanobacteria and algae for the detection of airborne CW agents has been reported.<sup>[15]</sup>

Degenhardt-Langelaan and Kientz<sup>[16]</sup> used a large-volume injection (200 µL) to detect the nerve agents sarin, tabun, soman, DFP, and VX at levels as low as parts per trillion in freshly prepared water samples. They used a gas chromatographic procedure in which intact nerve agents were isolated from water by solid-phase extraction with Amberlite resin (XAD-4) followed by extraction with ethyl acetate. Jones and Hoegh-Guldberg<sup>[17]</sup> studied the effects of cyanide on the photosynthesis of symbiotic algae in hard coral from Australia. As in our study, they used pulse-amplitude-modulated (PAM) chlorophyll fluorescence techniques to measure the maximum potential quantum yield of PSII in dark-adapted samples. Examining photochemical and nonphotochemical quenching, they observed that cyanide inhibited the Calvin cycle and damaged the PSII reaction center. Singh and colleagues<sup>[18]</sup> reported the use of activated carbon for the removal of dichloroethyl ether, the oxygen analog of sulfur mustard agent, and phenol from water. This analog possesses higher stability in water than sulfur mustard, which has a hydrolysis half-life of 3 min.

However, this procedure has disadvantages. Activated carbon must be dried at 120°C for 6 h prior to the experiment. Also, a period of 4 h is required for the adsorbed material to reach steady state in solution before analysis.

Wang and associated researchers<sup>[19]</sup> utilized a miniaturized analytical system with combined on-chip micellar electrokinetic chromatographic separation for amperometric detection of organophosphate nerve agents. They reported a lower detection limit of  $2.4 \times 10^{-6}$  M for MPt in spiked samples from the Rio Grande River at Las Cruces, NM. Their microsystem was composed of microphotolithographically fabricated capillary electrophoresis glass chips with planar thick-film electrodes on ceramic wafers.<sup>[20]</sup> Finally, solid-phase microextraction is a new technique that has been developed in the last decade for the determination of CW agents<sup>[21]</sup> and organophosphorus pesticides<sup>[22]</sup> in freshwater samples. It enables detection of toxic agents at very low levels. However, the analytes may require a period of at least 30 min to reach equilibrium.

### Detection of Chemical Warfare Agents in Air

Photosynthetic conversion of electromagnetic energy into stored chemical energy is triggered by the absorption of light by chlorophyll pigment molecules. Visible photons energize the electron transport chain of the photosynthetic apparatus via the photoreaction centers, PSI and PSII, that do the work of photosynthesis. Some of the absorbed energy is dissipated as heat or emitted as fluorescence at a wavelength that is typically longer than the initial excitation energy. Only a small portion (~3% of absorbed light) is released from PSII as fluorescence.<sup>[23]</sup> Photosynthetic prokaryotes and eukaryotes fluoresce when illuminated by light following a period of darkness. However, structural differences between the two types of organisms affect the fluorescence signal produced and their sensitivity to perturbing factors, such as toxic agents, which alter the characteristic fluorescence pattern of healthy photosynthetic tissue. The kinetic time profile and interpretation of the fluorescence induction curve and the overall fluorescence yield are dependent upon the structure of the photosynthetic apparatus, the proximity of antennae to reaction centers, and the composition and concentration of photosynthetic pigments.<sup>[24]</sup> The time course of fluorescence is an indication of the organism's ability to perform photosynthesis and is directly related to its physical well being. One of the most useful parameters in fluorescence analysis from photosynthetic tissue is the efficiency of PSII photochemistry. It may be calculated from a measurement of the ambient and maximum values of

fluorescence from photosynthetic tissue that is subjected to a saturating flash of light.<sup>[25,26]</sup>

These principles have been applied to the detection of fluorescence emitted by *C. vulgaris*, a unicellular green alga, and *Nostoc commune*, a cyanobacterium. Whole cell microorganisms were immobilized onto glass fiber filter disks. The sensor fluorescence detection system compared fluorescence emissions from algae and cyanobacteria exposed to a benign stream of air with air carrying a toxic chemical agent and used this information to calculate the efficiency of PSII photochemistry. The development of a field-deployable biosensor requires that the immobilized biological tissue comprising the sensor retains viable fluorescence and PSII efficiency after it has been stored as inventory prior to field applications and then transported overland or by air to a remote location. *N. commune* was chosen for study as a biosensor because it has been extensively characterized by Potts and his research group as being inherently resistant to dehydration stress for long periods of time.<sup>[27–30]</sup> Also, the well-studied alga of photosynthesis research, *C. vulgaris*, was chosen because it, like *Nostoc*, can grow using atmospheric CO<sub>2</sub> as the sole carbon source, thereby eliminating the need for complicated media formulations. Systematic control experiments of fluorescence emissions from these organisms measured before and after storage give a clear indication of the storage conditions most favorable for preserving their long-term stability for use as biosensors. Generally speaking, this includes storage in 0.5 mL growth medium in darkness. After 40 days, a normal fluorescence signature was restored within 1 hr.

The CW agents and CW simulants used in this study were airborne when they contacted the biosensors. Live CW agents pose a credible threat to military personnel and large population centers. The agents were developed specifically to be highly toxic to humans at low concentrations. They are easily produced from inexpensive raw materials and can be readily released into the environment. Fig. 1 displays

the agents and simulants tested in this study and their chemical structures. The nerve agents tabun (GA) and sarin (GB) are organophosphorus anticholinesterase compounds. GA is more volatile than GB, but both are lethal, resulting ultimately in death from respiratory failure.<sup>[31]</sup> Bis(2-chloroethyl)sulphide, better known as distilled sulfur mustard agent (HD), is a vesicant (blister agent) which affects eyes, lungs, and the skin. Dibutylsulfide (DBS) is a simulant of mustard gas. It is structurally similar to mustard agent, but not as lethal. Tributylamine (TBA) is a nerve agent (GB) stabilizer<sup>[32]</sup> with 2% of the toxicity of GB.

There are several instruments currently in use for measuring airborne CW agents. The SAW MINICAD is a surface-acoustic-wave gas microsensors.<sup>[33]</sup> Chemical vapors alter the resonant frequency of the chemical coating on the SAW sensor surface. The Improved Chemical Agent Monitor (ICAM)<sup>[34]</sup> and Bruker IMS<sup>[35]</sup> detect CW agent vapors by ion mobility spectrometry. These are all handheld instruments to be operated by personnel in protective clothing in the field. The M21 Remote Sensing Chemical Agent Alarm is a stand-off detector (remotely operated) which senses agents by infrared spectroscopy but is not mobile or launchable. Tissue biosensors made from immobilized bacteria are being developed to detect levels of gas-phase solvents such as benzene.<sup>[36]</sup> Using a Clark electrode, Naessens and Tran-Minh<sup>[37,38]</sup> monitored oxygen evolution from algal films to study the antagonistic effect of methanol and volatile organic compounds on the algae. Lee and Karube<sup>[39]</sup> also used a Clark electrode to measure dissolved oxygen to study the inhibitory effect of potassium cyanide. Recently, Naessens and colleagues<sup>[13]</sup> developed a fluorometric fiberoptic biosensor using *C. vulgaris* for the determination of herbicides in water. To this point, however, photosynthetic tissue-based biosensors have not been tested for the detection of CW agents. It is well known that toxic compounds can affect fluorescence induction in algae.<sup>[7,13]</sup> CW agents and simulants are known for their detrimental effects on mammalian tissue.

Fig. 1 Structures of selected chemical warfare agents and simulants. Source: From Ref.<sup>[15]</sup>.

The objective of the present work is to test whether they can affect electron transport and/or excitonic energy transfer mechanisms in photosynthetic organisms at concentrations that may be useful for possible field applications.

## METHODOLOGY

### Detection of Chemical Warfare Agents in Water

Prior to the experiments with river water samples, preliminary studies used axenic cultures of *C. vulgaris* that were grown on rotary shakers in liquid culture in minimal medium for 2 weeks under a bank of fluorescent lamps at an intensity of  $50 \mu\text{E m}^{-2} \text{sec}^{-1}$ . Total chlorophyll ( $a + b$ ) was determined in warm methanol ( $60\text{--}70^\circ\text{C}$ ) extracts in dim light according to the method of Wellburn and Lichtenthaler.<sup>[40]</sup> Field studies were performed using “as-is” freshwater samples and their naturally occurring populations of phytoplankton.

### Cell Chamber, Fluorescence Measurements, and Toxic Agents

Two classes of experiments are reported: batch and continuous. In the batch experiments, chemical agents were added directly to a fluorescence cuvette that contained the water sample and the progressive effect of the agent was monitored as a function of time. The second class of experiments, illustrated in Fig. 2, was designed to mimic the flow of river or lake water

through the fluorescence detection system. The cell chamber/optical unit (Fig. 2) is a flow system containing the fluorescence cell. Continuous experiments were performed using a flow-through cell (Hellma Cells, Inc., Model QS-131, Plainview, NY). Fluorescence induction curves were measured before and during exposure to toxic agents using a Walz XE-PAM fluorometer (Walz, Effeltrich, Germany). Fluorescence excitation and emission wavelengths were 660 and 685 nm, respectively. A halogen lamp actinic light source illuminated the cuvette at an intensity of  $500 \mu\text{E m}^{-2} \text{sec}^{-1}$  via a fiberoptic cable through direct connection to the cell chamber. Fluorescence induction curves were recorded every 5 min, and data collection for each curve was completed within 10 sec. Data extracted from the fluorescence induction curves were used to calculate  $F_s$ ,  $F_{\text{max}}$ ,  $F_v$  (variable fluorescence,  $=F_{\text{max}} - F_s$ ), and the efficiency of PSII photochemistry ( $F_v/F_{\text{max}}$ ). A 200-mL water sample was placed in a jacketed reservoir. The sample was continuously stirred and maintained in darkness with a black cloth. The reservoir was connected to the flow-through fluorescence cell with flexible tubing. To obtain a homogeneous sample before each recording, the volume in the fluorescence cell was replaced three times. After control data were collected, the volume in the reservoir was adjusted to 100 mL and the toxic agent was added. The toxic agents (Fig. 3) were prepared as stock solutions prior to addition to the reservoir and were injected directly into the top of the vessel and immediately mixed with the sample. Spent samples were drained into a waste bottle (Fig. 2). Upon arrival in the laboratory from collection sites at the rivers, the

**Fig. 2** Experimental apparatus for continuous water quality monitoring. Batch experiments used a static fluorescence cuvette. Continuous experiments used a flow-through cuvette. Source: From Ref.<sup>[3]</sup>.

**Fig. 3** Chemical structures of selected toxic agents used for water quality monitoring. (From Ref.<sup>[3]</sup>)

water samples were kept under a fluorescent lamp at an illumination of  $50 \mu\text{E m}^{-2} \text{sec}^{-1}$  until use.

## Detection of Chemical Warfare Agents in Air

### Microorganisms and biosensor preparation

Axenic cultures of *N. commune* (UTEX 584) were grown on rotary shakers in BG-11 medium for 2 weeks under a 400-W high-pressure sodium lamp with an illumination intensity of  $1000 \mu\text{E m}^{-2} \text{sec}^{-1}$ . *Chlorella vulgaris* was grown on rotary shakers in liquid culture in minimal medium for 2 weeks under a fluorescent lamp light bank at  $50 \mu\text{E m}^{-2} \text{sec}^{-1}$ . *Nostoc* was harvested, homogenized to break up large colonies, and

resuspended in BG-11. *Chlorella* is unicellular; it does not require further processing before biosensor preparation. Total chlorophyll (*a* + *b*) in *Chlorella* and chlorophyll *a* in *Nostoc* were determined in warm ( $60\text{--}70^\circ\text{C}$ ) methanol extracts by the method of Wellburn and Lichtenthaler.<sup>[40]</sup> To make the sensors, 0.2–0.6 mL of the whole-cell suspensions containing 1.2–6  $\mu\text{g}$  chlorophyll were immobilized onto Millipore APFD fiber glass filter disks (Bedford, MA.) using a Millipore filtration apparatus and bench vacuum.

### Cell chamber and fluorescence measurements

The cell chamber (Fig. 4) is a closed system aeration apparatus designed to infuse bench air through the fiber glass entrapped biosensor at a constant rate of 200 mL/min. The sensor is housed in the top of the cell chamber on a glass frit. The humidifiers contain water for regulation of the relative humidity in the gas stream. Flow rates were adjusted with needle valves in the rotameters illustrated in Fig. 4, allowing alterations in the flow of air through the toxic agent while maintaining a total flow rate of 200 mL/min and relative humidity of 85%. The absolute flow rate was measured with a soap film flow meter connected to the cell chamber vent. The toxic agent in the U tube was isolated from the clean air flow path by a three-way valve while control fluorescence measurements were made. When the valve was switched, air flowed through the toxic agent tube carrying vapors directly to the sensor.

**Fig. 4** Experimental apparatus for exposing algal and cyanobacterial biosensors to airborne CW vapors. Source: From Ref.<sup>[15]</sup>.

Fluorescence induction curves were measured before and during exposure to toxic agents using Opti-Sciences OS1-FL and OS5-FL modulated fluorometers (Tyngsboro, MA). The OS1-FL is a handheld fluorometer with a pulse modulated detection system. The modulation was adjusted so that the minimal fluorescence signal in low background laboratory light ( $F_s$ ) was in the range of 90–150 relative fluorescence units (RFU). A halogen lamp from the actinic light source of a Walz XE-PAM fluorometer illuminated the sensor at an intensity of  $1500 \mu\text{E m}^{-2} \text{sec}^{-1}$  via the OS1-FL fiberoptic cable through a window over the sensor in the top of the cell apparatus. Fluorescence induction curves were recorded every 5 min and data collection for each curve were completed within 10 sec. The OS5-FL fluorometer was fitted with an avalanche photodiode to improve signal-to-noise ratio. The minimal fluorescence signal was set to 130–150 RFU in low laboratory light. Fluorescence induction curves were recorded when the sensors were illuminated from the OS5-FL fiberoptic cable at 5-min intervals (3-sec duration) at an intensity of  $1570 \mu\text{E m}^{-2} \text{sec}^{-1}$ . Data extracted from the fluorescence induction curves were used to calculate  $F_s$ ,  $F_{\text{max}}$  (maximum fluorescence),  $F_v$  (variable fluorescence,  $=F_{\text{max}} - F_s$ ), and the efficiency of Photosystem II photochemistry ( $F_v/F_{\text{max}}$ ).

### Chemical warfare agents and simulants

The mustard agent simulant DBS (300  $\mu\text{L}$ ) and the nerve agent stabilizer TBA (300  $\mu\text{L}$ ) were injected in the bubbler U tube in the cell chamber, and the output vapors were contacted with the algal biosensors. Initial control fluorescence curves were taken without the agents in an air-only gas stream. The airflow through the tube was altered to vary the concentration of the simulant vapor reaching the sensor per unit time. Sensor fluorescence was measured at 5-min intervals during exposure to the toxic agents. Control chlorophyll fluorescence signals emitted from a sensor were compared with signals from the same sensor measured during DBS or TBA exposure. The concentration of the agents in the gas stream was measured on an Alltech  $30 \text{ m} \times 0.25 \text{ mm}$  I.D. capillary column in a Hewlett-Packard 5890 Gas Chromatograph (GC). The detector was a Hewlett-Packard 5971 Series Mass Selective Detector. Standard curves were constructed from solutions of known concentration solubilized in acetone. The initial temperature of the GC temperature ramp program was  $50^\circ\text{C}$ , rising to a temperature of  $150^\circ\text{C}$  ( $10^\circ\text{C}/\text{min}$ ), then  $20^\circ\text{C}/\text{min}$  to a final temperature of  $280^\circ\text{C}$ . In the Applied Chemistry Laboratory, Edgewood Laboratories, Aberdeen Proving Ground, MD, the same cell apparatus was used on experiments with GA, GB, and HD on *Nostoc* and *Chlorella* biosensors.

## RESULTS

### Detection of Chemical Warfare Agents in Water

#### *Chlorella* batch experiments

Fig. 5 illustrates typical raw fluorescence data obtained with healthy naturally occurring algae from the Clinch River and associated parameters that are used to analyze these data. The parameters  $F_{\text{max}}$ ,  $F_s$ , and  $F_v$  ( $=F_{\text{max}} - F_s$ ), as well as their interpretation, are well known in the literature of photosynthesis.<sup>[25]</sup> We were able to detect changes in the photochemical yield of *Chlorella*, defined as  $F_v/F_{\text{max}}$ , at the relatively low chlorophyll concentration of  $0.063 \mu\text{g}/\text{mL}$  (Figs. 6 and 7). Fig. 6 shows the percentage decrease in photochemical yield for DCMU exposure over time. Fig. 7 presents similar data for MPT. After testing and optimizing the experimental setup with laboratory-cultured *Chlorella*, we proceeded to experiment with samples drawn directly from the Clinch and Tennessee Rivers.

#### Freshwater batch experiments

Field samples were drawn from selected locations of the Clinch River, Oak Ridge, TN, and the Tennessee River, Knoxville, TN. Fig. 8 presents the decrease in photochemical yield of toxic agent-exposed water samples from the Clark Center Recreation Park. Fig. 9 presents the decrease in photochemical yield for samples drawn from the Tennessee River. Fig. 10 contains

**Fig. 5** A typical fluorescence induction curve recorded from naturally occurring algae in untreated Clinch River (Clark Center Recreation Park) water, illustrating the basic data output from the Walz XE-PAM fluorometer. Data extracted from fluorescence induction curves provided the values of  $F_s$  and  $F_{\text{max}}$  that were used to calculate the variable fluorescence,  $F_v = F_{\text{max}} - F_s$ , and the photochemical yield ( $Y$ ),  $F_v/F_{\text{max}}$ . Source: From Ref.<sup>[3]</sup>.

**Fig. 6** Decrease in photochemical yield in laboratory-grown *Chlorella vulgaris*. The first data point was taken after 5 min of dark adaptation. DCMU was added to the sample at 14 min, and fluorescence yields were measured at 15, 20, and 25 min. Yields were computed from two runs and are expressed as means  $\pm$  1 S.D. *Source:* From Ref.<sup>[3]</sup>.

paraquat data for Tennessee River water samples. Following injection of paraquat into the cuvette, the sample was exposed to a light intensity of  $50 \mu\text{E m}^{-2} \text{sec}^{-1}$  for 10 min. Unlike the herbicide DCMU, which binds directly to the reducing site of the PSII reaction center (in the presence or absence of light), the destructive action of paraquat (methyl viologen) results from its reduction by PSI. Reduced paraquat reacts with dissolved molecular oxygen, which leads to the formation of superoxide anions and hydrogen peroxide, both of which are toxic to the cell.

**Fig. 7** Time-dependent values of the PSII photochemical yield of *Chlorella vulgaris* in the presence of MPt (plus accompanying control). The first data points were taken after 5 min of dark adaptation. As indicated by the vertical arrow, MPt was added to the sample at 12 min, and fluorescence was measured at 15, 20, and 25 min. Yields were computed from two runs and are expressed as means  $\pm$  1 S.D. *Source:* From Ref.<sup>[3]</sup>.

**Fig. 8** Decrease in photochemical yield of naturally occurring algae in Clinch River (Clark Center Recreation Park) water. The first data points were taken after 5 min of dark adaptation. MPt was added at 12 min, and KCN and DCMU were added to the sample at 14 min. Fluorescence was measured at 15, 20, and 25 min. These are three separate experiments (plus control), with the data values normalized to their respective values at 5 min. Yields were computed from three experimental runs and two control runs. Results are expressed as means  $\pm$  1 S.D. *Source:* From Ref.<sup>[3]</sup>.

### Continuous experiments

Following the batch experiments, the standard fluorescence cuvette in the Walz fluorometer was replaced with the flow-through model. The cuvette inlet was connected to a glass-bottle reservoir that contained the water samples, and the outlet drained to waste.

**Fig. 9** Decrease in the photochemical yield of naturally occurring algae in Tennessee River water. The first data point was recorded after 5 min of dark adaptation. MPt was added at 12 min, and KCN and DCMU were added to the sample at 14 min. Fluorescence was measured at 15, 20, and 25 min. Yields were computed from three experimental runs and two control runs. Results are expressed as means  $\pm$  1 S.D. *Source:* From Ref.<sup>[3]</sup>.

**Fig. 10** Decrease in photochemical yield in the Tennessee River biosensor. Paraquat was added to the sample cuvette at 10 min, and fluorescence was measured at 5 and 10 min after an illumination period of 10 min at 50  $\mu$ E. Control runs were performed in a similar manner with the addition of deionized water. Yields were computed from four experimental runs and two control runs. Results are expressed as means  $\pm$  1 S.D. *Source:* From Ref.<sup>[3]</sup>.

This experimental arrangement allowed continuous monitoring and replacement of water samples in a manner similar to that for the contemplated operation of a real-world biosensor system. Continuous experiments were performed with samples drawn from the Clark Center Recreation Park (Fig. 11).

**Fig. 11** Decrease in photochemical yield of naturally occurring algae in Clinch River (Clark Center Recreation Park) water. The first data points were recorded after 5 min of dark adaptation. MPT, KCN, and DCMU were added at 18 min (indicated by arrow), and fluorescence data were recorded at 30, 35, 40, and 45 min. All yields were computed from three runs, except for MPT yields, which were computed from data collected from two runs. Results are expressed as means  $\pm$  1 S.D. *Source:* From Ref.<sup>[3]</sup>.

**Fig. 12** Typical fluorescence induction curve recorded from the cyanobacterial sensor *Nostoc commune*. *Source:* From Ref.<sup>[15]</sup>.

## Detection of Chemical Warfare Agents in Air

### Sensor response to dBS

A typical fluorescence induction curve of the biosensor *N. commune* (6  $\mu$ g chlorophyll *a*) is shown in Fig. 12. The parameters indicated on the curve are used to evaluate the photosynthetic capacity of the algae or cyanobacteria. The fluorescence yield ( $Y = 0.46$  for the data of Fig. 12) represents the total PSII photochemical efficiency of the sensor under control conditions with no toxic agent present.

In Fig. 13, *Nostoc* sensors were placed in the cell chamber in an air stream flowing at 200 mL/min. At

**Fig. 13** *Nostoc* sensor. DBS concentration-dependent change in photochemical yield. DBS was injected into the carrier gas stream at 12 min and was measured at 15, 20, 25, and 30 min. Yields were computed from data collected from three runs and are expressed as means  $\pm$  1 S.D. *Source:* From Ref.<sup>[15]</sup>.

Fig. 14 Typical fluorescence induction curve from the algal biosensor *Chlorella vulgaris*. Source: From Ref.<sup>[15]</sup>.

5-min intervals, light from the OS1-FL fluorometer illuminated the sensors for 10 sec and fluorescence induction curves were recorded. Flow rates through the DBS U tube were adjusted to obtain 0.42, 2.9, and 5.2 mg/L DBS in a constant-flow air stream of 200 mL/min. Fig. 13 presents the change in yield of PSII photochemistry with DBS in the air stream. Fig. 14 shows a typical fluorescence induction curve for the *C. vulgaris* (1.2 µg total chlorophyll) sensor. *Chlorella* fluorescence, following exposure to DBS (5.2 mg/L) under the same conditions as the *Nostoc* sensor, is presented in Fig. 15.

#### Biosensor response to TBA

The response of the *Nostoc* (6 µg chlorophyll *a*) sensor to TBA was tested in the cell chamber by recording fluorescence induction curves every 5 min during

Fig. 15 Time-dependent fluorescence induction curves from the *Chlorella* sensor during exposure to DBS. DBS entered the air stream at 12 min. Source: From Ref.<sup>[15]</sup>.

Fig. 16 Fluorescence induction curves from the *Nostoc* sensor during exposure to TBA. TBA exposure began 12 min into the run. Source: From Ref.<sup>[15]</sup>.

contact of the sensor with TBA (Fig. 16). Dose-response curves (Fig. 17) for 7.4, 248, and 642 µg/L TBA showed a good correlation between TBA concentration and change in yield.

#### Sensor response to live chemical warfare agents

In the Applied Chemistry Laboratory, Edgewood Laboratories, Aberdeen Proving Ground, MD, *Nostoc* and *Chlorella* sensors were contacted with GA (9, 10, and 11 µg/L), GB (6, 7, and 21 µg/L), and HD (7, 8,

Fig. 17 TBA concentration-dependent decreases in photochemical yields of the *Nostoc* sensor with time of exposure. TBA was injected in the gas stream at 12 min and fluorescence was measured at 15, 20, 25, and 30 min. Yields were computed from data collected from three runs of 642 and 7.4 µg/L TBA and two runs of 248 µg/L. Results are expressed as means  $\pm$  1 S.D. Source: From Ref.<sup>[15]</sup>.

**Fig. 18** Fluorescence yields vs. time from the *Nostoc* sensor, recorded before (control) and after exposure to 9 µg/L GA. Source: From Ref.<sup>[15]</sup>.

17, and 23 µg/L). Fig. 18, shows the average of two runs using GA (9 µg/L) on the *Nostoc* sensor. Changes in the PSII photochemical efficiency of the *Chlorella* sensor were apparently not affected by exposure to GA at the stated levels, but preliminary data do suggest differences in the overall kinetic time profile, especially near the end of the respective traces between sample and control (fluorescence induction curves not shown). No changes in the fluorescence induction curves of either sensor were observed with GB or HD at the stated concentrations.

## DISCUSSION

### Detection of Chemical Warfare Agents in Water

Fluorescence induction curves can be used as real-time diagnostic assays for exposure of photosynthetic microorganisms to environmental stress. The availability of portable commercial fluorimeters has simplified the use of chlorophyll fluorescence measurements under field conditions to study the effects of toxic agents on photosynthetic organisms. Fluorescence techniques have been refined over recent years, and dark-adapted measurements made in combination with those in the light now allow extremely detailed analyses of photosynthetic performance in situ.<sup>[41]</sup> Because of their sensitivity and reliability for measurement of in vivo biological activity, these techniques have led to the development and refinement of environmental biosensors. Our results demonstrate that naturally occurring freshwater algae can be used as biosensor material for the detection of toxic agents in sunlight-exposed primary drinking water supplies. These agents block electron transport, impair light energy transfer, or generate toxic secondary photoproducts,

all of which provide signals that can trigger an alarm. Our results showed that the tissue-based biosensors experienced a decrease in photochemical yield when exposed to MPt, KCN, paraquat, and DCMU. A detectable effect was observed in every freshwater sample tested.

### Detection of Chemical Warfare Agents in Air

Fluorescence induction curves from photosynthetic organisms are good indicators of the presence of environmental stresses surrounding the organisms and the effects those stresses have on the photosynthetic apparatus.<sup>[41]</sup> In this respect, fluorometric assays form a potentially attractive approach to the development of environmental biosensors because they are rapid, sensitive, non-invasive, and non-destructive monitors of in vivo biological activity. The sensors are relatively rugged and mobile, and may be stored and transported for use in the field. Exposing the algal and cyanobacterial sensors to CW agents and simulants can impair energy migration in the chlorophyll antenna lattice and electron transport reactions within the photosynthetic membrane, thereby altering the normal fluorescence induction curve in measurable and predictable ways. Sensors in a gas stream containing DBS and TBA showed concentration-dependent decreases in the efficiency of PSII photochemistry. Yields measured during DBS contact decreased in both sensors. The yield reduction in the *Nostoc* sensor was due solely to an increase in minimal fluorescence,  $F_s$ , whereas that of the *Chlorella* sensor was due to a decrease in  $F_{max}$ . In both sensors the loss of fluorescence was dependent on the concentration of the toxic agent contacting the sensors. The different responses of the two sensors are related to differences in the structure of their photosynthetic apparatus. Minimal fluorescence in algae arises only from antennae pigments. Cyanobacterial minimal fluorescence, however, is emitted not only from antennae but also from PSII and possibly PSI reaction centers and photosynthetic pigments other than chlorophyll.<sup>[24]</sup> Ögren and Sjöström<sup>[42]</sup> credited the increase in minimal fluorescence observed following photoinhibition of willow leaves to a decrease in the efficiency of PSII photochemistry. A decrease in minimal fluorescence would indicate enhanced non-light-induced quenching in the antennae of PSII, but an increase is directly related to the photochemical state of the reaction center itself. The decrease in maximal fluorescence seen in the algal sensor reflects an increased quenching of fluorescence by non-photochemical quenching. Genty and colleagues<sup>[43]</sup> have determined that the quantum yield of fluorescence can be calculated from measured parameters of the induction curve and, as noted above, is a measure of both PSII reaction center efficiency and total

availability of reaction center sites for electron transport. Rizzuto and associated researchers<sup>[8]</sup> showed that the activity of their PSII particle sensor was reduced when herbicides contacted it in aqueous solution. Merz and coinvestigators<sup>[6]</sup> analyzed the effect of triazine and phenylurea herbicides on the kinetics of chlorophyll fluorescence induction curves from isolated plant chloroplast biosensors in water. DBS and TBA vapors may damage sensor PSII reaction sites and induce non-photochemical fluorescence quenching. Reaction centers that remain partially closed or are no longer functional will report higher minimal fluorescence compared to non-treated controls.

Contacting the algal and cyanobacterial biosensors with the real CW agents HD, GA, and GB can produce results analogous to the simulants; however, changes in total fluorescence yields were evident only with GA at the concentrations used. The concentrations of the CW agents were lower than the simulants, indicating that sensor sensitivity is a factor for HD and GB. This, however, is not true for GA, because it showed alterations in the fluorescence induction curves with both sensors as well as characteristic decreases in fluorescence quantum yield. The sensor responses show that they are particularly sensitive to GA and not to nerve agents in general. Previous experiments in our laboratory with these sensors have shown a good response to cyanide, a key component in the structure of GA (Sanders and Greenbaum, unpublished data). Jones and Hoegh-Guldberg<sup>[17]</sup> examined the effect of cyanide on the photosynthesis of algae using chlorophyll fluorescence techniques. Cyanide reduced the maximum quantum yield of PSII. The effect was light-dependent, indicative of photoreactions mediated by cyanide inhibition of NADP<sup>+</sup> and ATP production and light-driven over stimulation of the electron transport chain. Photoinhibition may also contribute to damage to the PSII reaction centers when biosensors are exposed to GA.

## CONCLUSION

### Detection of Chemical Warfare Agents in Water

The data presented in this entry indicate that biosensors based on fluorescence induction curves of naturally occurring freshwater algae can be used to detect methyl parathion, cyanide, paraquat, and DCMU in primary water supplies under appropriate experimental conditions. In the context of current state-of-the-art biosensor research, they are unique: in the case of sunlight-exposed drinking water, the biosensors occur naturally in the medium to be protected. When combined with encrypted telecommunication data and a database-lookup library containing

pertinent data for healthy algae, this approach to protection of sunlight-exposed primary drinking water supplies may be of practical value under real-world conditions.

### Detection of Chemical Warfare Agents in Air

The data presented in this entry indicate that biosensors based on fluorescence induction curves of the cyanobacterium *N. commune* and the green alga, *C. vulgaris*, can be used to detect GA and CW simulants under appropriate experimental conditions. In the context of current biosensor state-of-the-art research they are relatively inexpensive to prepare and reasonably rugged. Moreover, they can be integrated into commercially available handheld fluorescence instrumentation for field applications. However, in our hands at least, they should not be thought of as ultrasensitive, early warning sensors. Their presently contemplated utility lies in the fact that they can be constructed to withstand inertial forces of launching or dropping into suspected danger zones and, with encrypted telecommunication data transmission, provide a survey of potential hazards in remote locations at levels that are expected to be encountered under real-world combat conditions.

## ACKNOWLEDGMENTS

“Detection of Chemical Warfare Agents in Water” (from Ref.<sup>[3]</sup>).

The authors thank Drs. John W. Barton and Brian H. Davison for their assistance with the methyl parathion experiments. We also thank Dr. K. Thomas Klasson for designing spreadsheets for data analysis, Ms. Angela R. Jones and Ms. Patricia A. Wilson for secretarial support, and Drs. Barton and Marsha K. Savage for reviewing the manuscript. ## INTRODUCTION

Colloids, which are basically a dispersion of one of the states of matter, i.e., gas, liquid or solid, in the other, are important for a variety of reasons. From natural colloids such as milk, blood, and egg white, etc. to synthetic ones such as paints, inks, creams, sprays, and fire extinguishers, we encounter colloidal systems daily in one way or the other. Generally, the usage of the term colloids would refer to the dispersion of particles (usually polydisperse) in the size range  $1\ \mu\text{m}$ – $1\ \text{nm}$  in another medium without any order. The class of colloids called micelles are formed when molecules consisting of long hydrocarbon tails and polar head groups self-assemble into an ordered structure beyond a critical concentration. Another class of colloid systems, where the particles are highly monodisperse in nature especially in the size range of few nanometer ( $1\ \text{nm} = 10^{-9}\ \text{m}$  or  $10^{-7}\ \text{cm}$ ), have recently attracted renewed interest because of the enormous promise these materials hold for future technologies. These materials—generally called nanoparticles or, if they consist single crystalline phase, nanocrystals—are envisioned to be the building blocks of every new technology from here onward. The control of size and shape of these particles with a penchant to form long-range ordered structures is expected to be very crucial for the fields of electronics, optoelectronics, and smart chips for future devices. Unlike the traditional atomic or molecular crystal lattices, these superlattices consist of a two-tier structure. Here each nanocrystal results from the regular arrangement of the atoms or molecules of the constituent material, in which the crystal sizes are restricted to a few nanometers only. These nanocrystals then become the building blocks of the superlattices. The properties of the resulting superlattices are controlled both by the constituent materials and their structural order.

The purpose of this entry is to introduce the reader to the field of colloids, focusing on two subclasses of these systems—micelles and nanocrystals and the

superlattices of nanocrystals. Among these, micelles have been studied for a long period of time and there are excellent reviews and books that are dedicated to these systems.<sup>[1]</sup> Hence only a brief introduction to these systems is given here. The reader is encouraged to refer to more elaborate treatises on this subject for further details. On the other hand, nanocrystals and their superlattices are relatively new entries to this field, and a great deal of attention is being given to them recently because of their applications to various fields, either already established or envisioned. Here we present the recent advances in the synthesis of monodisperse nanocrystals and their arrangement into 2-D or 3-D superlattices. Factors governing their arrangement into different types of superlattices are presented and discussed.

## COLLOIDS

We start this entry by giving a brief introduction to colloids. Usage of colloids by mankind dates back to the earliest traces of civilization.<sup>[1]</sup> Evidences of colloidal pigments were found in the stone-age paintings in the Lascaux caves of France and the written records of Egyptian Pharaohs. Many of the initial technological processes such as paper making, pottery making, and the making of soap and cosmetics, involved the manipulation of colloidal systems. However, the establishment of colloid science as a scientific discipline can be traced back only to the mid-nineteenth century. Initially, Francesco Selmi called these processes “Pseudo Solutions” while he was studying the clear or slightly turbid solutions of silver chloride, sulfur, and Prussian Blue in water. Faraday’s extensive studies on gold sols in water are another classical example of colloidal systems, although he never used the term “colloid.” He observed that the dispersion of the solid gold particles in water is kinetically stabilized, and that once they are coagulated, the process cannot be reversed. On the other hand, if properly prepared,

these colloidal systems are stable for years, and some of the colloidal systems that Faraday himself has prepared are, in fact, still on display in the British Museum in London.

The word “colloid” was first introduced by Thomas Graham in 1860s,<sup>[2]</sup> while he was studying diffusion. He classified materials as crystalloids—substances which, in water solution, would easily diffuse through a membrane, and colloids (after a Greek word for glue)—substances which have very slow diffusion rates through the membranes. From the slow diffusion rates of these materials, he deduced that the particles of these materials must be very large, at least on the order of  $10^{-7}$  cm (1 nm in modern terms). On the other hand, the failure for sedimentation implied a minimum size limit of  $10^{-4}$  cm (1  $\mu$ m). In fact, his size range for colloidal domain is still valid today.

Apart from their size, which prevents individual colloidal particles from sedimentation, there are several other parameters that stabilize these from the close approach of two colloidal particles and consequent collapse into a single particle, called coagulation. For example, there might be a protective film that stabilizes the interface and that cannot be penetrated when the two particles touch each other. Another major source of kinetic stability is the existence of an electric charge on the particle surfaces. Because of this, particles having similar charges oppose each other, thereby preventing coagulation. The charges are usually a result of adsorption of ions from the solution due to the defect sites on the surfaces of the particles. Surface charges on the particle are usually compensated by an array of ions of opposite charge from solution, forming an electric double layer.<sup>[3,4]</sup>

The principal character of colloids is the greater surface area they possess compared to their bulk material counterparts. For example, a material is in the form of a sphere with a radius of 1 cm. It has a surface area of  $4\pi\text{cm}^2$ , whereas a 1-nm radius sphere of the same material has a surface area of  $4\pi \times 10^{-14}\text{cm}^2$ . Therefore if the 1-cm sphere is cut and redispersed as 1021 spheres with a radius of 1 nm, the total surface area would increase from  $4\pi\text{cm}^2$  to  $4\pi \times 10^7\text{cm}^2$ . Another important feature is the significant increase in the surface-to-volume ratio. The surface to volume ratio of a sphere is equivalent to  $3/r(\frac{4\pi r^2}{4/3\pi r^3})$ . For a 1-cm radius sphere, the ratio is  $3\text{cm}^{-1}$ , whereas for a 1-nm sphere the ratio is  $3 \times 10^{-7}\text{cm}^{-1}$ , indicating the importance of surface species in the colloidal particles.

The different classes of colloids that we encounter are sols (dispersion of solid in liquid), emulsion (liquid in liquid), aerosols (liquids or solids in gases), and foams (gases in liquids or solids). In general, sols are further classified as lyophilic (solvent liking) and lyophobic (solvent disliking).

A number of techniques can be used to study the colloidal systems. Because colloidal particles are substantially smaller than the wavelength of light, these could be studied by scattering techniques. In 1924, Svedberg invented the ultracentrifuge, which can cause sedimentation in colloidal sols at observable rates. From these rates, the particle sizes and masses could be accurately determined. The electron microscope is another valuable tool in viewing the colloidal particles.

## MICELLES

One of the most extensively studied colloidal systems is micelles.<sup>[5]</sup> Micelles result from the self-assembly of surfactants in a dispersion medium. As the name implies, surfactants are species accumulating at the interface of two fluids. A typical surfactant consists of a long hydrocarbon tail and a polar head group. The long hydrocarbon tail favors hydrocarbon or other non-polar solvents, while the polar head group preferentially dissolves in a polar solvent. The best examples of such compounds are the sodium salts of the long alkylchain fatty acids, which are extensively used in soaps. In aqueous solutions, the solubility of the surfactants is conferred by their polar head groups, usually either cationic or anionic. As the surfactant concentration increases, these molecules try to cluster together in aggregates called micelles. The concentration above which they are formed is called as critical micelle concentration (CMC). The size of the micelle formed as such mainly depends on the size of the surfactant molecules, but is typically in the range of colloidal domain. The shape of individual micelles varies with concentration. Close to critical micelle concentration, they are spherical and, at higher concentration, they assume lamellar or rodlike structures (Fig. 1). Micelles are very important in industry and biology because of their solubilizing properties. They are extensively used as detergents and soaps, and as drug carriers. They are also increasingly used in natural synthesis and petroleum recovery.

There are several methods that give us vital insights on the structure and properties of micelles. Many physical properties of surfactants undergo an abrupt change at the CMC. Surface tension and conductance are two simple and widely used methods for measuring the CMC. For example, at concentrations below CMC, adding sodium dodecylsulphate (SDS) to water decreases the surface tension with increase in SDS concentration. An abrupt decrease in surface tension is observed as the concentration reaches the CMC. It then slowly decreases and reaches a plateau as more SDS is added to the water. In the initial stages, as the hydrocarbon chain of SDS is not soluble in water, the molecules are concentrated at the air–water

**Fig. 1** Structural transitions associated with the ordering of surfactant molecules as the concentration is increased.

interface with the hydrocarbon chain oriented toward the vapor phase. Because the surface tension of water is higher than that of the hydrocarbons, adding more surfactant results in a decrease in surface tension. However, above the CMC, the surfactant molecules self-assemble to form micelles, in which the hydrocarbon chains orient themselves inside the aggregate and the polar head groups orient toward the aqueous phase. Above the CMC, adding more surfactants simply produces more micelles, keeping the surface tension almost constant. Similarly, the conductivity of many surfactants display (especially anionic or cationic surfactants) a slow decline in conductance at concentrations below the CMC. Above CMC, the conductance shows a sharp break as a result of the micellization.

## NANOCRYSTALS AND THEIR SUPERLATTICES

Although nanocrystals are nothing but crystalline colloidal particles, they were not specifically targeted for systematic studies until recently.<sup>[7]a</sup> The main interest in this area stems from the unique physical properties

of these nanoscale materials, such as quantum confinement. Quantum confinement results from the size of the particle where the electron trapped in the nanoparticle cannot jump to other particles because of the potential barrier between them, which arises as a result of the insulating, protective ligand shell on each particle and the distance between the particles. However, if the particles are brought sufficiently closer, the electrons can tunnel between the particles and the tunneling strength decreases exponentially with distance. Thus the quantum confinement properties of the nanoscale particles crucially depend on the choice of the material, the size of each particle, the temperature, and the surrounding environment. Apart from this, ordered arrays of these nanoscale particles are expected to manifest novel electronic, magnetic, and optical properties because of the cooperative interactions between the particles.

There are two interesting directions in the study of nanoparticles and their ordered arrays. The first one is the packing of individual atoms inside a nanoparticle. The other one is the packing of these nanoparticles into ordered 2-D or 3-D arrays. It is often observed that in the nanoscale regime, atoms aggregate into many interesting crystal motifs quite different from their bulk crystal structures. For example, X-ray diffraction pattern of cobalt nanoparticles prepared by reduction of hot cobalt chloride solution revealed a complex cubic structure related to the  $\beta$ -phase of elemental manganese ( $\epsilon$ -Co).<sup>[8,9]</sup> On the other hand, bulk cobalt adopts a hexagonally close packed structure. Sometimes the stabilization of different crystal motifs in the nanoscale regime is attributable to kinetic considerations, where the particles are arrested in a metastable state. In other cases, the different motif is actually found to be energetically favorable for that particular size due to surface considerations.

The second direction, formation of ordered arrays of nanoparticles in 2-D and 3-D, is one of the major areas of research attracting the attention of innumerable research groups in the world today.<sup>[10]</sup> The main requirement for the formation/self-assembly of the nanoparticle arrays (superlattices) is the synthesis of monodisperse colloids. Strictly speaking, a monodisperse colloid means particles with sizes indistinguishable from each other. However, in the field of nanocrystal superlattices (NCs), a standard deviation of ( $\sigma$ )  $\leq 5\%$  in the size is accepted as monodisperse. Apart from the size, the crystallinity of the core and the shape of surfaces play an important role in controlling the formation of superlattices.

There are several techniques generally employed to synthesize monodisperse nanoparticles, which differ slightly from each other depending on the type of material to be synthesized. Some of the important synthetic methods are detailed below. For synthesizing

<sup>a</sup>See the articles in the special Issue of *Sci. Am.* Ref.<sup>[6]</sup>.

**Fig. 2** Schematic of the nano-reactors in which the formation of nanoparticles takes place.

noble metal nanoparticles (Ag, Au, Pt, etc.), the most popular synthetic procedure is to reduce the metal salt in the presence of surfactant and stabilizing agent.<sup>[11]</sup> In a typical procedure, aqueous solution of the metal salts are mixed with a toluene solution containing surfactants such as long-chain alkylammonium salts. The metal ion is then transferred to the organic phase by vigorous stirring. A capping agent (usually alkane-thiols) is subsequently added to this solution. The metal salt is then reduced by a reducing agent ( $\text{NaBH}_4$  or hydrazine) to nucleate the metal nanoparticles. Here the size of the nanoparticle is restricted in the nanometer scale, because the reaction itself takes place in the nano-reactor formed by the long-chain-length alkylammonium ions. These ions self-assemble into a micellar structure, where the polar head groups trap the metal ions in the aqueous phase (Fig. 2). The size of the nanoparticles can also be controlled by the reaction rate, by temperature, and by adjusting the ratio of capping agents to the initial metal salt concentration. The size distribution is further narrowed by size-selective precipitation. A similar procedure based on inverse micelles, where the metal salt is dissolved in a solution of surfactant in a hydrocarbon solvent and subsequently reduced by the addition of an aqueous solution of the reducing agent, is found to be equally effective.<sup>[12,13]</sup>

Transition metal nanoparticles are usually prepared by a very similar technique but at slightly higher temperatures.<sup>[8–10]</sup> Here the metal salts and the capping agents are dissolved in very high boiling solvents such as dioctylether or phenyl ether. After heating the mixture to  $\sim 200\text{--}250^\circ\text{C}$ , a hot reducing agent is added, leading to the nucleation and growth of metal nanoparticles stabilized by the capping agents. In the

semiconductor nanoparticle synthesis, the solvents usually employed are mixtures of long-chain alkyl phosphines, phosphine oxides, alkyl amines, etc. Generally, a metathesis ( $\text{AB} + \text{CD} \rightarrow \text{AC} + \text{BD}$ ) reaction of metal alkyls (dimethyl cadmium, diethyl zinc, dibenzyl mercury) and organophosphine or silylchalcogenides ( $\text{R}_3\text{PE}$  or  $\text{TMS}_2\text{E}$ , where TMS = trimethylsilyl and E = S, Se, or Te) is carried out to prepare semiconductor nanoparticles.<sup>[10]</sup> However, all these procedures require a size-selective precipitation step to achieve the narrow size distribution mandatory for the formation of the ordered arrays of the respective nanoparticles. Other drawbacks of the above chemical synthetic procedures are the usage of highly toxic chemicals and difficulty in scaling up the yields.

Alternative procedures, such as aerosol and solvated cluster dispersion techniques, have been reported which alleviate some of the problems associated with the above chemical routes. In these methods, the required material is directly evaporated (Au, Ag, Pt, or CdS, ZnS, etc.) and captured in a solvent or inert gas stream.<sup>[14,15]</sup> The solvent or inert gas employed works as a stabilizing agent or diluent, respectively. The matrix is then allowed to mix with the capping ligand, which preserves the size of the clusters in the nanoscale region. Although large quantities of the required nanomaterials could be prepared via these routes, they also usually result in broad size distributions of the nanoparticles. In a significant development, Klabunde et al.<sup>[16–18]</sup> proposed a digestive ripening technique which allows researchers to convert a broad size distributed colloid to a nearly monodisperse one. In this technique, a broad size distributed colloid in a solvent is refluxed in the presence of a surface active agent. This simple procedure significantly narrows down the size distribution and allows the synthesis of large quantities of monodisperse particles.

An important point to remember in the synthesis of monodisperse nanoparticles is the choice of capping agent. The selection of capping agent is usually determined by the material to be synthesized. The popular capping agents for several materials synthesized are provided in Table 1. The list is not very exhaustive

**Table 1** Popular ligand groups used to stabilize different materials in the nanoscale regime

Material	Ligand groups
Noble metals (Au, Ag, Pt, etc.)	RSH, $\text{RNH}_2$ , $\text{R}_3\text{P}$ , and $\text{RSiH}_3$
Transition metals and magnetic compounds	$\text{RCOOH}$
Semiconductors	RSH, $\text{R}_3\text{P}$ , and $\text{R}_3\text{PO}$

The most popular “R” groups employed are  $\text{C}_8\text{H}_{17}$ – (for RSH,  $\text{R}_3\text{P}$ , and  $\text{R}_3\text{PO}$ ),  $\text{C}_{12}\text{H}_{25}$ – (for RSH and  $\text{RNH}_2$ ), and  $\text{C}_{18}\text{H}_{37}$ – (for  $\text{RSiH}_3$ ).

**Fig. 3** Single crystalline and polycrystalline gold nanoparticles resulting from different procedures.

but should provide a guideline in finding the popular ligands generally used.

Thus there are several methods now available to prepare monodisperse nanoparticles of different materials protected by several capping agents. However, the size, shape, and morphologies of these nanoparticles are crucially dependent on their synthetic routes. These differences not only determine their different physical properties but also control the way the 2-D and 3-D superlattices are formed from these nanoparticles. For example, the two-phase procedure for noble metal nanoparticles generally results in the formation of 2–3 nm particles.<sup>[11]</sup> The routes involving inverse micelles and the subsequent digestive ripening lead to the formation of 5–6 nm particles.<sup>[16–18]</sup> As mentioned above, the individual morphology of each particle also is critically determined by the procedure used. While methods involving surfactants routinely lead to single crystalline gold nanoparticles with truncated

**Fig. 4** Self-assembled superlattices of the monodisperse gold nanoparticles prepared by two different methods: (A) solvated metal atom dispersion method, (B) inverse micelle method.

**Fig. 5** Schematic of the two different superlattice formations.

octahedral shapes, solvated dispersion and aerosol techniques result in polycrystalline particles with many defects (Fig. 3).<sup>[15,19]</sup> This difference in morphology is known to critically determine the final ordering of the superlattices, either in face centered cubic (*fcc*) type or hexagonally close packed (*hcp*) type.

In this respect, it is generally observed that particles with multiple defects usually behave like hard spheres and arrange themselves into an *hcp* lattice.<sup>[15,19]</sup> A typical triangular-shaped contrast image observed by electron microscopy of the superlattices formed by

Individual nanocrystals in a colloidal solution. Notice the ligands form self assembled layers on the surface.

Superlattices of nanoparticles. Notice the interdigitation of ligands on adjacent particles.

**Fig. 6** Schematic of the self-assembled monolayers of ligand molecules on the nanoparticle surfaces and the formation of the superlattices with interdigitation of ligand molecules on adjacent particles.

the polycrystalline particles is presented in Fig. 4A. This image results from the organization of roughly 5-nm Au nanoparticles oriented along the [0001] direction in an *hcp* arrangement. In an *hcp* arrangement, the hexagonally packed particles of adjacent layers are arranged in an *ABAB...* fashion. In contrast, the superlattice resulting from the *fcc* arrangement of a similarly sized, perfect single crystalline nanoparticles is shown in Fig. 4B.<sup>[19]</sup> This specific arrangement results from the [110] projection of *fcc* lattice. Here the particles from the adjacent layers are arranged in an *ABCABC...* type fashion.<sup>[19,20]</sup> A pictorial difference of the *hcp*- and *fcc*-type arrangements is presented in Fig. 5.

It is also generally observed that the 3-D superlattice formation is encouraged by interdigitation (bundling) of the capping agents on adjacent particles. It is well known that ligands such as thiols form self-assembled monolayers on flat bulk Au (111) surfaces. They form similar self-assembled monolayers on the 3-D nanoparticles as well, fixing the alkyl chain length of the thiol molecule preferentially in an all *trans* arrangement.<sup>[21]</sup> Then, the alkyl chains of the adjacent particles can penetrate into each other leading to the phenomenon called interdigitation (Fig. 6). Particle-to-particle distance obtained by electron microscopy pictures and diffraction patterns reveal that the distance between the adjacent particles in a superlattice is generally equivalent to one ligand chain length supporting this phenomenon.<sup>[22]</sup>

Until now, superlattices of several materials (most of the noble metals, numerous semiconductor and transition metal nanoparticles, and numerous magnetic compounds) have been prepared and well characterized. However, most of these superlattices are grown on some substrates. Isolation of a big “supercrystal” formed by the nanoparticles still remains elusive at this point. Nevertheless, with the amount of activity currently going on in this field, it appears that this goal might be achieved soon. This might open the hitherto unknown new avenues for the scientific community in the nanotechnology field.

## ACKNOWLEDGMENTS

The authors wish to sincerely thank Prof. Kenneth J. Klabunde and Prof. Christopher M. Sorensen for many enlightening discussions. We also thank Dr. Vladimir Zaikovski of Boreskov Institute of Catalysis, Novosibirsk, Russia, for the high-resolution TEM pictures.

# Colloidal Nanometals as Fuel Cell Catalyst Precursors

Helmut Bönnemann

K. S. Nagabhushana

*Department of Heterogeneous Catalysis, Max Planck Institut für Kohlenforschung,  
Mülheim an der Ruhr, Germany*

## INTRODUCTION

The goal of this entry is to highlight the incentives and methods that are typically used for using nanomaterials as precursors of fuel cell catalysts. Our “precursor” concept for the manufacturing of heterogeneous metal colloid catalysts was developed in the last decade.<sup>[1–8]</sup> This method facilitates ready accessibility to homogeneous alloys, segregated alloys, layered bimetallics, or “decorated” metal particles and because of which it is now possible to tailor the precursor metallic colloids with controlled structures and metal interfaces. The advantage here is one can preprepare and thoroughly characterize active components of the electrocatalysts using modern analytical tools.

Nanostructured metal particles were considered potential catalysts essentially because of their unique electronic structures combined with extremely large surface areas. In general, isolable particles between 1 and 50 nm that are prevented from agglomeration by protective shells are termed “nanostructured metal colloids.” These colloids can be redispersed in both water (“hydrosols”) and organic solvents (“organosols”) depending on the nature of the protecting shell used. A wealth of knowledge has been acquired about these materials over the past decades.<sup>[1–3,9–18]</sup> Highly dispersed mono- and bimetallic colloids have been used as precursors for a variety of catalysts applicable in chemical catalysis.<sup>[4,19–27]</sup> This contribution, however, will deal only with those applications significant to fuel cell technology.

## BACKGROUND

Numerous methods have been explored to manipulate colloidal metal precursors. There are manifold advantages of using the precursor method over the conventional salt-impregnation method in that both size and composition of the colloidal metal precursors may be tailored independent of the support. Metal particle surfaces may be modified by different protective shells and coated by intermediate layers, e.g., by using metal oxides. A change in the precursor can be brought about

by SnO<sub>2</sub> and WO<sub>3</sub> dopants. Dipping the support in the appropriate solution of the preprepared particles results in the adsorption of the particles on to the support. The result of such an exercise is an eggshell catalyst, which contains a thin layer of the active metal particles on the surface of the support. It is important to note that no subsequent calcination is required. Supports such as charcoal, various oxidic support materials, and even low-surface materials such as quartz, sapphire, and highly oriented pyrolytic graphite (HOPG) have been used (Fig. 1).<sup>[1–8]</sup>

Interaction of platinum hydrosols with oxide (sapphire, quartz) and graphite single-crystal substrates have been monitored by the combination of X-ray and microscopic techniques<sup>[28,29]</sup> (Fig. 2). The protected Pt metal colloid is immediately adsorbed on to the surface of the dipped support, resulting in a carpetlike coat of the protected colloids. Upon annealing at 280°C and higher within an ultrahigh vacuum, the protecting shell decomposes. Thermal degradation studies monitored by X-ray photoelectron spectroscopy (XPS) and scanning tunneling microscopy (STM) revealed Pt particles virtually unchanged up to 800°C, above which sintering is observed.

## Fuel Cells and Catalysts

Fuel cells convert chemical energy into electrical energy and the catalyst system forms the most important component of this conversion.<sup>[30]</sup> The wide-ranging applications of fuel cells include low-emission transport systems, stationary power stations, and combined heat and power sources for small devices. Although metal Pt is adequate as a fuel cell catalyst for pure hydrogen feed, Pt alloy particles (e.g., Pt–Ru) of 1- to 3-nm size best serve as the active catalyst component for reformer gas or methanol into electricity. These systems offer improved efficiency and tolerance against contaminants, especially CO in the anode feed.<sup>[31–36]</sup> It is not clear what type of fuel will be the best to supply the cells in future vehicles. The options currently available include hydrogen, methanol, and synthetic fuel.<sup>[37]</sup> Whereas engineers and clean air experts favor pressurized hydrogen,

**Fig. 1** The precursor concept. *Source:* From Ref.<sup>[2]</sup>. Adapted with permission from Elsevier Science.

automakers are banking on methanol because of the ease of distribution.

In essence, bi- or multimetallic colloids are the need of the hour. Bimetallic colloids are readily accessible by the controlled coreduction or stepwise reduction of two different metal ions.<sup>[1,2,4,38–54]</sup> The catalytic aspects and structural characterization of some bimetallics have been reviewed.<sup>[15]</sup> Influences of each metal in a nanostructured bimetallic colloid catalyst combined with recent advances in the preparation of bimetallic colloids have provided catalysts of several compositions. Composition gradients from the core to the shell bimetallic particles have been prepared by successive reduction of mixed metal ions.<sup>[55–59]</sup> Truly, layered particles consisting of a gold core plated by palladium or vice versa have also been synthesized.<sup>[60]</sup> Electronegativity differences between two elements brings in a novel electronic structure and is seen in the case of Pd and Au as they contain partially filled and completely filled d bands, respectively.<sup>[61–69]</sup> Simon and coworkers have successfully prepared  $\text{Au}_{\text{core}}\text{Pd}_{\text{shell}}$ ,  $\text{Pd}_{\text{core}}\text{Au}_{\text{shell}}$  bimetallic colloids of 20–56 nm using classical seed growth method, which is complimented by sequential reduction of the metals followed by stabilization using trisulfonated triphenylphosphane and sodium sulfanilate, resulting in more than 90% metal to be isolated in the solid state and which is redispersible in water in high concentrations.<sup>[60]</sup>

Formic acid in the presence of different amounts of alkaloid (colloidal stabilizer) has given rise to platinum colloidal catalysts with varied particle sizes from platinum tetrachloride. The preparation of a fully alloyed Pd–Au colloid of 3.0-nm particle size, by the coreduction of Pd and Au salts with tetraalkylammonium triethylhydroborate<sup>[1]</sup> in a modified sol–gel procedure using tetrahydrofuran (THF) as the solvent, has been described.<sup>[70]</sup> The integrity of the incorporated Pd–Au alloy particles remained virtually untouched.

**Fig. 2** (A) AFM investigation of a sulfobetaine-12 stabilized Pt hydrosol (3 nm) absorbed on highly oriented pyrolytic graphite (HOPG) after dipping (left) and after additional washing (right). (B) Scheme of the Pt hydrosol adsorption on HOPG derived from a combined STM and XPS study. *Source:* From Ref.<sup>[29]</sup>. Adapted with permission from Elsevier Science.

A mesoporous texture with a comparatively narrow pore distribution remained after removing the protecting surfactant. According to physical characterization by a combination of techniques,  $\text{SiO}_2$  is seen to preserve the size and structural characteristics of the embedded Pd–Au colloidal metal precursor. The material exhibits excellent catalytic properties in selective hydrogenation test reactions. The following sections give various methods applied for the synthesis of colloidal nanoparticles.

## PREPARATION METHODS

The two principles of obtaining nanostructured metal colloids are “top-down” and “bottom-up” methods. The top-down method makes use of stabilizing the broken-down smaller structures from the bulk metal

using protecting agents.<sup>[71,72]</sup> An offshoot of this principle is the metal vapor technique,<sup>[73–78]</sup> a highly demanding proposition. On the other hand, the bottom-up method of wet chemical nanoparticle preparation relies on the chemical reduction of metal salts, electrochemical pathways, or the controlled decomposition of metastable organometallic compounds. The primarily formed nanoclusters are prevented from agglomeration using stabilizers, e.g., donor ligands, polymers, and surfactants.

## Modes of Stabilization

Protective agents are imperative for the stabilization of nanostructured metals and for prevention of their coagulation. Two basic modes of stabilization have been distinguished.<sup>[79]</sup>

Electrostatic stabilization is caused by the coulombic repulsion between the particles adsorbed at the particle surface (e.g., sodium citrate) and the corresponding counter ions. This causes an electrical double layer by ions. An example is gold sols prepared by the reduction of  $[\text{AuCl}_4^-]$  using sodium citrate.<sup>[9–11]</sup> A second mode is steric stabilization, achieved by the coordination of sterically bulky organic molecules that act as protective shields on the metallic surface. The nanometallic cores are thus separated from each other, preventing coagulation. The main classes of protective groups studied to date are the following: polymers<sup>[38–41]</sup> and block copolymers;<sup>[80–91]</sup> P, N, S donors (e.g., phosphines, amines, thioethers);<sup>[4,60,92–104]</sup> solvents such as THF;<sup>[4,105]</sup> THF/MeOH,<sup>[106]</sup> or propylene carbonate;<sup>[48]</sup> long-chain alcohols;<sup>[80–91]</sup> surfactants;<sup>[1–8,42–53]</sup> and organometallics.<sup>[107–111]</sup> Lipophilic protective agents yield metal colloids that are soluble in organic media (“organosols”); hydrophilic agents yield water-soluble colloids (“hydrosols”). A monolayer of the surfactant coat in the form of tetraalkylammonium halides is seen over the metal core in the case of Pd organosols.<sup>[109]</sup> Pt or Pt/Au particles have been hosted in the hydrophobic holes of nonionic surfactants, e.g., polyethylene monolaurate.<sup>[112,113]</sup>

## WET CHEMICAL REDUCTION

### Metal Salt Reduction Method

In 1857, Faraday was the first to report on the chemical reduction of transition metal salts in the presence of stabilizing agents to generate metal colloids.<sup>[114]</sup> This reliable approach has been extensively used.<sup>[15,16,79]</sup> Turkevich, nearly a century later,<sup>[9–11]</sup> gave the first reproducible standard recipe for the preparation of gold metal colloids by using sodium citrate for the

reduction of  $[\text{AuCl}_4^-]$ . He proposed a step-by-step formation of nanoclusters based on nucleation, growth, and agglomeration mechanisms. A refinement of this model was done (Fig. 3) based on the results from recent thermodynamic and kinetic results and modern analytical techniques.<sup>[115–124]</sup>

The general understanding is zerovalent metal atoms are generated in the embryonic stage of nucleation<sup>[115]</sup> by metal salt reduction. These atoms can collide in solution with other metal ions, metal atoms, or clusters to form an irreversible “seed” of stable metal nuclei. Depending on the strength of the metal–metal bonds, the difference in redox potentials of the metal salt, and the reducing agent used, the diameter of the “seed” nuclei can be well below 1 nm.

On the mechanism of colloidal particle formation, there have been some advances in the recent past.<sup>[119–123]</sup> Platinum colloid formation by using trialkylaluminum as both reducing agent and protecting group has been carefully studied with the formation of an intermediate, which decomposes in solution to result in nanoparticles having an average diameter of 1.2 nm. This sequence of reactions is shown in Fig. 4.

**Fig. 3** Formation of nanostructured metal colloids via the “salt reduction” method. *Source:* Adapted from Ref.<sup>[124]</sup>.

and Ir.<sup>[131–134]</sup> Colloidal Pt in water was obtained using CO, formic acid or sodium formate, formaldehyde, and benzaldehyde as reductants.<sup>[10,135,136]</sup> Silanes were found to be effective for the reductive preparation of Pt sols.<sup>[137,138]</sup> A reducing agent in tetrakis(hydroxymethyl) phosphonium chloride (THPC), which allows the size- and morphology-selective synthesis of Ag, Cu, Pt, and Au nanoparticles from the corresponding metal salts has been successfully introduced by Duff et al.<sup>[139,140]</sup> and Vogel, Duff, and Baiker<sup>[141]</sup> Furthermore, hydrazine,<sup>[142]</sup> hydroxylamine,<sup>[143]</sup> and electrons trapped in  $K^+ [(crown)_2K]^-$ <sup>[144]</sup> have been applied as reductants. In addition,  $BH_4^-$  is a powerful and valuable reagent for the salt reduction method. A disadvantage, however, is that transition metal borides are often found along with the nanometallic particles.<sup>[145,146]</sup> Very recently, solvent-stabilized platinum and its alloy with Ru, Mo, W, and Ni with an average diameter of 1.7 nm have been reported. In an attempt to produce direct methanol fuel cell (DMFC) catalysts, the reduction of a mixture of platinum and the second metal halides was performed using  $LiBH_4$  as a reducing agent. The resulting nanoparticles are stabilized by the solvent THF and later recovered by suitable treatment.<sup>[147]</sup>

### Stabilized Metal Colloids

Tetraalkylammoniumhydrotriorganoborate<sup>[1–8]</sup> offers a wide range of application in the wet chemical reduction of transition metal salts. In this case, the reductant  $[BEt_3H^-]$  is combined with the stabilizing agent (e.g.,  $NR_4^+$ ). The surface-active  $NR_4^+$  salts are formed immediately at the reduction center in high local concentration that prevents particle aggregation. The advantage here is that trialkylboron can be recovered from the reaction and no borides contaminate the products.

M = metals of the groups 6–11; X = Cl, Br;  $v = 1, 2, 3$ ; and R = alkyl,  $C_6-C_{20}$ .

As obtained, the  $NR_4^+$ -stabilized metal “raw” colloids typically contain 6–12 wt.% of metal. This, upon work up with ethanol or ether and subsequent reprecipitation by a solvent of different polarity (Table 9 in Ref.<sup>[1]</sup>), yields “purified” transition metal colloids containing ca. 70–85 wt.% of metal. When  $NR_4X$  is coupled to the metal salt before the reduction step, the preparation of  $[NR_4^+BEt_3H^-]$  can be avoided.  $NR_4^+$ -stabilized transition metal nanoparticles can also be obtained from  $NR_4X$ -transition metal double salts. Because the local concentration of the protecting group is sufficiently high, a number of conventional reducing agents may be applied (Eq. 2).<sup>[2,4]</sup>

M = metals; Red =  $H_2$ , HCOOH, K, Zn, LiH,  $LiBEt_3H$ ,  $KBEt_3H$ ; X, Y = Cl, Br;  $v, w = 1-3$ ; and R = alkyl,  $C_6-C_{12}$ .

In a recent review, the scope and limitations of this method have been evaluated.<sup>[16]</sup> Isolable metal colloids of the zerovalent early transition, which are stabilized only with THF, have been prepared via the  $[BEt_3H^-]$  reduction of the preformed THF adducts of  $TiBr_4$  (Eq. 3),  $ZrBr_4$ ,  $VBr_3$ ,  $NbCl_4$ , and  $MnBr_2$ . Table 1 summarizes the results.

Detailed studies of  $[Ti \cdot 0.5THF]^{[105]}$  show that it consists of  $Ti_{13}$  clusters in the zerovalent state, stabilized by six intact THF molecules (Fig. 5).

By analogy,  $[Mn \cdot 0.3THF]$  particles (1–2.5 nm) were prepared<sup>[148]</sup> and their physical properties studied.<sup>[149]</sup> The THF in Eq. 3 has been successfully replaced by tetrahydrothiophene (THT) for Mn, Pd, and Pt organosols; but attempts to stabilize Ti and V this way led to decomposition.<sup>[4]</sup>

Fig. 6 gives a survey of the  $[BEt_3H^-]$  method.

**Table 1** THF-stabilized organosols of early transition metals

Product	Starting material	Reducing agent	Temperature (°C)	Time (hr)	Metal content (%)	Size (nm)
[Ti·0.5THF]	$TiBr_4 \cdot 2THF$	$K[BEt_3H]$	RT	6	43.5	(<0.8)

The advantages of this method are as follows (Fig. 6): the method is generally applicable to salts of metals in groups 4–11 in the periodic table; it yields extraordinarily stable metal colloids that are easy to isolate as dry powders; the particle size distribution is nearly monodisperse; bimetallic colloids are easily accessible by coreduction of different metal salts; and the synthesis is suitable for multigram preparations and is easy to scale up. The only drawback to this method is that by altering the reaction conditions the particle size of the resulting sols cannot be varied.

<b>Ti</b> <0.8	<b>V</b>	<b>Cr</b> 3.0	<b>Mn</b> 1-2.5	<b>Fe</b> 3.0	<b>Co</b> 2.8	<b>Ni</b> 2.8	<b>Cu</b> 8.3

Protecting groups in betaines instead of  $NR_4^+$  salts [in Eq. (1)] can be conveniently used to generate zero-valent precious metal hydrosols. In Eq. 2, a broad variety of hydrophilic surfactants can be used.<sup>[2,4,6,7]</sup> Reetz and Maase<sup>[150–152]</sup> have reported a new method for the size- and morphology-selective preparation of metal colloids using tetraalkylammonium carboxylates of the type  $NR_4^+R'CO_2^-$  ( $R = \text{octyl}$ ,  $R' = \text{alkyl, aryl, H}$ ) [Eq. (4)]. The resulting particle sizes were found to depend on the electronic nature of the  $R'$  group in the carboxylate with electron donors producing small nanoclusters while electron-withdrawing substituent  $R'$ , in contrast, yielded larger particles. Pd particles of 2.2-nm size are found when  $Pd(NO_3)_2$  is treated with an excess of tetra(n-octyl)ammonium carboxylate bearing  $R' = (CH_3)_3CCO_2^-$  as the substituent, but the particle size was 5.4 nm when  $R' = Cl_2CHCO_2^-$  (an electron-withdrawing substituent) was used.

$R = \text{octyl}$  and  $R' = \text{alkyl, aryl, and H}$ .

A number of bimetallic colloids were obtained with tetra(n-octyl) ammonium formate as the reductant: Pd/Pt (2.2 nm), Pd/Sn (4.4 nm), Pd/Au (3.3 nm), Pd/Rh (1.8 nm), Pt/Ru (1.7 nm), and Pd/Cu (2.2 nm). The shape of the particles was also found to depend on the reducing agent used, e.g., with tetra(n-octyl) ammonium glycolate  $Pd(NO_3)_2$  a significant amount of trigonal particles in the resulting Pd colloid was detected.

Mono and bimetallic nanoparticles have been prepared by “reductive stabilization” using organoaluminum compounds [Eq. (5) and Table 2].<sup>[107,110,149]</sup>

**Fig. 6** Nanopowders and nanostructured metal colloids accessible via the  $[Bet_3H^-]$ -reduction method (Eqs. 1 and 2) (including the mean particle sizes obtained). *Source:* From Ref.<sup>[2]</sup>. Adapted with permission from Elsevier Science.

M = metals of groups 6–11 periodic system of elements (PSE); X = halogen, acetylacetonate;  $n = 2-4$ ; R = C<sub>1</sub>–C<sub>8</sub> alkyl, particle sizes 1–12 nm.

From Eq. (5), it is clear that colloids of zerovalent elements of groups 6–11 of the periodic table (and also of tin) can be prepared in the form of stable, isolable organosols. This method is now shown to be a reliable approach for the production of a wide range of small zerovalent transition metal particles. The key feature of this synthesis is the formation of an organometallic colloidal protecting shell (e.g., Al–C<sub>2</sub>H<sub>5</sub> or Al–CH<sub>3</sub>) around the particles. Formation of alkyl aluminum protecting shell over platinum nanocluster was confirmed by quantitative protonolysis experiments using modifiers (monofunctional) and spacer molecules (bifunctional) [Eq. (6)].

Modifiers are alcohols, carbonic acids, silanols, sugars, polyalcohols, PVP, surfactants, silica, alumina, etc.

By suitable “modification” [Eq. (6)] of the organoaluminum protecting shell it is possible to tailor the dispersion characteristics of the original organosols. A vast spectrum of dissolubilities of the colloidal metals in hydrophobic and hydrophilic media (including water) has been achieved in this manner.

### Electrochemical Synthesis

Mono- and bimetallic nanostructured colloids have been prepared by this versatile method by Reetz and his group since 1994.<sup>[14,42–44]</sup> The overall process of electrochemical synthesis can be divided into six steps. They are (1) oxidative dissolution of the sacrificial  $\text{Met}_{\text{bulk}}$  anode, (2) migration of  $\text{Met}^{n+}$  ions to the cathode, (3) reductive formation of zerovalent metal atoms at the cathode, (4) formation of metal particles by nucleation and growth, (5) arrest of the growth process and stabilization of the particles by colloidal protecting agents, e.g., tetraalkylammonium ions, and (6) precipitation of the nanostructured metal colloids [Eq. (7)].

The advantages of the electrochemical pathway include no contamination in by-products and easy isolation of product as precipitate. Reetz et al. have conducted several experiments using a commercially available Pd sheet as the sacrificial anode and the surfactant as the electrolyte and stabilizer. Parameters such as solvent polarity, current density, charge flow, distance between electrodes, and temperature are found to have an effect on the particle size of the  $(\text{C}_8\text{H}_{17})_4\text{N}^+\text{Br}^-$ -stabilized  $\text{Pd}^{(0)}$ . These manipulations are used carefully to control the size of Pd nanoparticles in the range of 1.2–5 nm.<sup>[42,53]</sup> In other words, it is possible to have size-selective particle formation by electrochemical preparation. With the electrochemical method, a number of monometallic organosols and hydrosols including Pd, Ni, Co, Fe, Ti, Ag, and Au have been successfully prepared on a scale of several hundred milligrams with yields >95%.<sup>[42–53]</sup> In addition, solvent-stabilized (propylene carbonate) palladium particles (8–10 nm) have also been obtained.<sup>[48]</sup> When two sacrificial  $\text{Met}_{\text{bulk}}$  anodes are used in a single electrolysis cell, bimetallic nanocolloids (Pd/Ni, Fe/Co, and Fe/Ni) are obtained.<sup>[49]</sup> Metals such as Pt, Rh, Ru, and Mo, which are anodically less readily soluble, have been prepared using the corresponding metal salts that were electrochemically reduced at the cathode (Table 3).

**Table 3** Electrochemical colloid synthesis

Metal salt	<i>d</i> (nm)	EA <sup>a</sup>
PtCl <sub>2</sub>	2.5 <sup>b</sup>	51.21% Pt

<sup>a</sup>Based on stabilizer-containing material.

<sup>b</sup>Current density: 5.00 mA cm<sup>-2</sup>.

<sup>c</sup>Current density: 0.05 mA cm<sup>-2</sup>.

<sup>d</sup>Pt–Ru dimetallic cluster.

Nanocolloids with layered bimetallics (e.g., Pt/Pd) have been synthesized by modifying the electrochemical method.<sup>[45,52]</sup> It has been recently reported that preparation of bimetallic colloids electrochemically uses a new strategy based on the use of a preformed colloid, e.g.,  $(\text{n-C}_8\text{H}_{17})_4\text{N}^+\text{Br}^-$  stabilized Pt particles and a sacrificial anode, e.g., Pd sheet<sup>[53]</sup> (Fig. 7).

The preformed Pt core may be regarded as a “living metal polymer” on which the Pd atoms are deposited to give “onion-type” bimetallic nanoparticles (5 nm) the structure of which has been characterized by a combination of analytical methods.

**Fig. 7** Modified electrolysis cell for the preparation of layered bimetallic Pt/Pd nanocolloids. *Source:* Adapted from Ref.<sup>[45]</sup>.

## Decomposition of Low-Valent Transition Metal Complexes

Decomposition of low-valent organometallic complexes and several organic derivatives of the transition metals generate short-lived nucleation particles of zerovalent metals. As an example, thermolysis<sup>[153–160]</sup> of cobalt carbonyl leads to rapid decomposition to give colloidal cobalt in organic solutions.<sup>[153,154]</sup> Colloidal Pd, Pt, and bimetallic Pd/Cu nanoparticles have been obtained by thermolysis of labile precious metal salts in the absence of stabilizers.<sup>[155]</sup> These results were improved when the thermolysis was performed in the presence of stabilizing polymers, such as PVP.<sup>[156]</sup>

Microwave heating in a simple household oven was recently used to prepare nanosized metal particles and colloids.<sup>[157–160]</sup> Recent work by Boxall et al. demonstrated the applicability of this technique to fuel cell catalyst preparation.<sup>[159,160]</sup> Through the use of microwave heating of an organometallic precursor, which contains both Pt and Ru, PtRu/Vulcan nanocomposites have been prepared, which consist of PtRu alloy nanoparticles highly dispersed on a powdered carbon support.<sup>[159]</sup> Two types of these nanocomposites containing 16 and 50 wt.% metal with alloy nanoparticles of 3.4 and 5.4 nm, respectively, are formed with only 100 or 300 sec of microwave heating time. The 50 wt.% supported nanocomposite has demonstrated fuel cell anode activity superior to that of a 60 wt.% commercial catalyst in preliminary measurements.

The energy induced in the sonochemical decomposition of metal salts and organometallic complexes<sup>[161–166]</sup> is produced by the formation, growth, and implosive collapse of bubbles in a liquid. Sonochemical preparations have been successfully developed by Suslick et al.<sup>[161]</sup> and Gedanken et al.<sup>[162–164]</sup> With this method Fe, Mo<sub>2</sub>C, Ni, Pd, and Ag nanoparticles in various stabilizing environments have been prepared, and size control has been observed in the case of Pd nanoparticles immobilized on alumina.<sup>[165]</sup>

The growth of very clean colloidal metals has been achieved by the photolysis of organometallics and metal salts.<sup>[112,167–171]</sup> Henglein et al.<sup>[172–180]</sup> and Belloni et al.<sup>[181]</sup> have studied the  $\gamma$ -radiolytic decomposition of metal ions to give nanostructured metal colloids. Although there are many studies aimed at synthesizing mono- and bimetallic systems,<sup>[173,176,179,182]</sup> there is serious drawback in that nanostructured colloids cannot be obtained on a preparative scale.

Upon the addition of CO or H<sub>2</sub> in the presence of appropriate stabilizers, multigram amounts of the isolable products can be obtained by controlled chemical decomposition of zerovalent transition metal complexes.<sup>[183–190]</sup> The growth of metallic Ru particles from Ru(COT)(COD) (COT = cyclooctatetraene,

COD = cycloocta-1,5-diene) with low-pressure dihydrogen was first reported by Ciardelli and Perticci.<sup>[183]</sup> Bradley et al. and Chaudret et al.<sup>[101–104,184–190]</sup> have demonstrated the use of low-valent transition metal olefin complexes as a very clean source for the preparation of nanostructured mono- and bimetallic colloids.

Organometallic complexes of the type [M(dba)<sub>2</sub>] (dba = dibenzylidene acetone, M = Pt, Pd) decompose under low carbon monoxide pressure in the presence of PVP to give nanosized colloidal Pt or Pd particles with a FCC structure. Remarkably, the surface of the resulting particles undergoes no measurable interaction with the stabilizing polymer or with the solvent. Nanoparticles of Ru, Au, and Cu were obtained analogously from Ru(COT)(COD), (THT)AuCl (THT = tetrahydrothiophene), and (C<sub>5</sub>H<sub>5</sub>)Cu(Bu<sup>4</sup>NC). Colloidal molybdenum, silver and bimetallic Cu/Pd colloids were also reported where a polymer matrix of PVP, dimethylphenylene oxide (PPO), or nitrocellulose (NC) was used as the stabilizing agent.<sup>[101,102,183,188–190]</sup> Chaudret and Bradley have described ligand-influenced platinum and palladium nanoparticles when stabilized by carbonyl and phosphines.<sup>[103,104]</sup> The hydrogenolysis of zerovalent organometallic olefin complexes has been established in the literature as a very clean and elegant method, e.g., for the manufacture of monometallic colloids via the decomposition of Fe(COT)<sub>2</sub>, Ru(COT)(COD), Co(C<sub>8</sub>H<sub>13</sub>)(COD) (C<sub>8</sub>H<sub>13</sub> =  $\eta^3$ -cyclooctenyl), and Ni(COD)<sub>2</sub> under H<sub>2</sub>. The hydrogenolysis method has been used to obtain a number of nanostructured Au, Pd, Pt colloids and of bimetallic systems (Pt/Ru, Pt/Co, and Cu/Pd) in a polymer matrix.<sup>[184–186]</sup> Ultrafine cobalt particles have been obtained by the hydrogenolytic decomposition of Co( $\eta^3$ -C<sub>8</sub>H<sub>13</sub>)( $\eta^4$ -C<sub>8</sub>H<sub>12</sub>) in the presence of polyphenylphenyleneoxide to give particles of 4.2-nm size. When the same procedure was performed with PVP, the size of the resulting particles was 1.4 nm. These results indicate that a close relationship exists between the synthesis conditions and the structure of the resulting particles.<sup>[187]</sup>

## APPLICATION IN FUEL CELL CATALYSIS

This section focuses on recent catalyst developments in phosphoric acid fuel cells (PAFCs), proton exchange membrane fuel cells (PEMFCs), and the previously mentioned DMFCs. A PAFC uses orthophosphoric acid as the electrolyte with the operating temperature between 160° and 220°C; the anode catalyst is Pt and the cathode can be, e.g., Pt/Cr/Co.<sup>[37,191–194]</sup> A trimetallic colloidal precursor of the composition Pt<sub>50</sub>Co<sub>30</sub>Cr<sub>20</sub> (size 3.8 nm) was prepared for this purpose by the coreduction of corresponding metal salts.<sup>[195–197]</sup>

From XRD measurements, an ordered FCT structure attributed to the alloyed trimetallic particle was evidenced. The electrocatalytic performance was compared with an industrial standard catalyst (trimetallic crystallites of 5.7-nm size) manufactured by coprecipitation and subsequent annealing to 900°C in a standard half cell. The advantage of the trimetallic colloid catalysts lies in their improved durability, which is essential for PAFC applications. After 22 hr, the potential had decayed by less than 10 mV.<sup>[198]</sup>

In a PEMFC, a solid proton-conducting polymer is used as the electrolyte and operated between 50° and 125°C. The cathode catalysts are based on Pt alone, but because of the required tolerance to CO, a combination of Pt and Ru is preferred for the anode.<sup>[31–36]</sup> Colloidal Pt/Ru catalysts are currently under broad investigation for low-temperature (80°C) polymer membrane fuel cells (PEMFCs). These have also been proposed for use in DMFCs or PEMFCs, where the feed is CO-contaminated hydrogen produced in on-board methanol reformers. The ultimate dispersion state of the metals is essential for CO-tolerant PEMFC, and alloyed Pt/Ru colloid particles of less than 2-nm size seem to fit these requirements.<sup>[22,23,25,31,33,199–202]</sup> Alternatively, bimetallic Pt/Ru PEM catalysts have been developed for the same purpose, where non-alloyed Pt nanoparticles <2 nm and Ru particles <1 nm are dispersed on the carbon support.<sup>[33]</sup> It can be concluded from the results that a Pt/Ru interface is essential for the CO tolerance of the catalyst regardless of their alloying. For the manufacture of DMFC catalysts, in contrast, Pt/Ru nanopowders of 3- to 5-nm size or thin films are used as precursors.<sup>[34–36]</sup> For the electrocatalytic methanol oxidation, a Pt metal or a Pt metal alloy catalyst has been developed where a Ru phthalocyanine complex is added as a dopant to reinforce the catalytic effect substantially.<sup>[197]</sup> The electrocatalytic activity of this was compared with that of a bimetallic Pt<sub>50</sub>/Ru<sub>50</sub>-N(Oct)<sub>4</sub>Cl colloid prepared by the salt coreduction method.<sup>[1,5–8]</sup> Alloyed state of the particles was verified by point-resolved energy dispersive X-ray (EDX) analysis, while from high-resolution transmission electron microscopy (HRTEM), the mean particle diameter was 1.7 nm.

A new method for the preparation and characterization of Pt–Ru alloy colloids, which are suitable as precursors for fuel cell catalysts, has been reported.<sup>[111]</sup> This method uses an organometallic compound both for reduction and as colloid stabilizer, leading to a Pt/Ru colloid with lipophilic surfactant stabilizers that can easily be modified to demonstrate hydrophilic properties. Reactive annealing in O<sub>2</sub> and H<sub>2</sub> ensures surfactant shell removal before electrochemical measurements. This colloid had nearly identical electrocatalytic activity to several other recently developed

Pt/Ru colloids as well as commercially available Pt/Ru catalysts. This demonstrates the potential for the development of colloid precursors for bimetallic catalysts especially when considering the ease of manipulating the alloy composition using these methods.

Recently, X-ray absorption near edge structure spectroscopy (XANES) has been used to examine Pt/Ru alloy catalysts.<sup>[111,203]</sup> An industrial (DMFC) alloy catalyst black and a carbon-supported Pt/Ru catalyst were both found to be predominantly in the form of Pt and Ru oxides. These catalysts were reduced to the metallic form upon introduction into an electrochemical cell and brought to the potential region where methanol oxidation occurs. Glassy carbon-supported Pt<sub>50</sub>/Ru<sub>50</sub>-N(Oct)<sub>4</sub>Cl colloids were examined by CO-stripping voltammetry and the data were essentially identical with those found in well-characterized bulk alloy electrodes. In a rotating disk electrode, the activity of the colloid toward the continuous oxidation of 2% CO in H<sub>2</sub> was determined at 25°C in 0.5 M H<sub>2</sub>SO<sub>4</sub>, and the results led to the conclusion that these Pt/Ru colloids are very suitable precursors for high-surface-area fuel cell catalysts.<sup>[25]</sup> In situ XRD via Debye function analysis helped in getting the structural information of the precursor. In addition, the XANES data support the bimetallic character of the particles. In situ XRD revealed the catalytic function of the alloyed Ru in the CO oxidation: surface oxide species, which slowly coalesce to RuO<sub>2</sub> particles, are formed on the Ru surface at 280°C. After re-reduction, the catalyst shows a pure hexagonal close packing (HCP) ruthenium phase and larger platinum-enriched alloy particles.<sup>[203]</sup> Scanning probe microscopy (SPM) has been applied to characterize the real-space morphology of the electrode surfaces of supported nanostructured metal colloids.<sup>[204]</sup> Colloidal Pt<sub>50</sub>/Ru<sub>50</sub> precursors (<2 nm) raise the tolerance to CO, allowing higher CO concentrations in the H<sub>2</sub> feed of a PEMFC without a significant drop in performance.<sup>[23,25]</sup> A selective Pt/Mo oxidation catalyst for the oxidation of H<sub>2</sub> in the presence of CO in fuel cells comprises Pt<sub>x</sub>Mo<sub>y</sub> particles where *x* is 0.5–0.9 and *y* is 0.1–0.5.<sup>[205]</sup> The colloid method was found to be a highly suitable exploratory approach to finding improved formulations for binary and ternary anode electrocatalysts. The metals used include Pt, Ru, W, Mo, and Sn.<sup>[24]</sup> Results of electrochemical measurements demonstrated that the introduction of a transition metal oxide (WO<sub>x</sub>, MoO<sub>x</sub>, VO<sub>x</sub>) leads to an improvement of catalytic activity toward methanol oxidation.<sup>[27]</sup> The combinatorial screening method has successfully been applied to electrocatalysts,<sup>[206]</sup> and it is an obvious step to include colloids in these experiments. As an alternative to the reductive metal colloid synthesis, the so-called “metal oxide concept” was developed, which allows the fabrication of binary and ternary colloidal metal oxides as

electrocatalyst precursors [Eq. (8)].<sup>[207–209]</sup>

Surfactant-stabilized colloidal Pt/RuO<sub>x</sub> (1.5 ± 0.4 nm) was prepared by cohydrolysis of PtCl<sub>4</sub> and RuCl<sub>3</sub> under basic conditions. By varying the stoichiometry of the transition metal salts, the Pt:Ru ratio in the colloids was between 1:4 and 4:1. The corresponding zerovalent metal colloids are obtained by the subsequent application of H<sub>2</sub> to the colloidal Pt/Ru oxides (optionally in the immobilized form). To prepare binary and ternary mixed metal oxides in the colloidal form, additional metals have been included in the “metal oxide concept” [Eq. (8)]. Pt/Ru/WO<sub>x</sub> is regarded as a good precatalyst especially for the application in DMFCs. Main group elements such as Al have been included in multimetallic alloy systems to improve the durability of fuel cell catalysts. Pt<sub>3</sub>AlC<sub>0.5</sub> alloyed with Cr, Mo, or W particles of 4- to 7-nm size has been prepared by sequential precipitation on conductive carbon supports such as highly disperse Vulcan XC72<sup>®</sup>.<sup>[210]</sup> Alternatively, colloidal precursors composed of Pt/Ru/Al allow the manufacture of multimetallic fuel cell catalysts (1–2 nm) having a metal loading of >20%. The three-step catalyst preparation is summarized in Fig. 8.

The organoaluminum route discussed earlier is used to prepare colloidal Pt/Ru/Al precursor. In the absence of stabilizers, the coreduction of organic Pt and Ru salts using Al(CH<sub>3</sub>)<sub>3</sub> gives halogen-free, multimetallic Pt colloids, e.g., Pt<sub>50</sub>Ru<sub>50</sub>/Al (size 1.2 ± 0.3 nm). When the stoichiometric ratio of the metal salts is changed, the ratio of Pt to the second metal in the

colloid can be adjusted. The addition of alcohols or suitable surfactants allows the dispersivity of the colloidal precursor in organic media or water to be tailored without affecting the particle size. In the second step, the Pt/Ru/Al colloid is adsorbed on high-surface-area carbon by treatment at 40°C for 24 hr. In the third step (conditioning) the dried Pt/Ru/Al Vulcan catalyst powders are exposed to O<sub>2</sub> and H<sub>2</sub> for 30 min each at 250–300°C to remove the surfactants completely. The particle size of the Pt/Ru/Al colloid adsorbed on the support was found to be virtually untouched (1.3 ± 0.4 nm), and after the thermal treatment only a moderate growth was determined (1.5 ± 0.4 nm). The aluminum was found to be present on the Pt/Ru surface in an oxidized form. This accounts for the size stabilization observed in the Pt/Ru particles and for the improved durability of the resulting electrocatalysts. Based on combustion method,<sup>[211]</sup> Colomer et al. have recently obtained Pt/Ru/Al and Pt/Ru/La precursors. The structure of these novel precursors has recently been analyzed by XAS and it showed that Pt(0) clusters are associated with Al oxide.<sup>[212]</sup> Recently, a fuel cell for generating electric power from a liquid organic fuel (“synfuel”) was described. It comprised a solid electrolyte membrane directly supporting the anode and cathode layers, containing 7–10% Pt and Ru, 70–80% of perfluorovinyl ether sulfonic acid, and 15–20% polytetrafluoroethylene.<sup>[202]</sup> Since 2000, there has been a tremendous input into the production of electrocatalysts with enhanced performance.<sup>[213–216]</sup> The goal here is to produce a better-performing catalyst in terms of their CO tolerance and its long-time durability under the fuel cell conditions. The creation of a potential

**Fig. 8** Scheme of the preparation of colloidal Pt/Ru/Al PEMFC anode catalyst (>20% metal on Vulcan XC72) via the “precursor concept.” Source: Adapted from Ref.<sup>[199]</sup>.

anode is quite advanced and there are a number of catalyst systems generated for this purpose. A concerted effort in generating an efficient cathode will continue, as there is still room for generating a better-efficiency cathode.

## CONCLUSION

Nanostructured metal colloids are promising precursors for manufacturing multimetallic fuel cell catalyst precursors that are truly nanosized. The advantages of using the "precursor concept" in generating colloidal metal catalysts has been highlighted. A survey of wet chemical preparation methods with emphasis on preparing fuel cell catalysts has been discussed. It remains to be seen how this research will meet the environmental and industrial requirements in the next few years.

## INTRODUCTION

Apart from some specific applications related to microfluidics and targeted delivery where functionalized and freely moving nanocolloids are suited, nanoparticles mostly enter nanostructured materials as one-, two-, or three-dimensional networks, either grown (or embedded) at a solid–solid, solid–fluid, or fluid–fluid interface.<sup>[1–5]</sup> As in many natural and technological processes and phenomena, this brings the basic question on the role of the underlying substrate properties on the spatial organization and stability of the nanoparticle network. The answer to this question at least partly depends on the methodology used to create the nanoparticle patterns. The following discussion mainly deals with some of the basic features related to nanoparticle assemblies that may result from the adsorption and drying of nanocolloidal suspensions onto a substrate. In addition to the elaboration of well-ordered, two-dimensional nanoparticles arrays,<sup>[6]</sup> applications and phenomena related to nanocolloidal dispersions nearly concern all domains and materials, ranging from inorganic,<sup>[2–4,7]</sup> to polymers<sup>[1]</sup> and biological objects.<sup>[8]</sup> For these nanocolloidal suspensions, the evaporation of the solvent may either result in random and featureless aggregates<sup>[4]</sup> or lead to the formation of well-ordered complex fractal or dendrites structures<sup>[7,8]</sup> of nanosize particles on the substrate (Fig. 1A–B). For some of these drying patterns, the mechanisms and interface phenomena that drive the aggregation and ultimately determine their fascinating topological features (order, fractality, symmetry) still remain insufficiently understood. Comprehension of the underlying mechanisms and critical parameters governing the emergence and topological features of these nanocolloid drying patterns is thus fundamental for both biocolloid applications and the controlled elaboration of fractal surface networks that are increasingly used by engineers to model flow and percolation in complex media.<sup>[9]</sup>

Even on an ideal substrate, pattern formation in drying nanocolloids suspensions is a rather complex

process, involving the whole range of interface phenomena (wetting dynamics, adsorption, adhesion). This complexity essentially arises from the strong time dependence of both the internal flow (particle diffusion) and competing interparticle and particle–substrate interactions through the solvent, which govern the particle aggregation, especially in low-to-semidilute suspensions. This, of course, is less the case for highly concentrated suspensions that are already close to their gelation point at drop deposition. For these gel-like suspensions, it is the extraction kinetic of the residual (interstitial) solvent and the very short-range repulsive interactions, rather than the interparticle and particle–substrate interactions, that dominates the final morphology (porosity) and mechanical properties of the particle network, as observed for solvent-based synthesis of ceramic and zeolite films.<sup>[10–12]</sup> As opposed to these dense and relatively “thick” gel particle networks, the drying of low- to semiconcentrated nanocolloid dispersions rather form open aggregates of lower surface coverage  $\Gamma_s$  and fractal dimension  $D \leq d_{\text{space}}$ . It is these structures that are strongly sensitive and critically determined by the drying kinetics and the above-mentioned competitive interparticle and particle–substrate interactions that constitute the main focus of the following discussion. One can produce nanoparticle assemblies (well-ordered arrays, open aggregates, or thick deposits) from colloidal suspensions, either by deep coating or by drying deposited drops or films. In both cases, the final morphology of the assembly is strongly determined by the surface properties of the underlying substrate, which control the extent of the surface coverage, the particle–substrate adhesion, and henceforth, the whole late-stage drying events. These involve the contact line pinning vs. slip, the often-observed thick particle deposit at the drop edge,<sup>[13–16]</sup> the hydrodynamic flow and related shear at the substrate–suspension interface, and the possible formation and rupture of a residual film. A complete understanding of these structure formations thus requires both the use of model surfaces and the simultaneous investigations and correlation between the aggregation patterns forming in

**Fig. 1** (A)  $15 \times 15 \mu\text{m}$  height scans of adsorbed  $\alpha\text{-Al}_2\text{O}_3$  colloids for contact time  $t_c$  of 600 sec. deep-coating adsorption, and may also develop to some extent in evaporating drops, and serve as sub-layer to the arising patterns. Therefore, we will successively discuss and relate these *adsorption and drying nanocolloidal patterns*, highlighting the *critical role of the surface and the potential its functionalization offers toward the elaboration of nanocolloidal patterns of well-defined morphology*. But first, we will start with the section “Materials,” which briefly describes the elaboration and main characteristics of both the model molecular surfaces and nanocolloidal gold particles used herein.

## MATERIALS

An ensemble of three model homogeneous and two heterogeneous binary surfaces, consisting of self-assembled organosilane molecular films onto rigid silicon wafers, were used. The organosilane compounds composing the molecular films were 1) hexadecyltrichlorosilane (hydrophobic compound referred to as  $\text{CH}_3$ ), 2) amine terminated, 6-aminopropyltrimethoxysilane (hydrophilic electron acceptor compound referred to as  $\text{NH}_2$ ), and 3) nitrogen dioxide terminated 3-(2,4-dinitrophenylamino)propyltriethoxysilane (hydrophilic electron donor compound referred to as  $\phi\text{-NO}_2$ ). The homogeneous molecular films were obtained by vapor-phase adsorption<sup>[17]</sup> of the silanes onto clean silanol-enriched silicon wafers ( $\text{SiO}_x\text{H}$ ), in a dynamically evacuated chamber (40 min at  $5 \times 10^{-3}$  Torr). The binary heterogeneous surfaces were sequentially elaborated, based on the time control of the early-stage nucleation and domain growth mechanisms already known for solvent-coated organosilanes films.<sup>[18]</sup> The nanodomains were first realized by immersing the virgin silicon wafers in millimolar (1 mM) solutions of either the  $\text{CH}_3$  terminated compound in carbon-tetrachloride ( $20^\circ\text{C}$ , for 1 min), or  $\text{NH}_2$  terminated compound in ethanol ( $20^\circ\text{C}$ , for 6 min). The complete

heterogeneous binary molecular surfaces were obtained by assembling, in the remaining room of the silicon substrate, a continuous monolayer of the  $\text{NH}_2$  terminated compound around the  $\text{CH}_3$  nanodomains (and vice versa), via vapor-phase deposition technique.<sup>[17]</sup> The compositional (chemical) and topographical heterogeneities of the binary surfaces were characterized by X-ray photoelectron spectroscopy (XPS), contact angle, and atomic force microscopy (AFM) analyses. Typical structures of these nanoscale heterogeneous surfaces, as revealed by AFM in both height and phase contrast modes, are shown in panels

**Fig. 2** Height and phase AFM images of the binary heterogeneous molecular films: (A) and (B)  $\text{CH}_3\text{-NH}_2$  surfaces; (C) and (D),  $\text{NH}_2\text{-CH}_3$  surfaces. In both (A)–(B) and (C)–(D) panels, the lighter patches correspond to  $\text{CH}_3$  domains (in  $\text{NH}_2$  continuum) and  $\text{NH}_2$  domains (in  $\text{CH}_3$  continuum), respectively.

**Table 1** Wetting properties of the model molecular surfaces

Substrates	Contact angles $\theta$ of water drops ( $\pm 2^\circ$ )			
	Equilibrium $\theta_e$	Static advancing $\theta_a$	Static receding $\theta_r$	Hysteresis ( $\theta_a - \theta_r$ )
CH <sub>3</sub>	105	112	103	9
NH <sub>2</sub>	45	60	20	40
$\phi$ -NO <sub>2</sub>	50	64.5	25	39.5
CH <sub>3</sub> -NH <sub>2</sub>	66	85	59	26
NH <sub>2</sub> -CH <sub>3</sub>	67	86	51	35

(A)–(B) of Fig. 2 for the heterogeneous substrate composed of CH<sub>3</sub> domains in NH<sub>2</sub> continuum (referred to as CH<sub>3</sub>-NH<sub>2</sub>), and in panel (C)–(D) for NH<sub>2</sub> domains in CH<sub>3</sub> continuum (referred to as NH<sub>2</sub>-CH<sub>3</sub>). The wetting properties of the different substrates, including equilibrium, static advancing, and static receding contact angles against water drops are reported below in Table 1.

As in most of the current investigations dealing with the formation and functional properties of nanosize metal particles, this discussion is deliberately confined to aqueous nanocolloidal gold suspensions that are becoming a “standard,” both for their immense technological significance and their relatively easy synthesis. These colloidal suspensions are commonly synthesized using tetrachloroauric(III)-acid hydrate [HAuCl<sub>4</sub>] · H<sub>2</sub>O, a crystalline powder. Tetrachloroauric(III)-acid hydrate is dispersed by vigorous stirring in water, and stabilized by adding citric acid trisodium salt dihydrate C<sub>6</sub>H<sub>5</sub>Na<sub>3</sub>O<sub>7</sub> · 2H<sub>2</sub>O. The reduction of HAuCl<sub>4</sub> by trisodium citrates molecules in the aqueous phase leads to stabilized Au nanoparticles bearing the negative charge of the citrate ions.<sup>[2,19]</sup> Four nominal (here, meaning initial) concentrations of nanocolloidal suspensions of particle size  $d_p = 30 \pm 5$  nm, referred to as “30 nm susp,” were prepared in this manner.<sup>[17,20]</sup> A smaller particle size suspension,  $d_p = 10 \pm 3$  nm, referred to as “10 nm susp” was also prepared following the same general procedure, supplemented in this case by the addition, under stirring, of an aqueous solution of NaBH<sub>4</sub> to enhance the dispersion toward smaller particle size.<sup>[2,19,20]</sup> The nominal characteristics of these suspensions and their wetting parameters on

the model surfaces are reported in Tables 2 and 3, respectively.

## ADSORPTION PATTERNS

Here the main issue is addressed as follows. How the lateral ordering, topology, and characteristic length scales of a two- or three-dimensional assembly of nanoparticles are, or can be, controlled by the physical and chemical properties of the underlying substrate, when these particles are allowed to “freely” adsorb from a colloidal suspension onto these substrates? Are model hydrophobic and hydrophilic surfaces, such as electron donating-accepting surfaces, and their structuring in antagonistic binary hydrophobic/hydrophilic domains, capable of tuning the binding, coverage, and lateral organization of the Au nanoparticles during adsorption? To answer these questions, the model substrates were simply immersed for different times in the suspension bath, at 21°C. After this adsorption step, the samples were taken from the bath and washed off with pure water to remove the remaining thick dispersion film that is drawn from the bath. The thin water film, which may result from this washing step (depending on the substrate’s wetting property), is then allowed to dry in ambient conditions [21°C, 30% relative humidity (RH)], and the samples characterized for the lateral ordering of the adsorbed and self-organized nanoparticles arrays. The AFM pictures of Fig. 3A–E represent the typical adsorption patterns obtained on the different substrates, after 1 hr immersion in the reference “30 nm susp” of volume fraction  $\phi_{ref} = 1.5 \times 10^{-5}$ . For CH<sub>3</sub>,  $\phi$ -NO<sub>2</sub>, and NH<sub>2</sub>, the extent of the surface coverage during the deep coating is readily accounted for by classical surface thermodynamics, based on the balance of the intermolecular forces involved in these adsorption processes. Neglecting gravity-driven precipitation, the adsorption at the hydrophobic substrate solely arises from the low-magnitude CH<sub>3</sub>-particle interactions, which mainly involves the long-range London-van der Waals dispersion forces (vdW). Thus the very low coverage of CH<sub>3</sub> substrates (Fig. 3A) simply arises from the unfavorable competition between the higher

**Table 2** Nominal characteristics of the investigated nanocolloidal gold suspensions

	Particle size (nm)	Nominal concentration		Nominal pH
		Wt. %	Volume fraction $\phi$	
Reference <sup>a</sup> “30 nm susp”	30 ± 5	0.03	$1.5 \times 10^{-5}$	~6.5
“10 nm susp”	10 ± 3	0.01	$5 \times 10^{-6}$	~6.5

<sup>a</sup>“10 nm susp” refers to the smaller particle size suspension,  $d = 10$  nm.

<sup>a</sup>Reference “30 nm susp” refers to the suspension of particle size and volume fraction of  $d = 30 \pm 5$  nm and  $\phi_{ref} = 1.5 \times 10^{-5}$ , respectively. Three other concentrations, prepared from this reference “30 nm susp” were investigated: 1)  $\phi = 10^{-2}\phi_{ref}$ ; 2)  $\phi = 0.1 \times \phi_{ref}$ ; and 3)  $\phi = 5\phi_{ref}$ .

**Table 3** Equilibrium and receding wetting parameters of the reference “30 nm susp” drop on the different model substrates, measured at 20°C and 30% relative humidity (RH), using 8  $\mu\text{L}$  drops (the one hereafter used for drying experiments)

Model molecular surfaces	$\text{CH}_3$	$\text{NH}_2$	$\phi\text{-NO}_2$	$\text{CH}_3\text{-NH}_2$	$\text{NH}_2\text{-CH}_3$
Equilibrium contact angle ( $^\circ$ )	101	5	57	85	85
Contact diameter $2R$ (mm)	$\sim 2$	10	4	$\sim 3$	$\sim 3$
Receding contact angle ( $^\circ$ )	$\sim 90$	$\sim 0$	$\sim 15$	—	—

solvent retention (higher solvent–particle interaction) and the low-magnitude vdW particle–substrate ones. In addition, the washing step that follows the deep coating also contributes to draw away loosely attached particles. On the other hand, a highly packed and cohesive array, mainly composed of single Au nanoparticles, is formed onto the hydrophilic and electron-accepting amine terminated  $\text{NH}_2$  substrate (Fig. 3B). The formation of the dense particle arrays here is driven by the strong specific particle–surface interactions involved in this system. At  $\text{NH}_2$  terminated surfaces that can protonate ( $\text{NH}_3^+$ ) in the aqueous suspension during adsorption, the negatively charged gold particles  $[\text{Au}(\text{citrate})_{\text{ads}}^-]$  can either bind to the substrate via hydrogen bonds (H-b) or electrostatic interactions. At ambient temperature (298 K), the strength of these specific interactions lies between 10 kT per bond, for electron donor–acceptor and H-bonds such as in  $[\text{Au}(\text{citrate})_{\text{ads}}^- \text{H}_2\text{N}]$ , and 200 kT per bond for interactions, such as in the ionic structure  $[\text{Au}(\text{citrate})_{\text{ads}}^- \text{H}_3^+\text{N}]$ . These bonds are much stronger than  $\sim 1$  kT/bond of the vdW forces involved in  $\text{CH}_3$  substrate–particle interactions. As a result, one thus expects both the strength of the particle–substrate attachment as well as the rate and extent of the surface coverage to be of higher magnitude at  $\text{NH}_2$  substrates. This extent of surface coverage  $\Gamma$  is finally well

accounted for by the Gibbs equation  $\Gamma \sim sC_{\text{vi}} \exp(-\Delta F/kT)$ , where  $s$  and  $C_{\text{vi}}$  are the particle size and concentration at the interface and  $\Delta F$  is the free energy of adsorption. Assuming the entropy loss,  $-T\Delta S$ , for the adsorbed particles (clusters) to be comparable at both substrates, it is essentially the energy term,  $\Delta U = (U_{\text{ads}} - U_{\text{sol}})$ , that drives the adsorption amount at equilibrium, as discussed above. This naturally applies to the hydrophilic electron-donating  $\phi\text{-NO}_2$  substrate (Fig. 3C), where one may even expect  $\Delta U$  to be  $> 0$  (or, at least,  $\sim 0$ ), because of the repulsive electrostatic interactions between the identically charged gold particles and electron-donating  $\phi\text{-NO}_2$  surface groups. Of particular interest is the strong cohesion and stability of the nanogold particle assemblies formed at the amine terminated substrate that remains unchanged, at the same AFM observation scale, after  $\sim 30$  sec sonication in water. Although heterogeneous substrates present comparable surface fraction<sup>[21]</sup> of the two molecular phases and wetting properties (Tables 1 and 3), the adsorption structures formed at these substrates are significantly different in both their coverage and aggregation topology. As for homogenous substrates, the adsorption pattern at the binary  $\text{NH}_2\text{-CH}_3$  surface (Fig. 3D) is dominated by the intermolecular forces and related adsorption thermodynamics. This leads to an aggregation pattern

**Fig. 3** AFM images represent the adsorption patterns obtained after 1-hr immersion in the “30 nm susp” on the homogeneous (A)  $\text{CH}_3$ , (B)  $\text{NH}_2$ , (C)  $\phi\text{-NO}_2$  substrates, and binary heterogeneous (D)  $\text{NH}_2\text{-CH}_3$  and (E)  $\text{CH}_3\text{-NH}_2$  substrates. The growth mechanism of the interconnected network [panel (E)] is sketched out in (F). Here the reorganization of the particles arise from both the specific surface structure and the balance between shear and resisting adhesion forces,  $\tau a_c > \mu F_{\text{adh}}$ , that drive the collection of the particles ( $a_c$  and  $\mu$  being the particle/substrate contact area and friction coefficient, respectively).

similar (although less dense) to the one formed on  $\text{NH}_2$  substrates. On the other hand, a more complex pattern, not easily predictable from the above thermodynamic considerations, is observed at the heterogeneous  $\text{CH}_3\text{-NH}_2$  (Fig. 3E). Furthermore, there is no trivial length-scale correlation between the emerging adsorption patterns and the nanoscale organization of the antagonistic molecular domains at the underlying heterogeneous substrates, as one could expect, for instance, from simple size matching and selective adsorption at the  $\text{NH}_2\text{-CH}_3$  substrate. Thus it seems that neither the macroscopic surface properties, which are comparable for both  $\text{NH}_2\text{-CH}_3$  and  $\text{CH}_3\text{-NH}_2$  (Tables 1 and 3), nor the discrete organization of the domain phases can independently account for the emergence and topological features of nanocolloidal adsorption patterns at these nanoscale heterogeneous substrates. As sketched out in Fig. 3F, it is the late-stage drying of the residual film, either drawn from the immersion bath or left behind by the washing step, that definitely determines the topology of these adsorption patterns, especially the interconnected network observed at the heterogeneous  $\text{CH}_3\text{-NH}_2$  substrate. This is particularly the case when an adsorbed sublayer particle array exists, to which the drying of the residual film (dewetting, drainage) can be correlated to some extent. This was shown to be the case for the heterogeneous  $\text{CH}_3\text{-NH}_2$  by a closer (nanoscale) observation of the intersegments space,<sup>[17]</sup> contrary to the low coverage  $\text{CH}_3$ ,  $\phi\text{-NO}_2$ , and  $\text{NH}_2\text{-CH}_3$  substrates. Fig. 3F describes the three steps involved in this possible mechanism of formation of the segments network: the late-stage dewetting (rupture) of the drying film, the collection of loosely adsorbed particles in the moving rims around the opening holes, and the formation of the interconnected segments by conjoining rims that are stable against Rayleigh instabilities.<sup>[22]</sup> Finally, these results show that two parameters, both related to the surface properties of the substrate, can structure the aggregation pattern arising from the adsorption of nanosize particles from a colloidal suspension. On smooth and homogenous substrates, it is the macroscopic surface properties (surface energy, intermolecular forces, wetting) that predominate, at both length scales the final pattern. On the other hand, this pattern is determined on substrates which are heterogeneous at the nanoscale by the organization of the heterogeneities that strongly couple with the late-stage dewetting, thus causing redistribution and reorganization of particles at the substrate.

## DRYING PATTERNS

The drying of suspension drops, and in particular, the growth mechanisms of the often-observed thick

peripheral particle deposits (rings) have been extensively addressed in the literature.<sup>[13–16]</sup> Such particle rings were shown to arise as a result of the pinning of the contact line and the outward solvent (and particles) flow that is driven by the evaporation gradient along the drop radius, as illustrated in Fig. 4.<sup>[23]</sup> On the other hand, the dependence of these drying patterns on the structural properties of the underlying substrates, and more specifically, those involving nanosize colloidal particles have received considerably less attention. As shown in the central region of the drying drop in Fig. 4, micronsized particles can already form structures that are significantly different from the peripheral rings, even at non-attaching (adsorbing) substrates. In drying nanocolloidal suspensions, large-scale patterns of much higher complexity can form,<sup>[4,8,24]</sup> because of the stronger coupling between the late-stage dewetting and the time evolution of the suspension bulk properties,<sup>[24]</sup> which are here amplified by size effects: high number of particles in the drop for comparable volume fraction, low hydrodynamic radius and inertia, and high diffusion. The present section is focused on the discussion of large-scale complex patterns emerging in drying nano-colloidal suspensions, with a special emphasis on the underlying mechanisms and critical parameters governing both their formation and topological features.

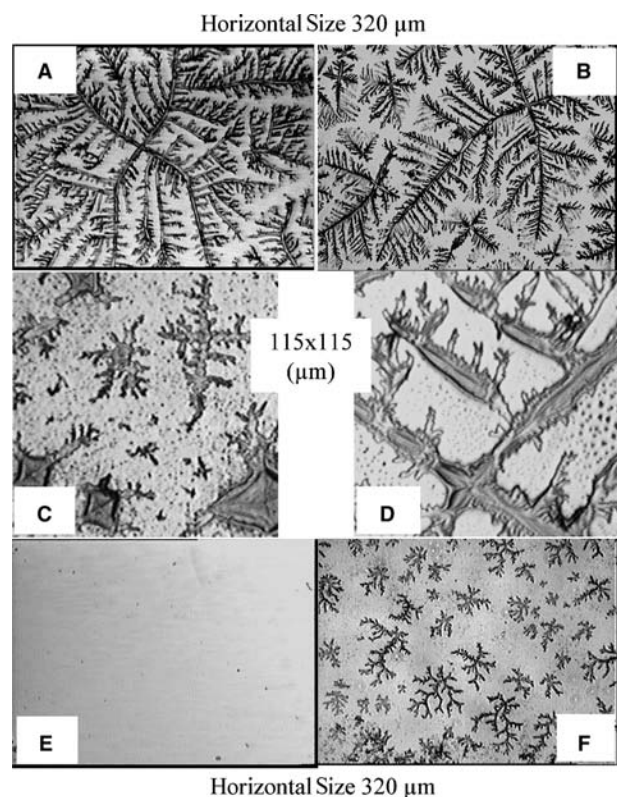

The experiments were generally performed (unless otherwise specified) by depositing 8  $\mu\text{L}$  drop of suspension on the substrates, and drying under ambient conditions (21°C, 33% RH). The drying kinetics was observed and recorded by using an optical microscope equipped with a video-camera device. Under these conditions, the evaporation rate  $v_e$  and time scale at complete evaporation  $t_e$  of the reference “30 nm susp” drop ( $d_p = 30 \text{ nm}$ ,  $\phi_{\text{ref}} = 1.5 \times 10^{-5}$ ), as measured by weighing its mass on a microbalance, were found to be  $\sim 3 \mu\text{g}/\text{sec}$  and  $\sim 30 \text{ min}$ , respectively, in  $\text{NH}_2$  and  $\phi\text{-NO}_2$  substrates.

Fig. 5 shows the most relevant results obtained for the three volume fractions of the “30 nm susp”

**Fig. 4** Evaporation of a micronsized (3  $\mu\text{m}$ ) polystyrene suspension drop on a nonwetting substrate, showing both the peripheral aggregation and the late-stage dewetting structure in the center of drying spot. *Source:* From Ref.<sup>[23]</sup>, unpublished result.

**Fig. 5** Drying patterns of “30 nm susp” drops formed at the virgin (A)  $\text{NH}_2$ , (B)  $\phi\text{-NO}_2$ , (C)  $\text{NH}_2\text{-CH}_3$ , and (D)  $\text{CH}_3\text{-NH}_2$  substrates using  $8\ \mu\text{L}$  of the reference volume fraction  $\phi_{\text{ref}} = 1.5 \times 10^{-5}$ , (E) at the virgin  $\text{NH}_2$  substrate using  $8\ \mu\text{L}$  of volume fractions  $\phi = 10^{-2}$  to  $0.1\phi_{\text{ref}}$ , and (f) using  $40\ \mu\text{L}$  of volume fraction  $\phi = 0.1\phi_{\text{ref}}$ .

(Table 2) at the virgin model substrates. At hydrophobic  $\text{CH}_3$  substrates (not represented here), only a thick and featureless particle deposit is obtained at the center of the drop at the end of the drying. The absence of structured pattern on this substrate was somehow predictable because of the high contact angle and the too-low contact area of the suspension drop. In this case, both the nonwetting solvent and nonattaching particles accumulating in the wedge are entrained by the retiring drop, up to the complete line pinning for some critical amount of the peripheral aggregate. This results in a residual gel-like droplet that dries and forms the observed single deposit. Panels (A) and (B), on the other hand, show large-scale and coarse multibranch aggregates, characterized by a main fourfold dendrite-like structure, along which  $\pi/2$ -oriented and bifurcating secondary branches are formed on the hydrophilic wetted  $\text{NH}_2$  and  $\phi\text{-NO}_2$  substrates. The early line pinning resulting from these wetting properties is further increased throughout the evaporation by the outward particles–solvent flow. Nevertheless, because of the low contact angles (reduced wedge volume) and large contact areas

(especially for  $\text{NH}_2$ ), which favor the confinement of the particles in the center of the drop and impede their convective migration, substantially less peripheral deposits are formed in these cases. It is this particular distribution of particles and clusters within a rather extended remaining suspension film (as opposed to non-wetting substrates) and the late-stage dewetting process of this film that give rise to the complex structure formation on  $\text{NH}_2$  and  $\phi\text{-NO}_2$ . At the heterogeneous and low wettability substrates (Tables 1 and 3), the aggregation patterns are of lower complexity (Fig. 5C,D) and are mostly composed of coarse fourfold dendrites and pyramidal (“degenerated” dendrites) aggregates. Although they strikingly demonstrate the non-random character and critical dependence of the observed patterns on the surface properties of the underlying substrate, the above results (Fig. 5A–D) involving unique “30 nm susp” drops of nominal volume fraction  $\phi_{\text{ref}} = 1.5 \times 10^{-5}$  cannot account for the influence of the bulk parameters (concentration) in this pattern formation. This influence is illustrated in Fig. 5E, using suspension drops of concentrations  $\phi = 0.1\phi_{\text{ref}}$  (or  $10^{-2}\phi_{\text{ref}}$ ), at the pattern-forming  $\text{NH}_2$  substrate (in the sense of its wetting properties). The absence of pattern in this dilute regime ( $\phi \leq 0.1\phi_{\text{ref}}$ ) and the densification of the emerging aggregates (not shown here, see Ref.<sup>[20]</sup>) at higher concentrations ( $\phi \geq 5\phi_{\text{ref}}$ ) clearly indicate that a nominal volume fraction range exists that allows, through its time evolution, a critical (threshold) volume fraction  $\phi^*$  to be reached, which is required for complex structures to form in the late stage of drying. To obtain further insights regarding the influence of these time-dependent bulk properties (namely the time increase of the volume fraction with the evaporation) on the emergence and morphology of the aggregates, the structural evolution within “30 nm susp” drops of nominal volume fractions  $\phi_{\text{ref}}$  and  $0.1\phi_{\text{ref}}$  was investigated at both pattern-forming  $\text{NH}_2$  and  $\phi\text{-NO}_2$  substrates. As shown in Fig. 6, large-size ( $\sim 50\ \mu\text{m}$ ), interconnected wormlike clusters<sup>[7,24]</sup> are formed in the late stage of the evaporation within the “30 nm susp” drop of volume fraction  $\phi_{\text{ref}}$ , at both pattern-forming substrates. In the low volume fraction drop ( $0.1\phi_{\text{ref}}$ ), only micronsize aggregates, comparable to those formed in the early drying stage of the “30 nm susp” drop of volume fraction  $\phi_{\text{ref}}$ , were observed in the late stage of the drying (Fig. 6C). Thus these results strongly suggest that the emergence of the complex drying patterns requires, in addition to the surface properties of the underlying substrate, that a threshold volume fraction  $\phi^*$ , at which interconnected bulk aggregates appear in the suspension, be reached during the evaporation. One now can reasonably think that these large-size, wormlike bulk clusters actually constitute the initial seeds for the formation of the complex

**Fig. 6** Structural evolution of the drying suspension in the (A) early, (B) medium, and (C) late stages of the evaporation where bulk clusters appear, and (D) phenomenological picture of this structural evolution in terms of the time and spatial variations of the suspension volume fraction  $\phi(R,t) = \phi_t$ , where  $R$  is the radius of the drying drop.

aggregations patterns that develop through the late-stage dewetting of the remaining film and related hydrodynamic effects (see below). We actually brought an indirect evidence of this conjuncture by depositing on the pattern-forming  $\text{NH}_2$  substrate a larger drop volume (40 vs.  $8\ \mu\text{L}$ ) of the “30 nm susp” suspension of concentration  $\phi = 0.1\phi_{\text{ref}}$ , which is subcritical as regards the pattern formation, when deposited at the standard volume of  $8\ \mu\text{L}$ . By doing this, one could restore both the formation of wormlike bulk clusters and complex aggregation patterns on the substrate (Fig. 5F). Basically, this experiment simply amounts to increasing the total number of particles  $n_0$  in the reservoir (drop). If  $v_p$  is the average nanoparticle volume, this total number of particles, which is conserved during the evaporation, is related to the nominal concentration  $\phi$  and initial drop volume  $v_0$  as  $n_0 \sim (\phi v_0 / v_p)$ , from which the time dependence of the evaporating drop volume fraction follows as  $\phi_t = (\phi v_0) v_t^{-1}$ , where  $v_t$  is the actual drop volume at time  $t$ . In the late stage of the drying,  $v_t \ll v_0$ , and the volume fraction  $\phi_t$  of the suspension that remains subcritical for smaller initial drop volumes is now shifted toward the threshold value  $\phi^*$ , where both interconnected bulk clusters and complex aggregation patterns appear on a pattern-forming substrate. And as long as the total number of particles in the drop is below a certain value, the interparticle separation during drying will always lie above length scales (hundreds nm to  $\mu\text{m}$ ), where long-range intermolecular and hydrodynamic forces usually develop and drive particle–particle aggregation. Using a simple scaling, the dependence of this interparticle separation  $d_{\text{pp}}$  on the residual
