Armed with an understanding of the mechanisms responsible for the creation of these hole lattices, we will be able to predict new nanostructures and tune their elastic properties by employing new materials. The first attempt in growing new test structures is to vary the film stress in the Ag layer by adding a second metal that will not phase-separate from the Ag nor absorb into the substrate. It has been shown that monolayer films of Ag and Cu alloy on Ru(0001), although all three metals are immiscible in their bulk form.<sup>[43]</sup> Small amounts of Cu added to the Ag film mix upon deposition at room temperature. After annealing to 500°C, it was observed that the smaller Cu atoms preferentially occupy regions in between the corrugation maxima of the Ag dislocation network. The dispersion of Cu in the Ag film had changed the strain-relief pattern and we can expect that the exposure of this alloy film to sulfur will result in a vacancy island array with different dimensions and elastic properties. Measuring the lattice constant  $b^*$ , the Lamé coefficients  $\mu^*$  and  $\lambda^*$ , and the melting temperature  $T_m^*$  as a function of concentration ratio of Cu to Ag will give insight into the ordering forces that drive self-assembly in these strained metal systems.

A variety of other metals such as Au, Co, and Cu display well-ordered characteristic dislocation network when deposited in the monolayer regime on Ru(0001). We are currently studying their reaction as well as their bimetallic combination with etching agents such as sulfur, oxygen, and hydrogen in the second phase of the experiments. A detailed exploration of the phase diagram will reveal important insight in the ability to tune such nanostructures. In addition, once the feature size and spacing in the array is calibrated, it can be used to measure surface stress in strained metal films, according to Eqs. (1) and (2).

We will use the connection between elastic constants and lattice phonons to discuss self-assembly in nanostructures grown on reconstructed surfaces, such as Au(111) and Pt(111), by depositing metals such as Ag, Cu, Co, Fe, or Ni. These measurements will reveal the balance between the short-ranged atomic forces that stabilize the dislocation cores and the long-ranged elastic interactions between the misfit dislocations that make up the reconstruction of the Au(111) and Pt(111) surface.

## CONCLUSION

We have shown that it is possible to grow self-assembled nano-arrays on strained metal films with large-scale ordering and great size uniformity. In particular, we have identified and measured the ordering

forces of a nearly perfect triangular lattice of nanometer-size vacancy islands which forms when a single atomic layer of Ag on Ru(0001) is exposed to sulfur at room temperature. We applied time-resolved scanning tunneling microscopy (STM) to monitor the thermal fluctuations of the centers-of-mass of the vacancy islands around their final positions in the lattice. From analysis of this island motion, we obtained the elastic constants of the lattice,  $\lambda \approx \mu \approx 0.02\text{--}0.04$  (N/m), which shows that, although weak, the forces responsible for the stability of this two-dimensional island crystal can be confidently measured. Our results are consistent with general theories of strain-mediated interactions between surface defects in strained films.

Future studies of the thermodynamics of these equilibrated two-dimensional nanostructures will lead to a refined understanding of the nature of phase transitions in two dimensions, e.g., surface melting. A variety of two-dimensional nano-arrays in thermal equilibrium of large-scale order and size uniformity will be grown on strained interfaces between a bimetallic atomic layer and a dissimilar substrate in ultrahigh vacuum. Combining the structural information (from unique real-time variable-temperature STM measurements) with quantum-size effects in the electronic structure (from high-resolution UV photoemission) will guide the development of new dynamic models to describe the evolution and properties of nanoscale structures on surfaces.

## ACKNOWLEDGMENTS

I am very grateful to Maria C. Bartelt, Norman C. Bartelt, Juan de la Figuera, Jan Hrbek, and Robert Q. Hwang for their support in the original experiments at Sandia National Laboratories in California.

## INTRODUCTION

Long-chain alkanes [ $\text{CH}_3(\text{CH}_2)_n\text{CH}_3$ ,  $n > 8$ ] and their derivatives such as alkenes, alkanols, ethers, and carboxylic acids physisorb on highly oriented pyrolytic graphite (HOPG) surfaces to form very stable self-assembled monolayers (SAMs). These monolayer structures, with nanometer dimensions, form an entire class of nanoscale objects whose properties are of considerable interest. These nanoscale objects provide important models that are relevant to the understanding of molecular electronic devices, biological recognition chips, tribology, and corrosion inhibition systems. These very interesting nanoscale structures have been extensively studied in recent years.<sup>[1–18]</sup> Unlike the close packed self-assembled monolayer in the alkanethiol/Au(111) system, where the alkane chain stands up from the surface, in the alkane derivative/HOPG SAMs, the alkane chain adsorbs parallel to the graphite basal plane. The alkane molecule adsorbs in an *all-gauche* conformation, which has the lowest energy. In this conformation, the carbon–carbon backbone of the molecule has a zigzag shape. Theoretical and experimental results indicate that in the long-chain alkane self-assembled monolayer on HOPG, the zigzag is parallel to the HOPG basal plane.<sup>[4,6]</sup> Under such packing conditions, the distance between the hydrogens of the neighboring methylene units in the alkane chain is 2.52 Å and the distance between six-fold hollows of HOPG is 2.46 Å. Fig. 1 is a model showing the actual dimensions for an alkane molecule adsorbed on the HOPG surface. This good match between the substrate lattice and the organic molecule adsorbate dimension results in a relatively strong interaction between the substrate and the adsorbate. Such interaction is the basis for formation of a stable monolayer on the HOPG surface. The van der Waals interactions between the long-chain alkane

molecules provide the basis for the self-assembly process.

Sometimes these stable self-assembled monolayers exhibit chirality, or handedness. This can result from the segregation of chiral molecules into chiral domains on the surface, from the distortion of achiral molecules to form an overall chiral structure, or from the pairing or self-assembly within the unit cell to make a chiral structure from an enantiomeric mixture. This entry discusses several examples of self-assembled monolayers formed on HOPG that exhibit chirality. These nanoscaled materials may have interesting applications in chirally selective catalysis and separations, and certainly help us to understand the interactions between molecules and the substrate that govern the self-assembly process. In the following entry, the structures of three separate racemic mixtures of iodine substituted octadecanol and octadecanoic acids adsorbed on the (0001) plane of HOPG are examined. Chiral pairs are formed and the pairs form ordered monolayers, in which different faces of the same molecule are exposed and imaged. These examples illustrate the formation of chiral nanostructured monolayers in this self-assembly process.

## CHIRAL MONOLAYERS

Certain chiral molecules have been observed to spontaneously separate during crystallization in three dimensions, as Louis Pasteur discovered in 1848 for sodium ammonium tartrate. Most racemic mixtures do not spontaneously separate upon crystallization. Lattice structures of these crystals formed by heterochiral enantiomers can be solved by X-ray single crystal diffraction as long as the heterochiral single crystal can be obtained. In the two-dimensional realm, diffraction methods such as grazing incidence X-ray

**Fig. 1** Model of alkane molecule on HOPG. For an alkane molecule adsorbed on HOPG, the alkane zigzag chain is parallel to the basal plane. The distance between the neighboring hydrogen atoms is 2.52 Å. The graphite lattice unit is 2.46 Å.

diffraction (GIXD) and helium diffraction provide structural information for well-ordered domains. This information reflects the overall order. To obtain atomic-level structural information inside the unit cell by diffraction methods is still very difficult. However, scanning probe microscopy offers a local, microscopic view of the structure on the surface and is ideal for probing the structure of two-dimensional crystals. Chiral organic molecules adsorbed on the HOPG surface are particularly interesting because of the potential applications in biologically active chiral molecule recognition and separation, as well as in the design of chirally selective catalysts. Some chiral long-chain alkane derivatives form crystalline monolayers on the basal plane of HOPG. Different optical isomers have been observed to spontaneously separate, each forming a chiral domain on the HOPG surface. With the help of scanning tunneling microscopy (STM), these enantiomers have been identified either by the chiral shape of the domains,<sup>[16,19–21]</sup> or in the case of very high resolution images, by directly identifying the chiral center.<sup>[18]</sup> Studies of racemic mixtures that are not observed to form separate chiral domains on the surface are still quite rare, partly because of the lack of very high resolution techniques that would allow direct identification of the chiral center of the molecule.<sup>[18]</sup>

Scanning tunneling microscopy is widely used in characterizing these long-chain alkane and substituted alkane SAMs. Because of the strong adsorbate/substrate and adsorbate/adsorbate interactions, atomic resolution can generally be achieved. Depending on the structure of a monolayer, different aspects of the same molecule can be imaged. For example, in the case of the striped phase of self-assembled alkanethiol monolayers on Au(111), the molecule is imaged with the

chain parallel to the substrate. In contrast, in the  $\sqrt{3} \times \sqrt{3} R30$  phase, the alkanethiol is imaged with the chain standing up. Relatively flat chiral molecules, with no mirror symmetry, can expose two different “faces.” When such molecules adsorb on a surface, usually only one “face” is exposed. The overall adsorption energy of the system will normally favor a specific molecular orientation upon adsorption.

## EXPERIMENTAL SECTION

The STM used in these experiments is a laboratory-built, ultrahigh vacuum, variable temperature STM. The microscope is mounted in an ultrahigh vacuum chamber on a 10-in. diameter ConFlat flange. The suspension stage hangs by four springs enclosed in spring houses attached to the 10-in. flange. Eddy current damping is used for vibrational isolation of the suspension stage. An InchWorm motor is horizontally mounted on the suspension stage. A single tube scanner and tip are mounted on the head of the InchWorm. The tip used for scanning is cut from 0.01-in. diameter platinum iridium wire (Pt/Ir = 90:10) from Good-fellow. Samples are positively biased and all scans were carried out under ambient condition at the liquid/solid interface.

Oleyl alcohol, oleic acid, elaidic acid, phenyloctane, and iodine were purchased from Sigma-Aldrich and used without further purification. Highly oriented pyrolytic graphite is from Union Carbide, ZYA grade.

One drop of iodine-saturated  $\text{CCl}_4$  solution was added to 1 mL of oleyl alcohol to halogenate the alcohol. Halogenation of the central double bond in the oleyl alcohol results in a solution that is a mixture of oleyl alcohol, (9*R*,10*R*)-9,10-diiodooctadecan-1-ol, (9*S*,10*S*)-9,10-diiodooctadecan-1-ol, and  $\text{CCl}_4$ . Composition of the solution following iodination was confirmed by [<sup>1</sup>H]NMR and mass spectrometry. One drop of the resulting solution is directly applied onto a newly cleaved HOPG surface, and this surface is imaged.

Saturated solutions of oleic acid and elaidic acid in phenyloctane were used for imaging. One drop of iodine-saturated  $\text{CCl}_4$  solution was added to 1 mL of these solutions for iodination of these molecules.

Scanning tunneling microscopy studies of pure oleyl alcohol and pure carbon tetrachloride applied to the HOPG surface were also performed. Neither oleyl alcohol nor carbon tetrachloride can be seen by STM to form stable-ordered structures on HOPG. For oleic acid, after iodination, there are mixtures of oleic acid, racemic (9*R*,10*R*)-9,10-diiodooctadecanoic acid/(9*S*,10*S*)-9,10-diiodooctadecanoic acid, and  $\text{CCl}_4$ . Oleic acid does not form a stable structure on HOPG.

For elaidic acid, after iodination, there are mixtures of elaidic acid, racemic (9*R*,10*S*)-9,10-diiodooctadecanoic acid/(9*S*,10*R*)-9,10-diiodooctadecanoic acid, and CCl<sub>4</sub> in the solution. Although elaidic acid does form a stable self-assembled monolayer on HOPG, the appearance of the elaidic acid SAM is different from the (9*R*,10*S*)-9,10-diiodooctadecanoic acid/(9*S*,10*R*)-9,10-diiodooctadecanoic acid SAM. The structures observed by STM and described here are the structures of the corresponding iodination products.

All images were calibrated using the bare HOPG hexagonal lattice. Scanning tunneling microscopy images of the mixture solutions are taken under various tunneling conditions ( $V_b = 0.3\text{--}1.2$  V, tunneling current = 0.4–1.2 nA). Several different tips and HOPG samples were used to ensure reproducibility.

## RESULTS AND DISCUSSION

### Monolayer of Oleyl Alcohol Iodination Products

When alkanols are adsorbed on HOPG, the molecules self-assemble into parallel rows.<sup>[4,5,9,10]</sup> Inside each row, the molecules pack side by side. The molecule chain has a 60° angle to the row boundary. The molecules in adjacent rows have a 120° angle to satisfy the geometric requirement of hydrogen bonding between the two alkanol molecules in these rows. The oxygen atoms at one side of the row boundary appear as a straight dark line in the STM, which bisects the 120° herringbone angle. Fig. 2 is a molecular resolution image of the diiodooctadecanol adsorbate structure.<sup>[22]</sup> The herringbone angle is measured to be  $124 \pm 2^\circ$  in this image. The length of the molecule is  $22.5 \pm 0.3$  Å, which is very close to the length calculated from an extended model of the iodinated oleyl alcohol molecule (22.4 Å).<sup>[22]</sup> Structural features different from those seen with the parent alkanol (1-octadecanol) can be identified.

1. The apparent heights of the neighboring rows of the diiodooctadecanols are different. The diiodooctadecanol rows form a high/low/high/low pattern as seen from the profile scan in Fig. 2.
2. At the center of each row, there is a dark trough.
3. The dark troughs in the lower rows are darker than the troughs in the higher rows.
4. For each row of diiodooctadecanol, the left half of the molecule is brighter (higher) than the right half.

To help explain this fine structure, a model study of diiodooctadecanol using Spartan<sup>[23]</sup> was carried out.

**Fig. 2** High-resolution image of 9,10-diiodooctadecanol on HOPG. Scan size is  $135 \times 135$  Å.  $V_b = 0.99$  V, tunneling current  $I = 1.03$  nA. The image is low pass filtered to remove noise. The angle between each pair is  $124 \pm 2^\circ$ . The length of the molecule measured from this image is  $22.5 \pm 0.2$  Å. Line profile (A–B–C) is along the axis of one molecule pair. Source: From Ref.<sup>[22]</sup>.

The molecule must twist at the C9–C10 bond to provide space for the two bulky iodine atoms. It is very clear from the model that the two iodine atoms must be on the same side of the backbone chain. It is well known that the good match between the H–H distance on the alkane chain and the HOPG unit cell distance leads to well-ordered adsorption of long-chain alkane molecules on the HOPG basal plane. For diiodooctadecan-1-ol, the zigzag of the hydrocarbon backbone chain must adsorb parallel to the HOPG basal plane. In this case, the two iodine atoms have only two possible positions: facing up, above the alkane chain, and facing down, buried underneath the alkane chain. Flipping the molecule over converts one orientation into the other. This suggests an explanation for the high/low/high/low height modulation of the neighboring rows of the diiodooctadecanols. If the two iodine atoms are buried under the alkane chain, the diiodooctadecanol molecule will be a “high” molecule; if the two iodine atoms are facing up, above the alkane

chain, the diiodooctadecanol will be a “low” molecule. In Fig. 2, row A is a row of “high” molecules packed together and the neighboring row B is a row of “low” molecules packed together. This packing model can be verified by examining the depth of the center trough in each row. Because the iodine atoms are at the center of the 9,10-diiodooctadecanol molecule, it is natural to assign the center trough as the positions of these marker atoms.<sup>[17]</sup> In the high row, the iodine atoms are blocked by alkane chains, while in the low row, the iodine atoms are exposed. Exposed iodine atoms appear darker than the alkane-chain-blocked iodine atoms in the high rows. The high/low/high/low height modulation of the neighboring rows suggest that two opposite faces of the same molecule are being imaged.

The model calculated using PM3 suggests that the dihedral angle of I1–C9–C10–I2 is  $89^\circ$  instead of the  $63^\circ$  dihedral angle of H–C9–C10–H. As a result of this rotation, half of the molecular backbone is twisted with respect to the other half. The hydrogen atoms on one half move to a higher position, making half of the molecule brighter (higher) than the other half.

Fig. 3 shows a high-resolution image of the adsorbed layer. The racemic mixture of (9*S*,10*S*)-9,10-diiodooctadecan-1-ol (*S*) and (9*R*,10*R*)-9,10-diiodooctadecan-1-ol (*R*) has been imaged. Long-chain *n*-alkanols adsorbed on HOPG typically form a herringbone structure. Between the rows, the alkanol molecules are packed head to head, with the OH groups close enough to form strong hydrogen bonds. Within each row, the long chain of the molecule is packed side by side. This structure is governed by the requirements of hydrogen bonding.<sup>[6]</sup> Because the angle between the molecular axis and the trough

**Fig. 3** Very high resolution image of 9,10-diiodooctadecanol adsorbed on HOPG. Scan size is  $76 \times 76 \text{ \AA}$ ,  $V_b = 0.31 \text{ V}$ , tunneling current  $I = 1.0 \text{ nA}$ . Source: From Ref.<sup>[22]</sup>.

(row boundary) is  $61^\circ$ , inside the row, each alkanol molecule can only shift one methylene unit ( $2.52 \text{ \AA}$ ) while packing.

In Fig. 3, it is seen that in each row, the angle between the molecular axis and the trough (row boundary) is about  $61^\circ$ , and the angle between the hydrogen-bonded pair is around  $122^\circ$ , which is the same as in the *n*-alkanol case. In row A of Fig. 3, the row is entirely composed of “high”-type molecules, and in row B, the row is entirely composed of “low”-type molecules. If within the row, the molecules are a mixture of *R* and *S* types, only *RR* (or *SS*) packed side by side could satisfy the single methylene unit shift (the angle of  $60^\circ$  between the molecular axis and the trough) and maintain the correct registry with the graphite lattice. From the STM image, it is clear that all molecules within a row are either all high (two iodine atoms facing down) or all low molecules (two iodine atoms facing up). If *R* and *S* are packed side by side, they could not form a  $60^\circ$  angle between the molecular axis and trough because only half-integer ( $1/2, 3/2, 5/2, \dots$ , etc.) methylene unit shifts along the neighboring molecule are allowed. Thus each row must be composed of one type of optical isomer, either *R* or *S*, but cannot be composed of both.

A line profile across several rows identifies the position of the OH group because in the line profile, the groove where two oxygen atoms from adjacent molecules meet must be deeper than where two methyl groups meet. After locating the OH position in Figs. 2 and 3, it can be seen that in the high row, the C18 side is higher; in the low row, the C1 side is higher.

This implies only four possible structural combinations, which satisfy the packing constraints described above:

- High-type *R*, C18 part high and low-type *R*, C1 part high (*RR*).
- High-type *R*, C18 part high and low-type *S*, C1 part high (*RS*).
- High-type *S*, C18 part high and low-type *R*, C1 part high (*S'R'*).
- High-type *S*, C18 part high and low-type *S*, C1 part high (*S'S'*).

From the very high resolution image of this adsorbate structure shown in Fig. 3, several points can be noted:

1. For each row, the higher half has only molecular resolution, i.e., only the overall alkane chain is visible, while the lower half shows submolecule resolution, i.e., the individual atoms inside the chain can also be seen.
2. Along the oxygen trough direction, in the lower part, there are five pairs of small raised features

in the high row (row A) while only three pairs are visible in low row (row B).

3. In the low row (row B), in the center of the molecule, the central dark band now appears as a set of discrete dark spots. Each chain has two spots, one on each side. If the upper and the lower iodines are labeled as I1 and I2, the I1–I2 molecular chain cross point is Z, and the angle C18–Z–I1 is an acute angle.

Only the *RS* packing described above can explain all the observations. Hence the high row (row A) is directly identified as (*9R,10R*)-9,10-diiodooctadecan-1-ol (iodines up) and the lower row (row B) as (*9S,10S*)-9,10-diiodooctadecan-1-ol (iodines down). Interestingly, because of the HOPG substrate, although (*9R,10R*)-9,10-diiodooctadecan-1-ol in the high row and (*9S,10S*)-9,10-diiodooctadecan-1-ol in the low row are enantiomers in solution, on the surface the mirror image of the *R* type is not superimposable on the *S* type, and vice versa. The entire domain formed by alternating chirally pure *R* rows and *S* rows is also a chiral structure. Thus an achiral racemic mixture is observed to form a chiral structure on an achiral surface in the regions examined here, because of the chiral pairing across the unit cell.

### Monolayer of Iodination Products of Oleic Acid and Elaidic Acid

Most long-chain carboxylic acid self-assembled monolayers on the HOPG surface pack in the same way: Molecules self-assemble into parallel rows. Inside each row, the molecule chain is perpendicular to the row boundary. The molecules pack antiparallel inside the row, i.e., side by side and head to tail. When a carboxylic head group meets another carboxylic head group from another molecule in a neighboring row, the two carboxylic head groups hydrogen bond to form a hexagonal ring. The ring appears as a dark hole in the STM image. This packing arrangement has two characteristics:

1. At both ends of a row of molecules, there are dark holes.
2. The distance between the dark holes along the row boundary direction corresponds to twice the molecule width (8.8 Å in the long-chain carboxylic acid case).

The iodination of oleic acid generates a racemic mixture of enantiomers: (*9R,10R*)-9,10-diiodooctadecanoic acid and (*9S,10S*)-9,10-diiodooctadecanoic acid. The diiodooctadecanoic acid forms an ordered

**Fig. 4** Submolecular resolution image of (*9R,10R*)-9,10-diiodooctadecanoic acid/(*9S,10S*)-9,10-diiodooctadecanoic acid SAM. Scan size is  $91 \times 91$  Å,  $V_b = 1.00$  V, tunneling current  $I = 0.73$  nA.

self-assembled monolayer on the HOPG surface in phenyloctane solution.

Fig. 4 is a high-resolution STM image of the diiodooctadecanoic acid SAM. The acid molecules self-assemble into parallel rows. At both sides of the row, there are dark holes at the row boundary. The distance between the dark holes along the row boundary direction seems to be only one molecule wide, which suggests that the acid molecules might pack in parallel style, i.e., side by side and head to tail. Careful study of the image reveals more details: There are two types of dark holes, one type is a plain hole, the other type has many white spikes around it. This implies a different chemical nature for the two features. Thus the periodicity along the row boundary direction is still the expected two-molecule width. Such structure characteristics fit the description of the general packing style of the carboxylic acid. This means that the diiodooctadecanoic acid is also packed antiparallel inside the row.

Several interesting features are seen in this image as well. There are two types of rows. They are labeled in the image as row A and row B. Each molecule inside the row is bent, in a V shape. At the center of the row, where the molecule bends, a bright bump (point U, in Fig. 4) is visible. In row A, it is especially clear that there is also a small dark pit (D, in Fig. 4) beside every white bump. Previous STM studies show that the halogen atom in long-chain alkanes appears as a bright spot when it points upward and as dark when it points downward in phenyloctane solution.<sup>[24]</sup> Considering the position of this bright/dark spot pair, the bright spot is assigned to the iodine atom pointing upward

and the dark spot is assigned to the iodine atom pointing downward.

All molecules in row A appear identical except for the terminal part, i.e., the relative position of the upward and downward iodine atoms are also the same for all molecules in row A. The bending direction is the same for all molecules. It is also clear that molecules in the row pack antiparallel. To satisfy the above two observations, there is only one conclusion: All molecules in row A are one optical isomer. Specifically in Fig. 4, the downward iodine is at the lower side of the upward iodine. Thus the molecule in row A is directly identified as the *R* acid [(9*R*,10*R*)-9,10-diiodooctadecanoic acid].

For row B, the structure characteristics are similar as for row A: All molecules look identical except for the terminal part, and the molecules pack antiparallel. The result is the same, row B is composed of entirely one type of optical isomer, either *R* acid or *S* acid. In row B, the structural details at the center of the molecule are different from row A. The bright spot is visible; unfortunately, the dark spot is not very clear. It is difficult to determine the relative position of the bright spot and dark spot. Hence the identity of the molecules in row B could not be directly identified as in row A. However, a length measurement from the bright spot to the row boundary provides the assignment. If molecules in row B are also *R* type, the whole structure would be centrosymmetric. The distances from bright spot to row boundary in row A and row B would be identical. The ratio  $d_a/d_b$  would be 1. If

**Fig. 5** Proposed unit cell structure corresponding to the SAM in Fig. 4. *R*-type acid: (9*R*,10*R*)-9,10-diiodooctadecanoic acid. *S*-type acid: (9*S*,10*S*)-9,10-diiodooctadecanoic acid.

**Fig. 6** Scanning tunneling microscopy image of (9*R*,10*R*)-9,10-diiodooctadecanoic acid/(9*S*,10*S*)-9,10-diiodooctadecanoic acid (elaidic acid iodination products) SAM. Scan size is  $79 \times 79 \text{ \AA}$ ,  $V_b = 0.71 \text{ V}$ , tunneling current  $I = 0.82 \text{ nA}$ .

the molecules in row B are *S* type, the distance from the bright spot to the row boundary would be 4 methylene units (1 methylene unit =  $2.5 \text{ \AA}$ ), while in row A, this distance would be 4.5 methylene units. The ratio of  $d_a/d_b$  would be 1.125. The actual ratio measured from Fig. 4 is  $d_a/d_b = 1.13 \pm 0.04$ , which clearly indicates that all molecules in row B are *S* acid [(9*S*,10*S*)-9,10-diiodooctadecanoic acid].

Fig. 5 is a model of the derived unit cell structure of the observed diiodooctadecanoic acid SAM. Each unit cell is composed of four molecules, two are *R* type,

**Fig. 7** Scanning tunneling microscopy image of (9*R*,10*S*)-9,10-diiodooctadecanoic acid/(9*S*,10*R*)-9,10-diiodooctadecanoic acid (elaidic acid iodination products) SAM at higher resolution. Scan size is  $44 \times 44 \text{ \AA}$ ,  $V_b = 0.33 \text{ V}$ , tunneling current  $I = 1.22 \text{ nA}$ .

**Fig. 8** Two possible unit cell structures that could explain all observed features in the STM image of (9*R*,10*S*)-9,10-diiodooctadecanoic acid/(9*S*,10*R*)-9,10-diiodooctadecanoic acid (elaidic acid iodination products).

two are *S* type. The molecules in the same row are not identical; they expose different faces upon adsorption on the surface. A  $C_2$  rotation (flipping) along the row direction at the center of the row converts one into the other. This unit cell is composed of a racemic mixture of two optical isomers, and is still a chiral structure. The mirror image structure is also observed by STM in other domains on the graphite surface.

The iodination of elaidic acid also generates a racemic mixture of enantiomers: (9*R*,10*S*)-9,10-diiodooctadecanoic acid and (9*S*,10*R*)-9,10-diiodooctadecanoic acid. The diiodooctadecanoic acids are observed to form ordered self-assembled monolayers on the HOPG surface in phenyloctane solution by STM. Fig. 6 is an STM image of the self-assembled monolayer formed by (9*R*,10*S*)-9,10-diiodooctadecanoic acid and (9*S*,10*R*)-9,10-diiodooctadecanoic acid. The molecules self-assemble into parallel rows. Unlike the SAMs discussed above, each row looks identical. At both sides of the row, dark holes are clear. The distance between the holes along the row boundary corresponds to the two-molecule width. These features fit very well with the general long-chain carboxylic acid SAM structure that is described above. Hence in Fig. 6, the molecules inside a row pack antiparallel as well.

However, there are some features different from the parent carboxylic acid (stearic acid) structure. In the center of a row, there is a bright band. There is also a dark band beside the bright band. Fig. 7 is an STM image of the same type SAM at another domain with higher resolution. In this image, the bright line and dark line inside a row become discrete bright and dark spots. The bright spots are always on the alkane chain; the dark spots are always at the same side of the bright spot and always between the chains. The distance between the bright spots is one alkane chain width (4.8 Å), which is also the distance between the dark spots. The positions of these spots are at the center of the molecule, where the iodine atoms should be. It is natural to assign the bright spot as the iodine

atom pointing upward and the dark spot as the iodine atom pointing downward.

To derive the packing model, three observations must be considered:

1. The unit cell structure must be inside the same row because all rows in the (9*R*,10*S*)-9,10-diiodooctadecanoic acid/(9*S*,10*R*)-9,10-diiodooctadecanoic acid SAM look identical.
2. The molecules pack antiparallel.
3. The upward/downward iodine atom has a single-molecule-width periodicity.

The only possible solution to these requirements is for the two enantiomers to pack in a side by side and head to tail arrangement inside the row. The unit cell is composed of a heterochiral pair of enantiomers of diiodooctadecanoic acid molecules. Although the pair is composed of enantiomers, it is still a chiral structure on the surface. There are two possible arrangements to satisfy the observed requirements, which are shown in Fig. 8A and B, respectively. These two packing arrangements are mirror images of one another. At this time, the STM resolution is not sufficient to determine which of the two possible structures is the actual structure in the image.

## CONCLUSION

The self-assembled monolayers of racemic mixtures of (9*R*,10*R*)-9,10-diiodooctadecanol/(9*S*,10*S*)-9,10-diiodooctadecanol, (9*R*,10*R*)-9,10-diiodooctadecanoic acid/(9*S*,10*S*)-9,10-diiodooctadecanoic acid, (9*R*,10*S*)-9,10-diiodooctadecanoic acid/(9*S*,10*R*)-9,10-diiodooctadecanoic acid have been examined by STM. Each mixture exhibits an interesting chiral grouping upon adsorption, forming a nanoscale surface structure.

In the case of the (9*R*,10*R*)-9,10-diiodooctadecanol/(9*S*,10*S*)-9,10-diiodooctadecanol SAM on HOPG,

the ordered monolayer exhibits a periodic surface height modulation within the monolayer. Analysis of the STM images shows that the molecules are found to pack in alternately high and low rows. As a result of the unique molecular geometry, opposite faces of the molecule are imaged. High-resolution STM images show that the high/low rows correspond to different optical isomers. The enantiomers spontaneously separate into different rows, and inside each row, chirally pure molecules assemble together. The unit cell is a herringbone-shaped heterochiral pair with different molecular faces exposed. Although the molecules in the pair are enantiomers, because of the adsorption exposing different molecular faces, the mirror image of one molecule cannot superimpose on the other.

In the case of the (9*R*,10*R*)-9,10-diiodooctadecanoic acid/(9*S*,10*S*)-9,10-diiodooctadecanoic acid SAM, each type of enantiomer also self-assembles into homochiral rows. Each unit cell is composed of four molecules in the neighboring rows. The same type of isomer in the same row adsorbs exposing opposite faces.

In the case of the (9*R*,10*S*)-9,10-diiodooctadecanoic acid/(9*S*,10*R*)-9,10-diiodooctadecanoic acid SAM, this quasi phase separation does not occur. The two enantiomers pack antiparallel inside the row, still forming a chiral structure.

These SAMs formed by chiral molecules do not spontaneously separate into homochiral domains. Their unit cell structures are revealed by high-resolution STM studies. The unit cells are composed of an equal number of enantiomers. Although the structure of the unit cells are different in these three self-assembled monolayer examples, the unit cell itself is also chiral. In all three cases, an achiral racemic mixture is observed to form chiral domains on an achiral surface. Such a structure is in contrast to the more common instance of chiral molecules that spontaneously separate into pure chiral domains at a surface.

# STEM: Self-Assembly on Graphite

Thomas Müller

Veeco Metrology Group, Santa Barbara, California, U.S.A.

## INTRODUCTION

The two-dimensional self-organization of molecules on surfaces and at interfaces is at the center of vigorous research activity. Thin interfacial films have numerous longstanding technological applications; however, the interest in a fundamental understanding of the self-assembly process has surged in recent years due to the central role envisioned for the controlled bottom-up assembly in future nanoscale molecular engineering. Monolayers physisorbed on the basal plane of graphite can serve as ideal model systems for such studies.

Highly ordered adsorbate monolayers have been generated on graphite substrates for a broad range of molecular species and experimental conditions. On this inert substrate, the dominant dispersion and electrostatic interactions often afford sufficient adsorbate mobility to aid in the self-assembly of thermodynamically favored monolayer structures. A combination of theoretical and experimental approaches, including proximal probes, diffraction-based techniques, and thermal desorption, has been employed to interrogate adsorbate structures and dynamics, and ultimately unravel the delicate balance of forces driving the self-assembly process.

Among experimental techniques, scanning tunneling microscopy (STM) plays a prominent role in elucidating the spatial orientation and conformation of individual adsorbate molecules. The present entry focuses mainly on STM studies addressing the role of interactions associated with functional groups and with saturated hydrocarbon chains in driving self-assembly on the basal plane of graphite. The structure and dynamics of the observed ordered, lamellar monolayers are seen to result from a set of competing geometric requirements. In addition, a brief discussion of STM image contrast is included, highlighting the ability of STM to provide information about the role of individual adsorbate electronic states in mediating electron transport. The final section of this entry is concerned with recent studies exploiting both geometric and electronic contributions to STM image

contrast to address molecular device properties in carefully tailored model systems self-assembled on graphite.

## MONOLAYER GENERATION AND INTERROGATION

Self-assembled, physisorbed monolayers on graphite have been generated at the liquid–solid interface, at the air–graphite interface, and in ultra-high vacuum (UHV).<sup>[1–10]</sup> Structural information has been obtained through both diffraction techniques and scanning probe microscopies (SPMs).<sup>[1,11–17]</sup> Structural data obtained for sets of related compounds and for different experimental conditions in conjunction with thermal desorption data and results from theoretical studies have given insight into the interactions driving the self-assembly process.<sup>[1,12,18–25]</sup>

As STM can provide high resolution locally (i.e., true atomic as opposed to lattice resolution) on a flat, conductive substrate, it has been the most prominent SPM utilized for the study of self-assembly on graphite.<sup>[26]</sup> As shown by Tersoff and Hamann, the tunneling current between a metallic tip and a metallic surface (note that graphite is a semimetal) is proportional to the surface local density of states (LDOS) at the Fermi level,  $E_F$ , evaluated at the location of the tip.<sup>[27,28]</sup> While this simple result is subject to approximations (e.g., small bias, low temperature, and spherical tip represented by an  $s$ -wave function), the interpretation of STM images in terms of the surface LDOS at (or near)  $E_F$  has met with overwhelming success. In general, the LDOS near  $E_F$  at the location of the tip is sensitive to the electronic structure of any molecular adsorbate present in the tunneling junction. For molecules with moderate ionization potentials and moderate gaps between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO), frontier orbitals can play an important role in mediating the electron tunneling process. Therefore, STM images of molecules with extended

$\pi$ -electron systems or functional groups contain an “electronic” component and can reflect the electron density distribution associated with individual molecular orbitals.<sup>[1,8,29,30]</sup> In contrast, STM images of unsubstituted saturated hydrocarbons are dominated by “geometric” effects and provide a topographic map. Here, the topmost atoms dominate the LDOS near  $E_F$  at the location of the tip.<sup>[30,31]</sup> In addition, the electronic structure of the underlying graphite substrate is often found to contribute to the image contrast, allowing STM images to address questions of substrate commensurability.<sup>[32]</sup>

Numerous studies have addressed self-assembly on graphite by utilizing STM to interrogate ordered monolayers formed by substituted alkanes at the interface between an organic solution and the basal plane of graphite.<sup>[26,31–34]</sup> Aside from monolayer structures, these studies have elucidated dynamics associated with the self-assembly process by probing two-component systems, domain boundaries, temperature-dependence, and the response to external perturbations.<sup>[21,35–39]</sup> In addition, the structure and dynamics of monolayer formation have been examined in light of the requirements for topochemical transformations.<sup>[4,5,40–42]</sup> The success of interrogations of substituted alkanes at the liquid–solid interface has led to extensions of this approach to codeposition of several solutes and monolayers serving as templates for organizing other molecules and nanoparticles, and to ring systems (e.g., porphyrins) with alkyl chains or functional groups at their periphery facilitating self-assembly.<sup>[7,10,43–49]</sup> In contrast, the ambient self-assembly of ring systems without alkyl chains or functional groups at their periphery has been reported less frequently.<sup>[50,51]</sup> Substituted alkanes and hydrogen-bonded systems have also been investigated at the air–graphite interface upon generating monolayers through evaporation of the organic or aqueous solvent or by Langmuir–Blodgett deposition from aqueous solution.<sup>[2–5,45,52,53]</sup>

To address self-assembly on graphite under UHV conditions, vapor-deposited monolayers have been probed using STM and diffraction techniques.<sup>[6–11,14,54]</sup> Ultra-high vacuum studies of self-assembly on graphite have served to extend the scope of self-assembled monolayers to include those not stable under ambient conditions, to assess the influence of solvent by interrogating monolayers analogous to those that do exist at the liquid–solid interface, to study monolayer dynamics (including melting and desorption) over a wide temperature range, and to provide ideal conditions for direct comparisons with theoretical results.<sup>[10–14,18–20,23,25]</sup> Vapor deposition has allowed the generation of ordered monolayers on graphite substrates for hydrocarbon chains as well as ring systems, irrespective of the presence of functional groups.<sup>[6,8,10,14,25,54]</sup> The most important factor limiting

the applicability of this approach might be the need for the species of interest to survive vaporization in a vacuum.

## MONOLAYER STRUCTURE AND DRIVING FORCES FOR SELF-ASSEMBLY

### Substituted Alkanes

Substituted alkanes form weakly physisorbed monolayers on graphite.<sup>[1,26]</sup> Dispersion interactions between alkyl chains and the graphite substrates provide adsorption energies of  $\sim 1$ – $3$  kcal/mol per methylene group, depending on chain length and functionalization, making desorption barriers substantially higher for monolayer than for multilayer adsorption sites.<sup>[18–20]</sup> Substituted alkanes form stable monolayers (i.e., as opposed to three-dimensional island growth) on graphite in a vacuum although no directed chemical bonds are formed between adsorbate molecules and individual carbon atoms of the graphite substrate. Consistent with the absence of covalent adsorbate–substrate bonds, the adsorption energies are accompanied by comparatively smaller barriers to lateral motion. High lateral mobility enables the annealing of monolayers to form minimum energy structures in a vacuum, while solution exchange may provide an alternate path at the liquid–solid interface where ordered monolayers exist in equilibrium with a supernatant solution or melt.<sup>[1,26,55]</sup> Thus, conditions can often be found both in vacuum and in liquid–solid interface for probing such ordered monolayers unimpeded by any formation of additional ordered adsorbate layers.

In self-assembled monolayers of substituted alkanes on graphite, the alkyl chains assume an extended, all-*trans* conformation. In contrast to the dense self-assembled monolayers formed by alkane thiols on gold substrates, the backbone axis is parallel to the surface plane bringing the entire alkyl chain into contact with the graphite substrate.<sup>[1,56–59]</sup> In general, a lamellar structure is formed where the lamella–backbone angle depends on alkane functionalization. In the case of long linear alkanes without any functional group, a lamella–backbone angle of  $90^\circ$  is found. In the all-*trans* conformation of alkanes, all carbon atoms lie in a plane and form a zigzag pattern. As STM images of alkanes on graphite provide a map of the topmost hydrogen atoms, they can reveal the orientation of the carbon backbone plane with respect to the substrate surface plane.<sup>[31]</sup> Fig. 1 shows STM images of hexatriacontane at the interface of a 1-phenyloctane solution and the basal plane of graphite.<sup>[31]</sup> As expected, a rectangular, lamellar structure can be discerned with the lamella width equal to one molecular

**Fig. 1** Constant current STM image (sample bias—168 mV, 300 pA tunneling current) of hexatriacontane at the interface between a dodecane solution and the basal plane of graphite. Raw data of two successive scans are shown in (A) and (B). Filtered versions of the images in (A) and (B) are shown in (C) and (D), respectively. *Source:* Used with permission from Ref.<sup>[31]</sup>. © 1993 VCH Verlagsgesellschaft mbH, Weinheim.

length,  $\approx 4.5$  nm for  $C_{36}H_{74}$  in its all-*trans* conformation. However, the STM images shown in panels (A) and (B) exhibit different spot patterns within each molecule, even though they represent subsequent scans of the same area. While panel (A) [and the filtered image in (C)] shows the double-spot pattern expected for a vertical orientation of the carbon backbone plane (i.e., perpendicular to the substrate surface), the zigzag pattern in panel (B) [and the filtered image in (D)] is consistent with a horizontal orientation (i.e., parallel to the substrate surface). Apparently, both orientations can (co) exist at the liquid–solid interface.

The spatial requirements of individual alkane molecules may depend on the angle assumed by the carbon backbone plane. In three-dimensional alkane crystals, lateral nearest neighbor spacings of  $\sim 4.8$  and  $\sim 4.2$  Å are found parallel and perpendicular to the molecular carbon planes, respectively.<sup>[60]</sup> In STM studies of long-chain alkane monolayers at the liquid–solid interface, lateral spacings have been found to be closer to 4.2 Å.<sup>[32]</sup> If the molecular backbone axis is aligned with one of the high-symmetry directions of the underlying graphite substrate, a spacing of 4.26 Å is required for each alkane molecule to occupy an equivalent surface site. Such a commensurate monolayer structure is consistent with the absence of moiré patterns in STM images of alkanes at the interface between an organic solution and the basal plane of graphite.<sup>[32]</sup> At first it

may appear to be inconsistent with the substantially larger spacings reported by Herwig et al. based on diffraction studies of vapor-deposited monolayers composed of similarly long alkanes (i.e.,  $C_{32}H_{66}$ ).<sup>[14]</sup> However, Herwig et al. found that the presence of “solvent” (i.e., heptane adsorbed atop a monolayer formed by dotriacontane) leads to a contraction of the monolayer structure accompanied by a change in the distribution of angles assumed by the molecular backbone plane.<sup>[14]</sup> The observed shifts in diffraction maxima are consistent with a commensurate monolayer in the limiting case of full solvent coverage.<sup>[14]</sup> The sensitivity of alkane monolayer structures to the presence of additional alkane layers may also explain the existence of ordered alkane monolayers substantially above the bulk melting temperature in the presence of bulk alkane melt, while essentially no increased melting temperature (i.e., when compared to the bulk melting point) is found for analogous vapor-deposited alkane monolayers in vacuum.<sup>[13,55]</sup> Further variations in alkane monolayer structures exist as a function of alkane chain length.<sup>[11,15,16]</sup> Diffraction studies of short alkanes on graphite have revealed the existence of a herringbone structure for monolayers composed of some short alkanes with an even number of carbon atoms with the transition to a rectangular structure depending on coverage and temperature.<sup>[16]</sup>

Like alkanes, alkanic acids form monolayers at the interface between an organic solution and the basal plane of graphite. As shown in Fig. 2, STM images reveal a lamellar monolayer structure where the molecular backbone axis is perpendicular to the lamellar axis, just as with alkane monolayers.<sup>[32]</sup> Close inspection of Fig. 2 reveals the formation of acid dimers and a zigzag spot pattern associated with each alkyl chain. Introduction of the carboxylic head group has not changed the lamella–backbone angle but has forced

**Fig. 2** Constant current STM images (sample bias—1.3 V, 800 pA tunneling current) of behenic acid at the interface between a 1-phenyloctane solution and the basal plane of graphite. The arrangement of molecules in (A) is the mirror image of that observed in (B). Parallelograms represent the unit cell of the monolayer. *Source:* Reprinted with permission from Ref.<sup>[61]</sup>. © 1998 American Chemical Society.

the entire molecular backbone plane into a “flat” orientation (parallel to the substrate surface). Lateral intermolecular spacings are expanded to  $\sim 4.8$  Å, and STM images of alkanolic acid monolayers often show moiré effects due to the lack of commensurability.<sup>[32]</sup>

The monolayer domains displayed in Fig. 2 are enantiomorphous, although alkanolic acids are achiral in three-dimensional space.<sup>[61]</sup> Due to the symmetry break at the interface and lack of free molecular rotation, individual adsorbed alkanolic acid molecules (and their dimers) can exist in two non-superimposable states that constitute mirror images of each other (i.e., they are prochiral or enantiomorphous). For alkanolic acids with an even number of carbon atoms, each self-assembled domain is constituted of adsorbed molecules in only one of the two enantiomorphous states, making the whole domain enantiomorphous. In contrast, both enantiomers are present in a given domain for an odd number of carbon atoms.<sup>[61]</sup> Thus, the presence of one additional methylene group in an (achiral) alkanolic acid molecule alters the chirality of self-assembled domains at the liquid–solid interface while having no analogous influence in three-dimensional space.

The expression of chirality in two dimensions has been interrogated in more complex situations, where several solutes are codeposited in self-assembled domains at the liquid–solid interface.<sup>[62]</sup> The enantiomorphous domains formed by achiral alkanolic acids with an even number of carbon atoms can be used to induce chiral segregation among codeposited chiral cosolutes.<sup>[46]</sup> As shown in Fig. 3, only one enantiomer of the chiral 2-bromohexadecanoic acid is present in a given enantiomorphous domain formed by the achiral hexadecanoic acid.<sup>[46]</sup> The mixed self-assembly of chiral and achiral species can also lead to the opposite effect, where the chiral component induces the achiral species to be adsorbed in a prochiral state and chirally segregated. De Feyter et al. have shown that the chiral 5-[10-(2-methylbutoxy)-decyloxy]isophthalic acid dissolved in heptanol forms enantiomorphous domains at the liquid–solid interface incorporating heptanol in a prochiral state.<sup>[44]</sup>

Alkanes and alkanolic acids exemplify limiting cases regarding (hindered) molecular rotation about the backbone axis in self-assembled monolayers of substituted alkanes. The structural variations for unsubstituted alkanes point to a shallow potential along several degrees of freedom (as long as a close-packed structure is maintained). In contrast, the carboxylic acid head group apparently forces the entire molecular backbone plane of alkanolic acids into a flat configuration. Terminal halogen substituents represent an intermediate case.<sup>[25]</sup> In general, alkane functionalization affects such structural parameters as the backbone plane rotation angle, backbone–lamella angle, lateral nearest

**Fig. 3** (A) Constant current STM image ( $15 \times 15$  nm, sample bias—1.5 V, 300 pA tunneling current) of a hexadecanoic acid domain interspersed with (*R*)-2-Br-hexadecanoic acid. The blue bar represents one molecular length. (B) Corresponding molecular model. The bromine substituent (bright marker) lies in a fixed orientation to the carboxyl group (dark marker) as indicated by the black bars in (A) and (B). The curved arrow in (B) identifies the brominated molecule as *R* enantiomer. (C) Constant current STM image ( $18 \times 18$  nm, sample bias—1.5 V, 300 pA tunneling current) of a hexadecanoic acid domain interspersed with (*S*)-2-Br-hexadecanoic acid. neighbor spacing, and substrate commensurability as functional group interactions can exhibit a pronounced angular dependence (in addition to steric requirements) compared to the more isotropic alkane–alkane and alkane–graphite dispersion forces. Interactions between terminal functional groups and the graphite substrate are not overwhelming in magnitude, even for substituted alkanes of moderate chain length (i.e.,  $C_nH_{2n+1}X$  with  $n = 6$ ).<sup>[25]</sup> In analogy to alkane thiols on Au(111), one might expect overwhelming head group–substrate interactions to be associated with a high-density monolayer structure, where only the terminal functional groups are in direct contact with the substrate.<sup>[56–59]</sup> With the possible exception of 1-fluorohexane this has not been observed.<sup>[25]</sup> The competing geometric requirements associated with functional group and alkyl chain interactions lead to energetic trade-offs that are apparent in the chain length dependence of monolayer desorption energies.<sup>[20]</sup> In the case of alkanes and 1-bromoalkanes, solvent interactions can shift the resulting balance of interactions.<sup>[14,25]</sup>

## Ring Systems

The success in the formation and interrogation of ordered monolayers for a wide range of substituted alkanes suggests strategies for the self-assembly of monolayers composed of ring systems. Large cycloalkanes have been found to self-assemble at the liquid–solid interface forming structures analogous to those of unsubstituted *n*-alkanes.<sup>[63]</sup> In the case of more rigid, planar ring systems with extended  $\pi$ -electron systems, alkyl chains, functional groups, or both have been attached at their periphery to mediate self-assembly on the basal plane of graphite. Reports of self-assembled monolayers composed of such tailored ring systems include polyphenylenes, phthalocyanines, and porphyrins.<sup>[3,53,64]</sup> Fig. 4 shows a high-resolution STM image of 21,23-dihydro-5,10,15,20-tetrakis[4-(tetradecyloxy) phenyl] porphyrin (TPPP) at the air–graphite interface.<sup>[53]</sup> Clearly, an ordered monolayer structure is observed, presumably stabilized by the interdigitization of the 14-carbon long alkyl chains attached to each porphyrin. Consistent with this hypothesis, shorter-chain analogs were found to produce less ordered monolayer structures.<sup>[53]</sup> Ring systems such as trimesic acid and DNA bases lack alkyl chains at their periphery. Here, the formation of intermolecular hydrogen bonds drive the formation of ordered monolayers at the basal plane of graphite.<sup>[2,7,54]</sup> The ability to form intermolecular

**Fig. 4** High-resolution STM image ( $15 \times 15$  nm, sample bias—752 mV, 1.032 nA tunneling current) of TPPP on graphite. Rows of bright porphyrin cores are interspersed with ordered, interdigitated alkyl chains. *Source:* Reproduced with permission from Ref.<sup>[24]</sup>. © 2001 John Wiley & Sons Limited.

hydrogen bonds is essential to the biological function of DNA bases. It has been suggested that the stabilization of self-assembled monolayers (composed of DNA bases) by intermolecular hydrogen bonding may have played an equally important role in the emergence of life.<sup>[65]</sup>

Monolayers formed by ring systems lacking both alkyl chains and functional groups at their periphery have been studied on a variety of substrates under UHV conditions. Fig. 5 shows an STM image of a naphthalocyanine monolayer that was vapor-deposited onto graphite.<sup>[8]</sup> All molecules are adsorbed with their ring plane parallel to the surface plane. An individual vacancy can be seen which aids in determining the azimuthal orientation of individual adsorbate molecules. The overlaid molecular models in panel (B) reveal the seamless monolayer packing, apparently maximizing the number density of adsorbed molecules. However, substrate commensurability is maintained, indicating that the periodic corrugation of adsorbate–substrate interactions plays a significant role in the formation of this monolayer structure.<sup>[8]</sup> Commensurable monolayer structures have been observed also for other planar ring systems with delocalized  $\pi$ -electron systems, even when intermolecular hydrogen bonds are present.<sup>[2]</sup>

In some cases, the monolayers formed by ring systems without alkyl chains or functional groups have been interrogated under ambient conditions. Both very large polycyclic aromatic hydrocarbons and porphyrins form ordered monolayers at the liquid–solid interface, where the molecular ring plane is either parallel or slightly tilted with respect to the surface plane.<sup>[50,51]</sup> However, in the presence of a supernatant solution such monolayers often coexist with a significant number density of  $\pi$ -stacked aggregates and adsorbate multilayers suggesting at most a weak selective stabilization of the adsorbate monolayer.<sup>[1,50,51]</sup> This may not impede the interrogation of vapor-deposited monolayers composed of the same species under UHV conditions, where the different adsorption procedure and the absence of a supernatant solution change both energies and kinetics. For ring systems that form stable monolayers both in UHV and at the liquid–solid interface, the presence of solvent can have subtle effects such as changing the phase relation with respect to the substrate.<sup>[10]</sup>

## MODEL SYSTEMS FOR MOLECULAR ELECTRONICS

Recently, STM studies of self-assembly on graphite have included molecules specifically tailored both to facilitate both two-dimensional self-assembly and as model systems for molecular electronics. Following

**Fig. 5** (A) Constant current STM image ( $25 \times 25$  nm, sample bias—1.83 V, 83 pA tunneling current) of naphthalocyanine on graphite at a surface temperature of 50 K. The close-packed monolayer contains a single vacancy, allowing the azimuthal orientation of individual molecules to be determined. The inset shows the chemical structure of naphthalocyanine. (B) Expanded section (mean filtered,  $9 \times 9$  nm) as marked in (A). The measured azimuthal angle was applied to the overlaid molecular model. *Source:* Reprinted with permission from Ref.<sup>[8]</sup>. © 2004 American Chemical Society.

early suggestions by Aviram and Ratner, molecular analogs for current rectifiers (diodes) and transistors are being investigated where electron donors (D) and acceptors (A) are linked covalently.<sup>[66]</sup> In addition to providing high spatial resolution, the STM tunneling junction is a probe of charge transport at the nanoscale. Scanning tunneling microscopy studies of molecules adsorbed on surfaces intrinsically address the mediation of charge transport by molecular states and their coupling to one of the electrodes (i.e., the conducting substrate supporting the molecule).

Miura et al. have investigated a large, symmetric D–A–D system composed of oligo-*p*-phenylene vinylene D-units and a perylenediimide A-core as shown in Fig. 6(A).<sup>[48]</sup> The STM images shown in Figs. 6(B), (C), and (E) reveal the formation of ordered monolayer domains at the interface of a 1-phenyloctane solution and the basal plane of graphite. As illustrated in Fig. 6(D), the monolayer structure is stabilized by interdigitated dodecyloxy chains. The ordered monolayer structure observed in STM images of this large molecule permits the identification of D and A subunits within each molecule so that their relative image contrast can be examined as a function of bias voltage. As shown in Fig. 6(E), the D moieties are brighter (i.e., give rise to higher tunneling current) at negative sample bias, while the A moieties are brighter at positive sample bias. Miura et al. have proposed an explanation relating the observed bias dependent charge transmission to the electronic structure of the D–A–D system.<sup>[48]</sup> Among all molecular states, the HOMOs of D-subunits have a dominant influence on the surface LDOS just below the Fermi level, as they are the highest filled states of the D–A–D molecule. Thus,

the D-moieties support a higher tunneling current at negative sample bias, where filled surface states are being probed. Conversely, the LUMOs of A-subunits dominate the density of empty surface states just above the Fermi level, making the A-moieties more transmissive at positive sample bias. Thus, a simple physical picture emerges where the bias dependent charge transmission through this molecular device analog can be understood in terms of resonantly enhanced electron tunneling dominated by individual electronic states associated with molecular subunits.<sup>[48]</sup>

Jäckel et al. have reported STM studies of a prototypical single-molecule chemical-field-effect transistor, where nanometer-sized charge transfer (CT) complexes control current rectification through a covalently linked ring system.<sup>[67]</sup> An electron-rich (or electron donor, D) hexa-peri-hexabenzocoronene (HBC) core, surrounded by six electron-poor (or electron acceptor, A) anthraquinone (AQ) subunits is at the center of these studies.<sup>[67,68]</sup> Again, STM images reveal the formation of an ordered monolayer at the liquid–solid interface, where the high degree of order and large molecular size permits the identification of the covalently linked D and A subunits.<sup>[67]</sup> And once more, the consideration of frontier orbitals associated with the D and A subunits suggests that the bias polarity dependent tunneling probability can be understood in terms of resonantly enhanced electron tunneling. Addition of the electron-rich 9,10-dimethoxyanthracene (DMA) to the solution leads to the formation of DMA–AQ–CT complexes. Self-assembled domains with and without CT complexes coexist and are easily distinguished in STM images and interrogated individually. Current–voltage curves obtained atop the

(B) Constant height STM image ( $70.2 \times 70.2$  nm, sample bias— $0.96$  V,  $150$  pA tunneling current) of a D–A–D monolayer at the interface between a 1-phenyloctane solution and the basal plane of graphite. Arrows indicate mirror-image type packing. (C) High-resolution STM image ( $15.5 \times 15.5$  nm, sample bias— $0.70$  V,  $400$  pA tunneling current) with overlaid parallelogram indicating a monolayer unit cell. (D) Proposed molecular model reflecting the ordering in (C). (E) Bias-dependent imaging of the D–A–D triad ( $10.1 \times 10.1$  nm,  $400$  pA tunneling current; sample bias indicated below each image). In order from top to bottom, the arrows on the left refer to alkyl chains, donor units, acceptor units, and donor units. *Source:* Reprinted with permission from Ref.<sup>[48]</sup>. © 2003 American Chemical Society.

HBC cores are asymmetric (rectifying) with the degree of asymmetry controlled by the presence (or absence) of the DMA–AQ–CT complex.<sup>[67]</sup> Jäckel et al. have proposed that the interfacial dipole associated with formation of the CT complex causes a relative shift between the adsorbate's electronic states and the Fermi level of the substrate.<sup>[67]</sup> Thus, current transmission through a single molecule is controlled by a field effect of chemical origin.<sup>[67]</sup>

The STM studies discussed in this section have combined self-assembly on graphite with detailed single-molecule conductance measurements by using specifically tailored molecules synthesized prior to deposition on the graphite substrate. On the other hand, the post-assembly modification of self-assembled monolayers (e.g., topochemical polymerization of diacetylene derivatives) on graphite has been demonstrated.<sup>[4,5,40,42]</sup> Furthermore, self-assembled monolayers of substituted alkanes on graphite have been used as templates for

organizing nanoparticles.<sup>[47]</sup> Based on combinations of these ingredients one could envision powerful recipes for the targeted creation of nanostructures and complex model systems for molecular devices with self-assembly on graphite playing a central role.

## CONCLUSIONS

A wide range of molecular species has been shown to form highly ordered monolayers physisorbed on the basal plane of graphite in vacuum and under ambient conditions. Experimental approaches including proximal probes, diffraction, and thermal desorption have been used in concert with theoretical predictions to interrogate structures and dynamics and unravel the driving forces of the self-assembly process. A large fraction of studies have employed STM and have focused on substituted alkanes self-assembled at the liquid–solid interface. In general, lamellar monolayer structures are observed with structural parameters depending on the balance of interactions associated with the alkyl chains and the functional group. In ambient studies of planar ring systems, monolayer formation is often driven by alkyl chains or functional group interactions. In contrast, UHV studies have been less dependent on substituents at the periphery of ring systems facilitating monolayer stabilization through specific intermolecular interactions.

Aside from providing information about monolayer structure and dynamics, STM studies of self-assembly on graphite can address the mediation of charge transport by individual molecular states. Recent years have witnessed a synthesis where STM studies have combined both aspects to interrogate model systems for molecular devices. Future studies can be envisioned, where the power of this approach is augmented further through combination with postassembly modification and coassembly of multiple nanoscale components, thus allowing self-assembly on graphite to play an even more important role in nanoscience.

# Structural Color

Pete Vukusic

*School of Physics, Exeter University, Exeter, U.K.*

## INTRODUCTION

Modern technology is increasingly interested in attaining the ability to carefully mold and control the flow of light. The interest in this is underpinned by the drive toward the use of all-optical signals, rather than electrical ones, for a variety of purposes. Among the more interesting and potentially revolutionary are those associated with high-bandwidth communication and with the miniaturization of digital processing. There is currently a huge research investment dedicated to reaching goals in these areas. As a result, technologists have discovered something nature has been exploiting for a very long time, namely, that the careful design of the structural shape and form of a material will allow it to manipulate the way specific colors propagate within or along it. In this way, the issue of structural color has arisen in physics and engineering, and the subject is predicted to affect our future lives in a fundamental way. As an introduction to the associated optics, this article will principally describe the physical mechanisms associated with structural color, presenting natural examples that offer inspiration and design protocols to current technologists.

## STRUCTURAL COLOR

Color may be defined as the property associated with an elicited physiological perception when light of a certain wavelength impinges on the photoreceptors in a visual system. In human vision, such color is said to comprise the range of wavelengths from red, at around 700 nm, to violet, at around 400 nm.

Colored light can be produced through one of 15 possible mechanisms,<sup>[1]</sup> each of which is independent of the visual system or device that detects it. The more common mechanisms are those associated with optically induced electronic transitions in atomic or molecular orbitals; energy-band effects in metals, alloys, and semiconductors; the vibrations and atomic excitations associated with incandescence; and the geometrical and physical optics involved in the interaction of light with periodicity. All mechanisms may, broadly speaking, be categorized into two groups: color resulting from the transition of electrons between specific

energy levels (such as with pigments or dyes) or color resulting from the interaction of light with the physical structure of a system. The latter group is commonly referred to as structural color and is the subject of this entry.

Structural color first proliferated in the animate natural world in the Cambrian period (515 million years ago) and even earlier with inanimate systems. Many examples are well known, but the color of rainbows and of certain invertebrates and vertebrates have always been both fascinating and intriguing. Much serious scientific research has taken place for many centuries. Through such examples as the investigative work of Theodoric<sup>[2]</sup> in the 13th century examining refraction in a rainbow, to that of Hooke in the 17th century on the color of silverfish,<sup>[3]</sup> to Newton's thesis in the 18th century on the iridescent color of peacock feathers,<sup>[4]</sup> even to modern-day scientists discovering photonic crystals in lepidopteran wing scales,<sup>[5]</sup> the principles of physical optics that underpin natural structural color have become well understood.

Four mechanisms govern such natural structural color: refraction, interference, diffraction, and scattering. These mechanisms also underpin all artificially produced incidences of structural color used by, or associated with, modern technological systems. Fundamentally, color is produced because of the existence of either nonparallel interfaces between media of different refractive index or of a distribution of centers of high or low refractive index, the 1-D, 2-D, or 3-D periodicity of which is similar in spatial dimension to that of visible light. The brevity of such a terse summary may be misleading, however. Each one of the four structural color mechanisms is distinctive enough to merit its own detailed description and discussion of examples. In each case, owing to the length constraints of this article and the existence of eminent and fully detailed explanations elsewhere in the literature, descriptions of these mechanisms in this entry will be condensed and centered on paradigmatic examples.

## Structural Color from Refraction

The rainbow is among the best known natural examples of color by refraction.<sup>[6]</sup> Other examples include atmospheric phenomena known as arcs, glories,

**Fig. 1** The formation of a rainbow is caused by the refraction of sunlight by raindrops. The primary bow is produced by a single reflection within a drop (top image) combined with the dispersion of light associated with the variation of refractive index with wavelength. To observe a rainbow (bottom image), sunlight must come from behind the observer; the red portion forms a bow of  $43^\circ$  cone angle, the violet, a  $41^\circ$  cone angle.

columns, parhelia, and sun and moon haloes produced by refraction and reflection in airborne hexagonal ice crystals.<sup>[7]</sup> One rarely observed yet spectacular phenomenon is the green flash, produced for just a few seconds at sunset under the right circumstances, where the density gradient of the atmosphere acts as a refractive medium to produce distinctive green coloration.<sup>[8]</sup> However, there are no known examples whereby refraction produces significant structural color in animate systems.

Among the most frequently encountered examples of structural color due to refraction are those associated with shaped transparent glass, the best example being a high-index glass prism. Even the incidence of sunlight through a window and onto a glass ornament or the beveled edge of a wall mirror will produce the characteristic spectrum of colors associated with refraction.

Many studies discuss the spectral colors produced in this way through a glass prism.<sup>[9]</sup> The underlying principle is the dispersion of light through glass—the index of refraction of glass increases as the wavelength

decreases. Consequently, blue light refracts through a larger angle than red light at a glass–air (or water–air) interface (with intermediate wavelengths falling between these limits). Parallel front and rear interfaces, such as with a plain rectangular glass block, prevent the production of a spectrum. However, the non-parallel faces of a glass prism bring about and retain an angular displacement between the paths of differently colored light, producing individual colors beyond the prism. The refraction of white light by raindrops is responsible for rainbows.<sup>[6]</sup> They form when sunlight from behind an observer refracts on entering and exiting a raindrop (Fig. 1).

Light forming a primary rainbow will have internally reflected once within each drop (assigning a distinct polarization to the spectral color), whereas light forming a secondary rainbow will have internally reflected twice.<sup>[10]</sup> The formation of supernumerary bows, existing on the inside of primary and secondary arcs and rather rarely observed, involves the additional mechanism of optical interference rather than solely refraction.<sup>[6]</sup>

### Structural Color from Interference

Interference is by far the most common mechanism by which structural color is produced, both naturally and artificially. To describe it, we consider white light incident on a series of overlapping thin films of alternating high and low refractive index. Colored light may be strongly reflected by constructive interference between reflections from the individual interfaces forming this stack of films.<sup>[11]</sup> For this to occur, the resultant reflections from each interface must emerge from the stack with identical phases, i.e., the optical path differences between them must be an integral number of whole wavelengths. This condition is satisfied only by a specific color, or selection of colors, and is additionally influenced by the angle at which the light is incident and reflectivity is observed. The critical variables that determine which color is brightly reflected are the refractive indices of the films in the stack, their individual thicknesses, and the angle of incidence or observation. Any imposed variations on these variables alter the optical conditions that create the interference, thereby producing a reflection and transmission of a different color. The hue from such interference is clearly angle dependent, a property that is implicit in the definition of iridescent color produced by this mechanism. The most favorable narrow-band reflection condition is produced when the optical thickness of each layer in the stack corresponds to a quarter of the wavelength required for optimal reflectivity.<sup>[12]</sup> For a large number of such layers of high refractive index contrast, the reflectivity will be bright, saturated,

**Fig. 2** The top image is a schematic diagram that illustrates the multiple reflections associated with two types of multilayer structure; the left one is that of a *Morpho* butterfly iridescent scale while the right one represents more conventional flat and continuous layering. The bottom image shows a transmission electron micrograph of a cross section through a *Morpho* iridescent scale. (Scale bar: 700 nm).

and of a narrow spectral band. The brightness of this reflectivity will increase with the number of layers:<sup>[12]</sup> if the dimensions or indices of the system deviate from the quarter-wave condition (something that is common in natural systems), the reflected intensity may be proportionally reduced and the reflected wavelength band will adopt a more complex form.<sup>[13]</sup>

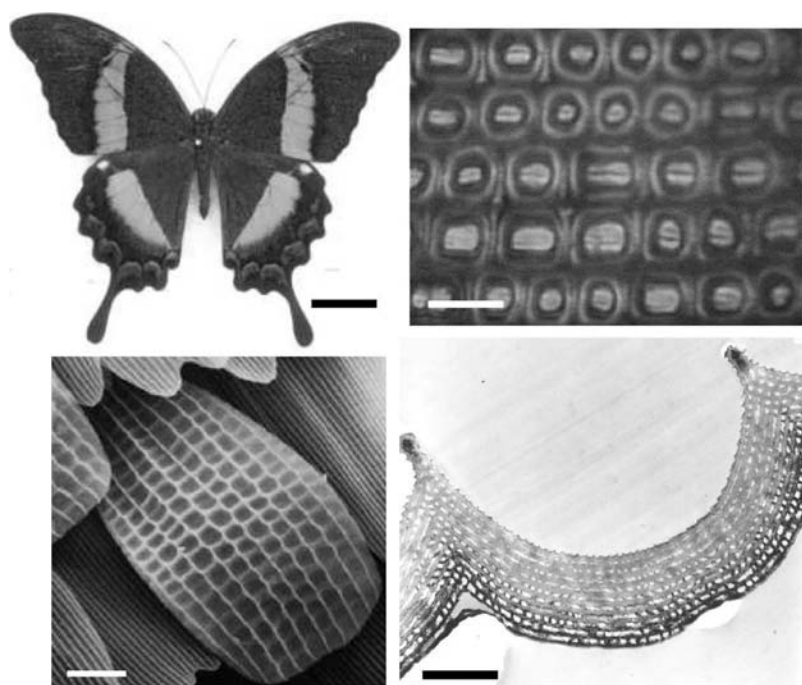

Among the innumerable examples of interference color in nature, those that are most vivid and spectrally pure tend to catch the eye most readily. An excellent example of such stunning structural color is the iridescence associated with several of the male *Morpho* butterflies that are indigenous to South and Central America.<sup>[14]</sup> The striking deep blue color of their dorsal wing surfaces is produced without the aid of any blue pigmentation, generated instead by optical interference within nano-sized laminations in the wing scales<sup>[15]</sup> (Fig. 2).

There is a profound complexity associated with this *Morpho* multilayer system. Whereas conventional technological multilayer systems generally comprise continuous layering over what is often a substantial area, the *Morpho* laminations are distinctly discreet in character, comprising assemblies of up to 10 layers of high-index material called cuticle, separated by intervals of air. This high number of layers yields up to 85% blue light reflectivity despite the presence of some inherent optical absorption because of the presence of melanin pigmentation within the scale structure.<sup>[15]</sup> The laminations are built into long and near-parallel ridge structures that run the length of each iridescent scale and have a spatial periodicity of between 700 and 1200 nm. Analysis of the optics of such *Morpho* structure confirms that the observed layers of thickness approximately 80 nm, separated by “layers” of approximately 100 nm of air, produce blue coloration at normal incidence through interference. The laminations appear to be embedded into the scale ridging to reflect the interference-produced blue light over a much broader angle than would be possible with flat or even curved continuous multilayers.<sup>[15]</sup> Variations in the design of this type of discrete multilayering in other butterfly species lead to more specific, angular-dependent reflection properties.<sup>[16]</sup>

In the case of butterfly systems, one finds that a more complex structure (such as the sculpting of an otherwise continuous multilayer) may produce surprising effects. The butterfly *Papilio palinurus* exhibits structural color that is green to human vision. Close examination of the structure of its wing scales reveals a continuous multilayer that is shaped into juxtaposed concavities<sup>[17]</sup> (Fig. 3).

The multilayers follow the profile of these concavities in such a way that the physical dimensions of each layer remain approximately constant regardless of position across each concavity. This creates the effect of a curved multilayer with uniform layer dimensions, rather than a patterned multilayer of variable dimensions. This particular sculpting simultaneously produces two structural colors, namely, blue and yellow, which combine additively to give the stimulus of a third color, the green that we observe.<sup>[17]</sup>

On close optical inspection (a color image of this detail is included in the on-line version of this entry), a yellow color is produced at or near normal incidence via reflection from the flat center of each concavity, whereas a blue annulus is produced via a double reflection across each opposite side of the concavity. This is possible only because each angled side combines with the surface that is orthogonal to itself on the opposite side of each concavity. The blue annulus pattern is produced in this way: normally incident blue light reflected from one 45°-inclined surface is directed across the concavity to the opposite orthogonal surface from

**Fig. 3** Optical images showing the structural color (top left) and scale patterning (top right) of a *P. palinurus* butterfly, together with electron micrographs of one of its iridescent scales (bottom left) and the cross section through one of the concavities (bottom right) of such a scale. The green coloration of *P. palinurus* is produced through color mixing of juxtaposed yellow and blue regions (top right), both colors of which are produced from the same multilayer profile. (The on-line version of this figure is in color.) (Scale bars: top left, 1 cm; bottom right, 6  $\mu\text{m}$ ; bottom left, 10  $\mu\text{m}$ ; bottom right, 1  $\mu\text{m}$ ). Source: From Ref. [18] © 2001.

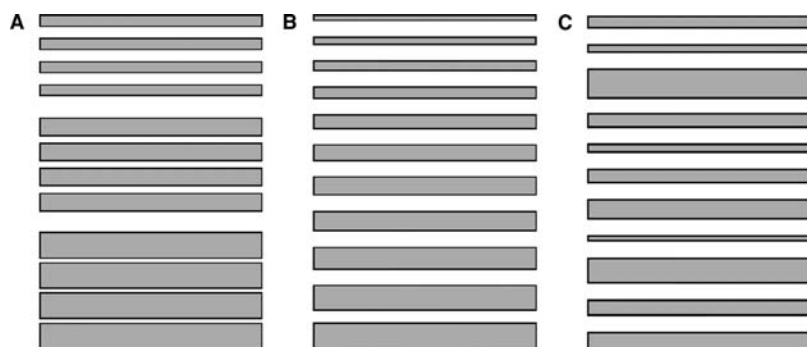

where it returns parallel to the incident direction. These pairs of inclined surfaces comprise nearly identical multilayering and are both inclined at approximately  $45^\circ$  to the direction of normally incident light on the scale surface. Accordingly, their spectral reflectivity characteristics are closely matched. Furthermore, through a double reflection from the opposite sides of each concavity, the polarization of only one of the colors may be rotated by  $90^\circ$ , a property that is thought to have evolved due to selection pressures associated with both cryptic and conspecific signaling.<sup>[18]</sup>

The examples of *Morpho* and *P. palinurus* are very advanced and complex multilayer systems. Similarly complex multilayer systems have been shown to exist in many different animal taxa, both terrestrial and aquatic.<sup>[19,20]</sup> For instance, the reflecting properties of some scarabaeid beetles are not based on periodicities in refractive index, but rather result from the helicoidal ordering of chitin microfibrils in planes that make up the insect integument.<sup>[21]</sup> Such cuticle is composed of laminar planes of chitin fibers, the axes of which are systematically rotated by a small amount with each consecutive plane. After a certain number of layers through the system corresponding to a specific distance perpendicular to the planes, the fiber axis is rotated  $180^\circ$  and is once again parallel to that of the first layer. In this way, two corresponding planes of cuticle occur over a distance that corresponds to half the helical pitch of the system. The consequent optical effect is that of constructive interference associated with consecutive planes that have unidirectional chitin axes

and which are separated by half the helical pitch. Thus the system may be treated as a multilayer reflector, which reflects a band of wavelength of unpolarized polychromatic light in an analogous way to cholesteric liquid crystals. As a further consequence of the helical arrangement of chitin fibers, optical reflection from these taxa of beetles is circularly polarized. This is not due to any optical rotation arising at a molecular level owing to the L-amino acids of the cuticle protein and the D-amino sugar of the chitin. It instead arises at the supermolecular level and has been termed *form optical rotation*,<sup>[12]</sup> in contrast to the optical rotation exhibited by cholesteric liquid crystals. It should be noted, however, that similar helicoidal structure, found in many other iridescent insect and plant taxa,<sup>[22]</sup> is not responsible for their strong coloration and does not produce anomalous optical properties such as optical activity. For these species, inherent refractive index periodicity within the species' exocuticle is responsible for the iridescence. For optically active beetles, the sub-wavelength pitch of the helical order is responsible for the observed form of optical activity and iridescent color.

Whereas the natural multilayer systems described so far are designed for rather narrow-band reflectivity, modifications to this design can produce broad-band color reflectivity, creating the appearance of gold or silver coloration. Three variations of multilayer design can generate this effect (Fig. 4).

The first of the three variations is known as a *chirped* system, in which the dimensions of the high- and low-refractive-index layers within the stack

**Fig. 4** Schematic diagrams to illustrate three arrangements of multilayer systems that can produce broad band reflectance: (A) a system comprising three overlapping quarter-wave filters tuned for different portions of the overall reflection band, (B) a chirped system comprising gradually changing layer thicknesses, and (C) a chaotic system in which there is little order in the arrangement of layer thicknesses.

systematically increase or decrease through the system.<sup>[23]</sup> A variation on this, described as a chaotic reflector, produces a similar effect by randomly varying the thicknesses of high- and low-index material. In both of these systems, the range of layer dimensions developed by the specimen, combined with layer refractive index, determine the position and width of the reflected wavelength band and the quality of the silver or goldlike mirror on its surface.<sup>[24]</sup> The third type of layered system incorporates a composite of three overlapping but regular multilayer systems, each tuned to a different wavelength band.<sup>[25]</sup>

There are many applications for artificially manufactured multilayer films, ranging from antireflection coatings on optical instruments such as spectacles, binoculars, and telescopes to specific-band optical filters for transmission or reflection for wavelengths ranging from infrared to X-ray. Their design is based on production of constructive or destructive interference in alternating layers of high- and low-refractive-index dielectric materials deposited onto surfaces. Other multilayer devices that additionally facilitate polarized beam splitting accompany interference by Brewster angle reflection.<sup>[26]</sup>

### Structural Color by Diffraction

Diffraction can produce structural color when white light is incident on the edge of an object or on a medium that comprises a periodicity in structure or refractive index. Such a medium may be called a diffraction grating and may function in reflection or in transmission, depending on its geometry. A high periodicity is generally required for bright structural color, the spatial dimension of which can range from a few thousand to a few hundred nanometers.<sup>[27]</sup>

Consider white light incident on a medium bearing a sinusoidally periodic surface profile of approximately 1- $\mu\text{m}$  pitch. Owing to the presence of the periodicity on the surface, the incident planar wave fronts of all wavelengths comprising the white light are diffracted to form a large number of series of circular wave fronts

for each wavelength. These series of reflected circular wave fronts then interfere strongly with each other, constructively in certain specific directions and destructively in others. Accordingly, diffraction, especially that associated with surface periodicities, manifests itself by the production of colored bands of light in reflection or transmission at different angles from the periodic surface onto which white light is incident.

The use of diffraction gratings is widespread. Measurements of signals are frequently based on the analysis of wavelength content in an incoming light beam.<sup>[27]</sup> Such analysis requires a diffraction grating to discriminate between constituent wavelength components. Within optical devices such as interferometers, laser systems, multiplexers, and microphotonic components (integral in most modern optical communication and instrumentation systems) such as gratings perform an essential function. Structural color produced from diffraction is often observed from objects such as CD or vinyl record surfaces that incorporate micron-sized periodicity. When incident white light diffracts from the periodic data tracks and grooves on their surfaces, color spectra are observed. The production of such color, however, is a side effect. One must look to natural systems for diffractive structural color that is produced for specific purposes.

Until recently, the occurrence of diffractive systems in the natural world was believed to be rather rare.<sup>[28]</sup> They are now known to be fairly common, especially in certain invertebrate phyla. In the phylum Mollusca, iridescence is observed on the outer surfaces of many mollusk shells. The surface of the shell of *Pinctada margaritifera* exhibits bright iridescence that results from diffraction of approximately 3.4- $\mu\text{m}$  pitch from a series of shallow parallel grooves on the shell surface.<sup>[29]</sup> This iridescence is distinctly different from the “milky” opalescence or pearlescence observed in many mother-of-pearl shells, where thick flat  $\text{CaCO}_3$  crystals cemented together with layers of protein yield interference of several colors simultaneously.<sup>[12]</sup>

Series of parallel narrow surface grooves are extensively found on the elytra of scarabaeid beetles, some of which are known to produce structural color

**Fig. 5** A single setae from the polychaete worm *Pherusa*, viewed by optical microscopy (left) and in cross section by electron microscopy showing increasing magnifications of transverse sections through the setae. Structural color effects are visible in the optical image (the on-line version of this figure is in color), produced from highly periodic microstructure derived through the longitudinal stacking of hollow cylinders within each seta. The images on the right show magnified regions of the central portion of the middle image. (Scale bars: left, 0.25 mm; middle, 60  $\mu\text{m}$ ; top right, 4  $\mu\text{m}$ ; bottom right, 250 nm.)

through diffraction.<sup>[30]</sup> For instance, many of the members of the Phalacridae family of scarabs exhibit surface gratings of approximately 1  $\mu\text{m}$  pitch, resulting in several bands of colored reflection. The intensity of these reflected color bands is relatively low, however, because of the heavily melanized cuticular integument that has a relatively low reflection coefficient.

The setae (hairs) of many Crustacea comprise series of juxtaposed rings having walls that are circular in cross section with a pitch of approximately 700 nm. Bright diffracted colors are visible to the eye when the specimen is tilted at an angle under a fixed light source.<sup>[28]</sup>

An interesting example of structural color caused by 2-D periodicity is that exhibited by certain taxa of marine polychaete worm. One of these, *Aphrodita*, a genus of polychaete worm commonly known as the sea mouse, has a short segmented body that is covered with hairlike structures called setae. These setae, extruded by epidermal cells, are exceptional because of their strong iridescence. They are composed of bundles of thin-walled cylinders of chitin held together by sclerotized protein to form fine and threadlike hairs. The diameter of the cylinder centers varies between approximately 100 and 360 nm in *Aphrodita*,<sup>[31]</sup> in another polychaete species, *Pherusa*, optically similar setae exhibit a greater number of cylinder periodicities with a more uniform diameter of approximately 220–270 nm<sup>[32]</sup> (Fig. 5).

The iridescent color in these setae (shown in color in the on-line version of this article) is produced through diffraction from the periodicity of the cylinder elements. Detailed optical analysis associated with the structure of *Aphrodita* is presented elsewhere.<sup>[33]</sup>

A variation of the structure found in iridescently colored polychaete setae is also found in the tapeta

of the eyes of cats. However, whereas polychaete setae consist of bundles of hollow cylinders, the tapeta of cats' eyes consist of bundles of solid cylinders or rods made of cuticular material. Within each bundle, rods of diameter 200–350 nm are spaced 300–500 nm apart and are arranged in a mutually parallel geometry that yields hexagonal symmetry in transverse cross section (Fig. 6).

Strong diffraction, specifically Bragg diffraction, arising as a result of the periodicity of these rods produces the colored eye shine normally observed with cats' eyes.<sup>[34]</sup> This mechanism is similar to the Bragg diffraction of X-rays from a crystalline material,<sup>[35]</sup> except that the difference of scale means the effect is seen for ordinary light. Its physiological function, similar to that of tapeta in certain arthropods, is believed to be optimization of photoreception in the cats' visual system.

In certain Lepidoptera, rather than 2-D periodicity such as that just described for polychaete worm setae, a remarkable 3-D periodicity exists. Such 3-D structures are sometimes referred to as volume diffraction gratings or photonic solids. It is, in principle, possible for photonic solids to expel light of certain frequencies in all directions; this implies that light of these frequencies will simply not propagate in the material and that all of it will be reflected from the surface of the solid. When this occurs, the material is said to exhibit a *photonic band gap*, which is analogous to the familiar electronic band gap of solid-state physics, except that it applies to photons instead of electrons.<sup>[36]</sup> However, for a photonic solid of specific symmetry to exhibit a full photonic band gap, there must be a minimum refractive index contrast between the two media that make up the periodic solid. Natural structures that exhibit these photonic solids are generally composed

**Fig. 6** Curious color effects and nocturnal eye shine in cats is produced by domains of ordered 2-D lattices of rodlet bundles in the tapetum lucidum of their eyes. Each rodlet is approximately 200 nm in mean diameter.

of cuticle and air or cuticle and water, both refractive index combinations of which are insufficient to create a full photonic band gap. However, their combination and structural symmetry can be enough to produce considerable reflectivities over a significant range of angles and over a relatively small wavelength band. The selective advantage of color production using this manner of microstructure rather than a surface grating or a multilayer system, excluding physiological considerations, is that it can sometimes be incorporated into multiple neighboring grains, each oriented slightly differently, to produce a macroscopic, completely angle-independent, structural color. This effect is found in several butterflies, e.g., *Parides sesostris*, and is shown in color in the on-line version of this entry<sup>[37]</sup> (Fig. 7).

### Structural Color by Scattering

The final category of structural color exists in addition to those that cause refraction, interference, and diffraction, producing wavelength-selective optical scattering.

The phenomenon of blue scatter is fairly widespread in nature. This color effect, associated with the selective scattering of shorter-wavelength light by small

particles, can be observed in the laboratory by using white light to illuminate droplets suspended in liquids (such as water containing small concentrations of milk). When it is viewed from the side, the suspension appears rather blue. Many other inanimate systems offer strong scattering in the laboratory such as highly dispersed systems of elementary sulfur or silver halides in aqueous media. In each case the exact hue and intensity of the scattered color depends on the degree of fineness of small particles in the suspension and on the magnitude of mismatch between the refractive index of the particles and their surrounding medium. Generally, particles that are sufficiently small yield deeply violet scattered color of striking intensity and purity: as particle size is increased, the scattered color passes from deep blue to pale blue. Increasing the particle size beyond approximately 1  $\mu\text{m}$  results in most visible wavelengths being scattered with sufficient intensity to produce the appearance of white.<sup>[20]</sup>

The mechanism that supports these laboratory examples of color by scattering also leads to the blue color of the sky; in this case, however, the scattering centers are the atmospheric molecules themselves rather than suspended solid particles.<sup>[38]</sup>

**Fig. 7** Optical micrographs showing *P. sesostris* scales in reflection under normal illumination (left) and a single *P. sesostris* scale viewed in reflection with linearly polarized white light illumination (bottom middle) with the image captured through a crossed linear analyzer. Top center and right images are electron micrographs of a fractured transverse section of a *P. sesostris* iridescent scale (the 3-D periodic lattice of cuticle is clearly visible). (Scale bars: left 90  $\mu\text{m}$ ; bottom middle 50  $\mu\text{m}$ ; top middle 3  $\mu\text{m}$ ; right 1  $\mu\text{m}$ .)

**Fig. 8** A schematic diagram illustrating the scattering of white light by a medium comprising small particles. Shorter wavelengths are preferentially scattered through larger angles according to the Rayleigh law of scattering. In this way, light directly transmitted through such a medium predominately comprises longer-wavelength radiation, whereas shorter wavelengths dominate when the medium is observed from any other perspective.

Scientists working with light scattering use several terms to evoke theories associated with different classes of scattering particles. Authors that detail scattering in animate specimens<sup>[20,39]</sup> have consistently used the terms Tyndall scattering, Tyndall effect, etc. to refer in the broad sense to colors produced through selective scattering of shorter wavelengths by small particles or optical heterogeneities when pigmentation and other structural phenomena are not predominant. In certain studies, Tyndall scattering is equated to Rayleigh scattering by particles that are small compared to the wavelength,<sup>[40]</sup> in others it applies to particles that are the same size or larger than the wavelength.<sup>[41]</sup> Tyndall's original experiments<sup>[38]</sup> embraced both groups of particle size and the expression is usefully retained by many biologists to describe scattering in animate objects. Physicists unfamiliar with such works on natural scattering systems tend to refer to the process as Rayleigh scattering if the sizes of the fluctuations or particles are very small compared to the wavelength of light, or Mie scattering if they become somewhat larger than those associated with Rayleigh scattering.

It is well known that the scattering of light in gases or fluids can involve certain quantum processes more normally associated with pigmentary color. However, in neutral nonabsorbing media a classical oscillator analysis<sup>[41]</sup> describes the relationship between scattered light intensity and wavelength for a specifically sized system of particles. This relationship is the well-known Rayleigh law of scattering, which states that scattered intensity is inversely dependent on the fourth power of wavelength. Physically, this implies that shorter-wavelength colors such as violet and blue are scattered much more strongly through greater angles than longer wavelengths such as red (Fig. 8).

This relationship can also apply to the scattering of light in transparent solid media, where the scattering centers are formed by irregularities in density or structure rather than by individual atoms or molecules. An important technological example lies in the transmission of light down long glass fibers. For this, the highest transmission can be largely limited by Rayleigh

scattering from small irregularities in the glass. Generally, to overcome this loss problem the longest wavelengths for existing and available light sources and detectors are used (but avoiding hydroxyl ion and other material-specific absorption resonances).

Tyndall scattering is believed to be the cause of the non-iridescent blue coloration in mammalian and reptilian integument and of much of the blue of both avian integument and feathers.<sup>[20]</sup> It is additionally attributed to some blues found in certain lower-class phyla such as Odonata and Lepidoptera.

The most conspicuous examples are found in certain mammals, particularly monkeys such as male baboons and mandrills. In these creatures, hairless patches may be deep violet or blue because of Tyndall scattering associated with strata of discrete black melanocytes arranged in an otherwise transparent layer within the epidermis.<sup>[20]</sup> Purple regions on these creatures correspond to areas where Tyndall blues color-mix with red pigmentation associated with blood corpuscles close to the surface: a color effect perhaps more commonly observed as port-wine birthmarks in some humans.<sup>[42]</sup>

Whereas Tyndall blue in mammals is caused by disperse systems of solid-in-solid where the melanin granules have a different refractive index to the surrounding epidermis, non-iridescent avian feathers generally achieve blue scatter using air-in-solid systems. In such feathers, air-filled subwavelength cavities within the keratin of the feather barbs act as the scattering centers from which Tyndall blues are produced. More often than not, the green color in avian feathers is the product of the superposition of yellow reflection from additional carotenoid pigmentation in the feathers with the underlying blue from Tyndall scattering.<sup>[20,39]</sup> Green and sometimes purple coloration in many other taxa, e.g., certain snakes, frogs, lizards, and fish, are produced by similar effects, namely, Tyndall scattering superposed with the effect of colored pigment.<sup>[20,39]</sup>

The bluish tinge on the chin of dark-haired men seen a few hours after shaving is attributed to Tyndall scattering. Without the dark roots of the hair, however, as

an absorbing background, the low-intensity scattered blue tinge would be unsaturated with back reflection from the epidermal surface and would not be seen.

The blue color of mammalian eyes is certainly structural in nature and has been attributed to Tyndall scattering. Early studies of the human eye<sup>[43]</sup> found that the colored portion is composed of a thin membrane bearing unstriped muscular fibers, nerves, and capillaries, all incorporated in a fine delicate reticulum of fibrous tissue. Small protein particles in this region preferentially scatter blue light away from the eye while the remainder enters the eye and is generally absorbed by a curtain layer of brown and black melanin at the back of the reticulum. This prevents back reflections out of the eye from reducing the saturation of the Tyndall blue color. Brown eyes possess an additional layer of some yellow pigmentation with significantly sized brown melanin granules among the interior fibrous structures. These produce a brown coloration through the natural color of the melanin. The transformation from initially blue colored eyes to brown eyes in babies and children is attributed to the gradual appearance and increase in size of melanin granules in the first few months and years.

There are several examples of Tyndall blue coloration in Lepidoptera. The wings of these species have been shown to be composed of scales that are colored through Tyndall scattering from subwavelength-sized nanostructures.<sup>[44]</sup> These structures extend from between series of ridges on the surface of the scales down into the body of the scale. In the butterfly *Papilio zalmoxis*, the scattering structures are in the form of air-filled alveoli approximately 2  $\mu\text{m}$  long and around 220 nm in internal diameter. The simultaneous presence within the alveoli of a UV-absorbing but blue-fluorescing pigment enhances the blue coloration.<sup>[44]</sup> A melanized underlayer of black scales acts as an absorbing background, preventing the reflection of other wavelengths.

## CONCLUSION

There are striking differences between the hues of objects or materials colored through structural means and those colored through pigmentary or other non-structural means. Depending on structure type and the color mechanism it facilitates, the optical properties of these structurally colored surfaces may manifest themselves through one or several properties: angle-dependent or angle-limited color; narrow or very broad spectral bandwidths; ultrahigh reflectivities or transmissivities; strong polarization effects including polarization rotation on reflection or circularly polarized reflection; bicolor production and subsequent

color mixing; and complementary coloration in reflection and transmission.

In modern technological systems, refraction and scattering are rarely used for the purpose of producing color. In the natural world too, relatively few separate examples exist whereby refraction and scattering in either animate or inanimate systems are the cause of color. True diffraction also occupies a place of relatively minor importance in the production of iridescence in natural systems, although a good number of examples are known to exist. By far the most common mechanism by which color is produced structurally in modern systems and those of the natural world is through interference in multilayered systems. Modern physics has an excellent understanding of both the optical properties of most materials and of the physics of multilayer systems; more importantly, the techniques by which such materials are deposited onto surfaces have been refined and advanced to such an extent that highly specialized systems can now be manufactured at reasonable cost for a variety of optical purposes. In nature too, we see evidence of highly specialized multilayer-based structural color. In most of such natural systems, millions of years of selection pressures have shaped and developed them for a variety of purposes, from that of crypsis to that of specialized conspecific signaling. It is rarely an accident that such complex architecture develops in animate systems without the structural color it produces being designated for a specific use or having a definite biological significance. We now find technology is, for its own purposes, increasingly taking lessons from the design protocols nature has created.

# Structural Nanomaterials

Joanna R. Groza

Jeffrey C. Gibeling

*Department of Chemical Engineering and Materials Science,  
University of California–Davis, Davis, California, U.S.A.*

## INTRODUCTION

By definition, structural materials are used for mechanical strength at room and elevated temperatures, to withstand cyclical loading and for wear and fracture resistance. Structural nanomaterials (with grain sizes less than 100 nm) are distinguished by unusually high strength, hardness, and wear resistance as well as good fatigue resistance, fracture toughness, and extensive high-temperature formability. However, commercial applications have only begun to tap the potential of high-strength parts (e.g., nearly 1 GPa in nano-Al alloys, known as GIGAS,<sup>[1]</sup> and high-strength nano-SiC springs). More commonly, they are used as thermal barrier coatings, or in friction-resistant and wear-resistant rotating parts (e.g., sleeves or bearings).

Nanomaterials used for structural applications may have nanometer size in one dimension (1D), two dimensions (2D), or three dimensions (3D). Generally, 1D nanomaterials are wires, 2D refers to coatings and films, and 3D solids are used to make bulk parts. In this entry, bulk or 3D materials are emphasized, but some 1D and 2D nanomaterials used for their mechanical properties are also presented.

## FABRICATION OF NANOSTRUCTURED MATERIALS

### Processing

The primary challenge in producing bulk nanostructures is to create and to maintain grain sizes less than 100 nm in defect-free, sizable, reproducible, and reliable parts. To date, the processing of raw nanomaterials (powders and thin films) has progressed farther than the formation of bulk parts. Nanosize powders of metals, ceramics, polymers, and composites are now available, sometimes in tonnage quantities. All of these nanostructured powders may be used for processing 2D and 3D parts.

The most common techniques to produce 2D parts are thermal spraying and electrodeposition (ED). The former includes arc, flame, plasma, detonation gun, and high-velocity oxyfuel spraying to produce metal, alloy, ceramic, and composite coatings.<sup>[2]</sup> In the spraying process, the fine microstructure develops when molten or semimolten particles rapidly solidify as they are deposited onto a substrate. Electrodeposition techniques include both electroplating and electroforming, and are typically applied to a limited number of metals, although some ceramics and composites have been also obtained.<sup>[3]</sup> Although electroplating is typically used for coatings, electroforming is a cost-effective method for free-standing ultrathin foils or thick structures, wires, plates, and complex shapes. Grain size is controlled by enhanced nucleation by charge transfer at the electrode surface, high deposition rates, and the inhibition of grain growth by using additives. Electrodeposition can be used to control grain boundary type and to achieve nanocrystalline structures with a relatively narrow grain size distribution and with few pores. Electrodeposition and sputtering also may be used to produce nanolayered materials.

Generally, the processing methods for bulk nanomaterials involve one or two steps. The more commonly used two-step methods consist of producing nanomaterials in a powder form and subsequently consolidating them to a final 3D part. These methods offer the greatest versatility in the shape, size, and weight of the final bulk parts. All powder processing methods have been applied to sinter nanostructured powders and many of them have achieved final grain sizes less than 100 nm.<sup>[4]</sup> The challenge is to fully densify nanopowders without losing the initial metastable features (nanoscale grain size and, sometimes, metastable phases). The consolidation methods use a full range of temperature and pressure conditions from conventional pressureless sintering to high pressure and shock consolidation. Inert gas condensation (IGC) of powders followed by densification has been a widely used technique to process bulk nanocrystalline materials.

Most of these methods leave processing flaws, including incomplete densification, poor interparticle bonding, cracks, or trapped gases.

The one-step methods include severe plastic deformation (SPD), crystallization of amorphous bulk parts, and ED. Severe plastic deformation comprises variants such as equal-channel angular forming and high-pressure torsion straining. Generally, SPD results in grain sizes greater than 100 nm, which are known as ultrafine-grained structures. However, smaller grain sizes (down to 20 nm) have occasionally been achieved.<sup>[5]</sup> Intense plastic deformation has also been used to produce in situ fiber or lamellar composites. A novel intense deformation process based on ball milling with in situ densification (BMID) was recently reported by Koch.<sup>[6]</sup>

The crystallization of bulk amorphous alloys to form nanophases occurs on controlled thermal processing.<sup>[7]</sup> The most challenging step is the formation of bulk amorphous precursors using slow cooling rates similar to conventional casting processes, to enable the fabrication of sizeable parts. This has been achieved in a few metal-based systems (Zr, Mg, and, partially, Al). Next, controlled direct or stepwise devitrification takes place at temperatures within the supercooled liquid region, or close to the onset of crystallization. The resultant structures are typically multiphase alloys formed by the precipitation of nanoscale metastable (metal-based or quasi-crystalline) or stable (intermetallic) phases in an amorphous matrix. The type and the size of nanocrystalline components vary with alloy chemistry and processing conditions.

### Dependence of Properties on Processing

Most processing methods result in some imperfections in the final bulk part. In conventional materials, well-established standards control flaw size and distribution, resulting in a negligible effect on mechanical properties. However, such flaws have a more critical effect on the mechanical properties of nanomaterials, and are different in nature and size than in conventional materials. The most common imperfections in nanocrystalline bulk materials are pores, trapped gases, impurity contamination, cracks, imperfect bonding, surface defects, residual stresses, and texture. Although some defects are common to several techniques (e.g., contamination, surface defects, or pores), texture is typical in ED, residual stresses are most severe in SPD, and incomplete bonding and densification are observed in powder consolidation and thermal spraying. Defect characterization in nanomaterials is a relatively new field, and appropriate guidelines are definitely required.

The most detailed defect characterization has been carried out for the flaws specific to the two-step powder consolidation methods, particularly pores that result from incomplete densification.<sup>[8,9]</sup> At small grain sizes (less than 10 nm), a density shortfall may also originate from the high volume of low-density grain boundaries. Van Swygenhoven, Spaczet, and Caro.<sup>[10]</sup> calculated densities of 97% for a 10- to 12-nm grain size Ni and 95.2% for a 3.4-nm grain size Ni. Experiments confirmed a 97.6% density value measured by a high-precision Archimedes method in 10-nm grain size samples produced by IGC.<sup>[11]</sup>

Processing flaws in nanomaterials have an adverse effect on mechanical properties. The modulus of elasticity or Young's modulus  $E$  is a reflection of interatomic bonding and is largely dependent on defects. The low experimental  $E$  values reported in early studies of nanocrystalline materials have been unquestionably attributed to defects such as pores, poor grain-to-grain bonding, or deficiencies in measuring techniques.<sup>[9,12]</sup> More recent experimental measurements on low-defect nanomaterials demonstrate that grain size has a negligible effect on Young's modulus.<sup>[13]</sup> Simulations also showed no variation in Young's modulus down to a grain size of 10 nm.<sup>[14]</sup> Below this limit, when the slightly lower-density grain boundary volume becomes predominant, the modulus decreases with decreasing grain size. Some calculated values are as low as about 75% of the modulus of bulk metals at 3–6 nm grain size.<sup>[14,15]</sup>

All other mechanical properties, including strength, hardness, and ductility, are sensitive to microstructure and are even more adversely affected by defects. Ample evidence exists for inferior strength and ductility values, particularly in tensile testing, because of pores and trapped gases, cracks, imperfect bonding, and surface defects. Agnew et al.<sup>[8]</sup> Sanders, Youngdahl, and Weertman.<sup>[9]</sup> Legros et al.<sup>[13]</sup> and Nieman, Weertman, and Siegel.<sup>[16]</sup> carefully documented the dependence of strength and ductility on processing flaws in metals. He and Ma<sup>[17]</sup> characterized the variation of hardness with porosity in the Fe<sub>3</sub>Al intermetallics. Hardness values were reported to double by processing improvements to produce dense metals.<sup>[9]</sup> The reduction of the surface imperfections has been shown to increase the tensile strength by up to a factor 4 by preventing premature fracture.<sup>[16]</sup> Consequently, reduced size specimens (e.g., micro and miniature tensile and bend specimens) have been used to lower the defect probability.<sup>[13,18,19]</sup> The elimination of some defects by annealing can also increase the strength of metals<sup>[20,21]</sup> and intermetallics<sup>[20–23]</sup> by decreasing porosity, relaxing the grain boundary structure toward equilibrium, or reducing internal stresses.

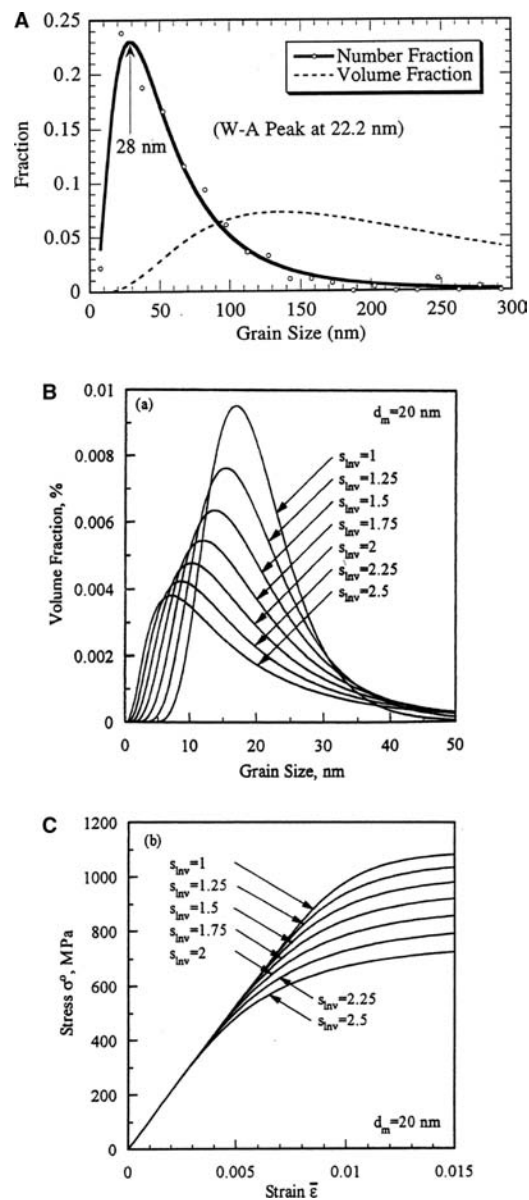

As is detailed in "Strength and Ductility," ductility is the property most affected by processing flaws. The

lack of good interparticle bonding is the major cause of brittle failure in consolidated samples tested in tension or bending.<sup>[9,24,25]</sup> As an example, 80-nm Fe<sub>3</sub>Al produced by shock wave consolidation of mechanically alloyed powders displayed brittle behavior in tension but a large plastic strain in compression (true plastic strain of 1.4).<sup>[26]</sup> Similar to strength, an improvement in ductility was reported after annealing at low temperatures without altering the grain size (e.g., an increase from 2 to 7.3% in 30-nm Cu) because of grain boundary relaxation.<sup>[27]</sup> Electrodeposition yields better ductilities than powder consolidation because of reduced porosity and good interparticle bonding. However, some ductility problems have been noted when using grain growth inhibitors, or because of texture development. Throughout this entry, an effort has been made to exclude materials with significant processing deficiencies, when these are reported.

In conventional materials, it is acceptable to use average grain size to characterize mechanical properties. This approach is not appropriate in nanomaterials because of the size dependence of the deformation behavior. For instance, some large recrystallized 1–5 μm size grains enabled larger ductility values in nano-Cu vs. nano-Ni, which had fewer such recrystallized grains and was consequently brittle.<sup>[13]</sup> All processing methods result in a distribution of grain sizes. In nanomaterials, grain size measurements are commonly carried out by X-ray diffraction (XRD) and transmission electron microscopy (TEM). Transmission electron microscopy enables a direct measurement of grain sizes and grain size distribution. In contrast, XRD techniques provide only an average grain size, the value of which also depends on the specific method used [e.g., Scherrer, Warren–Averbach (W–A), or Williamson–Hall].<sup>[28]</sup> Average TEM grain size and X-ray results are in good agreement when the grain size distribution is narrow and XRD corrections are made (Fig. 1A). Log-normal distributions of grain sizes are usually used. When grain size distribution is described by volume fractions, the peak value may be quite different from the TEM number fraction and XRD values (Fig. 1A). Volume fractions more realistically reflect the effect of large grains, which may be predominant on mechanical properties.<sup>[21]</sup> The standard deviation of the volume fraction also affects the grain size distribution (Fig. 1B) and, consequently, the mechanical properties (Fig. 1C).

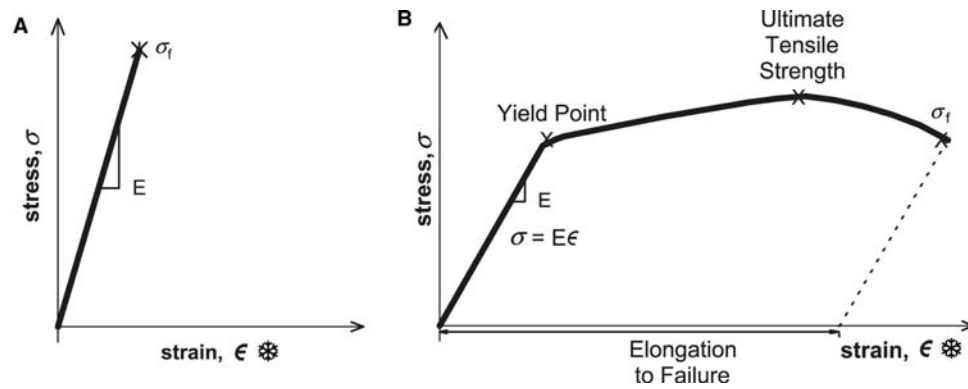

## STRENGTH AND DUCTILITY

The general description of the mechanical behavior in tension is given in Fig. 2.<sup>[29]</sup> Brittle materials are characterized by a linear elastic stress ( $\sigma$ )–strain ( $\epsilon$ )

**Fig. 1** Effects of grain size distributions on mechanical properties. *Source:* From Refs.<sup>[14,21]</sup> (A) Comparison of grain size values given by TEM and XRD in IGC copper. The open circles are the relative number of grains in a given size range. The solid and dotted lines indicate the log-normal fits of the data points as number–fraction and volume–fraction curves, respectively. (B) Effects of the standard deviation size  $S_{inv}$  on the grain size distribution and (C) on stress–strain curves for the same average grain size ( $d = 20$  nm). The IGC Cu is heavily twinned and the “grain size” value actually refers to the twin size. *Source:* *MRS Bulletin* and J. R. Weertman.

response and fracture with no plastic deformation (Fig. 2A). Ductile materials yield beyond the elastic region and then fracture after a certain elongation (Fig. 2B). Fig. 2B defines the yield strength ( $\sigma_y$ ), tensile strength ( $\sigma_{UTS}$ ), and elongation to fracture ( $\epsilon_f$ ). In the

**Fig. 2** Stress–strain curves for brittle (A) and ductile (B) materials. The slope of the linear portion of the  $\sigma$ – $\epsilon$  plot defines the elastic modulus by the Hooke's law ( $\sigma = E\epsilon$ ).

plastic region, work hardening is expressed using a true strain value  $\epsilon$  by:

$$\sigma = K \epsilon^n \quad (1)$$

where  $K$  is a constant and  $n$  is the strain hardening exponent. Strain or work hardening is attributed to the generation and interaction of the dislocations. It controls the amount of uniform elongation at stresses larger than yield strength  $\sigma_y$ . A dimensional instability in tension, or necking, typically starts to develop at maximum load.

Grain size refinement results in the classical grain boundary strengthening (expressed in terms of yield strength  $\sigma_y$  but also valid for  $\sigma_{UTS}$  or hardness  $H$ ), which is described by the Hall–Petch (H–P) relationship:<sup>[29]</sup>

$$\sigma_y = \sigma_0 + k d^{-1/2} \quad (2)$$

where  $\sigma_0$  is the friction stress to move dislocations,  $k$  is a material-dependent and temperature-dependent constant, and  $d$  is grain size.

The H–P relationship can be rationalized by two basic dislocation descriptions: 1) the dislocation pile-up model, in which yielding occurs as a result of stress concentrations caused by pileups (Fig. 3A); and 2) the dislocation network model, in which the slip is because

of dislocations emitted by grain boundaries (Fig. 3B). A third model developed by Meyers and Ashworth<sup>[29]</sup> is a variant of the dislocation emission model with localized plastic flow at a work-hardened grain boundary layer (Fig. 3C). Plastic deformation occurs when the applied stress exceeds the higher-flow stress of the grain boundary region. The resulting grain size dependence of the yield strength is the sum of  $d^{-1/2}$  and  $d^{-1}$  dependencies:

$$\sigma_y = \sigma_0 + k d^{1/2} + k' d^{-1} \quad (3)$$

where  $k'$  is a different constant from  $k$ . The second term is dominant at large grain sizes, whereas the third term becomes important at small grain sizes. All models assume conventional dislocation generation and mobility.

### Strength of Nanostructured Materials

By extrapolating the grain size to the nanometer range, both strengthening and an increase in ductility were predicted.<sup>[30]</sup> Experimentally, this prediction has been observed for a number of materials (Fig. 4).

According to the H–P relationship, a 1000-fold reduction in grain size from microns to nanometers yields more than a 30-fold increase in strength, provided that the same dislocation mechanisms are

**Fig. 3** Dislocations models to explain the H–P behavior developed by: (A) Cottrell (dislocation pile-up); (B) Li (dislocations generated at ledges in grain boundaries); and (C) Meyers and Ashworth. Source: From Ref.<sup>[21]</sup>.

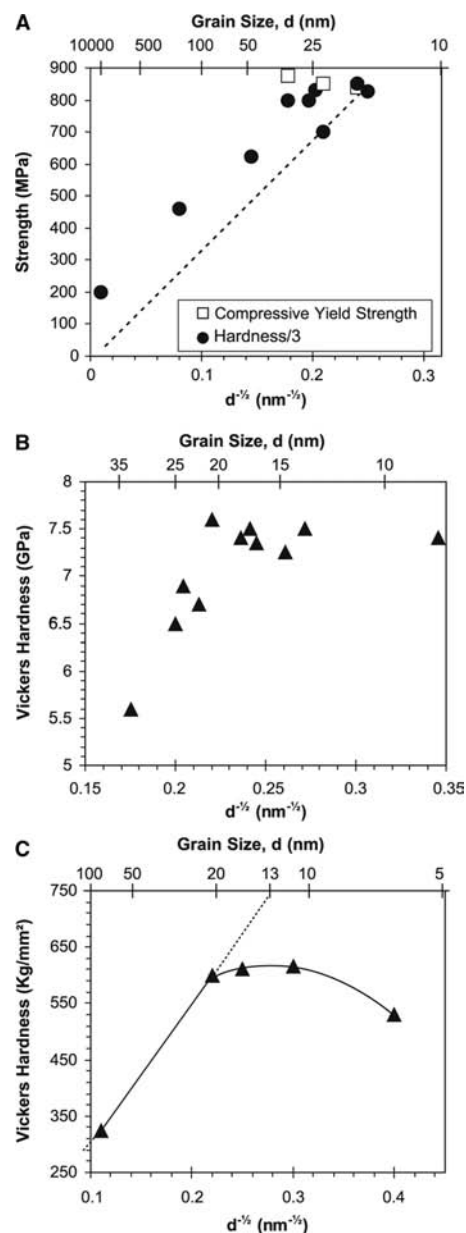

**Fig. 4** Strength–ductility values of nanostructured materials (filled symbols) compared to conventional counterparts (open symbols: circles—dispersion-strengthened Al alloys; triangles—cold-worked steels).

operational. Experimentally, strength or hardness was found to increase by a factor of 5–10 by reducing the grain size from microns down to the 30- to 50-nm level.<sup>[9,25,31]</sup> Similar high-strength values for nanocrystalline metals and alloys were observed in compression, or by hardness measurements, in which processing defects are less detrimental than in tension. Yield strengths greater than 1 GPa were found in Pd (40–50 nm), and yield strengths close to 1 GPa were found in Cu (20 nm).<sup>[9]</sup> Ball-milled and densified Fe (24 nm) had a true compressive strength of approximately 3 GPa,<sup>[24]</sup> whereas IGC-processed 21-nm Ni failed in compression at more than 2.1 GPa.<sup>[21]</sup>

Often the spread of experimental data is quite large, but reasonable H–P correlations at the smallest grain sizes have been revealed (i.e., stronger materials at smaller grain size) (Fig. 5). Deviations from H–P strengthening, where the slope decreases or the curve flattens, also have been reported, usually at grain sizes smaller than about 30 nm (Fig. 5B and C).<sup>[24,32]</sup> An inverse H–P effect, in which strength decreases at the smallest grain sizes, has been reported in alloys such as Ni–P.<sup>[33]</sup> This effect was most often reported in specimens annealed to increase the initial small grain size in metals or intermetallics.<sup>[20,22]</sup> Generally, these results must be treated with caution because either processing artifacts may not have been completely eliminated, or other processes (e.g., precipitation of a second phase in Ni–P alloys or in mechanically alloyed Fe) may have interfered with the measurements.<sup>[24,33]</sup>

Various mechanisms have been proposed to rationalize the deviations from H–P strengthening, such as the breakdown of dislocation pileups, lack of

The dotted lines are the H–P extrapolations of coarse grain data Source: *Materials and Metallurgical Transactions* and J. R. Weertman.

dislocation activity, and increased contributions from diffusional deformation mechanisms (creep and grain boundary sliding).<sup>[14,21,34,35]</sup> Cheng, Spencer, and Milligan<sup>[34]</sup> proposed a deformation mechanism map showing the transition from the dislocation mechanisms to intergranular processes. Transmission electron microscopy studies have confirmed the lack of dislocation structure below a critical grain size of 10–30 nm.<sup>[13,34]</sup>

To explain the H–P behavior, a model based on dislocation generation from grain boundary sources was recently proposed by Cheng, Spencer, and Milligan.<sup>[34]</sup> The model also predicts the observed tension/compression asymmetry based on the pressure dependence of dislocation self-energy during bowout. Composite models considered grain interior and grain boundary properties, and, sometimes, triple junction lines and quadruple nodes.<sup>[21]</sup> The width of grain boundary or adjacent area is still under debate, but the maximum yield strength was found at similar grain size value (about 10 nm). Composite models that are more consistent with microstructural results by accounting for a dispersion in grain sizes have been developed.<sup>[28,35]</sup> These models combine deformation mechanisms that are active in various grain size ranges. Masumara, Hazzledine, and Pande<sup>[35]</sup> considered a combination of dislocation glide for grains larger than a critical size  $d^*$  and Coble creep below  $d^*$ . In the model developed by Mitra et al.<sup>[28]</sup> the critical grain size  $d^*$  differentiates grains that undergo plastic deformation ( $d > d^*$ ) from grains that remain elastic ( $d < d^*$ ).<sup>[21]</sup> The overall calculation was based on the plastic deformation of grains in an elastic matrix that used the mechanics of non-deformable inclusions. The average grain size was given by a volume averaging of the grains, similar to previous work.<sup>[35]</sup> For the same average grain size, the volume fractions are shown to be greatly influenced by the standard deviation (Fig. 1B). In turn, a larger standard deviation (with more small-size grains deformed by creep) results in softer behavior (Fig. 1C).

### Two-phase alloys and nanocomposites

The addition of a second phase produces greater mechanical strength in nanomaterials just as in conventional materials. Bulk materials made of quasi-crystalline or icosahedral phases (less than 50 nm) in an Al matrix (5–10 nm; Al–Cr or Mn–Ln, e.g.,  $\text{Al}_{93}\text{Mn}_5\text{Co}_2$ ) exhibited strength values of 550–850 MPa with 5–25% elongations.<sup>[1]</sup> High strength and high ductilities also have been found in the case of nanoparticles reinforcing amorphous matrices in Mg-based, Al-based, and Zr-based alloys.<sup>[7]</sup> The nanosize particles prevent fracture because of improved interfacial bonding, which favors load transmission from one phase to the other.

Tensile strength doubled in ED Ni–SiC composites by reducing matrix grain size to 10–15 nm. SiC particles (400 nm) up to about 2 vol.% changed the fracture from brittle to nanocrystalline Ni to ductile ( $\epsilon > 2\%$ ) in Ni–SiC composites.<sup>[36]</sup> However, only a modest increase in hardness was observed by the addition of 5 vol.%  $\text{SiO}_2$  particles (20 nm) to 60 nm of SPD copper (microhardness of 2800 vs. 2600).<sup>[37]</sup> The hardness

increase in mechanically alloyed  $\text{Zr}_{55}\text{Al}_{10}\text{Cu}_{30}\text{Ni}_5$  reinforced with 35-nm W particles obeyed the rule of mixtures.<sup>[38]</sup> In contrast, fiber and lamellar composites (multilayers) display hardness values far in excess of the rule of mixture values because of the restriction of dislocation propagation by the second layer.<sup>[39]</sup>

### Ductility of Nanostructured Materials

Ductility is defined as the ability to plastically deform prior to fracture. Therefore it is a critical property for both the performance and the manufacturing of nanostructured materials.<sup>[18]</sup> Ductility is measured by percent elongation before failure (e.g., elongation to failure  $\epsilon_f$  in Fig. 2B), or percent reduction of area after necking in tension.

With the decrease of grain size to nanometer levels, increases in ductility have been predicted.<sup>[18,29,30]</sup> According to Coble's theory, the significantly larger interfacial area enhances deformation by diffusional transport and grain boundary sliding. This enhanced sliding at the more numerous grain boundaries should result in an increased deformation in metals even at room temperature. The most dramatic change of ductility was predicted for normally brittle materials such as intermetallic compounds.<sup>[18]</sup> The prediction is based on conventional material behavior, in which a fine grain size decreases the stress required to nucleate microcracks as compared with that required to propagate them. If crack propagation occurs only at high stress values, the fine-grained materials may undergo plastic strain and work hardening before failure. In other words, in tension testing (Fig. 2B), a material displays ductile behavior if plastic deformation occurs without the onset of catastrophic failure. Chan<sup>[40]</sup> calculated a critical grain size (e.g., 2.8  $\mu\text{m}$  in NiAl) below which crack growth occurs in a stable manner to render the intermetallics ductile. Experimentally, such behavior was observed in the now-classical results for NiAl alloys, which become ductile at a grain sizes below 20  $\mu\text{m}$ . A high ductility (e.g., greater than 11.5% in compression) was reported in NiAl with sub-micron grain size.<sup>[41]</sup> Ductility of more than 5% in compression was reported by Kimura<sup>[42]</sup> in TiAl (grain size less than 22 nm) crystallized from an amorphous precursor. However, this behavior was not reproduced in other intermetallics.

In metals and alloys, ductilities lower than in conventional materials have been reported.<sup>[18,43]</sup> Despite the efforts to improve the processing and testing, it is difficult to differentiate intrinsic from flaw-limited ductilities. When the grain size is reduced to less than 25 nm, ductility values in tension or bending decrease from about 50% in conventional materials to 1–2%.<sup>[18]</sup>

**Fig. 6** Tensile elongation vs. grain size in nanocrystalline Zn and Cu. Source: C. C. Koch.

Little tensile ductility (less than 2%), or completely brittle behavior is commonly reported in metals even after careful processing (e.g., in IGC-processed 28-nm Ni,<sup>[13]</sup> ED-processed 27.5- to 30-nm Ni,<sup>[44]</sup> and IGC-processed 27-nm Cu,<sup>[19]</sup>). An illustration of the variation of ductility with grain size is provided in Fig. 6 for two nanocrystalline metals. It is noteworthy that higher ductility is observed in the hcp metal (Zn) rather than fcc (Cu), which is contrary to the dislocation-based plastic behavior at conventional grain sizes. A few truly ductile nanomaterials ( $\epsilon_f > 5\%$ , as a structural design criterion) are shown in Figs. 4 and 6.

If the dislocation generation and interactions are similar to the coarse-grained materials, strain hardening can be expected in nanosize materials. Strain hardening controls the amount of uniform elongation at stresses larger than yield strength. Generally, hardening was observed, sometimes, to be of a significant value and at a large plastic strain such as in a 60-nm SPD Cu<sup>[37]</sup> or in tension or compression in other metals.<sup>[43]</sup> However, a different behavior with little or no strain hardening and shear banding has also been reported in nanomaterials, mostly bcc metals and alloys (Fe, Fe-Cu, and Ta), but also in fcc and hcp and intermetallics.<sup>[25,43,45]</sup> Perfectly plastic behavior with no strain hardening is typical for materials in which initial plastic flow is difficult (e.g., amorphous or highly strained metals). In nanomaterials, one assumption is that the grain boundaries introduce sufficient defects similar to amorphous materials such that unstable plastic flow is initiated as soon as the yield

strength is reached at a local stress concentration.<sup>[9]</sup> Crack growth will occur, resulting in failure without prior macroscopic ductility.<sup>[24]</sup> Brittleness may be observed if the stress to activate surface cracks is lower than the stress to activate Frank-Read dislocation sources and no crack blunting mechanism is in operation.<sup>[31]</sup> Calculations show that tensile stresses at which brittle fracture occurs indeed correspond to the stresses required for brittle fracture in materials with micron-size flaws.

The other source of low ductility may be the absence of effective mechanisms for plastic deformation, mainly the lack of dislocation activity in grains below a size of about 30 nm.<sup>[13,34]</sup> The lack of noticeable dislocations is consistent with the brittle fracture exhibited by a 28-nm Ni specimen.<sup>[13]</sup> Zimmerman et al.<sup>[36]</sup> also reported higher ductilities in 40- vs. 14-nm grain size ED Ni.

Grain boundary sliding and grain rotation were shown to be the deformation mechanisms in some nanomaterials that exhibited ductile behavior such as electrodeposited Ni or 10-nm sputtered gold films.<sup>[45,46]</sup> Indirect evidence of grain boundary sliding is provided by the strain rate increase as the grain size becomes smaller and there is no change in the total amount of grain boundary deformation.<sup>[14]</sup> Strain rate shows no grain size dependence at larger grain sizes (greater than 10 nm). Molecular dynamics simulations showed grain boundary sliding responsible for inverse H-P behavior even at low temperature and without any porosity.<sup>[14,15]</sup>

## Two-phase nanomaterials

Second-phase particles increase the flow stress on local shear planes, thus resulting in more uniform deformation and higher elongation. High elongations (5–25%) are exhibited by Al-based alloys with nano-scale icosahedral quasi-crystalline phases in a ductile fcc Al matrix (obtained by extrusion).<sup>[1,7]</sup> A homogeneous dispersion of nanosize crystalline particles in an amorphous matrix is able to suppress local shear deformation in Mg-based and Zr-based alloys.<sup>[7]</sup> In some Zr-based or Al-based alloys, the precipitation of nanoscale particles induces considerable strengthening but decreases ductility, as compared with a fully amorphous alloy.<sup>[7]</sup> When the precipitate amount is greater than 50%, the alloys become brittle. However, second-phase particles in metal-based alloys seem to have a different effect in nanosize matrices than in conventional dispersion-strengthened alloys. For instance, an addition of 0.7 vol.% SiC to a nano-Ni matrix increased the ductility to 3.4% as compared with 0.2% in pure 14-nm Ni.<sup>[36]</sup>

## FRACTURE AND FAILURE

Fracture toughness ( $K_c$ ) is defined as the value of a stress intensity factor at a crack tip to induce crack propagation and failure as given by:<sup>[29]</sup>

$$K_c = Y\sigma_f\sqrt{a} \quad (4)$$

where  $Y$  is a dimensionless geometry factor,  $\sigma_f$  is the applied stress at fracture, and  $a$  is the crack length. Usually, a high fracture toughness value is an indication of ductile behavior because work is needed to produce local plastic strain at the crack tip. There is some expectation that decreasing grain size would also result in increased  $K_c$ . This effect was expected to be particularly beneficial for normally brittle materials such as intermetallic compounds. However, Armstrong<sup>[47]</sup> showed that there is a limit when the crack tip plastic zone size is approximately equal to the grain size, below which the toughness should decrease as the grain size decreases.

Only limited measurements of fracture toughness of nanomaterials are available in the literature, owing in part to the stringent specimen size requirements.<sup>[29]</sup> The available data suggest that, in general, the anticipated improvement in fracture toughness with decreasing grain size has not been realized. Rather, experiments and modeling indicate that the fracture resistance in both metals and intermetallics appears to be limited by the nucleation of nanovoids at grain boundaries and intergranular crack propagation.<sup>[48–50]</sup>

Fracture toughness was found to decrease with a reduction in grain size below 1  $\mu\text{m}$  in TiAl, whereas it remained constant down at 12 MPa  $\text{m}^{1/2}$  to  $\sim 40\text{ nm}$ , and then decreased to about 5 MPa  $\text{m}^{1/2}$  in FeAl.<sup>[23,51]</sup> Similarly, very low values of fracture toughness (2 MPa  $\text{m}^{1/2}$ ) were reported in Fe–45% Al and Al<sub>3</sub>Ti.<sup>[52]</sup> Because grain boundary diffusion and sliding can occur in nanocrystalline solids at room temperature, these processes may control toughness at low crack propagation rates. This suggestion is supported by the observation of Mirshams et al.<sup>[53]</sup> of the  $R$ -curve fracture behavior in nanocrystalline nickel produced by ED, in which  $K_c$  increases with the growth of a crack in a slow, stable manner. As with other mechanical properties, these differences in behavior may be partially attributable to the different defect densities associated with the various processing techniques. Additional data are needed to more fully distinguish between intrinsic grain size effects and the influence of processing on fracture toughness.

## FATIGUE PROPERTIES

The study of fatigue is normally divided into two important aspects: 1) deformation under cyclical loading conditions leading to crack initiation; and 2) the rate of growth of a preexisting flaw or crack. Only a few studies of fatigue of nanocrystalline or ultrafine-grained materials, dealing mainly with cyclical deformation, have been published to date. As with other mechanical properties, these studies suggest that the processing method is important.

Nanocrystalline copper prepared by IGC and compaction revealed no cyclical hardening or softening during tension–tension loading.<sup>[54]</sup> However, some creep strain superimposed on the cyclical response was evident. Of particular note is the observation of shear bands extending over many grain diameters on the surface of the fatigued specimens. In addition, the material was observed to protrude from the surface much like the extrusions observed in conventional copper alloys. This finding suggests that some mechanism of strain localization on a scale larger than the grain size is operating. Similar surface observations were reported for SPD-processed ultrafine-grained copper.<sup>[55]</sup> On a strain–life basis, this ultrafine-grained copper was less fatigue-resistant than conventional materials. However, the mechanical response of this material reveals a decreasing stress amplitude with an increasing number of cycles or cyclical softening, as expected for a predeformed metal. A similar material was more fatigue-resistant than conventional copper when compared on a stress–life or S–N basis.<sup>[56]</sup> Surface markings have also been observed in a yttria-stabilized zirconia ceramic, although in this case the strain localization is most likely

because of diffusional deformation processes rather than dislocation processes.<sup>[57]</sup>

It is not yet clear whether any of our understanding of fatigue in conventional materials can be extended to the nanometer grain size level. However, it is important to recognize that the features observed in fatigue are normally on the order of 1  $\mu\text{m}$  in scale, hence are clearly coarser than the nanocrystalline grain size. Additional fundamental studies are needed.

## WEAR

The processes involved in tribological conditions are heavy local deformation, work hardening, cyclical loading, and fracture, collectively resulting in material removal. Nanocrystalline materials have been used for wear resistance in bulk (e.g., cutting tools), or for surface applications (coatings) because of their high hardness. The materials for cutting tools are carbides ( $\text{WC}$  or  $(\text{Fe}, \text{Mo}, \text{Cr}, \text{V})_x\text{C}$ ) in soft matrices ( $\text{Co}$ ,  $\text{Fe}$ , or intermetallics), but most materials used commercially have grain sizes in the submicron range. Wear resistance has been shown to scale with hardness in metal ( $\text{Ni}$  and  $\text{Ni-P}$ ), composites ( $\text{Ni-SiC}$ ), and lamellar coatings (e.g.,  $\text{Cu-Ni}$ ).<sup>[25]</sup> The friction coefficient in sliding and rubbing wear was found to decrease by a factor of 2–3 by decreasing grain size (e.g., in sputtered  $\text{Al}$  layers).<sup>[3,25]</sup> The scratch indentation of 10 wt.%  $\text{TiO}_2$  (32 nm) in an epoxy matrix was 33% smaller than for pure epoxy.<sup>[58]</sup>

## ELEVATED TEMPERATURE BEHAVIOR

At elevated temperatures, creep deformation under sustained loads is of importance in structural materials. Whereas a fine grain size is beneficial in promoting high strength at low temperatures, creep resistance normally becomes worse as the grain size decreases. Rather than deforming by dislocation motion, the principle mechanisms of creep deformation in nanomaterials involve diffusional processes because of enhanced high diffusivity at grain boundary and triple junction paths.

Specific creep mechanisms are characterized by the dependence of creep rate on stress, temperature, and grain size. Temperature dependence is expressed through the activation energy for the diffusion of vacancies. For nanocrystalline materials, the most commonly reported mechanisms involve vacancy transport along grain boundaries. This process is known as Coble creep, and the strain rate is represented by an equation of the form:<sup>[29]</sup>

$$\dot{\epsilon} = A_C \frac{\delta D_b G b}{kT} \left(\frac{b}{d}\right)^3 \frac{\sigma}{G} \quad (5)$$

where  $A_C$  is a constant,  $\sigma$  is the stress,  $G$  is the shear modulus,  $b$  is the Burgers vector,  $\delta$  is the grain boundary thickness,  $D_b$  is the grain boundary diffusivity,  $k$  is the Boltzmann's constant, and  $T$  is the temperature. The Coble mechanism is favored at high stresses and low temperatures, even down to room temperatures in nanocrystalline materials. An alternative deformation mechanism involves grain boundary sliding, accommodated by the diffusion of vacancies in the grain boundaries, and is described by a similar equation:<sup>[29]</sup>

$$\dot{\epsilon} = A_{\text{GBS}} \frac{\delta D_b G b}{kT} \left(\frac{b}{d}\right)^3 \frac{\sigma^2}{G} \quad (6)$$

Grain boundary sliding is the mechanism to control superplastic deformation, in which fine-grained materials exhibit extended ductilities of up to several thousands of percent. One key question is whether nanocrystalline solids exhibit superplasticity at low temperatures and high strain rates. If so, this would enable these materials, especially otherwise brittle ceramics and intermetallics, to be formed readily into near-net shapes. Finally, we note that the above two equations differ primarily in the dependence of strain rate on grain size and stress. Thus by measuring these two dependencies, it is possible to distinguish which mechanism controls the creep deformation.

A variety of pure metallic, intermetallic, and ceramic materials have been creep-tested in nanocrystalline form.<sup>[59]</sup> In addition to the usual processing problems (porosity and suitably large specimens), the interpretation of the creep results is hampered by possible grain growth during testing, testing under constant load rather than constant stress, and often limited amounts of creep strain that may not represent a steady state to which the above equations apply. In spite of these difficulties, a number of common ideas have emerged from the available data. Tests of nanocrystalline pure copper and nickel produced by ED appear to demonstrate Coble creep, even at room temperature.<sup>[60–62]</sup> However, there is some evidence that grain boundary sliding controls the deformation of  $\text{Ni}$  with the finest grain sizes (6 nm).<sup>[61]</sup> In addition, when the grain boundaries are of low angle rather than of high angle as in materials prepared by IGC,<sup>[63]</sup> the creep rates are orders of magnitude slower than those predicted by the Coble creep equation. The creep of nanophase  $\text{Ni-P}$  and  $\text{Fe-B-Si}$  alloys (approximately 25 nm in grain size) produced by crystallizing amorphous alloy ribbons also follows the Coble creep equation, although absolute comparisons cannot be made in the former case because of a lack of diffusivity data.<sup>[64,65]</sup>

In a similar manner, nanocrystalline ceramics such as monoclinical zirconia and yttria-stabilized zirconia

exhibit creep deformation at elevated temperatures with stress dependencies of 1.7 and 1.4, respectively.<sup>[66,67]</sup> These values are difficult to interpret, but the grain size dependence in the former case clearly suggests that Coble creep is the operating mechanism.

Superplastic-like behavior has been observed in nanocrystalline nickel<sup>[68]</sup> and copper,<sup>[69]</sup> which exhibited strains up to 5100% during cold rolling of 28-nm grain size material at room temperature. The intermetallic Ni<sub>3</sub>Al has also been shown to undergo superplastic deformation, with a stable grain structure because of the ordered nature of this material.<sup>[70]</sup> Perhaps the greatest interest is in the potential of nanocrystalline ceramics to deform superplastically. An evidence of such behavior has been presented by a number of authors for TiO<sub>2</sub>, yttria-stabilized zirconia, and MgO–Al<sub>2</sub>O<sub>3</sub> spinels.<sup>[71]</sup> At elevated temperatures, grain growth inevitably occurs and may even contribute to achieving high elongations.

## Two-Phase Nanomaterials

Current experimental evidence suggests that multiphase nanocrystalline materials may exhibit superior ductility, especially at elevated temperatures. For example, Al alloys with nanoscale quasi-crystalline icosahedral (I) phases retain their good mechanical strength up to high temperatures (350 MPa at 473 K and 200 MPa at 573 K).<sup>[72]</sup> This high strength is stable on long exposure to elevated temperatures (1000 hr at 573 K) because of the high microstructural stability of the I phase. In Mg-based alloys (e.g., Mg–Al–Ga), ductility increases with temperature, and superplastic behavior was reported.<sup>[73]</sup> However, much like the ceramic materials, the microstructure had coarsened.

## CONCLUSION

The production and study of structural nanomaterials have challenged the conventional description of microstructural features and mechanical properties. New demands have surfaced to carefully monitor grain sizes and distributions, dislocation structures, as well as other defects (pores, cracks, impurities, and surface and internal stresses). The full characterization of the property dependence on processing is yet to be performed. The fabrication of sizable, reproducible, and reliable parts is an additional challenge driven by the high strength values achieved so far.

The conventional dislocation-based strengthening and yielding mechanisms show limitations, which have fostered an exploration of new mechanisms specific to the nanoscale. The inherently large fractions of atoms in non-equilibrium positions (at grain boundaries)

enhance the interface processes to contribute to plasticity. A better understanding of the deformation mechanisms as a function of crystal structure, stacking fault energy, grain size, and distribution is yet to be developed. Additional data are needed to more fully distinguish between intrinsic grain size effects and the influence of processing on mechanical properties. Simulations of deformation behavior at larger grain sizes, in bcc, hcp, or complex crystal structures, are desirable.

A wider application of structural nanomaterials requires a more reliable mechanical property characterization and a more aggressive shift from the concept to the design and fabrication of optimum parts with unique properties at low cost.

## ACKNOWLEDGMENTS

NSF and ARO support for the work on nanomaterials is gratefully acknowledged. We are grateful to colleagues who provided their preprints and to Crystal Merrill for her help with figures.

# Structural Transitions in Thin Films

Rajarshi Banerjee

## INTRODUCTION

When thin films are deposited on suitable substrate surfaces, they can exhibit crystal structures that would be metastable for the same materials in bulk form (in this entry, the terms *stable* and *metastable* refer to bulk forms). The non-equilibrium crystal structure may arise when the lattice constant or symmetry of film and substrate material are different. An example of such a situation is the pseudomorphic growth. When we start depositing a thin film on a substrate, in the initial stages, the film tends to adopt the crystal structure of the substrate. When the energy gain from the lattice fit becomes smaller than the increase in the volume energy of the strained film, pseudomorphic growth breaks down and the layer usually grows in its natural crystal structure with misfit dislocations at the interface accommodating the strain. Therefore such structures which are metastable in the bulk form of a material can be grown by epitaxial growth techniques on different substrates as well as in the form of multilayers, provided the thickness of the layers is sufficiently small, typically in the nanometer or subnanometer regime. In general, metastable pseudomorphic deposits transform to their bulk-stable polymorphs upon thickening, and the transition thickness is on the order of nanometers.

With the continuing thrust toward thinner films in devices and the potential of exploiting novel properties of such dimensionally constrained systems, it is increasingly evident that such pseudomorphic phases will be continually encountered. Furthermore, because the properties of interest, electronic, magnetic, optical, and structural, are intimately linked to the crystal structure of these nanolayered films, it is important to rationalize the formation of pseudomorphic phases and, if possible, even predict their formation. Such metastable structures have been documented for many systems in the literature, including metal/metal (e.g., Refs.<sup>[1,2]</sup>) and metal/semiconductor systems (e.g., Refs.<sup>[3,4]</sup>). Experimental observations on multilayers include ones where either one (e.g., Refs.<sup>[5-7]</sup>) or even both layers<sup>[8]</sup> can exist in metastable structures. The objective of this

entry is twofold: first, to briefly review the reports in the published literature of stabilization of pseudomorphic phases in nanolayered thin films, and second, to attempt rationalizing these observations based on a simple classical thermodynamic model. This model is a generic one which aids in the understanding of phase stability and structural transitions and leads to the development of a phase stability diagram for multilayered thin films.

## SUMMARY OF STRUCTURAL TRANSFORMATIONS OBSERVED IN NANOLAYERED THIN FILMS

### Titanium/Silver Multilayers

For the motivation of producing a one-dimensional diffraction grating to be used as a soft X-ray monochromator, Zheng, Ketterson, and Felcher<sup>[9]</sup> deposited layered films of Ti/Ag using electron-beam vaporization techniques.<sup>[9]</sup> Ti and Ag exhibit hexagonal close-packed (*hcp*) and face-centered cubic (*fcc*) structures in their bulk equilibrium forms at standard temperature and pressure (STP), respectively. The substrate used was mica and the rate of growth was about 0.8 nm/sec. Epitaxial growth was achieved by first depositing 80 nm of silver on virgin mica held at 250°C. Following the deposition of Ag, alternate layers of Ag and Ti were deposited with a bilayer thickness ( $\lambda$ ) or compositionally modulated wavelength (CMW) of 1.9 nm. The bilayer thickness is the sum of the thicknesses of a single Ti and single Ag layer that forms the repeat period of the multilayer. The films were deposited at a series of different substrate temperatures. Structural characterization of the films was performed using X-ray Laue diffraction in the transmission mode. The Ti/Ag multilayers normally develop a preferred growth texture arising from the layering of close-packed planes. Coherent stacking was observed for the {111} *fcc* planes of Ag and {0001} *hcp* planes of Ti for thicker films, suggesting that both Ti and Ag retained their bulk equilibrium

structures. However, for bilayer thicknesses below 1.9 nm, a single *fcc* structure was observed in these multilayers, suggesting the structural transition from *hcp* Ti to *fcc* Ti in the Ti layers of this multilayer.

### Niobium/Zirconium Multilayers

Nb/Zr multilayers were deposited by the process of magnetron sputtering for studying the effect of structure on the superconductivity in these multilayers.<sup>[10]</sup> Bulk Nb exhibits a body-centered cubic (*bcc*) structure, while bulk Zr exhibits the *hcp* structure at STP. The samples had  $\lambda$  values ranging from 20 down to 0.4 nm with equal Nb and Zr layer thickness. These multilayers were characterized by X-ray diffraction experiments (both high-angle as well as low-angle or grazing incidence). The composition profile, which was calculated from the low-angle X-ray diffraction profile, was not square, but rather the Zr component had partially diffused into the Nb layer. For  $\lambda > 10.9$  nm, the structure of the Zr layer was purely hexagonal with lattice constants of  $a = 0.324$  nm and  $c = 0.521$  nm. Within the region of modulation wavelengths,  $10.9 \text{ nm} > \lambda > 5.1$  nm, the Zr lattice undergoes a gradual phase transition from *hcp* to *bcc*. For  $\lambda < 3.1$  nm, the Zr layer is purely *bcc* and forms a coherent interface with the *bcc* Nb layer. Once the multilayer becomes fully coherent and exhibits a *bcc* structure, the superconducting transition temperature increases sharply with decreasing  $\lambda$ .<sup>[10]</sup>

### Nanolayered Cobalt on Gallium Arsenide

Bulk Co exhibits the *hcp* structure at STP.<sup>[4]</sup> A *bcc* form of Co was stabilized in nanolayered Co deposited epitaxially on GaAs substrates by molecular beam epitaxy (MBE), reported by Prinz<sup>[4]</sup> in 1985. The idea which leads to this discovery was a well-known property of the  $\text{Fe}_x\text{Co}_{1-x}$  alloy system which forms a *bcc* phase over the range  $1 > x > 0.25$ . By a simple linear extrapolation of the lattice constant from the *bcc* phase in these alloys, one obtains a predicted value for the lattice constant of metastable *bcc* Co to be 0.2819 nm. Prinz<sup>[4]</sup> found that by depositing Co on GaAs, it is possible to epitaxially grow Co with the desired lattice parameter and thereby form *bcc* Co.<sup>[4]</sup> Experimentally, epitaxial Co films were grown on GaAs by molecular beam epitaxy (MBE). The substrate used was (110) oriented single crystalline GaAs. Auger spectra of the as-deposited films showed small ( $\approx 2\%$ ) traces of carbon and oxygen on the surface. The films were characterized by reflection high-energy electron diffraction (RHEED). The Co diffraction patterns seem to have the same symmetry as that of *bcc* Fe and the same spacing in all the three principal

crystallographic directions on the (110) face. The film thickness of the Co film was 35.7 nm. X-ray diffraction studies showed that thicker films yield both cubic and hexagonal peaks. Very thick films showed the presence of only *hcp* Co. The critical thickness at which the Co film starts transforming from a *bcc* structure to an *hcp* structure depends on the growth conditions. In the report cited here, the authors found the 35.7-nm film to be the most thick *bcc* film without any bifurcation into *bcc* + *hcp* structures occurring. This is another case of stabilization of a metastable in bulk phase (*bcc* Co) because of epitaxial growth on (110) GaAs substrates.

### Iron/Ruthenium Multilayers

Bulk Fe exhibits the *bcc* structure at STP.<sup>[11]</sup> Fe grows in a hexagonal form in Fe/Ru superlattices. These multilayers were grown on freshly cleaved mica substrates or (11 $\bar{2}$ 0) sapphire substrates by MBE. On the basis of RHEED characterization, the authors conclude that during the initial stages of growth, the Fe layers stack pseudomorphically on the (0001) Ru planes. Around 6 to 7 monolayers of Fe, the structure of the Fe layer deteriorates as evidenced by the appearance of diffuse scattering in the RHEED patterns. The authors have attributed this to the loss of complete coherency between the Fe and Ru layers leading to the introduction of misfit dislocations at the interface. The structure of the Fe layer, however, still remains hexagonal. X-ray diffraction does not reveal any dramatic structural modification in multilayers which have 2.1 nm Fe/4.2 nm Ru. A hexagonal symmetry still persists in both the Fe and Ru layers. The authors have not reported a critical thickness at which Fe reverts back to its bulk stable *bcc* structure.<sup>[11]</sup>

### Cobalt/Copper Multilayers

Continuing on structural transitions in Co, metastable *fcc* Co was reported in Co/Cu multilayers by Lamelas et al.<sup>[12]</sup> Co and Cu are interesting candidates for superlattice studies because both elements have a close-packed structure in the bulk with a 2% mismatch within close-packed planes.<sup>[12]</sup> The Co/Cu superlattices were deposited by MBE on annealed GaAs substrates. The Co layer thicknesses investigated were 0.5, 1.0, 1.5, 2.0, 3.0, and 4.0 nm alternating with Cu layers which were maintained at a constant thickness of 2.5 nm. The total superlattice thickness was  $\sim 150$  nm. In all the cases, the authors report the formation of *fcc* Co. They have used RHEED characterization to determine the structure of the films, but conclude that it is not possible to distinguish between (111) *fcc* growth and (0001) *hcp* growth with the

RHEED technique.<sup>[12]</sup> Therefore they have used complementary X-ray diffraction results to confirm the *fcc* structure in the Co layers. Another interesting finding is that the *fcc* stacking coherence increases dramatically for Co layers <2 nm thick. The issue of *fcc* stabilization is addressed to a certain extent. The authors claim that whereas it is possible to understand the stabilization of *fcc* Co on (001) Cu substrates because of the cubic symmetry of the Cu,<sup>[13]</sup> it is not clear as to why the (111) Cu substrate should lead to an *fcc* stacking sequence in the Co layers especially since the in-plane projected symmetry is the same for both (111) *fcc* and (0001) *hcp*. A possible explanation may be related to the change in d-band occupation which takes place across a transition series in the periodic table. The bulk equilibrium structures of *bcc-hcp-fcc* exhibited by Fe-Co-Ni have been accounted for in this way based on calculations by Skriver.<sup>[14]</sup> In addition, the authors have also attributed the large elastic strains in Co/Cu multilayers (1–1.3%) to possibly stabilizing the *fcc* Co phase. Charge transfer across the interface of two dissimilar metals may also be playing a part in this transition. Finally, the authors comment on the Redfield-Zangwill model for bimetallic superlattices based on oscillatory interlayer potentials arising from the interfaces.<sup>[15]</sup> When the modulation period in a superlattice is reduced, the overlap of Friedel-like potentials of stacking faults close to the interface can lead to the formation of periodic stacking faults in the layer transforming an *fcc* layer into *hcp* or vice versa.

### Cobalt/Manganese Multilayers

A more recent study on Co/Mn superlattices<sup>[8]</sup> reports stabilization of metastable forms of both *fcc* Co and *fcc* Mn for very thin layer thicknesses.<sup>[8]</sup> Mn exhibits four different allotropic forms in its bulk form,  $\alpha$  and  $\beta$  Mn, which have complex structures with 58 and 20 atoms per unit cell, respectively, and the  $\gamma$  and  $\delta$  phases, which are *fcc* and *bcc*, respectively. Up to 6 Mn monolayers, the Mn layers being highly strained, Co and Mn are stabilized in out-of-equilibrium close-packed structures (*fcc* stacking). The thin Mn layer (even for 2 monolayers) acts as an *fcc* template for the deposition of *fcc* Co. The stabilization of a metastable structure, such as the *fcc* Co at room temperature, arises through chemical and elastic interactions between Co and substrate atoms. The authors report that the *fcc* Co in-plane lattice parameter is initially strained by the thin Mn layer, but the value returns to that of bulk *fcc* Co within 7 monolayers. This indicates that elastic interactions are probably not the predominant factor in the stabilization of *fcc* Co on thin layers of *fcc* Mn. To consider the chemical

interactions, the authors considered the difference in binding energies between two types of sites on an (111) *fcc* surface: the normal sites which, when occupied, continue the *fcc* stacking sequence, and the fault sites, which, when occupied, lead to the formation of stacking faults. The binding energy of these two types of sites depends on the nature of the adatom. They contend that the experimental observations suggest that the binding energy of the normal sites is larger, and so both Co and Mn reduce their total energies by allowing the Co atoms to continue the *fcc* stacking sequence. As the thickness of the layers is increased, for Mn thicker than 6 monolayers, the dislocation density is maximum at the interfaces with very little strains in either layer. The increase in dislocation density is matched by an increase in the occurrence of stacking faults in the Co layer which eventually lead to the transformation into *hcp* Co.

### Iron/Nickel Multilayers

Unlike Co/Mn multilayers which are a ferromagnetic/paramagnetic pair, Fe/Ni multilayers have ferromagnetic components for both the layers.<sup>[16]</sup> They are also interesting because of their interesting magnetic properties. Molecular beam epitaxy was employed to grow Fe/Ni superlattices on 500-nm-thick Ag silver buffer layers. The layer thicknesses employed were very small, of the order of a few monolayers (ML). While Fe is *bcc* in its bulk equilibrium form, Ni is *fcc* in bulk at STP. Using a 2-ML Fe layer as a template, up to 8 ML of Ni could be grown pseudomorphically with the *bcc* structure. The orientation relationship was Fe (110)//Ni (110). All the growths were carried out under UHV with the substrate at 180°C. The structural characterization was carried out using RHEED, and X-ray fluorescence was used to determine the Ni density.

### Platinum/Cobalt Multilayers

Pt/Co multilayers are a new candidate for a magneto-optical (MO) rewritable, recording medium.<sup>[17]</sup> For Co layer thicknesses less than 1.2 nm, they have perpendicular magnetic anisotropy, which is a requirement in MO recording. The Pt/Co multilayers were deposited using d.c. magnetron sputtering using Ne, Ar, Kr, or Xe gas at pressures less than 10 mTorr. Substrates used were glass and Si. While Pt is *fcc* in its bulk form at STP, Co is *hcp*. The as-deposited specimens were characterized by cross-section transmission electron microscopy (TEM) and high-resolution electron microscopy (HREM). For about 0.4-nm-thick Co, the authors report that the structure was single-phase *fcc* with (111) texture, characterized

by a lattice spacing  $\approx 0.22$  nm along the direction of chemical modulation of film growth. This value corresponds to the average of the Co (111) and Pt (111) *fcc* d-spacings. When Co thickness was increased to 0.9 nm, in addition to the diffraction from the 0.22-nm superlattice spacing, faint diffraction spots appeared at a position corresponding to a lattice spacing of about 0.2 nm. For Co layers 1 nm thick, the large difference in Pt and Co lattice constants ( $\approx 10\%$ ) hindered pseudomorphic growth of Co on Pt and there were many misfit defects visible throughout the structure.

### Ruthenium/Iridium Multilayers

Ru exhibits the *hcp* structure and Ir exhibits the *fcc* structure in their bulk forms at STP.<sup>[18]</sup> Ru/Ir superlattices exhibited an *hcp* stacking sequence for very thin Ir layers. The Ru/Ir superlattices were deposited by MBE. The two samples investigated had wavelengths of  $\lambda = 4.1$  and 6.2 nm (bilayer thicknesses). The Ru layers were 2.4 nm thick, whereas the Ir layers were 8 and 15 atomic layers thick, respectively. While the 4.1-nm multilayer exhibited an *hcp* Ru/*hcp* Ir structure, the 6.2-nm multilayer exhibited an *hcp* Ru/*fcc* Ir structure. Thus the two thicknesses of the Ir layers are on either sides of the crossover thickness for *hcp*–*fcc* transition.

### Nanolayered Copper and Palladium Thin Films on Tungsten Substrate

Bulk Cu and Pd both exhibit the *fcc* structure at STP.<sup>[2]</sup> One of the most recent observations of structural transitions is the formation of *hcp* Cu and Pd films on W (100) substrates.<sup>[2]</sup> The interesting feature in this case is the stabilization of *hcp* phase of Cu and Pd on a *bcc* W substrate. The prismatic plane of *hcp* (11 $\bar{2}$ 0) has a 2-D unit cell that is almost square, the difference between the two orthogonal axes being determined by the length of the *c*-axis. The square *fcc* (100) unit cell of the same material differs from it by at least 25%. The *hcp* structure can be stabilized on the (100) *bcc* square substrate if the misfit is sufficiently small. The authors calculate the misfit as a function of ratio of the overlay atom to the W atom and find that it is almost zero between [1 $\bar{1}$ 00] of *hcp* Cu and W <011> axes. Similarly, the misfit is very small between the [0001] of *hcp* Pd and W <011>. This accounts for the pseudomorphic stabilization of the *hcp* phases of Cu and Pd on *bcc* W (100) substrates.

### Titanium Nitride/Aluminum Nitride Multilayers

Although Ti exhibits a bulk *hcp* structure, TiN has the B1 (rock salt) *fcc*-based structure in its bulk stable

form at STP.<sup>[19]</sup> AlN crystallizes in a hexagonal wurtzite phase at ambient temperature and pressure. At high pressures in AlN, a B1 rock-salt-type structure with a lattice parameter of  $a \sim 0.406$  nm and a zinc-blende-type structure with  $a \sim 0.437$  nm can form. A recent paper<sup>[19]</sup> reported the epitaxial stabilization of the high-pressure B1 phase of AlN in TiN/AlN superlattices grown on MgO (001) substrates. The superlattices were grown in a UHV magnetron sputtering chamber. The bilayer thicknesses ( $\lambda$ ) varied from 1.8 to 8.0 nm. There is a good lattice match between TiN and the cubic (B1) form of AlN which promotes the stabilization of the cubic structure in AlN. The authors have confirmed the epitaxial growth of the multilayers by low-energy electron diffraction and high-resolution electron microscopy. They have reported a critical thickness of 2 nm at which the AlN layer transforms from its epitaxially stabilized cubic structure to its bulk stable hexagonal form.

### Cobalt/Chromium Multilayers

Co/Cr multilayered thin films have been extensively studied because their perpendicular magnetic anisotropy makes them potential candidates for perpendicular magnetic recording.<sup>[20–22]</sup> In their bulk forms, Co and Cr exhibit the *hcp* and *bcc* structures at STP, respectively. Pseudomorphic *bcc*-Co was stabilized on (110) GaAs for the first time by Prinz.<sup>[4]</sup> Subsequently, there have been numerous reports of pseudomorphic phases in Co/Cr multilayers<sup>[20–22]</sup> wherein either Co transformed from its bulk stable *hcp* to *bcc* or Cr transformed from its bulk stable *bcc* to *hcp*. Boher et al.<sup>[20]</sup> reported that in Co/Cr multilayers, involving equally thick Co and Cr layers, with decreasing bilayer thickness, the Co layers transformed from *hcp* to *bcc*. In an independent study, Vavra et al.<sup>[21]</sup> reported that in multilayers with a constant Co layer thickness, with reducing Cr layer thickness, there is a transformation in the structure of the Cr layers from *bcc* to *hcp*. It should be noted that the multilayer deposition technique used by the two groups was also different: Boher et al.<sup>[20]</sup> used radiofrequency (RF) sputter deposition, while Vavra et al.<sup>[21]</sup> used molecular beam epitaxy. Based on these results, in a more recent paper, Metoki, Donner, and Zabel<sup>[22]</sup> suggest that the situation concerning Co/Cr multilayers is *controversial* because of reports of phase transitions in the Co layers in some cases and in the Cr layers in other cases. This apparent controversy between the experimental results of different groups has arisen because of the lack of a framework for understanding phase stabilities in multilayered thin films, which will be addressed later in this entry.

## Niobium/Titanium Multilayers

While Ti exhibits the *hcp* structure ( $\alpha$ -Ti) at STP, it undergoes an allotropic transformation at 880°C from *hcp* to *bcc*.<sup>[23]</sup> The high-temperature equilibrium *bcc* phase of Ti is referred to as  $\beta$ -Ti. Similar to Zr in Nb/Zr multilayers,<sup>[10]</sup> the Ti layers in Nb/Ti multilayers exhibit a transformation from *hcp* to *bcc* on reduction in layer thickness.<sup>[23]</sup> It should be noted that this *bcc* phase adopted by Ti in Nb/Ti multilayers is a pseudomorphic phase and not in equilibrium. An X-ray diffraction pattern in the Bragg reflection geometry from a relatively thicker Nb/Ti multilayer is shown in Fig. 1A. The distinctly split peak in this diffraction pattern can be indexed as a combination of the  $\{0002\}$  *hcp* Ti peak and the  $\{011\}$  *bcc* Nb peak. This observation in conjunction with additional electron diffraction evidence<sup>[23]</sup> clearly indicates the presence of *hcp* Ti and *bcc* Nb in this multilayer. When

**Fig. 1** (A) X-ray diffraction pattern in the reflection Bragg geometry from a thicker Nb/Ti multilayer showing two distinct peaks (part of the split peak) corresponding to  $\{0002\}$  *hcp* Ti and  $\{011\}$  *bcc* Nb. (B) X-ray diffraction pattern from a thinner Nb/Ti multilayer containing the same volume fraction of Nb as in (A) showing a single  $\{011\}$  *bcc* peak due to the transformation of the Ti layers from *hcp* to *bcc* on reduction in layer thickness.

the layer thickness is reduced, for a Nb/Ti multilayer containing the same volume fraction of Nb, the X-ray diffraction pattern changes and is shown in Fig. 1B. Instead of a split peak, only a single peak visible in this pattern can be consistently indexed as the  $\{011\}$  *bcc* peak. Electron diffraction results<sup>[23]</sup> are in agreement with this observation and indicate that in this multilayer, the Ti layers have transformed to a *bcc* structure. Thus the stacking in the thinner multilayer is *bcc* Nb/*bcc* Ti. The *bcc* Ti layers adopt the same lattice parameter as that of the high-temperature  $\beta$ -Ti equilibrium phase. The high-temperature  $\beta$ -Ti phase exhibits a lattice parameter that is nearly identical to that of Nb (0.33 nm). This allows the *bcc* Ti layers to maintain a coherent interface with the *bcc* Nb layers.

Based on TEM diffraction patterns of the Nb/Ti multilayers, it was determined that for thicker layers, the *hcp*/*bcc* interface has a Burgers or near-Burgers orientation relationship given as

$$\{0001\} \text{ hcp } // \{011\} \text{ bcc}$$

$$\langle 11\bar{2}0 \rangle \text{ hcp } // \langle 111 \rangle \text{ bcc}$$

Upon transformation to a *bcc* / *bcc* interface for thinner Nb/Ti multilayers, the orientation relationship is

$$\{011\} \text{ bcc } // \{011\} \text{ bcc}$$

$$\langle 111 \rangle \text{ bcc } // \langle 111 \rangle \text{ bcc}$$

## Titanium/*fcc* Metal Multilayers

As indicated earlier, bulk Ti is *hcp* at STP. The first report of a structural transition in Ti was by Wawner and Lawless,<sup>[24]</sup> who reported the formation of *fcc* Ti on single crystal NaCl substrates. The *fcc* Ti transformed to its bulk *hcp* structure when the film was between 35 and 300 nm thick (the value varied depending upon the orientation of the NaCl single crystal). There have been a few other reports of *fcc* Ti in epitaxial thin films on substrates.<sup>[25,26]</sup> However, the most recent studies dealing with structural transitions in Ti thin films and multilayers have been carried out by Jankowski and Wall,<sup>[7]</sup> Shechtman, Van Heerden, and Josell,<sup>[27]</sup> Josell, Shechtman, and Van Heerden,<sup>[28]</sup> Van Heerden, Josell, and Shechtman,<sup>[29]</sup> Ahuja and Fraser,<sup>[5]</sup> and Banerjee et al.<sup>[6,30,31]</sup>

Jankowski and Wall<sup>[7]</sup> studied Ti thin films deposited on Ni single crystals and also Ni/Ti multilayers. The multilayers were sputter-deposited with bilayer thicknesses of 26, 8.3, and 1.3 nm with the ratio of Ni to the bilayer thickness being 0.45, 0.46,

and 0.67, respectively. The multilayers were characterized by X-ray diffraction as well as cross-section TEM and HREM studies. Jankowski and Wall<sup>[7]</sup> reported the presence of *fcc* Ti in all the multilayers. Selected area diffraction (SAD) patterns from the multilayers in the cross-section geometry could be indexed on the basis of an *fcc* Ti phase with a lattice parameter of 0.440 nm. The measured d-spacings (from the ring diffraction pattern) for the 8.3- and 26-nm multilayers poorly fit the (1120) reflection of *hcp* Ti. Furthermore, both diffraction patterns did not contain the critical (0002) reflection which is essential for the *hcp* structure. The HREM studies coupled with image simulations also confirmed the *fcc* stacking sequence in the Ti layers of these multilayers. The SAD pattern from the 1.3-nm multilayer was found to fit a single *fcc* structure. There is no evidence of *hcp* Ti in this multilayer. Jankowski and Wall<sup>[7]</sup> also deposited a monolithic 1- $\mu\text{m}$ -thick Ti film on a Ni single crystal substrate. They also found *fcc* Ti in these films in HREM images of the cross-section geometry.

Van Heerden, Josell, and Shechtman,<sup>[29]</sup> Josell, Shechtman, and Van Heerden,<sup>[28]</sup> and Shechtman, Van Heerden, and Josell,<sup>[27]</sup> have also observed the formation of *fcc* Ti in both Ni/Ti as well as Al/Ti multilayers and have attributed the transformation as an artifact of sample preparation during cold-stage ion milling in the cross-section geometry. Their studies on Al/Ti multilayers have involved layer thicknesses of 45/45, 45/180, 45/300, and 45/750 Al/Ti (all in units of nm). An additional multilayer with 90/45 Al/Ti has also been studied. They have used glass substrates and evaporation at rates between 0.3 and 0.8 nm/sec. The authors have characterized their multilayers by X-ray diffraction and TEM/HREM studies. A typical X-ray pattern from the 90/45 multilayer in the Bragg geometry did not show any peak corresponding to (111) *fcc* Ti which should occur at a  $2\theta$  angle of  $35.14^\circ$  (calculated based on the lattice parameter measured for *fcc* Ti = 0.442 nm in cross-section TEM specimens). The authors complemented their X-ray diffraction results in the Bragg geometry with X-ray transmission diffraction studies in which they also found that all the peaks could be indexed on the basis of *fcc* Al and *hcp* Ti. There were no peaks corresponding to *fcc* Ti in any of the X-ray diffraction patterns. This evidence clearly supports the authors' contention that the Ti deposits in an *hcp* form and transform to *fcc* on cold-stage ion milling of the cross section. It should be noted at this point that all the X-ray diffraction results are for the 90/45 multilayer in which the Ti layer is 45 nm thick. This is quite a thick layer and epitaxial stabilization of an *fcc* structure from the Al substrate may not be feasible for such a thick layer. At this point, it is also important to point out that the same authors have reported an evidence for *fcc* Ti based

on X-ray diffraction studies in a Ni/Ti multilayer with composition wavelength of 5.5 nm<sup>[28]</sup> in which they find the absence of a (0002) *hcp* Ti peak. On thinning all these multilayers in cross section, TEM diffraction indicates the formation of *fcc* Ti in all these multilayers, including the one in which the Ti layer thickness is 750 nm.

Ahuja and Fraser<sup>[5]</sup> and Banerjee, Ahuja, and Fraser<sup>[6]</sup> reported a series of novel structural transitions in Ti/Al thin-film multilayers based on the results of TEM observations in the cross-section geometry. These transitions are dimensionally induced in the multilayers as the bilayer thickness was varied. The bilayer thicknesses for the multilayers that have been studied are 108, 21, 9.8, and 5.2 nm. In the first multilayer with  $\lambda = 108$  nm, both Ti and Al retain their bulk stable crystal structures resulting in a stacking sequence of *hcp* Ti/*fcc* Al. Transmission electron microscopy investigations have revealed that the Ti and Al layers grow with a {0001} and {111} texture parallel to the substrate, respectively. For  $\lambda = 9.8$  nm, nm, the stacking sequence is *fcc* Ti/*fcc* Al. A further reduction of the bilayer thickness to  $\lambda = 5.2$  nm results in a stacking sequence of *hcp* Ti/*hcp* Al. It should be noted that in both these papers, the phase stability observations were based on cross-section TEM specimens. The *fcc* Ti phase reported in these papers is  $a = 0.44$  nm, similar to the value reported by Jankowski and Wall<sup>[7]</sup> and Van Heerden, Josell, Shechtman.<sup>[29]</sup> The critical transition thickness for Ti (to transform from *hcp* to *fcc*) is less than 10 nm. Effects of interfacial stabilization are likely to play a much more significant role in these structural transitions than can be expected in the "thick" 750-nm *fcc* Ti layers observed by Van Heerden, Josell, Shechtman.<sup>[29]</sup> Furthermore, it should be noted that in the case of the study by Ahuja and Fraser, for Ti layer thicknesses  $>20$  nm, the structure as observed in ion-milled cross sections of the multilayer is *hcp*, in contrast to the observation of Van Heerden, Josell, Shechtman<sup>[29]</sup> wherein the structure transformed to *fcc* even when 750-nm-thick Ti layers were thinned in cross section.

While Ahuja and Fraser<sup>[5]</sup> studied Ti/Al multilayers in which both Ti and Al layers were equally thick (volume fraction of Ti = 0.5), in more recent investigations, Banerjee et al.<sup>[30,31]</sup> have studied Ti/Al multilayers in which the volume fractions of the components have been varied. For example, the structure of the Ti and Al layers in a 10.5-nm Ti/26-nm Al multilayer is visible in the cross-section high-resolution transmission electron micrograph shown in Fig. 2A. In the cross-section geometry, the planes of atoms parallel to the Ti/Al interface correspond to the close-packed planes in each layer.<sup>[30,31]</sup> From the *ababa*... stacking of the close-packed {0001} planes in Ti layer and the *abcabca*... stacking of {111} planes in the Al layer, it is

**Fig. 2** (A) High-resolution TEM micrograph from a 10.5-nm Ti/26-nm Al multilayer in the cross-section geometry. The stacking of close-packed planes in the Ti layer is *ababa* . . . , which is characteristic of the *hcp* structure, while the stacking in the Al layer is *abcabca* . . . , which is characteristic of the *fcc* structure. (B) Cross-section high-resolution TEM micrograph from a 5.5-nm Ti/13.5-nm Al multilayer, exhibiting an *abcabca* . . . stacking of close-packed layers in the Ti layer, indicative of a transformation from *hcp* to *fcc* in the thinner Ti layers.

apparent that the Ti layers exhibit an *hcp* structure while the Al layers exhibit an *fcc* structure. When the layer thickness in these multilayers is reduced to 5.5-nm Ti/13.5-nm Al, the structure of the Ti layers changes to *fcc*. This is clearly visible in the *abcabca* . . . stacking sequence of close-packed layers in the Ti layers, characteristic of the *fcc* structure, shown in Fig. 2B. Furthermore, Banerjee, Dregia, and Fraser<sup>[30]</sup> have studied the influence of thinning geometry (cross section vs. plan view) on the crystal structure exhibited by the Ti layer. Based on these results, it appears that the formation of an *fcc* Ti phase with a lattice parameter of  $a = 0.44$  nm is likely to be a consequence of hydrogen stabilization during cross-section ion-beam

thinning, and therefore a sample preparation artifact.<sup>[30]</sup> The diffusivity of hydrogen in Ti is considerably more than the diffusivity of hydrogen in Al.<sup>[32]</sup> Cross-section thinning would actually open up a large number of parallel short-circuit diffusion paths (Ti layers) through the multilayer, whereas in the plan-view specimens, the diffusion of hydrogen is rate-limited through the Al layers before they can reach the Ti layers. Furthermore, there are two titanium hydrides which have *fcc* structures with lattice parameters similar to the one observed for *fcc* Ti in the multilayers: TiH<sub>2</sub> which is *fcc* with  $a = 0.44$  nm and TiH which is *fcc* with  $c/a = 1.09$  and  $a = 0.42$  nm.<sup>[33]</sup> However, pseudomorphic stabilization of an *fcc* Ti phase, unrelated to specimen preparation, occurs in Ti/Al multilayers for substantially thinner Ti layers when sandwiched in between much thicker Al layers. This has been clearly established by Banerjee, Dregia, and Fraser<sup>[30]</sup> Unlike the hydrogen-stabilized *fcc* Ti phase, the pseudomorphic *fcc* Ti phase adopts a lattice parameter  $a = 0.403$  nm, which is similar to that of *fcc* Al.

#### MODELING OF PHASE STABILITY IN NANOLAYERED THIN FILMS

Previous descriptions of phase stability in nanolayered thin films and multilayers can be categorized into three groups based on either classical thermodynamics, the effect of coherency strains, or interface-induced modulations in the stacking fault potential in close-packed structures. In thermodynamic analyses of thin films, the competition between interfacial (area) and bulk (volume) contributions to the free energy defines a thermodynamic critical thickness for structural transitions such as the coherent-incoherent transition in epitaxy, as well as polymorphic transitions in thin surface films.<sup>[34,35]</sup> In this view,<sup>[34]</sup> a metastable structure is stabilized in a deposit as a result of lowering the (surface and) interfacial energy. Thus the metastable structure itself is not necessarily dictated by coherency strains or any other influence of the substrate. However, in models based on coherency strains (e.g., Ref.<sup>[35]</sup>), the metastable structure is considered to result from the natural response of the deposit to large coherency strains induced by the substrate. Both types of thermodynamic models were strictly developed for the case of a thin deposit on a thick substrate, with a single degree of freedom corresponding to film thickness. However, in a multilayer, the need to treat both components in this way adds another degree of freedom. Therefore it is important to expand on the thermodynamic model when it is applied to multilayers, where the total energy of the “unit system,” defined as two layers and *two interfaces*, is minimized (as described below).

In the third type of model proposed by Redfield and Zangwill<sup>[15]</sup> the metastable phase is formed because of the stabilization of stacking faults in a close-packed structure. The lowering of the stacking fault potential results from the superposition of interface-induced modulations in this potential. This model only applies to multilayered systems which involve only close-packed structures, and it is unable to predict phase stability when volume fractions of the two components are varied. Because of these limitations of previous models, recently, a new model based on classical thermodynamics has been developed, *specifically* for rationalizing phase stability in thin-film multilayers.<sup>[30,31,36]</sup>

To expand on the *classical view*, consider as reference a unit bilayer of two metals, A and B, in their strain-free, stable crystal structures. Let the component layer thicknesses be  $h_A$  and  $h_B$ , so that the thickness of the reference bilayer  $\lambda = h_A + h_B$ . The free energy of the reference bilayer is thus:

$$G = N_A\mu_A + N_B\mu_B + 2\gamma S \quad (1)$$

where  $N_i$  is the number of atoms of species  $i$ ,  $\mu_i$  is its chemical potential,  $\gamma$  is the interfacial free energy, and  $S$  is the area of the interface. Note that other terms, for example, describing the interfacial defect content and/or elemental intermixing across interfaces, can be included in Eq. (1), but for simplicity, these are considered to be included in the interfacial energy term. Suppose this reference bilayer is transformed to a candidate state where at least one of the members exists in a metastable structure. The free energy after transformation is given by:

$$G' = N_A\mu'_A + N_B\mu'_B + 2\gamma'S \quad (2)$$

where the prime refers to the candidate state. Note that the  $N_i$ 's are constant in the closed system, and both the lamellar morphology and interfacial area  $S$  are fixed in the variation of state. Whereas the density of both layers is allowed to change on transformation, the constraint of constant area is necessary. Clearly, if the interfacial area was allowed to vary, the thermodynamic problem would include a search for the equilibrium shape, and therefore it would be ill-posed and intractable without some factors opposing the reshaping of the multilayer by an endless decrease in the interfacial area. Thus it is recognized that the proper thermodynamic potential for the problem at hand must be normalized by the interfacial area.

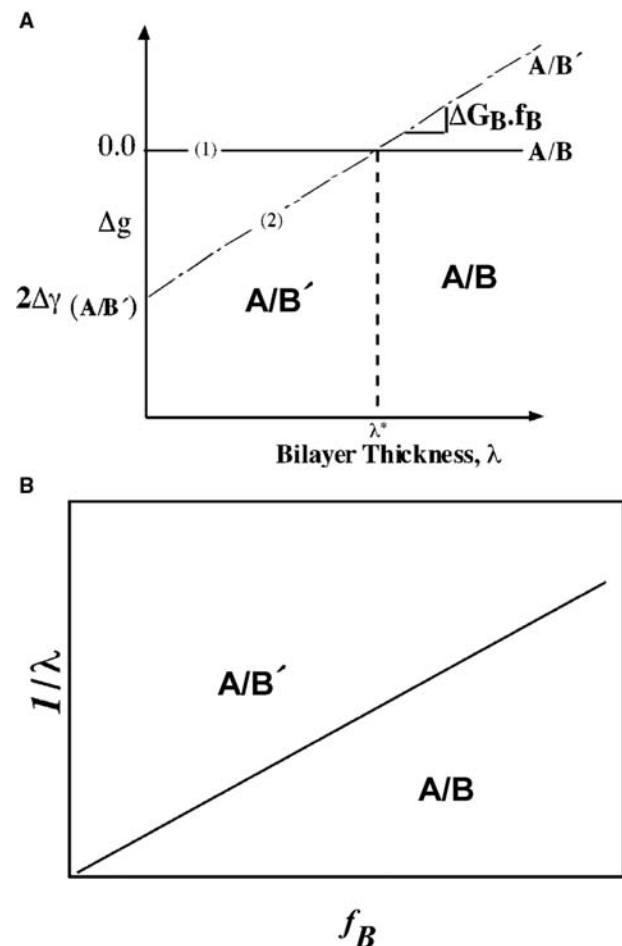

The specific free energy of formation of the candidate bilayer,  $\Delta g$ , is given as follows:

$$\Delta g = 2\Delta\gamma + [\Delta G_A(1 - f_B) + \Delta G_B f_B]\lambda \quad (3)$$

where  $\Delta g$  is normalized by the area of the interface,  $\Delta\gamma$  is the change in interfacial free energy,  $\Delta G_i$  is the allotropic free energy change per *unit volume* of reference

phase for metal  $i$ , and  $f_B$  is the volume fraction of metal B in the reference bilayer. Note that the product  $f_i\lambda$  gives the layer thickness for metal  $i$  in the reference bilayer. It is recognized that there may be several contributions to the terms  $\Delta\gamma$  and  $\Delta G_i$ , including, for example, impurity effects, local elemental intermixing, alloying in miscible systems, interface strain, and defect interactions. However, while these effects may modify the values of interfacial and bulk energies, providing the composition and interfacial area do not change during the given phase transition, such contributions to the energy terms do not invalidate the current thermodynamic analysis. Of course, these various contributions must be taken into account when determining values for these various parameters by, for example, first principles calculations.

To illustrate how the thermodynamics contained in Eq. (3) applies to phase stability in multilayers, consider a multilayered system in which below a critical value of  $\lambda = \lambda^*$ , the crystal structure of component

**Fig. 3** (A) A constant volume-fraction cut of the  $\Delta g(\lambda, f)$  surface showing the stabilization of the metastable B' phase by the reduction in interfacial energy ( $\Delta\gamma$ ). (B) A biphasic diagram for A/B multilayers.

B undergoes a transition to a metastable form B'. This situation can be depicted conveniently by a constant volume-fraction cut of the  $\Delta g(\lambda, f)$  surface, i.e., by a plot of  $\Delta g$  vs.  $\lambda$ , as shown in Fig. 3A. As the scale of the multilayer is reduced from an arbitrarily large value of  $\lambda$ , the lowest free energy corresponds to the components adopting their bulk stable forms. However, below the critical value,  $\lambda^*$ , the energy of the system is minimized by transforming component B to its metastable form. As noted above, in the present model, the transition is driven by the reduction in interfacial energy, which is represented in Fig. 3A by the negative intercept  $2\Delta\gamma_{A/B'}$ . There are several factors which influence interfacial energy, and these are conveniently grouped under chemical and structural contributions.

Eq. (3) describes a thermodynamic potential surface that varies as a function of two independent variables,  $f$  and  $\lambda$ . Formally, the thermodynamics is similar to that of phase equilibria in a one-component system under varying temperature and pressure. Here each "biphase" (i.e., one phase for each of the two layers) is represented by a surface in  $f$ - $\lambda$  space, and the equilibrium multilayer structure is the one with the lowest specific free energy of formation  $\Delta g$ . Conditions for coexistence of biphases are determined by the intersection of  $\Delta g$  surfaces, and a variety of biphase diagrams can be constructed, e.g.,  $h_A$ - $h_B$ ,  $\lambda$ - $f$ , and  $(1/\lambda)$ - $f$  diagrams. For example, Fig. 3B is the biphase diagram corresponding to the multilayers of Fig. 3A. For this hypothetical system, only two biphase fields appear on the diagram—one for the biphase composed of the two bulk-stable phases, A/B, and the other field is for the A/B' biphase, where component B is present in a metastable structure. The slope of line (1) in Fig. 3B is given by  $-\Delta G_B/2\Delta\gamma_{A/B'}$ , and because the metastable structure is stabilized by the lowering of the interfacial energy, this slope is positive (i.e.,  $\Delta\gamma$  is negative with respect to the reference state; see Fig. 3A). In a system where metastable forms can be stabilized in both layers, there may be three biphase fields meeting at a triple point. As in the case of conventional pressure-temperature phase diagrams, at the triple point, all phases coexist in equilibrium.

Equilibrium predictions of phase stability are realized experimentally only by permission of kinetics. For example, because of kinetic constraints, multiple biphases may be observed in the same multilayer, especially under experimental conditions near a boundary on the biphase diagram. Of course, it should also be noted that for systems represented by the terminal fractions ( $f_B = 0$  and 1), because there are no interfaces, then  $\Delta\gamma = 0$ , and the coexistence curves become undefined.

The biphase boundaries such as in Fig. 3B are linear because  $\Delta G$  and  $\Delta\gamma$  are assumed to be independent of  $\lambda$  and  $f$ . However, this simple result would not be

obtained in coherently strained multilayers, where the equilibrium coherency strain in each layer is inversely proportional to its thickness.<sup>[37]</sup> If the coherency strain energy was included in the thermodynamics, the resulting  $\Delta g$  would depend non-linearly on volume fraction, and this would ultimately lead to curved boundaries on the  $1/\lambda$ - $f$  biphase diagram. In the present analysis, coherency effects are ignored because they are not necessary for illustrating the basic principles underlying the biphase diagram.

As an example, the concept of the biphase diagram has been applied for rationalizing the experimental trends reported for Co/Cr multilayers. The results reported in the literature may be used to produce a preliminary biphase diagram for these multilayers, which is shown in Fig. 2. Included in this diagram are the results from Boher et al.<sup>[20]</sup> as well as the results from Vavra et al.<sup>[21]</sup> The biphase boundaries marked (1) and (3) in Fig. 4 have been drawn with the data as a guide. The triple point is constrained to be drawn at a value of  $f_{Cr} \approx 0.3$ . The slopes of biphase boundaries (1) and (3) are given by  $-\Delta G_{Cr}/2\Delta\gamma_{hcp/hcp}$  (i.e., positive slope) and  $\Delta G_{Co}/2\Delta\gamma_{bcc/bcc}$  (i.e., negative slope), respectively. From the measured slope of line (1),  $1.45 \times 10^9 \text{ m}^{-1}$ , and the literature value of  $\Delta G_{Cr} = 7.45 \text{ kJ mol}^{-1}$ ,<sup>[38]</sup> one calculates a value of  $\Delta\gamma_{hcp/hcp} = -356 \text{ mJ m}^{-2}$ . Similarly, using the slope of line (3) in Fig. 2 ( $-5.9 \times 10^8 \text{ m}^{-1}$ ) and  $\Delta G_{Co} = 4.2 \text{ kJ mol}^{-1}$ ,<sup>[38]</sup> one obtains  $\Delta\gamma_{bcc/bcc} = -537 \text{ mJ m}^{-2}$ . The  $\Delta\gamma$ 's obtained from lines (1) and (3) were used in conjunction with the available  $\Delta G$ 's to determine the slope of line (2) in Fig. 4 [given by  $(\Delta G_{Co} + \Delta G_{Cr})/2(\Delta\gamma_{bcc/bcc} - \Delta\gamma_{hcp/hcp})$ ]. Note that the resulting line (2) completes the biphase diagram self-consistently, i.e., without violating the phase rule and without conflicting with the experimental data.

Fig. 4 A biphase diagram for Co/Cr multilayers.<sup>[36]</sup> This diagram has been constructed on the basis of the experimental results from Boher et al.<sup>[20]</sup> and Vavra et al.<sup>[21]</sup>

With the aid of the biphasic diagram, it has been possible to present the various “confusing” experimental results, as noted by Metoki, Donner, and Zabel,<sup>[22]</sup> on a comprehensive, rational basis. In addition, the diagram was used to obtain reasonable values for the model parameters  $\Delta\gamma_{\text{hcp/hcp}} = -356 \text{ mJ m}^{-2}$  and  $\Delta\gamma_{\text{bcc/bcc}} = -537 \text{ mJ m}^{-2}$ . The absolute values of  $\Delta\gamma$  are similar to typical values of interfacial energy for incoherent solid/solid interfaces<sup>[39]</sup> and are significantly less than the value of about  $3 \text{ J m}^{-2}$  deduced from experiments on AlN/TiN multilayers.<sup>[19]</sup> It should be noted that these deduced values of interfacial energy differences, while being influenced by the accuracies of the  $\Delta G$ 's used [i.e., here based on the calculation of alloy phase diagrams (CALPHAD) technique], refer to the experimental samples studied in the referenced works. Hence these multilayers may be characterized to various degrees by elastic strains, defects in the bulk and at interfaces, elemental intermixing across interfaces, and impurities (among other factors). These types of factors will influence the *actual* values of  $\Delta G$ 's and  $\Delta\gamma$ 's and therefore the slopes of the lines in the biphasic diagrams. Therefore it is important to consider these factors when interpreting the values of, for example,  $\Delta\gamma$ 's deduced from biphasic diagrams. The results of applying the model to Co/Cr are encouraging and lend credence to the use of the biphasic diagram as a predictive tool for phase stabilities in the multilayers. Interestingly, one prediction afforded by the biphasic diagram shown in Fig. 4 is the possibility of observing a double transition in one of the metals, as  $\lambda$  is increased at a fixed volume fraction. For Co/Cr multilayers with  $f_{\text{Cr}}$  below the triple-point fraction, e.g.,  $f_{\text{Cr}} \approx 0.25$ , and as a function of increasing  $\lambda$ , the Co is predicted to transform once, from metastable *bcc* to stable *hcp*, but the Cr should transform twice, from stable *bcc* to metastable *hcp*, then back to *bcc*.

## CONCLUSION

Structural transitions often occur in nanolayered thin films and multilayers when the layer thickness is reduced to the nanometer scale. These transitions are usually observed when there is a difference between the bulk equilibrium crystal structures of the film and the substrate or the two layers comprising the multilayer and lead to the stabilization of pseudomorphic phases in these nanolayers. A new model has been presented to account for structural stability in thin-film multilayers, based on classical thermodynamics of the competition between bulk and interfacial free energies in nanolayers. The reduction in interfacial energy is considered to be the main driving force behind the stabilization of pseudomorphic phases in thin-film

multilayers. The thermodynamic analysis permits a new type of phase diagram to be derived for multilayers, the *biphase* stability diagram, in which phase stability is depicted as a function of *size scale* (a natural state variable associated with thin multilayered materials). While the thermodynamic model and the concept of the *biphase* stability diagram are quite simple, their applicability is quite generic.

## ACKNOWLEDGMENTS

The authors would like to thank Professor Suliman A. Dregia for many useful discussions on the subject matter of this article. Financial support for part of this work from the Center for the Accelerated Maturation of Materials at the Ohio State University is also gratefully acknowledged.

## INTRODUCTION

Ultrathin superconducting nanowires (SNWs) can be classified as “weak superconducting links”.<sup>[1]</sup> They have properties in many ways similar to Josephson junctions. Thus, SNWs can find possible applications in superconducting information processing devices: either classical<sup>[2,3]</sup> or quantum.<sup>[4–7]</sup> Nanowires can also be used as detectors and mixers of microwave radiation.<sup>[8,9]</sup> Fundamentally, the SNW is a model system for understanding coherence and decoherence effects, quantum phase transitions, and macroscopic quantum tunneling phenomena in one-dimensional (1-D) superfluids.<sup>[10–21]</sup>

Because of the strong thermal fluctuations in 1-D, the resistance of a nanowire cannot be zero at any finite temperature. The limit of zero temperature is governed by quantum fluctuations, which are not well understood. Therefore, SNWs can fall into one of three different categories: 1) truly superconducting, i.e., with zero resistance in the limit of zero temperature, 2) resistive or normal, with a non-zero but finite resistance ( $R$ ) at zero temperature ( $T$ ), and 3) insulating, with  $R \rightarrow \infty$  as  $T \rightarrow 0$ . On general grounds, it is expected that extremely thin nanowires should lose their ability to carry a supercurrent. General conditions under which this happens are not known. Many experiments show that nanowires having their normal state resistance,  $R_N$ , lower than the superconducting quantum resistance,  $R_Q = h/(2e)^2 \approx 6.5 \text{ k}\Omega$ , obey the predictions of the Langer, Ambegaokar, McCumber, and Halperin (LAMH) theory of thermally activated phase slips (TAPS). Such wires can be considered true superconductors because this theory predicts zero resistance at zero temperature. On the other hand, SNWs with  $R_N > R_Q$  frequently show deviations from LAMH or even an insulating behavior.<sup>[11]</sup> In some cases, these deviations can be explained by the effect of quantum phase slips (QPS).<sup>[12]</sup>

Here we focus on superconducting nanowires produced by sputter-coating single linear molecules (carbon nanotubes, DNA) with thin metallic films. Such molecular templating technique<sup>[11]</sup> results in nanowires that are thinner than 10 nm in diameter. Continuous SNWs were produced with the following two materials:<sup>[11,12,22]</sup> 1) amorphous alloy of MoGe, which is usually used for making extremely thin (down to  $\sim 1.5 \text{ nm}$ ) and homogeneous films,<sup>[23–25]</sup> and 2) Nb metal, which finds applications in superconducting electronic circuits. Although Nb wires are polycrystalline,<sup>[22]</sup> the critical current density in them is  $\sim 10^7 \text{ A/cm}^2$ , i.e., is similar to bulk practical superconductors (Ref.<sup>[26]</sup>, p. 372).

## PROPERTIES OF SUPERCONDUCTING NANOWIRES

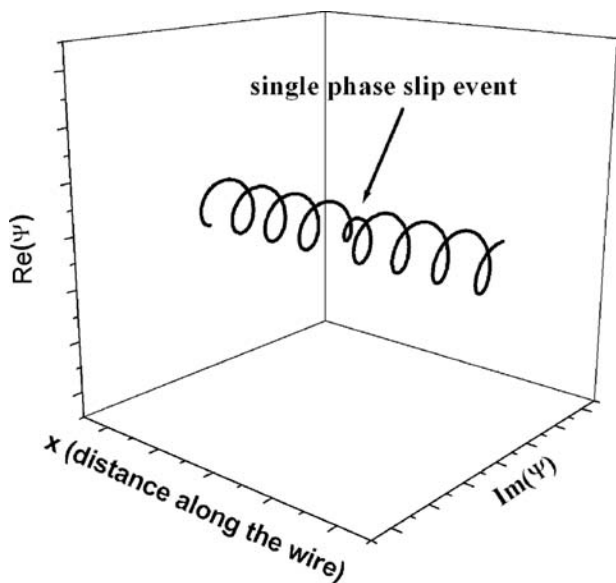

### Thermally Activated Phase Slips

The physics of superconducting nanowires is extremely rich and many puzzles remain unresolved. Perhaps the most striking property of SNWs is their inability to reach zero resistance at any nonzero temperature.<sup>[27]</sup> This property agrees with the Mermin–Wagner theorem,<sup>[28]</sup> which prohibits thermodynamic phase transitions in 1-D systems.<sup>a</sup> In particular, a thin 1-D wire made of a superconducting metal cannot undergo a phase transition into a fully superconducting state, i.e., a state with  $R = 0$  at any non-zero temperature. The mechanism of acquiring a non-zero resistance is known as phase slippage (PS) process. It is due to strong thermal (or possibly quantum) fluctuations in 1-D wires.<sup>[29]</sup> The theory of thermally activated phase

<sup>a</sup>A superconducting nanowire is considered 1-D if the diameter of the wire is the same as the superconducting coherence length or smaller.

slips (TAPS) was developed by Langer, Ambegaokar, McCumber, and Halperin (LAMH).<sup>[30,31]</sup> Thermally activated phase slips have been studied since the 70s and are quite well understood. Early experiments on 0.5- $\mu\text{m}$ -diameter tin whiskers confirmed the LAMH theory.<sup>[32,33]</sup>

Each TAPS is a strong and short-lasting thermodynamic fluctuation occurring in a short segment of length,  $\sim 2\xi(T)$ , somewhere along the wire. The order parameter,  $\psi = |\psi|e^{i\varphi}$ , is zero [ $\psi(x,t) = 0$ ] at the center of the TAPS and, correspondingly, the phase,  $\varphi(x,t)$ , is indeterminate at this point. So, with each TAPS the phase difference  $\Delta\varphi = \varphi(L) - \varphi(0)$  along the wire changes by  $\pm 2\pi$ . Here  $x$  is the position along the wire and  $L$  is the wire length. In the absence of phase slips, a state of constant supercurrent,  $\psi(x) = |\psi|e^{ikx}$ , is realized. The wave vector,  $k$ , is proportional to the supercurrent,  $I_S$ . The amplitude,  $|\psi|$ , is constant along the wire if  $I_S = \text{constant}$ . A convenient presentation of  $\psi(x)$  is given in Fig. 1. Here two axes correspond to the real and imaginary parts of  $\psi(x)$ , and the third axis is the space coordinate  $x$ . In this representation a spiral of a constant radius represents a state with  $I_S = \text{constant}$ . The number of turns in the spiral is proportional to  $I_S$ . Thus, if the winding number does not change then the current remains constant. On the other hand, if a phase slip occurs, the order parameter goes to zero at one point and the spiral loses one loop, so the supercurrent diminishes. A phase slip (PS) event is shown in Fig. 1. An antiphase slip (APS) is a similar fluctuation that

**Fig. 1** Superconducting order parameter of a thin wire with a phase slip (PS) in the center. The PS is a short-lived event ( $\sim 10^{-12}$  sec) during which the order parameter goes to zero at one point. During the PS, the spiral loses one loop and the supercurrent becomes smaller.

increases the winding number by one. Thus, the phase difference between the ends of the wire changes by  $-2\pi$  for each PS and by  $+2\pi$  for each APS.

The problem of calculating the resistance reduces to finding the rate at which phase slips occur in the nanowire. The voltage on the wire (at a fixed small bias current,  $I$ ) is given by the Josephson relation  $2eV = \hbar(d\varphi/dt) = 2\pi(n_+ - n_-)\hbar \equiv 2\pi\hbar\Delta n$ , where  $n_+$  and  $n_-$  are the rates of PS and APS, respectively. The predicted volume of the phase slip is  $V_{\text{PS}} \approx 3.77\xi A$ , where  $A$  is the cross section area of the wire.<sup>[30]</sup> The free energy of a PS is  $\Delta F(T) = [H_C^2(T)/8\pi]V_{\text{PS}}$ , where  $H_C(T)$  is the thermodynamic critical field. At zero bias current,  $I = 0$ , the rates of PS and APS are equal:  $n_+ - n_- = n = \Omega \exp[-\Delta F(T)/k_B T]$ , where  $\Omega = [8k_B(T_C - T)/\pi\hbar][L/\xi(T)]\sqrt{\Delta F/k_B T}$  is the so-called attempt frequency,  $k_B$  the Boltzmann constant,  $\hbar$  Planck's constant,  $T$  the temperature, and  $T_C$  the critical temperature. At  $I > 0$  the barrier corresponding to PS is lower than the APS one, leading to a net phase flow,  $n_+ > n_-$ . We have  $n_{\pm} = \Omega \exp[-(\Delta F(T) \pm \delta F)/k_B T]$  and  $\Delta n = 2\Omega \exp[-\Delta F(T)/k_B T] \sinh(\delta F/k_B T)$ , where  $\delta F = \pi\hbar I/2e$  is half of the free energy difference between PS and APS. Using the relation  $R = dV/dI = (\pi\hbar/e)d(\Delta n)/dI$  one gets the following resistance vs. temperature dependence (here  $t = T/T_C$ ):

$$R_{\text{LAMH}}(T) = Dt^{-3/2}(1-t)^{9/4} \times \exp\left[\frac{-c}{t}(1-t)^{3/2}\right] \quad (1)$$

Because of the normal quasiparticles present in the wire close to  $T_C$ ,<sup>[27]</sup> the final expression for the wire's resistance,  $R(T)$ , is:

$$R^{-1} = R_{\text{LAMH}}^{-1} + R_N^{-1} \quad (1a)$$

where  $R_N$  is the normal-state resistance of the wire. The LAMH defines the constants  $D$  and  $c$  as follows:<sup>[12]</sup>

$$c \equiv \frac{\Delta F(0)}{kT_C} = \frac{1.76\sqrt{2}}{3} \frac{R_Q}{R_N} \frac{L}{\xi(0)} \quad (2)$$

and

$$D = (8/\pi)[L/\xi(0)]R_Q\sqrt{c} \quad (3)$$

where  $\xi(0)$  is zero temperature coherence length [ $\xi(0) \approx 7$  nm for MoGe samples].

## Quantum Phase Slips

Two types of phase slips are usually distinguished: TAPS, discussed above, and QPS. The QPS can be

observed only in very thin wires, about 10 nm in diameter or less.<sup>[14]</sup> Such nanowires can be made using the technique of suspended molecular templates (SMT).<sup>[11]</sup> The SMT method is unique because it results in nanowires that are not only very thin (down to ~3 nm) but also can be made very short, less than 100 nm if necessary. This length is comparable to or shorter than the electronic inelastic mean free path  $L_i = \sqrt{D\tau_i} \simeq 100\text{--}1000$  nm (here  $D = lv_F/3 \sim 10^{-3}\text{--}10^{-4}$  m<sup>2</sup> sec is the diffusion constant and  $\tau_i \sim 10^{-9}\text{--}10^{-10}$  sec is the inelastic scattering time). The electrons in such short SNWs can diffuse through the entire wire without undergoing inelastic collision, and so they are able to preserve quantum phase information.

The possibility of quantum tunneling of phase slips attracts much attention because QPS can be regarded as a macroscopic quantum phenomenon. On general grounds, it is expected that the probability of quantum phase slips should be proportional to  $\exp[-\Delta F(0)/\hbar\omega_S]$ , where  $\hbar$  is the Planck's constant and  $\omega_S$  is some characteristic frequency of quantum fluctuations of the superconducting order parameter. A semiquantitative model of quantum phase slips was suggested by Giordano.<sup>[10]</sup> Recent experiments on MoGe wires showed good agreement with Giordano's model<sup>[12]</sup> (see discussion below). The QPS contribution is explained in detail in Ref.<sup>[12]</sup>. The expression for the resistance in the case of QPS is similar to Eq. (1a) but an additional term is added that represents the contribution of the macroscopic quantum tunneling (MQT) of the phase slips (i.e., the contribution of QPS):

$$R^{-1} = (R_{\text{MQT}} + R_{\text{LAMH}})^{-1} + R_{\text{N}}^{-1} \quad (4)$$

Here  $R_{\text{MQT}} = \rho_{\text{QC}}R_{\text{LAMH}}$  and  $\rho_{\text{QC}} = B[\pi t/8(1-t)]^{3/2} \exp[c\sqrt{1-t}((1-t)/t - a\pi/8)]$ . The coefficients  $a$  and  $B$  are the two fitting parameters. These formulas are equivalent to those used in Ref.<sup>[12]</sup>. Here we explicitly introduce the temperature-dependent ratio  $\rho_{\text{QC}} \equiv R_{\text{MQT}}/R_{\text{LAMH}}$ . By using the formulas from Ref.<sup>[12]</sup>, it can be shown that the  $\rho_{\text{QC}}$  ratio is larger than unity (meaning that quantum tunneling of phase slips occurs with a higher rate than the thermal activation) if the temperature is  $T < 0.7T_C$ . This ratio of the quantum and thermal contributions (i.e.,  $\rho_{\text{QC}}$ ) is plotted in Fig. 8 (inset).

QPS and TAPS have different implications. If only TAPS is present, then the wire is classified as "truly superconducting" in the sense that its resistance approaches zero as the temperature approaches zero. If QPS is also present, the resistance stays above zero even in the limit of zero temperature so the wire remains resistive or normal. Thus, TAPS is responsible for breaking superconductivity at finite temperature and QPS destroys superconductivity in the limit of

zero temperature. The existence of QPS is regarded as a limiting factor for miniaturization of superconducting devices.<sup>[34]</sup> Under certain conditions, a proliferation of QPS can suppress superconductivity and can cause a superconductor-insulator (SI) quantum transition.<sup>[11,14-16]</sup>

## FABRICATION OF SUPERCONDUCTING NANOWIRES

### Molecular Templating with Nanotubes

The suspended molecular templates (SMT) method<sup>[11]</sup> uses suspended, linear rigid molecules as templates for metal coating. Three types of molecules have been tested: 1) ordinary single-wall carbon nanotubes,<sup>[11,12]</sup> fluorinated carbon nanotubes,<sup>[35,36]</sup> which are 100% insulating, and DNA molecules (see below). Because these molecules are very thin, 1–3 nm in diameter, the resulting nanowires can be made thinner than 10 nm. It was found that MoGe wires made on insulating fluorotubes have similar properties to those made on regular nanotubes. Thus the nanotube does not contribute significantly to the total conductance of the wire. Note that suspended nanotubes can also be used for the fabrication of magnetic nanowires.<sup>[37]</sup>

The SMT technique is described in detail in Ref.<sup>[11]</sup>. The fabrication process starts with an Si(100) wafer covered with a layer of 500-nm-thick SiO<sub>2</sub> and 60-nm-thick film of low-stress SiN.<sup>[38]</sup> A narrow and very long trench is then defined in the SiN film using e-beam lithography and reactive ion etching in SF<sub>6</sub> plasma. The resulting trench (Fig. 2) has a width of ~100 nm and length of ~5 mm. An undercut is then formed by placing the sample in HF for 10 sec.

Fluorinated nanotubes are deposited from a solution in isopropyl alcohol. After drying, the sample is sputter-coated with the desired superconducting metal, typically ~4–8 nm of Mo<sub>79</sub>Ge<sub>21</sub> (Fig. 2A). After sputtering, each nanotube suspended over the trench becomes decorated with metal and thus forms a metallic nanowire. A nanowire of desired width is then selected under scanning electron microscopy (SEM) (Fig. 2B) and photolithography is used for making the electrodes and etching all nanowires except the selected one (Fig. 2C).

### Molecular Templating with DNA

The DNA molecule is of course not as rigid as a carbon nanotube. Nevertheless, it is observed that when being suspended, the DNA stretches itself. Thus, DNA provides an excellent molecular template for metal deposition. For example, the micrograph in

**Fig. 2** The sample schematics. (A) The nanotubes are deposited over a trench, and a superconducting metal (Nb or MoGe) is sputtered over the entire surface of the Si chip. Thus the electrodes are formed on the banks of the trench and, at the same time, suspended nanowires form with nanotubes in their cores. Because the sample is sputtered only once, the wires have the same thickness as the electrodes. In addition, the wires are seamlessly connected to the electrodes, without any unwanted contact barrier. Photolithography and reactive ion etching are subsequently used to define the shape of the electrodes and destroy all wires but one. The d.c. sputtering is done in an argon atmosphere, in a sputtering chamber equipped with a cryogenic liquid nitrogen trap. (B) A scanning electron micrograph of a nanowire (gray line) suspended over a trench (black) and connecting to two MoGe electrodes (gray areas). (C) Schematic top view of the sample. The size of the Si chip is  $5 \times 5$  mm.

Fig. 3A shows six metal-coated DNA wires, which are visible as thin gray lines of length  $\sim 150$  nm. The tests were done on the same type of Si/SiO<sub>2</sub>/SiN substrate with trenches made as described earlier. The  $\lambda$ -DNA molecules have been deposited over the oxygen-plasma-cleaned SiN surface from a buffer solution with a 40  $\mu\text{g}/\text{mL}$  concentration. The samples were then dried and metal coated. Two important conclusions can be drawn from these experiments: 1) Because of some intrinsic mechanism, the suspended DNA molecules become stretched and appear very straight. 2) Many metals, such as Os, Cr, and MoGe, showed good adhesion to the DNA surface and produced visibly homogeneous wires. A coating of DNA with a thin ( $\sim 3$  nm) AuPd film produced granular wires (Fig. 3B). The fact that DNA appears so straight is somewhat unexpected because DNA is not nearly as rigid as carbon nanotubes. A possible explanation is that DNA interacts attractively with the substrate due to the

**Fig. 3** Metal decoration of suspended DNA molecules. The black region is the trench with an undercut. Nanowires appear as thin gray lines crossing the trench. The sample (A) has six surviving nanowires.  $\lambda$ -DNA molecules were deposited from a buffer dilute solution, dried, and sputter-coated with 4 nm of MoGe and 3 nm of SiO<sub>2</sub>. (B) Nanowires of gold-palladium templated by DNA. The trench was cut into SiN film using a focused ion beam. A 50-nm-thick gold film was deposited before the application of DNA. After the  $\lambda$ -DNA deposition, the sample was sputter-coated with gold-palladium.

van der Waals force. Thus, it is energetically favorable for the molecule to minimize the length of the freely suspended section. So, the suspended part becomes strained and perfectly straight.

### Morphology of Nb and MoGe Nanowires

The morphology of nanowires was determined using transmission electron microscopy (TEM).<sup>[22]</sup> The wires for these studies were prepared on a TEM grid. Typical micrographs of Nb nanowires are shown in Fig. 4A and B. It is clear from Fig. 4A that Nb wire is polycrystalline. It consists of randomly oriented 3- to 7-nm

**Fig. 4** (A) A high-resolution TEM (JEOL 2010) image of a Nb nanowire fabricated by sputter deposition of a 6-nm Nb film over a carbon nanotube. (B) Image of a Nb nanowire (4 nm of Nb) covered with a protective layer of Si (2 nm). (C) A TEM (JEOL 2010F) micrograph of an amorphous MoGe wire produced by sputter deposition of 7-nm MoGe film (with no Si) over a fluorinated carbon nanotube. The scale bar is 5 nm. The surface ( $\sim 1.5$  nm) of the wire appears oxidized but the core is intact.

grains. Lattice fringes have a spacing of  $\sim 0.24$  nm, which corresponds to the (111) lattice planes of Nb.

A thin,  $\sim 2$ -nm layer near the edges of the wire does not show any crystalline structure. This layer is probably an amorphous oxide formed on the surface because the wire was exposed to the atmosphere. To prevent Nb oxidation, all samples used for transport

measurements were sputter-coated with a 2-nm-thick Si film. The image of such a wire, protected with Si, is shown in Fig. 4B. The layer of Si (light layer at the surface) produces a uniform coverage of the Nb core (darker center). A typical micrograph of a MoGe nanowire is shown in Fig. 4C. The wire appears amorphous. The width variation of Nb wires (3 nm) appears larger and it has a longer characteristic length scale (along the wire) compared to MoGe wires.

## TRANSPORT MEASUREMENTS

### Setup and Resistance Measurements

In order to measure voltage vs. current,  $V(I)$ , curves of a nanowire, a sinusoidal a.c. current (at 12.7 Hz frequency and 1–10 nA amplitude) is injected through a pair of outer electrodes (Fig. 2C) and the voltage is measured on the inner electrodes, using a low-noise PAR 113 amplifier. The current is taken from the high-precision-function generator (Stanford Research Systems, DS 360) connected in series with a 1-M $\Omega$  resistor. The fifth electrode (Fig. 2C) is used to measure the resistance of the film electrodes, without involving the wire. The zero-bias resistance is determined from the slope of the best linear fit to the  $V(I)$  curves measured at low currents (1–10 nA). The temperature is measured using a Lakeshore calibrated thermometer, Cernox<sup>®</sup>. The leads connecting the sample to the room temperature amplifiers were made from a Teflon-coated resistive alloy wire, Stablohm 800, produced by California Fine Wire Co. Before reaching the sample, the wire is rolled over a cold Cu rod and coated with a layer of a conducting silver paste. Such an environment helps to thermalize the signal leads and acts as an external, microwave radiation filter (which helps to suppress the room temperature blackbody radiation propagating through signal leads). All electrical leads coming to the sample are additionally filtered with room temperature pi filters (BLP-1.9 from <http://www.minicircuits.com>). The measurements were done in an He-3 cryostat or in a pumped He-4 Dewar.

An example of a resistance vs. temperature,  $R(T)$ , curve is shown in Fig. 5. Because the wire is connected in series with some sections of the electrodes (Fig. 2C), two resistive transitions are observed. The first one (at  $\sim 6$  K) is due to the electrodes and the second transition (at  $\sim 3.5$  K) is due to the nanowire itself. Thus, the critical temperature of the nanowire is suppressed<sup>[39]</sup> compared to the film of the same thickness (i.e., the electrodes). The normal-state resistance of the wire,  $R_N$ , is determined right below the superconducting transition of the leads, as shown by an arrow in Fig. 5.

**Fig. 5** A typical resistance vs. temperature curve for a MoGe nanowire. The first resistance drop is due to the electrodes and the second, broadened, transition is due to the nanowire. The normal-state resistance of the wire is measured at a temperature slightly lower than the critical temperature of the electrodes, as shown by the arrow.

### Resistivity of Metallic Nanowires

It is important to determine the resistivity of the metal forming the nanowire and compare this to the known bulk values. The resistivity of the wire and its normal resistance should satisfy the following relation:

$$wt = \rho(L/R_N) + A_0 \quad (5)$$

Here  $R_N$  is the normal resistance of the nanowire,  $L$  is the length measured with SEM,  $t$  is the known thickness of the sputtered film,  $w$  is the apparent width of the wire measured in SEM, and  $A_0$  is the expected area of the insulating material on the surface of the wire, including an oxidized layer and/or protective Si or Ge layers, if any. It is necessary to include the “dead layer” area,  $A_0$ , in Eq. 5 because the width,  $w$ , is not the width of the conducting core of the wire, but is the total width, which is observed in SEM. In Fig. 6, we plot the total area of the nanowire,  $wt$ , vs. the unit length conductance,  $L/R_N$ . Three groups of points correspond to Nb wires (filled squares), unprotected MoGe wires (open circles) and Ge-coated MoGe wires (filled circles). The dependence is linear for each group of samples. The resistivities estimated from the best linear fits (Fig. 6) are  $\rho = 4.2 \times 10^{-7} \Omega \text{ m}$  for Nb wires,  $\rho = 2.35 \times 10^{-6} \Omega \text{ m}$  for unprotected MoGe wires, and  $\rho = 2.46 \times 10^{-6} \Omega \text{ m}$  for protected MoGe wires. This should be compared to bulk resistivity of MoGe,  $\rho_{\text{MoGe,BULK}} = 1.6 \times 10^{-6} \Omega \text{ m}$ <sup>[25]</sup> and to thin film resistivity for

**Fig. 6** Cross-section area of the wire,  $wt$ , is plotted vs. the unit length conductance,  $L/R_N$ . Here  $w$  is the width of the nanowire measured under SEM and  $t$  is the nominal thickness of the sputtered film. Each data point corresponds to a different sample. Filled squares represent Nb wires, open circles, unprotected MoGe wires, and filled circles, MoGe wire protected with a 1.5-nm Ge film. The best linear fits are shown and the parameters of the fits are indicated on the graph: dashed line for Nb, thick solid line for MoGe wires covered with 1.5 nm of Ge, and thin solid line for plain MoGe nanowires.

Nb:  $\rho_{\text{Nb,THINFILM}} = 2.4 \times 10^{-7} \Omega \text{ m}$ .<sup>[40]</sup> The resistivity of wires is slightly larger but of the same order of magnitude.

This indicates that the wires are continuous and contain no breaks or tunnel barrier between grains. The effective “dead area” is  $A_0 \approx 14.6 \text{ nm}^2$  for unprotected MoGe wires,  $A_0 \approx 38.8 \text{ nm}^2$  for Ge-protected MoGe wires, and  $A_0 \approx 40 \text{ nm}^2$  for Nb samples. Protected MoGe samples show a larger  $A_0$  because Ge on their surface contributes to the total width,  $w$ . It appears that such protection is not really necessary because the unprotected wires show a lower resistivity and thinner dead layer. In general, the following factors may contribute to large  $A_0$  values: 1) oxidation, 2) presence of a protective layer, 3) wire morphology, presence of grains on the surface, fluctuations of the wire width, and thickness, and 4) a limited resolution of SEM causing some smearing of the images.

### Superconductivity in MoGe Nanowires

Parameters of studied amorphous  $\text{Mo}_{79}\text{Ge}_{21}$  nanowires of short length ( $L = 100\text{--}150 \text{ nm}$ ) and various diameters are given in Table 1.

Resistance vs. temperature plots (Fig. 7A) show two different types of behavior: superconducting and insulating. Samples A through F and sample X show

**Table 1** Parameters of unprotected MoGe wires deposited over fluorinated single-wall carbon nanotubes

Sample	$L$ (nm)	$w$ (nm)	$D_{\text{CALC}}$ (nm)	$t$ (nm)	$R_N$ (k $\Omega$ )
A	99 $\pm$ 10	21 $\pm$ 3	11.1	8.5	2.39
B	127 $\pm$ 10	19 $\pm$ 3	11	8.5	3.14
C	93 $\pm$ 10	17 $\pm$ 2	8.8	8.5	3.59
D	109 $\pm$ 12	13 $\pm$ 3	8.3	7.0	4.73
E	116 $\pm$ 12	12 $\pm$ 4	7.9	7.0	5.61
F	125 $\pm$ 7	14 $\pm$ 4	7.8	7.0	6.09
G	105 $\pm$ 8	11 $\pm$ 2	6.2	5.5	8.22
H	121 $\pm$ 14	9 $\pm$ 2	6.5	5.5	8.67
I	140 $\pm$ 9	11 $\pm$ 2	6.6	5.5	9.67
J	86 $\pm$ 15	14 $\pm$ 3	3.1	7.5	26.17

The length of the wire,  $L$ , and the width,  $w$ , are measured under SEM. The parameter  $R_N$  is the normal state resistance,  $t$  is the thickness of the sputtered film, and the diameter  $D_{\text{CALC}}$  is calculated from  $R_N$  and  $L$  as  $D \equiv \sqrt{(4/\pi)(\rho L/R_N)}$ , with  $\rho = 2.35 \times 10^{-6} \Omega \text{ m}$ .

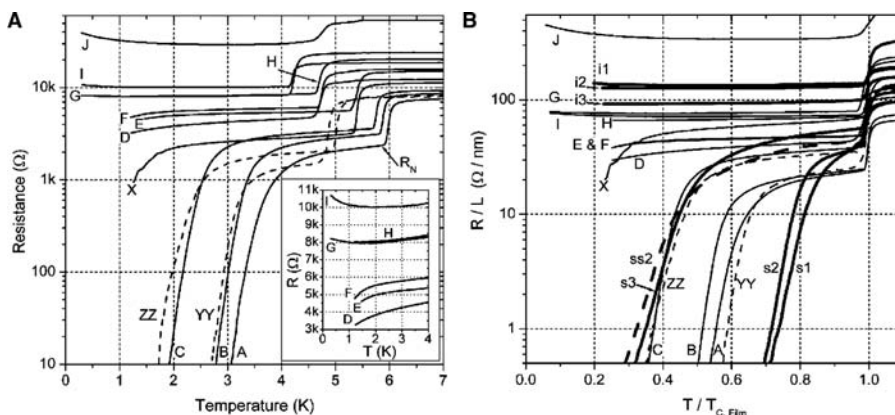

a superconducting behavior, i.e., their resistance decreases with temperature. Samples G through J exhibit an increasing resistance (with cooling) and thus considered insulating. Such dichotomy is an indication of an SI quantum transition.<sup>[35]</sup> The insulating samples not only show a slight increase of their resistance with cooling but also, unlike superconducting wires, they exhibit a maximum of the differential resistance at zero bias current (not shown). The SI transition happens when the normal resistance of the nanowire reaches the quantum resistance  $R_Q = h/4e^2 \approx 6.5 \text{ k}\Omega$ . Fig. 7A and the inset clearly show that all wires with  $R_N < 6.5 \text{ k}\Omega$  are superconducting, whereas all others are insulating. This same behavior was found in similar MoGe wires in Ref.<sup>[11]</sup>, in which case the wires were grown on regular (not fluorinated) nanotubes and were

protected with 1.5 nm of Ge. Note again that only  $\sim 100$ -nm-long wires are being considered.

An SI transition was also observed in Ref.<sup>[19]</sup>, but in that work the transition has been seen when the film square resistance (defined as  $R_W = \rho/d$ , with  $\rho$  being the resistivity of the metal and  $d$  the film thickness) reached a critical value close to  $R_Q$ . On the contrary, in our case the film square resistance at the SI transition is much lower than  $R_Q$  because  $R_W \approx R_N(w - \sqrt{A_0})/L \approx 600 \Omega \ll R_Q$ . The total resistance (or perhaps the wire diameter) appears to be a more plausible control parameters driving the transition. Fig. 7B presents all  $\sim 100$ -nm-long samples, including those of Ref.<sup>[11]</sup>. Here the resistance divided by the length of the wire is plotted vs. the temperature normalized by the critical temperature of the film electrodes of each sample. A clear dichotomy confirms the existence of a superconductor–insulator transition.

Now we compare the  $R(T)$  curves of superconducting MoGe samples with the LAMH theory. Fig. 8 shows  $R(T)$  plots for samples A, B, and C (From Fig. 7A) together with the LAMH fits computed using Eq. (1a). The fits show nearly perfect agreement with the experiment (except very near  $T_C$  where the LAMH theory does not work:<sup>[27]</sup>). The experimental fitting constants  $c_{\text{Exp}}$  and  $D_{\text{Exp}}$  are in good agreement with Eqs. (2) and (3). Thus, the wires act as homogenous 1-D superconductors, well described by the LAMH, without including QPS.

Experiments with considerably longer wires (up to 1000 nm) give significantly different results.<sup>[12]</sup> The dichotomy representing the superconductor–insulator transition was not observed in these longer wires. On the contrary, a smooth crossover from strongly superconducting to weakly superconducting wires has been seen (Fig. 9). It was possible to fit the entire series of  $R(T)$  curves of Fig. 9 using only two fitting parameters. The fitting procedure is explained in detail in Ref.<sup>[12]</sup>.

**Fig. 7** Resistance vs. temperature of MoGe nanowires. Each curve represents a different sample. (A) Log-linear plots of zero bias resistance vs. temperature. The dashed curves represent double-wire structures. (Inset) The same  $R(T)$  data magnified near  $R_Q$ . (B) Resistance divided by the length is plotted vs. the temperature normalized by the critical temperature of the film. This combined plot includes all samples listed in Table 1 and the samples from Ref.<sup>[11]</sup> (thicker lines). The sample X, with  $L \approx 50 \text{ nm}$ , is twice shorter than others. A pronounced dichotomy is observed.

**Fig. 8**  $R(T)$  data (open symbols) for samples A, B, and C compared to the LAMH theory of TAPS (continuous lines). The table shows the best LAMH fitting parameters  $c_{Exp}$ ,  $D_{Exp}$ , and  $T_C$  and compares them to the parameters ( $c_{Th}$  and  $D_{Th}$ ) computed from Eqs. (2) and (3). The dashed lines show the predictions of the Giordano model (Ref.<sup>[12]</sup>) that includes quantum phase slips (heavy dashed lines:  $a = 1.3$ ,  $B = 7.2$ ; light dashed lines:  $a = 1$ ,  $B = 1$ ). The coefficients  $a$  and  $B$  are defined in Ref.<sup>[12]</sup> and determine the ratio of attempt frequencies and the energy barriers for QPS and TAPS. (Inset) Computed plots of  $\rho_{QC} \equiv R_{MQT}/R_{LAMH}$  vs.  $t \equiv T/T_C$  for  $c = 8, 16, 24, 32,$  and  $40$  (assuming  $a = 1$  and  $B = 1$ ). The temperature  $T^* = 0.718T_C$  is a universal temperature below which the Giordano model predicts a higher QPS rate compared to TAPS.

The fits (dashed lines in Fig. 9B) are made using Eq. (4). The coefficients  $a$  and  $B$  are unknown and were used as free fitting parameters. The coefficient  $c$  is defined in Eq. (2). It represents the height of the barrier for the phase slips and it is the same parameter for TAPS as well as for QPS.

The same fitting procedure was applied to short MoGe wires with  $R_N < R_Q$  (Fig. 8). The fits, computed using Eq. (4), are shown by dashed lines in Fig. 8. They deviate from the experimental points considerably. Thus we conclude that in short wires with low enough normal state resistance (possibly defined as  $R_N < R_Q$ ) a new regime is realized. This regime can be called “true” superconductivity because the QPS rate is strongly suppressed and the LAMH theory gives correct predictions. This theory predicts that resistance should be zero at zero temperature. On the contrary, the wires that show finite contribution of QPS (such as those shown in Fig. 9) should have a non-zero resistance even at zero temperature.

The reason for different behavior in short and long wires is not well understood. Nevertheless, it might be significant that all long wires (Fig. 9) had their normal resistance above  $R_Q$ , whereas the superconducting wires (Figs. 7 and 8) have their normal resistance lower than  $R_Q$ . Thus, the above-mentioned short and long wires could simply be on different sides of the SI transition. In general, we find that the low-resistance wires show good agreement with the LAMH theory, whereas the highly resistive wires (i.e., those with  $R_N > R_Q$ ) show a considerable deviations from the LAMH (Fig. 9) or even act as insulators (samples G–J, Fig. 7A), possibly due to QPS.

**Fig. 9** (A) Resistances vs. temperature for longer (up to 1000 nm) MoGe wires reproduced from Ref.<sup>[12]</sup>. The wire’s normal-state resistances and lengths are 1: 14.8 kΩ, 135 nm; 2: 10.7 kΩ, 135 nm; 3: 47 kΩ, 745 nm; 4: 17.3 kΩ, 310 nm; 5: 32 kΩ, 730 nm; 6: 40 kΩ, 1050 nm; 7: 10 kΩ, 310 nm; 8: 4.5 kΩ, 165 nm. (B) Resistance divided by the length plotted vs. temperature, normalized by the critical temperature of the film electrodes. The solid lines represent the data. The dotted lines are calculated using the model of quantum phase slips (see Eq. (4) and Eq. (3) of Ref.<sup>[12]</sup>). The two fitting parameters that produced the best agreement with the experiment curves are  $a = 1.3$  and  $B = 7.2$  used for the entire family of experimental curves.

## Superconductivity in Nb Nanowires

Nanowires of Nb, grown on fluorinated carbon nanotubes, have properties similar to MoGe nanowires. Parameters of Nb samples are given in Table 2. All Nb wires were protected with a 2-nm Si film. As in MoGe samples, the resistance vs. temperature curves show two transitions (Fig. 10). The first one is due to the Nb film electrodes. Expectedly, this film transition temperature is lower for thinner films.<sup>[39]</sup> The resistance measured slightly lower than the film transition is taken to be the normal-state resistance of the wire,  $R_N$ . The second resistive transition is due to the nanowire itself. The LAMH theory fits, made using Eq. (1a) (Fig. 10, continuous lines), demonstrate very good agreement with the data (open circles). The dashed curves in Fig. 10 represent the Giordano model and include the QPS effect, calculated with Eq. (5).

They deviate from the experimental points. The effect of quantum phase slips is negligibly low, i.e., much lower than the Giordano model predicts. Thus, similar to MoGe wires,  $\sim 100$ -nm-long Nb wires show very strong suppression of QPS and good agreement with LAMH. The coherence length, extracted from the LAMH fitting procedure, is  $\xi(0) \approx 8$  nm for samples Nb2 and Nb3. This is comparable to  $\xi(0) \approx 7$  nm found in sputtered Nb thin films. It also agrees well with the estimate  $\xi(0) \approx (\xi_0 l)^{1/2} = 6.9$  nm, where  $\xi_0 = 40$  nm is the coherence length for clean Nb, and  $l \approx 1.2$  nm is the mean free path. For higher resistance samples  $\xi(0) \approx 15 \div 20$  nm, probably due to the suppression of the critical temperature.

Interestingly, all Nb wires that show good agreement with LAMH satisfy the condition  $R_N < R_Q$ . The only wire that deviates from LAMH (sample Nb6) satisfies  $R_N > R_Q$ . Thus, again, the quantum resistance appears as a critical point. Examples of SI transitions with a critical point at  $R_{ENV} = R_Q$  have

**Table 2** Parameters of Nb nanowires

Sample	$R_N$ ( $\Omega$ )	$L$ (nm)	$t$ (nm)	$w$ (nm)	$T_C$ (K)	$\xi(0)$ (nm)
Nb1	470	137	8	20	5.8	8.5
Nb2	650	120	7	18	5.6	8.1
Nb3	1610	172	6	16	2.65	18.1
Nb4	2350	177	6	15		
Nb5	4250	110	4	11.5	2.6	16.5
Nb6	9500	113	4	10.3	1.9	16.05
Nb7	15700	196	4	11		
Nb8	47500	235	4	11		

Parameters include the length,  $L$  (measured under SEM), the sputtered film thickness,  $t$ , the apparent width,  $w$  (measured under SEM), and the normal-state wire resistance,  $R_N$ . The critical temperature,  $T_C$ , and the coherence length,  $\xi(0)$ , are obtained from the LAMH best fits.

**Fig. 10** Temperature dependence of the resistance of Nb nanowires. The experimental points are given by open circles. The solid lines show the fits to the LAMH theory of thermally activated phase slips. These fits are made without including the quantum phase slips. The fitting parameters,  $\xi(0)$  and  $T_C$ , are indicated in Table 2. The dotted and dashed curves show the fits calculated under the assumption that quantum phase slips do occur. The dashed curves are calculated using generic fitting constants  $a = 1$  and  $B = 1$ , using Eq. (4). The dotted lines represent the constant obtained in Ref.<sup>[12]</sup>, i.e.,  $a = 1.3$  and  $B = 7.2$ . The other parameters are the same as obtained from LAMH fits.

been studied previously in different systems.<sup>[41,42]</sup> Such transitions are called dissipative phase transitions (DPT) and are controlled by the resistance of the environment. Typically, a transition into an insulating state takes place when the resistance of the environment (e.g., a shunting resistance) reaches  $\sim R_Q = 6.5$  k $\Omega$ . In short MoGe and Nb nanowires there are certain similarities to the DPT, in particular the fact that deviations from LAMH occur when the normal resistance approaches 6.5 k $\Omega$ . The dissipative environment for the nanowires could be the bath of normal electrons generated by phase slips in the nanowire itself. Thus, our preliminary conclusion is that such suppression of QPS is due to a quantum dissipation effect, i.e., the DPT. This question certainly requires further investigation.

## High-Bias Current Phenomena in Nanowires

Voltage vs. current measurements,  $V(I)$ , are presented below for a typical Nb nanowire, Nb2. With decreasing temperature, the  $V(I)$  undergoes the following transformations. Slightly below  $T_C$  and at high-bias

currents, the  $V(I)$  follows the exponential dependence predicted by the LAMH theory,  $V(I) \sim \exp(I/I_0)$  (Fig. 11A). The experimental value of the coefficient  $I_0 \approx 0.09 \mu\text{A}$  is close to the theoretical (Ref.<sup>[27]</sup>, p. 291) value,  $I_0 = 2ek_B T/\pi h = 0.06 \mu\text{A}$ . At lower  $T$ , the resistance becomes immeasurably low until the critical current is reached. At the critical current, the sample shows a few voltage steps (Fig. 11B) and then, at higher bias currents, enters a resistive (or dissipative) regime with a linear  $V(I)$ . Each new step in the  $V(I)$  curve is probably due to an appearance of a new phase slip center (PSC) in the wire.<sup>[27]</sup>

The multistep  $V(I)$  curves indicate that the dissipative size of a single PSC is less than the length of the wire. When temperature decreases further, the steps merge, possibly due to a synchronization of PSCs.<sup>[43]</sup> At low temperatures, only one large step is present at the critical current and the hysteresis is always observed (Fig. 11C). The hysteresis can be explained either by heating<sup>[44]</sup> or by the finite relaxation time of the order parameter.<sup>[43,45]</sup> The heating should not be

**Fig. 11** Voltage vs. current curves measured on one Nb nanowire, Nb2. (A) A  $V(I)$  dependence measured at  $T = 4.8 \text{ K}$  (open circles) in a log-linear representation. The straight solid line is a guide to the eye. (B) A family of  $V(I)$  curves measured at different temperatures, close to  $T_C = 5.6 \text{ K}$ . From the left to the right, the temperatures are:  $4.76 \text{ K}$ ,  $4.69 \text{ K}$ ,  $4.58 \text{ K}$ ,  $4.45 \text{ K}$ , and  $4.35 \text{ K}$ . Stepwise behavior corresponds to nucleation of phase slip centers. The other tested Nb samples showed similar steps. (None of the MoGe samples showed such steps.) (C) Hysteretic  $V(I)$  variation at the lowest temperature,  $T = 1.58 \text{ K}$ . The critical current,  $I_C$ , the “retrapping” current,  $I_R$ , and the offset current,  $I_S$ , are indicated by arrows.

the dominant effect because the  $V(I)$  curves in the dissipative state are linear and parallel to the normal-state dependence,  $V = R_N I$ , but shifted downward. In other words, they show a non-zero offset current,  $I_S$ , meaning that the linear part of the  $V(I)$  dependence, observed above the critical current, does not extrapolate to zero current, but rather to a positive offset current,  $I_S$ . The  $I_S$  represents a non-zero average supercurrent existing even at  $I > I_C$ . This fact suggests that superconductivity survives in some form in the resistive state.

The critical current for the sample Nb2 extrapolated to  $T = 0 \text{ K}$  is  $I_C(0) = 8 \mu\text{A}$ . This is close to the depairing critical current calculated as  $I_{DP} = (92 \mu\Omega) L T_C / R_N \xi(0)$ ,<sup>[34]</sup> using the parameters extracted from the LAMH fit. This expression gives  $I_{DP} = 12 \mu\Omega$ , reasonably close to experimental value, thus confirming the consistency of the  $I_C(T)$  and  $R(T)$  measurements. Because the measured values of  $I_C(T)$  fluctuate slightly ( $\sim 100 \text{ nA}$ ) from measurement to measurement, it is reasonable to assume that the critical current is suppressed below the expected depairing current due to the premature switching effect.<sup>[27]</sup>

Examples of  $V(I)$  curves of MoGe wires are shown in Fig. 12. They are similar to Nb, but they never show multiple steps as in Fig. 11B. This is an indication of a better homogeneity of amorphous MoGe wires or,

**Fig. 12** Voltage vs. current curves for the MoGe samples s1 and s3 (same samples as presented in Ref.<sup>[11]</sup>). The  $R-T$  curves for these samples are plotted in Fig. 8B. The measurement is done at  $1.5 \text{ K}$ . The sample s1 had a lower critical temperature and higher normal resistance, and was close to the SI transition. Correspondingly, the critical current for s1 is also lower. Yet, the general shape of both curves is similar. Note that the  $V(I)$  curve of this sample is shifted vertically for clarity (but not rescaled). Both curves show a non-zero offset current.

possibly the larger dissipative size of the phase slip centers in MoGe. This conclusion is confirmed by the observation that the differential resistance measured on the resistive part of the  $I(V)$  curve (i.e., above the critical current) coincides with the wire's normal resistance. Therefore, the dissipative size of the phase slip center is equal to the wire's length of  $\sim 100$  nm. The measured critical current of MoGe wires is close to the estimated depairing current and it diminishes with the wire's approaching the SI transition (Fig. 12). Some suppression of the critical current due to premature switching has also been observed.

## CONCLUSION

Suspended molecular templates have been used for the fabrication of sub-10-nm nanowires. This allowed an extensive research of 1-D superconductivity. The main results are: 1) The LAMH theory is tested in a wide range of temperatures and showed very good agreement with measurements carried on short wires ( $\sim 100$  nm), with  $R_N < R_Q$ . These wires behave as "true superconductors" and should approach zero resistance at zero temperature. 2) Deviations from the LAMH are observed on wires with  $R_N > R_Q$ . The Giordano model, involving quantum tunneling of phase slips, provides good fits for such wires. These wires should have a finite resistance at zero temperature. An insulating behavior is also observed in samples, which are short and satisfy the condition  $R_N > R_Q$ . Future work will address such issues as the origin of the superconductor-insulator transition and the nature of the insulating state.

## INTRODUCTION

The dispersion of solid nanoparticles within a polymeric matrix can dramatically improve the mechanical, thermal, or electrical properties of the material.<sup>[1]</sup> One of the challenges in fabricating such composites is controlling the distribution of the particles in the polymer. However, in multicomponent mixtures that involve blends of different polymers and the nanoparticles, one can exploit the polymer–polymer and polymer–particle interactions to direct the distribution of nanoparticles within the mixture. For example, consider the case where the polymer matrix is composed of a binary blend of A and B homopolymers. Most polymer pairs are immiscible and thus these blends usually undergo phase separation. Typically, one of the polymers in the blend preferentially absorbs onto, or wets, the particles; in particular, coating the particles with A-like chains provides a mechanism for obtaining the preferential wetting interaction between the particles and the A polymers. Now the interplay between the A/B phase separation and the polymer–particle wetting interactions controls the structure of the composite.<sup>[2]</sup> In particular, the A-like particles localize in the A domains, and depending on the composition of the AB blend, these solids can form a continuous network throughout the material or segregate into A domains that are dispersed in the B matrix.<sup>[3]</sup> The former case is of particular importance because particles that have percolated into an interconnected network can enhance the electrical or mechanical integrity of the system.

In a previous study,<sup>[4]</sup> we used computer simulations to determine the behavior of nanoscale rods that are immersed in a binary, phase-separating blend. The situation becomes even more complicated than the scenario described above because the rods can form liquid crystalline phases. Here the interplay among three phenomena—phase separation, wetting, and anisotropic interparticle interactions—controls the morphology of the material. We found that such

cooperative effects drive the rods to form a percolating structure at very low volume fractions of the nanoparticles. In effect, the rods form a supramolecular network that extends throughout the polymer matrix. These studies revealed that the synergistic interactions among the components provide a means of manipulating the motion of the nanoscopic objects and directing their association into extensive structures.

In addition to harnessing the phase separation of polymer blends, one can exploit the microphase separation of diblock copolymers to control the dispersion of nanoparticles.<sup>[5]</sup> Diblock copolymers are composed of an A chain that is chemically linked to a B chain. Although the A and B chains are incompatible, the diblocks cannot undergo macroscopic phase separation because of the chemical linkage between the two blocks. Instead, at a critical temperature, the diblocks microphase separate into spatially periodic structures that can exhibit spherical, cylindrical, lamellar, and other more complex geometries. Adding particles that are preferentially wetted by one of the blocks can yield spatially ordered hybrid materials. For example, adding particles to the cylindrical phase of the diblocks can result in the formation of solid “nanowires” that extend throughout the material.<sup>[6,7]</sup> If these nanoparticles are metals or semiconductors, the composite can exhibit the unique electrical, optical, or magnetic properties of the inorganics and the flexibility and processibility of the polymers. In addition, the “columns” of particles provide significant reinforcement of the polymer matrix and thus improve the mechanical properties of the material.

## OVERVIEW

Recently, there has been considerable interest in blending nanoparticles and diblock copolymers to create flexible batteries, photonic band gap devices, nanoelectrode arrays, and polymer/clay nanocomposites with significant mechanical strength and toughness.<sup>[5]</sup>

A major challenge in designing such complex materials is predicting the macroscopic behavior of the composite based upon such constituent characteristics as the diblock composition and the nanoparticle surface chemistry. By addressing this challenge, researchers could ultimately understand how choices made in the initial design stage affect the final material's performance and facilitate the efficient fabrication of composites with the desired properties.

In this entry, we describe a means of tackling this challenge by integrating two different computational approaches and thereby relating the polymer architecture, the wetting interactions between the polymer and particles, the structure of the mixture, and the mechanical behavior of the resulting material.<sup>[8]</sup> In particular, we use a hybrid method<sup>[5,8]</sup> that combines a Cahn–Hilliard (CH) model for the diblocks and a Brownian dynamics (BD) simulation for the particles to determine the structural evolution of the particle-filled copolymer melt. As we detail further below, the approach allows us to specify the architecture of the chains and the nature of the polymer–particle interactions. In this entry, we will refer to this hybrid method as the CH/BD model. In recent computational studies that involve this CH/BD model,<sup>[5]</sup> we showed that in the presence of the AB diblocks, A-like particles form a percolated network at a significantly lower volume fraction (essentially half) than would be required in a homogeneous material (i.e., homopolymer melt). In this study, one of our aims is to determine how these percolating networks act to reinforce the copolymer matrix.

To accomplish the above aim, we use the output of the CH/BD simulation as the input to the Lattice Spring Model (LSM), a micromechanical model that captures the elastic properties and mechanical response of the composite. By combining the CH/BD and LSM models, we can determine how the structural evolution, or the history of the material, affects the mechanical response.<sup>[9]</sup> Furthermore, we do not have to make ad hoc assumptions about the distribution of particles in the system; this distribution evolves naturally from the self-assembling interactions between the different components. Through the LSM, we can carry out three-dimensional simulations that include as many as 1564 particles.<sup>[8]</sup> The results allow us to determine how changes in the nature of the components influence the macroscopic properties of the composite.

In the section below, we provide a brief description of the simulation techniques for modeling the structural evolution of diblock/particle mixtures and the micromechanics of solid polymeric composites. In “Results and Discussion,” we investigate the effects of varying the diblock copolymer architecture and particle volume fraction on the morphological and mechanical behavior. The effects of size and polydispersity in the particle systems are also investigated.

In the final section, a summary of results is provided and conclusions are drawn.

## THE MODELS

### Determining the Morphology of Diblock/Particle Mixtures

The system consists of an AB diblock copolymer melt and mobile nanoparticles. We simulate the behavior of this mixture on a three-dimensional cubic lattice, which is  $64^3$  sites in size and has periodic boundary conditions in all three directions. The copolymer melt is characterized by the scalar-order parameter,  $\psi(\mathbf{r}) = \phi_A(\mathbf{r}) - \phi_B(\mathbf{r})$ , which describes the local concentration difference between the A and B components. Note that  $\psi(\mathbf{r}) = -1$  (1) corresponds to the equilibrium order parameter for A-rich (B-rich) phase. In this version of the model, the particles in the system are “soft” or penetrable because we neglect excluded volume interactions between the particles and the fluid. (Excluded volume interactions can be explicitly included in the model;<sup>[5]</sup> for corresponding systems, both the “hard” and “soft” fillers yield similar results for the particle distributions.) The particles have an affinity for the A block. This affinity is introduced via a polymer–particle coupling term in the free energy (as described below). Thus the microphase separation of the diblocks can affect the spatial distribution of the particles, and the particles can influence the size and morphology of the polymer domains.

The Cahn–Hilliard (CH) equation<sup>[10,11]</sup> describes the phase separation of a binary mixture by spinodal decomposition in the absence of hydrodynamics. The dynamics of microphase segregation for a diblock copolymer melt is described by the traditional CH equation with the addition of the term  $-\Gamma(\psi - f)$ , where  $\Gamma$  determines the thickness of the domain structure and  $f$  describes the asymmetry of the diblock.<sup>[12]</sup> The case of  $f = 0$  describes a 50:50 symmetric diblock. The kinetic equation for the order parameter for this system is:

$$\partial\psi/\partial t = M\nabla^2(\partial F\{\psi\}/\partial\psi) - \Gamma(\psi - f) + \xi \quad (1)$$

where  $M$  is the kinetic coefficient (mobility) of the order parameter field and  $\xi$  is the noise field (which is presently set to 0).  $F$  is the local energy term and is given by  $F = F_d + F_{\text{cpl}}$ . In the current study,  $F_d$  is given by

$$F_d = \int [-A \log(\cosh(\psi)) + \psi^2/2 + D(\nabla\psi)^2/2] \partial r \quad (2)$$

where  $A$  and  $D$  are material-specific parameters and the integration is over the volume of the system.

The nanoparticles are introduced through the coupling free energy,  $F_{\text{cpl}}$ . This free energy describes the interaction between the “soft” particles and the polymer and ensures that the forces on the particle as a result of the presence of the polymer induce equal and opposite forces within the polymer. The coupling free energy is of the form

$$F_{\text{cpl}}\{\psi\} = \int \sum_i U(r - x_i)(\psi(r) - \psi_s)^2 \partial r \quad (3)$$

where  $x_i$  is the position of the  $i$ th particle and  $\psi_s$  is the desired value of the order parameter at the particle surface. To model the fact that the particles have an affinity for the A phase, we set  $\psi_s = -1$ . The potential  $U(r - x_i)$  is non-linear and is given by

$$U(r - x_i) = \begin{cases} C \exp(-(r - x_i - R)/r_0) & \text{for } (r - x_i) > R \\ C & \text{for } (r - x_i) < R \end{cases} \quad (4)$$

where  $C$  captures the strength of the wetting interaction,  $r_0$  sets the range of this interaction, and  $R$  is the radius of the particle.

The motion of the particles is dictated by the Langevin equation

$$\partial x_i / \partial t = -M_p (\partial F_{\text{cpl}} / \partial x_i) + \eta \quad (5)$$

where  $M_p$  is the particle mobility and  $\eta$  is a Gaussian white noise term. There is an effective excluded volume interaction between the particles; if a given particle moves to a position that is already occupied by a particle, the move is rejected. Through the coupled Eqs. (1) and (5), the ordering dynamics of the diblock copolymers is integrated with the diffusive motion of the nanoparticles.

A Cell Dynamical Systems (CDS), or Cellular Automaton, methodology is used to evolve the order parameter field for the microphase-separating copolymer melt.<sup>[13,14]</sup> The use of CDS [rather than a conventional discretization of Eq. (1)] significantly reduces the computational expense of the simulations.

### Determining the Micromechanical Behavior of Solid Polymeric Composites

A Lattice Spring Model (LSM) enables the micromechanical investigation of a solid polymer to be undertaken.<sup>[8,9,15,16]</sup> Through the model, the continuum elastic behavior of a given material is discretized and mapped onto a simple cubic lattice. This lattice consists of a network of nearest and next-nearest neighbor interactions, which are harmonic in nature. These

harmonic interactions (springs) result in linear forces between lattice sites (nodes), which enable the emergence of linear elastic behavior. The energy associated with a site or node  $m$  in the lattice is taken to be of the form

$$E_n = (1/2) \sum_m (\mathbf{u}_m - \mathbf{u}_n) \cdot \mathbf{M}_{mn} \cdot (\mathbf{u}_m - \mathbf{u}_n) \quad (6)$$

where the summation is over all the neighboring nodes,  $n$ , connected to  $m$  by a spring. The term  $\mathbf{u}_m$  is the displacement of node  $m$  from its original position, and  $\mathbf{M}_{mn}$  is a symmetric matrix that introduces the elastic properties of the springs, through  $k$  and  $c$ , the central and noncentral force constants, respectively.

It has been shown that this system of springs obeys, to first order in the displacement, the equations of continuum elasticity theory for an isotropic elastic medium, whose elastic constants can be determined in terms of the elements of the matrices  $\mathbf{M}_{mn}$ .<sup>[15]</sup> These elastic constants are the Young's modulus,  $E$ , and Poisson's ratio,  $\nu$ , which are of the form.<sup>[15]</sup>

$$\begin{aligned} E &= (5k(2k + 3c))/(4k + c) \\ \nu &= -(k - c)/(c + 4k) \end{aligned} \quad (7)$$

The force constants are initially assigned to the nodes. Nodes that exist within the boundaries of the inclusions are assigned different force constants than nodes that exist within the matrix. The force constants for the bonds are averaged from the nodes that they connect.

The harmonic form of the energy results in forces that are linearly dependent upon the displacement of the nodes. If forces are applied to the nodes, and the spring constants are specified, then the nodal displacements can be obtained through a set of sparse linear equations. These equations are solved using a conjugate gradient method to find the equilibrium configuration that corresponds to no net force at each node.<sup>[15]</sup>

To present relevant deformation fields, the stress and strain tensors are calculated from these forces and displacements. The strain tensor can be obtained through a finite difference approximation of the displacement field. A central difference approximation can be used

$$\begin{aligned} \delta_x u_{(i,j,k)} &= (-u_{(i+2,j,k)} + 8u_{(i+1,j,k)} - 8u_{(i-1,j,k)} \\ &\quad + u_{(i-2,j,k)})/12h \end{aligned} \quad (8)$$

where  $u_{(i,j,k)}$  is the displacement field at coordinates  $i$ ,  $j$ , and  $k$  and  $h$  is the initial distance between adjacent nodes; alternatively, forward or backward approximations are considered at system boundaries. The stress tensor is directly obtainable from the forces acting on

a node (the center of a cubic unit cell),<sup>[17]</sup>

$$\sigma_{ij} = \sum_m F_m \cdot \mathbf{n}_{ij}^m / A \quad (9)$$

Here  $\sum$  represents a sum over the cube surfaces,  $F_m$  is the force<sup>m</sup> on any surface  $m$  of the cubic cell, while  $\mathbf{n}_{ij}^m$  is a unit vector either normal or parallel to the surface  $m$ , and  $A$  is the surface area. The scalar stress and strain values quoted here correspond to the normal stress and strain components in the tensile direction.

To assess the effective reinforcement provided by the particles within the composite, we determine the relative quantities  $(F - F_0)/F_0$ , where  $F$  is the field in question and  $F_0$  is the homogeneous response of the unreinforced polymeric matrix. The average strain in the system can be determined through the average nodal displacements at the system boundaries, in the tensile direction. The average strain and the applied stress can then be used to calculate the Young's modulus (stress of a material divided by its strain). This allows the global stiffness of this locally heterogeneous material to be determined.

As noted above, the elastic properties of the springs within a LSM simulation are assigned values depending upon whether the node is situated within a particle or the polymer matrix, as dictated by the results of the CH/BD calculation. To accurately capture the deformation fields in the vicinity of the particles within the LSM, the system size is doubled from that of the CH/BD simulation. A LSM consisting of  $148^3$  nodes is utilized; the central  $128^3$  nodes are assigned elastic properties as a function of the particle and polymer positions in the CH/BD calculation. The system is extended by 10 unit lengths in all directions, taking values from the periodicity of the CH/BD simulation, therefore ensuring that all areas of the CH/BD model are represented by bulk nodes in the LSM simulation.

## RESULTS AND DISCUSSION

### Uniform Particle Size

We initially consider the effects of diblock copolymer architecture and volume fraction of monodisperse particles (that is, the particles are uniform in size) on the morphological and mechanical characteristics of the resultant composite. In the following simulations, the parameters  $M$  and  $M_p$  (in Eqs. (1) and (5), respectively) are set equal to 1. Three different diblock copolymers are considered, corresponding to the following parameters: 1)  $\Gamma = 0.004$  and  $f = 0.0$ , 2)  $\Gamma = 0.016$  and  $f = 0.0$ , and 3)  $\Gamma = 0.004$  and  $f = 0.2$  [see Eq. (1)]. The parameter  $\Gamma$  is inversely proportional to  $N^2$ , where  $N$  is the degree of polymerization of the

copolymer. Thus an increase in  $\Gamma$  corresponds to a decrease in the domain size. Varying  $f$  from 0.0 to 0.2 changes the A:B composition from 50:50 to 60:40. Hence by altering  $\Gamma$  and  $f$ , we can model the respective effects of varying the domain size and composition of the diblocks. A range of particle volume fractions, varying from 5% to 25%, is also considered, where the particle radius is 3 unit lengths (6 unit lengths in the LSM). This range in particle volume fraction corresponds to a variation in the number of particles from 116 to 580 in the simulations.

The morphology of a filled diblock copolymer system at late times ( $t = 50,000$ ) is presented in Fig. 1. The parameters of the diblock copolymer are  $\Gamma = 0.004$  and  $f = 0.0$ , and the volume fraction of particles is 20%. The isosurface of the diblock copolymer at an order parameter of zero (midway between phase A and phase B) is colored red, while the regions where a positive order parameter intersects the system boundaries (termed isocaps) are colored blue. In other words, the red regions mark the edge of the B phase and the transparent regions indicate the A phase. The system shows elements of lamellar ordering on a short scale; however, the lamellae are interconnected, and the overall morphology is closer to a bicontinuous structure. While the system will tend toward the thermodynamic limit of a perfect lamellar phase, the timescales for reaching this state through a dynamic model are prohibitively large. In experimental systems, similar morphologies are found because again, it takes long times to reach perfectly ordered phases and the system can get kinetically trapped.

**Fig. 1** Three-dimensional morphology of a filled diblock copolymer system. An isosurface in between the A and B components is colored red, isocaps are colored blue, and the particles are colored black.

The black spheres in Fig. 1 are the particles, which are clearly confined within the transparent A phase of the diblock. The particles appear to form a continuous network within the polymer matrix. In effect, the interplay between the microphase separation of the diblocks and the particle–block wetting interactions has influenced the distribution of the solids within the system.

To quantify the confinement of the nanoparticles within the diblock copolymer domains, we calculate the particle correlation function. The particle correlation function adopted in this study is defined as  $V \sum_i \sum_{j \neq i} \delta(r - r_{ij}) / (4\pi r^2 N_p^2)$ , where  $V$  is the volume of the system and  $N_p$  is the number of particles. The results are averaged over three independent runs and plotted in Fig. 2. For clarity, only two diblock copolymer systems are shown ( $\Gamma = 0.004$  and  $\Gamma = 0.016$  at  $f = 0.0$ ) as the third exhibited similar results. There is only one discernible peak at a distance of 6 unit lengths, which corresponds to the diameter of the particles. This reveals that the system of particles exhibits strong short-range order, but does not display long-range order. The particles are forced to lie within close proximity of each other because of the confinement within the diblock copolymer, but long-range order is suppressed because of the tortuous structure of the diblock domains. For comparison, the particle correlation function for an equivalent number of randomly dispersed particles, which exhibit no such confinement, is also presented. As can be seen, there is no local ordering of the particle positions, and the peaks observed in the diblock copolymer systems are no longer present.

It is the clustering of the diblock-confined particles that is of primary interest in this study. To characterize

**Fig. 2** The pair correlation function [defined as  $g(r) = V \sum_i \sum_{j \neq i} \delta(r - r_{ij}) / (4\pi r^2 N_p^2)$ ] for particles confined in two diblock copolymer systems and for randomly dispersed particles.

the particle clusters, and determine whether or not geometric percolation occurs when the volume fraction of particles is 20%, we define particles that are closer than a certain distance to be part of the same cluster. Here we adopt a unit length in the LSM simulations as this characteristic distance. Using this definition, we find that the particles confined within the diblocks do in fact form a percolating cluster. (We note that Ginzburg, Qui, and Balazs<sup>[5]</sup> found the percolation threshold for particles confined in a similar diblock matrix to be approximately 10%.) At 20%, however, the randomly dispersed particles do not form such a supramolecular network. (The site percolation threshold for the simple cubic lattice is equal to 31%.<sup>[5]</sup>)

To assess the consequences of such morphological variations upon the resultant mechanical properties of the macroscopic material, we now use the output from our hybrid CH and Langevin dynamics simulations as the input for the LSM. The elastic deformation of the structures is undertaken, with both the force constants of the A and B phases being set to unity, while the particles are assigned a force constant of 100. Thus the effects of particle distribution are of primary interest in the current investigations, and the parameters are consistent with experimental values for filled polymers.<sup>[18]</sup>

The local relative strain field, as a result of the application of a constant stress at the simulation boundaries, for a system where the particles are confined within the domains of a diblock copolymer ( $\Gamma = 0.004$  and  $f = 0.0$ ) is depicted in Fig. 3A. The corresponding relative strain field for a system consisting of randomly dispersed particles is presented in Fig. 3B. The three-dimensional strain fields are displayed as orthogonal contours through the simulation. In both systems, the volume fraction of particles is 20%. The particles are clearly apparent as the dark regions of low strain. In particular, the strain values within the particles are significantly lower than that of the matrix because of the large disparity in elastic constants. The inability of stiff particles to deform to the same extent as the neighboring matrix results in strain concentrations at the particle–matrix interface. These strain concentrations lie along the tensile direction and emanate from the center of a particle. Perpendicular to the tensile direction, the lower deformations within the particle inhibit the deformation of the matrix and results in lower strain fields.

It is apparent from Fig. 3A that the diblock-confined particles are clustered together, forming a percolating network, while the particles in Fig. 3B are more randomly dispersed. The percolating structure inhibits the deformation of the entire material and results in significant reductions in the strain fields, as can be seen by the presence of the dark red domains in Fig. 3A. Alternatively, the randomly dispersed

**Fig. 3** The relative strain fields [defined as  $(F - F_0)/F_0$ , where  $F_0$  is the response of the unreinforced polymeric matrix] for (A) a system where the particles are confined within the domains of a diblock copolymer and (B) a system consisting of randomly dispersed particles.

system shows isolated regions of strain relaxation within the particles, but the inhibition of the neighboring matrix is less dramatic than in Fig. 3A. Consequently, the strain concentrations (shown in yellow and white) within the matrix of the randomly dispersed system are also more pronounced as regions within the matrix attempt to deform to the same extent as domains that neighbor the scattered particles. Such areas of strain concentration are less apparent in Fig. 3A. These plots indicate that the confinement of nanoparticles within one of the domains of the bicontinuous structure leads to a continuous network of stiff material, which reduces the overall strain field within the system.

To quantify the deformation of the above confined and randomly dispersed particle systems, the cumulative distribution functions of the local strain fields are plotted in Fig. 4. The cumulative distribution function

**Fig. 4** The cumulative distribution function of the relative local strain field for systems consisting of randomly dispersed particles and systems where the particles are confined within the domains of a diblock copolymer.

is defined as the probability that the field in the system takes a value less than or equal to a specific amount. A comparison between confined and randomly dispersed particle systems is made for particle volume fractions varying from 5% to 25%. The lower strains are invariably associated with the stiffer particles, while the regions of higher strains correspond to the matrix. At 5%, there would appear to be little difference between the two systems because the confined particles do not percolate at such a low value. At higher particle volume fractions, the disparity between the two systems becomes more apparent, with the confined particle systems possessing significantly lower strain fields. As noted above, the geometric percolation

**Fig. 5** The percentage increase in Young's modulus as a function of particle volume fraction. Systems containing particles confined within the domains of various diblock copolymers are compared with a system consisting of randomly dispersed particles.

inhibits the local strain fields and therefore stiffens the composite material.

In Fig. 5, we plot the percentage increase in the Young's modulus relative to the unreinforced polymer for the various systems described above. This parameter is a measure of the macroscopic mechanical properties of these composites. The results are averaged over three independent runs, with the error bars indicating the standard deviation. The three cases involving particles confined within the domains of diblock copolymers are significantly stiffer than the system containing randomly dispersed particles. There is no clear difference between the three confined particle systems, with the error bars showing a clear overlap. For the systems studied here, it is not possible to distinguish effects that diblock copolymer architecture or composition may have on the reinforcement efficiency of the nanoparticle fillers. There is, however, a significant benefit to confining the particles within the diblock copolymer domains.

### Binary Particle Systems

We also investigate the effects of adding a binary particle mixture to the copolymer matrix. The particles in the binary mixture are chemically identical (that is, they both favor the A phase) but differ in size. The smaller particles have a radius of 2, and the larger particles have a radius of 3 unit lengths. The total volume fraction of particles is held fixed at 20%. Note that at a fixed particle volume fraction, decreasing the size of the particles results in an increase in the total number of particles. The ratio of small to large fillers is varied between the limiting cases of all small (1564 particles) and all large (464 particles). These studies provide insight into the role that polydispersity in particle size plays in the distribution of particles within the matrix and, consequently, the mechanical properties of the composite. In these studies, the parameters that characterize the diblock copolymers are fixed at  $\Gamma = 0.004$  and  $f = 0.0$ .

Fig. 6 shows the morphology for a system containing 10% of large and 10% of small particles. The particles are again clearly confined within the A domains of the diblock copolymer. It is also clear from Fig. 6 that the small particles can readily penetrate and localize in regions between the large particles. We can characterize this arrangement quantitatively by measuring  $P$ , the fraction of particles that are a part of the largest cluster. When  $P$  is close to 1, almost all the particles belong to one cluster; when  $P$  is close to 0, the particles form many small clusters. In Fig. 7, we plot  $P$  as a function of the volume fraction of small particles. The results are averaged over three runs, with the error bars corresponding with the standard deviation.

**Fig. 6** Three-dimensional morphology of a filled diblock copolymer system. An isosurface in between the A and B components is colored red, isocaps are colored blue, and the small and large particles are colored black and gray, respectively.

Geometric percolation occurred in all systems. Because at a fixed volume fraction there are a greater number of small particles than large ones, these fillers would be expected to cluster to a greater extent than the larger species (as the characteristic distance used to indicate clustering is not radius-dependent, but is fixed at one unit in our studies). This is in fact the case, with the fraction of particles in the main cluster approaching 1 with increasing number of small particles.

The introduction of a relative fraction of small particle also results in an effective increase in the

**Fig. 7** The fraction of particles that are a part of the largest cluster as a function of the volume fraction of small particles. The overall volume fraction of small and large particles is maintained at 20%.

**Fig. 8** The volume fraction of polymeric material that is within a given distance (a unit length) of any particles,  $V_p$ , as a function of the volume fraction of small particles.

particulate surface area (because of the increase in the total number of particles). Consequently, there is a greater surface area available for possible polymer–particle interactions. To illustrate this point, we define  $V_p$  as the volume fraction of polymeric material (A and B) that is within a given distance (a unit length) of any particles and plot  $V_p$  as a function of the volume fraction of small particles (Fig. 8). The results are averaged over three runs and the standard deviations were found to be negligible. As the volume fraction of small particles is increased, the particles come in contact with and affect a greater volume of the matrix. This behavior, as well as the increase in clustering in the bidisperse system, is expected to translate through to the mechanical properties.

**Fig. 9** The relative strain fields [defined as  $(F - F_0)/F_0$ , where  $F_0$  is the response of the unreinforced polymeric matrix] for a system containing a 10% volume fraction of small and a 10% volume fraction of large particles, confined within the domains of a diblock copolymer.

**Fig. 10** The percentage increase in Young's modulus as a function of small particle volume fraction. The overall volume fraction of small and large particles is maintained at 20%.

Fig. 9 reveals the relative strain field for a system containing 10% large particles and 10% small particles. The regions of low strain, corresponding to the stiffer particles, are clearly observed as before. Now, however, the clustering of particles is more apparent than that in Fig. 3A. A significant difference between the cases in Figs. 3A and 9 is the area over which these particles cluster. The smaller particles spread out over a greater volume of the material and inhibit the deformation of the matrix to a greater degree than in the system containing just large particles. Effectively, a larger volume of polymer matrix is trapped or surrounded by the particles and therefore less capable of deforming.

The lower strain fields as a result of the decrease in particle size have a direct impact on the Young's modulus of the macroscopic material. The percentage increase in Young's modulus is plotted in Fig. 10, as a function of the volume fraction of small particles. The data are averaged over three runs, where the error bars represent the standard deviations. An increase in Young's modulus of over 30% is observed as the particle size is altered from all large to all small. This is attributable to an increase in the total particle surface area, a greater degree of clustering, and an increase in the volume of polymeric material that is effectively trapped by the particles. These effects result in lower strains throughout the system and hence an increase in the global Young's modulus.

## CONCLUSION

Through a combination of numerical techniques, we were able to interrelate the structure and micro-mechanical behavior of the copolymer/nanoparticle

composites. Through the CH/BD calculations, we could determine the effects of the microphase separation of the diblocks on the spatial distribution of the mobile particles. Through the LSM, we could capture the elastic deformation of the resultant hybrid material. Furthermore, we could investigate the behavior of systems that contain up to 1564 particles. For randomly dispersed fillers, simulations involving a relatively low number of particles can be sufficient to describe the overall stiffness of the material and thus be large enough to encompass a Representative Volume Element (RVE) of the composite. However, the tortuous spatial arrangement of particles confined in diblock copolymers introduces an additional length scale, that of the domain size. To determine the mechanical behavior of such complex materials, it is important to consider the morphology of a sufficiently large system that captures both the unique structural characteristics of the copolymer domains and the particles' spatial arrangement, which is, in part, templated by these diblock domains. The LSM has proven to be ideally suited for simulating the micromechanics of such large systems. While the utility of the LSM in analyzing two-dimensional RVEs has recently been reported,<sup>[19]</sup> it would appear that this technique might also prove useful in similar three-dimensional analyses.

Through the selective incorporation of nanoparticles into the domains of a diblock copolymer, three-dimensional bicontinuous nanoparticle structures were formed. As the volume fraction of particles was increased, geometric percolation of the particles occurred, and the particles effectively formed a rigid network throughout the system. The deformations within the polymer matrix are significantly suppressed by the presence of this rigid nanostructural network, and the global stiffness of the material is notably increased. It is worth noting that for materials containing randomly dispersed spheres, rods, and platelets, the rods and platelets offer superior reinforcement over the spheres.<sup>[16]</sup> Therefore the mechanical properties of diblock copolymers filled with such high aspect ratio particles may prove to be of particular interest.

Varying the size of the monodisperse particles and introducing bidispersity in the particle size were shown to exert an appreciable influence over both the morphology of the diblock copolymer and the resultant mechanical properties of the solid material. Systems containing small fillers exhibited a greater degree of clustering between the particles. This behavior could explain the increased stiffness that was observed in the corresponding macroscopic material. Also, of considerable consequence is the volume of polymeric material that is effectively trapped between neighboring nanoparticles. For a fixed volume fraction of particles, as the particle size is decreased, the number

of particles increases. Consequently, the volume of material in which the particles are dispersed increases, and the deformation of a greater volume of interparticle polymeric material is inhibited.

We conclude that the inclusion of nanoparticles into a bicontinuous diblock copolymer structure results in a significant increase in the reinforcement efficiency of the fillers. As polymeric nanocomposites become increasingly important, such confinement effects will play a dominant role in optimizing their mechanical behavior and result in an expansion of potential applications to which such novel materials could be employed.

# Surface-Enhanced Raman Scattering

Adam M. Schwartzberg

Jin Z. Zhang

Department of Chemistry and Biochemistry, University of California–Santa Cruz,  
Santa Cruz, California, U.S.A.

## INTRODUCTION

Surface-enhanced Raman scattering (SERS) is a process by which normal Raman scattering (RS) can be amplified by many orders of magnitude. The utility of this lies in the rich molecular structural information attainable from RS. It is possible to capitalize on the advantages of RS through this manifold increase in scattering intensity, while mitigating its major limitation, a very small cross-section.

Because of the great potential of this technique for practical applications, a significant amount of work has been performed over the last 30 years. This entry will outline the progression of SERS as an analytical technique, from its discovery to recent work. This will include new understanding of the fundamental principles of SERS, advances in experimental techniques, and current applications in various areas including materials and biological sciences.

## BACKGROUND

### RS

In 1928, a landmark spectroscopic phenomenon was discovered by C. V. Raman and K. S. Krishnan in which light, scattered off a molecule following photo-excitation, induces a change in molecular polarization.<sup>[1]</sup> The energy difference between the scattered and incident light is equal to one of many vibrational frequencies of the molecule (Fig. 1).<sup>[2–4]</sup> Therefore, RS, similar to infrared spectroscopy (IR), can provide structural “finger print” information about molecules, because each molecule has a unique set of vibrational frequencies. Because Raman is a zero-background measurement and the signal detected is usually in the visible region, it is much more sensitive than the non-zero background IR experiment, which is based on absorption. In the last several decades, RS spectroscopy has become a routine and powerful analytical technique in academic research and industry.

Even though Raman is molecule specific, it does have one major limitation: a small scattering cross-section

$\sim 10^{-30}$  cm<sup>2</sup>/molecule. Thus, the Raman signal is difficult to detect.<sup>[5]</sup> Fortunately, several techniques have been developed to significantly enhance the Raman signal while preserving the molecular specificity. These include both resonance and surface enhancements. Resonance Raman occurs when the excitation light is in resonance with an electronic transition of the molecule,<sup>[2–4]</sup> resulting in an enhancement factor of  $10^2$ – $10^4$  (Fig. 1). This has been used in the study of a variety of molecules including biological samples such as viruses and cells. However, resonance Raman requires excitation light at a shorter wavelength than that used for standard Raman. This can cause degradation of the sample and sometimes result in fluorescence interference.

Another method of enhancement is SERS.<sup>[6]</sup> In SERS, a molecule is adsorbed onto a noble metal surface with nanoscale features. When the surface plasmon absorption mode is excited by light, a local field enhancement on the surface is created that enhances RS of molecules on or near the surface.<sup>[5,6]</sup> For SERS on roughened metal films, the enhancement is in the order of  $10^3$ – $10^5$ . While isolated metal nanoparticles (NPs), primarily silver, have shown an enhancement of  $\sim 10^6$ , NP aggregates have shown even stronger enhancement of  $\sim 10^7$ – $10^9$ .<sup>[7]</sup> This large increase in Raman cross-section for aggregates is believed to be due to stronger field enhancement at the junctions between NPs.<sup>[8]</sup> Even larger SERS enhancement factors on the order of  $10^{15}$  have been reported for “single,” so called “hot” NPs or aggregates.<sup>[9–11]</sup> These SERS enhancement studies suggest that NP aggregates are better for SERS than isolated NPs and that the Raman signal can be very large and easily detected.

The local field enhancement is only one requirement necessary for SERS. Surface chemistry of metal NPs is another important factor.<sup>[12]</sup> Many studies have determined the first decay length (the length at which the enhancement decreases by half) to be  $\sim 1.5$  nm, virtually requiring that the analyte molecule be adsorbed or very close to the surface for detection.<sup>[13–15]</sup>

There have been several excellent review entries on SERS published previously; therefore this entry will focus on some of the latest developments in SERS.<sup>[5,6,16–18]</sup> These will include new understanding

**Fig. 1** Energy diagram of four different scattering schemes: Rayleigh, Stokes, anti-Stokes, and resonance Raman (Stokes) scattering. It should be noted that resonance Raman can also take place by either the Stokes or the anti-Stokes mechanism.

of the fundamental principles of SERS, advances in experimental techniques, and current applications in various areas including materials and biological sciences. In addition, SERS techniques based on optical fibers and single NPs or aggregates will also be highlighted.

## SERS

In 1977, SERS was discovered simultaneously by Jeanmaire and Van Duyne and Albrecht and Creighton.<sup>[19,20]</sup> In their experiments, they observed an unusually intense RS signal from pyridine adsorbed onto an electrochemically roughened silver electrode. Previous studies had observed an enhanced signal; however, the effect was assumed to be because of the increase in electrode surface area.<sup>[21]</sup> Van Duyne and Creighton were the first to realize that some other effect was taking place. Nevertheless, it was Moskovits who made the first correct interpretation of the data.<sup>[22,23]</sup> They surmised that the roughened electrode was essentially a 2-D array of silver NPs, and that these NPs possessed what was called, at that time, an “optical conduction resonance,” or surface plasmon as it is known today.

## Surface Plasmons

The surface plasmon is the collective oscillation of electrons within a metal NP, activated by an incident electromagnetic field.<sup>[24–26]</sup> Fig. 2 is a schematic of

**Fig. 2** Illustration of plasmon activation in metal NPs. Light interacts with the particle and at time  $t$  causes a polarization of the electrons into an electronic cluster. At a later time  $t + T/2$ , where  $T$  is the lifetime of the oscillation, the electronic cluster will have oscillated to the other side of the particle.

the surface plasmon mechanism. An incident field polarizes the NP, shifting the electrons collectively to one side of the system. This is only possible in metal particles with high electron mobility in the lattice such as gold, silver, copper, and, to some extent, platinum. After their initial perturbation, the electrons will oscillate, confined by the surface of the nanocrystal. The frequency of this oscillation corresponds to the energy at which photons will be most strongly absorbed. Because of this, the surface plasmon absorption is strongly dependent on the nature of the NP material and its structure including size and shape, and interparticle interaction (Fig. 3).

By changing the shape or size of the NP or interparticle separation, it is possible to change the resonance

**Fig. 3** Surface plasmon absorption of 20-nm silver and gold particles. The optical properties of the nanoparticle are strongly tied to the material they are made of.

energy of the plasmon mode. For example, by elongating the NP into a nanorod, two directions now exist along which the electrons may resonate—the so-called transverse (short axis) and longitudinal (long axis) axes. Any deviation from the spherical geometry will induce multiple resonances, including nanoshells,<sup>[27–30]</sup> and NP aggregates.<sup>[31–38]</sup> In fact, based on optical absorption alone, it is impossible to discern between nanoshells, nanorods, and NP aggregates.<sup>[39]</sup> This will be discussed in greater detail later.

## SERS ENHANCEMENT MECHANISM

### Electromagnetic and Chemical Enhancement

Two mechanisms are responsible for the SERS effect, the so-called electromagnetic and chemical. While the majority of observed enhancement can be explained in the electromagnetic regime, where NP-molecule contact is not required, there is a portion that seems to require physical contact. The chemical mechanism accounts for enhancement of ~10–100 and requires that the molecule be adsorbed directly to the metal surface. There have been several theories put forward, many of which have been discounted. The most widely referenced mechanism to date is the so-called dynamical charge transfer. For a complete discussion of this, please see the fine review article by Otto et al.<sup>[18]</sup> Briefly, on adsorption, a molecule-metal complex is formed, creating a new low-energy absorption band (assuming the molecular energy levels are spaced symmetrically about the Fermi level of the metal) representing a transition from the Fermi level of the metal to the lowest unoccupied molecular orbital (LUMO) of the molecule. This new electronic transition in the visible region can then behave similar to resonance Raman, at the proper excitation frequency. The steps of the charge transfer are as follows: First, a photon is absorbed, exciting an electron from the metal conduction band to the LUMO of the molecule. Second, if the LUMO is an antibonding or bonding molecular orbital, a change in bond length, a vibration, will take place. Third, charge is transferred back to its original state and a Stokes-shifted photon is released. The more important electromagnetic mechanism does not involve charge transfer but rather energy transfer, and is responsible for the majority of the enhancement.

In normal RS, the intensity of the signal ( $P^{RS}$ ) is directly related to the number of molecules in the probed volume ( $N$ ), the scattering cross-section of the molecule ( $\sigma$ ), and the intensity of the excitation laser ( $I$ ).

$$P^{RS} = N\sigma I \quad (1)$$

SERS intensity ( $P^{SERS}$ ) is dictated by a similar relation, with the addition of field enhancement factors relating to the laser ( $A^L$ ) and Stokes frequencies ( $A^S$ ).  $A^L$  is the enhancement of the laser by the SERS substrate,  $A^S$  is the enhancement of the scattered light. In addition, the increased RS cross-section of the molecule (chemical enhancement) is accounted for in the  $\sigma^{SERS}$  term.

$$P^{SERS} = N^{SERS}\sigma^{SERS}I|A^L|^2|A^S|^2 \quad (2)$$

$N^{SERS}$  is the number of molecules involved in SERS, which is not necessarily the same as the number of molecules in the laser volume. These enhancement factors are complicated functions, which depend on several parameters including the distance of the molecule from the surface and the properties of the molecule and the substrate.

The electromagnetic and chemical enhancements are directly related to the electron oscillations induced by plasmon excitation (Fig. 4). On excitation of the plasmon, the electron oscillations in the NP induce a strong electromagnetic field, or an evanescent wave at the surface, which is related to the  $A^L$  term discussed above. This field will transfer energy to molecules in close proximity to the surface, in the form of a dipole-dipole interaction. Once the energy transfer has taken place, the molecule is induced into a new vibrational state and transfers its energy, slightly changed by the vibration, back into the particle or released directly from the molecule with energy  $h\nu_{scattered}$ . This photon can then be reabsorbed and further enhanced. The  $A^S$  term takes this into account. Like normal RS, the emitted photon energy is related to the vibrations of the molecule by Eq. (3).

$$h\nu_{scattered} = h\nu_{incident} \pm h\nu_{vibration} \quad (3)$$

**Fig. 4** A diagram of the SERS electromagnetic mechanism. Incident light,  $h\nu_{incident}$ , is absorbed by the NP activating the plasmon mode; energy is transferred by means of dipole-dipole interaction to the molecule. A vibration is activated in the molecule, and energy is transferred back into the particle. The particle then emits a photon with new energy  $h\nu_{scattered}$ .

The requirement of the molecule to be in close proximity to the substrate is important for understanding the mechanism and application of SERS. Although not related to the chemical enhancement per se, this is a chemical concern. If the molecule in question does not bind or adsorb favorably onto the surface of the SERS substrate, or to something attached to the substrate, no enhancement will be seen. This notion has guided the direction of much of current SERS research.

## Current Applications

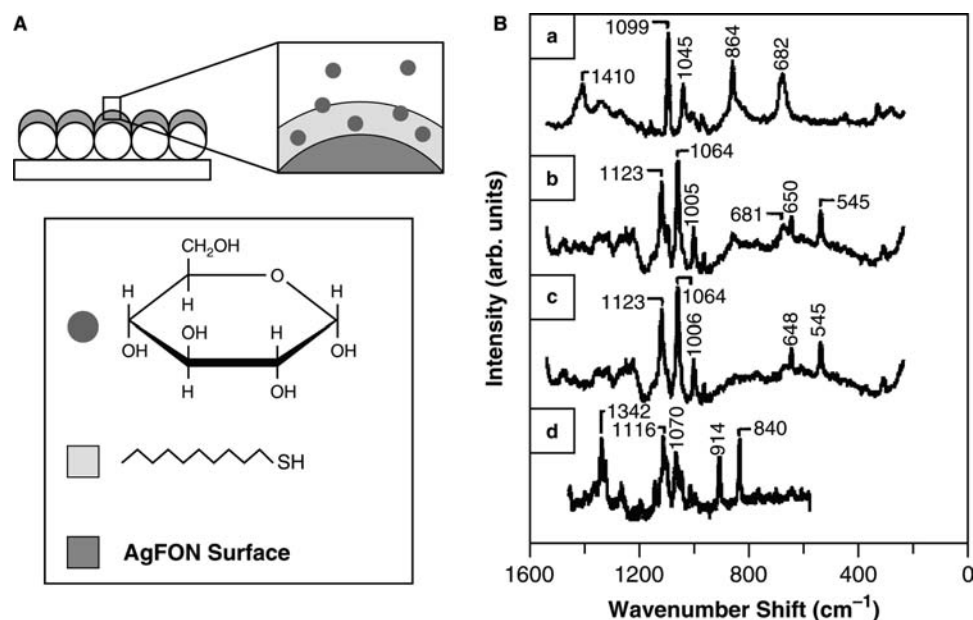

Some of the best work being done today in trace molecule detection is in the field of SERS. From biomolecules to chemical warfare agent detection, there are virtually endless possibilities for this technology. There is, however, a major hurdle, which has hindered wider practical SERS applications, till date. The NP-analyte collocation requirement mentioned earlier causes many difficulties. For molecules that bind strongly onto silver and gold surfaces, SERS detection is simple and straightforward; these include amine- and thiol-containing compounds. However, to devise a detection device for a wide variety of analytes, this limitation must be overcome.

For example, one of the most desired molecules for detection is glucose, owing to the prevalence of diabetes. Millions of people suffer from this disease, yet

little advancement has been made in terms of accurate glucose detection using SERS. Blood must still be drawn, and for serious cases this can be required multiple times per day; this leads to an inconvenient and painful lifestyle. The development of an in vitro, implantable, glucose-detection device could revolutionize the lives of millions.

To this end, there has been steady progress in the field of SERS glucose detection. The first work to demonstrate the possibility of glucose detection did so by utilizing a kind of sandwich method. A layer of glucose is dried between two layers of silver NPs, effectively forcing the glucose inside a silver aggregate inducing strong SERS.<sup>[40]</sup> This is not practical for building devices, as it is not stable or usable for real time detection.

More recently, Van Duyne et al. have shown significant progress in practical SERS detection of glucose.<sup>[41,42]</sup> This is achieved by first producing a stable silver substrate on silica, by using latex nanospheres as a template. The substrate is then covered with a self-assembled monolayer (SAM), which acts as a partition between the free solution and the silver. Fig. 5 shows a diagram of this configuration as well as the RS signal achieved. In this configuration, glucose can be detected within the biological range with reasonable accuracy. This is because of the glucose settling into the SAM, close enough to the surface to feel enhancement. This substrate could practically be used in device applications, being robust and simple to reproduce consistently by nanotemplating.

**Fig. 5** (A) Schematic showing hypothetical glucose concentration gradient created by 1-decanethiol (1-DT) partition layer and (B) spectra used in quantitative analysis: (a) 1-DT monolayer on AgFON substrate, (b) mixture of 1-DT monolayer and glucose partitioned from a 100 mM solution, (c) residual glucose spectrum produced by subtracting (a) from (b), (d) normal Raman spectrum of crystalline glucose for comparison. *Source:* From Ref.<sup>[41,42]</sup>.

**Fig. 6** (A) SERS spectrum of 2,4-DNT on the thiol-capped Ag nanowire monolayers; (B) transmission electron microscope image of nanowires cross-section; and (C) scanning electron microscope image of nanowires film. *Source:* From Ref.<sup>[44]</sup>.

Another important application is explosive compound recognition, which requires large enhancements from a technique like SERS to detect trace molecules. Surface-enhanced Raman scattering also has much higher molecular specificity than other current detection techniques; molecules similar to enantiomers can be differentiated by SERS. This is important when searching for explosives owing to their structural similarity to many other compounds, namely nitrate fertilizers, and can lead to false positive results. Several studies using varying techniques have attempted to detect trinitrotoluene (TNT) and similar compounds. The first study was done using electrochemically roughened gold films in which TNT at concentrations in vapor as low as 5 ppb were detected.<sup>[43]</sup> By blowing a vaporized sample over the film and monitoring the SERS via a RS fiber probe, this low detection limit was possible. Nevertheless, a significant amount of postacquisition work was still required to extract the signal from the data. A more recent study utilized oriented arrays of pyramidal tipped silver nanowires to detect the explosive 2,4-dinitrotoluene (DNT). Fig. 6 shows the enhanced RS of DNT on the nanowire substrate as well as electron microscope images showing the cross-section of the wires and how they are aligned. While they do not report a detection limit, they do report an enhancement of five orders of magnitude, enough for low-concentration detection.<sup>[44]</sup> It is theorized that the enhancement is increased by the pointed tips of the wires that concentrate the electric field strongly. Both studies show that detection of explosives with SERS is a viable technique and allows the detection of low concentrations of explosives with high spectral resolution.

The major problems that must be overcome for SERS to be a practical technique for detecting in vivo

or explosive and warfare agents are portability, mobility, and ruggedness of the substrate. Currently, most SERS studies are done with a tabletop RS instrument in a laboratory with colloidal solution or one-time use films. There are portable RS instruments; however, a SERS substrate that is portable, reusable, and sensitive has not been available. Recently, Vo-Dinh et al. have demonstrated a reusable fiber optic tip SERS substrate.<sup>[45,46]</sup> With this they are able to obtain SERS spectra from the fiber by merely making it touch a dry surface. Fig. 7 shows the Raman signal of a surface coated with the dye cresyl blue, before and after contact with the SERS fiber tip. It is clear that there is a large enhancement by mere contact. This is achieved by tapering the fiber and depositing silver island films on the surface. This configuration lends itself well to localized, non-destructive experiments, while maintaining a high spatial resolution owing to the small size of the fiber tip. Also, the ability to detect SERS through dry contact is a major advantage over any other currently known system. This type of a device could be used as a sensing probe for SERS detection in a wide variety of situations, whether in the body or in the field.

Many of these fiber-detection applications have extremely low sample volume, and commensurate low signal. Recently, in our lab, we have built a new detection system utilizing a D-shaped, high-surface-area fiber SERS sensor. By polishing down one side of the fiber to the core, light can be coupled into metal particles on the surface and activate SERS. This represents an increase in active SERS surface area of approximately 2800 times from end polished sensors, greatly increasing the total intensity.<sup>[47]</sup>

The studies presented above represent very few of the myriad works being done today. In biological

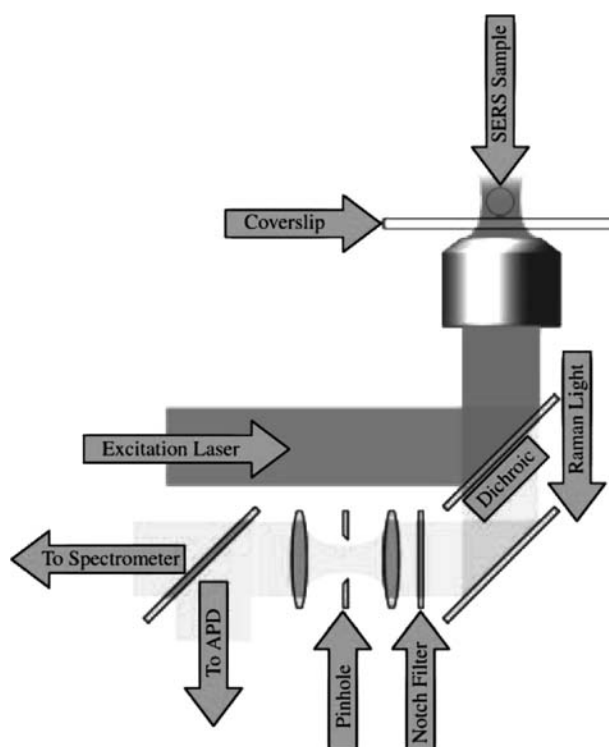

**Fig. 7** Raman spectra of a dry benzocyclobutene sample distributed on a glass slide, acquired A) before and B) after contact with the SERS-inducing nanoprobe. *Source:* From Ref.<sup>[46]</sup>.

detection, significant advances have been made in detection of cancer,<sup>[48–54]</sup> HIV,<sup>[55]</sup> insulin,<sup>[56,57]</sup> and many other exciting areas including amino acids, drugs, and vitamins in human samples.<sup>[58–63]</sup> Also the detection of pollution in sea water has been explored, important for rapid monitoring of environmental conditions.<sup>[64,65]</sup> Even illicit drugs and uranyl ions have been detected via SERS.<sup>[66–68]</sup> This speaks of the vast potential of SERS detection and what can be looked forward to in the future.

### Single Molecule SERS

The first researchers to report the detection of single molecules utilizing SERS were Nie and Emery, however, shortly thereafter Brus and coworkers and Kneipp et al. reported similar results.<sup>[9–11]</sup> This was made possible through the use of the confocal microscope, shown schematically in Fig. 8. The advantage of this system is that very small focal volumes may be probed, and stray light not within the focal volume is excluded by the pinhole. This allows for extremely high spatial resolution in three dimensions. By depositing silver NPs with rhodamine 6G on the surface of a glass slide, single particles can be observed, and by carefully controlling the concentration of the dye, it is possible to maintain a ratio of dye to particle, no

**Fig. 8** Schematic diagram of the confocal microscope setup. The excitation laser is coupled into the microscope through a dichroic into a high numerical aperture objective, which focuses it tightly onto the SERS sample that has been placed on a glass coverslip. The Raman scattered light then passes back through the objective used for excitation and is focused through a pinhole, excluding any scattered light not within the focal volume. This light can then be sent either to an avalanche photodiode (APD) to image the surface of the coverslip, or to a spectrometer to take the spectrum of the Raman scattered light.

greater than 1:1. To observe a signal at this concentration, the enhancement must be very large, and indeed, Nie and Emery report factors as large as  $10^{16}$ . Fig. 9 shows the spectra of a single rhodamine 6G molecule attached to, as Nie claims, a single silver NP. This is an impressive claim; however, there is disagreement in the literature as to whether a single spherical NP can produce this much enhancement.

As the enhancement is because of an electromagnetic field at the surface, it is strongly related to the shape of the particle. In a spherical particle, the charge is distributed evenly over the entire surface. However, if dislocations or points are present, the field will accumulate leading to regions of greater field strength.<sup>[69–71]</sup> Another source of increased fields is aggregation. Two or more particles approaching the enhanced fields will overlap, resulting in regions of high intensity between the particles.<sup>[8,37,72,73]</sup> This has led some to believe that to see SERS from a single

**Fig. 9** Emission-polarized surface-enhanced Raman signals of rhodamine 6G observed from a single silver NP with a polarization-scrambled confocal laser beam. A dichroic sheet polarizer was rotated  $90^\circ$  to select RS signals polarized parallel (upper spectrum) or perpendicular (lower spectrum) to the long molecular axis of rhodamine 6G. *Inset*: Structure of rhodamine 6G, the electronic transition dipole (along the long axis when excited at 514 nm), and the dichroic polarizer orientations. <http://www.sciencemag.org>. Source: From Ref.<sup>[9]</sup>.

molecule there must be aggregation.<sup>[74–76]</sup> However, Nie and Emery have continued producing results to confirm that they are indeed probing single NPs.<sup>[12]</sup> Regardless of the exact nature of enhancement, the power of single or near single molecule detection is clear and has brought about a new field of spectroscopic techniques.<sup>[77–82]</sup>

### Aggregation vs. Core Shell

Core/shell structures are creating a significant stir in SERS research today owing to their excellent optical and SERS properties.<sup>[30]</sup> Optically they are advantageous because of the near IR (NIR) absorption, which is highly desirable for in vivo studies as tissue absorbs weakly in this region.<sup>[16]</sup> Because SERS requires excitation resonance with NP absorption, purely spherical NPs of gold or silver will not absorb in the NIR region, making nanoshells a unique substrate for biological applications. Their SERS properties are also interesting. While they do not have excessively large enhancements, they are highly uniform, which is advantageous for single molecule or single particle studies.<sup>[83]</sup> Often in single particle SERS,

**Fig. 10** Diagram of the (A) crystalline shell and (B) aggregate shell core-shell structures. A shows schematically the path that the longitudinal and transverse resonances take.

one would want reproducible signals from particle to particle; however, most substrates that are aggregated have random shapes and sizes, leading to slight variations. Although in theory, core/shell systems could provide a solution to this problem, there are several complications.

The first major problem with this type of system is determining if core/shell particles are present at all. As stated earlier, a core/shell system can have very similar optical absorption as an aggregated system.<sup>[39]</sup> Therefore, without significant analytical work, it is difficult to prove whether a synthesis is producing aggregates or core/shell particles. The other complicating factor is that even with proper analytical techniques like high-resolution transmission electron microscopy, it may still be difficult to determine if the shell is a single crystal (Fig. 10A) or merely a conglomeration of small NPs on the surface of the core (Fig. 10B).<sup>[31–33]</sup> While this may not seem like a big distinction, the photophysics and SERS properties of the system are entirely dependent on this.

In a core/shell particle with a single crystal shell, the NIR or longitudinal absorption is because of resonance around the particle, as shown in Fig. 6A. However, if the shell is made up of aggregated particles, the transverse band originates in the individual particles, while the longitudinal mode is because of aggregation of the NPs. This is essentially a NP aggregate system and will not have the same properties or advantages as a true core-shell particle. While many report the synthesis of core-shell NPs, few are truly able to show conclusively that this is the case.<sup>[39]</sup>

### CONCLUSIONS

SERS is a powerful technique with great potential for research and analytical detection. In this entry, the

background and basic fundamentals of SERS have been briefly explained, and a quick overview of current research has been given. The importance of the structure of the SERS substrate and its implications in SERS activities has been discussed with core/shell and aggregate structures as examples. The future of SERS is dependent on the development and careful characterization of novel substrates with unique structures as well as on new techniques, to provide reproducible and accurate results for emerging technological applications in areas including biomedicine detection and advanced material characterization.

## INTRODUCTION

Interaction forces between two colloidal size bodies have been studied for several decades. They are known to originate from the interatomic forces acting between all of the atoms of those bodies, as well as the atoms of any intervening medium.<sup>[1]</sup> Surface forces especially play a role in many particulate systems, where they control powder flow, viscosity of ink and paint pigments, adhesion, coating, and interactions of biological molecules.<sup>[2,3]</sup> Surface properties of material can dominate bulk properties when the size is smaller than about 100  $\mu\text{m}$ . This is especially important as modern technologies require smaller dimensions and higher performance in application.

Understanding of surface forces is a matter of great importance for colloid science, where the stability and rheology of the colloidal suspension depend on the interaction forces between particles suspended in a liquid medium. The development of both theoretical and experimental approaches that can give qualitative and quantitative results has widely been performed for particles of varying sizes, ranging from several millimeters to several micrometers, and they fit each other well. However, the scalability of those theories down to the nanometer size range is questionable because the premises that were required to develop the current theories directly exclude nano size. For instance, the Derjarguin approximation, which translates from the interaction energy between two flat surfaces into other shapes, such as sphere–sphere and sphere–plane, is only valid when the radius of the particle is much greater than the separation distance between two particles.<sup>[4]</sup> Besides, only a few novel force measurement techniques are capable of directly measuring the surface forces of nanoparticles.

This entry will briefly describe the types of surface forces that are used to describe forces in colloidal suspensions, explaining the mechanisms and parameters attributing to those forces as well as the limitations

to nanoparticles. Then, the colloidal surface force measurement techniques will be reviewed, followed by new development of the direct force measurement for nanoparticles.

## SURFACE FORCES

With the development of the quantum theory, it was established that all surface forces are electrostatic and electrodynamic in origin. For colloidal particles suspending in the medium, complex fluctuating charge distribution takes place around the atom. Even in that case, once the Schrödinger equation solves the distribution of electron clouds of the given system, interaction forces between molecules can be calculated. However, it is not easy to obtain the exact solutions of the Schrödinger equation, even for a simple case such as two hydrogen atoms in vacuum. Thus surface forces are normally classified as short-range and long-range forces. For example, electrostatic force is a long-range force and van der Waals (vdW) force is considered as short-range on a macroscopic scale but long-range on an atomic scale. Surface forces on macroscopic scale will be discussed in the following sections.

### van der Waals

The van der Waals (vdW) force arises from the interaction between atomic and/or molecular dipoles. Those dipoles may exist, by the structure of the molecule, or they may be transient or induced by the molecule–molecule interaction. According to the origin of the dipoles, they are classified in three main categories.

1. Keesom interaction: The dipoles are permanent and are created by the structure of the molecule,

such as water. The dipole creates a finite electric field and this field can orient the neighbor dipoles so they are attracted to the first one.

2. Debye interaction: A permanent dipole can induce a dipole in a polarizable atom or molecule. The new induced dipole is oriented again in a way that it is attracted to the first one.
3. London or dispersion interaction: In this case, it is just the interaction between two polarizable atoms or molecules. The fluctuation of the electron distribution around the nucleus induces dipoles among the surroundings atoms or molecules and those induced dipoles are attracted to each other.

When molecules are close together, polarization is nearly instantaneous relative to relaxation time. At larger separation distances ( $>5$  nm), the synchronicity between instantaneous dipoles becomes less efficient and thus vdW attraction is less, decreasing as  $d^{-8}$ , which is known as retardation.

One way to calculate the vdW force is through the Hamaker approximation, which is based on a pairwise summation over all the atoms in the interacting bodies.<sup>[5]</sup> Hamaker showed that the non-retarded vdW interaction energy of two spheres of radius  $a$  is dependent on the center-center distance  $r$  as:

$$V_{\text{vdW}}(r) = -\frac{A}{6} \left[ \frac{2a^2}{r^2 - 4a^2} + 2\frac{a^2}{r^2} + \ln \left( 1 - 2\frac{a^2}{r^2} \right) \right] \quad (1)$$

and if  $a \gg r$ , this energy can be simply expressed with the separation distance  $D$ :

$$F(D) = -\frac{AR_S}{12D^2}, \quad (A = \pi^2 C \rho_1 \rho_2) \quad (2)$$

where  $A$  is the Hamaker constant and depends on the polarizability and the number of atoms per unit volume in the two interacting bodies ( $\rho$ ), and  $R_S$  is the radius of the sphere.

Because of a large number of body effects, by which an electric field of one given atom is induced not only by the closest atom but also by the other atoms in the vicinity, Lifshitz proposed to consider the bodies as continuum with certain dielectric properties.<sup>[6]</sup> The advantage of the Lifshitz theory is that accurate prediction of vdW force is possible if complete optical data are available. Spectral optical properties over very wide energy ranges can be obtained from optical reflectivity, valence electron energy loss spectroscopy

(VEELS), or band structure calculations.<sup>[7]</sup> The accuracy of the optical properties are critical to the accuracy of the calculated Hamaker constant, but simple index approximation method developed by Tabor–Winterton can be used when extensive data are not available.<sup>[8]</sup> Because the strongest contribution were found to be the high-frequency dielectric responses, the Hamaker constant between materials 1 in the medium 3 can be simplified as:<sup>[9]</sup>

$$A_{131} = \frac{3kT}{4} \left( \frac{\epsilon_1(0) - \epsilon_3(0)}{\epsilon_1(0) + \epsilon_3(0)} \right)^2 + \frac{3h\omega_e}{16\sqrt{2}} \frac{(n_1^2 - n_3^2)^2}{(n_1^2 + n_3^2)^{3/2}} \quad (3)$$

where  $\epsilon$  is the dielectric constant,  $\omega$  is the plasma frequency, and  $n$  is the index of refraction in the visible range.

However, for nano-size particles, it is very difficult to obtain accurate dielectric spectral parameters over the entire frequency range because quantum effects would influence the dielectric data of the given materials. In addition, local dielectric constant of the solvent may be changed because the mobility of the solvent molecules around small ions or particles is restricted in the solvation zone.<sup>[10]</sup>

## Electrostatic Forces

When particles are immersed in a polar liquid such as water, the surfaces are electrically charged. The main sources of this charge are the direct ionization of surface groups, specific ion adsorption, differential ion solubility, and substitution of surface atoms.<sup>[11]</sup> The charge induces an electrostatic potential, which has a certain value at the surface  $\Psi_0$ . Ions of opposite charge, the so-called counterions, dissolved in the polar liquid start to be attracted to the surface of the charged particles. There will be a local excess of counterions around the particles and the result is the development of two layers of different charges. This is known as the electric double layer (EDL), which is composed of the Stern layer and the diffuse layer, as illustrated in Fig. 1. In the Stern layer, counterions are strongly adsorbed and they lower the electric potential at points adjacent to the particle surface. The electrical potential at any point in the diffuse layer can be obtained from the Poisson–Boltzmann (PB) equation:

$$\nabla^2 \psi = \frac{-2nZe}{\epsilon_r \epsilon_0} \sinh \left( \frac{Ze\psi}{2kT} \right) \quad (4)$$

**Fig. 1** Schematic representation of the electric double layer (EDL). The surface due to the presence of charge has a potential  $\Psi_0$ . The outer Helmholtz plane (OHP) marks the closest distance that counterions can come to the surface. Next are the shear plane and the value of the potential at the point called  $\zeta$ -potential ( $\Psi_\zeta$ ).

where  $e$  is the electron charge,  $Z$  is the valence,  $n$  is electrolyte concentration,  $\epsilon_0$  is the dielectric permittivity of vacuum, and  $\epsilon_r$  is the dielectric constant of the solvent, respectively.

The solution of Eq. (4) can be obtained differently depending on the particle size and surface potential, as shown in the Table 1. If the particle size is large, the double layer can be treated as flat and Cartesian coordinates are applied. The Debye–Hückel length  $\kappa$ , which is the inverse of the Debye constant, gives the

thickness of that layer;

$$\Lambda = \kappa^{-1} = \left( \frac{2nZ^2e^2}{\epsilon_r\epsilon_0kT} \right)^{-\frac{1}{2}} \quad (5)$$

However, for nanoparticles, the double layer must be considered as spherical, and Debye–Hückel length can be expressed as:<sup>[12]</sup>

$$\frac{\sigma_d e}{\epsilon_r\epsilon_0\kappa kT} = 2 \sinh\left(\frac{e\xi}{2kT}\right) \left[ 1 + \frac{2}{\kappa a \cosh^2\left(\frac{e\xi}{kT}\right)} + \frac{8 \ln\left[\cosh\left(\frac{e\xi}{4kT}\right)\right]}{\kappa^2 a^2 \sinh^2\left(\frac{e\xi}{2kT}\right)} \right]^{\frac{1}{2}} \quad (6)$$

where  $\sigma_d$  is the diffuse layer charge,  $\xi$  is the potential at shear plane (i.e., zeta potential).

When particles of the same charge interact with each other, the repulsive interaction can be analyzed by considering the free energy change and the osmotic pressure generated by the accumulation of ions between the particles. The complete solution for this interaction is complicated, but simple expression for the electrostatic repulsive energy between two approaching spheres of radius  $a$ , with low surface potential  $\Psi_0$  in a medium of Debye length  $\kappa^{-1}$  is given by:

$$V_{\text{rep}}(r) = \frac{4\pi\epsilon_r\epsilon_0\psi_0^2 a^2}{r} \exp\left[-\kappa a\left(\frac{r}{a} - 2\right)\right] \quad (7)$$

### Derjaguin–Landau–Verwey–Overbeek (DLVO) Theory

van der Waals and EDL forces are the main forces that particles suspended in a solution can experience. Thus the summation of those forces to interaction should give a very good prediction about the interparticle forces. That concept was developed by Derjaguin–Landau–Verwey–Overbeek and is known as the DLVO theory.<sup>[13,14]</sup> The total energy in a particle system can be expressed by the summation of

**Table 1** Solution to the PB equation for high and low surface potentials in a symmetric electrolyte for high and low surface curvature

	$\kappa a \gg 1$	$\kappa a \ll 1$
$\psi_s < 25 \text{ mV}$	$\psi(x) = \psi_1 \exp(-\kappa x)$	$\psi(r) = \frac{a\psi_1}{r} \exp(-\kappa(r - a))$
$\psi_s > 25 \text{ mV}$	$\tanh\left(\frac{y}{4}\right) = \tanh\left(\frac{y_0}{4}\right) \exp(-\kappa x)$ where $y = \frac{ze\psi}{kT}$ and $\kappa = \left(\frac{2Z^2e^2n^\infty}{\epsilon_r\epsilon_0kT}\right)$	$\nabla^2\psi = \frac{d^2\psi}{dr^2} + \frac{2}{r} \frac{d\psi}{dr} = \frac{2ze}{\epsilon_r\epsilon_0} \sinh\left(\frac{e\psi}{kT}\right)$

vdW and EDL energies:

$$V_{\text{total}} = V_{\text{vdW}} + V_{\text{EDL}} \quad (8)$$

The normal criterion is that a barrier of  $25 kT$  is sufficient to achieve stability. The vdW (Eq. (1)), electrostatic (Eq. (7)), and total interaction energy (Eq. (8)) are

**Fig. 2** The calculated interaction energy between colloid particles as a function of the surface separation from micrometer- to nanometer-size regime of diameter. (A) The repulsive energy calculated from Eq. (7) and the parameters used are  $\Psi_0 = 25 \text{ mV}$ ,  $\kappa^{-1} = 100 \text{ \AA}$ , (B) the non-retarded vdW attractive energy calculated from Eq. (1) and Hamaker constant  $A = 6 \times 10^{-20} \text{ J}$ , (C) the total interaction energy due to both repulsive and attractive forces.

plotted as a function of particle size in Fig. 2. It clearly shows the dependence of the interaction energy on the particle size. The interaction energy increases with particle radius, and the barrier height of the colloidal stability consequently increases as the particle size increases. In other words, as particle size decreases, a greater Stern potential is needed to prevent coagulation. However, the primary and secondary minimum associated with particle coalescence also become deeper as the particle size increases. Thus the range and magnitude of the total interparticle forces is essential in controlling the stability of the given particles. If the relatively large particles coalesce in solution, they will not be separated again because their thermal energy will be insufficient to allow them out of the primary minimum. Nano-sized particles are theoretically easy to decoagulate because of the small primary minimum, although the repulsive barrier is small for nanoparticles. However, kinetics of decoagulation is more important in the practical application of nanoparticles.<sup>[15]</sup> If it is slow, the temporary agglomerate of nanoparticles behaves like a large particle and the vdW interaction energy will gradually increase, and they are difficult to disperse. From this theoretical calculation, it is clear that stabilization by small molecules such as adsorbed polymer or surfactant is much more efficacious than for larger colloidal particles. However, the effect of the repulsive layer thickness on the packing density of nanoparticles has to be considered. A thick repulsive layer is better for the stabilization of particles but it will reduce the achievable packing density.<sup>[16]</sup> Thus, to achieve stable high solids loading slurries, optimal thickness has to be just sufficient to prevent aggregation and minimize the occupied volume.

### Steric and Non-DLVO Forces

Polymeric dispersant molecules have been widely used for stability control in many industries such as ceramic processing, paper, and cosmetics.<sup>[17]</sup> When the polymers are added, they start to adsorb on the surface to minimize the total energy. When particles come close and the chains try to penetrate each other, the entropy is dramatically reduced. Consequently, this effect, known as steric force, prevents particles from coming in distance less than the gyration radius of the polymer. The interaction features of particles are dependent on the concentration of the added polymer. When the concentration is low and not sufficient to cover the surfaces of particles, polymer bridging may occur, where one polymer chain adsorbed on one surface attaches to another particle. The result will be the flocculation of particles. If the polymer concentration keeps increasing beyond full surface coverage, then another effect takes place. When the excess polymer exist in the solution

and the fully coated particles approach closer (i.e.,  $<$  radius of gyration), the non-adsorbed free polymers between them start to be excluded as a result of entropic effects. Eventually, the local concentration becomes lower than the surrounding level. The concentration difference creates osmotic pressure difference that attracts two particles. This is known as the depletion flocculation. If the concentration increases even more then, the polymer actually becomes the solvent and the depletion effect is reversed. The particles are pushed apart and the system is stabilized. This effect is known as depletion stabilization.

In further detail, the conformation of the polymer is important in determining the interactions between them. The conformation of polymers adsorbed to the surface of the particles depends on a number of parameters in the system, such as the solvency of the solution, relative charge of polymer and particles, as well as pH and ionic strength.<sup>[18]</sup> In addition, the relative size of the polymer and colloidal particle may affect the conformation of the polymer. When polymer molecules interact with the nanoparticles, which have a relatively similar size to the polymer molecules, different conformation features are expected. According to molecular dynamics (MD) simulations for the interaction of polyethylene oxide (PEO) with colloidal silica, polymers adopt a flat conformation on the surface when polymer molecules are much larger than the particles. In contrast, when the particle size increases, polymer adopts an extended conformation consisting of loops and tails.<sup>[19]</sup> The expected polymer conformation, depending on the particle size, is illustrated in Fig. 3.

Although the DLVO theory is universal and is mostly accepted to describe the macroscopic colloidal behavior, there are a number of cases where it does not adequately interpret the measured interaction profiles. Because DLVO is based on a continuum

approach, neglecting solvent effects such as ion–solvent interactions, surface–solvent interactions, and ion–ion correlation, non-DLVO forces occur when the property (e.g., density and mobility) and the molecular structure of solvent near surfaces of particles are different from the bulk property.<sup>[20]</sup> The existence of these forces to explain the stability of the fine powders was confirmed with the development of surface force measurement techniques. For example, it was first observed by Horn that oscillatory solvation (or hydration in water) forces occur between smooth surfaces such as mica at very short separation distances because of the overlap of two solvated surfaces, which arise from the specific solute–solvent and modified solvent–solvent interactions.<sup>[21]</sup> Alternatively, attractive hydrophobic forces may occur because of the unfavorable structure of water (i.e., rearrangement of H-bond) near an interface.<sup>[10]</sup> However, interpretation of these forces is not obvious when a radius of curvature of particle is of the order of a few nanometers. This will be further discussed later.

## SURFACE FORCE MEASUREMENT TECHNIQUES

The colloidal behavior of a particular system can be investigated in several ways such as turbidity,<sup>[22,23]</sup> sedimentation,<sup>[24,25]</sup> electrokinetics,<sup>[26]</sup> viscosity,<sup>[27,28]</sup> etc. Among them, surface force measurement techniques have been a useful method to directly characterize the interaction between particles. While the principal idea of direct force measurement is straightforward, which makes use of Hook's law, the challenge arises in measuring very weak forces at very small surface separations. Several different techniques for measuring interaction forces between macro- and microscopic surfaces have been developed including surface force apparatus (SFA), total internal reflection microscopy (TIRM), and atomic force microscopy (AFM). In this section, the fundamentals of operation of each technique will be described. Furthermore, a few modified techniques and the resultant interaction force measurements for nanoparticles will be introduced.

### Surface Force Apparatus (SFA)

Surface force apparatus (SFA) was first developed by Tabor and Winterton,<sup>[8]</sup> and further refined by Israelachvili and Tabor.<sup>[29]</sup> The principles of this technique are depicted schematically in Fig. 4. SFA is composed of two crossed cylinders, one of which is mounted on a spring and the other on a piezoelectric tube. The separation distance between the two surfaces is monitored through the use of optical

**Fig. 3** Expected polymer conformation with extremely large and small particle sizes.

**Fig. 4** A schematic diagram of the surface force apparatus (SFA) for directly measuring the surface forces between surfaces in liquid.

interferometry—fringes of equal chromatic order (FECO). Interaction force is determined by the difference in the applied and measured separation distances multiplied by the spring constant. The distance resolution is approximately 0.1 nm and the force sensitivity is about  $10^{-8}$  N. The advantages of this technique are: 1) true zero separation distance can be known; 2) large range of accessible forces; 3) refractive index of the medium may be simultaneously measured. However, the drawback of this technique is that available samples are limited because surfaces must be optically

transparent and atomically smooth, not to mention the long time-scale experiment.

### Total Internal Reflection Microscopy (TIRM)

This technique measures the change in intensity of an evanescent wave being refracted through the particle for determining the distance between a free particle and a flat surface.<sup>[30]</sup> Mean potential  $\phi(h)$  at separation distance  $h$  is determined by the Boltzmann distribution describing the Brownian motion:

$$p(h) = A \exp(\phi(h)/kT) \quad (9)$$

where  $p(h)$  is proportional to the probability of finding the particle at  $h$ . Force curve is produced by allowing the particle to oscillate in a potential minimum. This technique has an excellent sensitivity in the pN range, which makes it possible to measure the secondary minimum. However, the particles must be spherical, optically transparent, and homogeneous to refract light in a regular manner.

### Atomic Force Microscopy (AFM)

Atomic force microscopy (AFM) was developed as an imaging tool of surfaces in the atomic scale in the late 1980s.<sup>[31]</sup> The use of AFM in surface force measurement has been popular since Ducker introduced the colloidal probe technique, where a well-defined single colloidal particle was attached to the cantilever.<sup>[32]</sup> Force is calculated by the deflection of the cantilever multiplied by its spring constant. Separation distance determined by the constant compliance, which is the region that both cantilever and substrate move

**Table 2** Comparison of SFA, TIRM, and AFM techniques

	SFA	TIRM	AFM
Advantages	True zero separation distance is known Large range of accessible forces Forces measured at equilibrium	High force sensitivity Rotational movement of particle is not hindered	Any materials can be measured Changing solution is relatively easy Approach rate is variable
Disadvantages	Very sensitive to particle contamination Long time scale for experiments Surfaces must be optically transparent and molecularly smooth	True zero separation distance is unknown Particle must be spherical, optically transparent, and homogeneous Maximum force range is limited	True zero separation distance is unknown Sensitive to electrical noise
Sample size	1–2 cm	5–35 $\mu\text{m}$	1–50 $\mu\text{m}$
Force sensitivity	$10^{-7}$ N	$10^{-14}$ N	$10^{-12}$ N

**Fig. 5** Effect of the silica particle diameter ( $d_p$ ) on the force measured via AFM. Solid and broken lines are theoretical fits to the DLVO theory for a constant surface potential. *Source:* From Ref.<sup>[34]</sup>. © 2002 American Ceramic Society.

together after contact. Because the interaction surface area is smaller than SFA, this technique is less sensitive to the surface contamination, and another advantage is that almost all materials can be investigated, including hydrophilic and hydrophobic surfaces, and biological molecules. However, true separation distance is unknown because zero separation is assumed from the constant compliance. Force sensitivity is about  $10^{-12}$  N and distance resolution is 0.1 nm. Some

essential features of three techniques are summarized in Table 2.

### Surface Force Measurement for Nanoparticles

Although the techniques explained above have been powerful tools to measure the interaction force between particles, the size of the sample is limited to micrometers. In AFM, for instance, the attachable colloidal particle is normally a few tens of micrometers and the direct use of AFM tip in many studies have raised some controversy regarding measurement. For example, Cleveland, Schaffer, and Hansma<sup>[33]</sup> measured oscillatory hydration potential on calcite ( $\text{CaCO}_3$ ) and barite ( $\text{BaSO}_4$ ) by using thermal-mechanical noise of cantilever. On the other hand, Kamiya et al.<sup>[34]</sup> utilized the  $\text{Si}_3\text{N}_4$  AFM tip over one primary silica particle after imaging the silica compacts in water to study the effect of the particle size on the formation of hydration layer around the surface. They observed, with FTIR and force measurement, that no hydration force was found for nanoparticles with a diameter of less than about 30 nm (Fig. 5), and a different silanol structure on the surface of  $\text{SiO}_2$  was suggested, depending on the radius of curvature of the particle.

Normally, the typical AFM tip is of pyramidal or cone shape. In a much-sharpened tip, the radius of curvature is about few nanometers in size, but the

**Fig. 6** Calculated van der Waals interaction force between a cone-shaped AFM tip and a flat plate depending on the angle  $\theta$ .

Fig. 7 The calculated van der Waals interaction force of cone-shaped AFM tip, nanosphere, and nanotube tip with a flat plate.

effect from the side wall cannot be neglected in force measurement. Fig. 6 shows how interaction force is affected by the tip angle. The wider the tip, the larger is the expected contribution from the side. Although it is ideal to mount the single nanoparticle on the cantilever, handling and attaching it to the right position is empirically infeasible. To overcome the side effect from the AFM, the carbon nanotube attached tip, so called, the nano colloidal probe technique was recently presented.<sup>[35,36]</sup> Carbon nanotube has extraordinary electrical and mechanical properties such as high resilience. The possible use of the nanotube as an alternative to the single nanoparticle to investigate the interaction force of nanoparticles can be validated with a theoretical calculation as shown in Fig. 7. The calculated force with a conventional AFM tip is much deviated from the force of nanoparticle. On the other hand, the nanotube tip, which has a high aspect ratio, can well represent the interacting behaviors of the nanoparticles as a result of the minimum effect from the side wall. The schematic operation feature of the nanotube-attached AFM tip in force measurement is well described by Cho and Sigmund.<sup>[36]</sup> Unlike the typical deflection signal vs. separation distance, where only one constant compliance exists, two constant compliance regions are observed with a nanotube tip. One is from the contact between the nanotube and substrate, and the other from the consecutive contact between the AFM tip and substrate after bending of the nanotube.

Jarvis et al.<sup>[35]</sup> presented the structural force measurement using the nanotube AFM tip, and found out the scalability of the structural forces to nanoscale and observed the solvation shell on the non-rigid

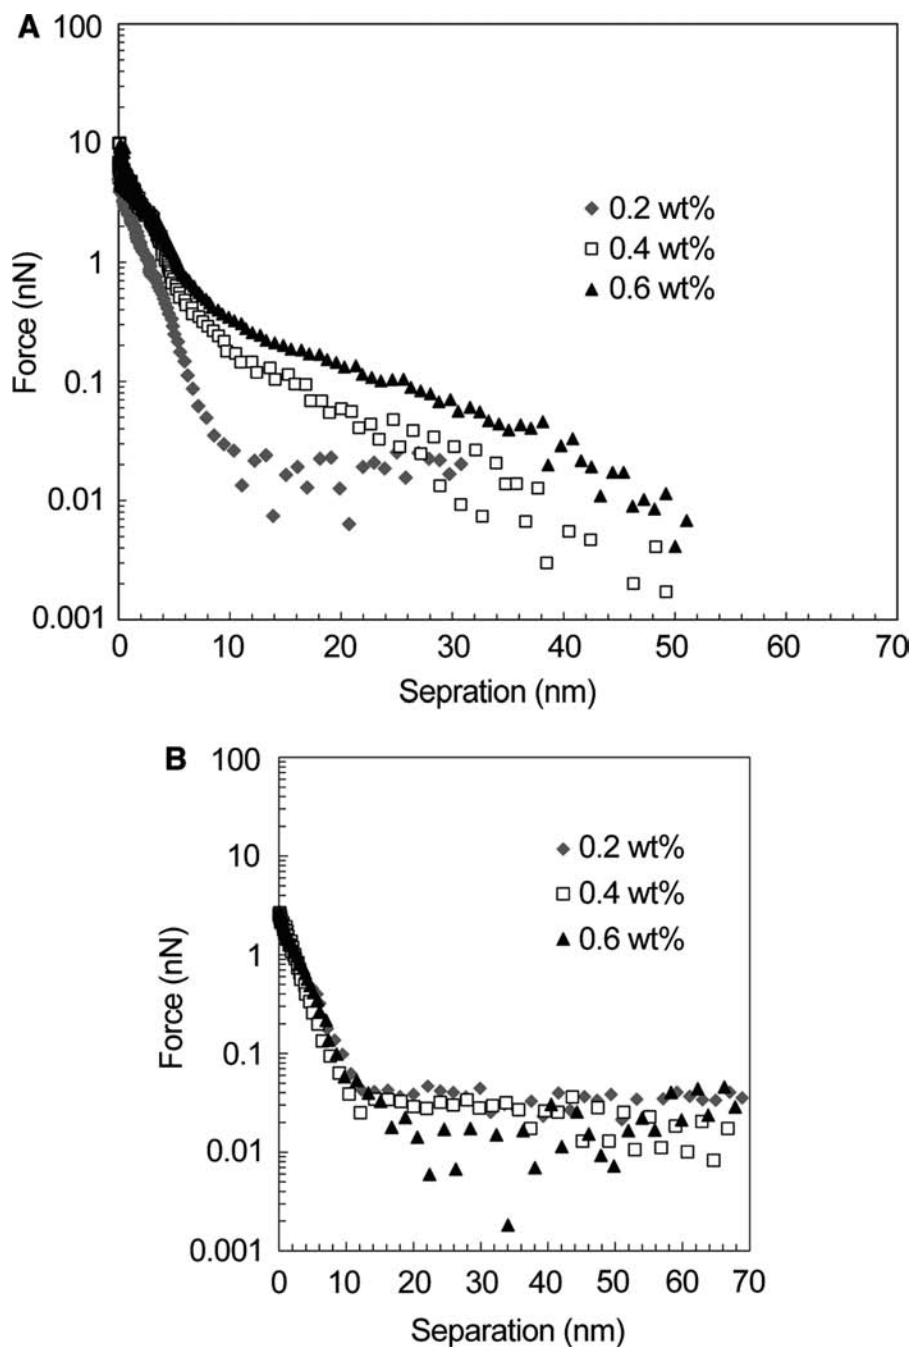

Fig. 8 Measurement of solvation shell between the carbon nanotube and hydrophilic self-assembled monolayer of  $\text{COOH}(\text{CH}_2)_{10}\text{-SH}$  on flat Au surface. Source: From Ref.<sup>[35]</sup>. © 2002 American Chemical Society.

**Fig. 9** (A) Force vs. separation plot between a bare Si tip and SiO<sub>2</sub> substrate (pH 10, 0.01 M NaCl). (B) Force vs. separation plot between a Multiwalled carbon nanotube (MWNT) probe and SiO<sub>2</sub> substrate. Measured forces were independent of the concentration of Polyethyleneimine (PEI) (pH 10, 0.01 M NaCl).

surface, as shown in Fig. 8. Curves showed a periodicity corresponding to the diameter of water molecule and an increase of dissipation at smaller separation due to layering of water. Interaction forces between the nanoparticles in the presence of polymer measured using the nanotube tip shows the different interaction force from one having a bare AFM tip. As shown in Fig. 9, while the forces between the silicon AFM tip and SiO<sub>2</sub> substrate increases with the concentration of polymer, the forces of nanotube tip are independent of the concentration of the polymer. The magnitude and range of the interaction force is

obviously small. This can be explained that, as the concentration of polymer increases, the more packing of the polymer is induced and the thickness of the incompressible layer increases, consequently the resultant interaction layer is also increased. However, the nanotube tip may penetrate into the layer of polymer up to a certain point irrespective of the polymer concentration.

The other application of force measurements using the carbon nanotube probe is to sense and manipulate the biological samples at the molecular level. Wong et al.<sup>[37]</sup> demonstrated the titration of

**Fig. 10** (A) Diagram illustrating the modification of carbon nanotube by coupling an amine to a pendant carboxyl group. (B) Adhesion force as a function of pH between hydroxy-terminated SAM. carboxyl-terminated nanotube by measuring the adhesion force (Fig. 10) and the possibility of detecting the binding force between single protein–ligand pairs.<sup>[37]</sup>

## CONCLUSION

Understanding of the fundamentals of the interacting forces between two objects has been an important issue in colloidal processing, chemistry, biology, etc. The classes and origins of the surface forces including

van der Waals, electrical double layer, steric, and solvation forces are reviewed. Reasonable theories predicting the forces acting on particles of micron size are available, but questions still remain if we scale them down to nanometer range. Currently available surface force techniques were briefly reviewed and a few of examples of direct measurement of surface forces of nanometer-scale objects were introduced. Nanotube-attached AFM tip will be capable of directly measuring the forces of matters at nano level and answering the questions arising from size effect on surface forces.

## INTRODUCTION

This work is a brief topical review of recent literature reports of the localized surface plasmon spectra of silver and gold nanoparticles (NPs) in various assemblies. The desire for such a review arises from the numerous recent reports of NP assemblies, their optical properties, and the importance of their potential applications. The optical properties can be viewed from the perspective of isolated particles, particles coupled by near-field light interactions (roughly when the interparticle separation is less than particle size), and those coupled by far-field interactions (for well separated particles in arrays or gratings). The NPs reviewed are sized from ca. 20–500 nm in diameter or major axis (except for wires), are of various shapes, e.g., spheres, triangles, cylinders, etc., and are arranged by various means including synthetic molecular linking architectures. The preparation of interesting NP systems builds, in part, on relatively recent NP synthetic strategies that yield NPs of uniform size and often organized 1-, 2- and 3-D NP assemblies. Methods for making NPs fall into two broadly defined categories: those based on physical metal deposition and those based on solution chemistry, the latter including electrodeposition. Physical metal deposition methods encompass electron beam lithography (EBL), nanosphere- and colloidal lithography, metal island films, and cosputtered composite materials. Powerful EBL methods can produce arbitrary NP shapes and arrangements, and sizes of about 50 nm and larger are in the literature. Nanosphere lithography, pioneered by Van Duyne et al. (vide infra), yields arrays of triangular and related particles in the 90–2500 nm range. Simple metal island films, e.g., from 2 to 3 nm mass thickness Au and Ag evaporated directly onto non-wetting oxide substrates, can yield reasonable NP distributions, as can cosputter-deposited composites of metal and oxide matrix (e.g., Ag and SiO<sub>2</sub>). Chemical NP preparations resulting in uniform size distributions (e.g., <10% variability) have been the subject of extensive recent development and are predominantly

from two methods: 1) solution phase synthesis (often with a fractional precipitation step); and 2) templating methods such as electrodeposition into nanoporous Al<sub>2</sub>O<sub>3</sub> membranes.

## Localized Surface Plasmon Resonance in Noble Metal Nanoparticles

Light of appropriate wavelength can excite collective oscillations of the conduction electrons in Au, Ag, and other metal NPs—the theoretical description of which by Mie dates back to the turn of the twentieth century.<sup>[1,2]</sup> This phenomenon is analogous to the surface plasmon polariton that can be excited by evanescent wave irradiation in planar metal surfaces. The plasma oscillation in metal NPs of spherical symmetry is well described by the Mie equations, which are solutions to Maxwell's equations for electromagnetic (EM) radiation interacting with small particles ( $d < \lambda/10$ ). The plasma oscillation is variably referred to as a (localized) surface- or particle-plasmon resonance—we adopt the term *localized* surface plasmon (LSPR) coined by Van Duyne et al. to distinguish the NP phenomenon from the propagating surface plasmon polariton of planar metal surfaces.<sup>[3]</sup> Because of the very high electronic polarizability of noble metal NPs, their LSPR oscillations couple very efficiently with light. Accordingly, extinction of transmitted light by NPs is enormous—equivalent to molecular absorption with a molar extinction coefficient  $10^{11} \text{ M}^{-1} \text{ cm}^{-1}$  in some cases.<sup>[4]a</sup> Similarly, a 100-nm Ag NP scatters light equivalently to the emission of  $10^6$  fluorescein fluorophores.<sup>[5]</sup> The strong extinction band ranges from the blue (e.g., 420 nm for 40 nm Ag spheroids in air<sup>[6]</sup>) throughout the visible and into the infrared (e.g., 6000 nm for 2500-nm Ag triangles<sup>[4]</sup>). In most cases,

<sup>a</sup>The term extinction refers to the aggregate effect of absorption and scattering and differentiates LSPR scattering and absorption from molecular absorption.

the peak wavelength of the LSPR band ( $\lambda_{\text{LSPR}}$ ) will red shift with increasing ambient or substrate dielectric constant ( $\epsilon$ ), increasing particle size, or aggregation.<sup>[7]</sup> The high sensitivity to dielectric constant ( $\Delta\lambda_{\text{LSPR}}/\Delta\epsilon$ ), and the highly localized nature of surface electric fields (projecting out from the NP surface by only a small fraction of the light wavelength in some cases) underpins the utility of NPs as surface-affinity based chemical and biosensors.<sup>[8]</sup> The high intensity of the surface electric fields associated with the LSPR of NPs and NP aggregates also underpin spectral enhancements such as the Raman effect.<sup>[9]</sup> NPs and NP films are also interesting for their potential applications in non-linear optics.<sup>[10,11]</sup> The dynamics of NP LSPR processes occur on the femtosecond time scale, and have been explored by Link and El-Sayed.<sup>[12]</sup>

### Theory and Simulation of Nanoparticle Surface Plasmon Spectra

There are a number of excellent recent papers covering theoretical aspects of the optical response, i.e., extinction, scattering, and electric field strengths, of Au and Ag NPs.<sup>[13–17]</sup> The following is merely an overview intended to elucidate points about: 1) the Mie theory,<sup>[18]</sup> 2) the calculation of the small-particle dielectric constants from the bulk-metal values,<sup>[13–15]</sup> 3) calculations of effective refractive index (RI) for particle aggregates,<sup>[15,19,20]</sup> and 4) computational solutions for arbitrary shapes and arrangements.<sup>[16,17]</sup> Discrete electronic structure is not seen in the LSPR spectra of Au and Ag particles larger than about 2 nm and is not discussed.

Mie theory is a set of exact solutions to Maxwell's equations for light interacting with small spherical particles, and is an excellent model for a wide range of NPs of spherical or nearly spherical symmetry. Typically, Mie theory is used to calculate the extinction cross section ( $\sigma$ ) of NPs, and for particles of less than about 20 nm, only the dipolar solution is important:

$$\sigma = \frac{9V\epsilon_M^{3/2}}{c} \frac{\omega\epsilon'(\omega)}{(\epsilon(\omega)' + 2\epsilon_M)^2 + \epsilon'(\omega)^2}$$

where  $\sigma$  is the scattering cross section,  $V$  is the particle volume,  $\epsilon_M$  is the dielectric constant of the medium, and the complex dielectric constant of the metal is  $\epsilon = \epsilon(\omega)' + i\epsilon(\omega)''$ . For a real and fairly constant  $\epsilon_M$ , resonance condition is fulfilled when  $\epsilon(\omega)' = -2\epsilon_M$  for spheres (or  $\epsilon(\omega)' = -\epsilon_M$  for long rods when the electric field is polarized perpendicular to the long axis). The wavelength dependence of  $\lambda_{\text{LSPR}}$  originates from three places—the wavelength and size dependence of  $\epsilon(\omega)$ , the appearance of quadrupole resonances (higher order Mie solutions) for particles

larger than about 20 nm, and damping when, because the particle is approaching or exceeds the light wavelength, the electric field is no longer homogeneous within the particle. Mie theory can also be used to calculate local field strengths.

Accurate application of Mie theory requires good estimates of the frequency-dependent dielectric [ $\epsilon(\omega)$ ] of the NP. But for smaller NPs, adjustments are needed, especially as the NP radius approaches the bulk metal electron mean free path,  $R_B$ . At this point,  $\epsilon(\omega)$  appears to diverge from that of bulk metal. If one considers the contribution to  $\epsilon(\omega)$  from the free electrons to be distinct from other sources, Drude theory can be applied to the confined conduction electrons, and accurate predictions of LSPR band position and shape can be made. This is accomplished by recalculating the electron damping frequency,  $\omega_D = v_F/R$ , where  $v_F$  is the Fermi velocity, using a reduced mean free path,  $R_{\text{EFF}} = (R_{\text{NP}}^{-1} + R_B^{-1})^{-1}$  that reflects electron scattering from the NP surface.<sup>[14,15]</sup> This adjustment also predicts the rapid broadening of NP LSPR bands into baseline as the radius falls below about 2 nm. Electronic fine structure is just discernible in the derivative spectra of Au particles of 1.4 nm and smaller, but does not substantially impact the overall band shapes.<sup>[14]</sup>

Prodan et al. very recently contributed a theoretical approach to the description of LSPR modes. This model is described as the electromagnetic analog of molecular orbital theory, in that it uses a hybridization approach directly analogous to that describing atomic and molecular electronic structures.<sup>[21]</sup> This approach is supported by successful calculations of nanoshell LSPR modes by Nordlander, who treat the electronic structure of the shell with ab initio electronic structure calculations (time-dependent local density approximation) and within the jellium approximation.<sup>[22]</sup> In this method, the nanostructure LSPR is described as the sum of simpler, interacting ones. Or, in other words, the plasmon modes of the simpler or elementary structures hybridize to form new modes. For example, the LSPR of a Au nanoshell (e.g., an Au-coated SiO<sub>2</sub> sphere) is well known to have two prominent LSPR modes. In the hybridization model, these are clearly seen to arise from the symmetric and antisymmetric combinations of the dipolar plasmons of two, more elementary structures: 1) an Au sphere; and 2) a dielectric cavity in an Au medium. Building on this result, two concentric nanoshells can then be described by the symmetric and antisymmetric sums of the inner and outer shell LSPR modes. Hybridization model spectra of concentric nanoshells are in excellent agreement with experiment.

For NP assemblies where the NP volume fraction is significant, there arises the problem of how to accurately account for NP contributions to the medium

dielectric constant  $\epsilon_M$ . In general, the Maxwell–Garnett (MG) theory seems to be the more successful, established theory, although the Bruggeman theory is also used.<sup>[15,19,20,23]</sup> The MG theory predicts the aggregate (complex) dielectric constant,  $\epsilon_C$ , assuming a composite material made up of a matrix of  $\epsilon_M$  and a volume fraction,  $f_M$ , significantly less than 0.5, of “infinitesimal” particles (i.e., much smaller than  $\lambda$ ) of dielectric  $\epsilon_0$ :

$$\frac{\epsilon_C - \epsilon_0}{\epsilon_C + \kappa\epsilon_0} = f_M \left( \frac{\epsilon_M - \epsilon_0}{\epsilon_M + \kappa\epsilon_0} \right)$$

The factor  $\kappa$  is a shape-dependent factor equal to 2 for spherical particles, and 1 for infinitely long “needles” oriented perpendicularly to the incident EM field. For example, Mulvaney<sup>[24]</sup> applied the MG theory to spherical SiO<sub>2</sub>-coated Au NPs of variable Au volume fraction. In this case, the MG theory was very well able to predict the red shift in  $\lambda_{\text{SPR}}$  for Au volume fractions less than about 0.5, but somewhat underestimated it thereafter. The MG theory was also adapted by Foss et al.<sup>[25]</sup> to apply to nanorods with variable aspect ratios through the incorporation of a wavelength-dependent  $\kappa_{\text{EFF}}$  value. The  $\kappa_{\text{EFF}}$  model, also known as dynamic Maxwell–Garnett theory, successfully predicts shape-dependent trends in  $\lambda_{\text{SPR}}$ , but systematically overestimates them. In contrast, naively applying Mie theory to the same rods leads to systematic underestimation of  $\lambda_{\text{SPR}}$ .

Clearly, a more general approach to the prediction of optical and electrostatic aspects of NPs and NP assemblies is desirable. These approaches are generally in the form of computational solutions to Maxwell’s equations using finite-difference approaches. An excellent example of this approach is the work of Schatz et al.<sup>[16]</sup> on the discrete dipole approximation (DDA), which divides the object of interest into a lattice of polarizable cubes whose individual dipole polarizations are determined self-consistently. According to Schatz et al., appropriately applied DDA calculations yield extinction spectra that are consistently within about 10% of the exact or experimental ones independent of the particle size or shape. Other approaches include the multipole–multipole<sup>[26]</sup> and finite difference time domain<sup>[27–29]</sup> variants.

## NANOPARTICLES AND THEIR ASSEMBLIES

The variety of NP shapes, sizes, architectures, and strategies for organizing and studying NPs inspires this section—hence it moves topically through a cross section of the literature by the dimensionality of the NP assembly in question. Other important themes such

as LSPR coupling and multipolar LSPR modes span various dimensionalities and are noted throughout. Nanoparticles have been studied individually, in random 2- and 3-D arrangements and in lithographically organized assemblies or as determined by molecular architectures. Various studies examine LSPR spectra as a function of particle size, shape, spacing, dielectric medium, polarization, and incident angle of light.

### Single Particles, Dimers, Trimers, and Tetramers

#### Single nanoparticle spectroscopy

Recent spectroscopic reports of single noble metal NPs characterizing roughly spherical and “wire” geometries with attention to their potential application as single-particle sensor platforms include reports by Shultz et al.,<sup>[6,30]</sup> Raschke et al.,<sup>[31]</sup> and McFarland and Van Duyne.<sup>[32]</sup> These studies are akin to single *molecule* spectroscopy, but are technologically easier because of the extremely large Rayleigh scattering efficiency (typically equivalent to 10<sup>5</sup>–10<sup>6</sup> fluorophors) of the surface plasmon peak in an NP.<sup>[5]</sup>

The first of these studies<sup>[30]</sup> examines silver, gold, and nickel nanowires (and various segmented variations) prepared by a combination of electroless and electrochemical deposition steps within the pores of commercial polycarbonate filtration membranes (by Nucleopore) and subsequently released. The nanoscopic pores are produced by high-energy alpha-particle perforation of polycarbonate films and are uniquely suited to the templating of nanoparticles because they are highly uniform in diameter and aspect ratio, the former controlled by the manufacturer by etching the filtration membrane, and the latter by variation of the electrodeposition time. In this case, the pores (and hence nanowires) have nominal dimensions of 15 × 7000 nm. As in the latter studies, the wires were imaged with conventional light microscopy under dark field illumination, and detected by virtue of their intense light scattering cross sections. Spectra were acquired by imaging scattered light onto a single monochromator with charge-couple device (CCD) detector.

In wires, the plasma resonance observed is a transverse (radial), dipolar one. The longitudinal (axial) resonance is not seen because the wires are very long. In these,<sup>[30]</sup> resonances that were evident as peaks in the scattering spectra at ca. 400 nm for Ag and 540 nm for Au–Ni wires did not yield a spectral peak. Mie scattering calculations gave an excellent fit to the observed Au and the featureless Ni spectra, but failed to capture the ca. 400 nm resonance for Ag.

In a subsequent report by Mock, Smith, and Shultz<sup>[6]</sup> the response of the dipole resonance to changes in refractive index for single, 60-nm quasispherical particles was measured by using a series of index matching oils. The observed  $\Delta\lambda_{\text{MAX}}/\Delta n$  was 160 nm—in qualitative agreement with Mie calculations (210 nm) that ignore the SiO<sub>2</sub> substrate half space.

More recently, Raschke et al.<sup>[31]</sup> and McFarland and Van Duyne<sup>[32]</sup> have examined single nanoparticles immobilized on glass in the context of their potential application as chemo- or biosensors with extremely low mass detection limits. Single NP sensors are a tantalizing prospect because of the extreme mass sensitivity and spatial resolution of single NP LSPR. For example, just 60,000 molecules could be detected in a volume smaller than a cellular organelle by single NP scattering, or conversely, a very large number of different assays might be simultaneously conducted in a very small area and volume with an assay based on many uniquely identifiable NPs.<sup>[33]</sup> In the report by McFarland and Van Duyne,<sup>[32]</sup> dark field microscopy/spectroscopy was used to detect alkanethiol adsorption to single Ag nanoparticles prepared by citrate reduction. The bulk refractive index (RI) sensitivity of selected particles,  $\Delta\lambda_{\text{MAX}}/\Delta n = 203$  nm, agreed well with Mie theory predictions. The response to monolayer alkanethiol adsorption was very large, with a hexadecanethiol self-assembled monolayer (SAM) producing an easily detectable 40.7 nm red shift at saturation, and corresponding to only ca. 60,000 molecules detected. The similar report by Raschke et al.<sup>[31]</sup> employed Au NPs derivatized with biotinylated bovine serum albumin and binding diffusing streptavidin. They observed a significant, but small 1.2 nm shift corresponding to saturation—again, just slightly less than that predicted by Mie theory for a  $4\pi$  steradian change in RI. These authors suggest that a rod NP would produce higher sensitivity.

### Nanoparticle dimers, trimers, and tetramers

A number of recent articles have examined the optical response of pairs, dimers, and trimers of NPs. In contrast to the above studies, these systems were studied as ensembles, but the degree of particle homogeneity is high and the results are likely to be representative of the 2-, 3-, or 4-particle systems. Novak and Feldheim<sup>[34]</sup> used rigid molecular linkers of variable lengths in the 2–30 nm range to create bridged NP structures. The thioactyl-terminated phenylacetylene bridges were prepared in three varieties; the first, simply a straight rigid rod-like molecule, and the second and third having a central branching point with three and four branches, respectively. These were reacted with 30-nm-diameter Ag NPs, and the resulting

symmetric dimers, trimers, and tetramers were confirmed with transmission electron microscopy. These important solution-extinction spectroscopy experiments confirmed that as the linker is shortened, the near-field coupling first slightly red-shifts, and then spawns a high-frequency band as the separation approaches about 4 nm.

A more recent paper by Sandrock and Foss<sup>[35]</sup> employs a template analogous to the Nucleopore<sup>TM</sup> ones employed above—transparent and porous Al<sub>2</sub>O<sub>3</sub> membranes to produce varied pairs of NPs within the individual pores and to study them in place, without releasing them from the Al<sub>2</sub>O<sub>3</sub> template. Au and Ag were alternately deposited and Ag later dissolved away to create controlled Au–Au spacing. In this way, sphere–sphere, rod–rod, and rod–sphere near-field interactions could be probed. An important aspect of this motif is that it allows the study of the linear dichroic properties of the NP pairs. For example, because all pores in the Al<sub>2</sub>O<sub>3</sub> support are normal to the surface, it is possible to control the polarization of the incident light such that it is predominantly axial or radial in character. Interparticle interactions were indicated by spectral results that showed splitting under polarization that put an E-field component along the particle–particle axis. A subsequent paper by Gluodenis and Foss<sup>[36]</sup> delves into simulation and theory for side–side and end–end interactions of NP rod pairs.

Subsequent reports by Rechberger et al.<sup>[37]</sup> and Su et al.<sup>[38]</sup> examine ensembles and individual NP pairs (respectively) fabricated by using electron beam lithography. Leitner et al. examined 150-nm disks, that were 17 nm thick and spaced between 150 and 450 nm apart; Zhang et al. studied elliptical particles in the 100–150 nm range. Zhang et al. report a red shift in  $\lambda_{\text{SPR}}$  as the particles are brought into proximity. By examining polarizations both parallel and perpendicular to the interparticle axis, Leitner et al. resolved a strong red shift (+78 nm) and a weaker blue shift (–30 nm) as the 150-nm particles were brought into edge contact. The red shift is attributed to favorable head–tail interparticle electrostatic interactions arising from parallel particle dipoles arranged end to end. The weaker blue shift is attributable to particle dipoles arranged side-by-side. Notably, these interactions did not produce band *splitting* observed for the smaller, chemically synthesized NPs of Novak and Feldheim.<sup>[34]</sup>

### Nanoparticle Chains with Near-Field Coupling

Au and Ag NPs arranged in chains, i.e., in a row, are of interest in the technological arena as “plasmonic light waveguides” for guiding light in subdiffraction spaces

and for the production of electron tunneling electronics such as single electron transistors. Chains have been reported in two predominant contexts: 1) systems such as those fabricated by Atwater et al.<sup>[39–41]</sup> using electron beam lithography for plasmonic waveguide experiments; and 2) smaller NPs templated by naturally faceted surfaces of  $\langle 1010 \rangle$   $\text{Al}_2\text{O}_3$ <sup>[42]</sup> and  $\langle 110 \rangle$   $\text{NaCl}$  (Ref.<sup>[43]</sup>, no optical data). Atwater et al. use sophisticated electron beam lithography to make chains of 50-nm diameter Ag NPs with varying interparticle spacing. For these systems, the *longitudinal* (E-field parallel to NP chain) and *transverse* SP modes slightly red and blue shift, respectively, as the interparticle spacing approaches 75 nm, but do not explore closer spacing. Atwater et al. are also one of the few groups to employ finite difference time domain (FDTD) simulations to simulate the optical responses of these systems. One of the qualities of the FDTD simulation is that in addition to  $E(x,y,z)$ , it gives  $E(t)$ , which is useful for characterizing the properties of NP chains as optical energy waveguides. FDTD simulations of the E-field intensities in these chains agree well with experiments, and are useful for estimating collective properties such as waveguide loss. The  $\text{Al}_2\text{O}_3$  templated Ag NPs are fabricated by pulsed laser deposition, followed by high-temperature (1400°C, 8 hr) annealing, yielding slightly prolate particles broadly distributed about 25 nm in diameter and about 31 nm apart. These chains exhibit a far more pronounced dichroism than those of Atwater et al.:  $\lambda_{\text{TRANSVERSE}} = 455 \text{ nm}$  and  $\lambda_{\text{LONGITUDINAL}} = 550 \text{ nm}$ , reflecting both the smaller particle sizes (ca. 25 nm) and their closer proximity (ca. 31 nm). Theoretical work by Zhao, Kelly, and Schatly<sup>[44]</sup> has also contributed to understanding of chains structures.

Previous examples have been of 1-D NP chains, but individual NP pairs have also been examined. For example, Sandrock and Foss made gold particle pairs by alternately electrodepositing Au and Ag into porous  $\text{Al}_2\text{O}_3$ . In this setting, the electrodeposition time controls the Au and Ag NP lengths, and the pore their widths. Following electrodeposition, Ag sections can be removed with  $\text{HNO}_3$ , leaving voids of controlled size between Au NPs of controlled length.<sup>[35]</sup> Accordingly, paired “spheres” (i.e., unity aspect ratio rods), paired rods, and rod–sphere pairs were studied. For these organized NP pairs, the effects of interparticle spacing and the light polarization and incident angle could be systematically studied. At higher angle of incidence ( $\theta_i$ ), the light E-field falls increasingly along the interparticle axis. For example, for large interparticle spacing (114 nm) between paired spheres,  $\lambda_{\text{SPR}}$  (= 548 nm) is independent of  $\theta_i$ . However, if a smaller interparticle spacing is employed (52 nm),  $\lambda_{\text{SPR}}$  redshifts with an increasing in incidence angle reflecting the favorable near-field coupling of LSPR

dipoles. Rod–sphere pair structures exhibited a long-wavelength shoulder with increasing  $\theta_i$ , similarly indicating near-field interactions. Theoretical models used to evaluate sphere pair systems such as simple quasistatic (i.e., total particle pair size  $\ll \lambda$ ), modified long wavelength approximation (MLWA), and discrete dipole approximation (DDA) models reflected experimental shifts in  $\lambda_{\text{SPR}}$  with  $\theta_i$ , but did not accurately reproduce peak position or shape.

## Two-Dimensional NP Arrays

A rich variety of structures, some highly organized, for example, by intermolecular interactions, have been reported for NPs on surfaces. Also, some of the more intriguing spectral behaviors come from 2-D arrays of optically coupled NPs.

### Two-dimensional NP arrays made by electron beam lithography (EBL)

Aussenegg et al.<sup>[45,46]</sup> have contributed important papers on the optical properties of NP arrays in the far-field coupling regime. The former report employs square arrays (spacing  $\Lambda = 350\text{--}850 \text{ nm}$ ) of circular ( $d = 150 \text{ nm}$ ) gold EBL-fabricated NPs studied by both extinction and femtosecond time resolved luminescence measurements. Interestingly, the arrays exhibited a correlated oscillation in  $\lambda_{\text{SPR}}$  and luminescence lifetime ( $2 \leq \tau_{\text{SPR}} \leq 8 \text{ fsec}$ ), as the particle spacing increased. Specifically, they observed a strong (60 nm) redshift and broadening of the LSPR band for  $\Lambda$  values corresponding first to  $\lambda_{\text{SPR}}/n_{\text{SUBSTRATE}}$ , and then to  $\lambda_{\text{SPR}}$ . This effect, called the “grating” effect, evidently reflects the increased radiative fields existing between particles as the particle spacing produces constructive interparticle interference first in the substrate (where the effective radiated wavelength is  $\lambda/n$ ), and then in the airspace above the gradient.

In the latter work, Aussenegg et al. reported studies of EBL-fabricated Ag nanowires (wire widths  $60 \leq w \leq 200 \text{ nm}$ ) and nanowire gratings (spacing  $290 \leq d \leq 680 \text{ nm}$ ) with extinction spectroscopy.<sup>[46]</sup> Similarly to NP chains, Ag nanowires exhibit strong LSPR bands under transverse magnetic (TM) irradiation—i.e., when the E-field is polarized perpendicularly to the long axis of the wire. For individual wires,  $\lambda_{\text{SPR}}$  was found to be linearly dependent on wire width,  $w$ , between 65 and 90 nm. For wire gratings, they similarly find  $\lambda_{\text{SPR}}$  to be a sensitive function of spacing,  $\Lambda$ .  $\lambda_{\text{SPR}}$  redshifts and broadens when  $\Lambda$  approaches  $\lambda_{\text{SPR}}/n_{\text{SUBSTRATE}}$ , corresponding to a transition between evanescent and radiative character for the light field in the substrate half space. This type

of effect also appears in recent computations by Zhao, Kelly, and Schatz<sup>[16]</sup> who simulated LSPR for arrays of period  $\Lambda$  equal to and greater than the particle size.

Haynes et al.<sup>[47]</sup> have also used EBL to produce silver and gold particle arrays. The arrays comprise triangular (170 nm) and circular (200 nm) particles (trigonal prisms and cylinders considering their 35 nm height) in both square and hexagonal lattices of variable spacing between 230 and 500 nm—smaller distances relative to  $\lambda_{\text{SPR}}$  when compared to the studies by Schider et al.,<sup>[45,46]</sup> but still interacting predominantly in the far field. Van Duyne and Schatz observe a linear red shift with increasing lattice constant (ca. 40 optical nm per 100 nm) that is supported qualitatively by coupled dipole simulations. Theoretical calculations used by Zhao and coworkers<sup>[44]</sup> on particle pairs also support far-field interparticle coupling effects seen for large lattice spacing.

### Two-dimensional NP arrays made by nanosphere lithography (NSL)

Van Duyne and coworkers have performed a large body of work using an NP fabrication method they had developed and dubbed “nanosphere lithography” (NSL). In NSL, a substrate is coated with hexagonally close-packed monolayer of highly monodisperse polymer nanospheres by a simple drop casting procedure. The nanosphere coating, in turn, serves as a mask for the evaporation of Ag or Au into the interstitial hollows where substrate surface is exposed. Metal evaporation at normal (or other) incidence, followed by rinsing away the nanosphere mask, thus produces well-ordered 2-D arrays of triangular metal nanoprisms (or variations thereof) (Fig. 1).<sup>[3]</sup> Nanospheres are commercially available in a wide range of sizes, corresponding to a range of NP sizes that exhibit  $\lambda_{\text{SPR}}$  spanning the entire visible, near, and mid infrared spectral regions (Fig. 2). The NP shape can also be

**Fig. 1** AFM image of a Ag nanoparticle array created by nanosphere lithography. *Source:* Reprinted with permission from Ref.<sup>[3]</sup>. © 2003 American Chemical Society.

**Fig. 2** Size dependence of the LSPR spectra of Ag NP's fabricated using nanosphere lithography. The dimension “*a*” refers to the NP diameter (for disk particles) or base–apex length (for triangular ones). Dimension “*b*” refers to the NP height. *Source:* Reprinted with permission from Ref.<sup>[3]</sup>. © 2003 American Chemical Society.

altered by evaporating through the nanosphere mask at variable angles—called angle-resolved nanosphere lithography (AR-NSL).<sup>[48]</sup> By sequentially depositing at different angles, AR-NSL can be used to fabricate structures such as “nanoverlaps,” “nanogaps,” and NP chains. Van Duyne et al. have employed NSL–NP arrays in numerous studies focusing on NP size, dielectric environment,<sup>[3]</sup> adsorbate binding (sensor),<sup>[14]</sup> and surface-enhanced Raman activity.<sup>[9]</sup>

The dielectric response of NSL–NP arrays is of considerable interest given the potential utility of these structures in a sensor platform. As is generally observed,  $\lambda_{\text{SPR}}$  increases with ambient dielectric;<sup>[49,50]</sup> however, in the case of a surface (i.e., alkanethiol adsorbate)-induced  $\Delta\epsilon$ , this red shift is larger (3 nm/CH<sub>2</sub>) than predicted for spherical particles of comparable size. This observation is supported (but somewhat overestimated) by discrete dipole approximation (DDA).<sup>[51]</sup> This is a promising property for a surface sensor because, for the most challenging SPR sensing applications, bulk  $\Delta\epsilon$  contributes to noise, whereas surface  $\Delta\epsilon$  reflects the binding of molecular analyte.

### Two-dimensional NP arrays made by colloidal lithography

Hanarp et al.<sup>[52]</sup> report a related “lithographic” preparation yielding disordered arrays of nearly identical nanodisks. As with NSL, this preparation begins with an adsorbed layer of monodisperse polymer nanospheres. However, in this case, the spheres are intentionally deposited such that they are separated

on the surface, and the surface is precoated with Au or Ag. Melting of the spheres creates a removable mask that withstands an ion etch removal of the unmasked metal film, and later, solvent removal of the polymer leaves circular metal NPs. Unlike the observations of Lamprecht et al.,<sup>[45]</sup> Schider et al.,<sup>[46]</sup> and Haynes et al.<sup>[47]</sup> for regular periodic arrays, the average interparticle spacing ( $d$ ) in the  $d \geq d_p$  regime does *not* change the  $\lambda_{\text{SPR}}$  of particles produced via nanosphere lithography, presumably because of the lack of long-range order. Otherwise, the particles' LSPR spectra were fairly well described by a simple oblate spheroid theory,<sup>[53]</sup> and showed the expected red shift in  $\lambda_{\text{SPR}}$  with increasing particle size and ambient dielectric.

### Spontaneously organized 2-D nanoparticle assemblies

The process of 2-D NP self-assembly has been recently reviewed in the context of microelectronics.<sup>[54]</sup>

In many examples in this category, NPs are modified with molecular adsorbates that, in turn, guide the NPs into organized, closely packed assemblies. For example, Tripp and Wei employ an alkane-tailed and “cup-shaped” resorcinarene tetrathiol to decorate 16–170 nm Au NPs. The ligand shell and its alkane tails have a very strong organizing effect leading to hexagonally packed NP arrays on the air–water interface that can be transferred to quartz substrates.<sup>[55]</sup> Kanehara et al.<sup>[56]</sup> find similar results for an amine-terminated disulfide surfactant. In this case, a carboxylic acid adjuvant helps to organize solvent cast NP films.

Stabilized (if not necessarily highly organized) NP assemblies on surfaces have also been made using bidentate ligands—one end of which has affinity for the NP and the other end for the surface of the support. For example, an amino-terminated alkylsilane monolayer on glass will bind mercaptopropionic acid coated NPs by forming covalent (amide) bonds to the surface amino group.<sup>[57]</sup> Similarly, alkanedithiols have been used to tether Au NPs to Au surfaces.<sup>[58]</sup> Single-stranded DNA (ssDNA)-derivatized Au NPs have also been (selectively) bound to Au surfaces by the complementary, surface-bound, DNA oligomers.<sup>[59,60]</sup> This is an important theme, because Au NPs interact strongly with Au film surface plasmon polaritons, and thus amplify the surface sensitivity of analytical surface plasmon polariton spectroscopy.

### Coupled LSPR in 2-D nanoparticle assemblies

Near-field LSPR coupling is evident in some spontaneously organized NP assemblies. This coupling manifests in a band splitting that is sensitive to

polarization, angle, and, as recently shown, interparticle spacing. Observations of this type of mode date back to the work by Ferrell et al. in 1987.<sup>[61,62]</sup> For example, Taleb et al.<sup>[63]</sup> examined arrays of Ag NPs cast from solution and stabilized by dodecanethiol. In these studies, an electrostatic model of coupled dipoles in a 2-D hexagonal array was compared to its experimental counterpart. Both model and experiment yield a high-frequency side band that grows with increasing out-of-plane electric field. In other words, the high-frequency band appeared for higher incident angle and under p-polarization only. Pileni et al. further observed that this mode is more pronounced for more organized assemblies, and appeared for both 4- and 5-nm Ag NPs.

Pileni's observation can be compared to a more recent one by Malynych and Chumanov,<sup>[64]</sup> who found a sharp, high-frequency band that appeared only for smaller interparticle separation of 100 nm Ag NP films. One fascinating aspect of this experiment was that the NP film could be transferred to an elastomer (poly(dimethylsiloxane)) that allowed continuous variation in interparticle spacing simply by stretching the substrate. Fig. 3 shows the resulting normal incidence transmission spectrum and the strong dependence of the sharp, high-frequency band on interparticle

**Fig. 3** LSPR spectrum of a closely spaced 100-nm Ag nanoparticle array on a silicone elastomer support. The collective nature of the sharp band at 420 nm is evident in its hypersensitivity to interparticle spacing. The band at 420 nm disappears as the elastomer is stretched and interparticle spacing decreases (as indicated by the arrow). *Source:* Reprinted with permission from Ref.<sup>[64]</sup>. © 2003 American Chemical Society.

**Fig. 4** Proposed in-plane dipolar and quadrupolar LSPR modes. Interparticle dipolar interactions in A are inequivalent (some dipoles are arranged head–tail and others are side-by-side), but interparticle forces for quadrupolar modes in B and C are all equivalent. *Source:* Reprinted with permission from Ref.<sup>[64]</sup>. © 2003 American Chemical Society.

separation. The mode disappears as the elastomer is stretched, presumably because this spoils the near-field coupling. In contrast to Pileni's observations, this band actually depends on *in-plane* optical fields and *diminishes* under higher incident angles for both p- and s-polarization. Chumanov hypothesizes that this is a result of an in-plane quadrupolar plasmon mode illustrated in Fig. 4. Chumanov argues that, for strong *coherent* interparticle coupling, the quadrupole mode has a more favorable symmetry because all interparticle forces are equivalent. In other words, neighboring particles experience either repulsive (as in Fig. 4B), or attractive (as in Fig. 4C) forces. In contrast, the dipolar excitation of Fig. 4A leads to some attractive interactions (head–tail) and some repulsive ones (side-by-side).

### Three-Dimensional Assemblies of Nanoparticles

A comprehensive discussion of the variety and properties of three-dimensional (3-D) NP assemblies is far beyond the scope of this review. Instead, we present a brief cross section of studies that touch on some important aspects of 3-D NP assemblies. However, one fairly general observation is that LSPR bands tend to broaden and red shift when the component NPs aggregate, or are assembled into a lattice.<sup>[65]</sup>

#### DNA linked 3-D assemblies

Similar to the case for 2-D assemblies, single-stranded (ssDNA) oligomers can be used as a linker in 3-D assemblies of NPs. For example, Taton et al.<sup>[66]</sup> use a strategy for controlled NP film growth wherein a substrate surface and NP's "a" and "b" are derivatized with different, non-complementary ssDNA oligomers, illustrated in Fig. 5. Adding ssDNA oligomers that are the complementary, on opposite ends, to the surface and to NP-a will make a monolayer of NP-a. Further aggregation will *not* take place because the linker

**Fig. 5** Controlled NP aggregate (A) and film (B) growth using "bidentate" single stranded DNA linkers. Linkers are specific to either (SiO<sub>2</sub>)–a, or a–b. *Source:* From Ref.<sup>[66]</sup>. © American Chemical Society, 2003.

ssDNA does not connect "a" to "a" or "a" to "b." Rinsing and subsequent treatment with an "a"–"b" linker will add a layer of NP-b, etc. In addition to 3-D NP architectures, this strategy has been exploited for colorimetric sensing of specific oligonucleotides in solution.<sup>[67]</sup> In this motif, a given target ssDNA strand is detected by a pair of ssDNA derivatized Au NPs, each NP complementary to the opposite half of the target ssDNA. When the target strand is hybridized by both NPs, a large red shift and broadening in the NP LSPR band occurs as a result of near-field coupling. This changes the NP solution from an intense red to a faint purple. Because of the enormous extinction coefficient of the NPs, a target as small as 50 pm could be detected with this simple colorimetric test. Other studies of DNA-linked assemblies are cited in Refs.<sup>[68,69]</sup>

#### Dithiol linked 3-D assemblies

Brust et al.<sup>[70]</sup> have used dithiol linkers to assemble NP films in a controlled layer-by-layer fashion. The oxide substrate was first derivatized with 3-mercaptopropyltriethoxysilane, so that it would present the –SH moiety to solution and bind bare Au, ca. 6 nm NPs from solution. Then, this NP-coated surface was rinsed and treated with an  $\alpha$ - $\omega$  dithiol that, in turn, leaves the NP-coated surface presenting the –SH moiety as a basis for further assembly. Assembly induced

considerable broadening and red shifting in the NP LSPR, but this did not increase after the first few layers.

### Silica encapsulated NPs

Mulvaney et al.<sup>[71]</sup> reviewed the field of silica encapsulation of NPs and noted that these can be assembled into densely packed films. Silica encapsulation is attractive for various technological reasons, i.e., transparency, stability, etc. but also because of the control with which the silica shell can be deposited by using siloxane hydrolysis chemistry, initiated on the NP surface by the S-terminus of 3-mercaptopropyltrialkoxysilane. Particles synthesized in this manner are stabilized by SiO<sub>2</sub>, and the interparticle distance in films made from encapsulated NPs are set by the SiO<sub>2</sub> thickness. Color-tuning in films prepared from SiO<sub>2</sub> encapsulated Au is accurately predicted with the Maxwell–Garnet effective medium theory.<sup>[15]</sup>

### Nanocomposite films

The designation “nanocomposite” is typically applied to materials made from disordered mixtures of Au or Ag NPs at substantial volume fraction in an inert host material. For example, composite films can be prepared by cosputter coating SiO<sub>2</sub>/Ag and thermally annealing the resulting film.<sup>[10]</sup> Similarly, sol–gel methods can be used to prepare Au/BaTiO<sub>3</sub> and other thin film nanocomposites.<sup>[72]</sup> In particular, nanocomposite films appear to be of interest for nonlinear optical applications due in part to the large third-order nonlinear susceptibility lent to these materials by the LSPR active NPs.<sup>[73]</sup> Similarly, nanocomposites are of interest for their potential applications to electronics and as sensors.<sup>[74,75]</sup> Al-Rawashdeh et al.<sup>[23,76]</sup> have prepared ordered polyethylene–Au nanorod composites. The plastic polyethylene matrix provided a means for shear orientation of the nanorods, which, in turn, lend dichroic optical properties to the material.

### CONCLUSION

The localized surface plasmon spectra of silver and gold nanoparticles are interesting in a number of contexts. Spherical NP LSPR spectra are often in good agreement with theory-given adjustments to the metal dielectric function for NPs comparable to, or smaller than, the electron mean free path. However, calculation of the LSPR spectra of nonspherical shapes are still quite challenging because exact electrodynamic solutions such as the Mie theory do not exist, and finite difference simulations, while sometimes quite successful,

are far from routine calculations. However, a recently reported approach based on hybridization of the LSPR modes of more elementary shapes that, in combination, describe others is quite promising.

Basic LSPR spectroscopic phenomena have been the subject of many recent articles. Examples include the observation of multiple LSPR bands for a given NP based on electronic polarization along the different principle axes of the NP, or sometimes for higher-order polarizations in particles with sizes comparable to or greater than  $\lambda$ . Films of NPs often exhibit optical dichroism because of electromagnetic interactions between particles, or, in the case of oriented NPs, because of the optical anisotropy of the particles themselves.

NP LSPR spectroscopy has potential application in numerous technological areas such as subdiffraction light guiding, nonlinear optical applications, Raman enhancement, and chemical sensing. Sensing applications are quite promising given the popularity of the related metal film reflection based surface plasmon sensors. NP sensing can, in theory, detect as few as 60,000 molecules in a volume far smaller than a typical cell.

# Template-Directed Assembly of Dinuclear Triple-Stranded Helicates

Markus Albrecht

RWTH-Aachen, Institut für Organische Chemie, Aachen, Germany

## INTRODUCTION

Helicates are oligonuclear coordination compounds in which linear organic oligodonor ligands wrap around two or more metal centers. The main focus in helicate chemistry is on double-stranded or triple-stranded helicates (for a schematic representation of dinuclear helicates, see Fig. 1), but quadruple-stranded or circular helicates are also well known.<sup>[1,2]</sup>

In dinuclear helicates, both metal complex units possess the same configuration, and a left-handed as well as a right-handed helix can be present. Usually the helicate is formed as a racemic mixture but some examples of enantiomerically pure helicates are known.<sup>[3,4]</sup> If the two metal complex units of a dinuclear complex are oppositely configured, an achiral *meso*-type coordination compound is obtained—the *meso*-helicate (“side-by-side complex,”<sup>[3]</sup> “*meso*-cate”).<sup>[5,6]</sup>

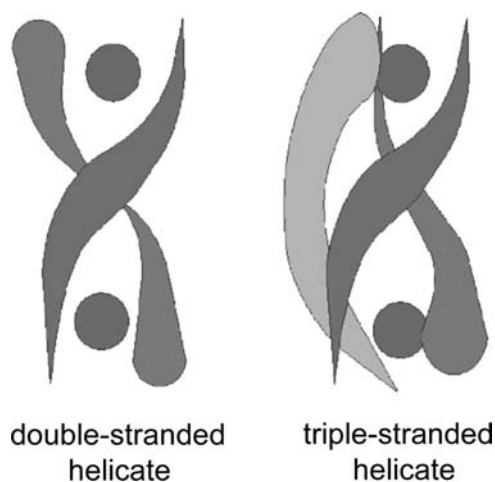

Since the introduction of the term “helicate” by Lehn et al.<sup>[7]</sup> in 1987, the chemistry of helicates has become one of the most intensely studied topics of metallocupramolecular chemistry. This is because of the simplicity of the helicates, which allows the study of fundamental aspects of metal-directed self-assembly such as mechanisms,<sup>[8]</sup> stereochemistry,<sup>[6]</sup> or regiochemistry.<sup>[9]</sup> In this chapter, we will focus on an important mechanistic feature of helicate chemistry—the influence of templates on the formation of triple-stranded dinuclear helicates. This can be observed for several helicates, although templation is not a general requirement for the formation of the complexes. Many helicates that are formed without a template present were observed.<sup>[2]</sup> Here, very often, other stabilizing interactions (e.g., steric constraints) are at work, which support the formation of the helicate.<sup>[10]</sup>

## WHAT IS THE DRIVING FORCE FOR THE SPECIFIC ASSEMBLY OF HELICATES?

Fig. 2 schematically outlines an experiment in which metal ions and appropriate linear ligands with two binding sites for metals are brought to reaction A. If an “undesired” non-specific complex formation takes

place between the metal ions and the ligands, a mixture of oligomers or polymers is obtained by unselective bridging of the organic donors between metal centers, as is shown in reaction B.

Of course, the specific formation of dinuclear triple-stranded helicates (C/D) is the desired reaction path. What will be the driving force to follow this path to obtain helicates and not the oligomers and polymers? To answer this question, it is important to look at the thermodynamics of the reactions. In a thermodynamically controlled self-assembly process, we have an enthalpic ( $\Delta H^\circ$ ) and an entropic term ( $T\Delta S^\circ$ ), which can both influence the reaction path. Looking at this system in a very naive way, the enthalpy change is the same if a polymer or a dinuclear complex is formed. In an ideal system,  $\Delta H^\circ$  only refers to the formation of coordinative bonds between metals and ligands. This happens in cases B and C in a similar way. Therefore entropy favors in our “ideal system” the formation of a maximum number of complexes C over (in extreme) only one polymeric molecule B. However, if no ideal system is present (which usually is the case), the buildup of strain during the complex formation should lead to an enthalpic control of the complex formation. In this case, we usually cannot predict the outcome of a coordination study; the geometry can lead to the formation of either the polymer or the dinuclear complex. However, if we are able to introduce some secondary stabilizing effects, which are in favor for the dinuclear helicate over the polymer, enthalpic forces will direct the complex formation toward the dinuclear complex. As an example, the template-directed assembly of helicates is indicated in Fig. 2D. The binding of a template in the interior of the complex here is the secondary effect that stabilizes the helicate by enthalpic reasons.<sup>[11]</sup> However, there are many possible stabilizing effects other than templating (e.g., in the first paper on helicates in 1987, Lehn et al. already assumed that  $\pi$ -stacking between bipyridine units of different ligand strands of a dinuclear helicate supports the formation of the complex). In this case, a similar stabilizing effect, as in double-stranded DNA, is active in the formation of the simple double-stranded helicate.<sup>[7]</sup> In addition, rigid ligands

**Fig. 1** Schematic representation of a double-stranded and a triple-stranded helicate.

often favor the discrete helicate enthalpically because of a minimization of the buildup of strain energy.<sup>[12,13]</sup>

### TEMPLATING IN THE FORMATION OF DOUBLE-STRANDED AND CIRCULAR HELICATES

Template-directed formation is not restricted to triple-stranded helicites. The assembly of double-stranded as well as circular helicites sometimes also depends on templates. For example, if a coordination study is performed with the bis(bipyridine) ligand **1** and zinc(II) or copper(I) ions, an undefined mixture of coordination compounds is observed. Without a template, the formation of dinuclear complexes is not favored over the formation of oligomers<sup>[14,15]</sup> (Scheme 1).

**Fig. 2** Schematic representation of a theoretical coordination study of linear ligands and metal ions (A) leading to a non-specific complex formation of oligomeric or polymeric materials (B) or, specifically, to a spontaneous (C) or template-directed (D) self-assembly process of triple-stranded dinuclear helicites.

### Template-Directed Assembly of Dinuclear Triple-Stranded Helicites

**Scheme 1** Veratrole as a template for the formation of helicate **2**.

However, on addition of veratrole, the undefined mixture transforms into only one defined species, the dinuclear double-stranded complex **2**, in which the electron-rich veratrole is bound between two electron-poor aromatic moieties of the ligand spacer. The veratrole acts as template and, by attractive  $\pi$ - $\pi$  charge transfer interactions, stabilizes the helicate.<sup>[14,15]</sup> This principle impressively was used to prepare catenanes and rotaxanes based on dinuclear metal complexes.<sup>[16]</sup>

The formation of circular helicites also highly depends on templates that are present during the formation of the complexes (Scheme 2).

The complexation of nickel(II) with the tris(bipyridine) ligand **3** leads to the trinuclear triple-stranded helicate **4**.<sup>[17]</sup> The analogous iron complex also can be observed as a product of the kinetically controlled reaction between **3** and iron(II). However, the outcome of the reaction of **3** with iron(II) ions under thermodynamic reaction control (long reaction times) highly depends on the counterion, which is present. If the small chloride is introduced as a counterion, the pentanuclear circular helicate **5** is obtained, which encapsulates one of the anions in its interior. The larger anions  $\text{BF}_4^-$ ,  $\text{SO}_4^{2-}$ , or  $\text{SiF}_6^{2-}$  favor the formation of the larger hexanuclear circular helicate **6**. The intermediate-sized bromide ion leads to the pentanuclear complex **5** as well as the hexanuclear complex **6**.<sup>[18]</sup>

The example of coordination studies with ligands **1** and **3** shows how effective templating can be in controlling the metal-directed self-assembly of discrete supramolecular species.

### TEMPLATING IN THE FORMATION OF TRIPLE-STRANDED HELICITES

In 1985—2 years before the term helicate was introduced by Lehn et al.—Raymond described a

**Scheme 2** Template directed formation of circular helicates.

triple-stranded dinuclear helicate, which is formed from three bis(hydroxypyridinone) ligands **7** and two iron(III) ions. In the solid state, the helicate binds a water molecule in its interior.<sup>[19]</sup> However, it is not known if this small guest molecule is important for the stabilization of the dinuclear complex. Twelve years later, in 1999, Raymond showed that the related

ligand **8** forms a *meso*-helicate with gallium(III) or aluminum(III) ions if no water is present. However, if water is added, it is encapsulated in the interior of the dinuclear complex and it stabilizes the structure of the corresponding chiral helicate<sup>[5]</sup> (Fig. 3).

A similar structure dependence (helicate vs. *meso*-helicate) based on the presence or absence of a

**Fig. 3** Raymond's ligands **7** Source: From Ref.<sup>[19]</sup> and **8** Source: From Ref.<sup>[5]</sup> and Saalfrank et al.'s ligands **9a** and **9b** Source: From Ref.<sup>[20]</sup>, which were introduced for the formation of triple-stranded helicate-type complexes.

template is observed for the complexes of the ligands **9a** and **9b**. Both compounds form triple-stranded complexes with iron(III) ions. However, **9a** is not able to bind a template, and a dinuclear helicate without an encapsulated guest is obtained. In the case of ligand **9b**, the triple-stranded complex with the internal pyridine moieties and oxygen atoms binds potassium as a template in its interior, which stabilizes the structure of an achiral *meso*-helicate.<sup>[20]</sup>

### Dicatechol Ligands as Building Blocks for Helicate-Type Complexes

Alkyl-bridged dicatechol ligands **10a–d** diastereoselectively form either triple-stranded helicates or *meso*-helicates. Diastereoselectivity is controlled by the alkyl chains in the spacer. If an odd number of methylene units is present, the ligand adopts a “C”-type arrangement because of the preferred zigzag conformation of the alkyl chain. Therefore the ligands **10a** and **10c** are predisposed to the formation of the *meso*-helicate. With an even number of methylene units (**10b** and **10d**), an “S”-type arrangement is favored, which leads to the helicate.<sup>[6]</sup> In the case of ligands **10**, the self-assembly process shows a very strong dependence based on the counteranions that are present<sup>[21]</sup> (Scheme 3).

The reaction of the dicatechol ligands **10a–d** with titanium(IV) ions in the presence of base leads to the quantitative formation of dinuclear triple-stranded helicate-type complexes **11a–d**. However, appropriate alkaline metal cations have to be present as counteranions. The X-ray structures of Li-**11a**,<sup>[22]</sup> Li-**11b**,<sup>[23]</sup> Na-**11c**,<sup>[24]</sup> and K-**11d**<sup>[25]</sup> show that in the solid state, cations are bound in the cryptand-type cavity, which is formed by the internal oxygen atoms of the helicate (Fig. 4).

**Scheme 3** Dinuclear helicates from alkyl-bridged dicatechol ligands.

In the case of **11a**, the interior of the complex is too small to encapsulate a counteranion. Therefore in Li-**11a**, three lithium cations bind from the outside to the internal oxygen atoms, and thus “block” the open faces of the self-assembled metallacryptand **11a**.<sup>[22]</sup> On the other hand, in Li-**11b**, the internal cavity is somewhat too big for the small lithium cation, and therefore in addition to Li<sup>+</sup>, two water molecules are observed inside the metallacryptand.<sup>[23]</sup> The bigger sodium cation fits much better into the interior of **11b** and only one cation is found in the interior of Na-**11b** (not shown). In the solid-state structure of Na-**11c**, a sodium cation is encapsulated in the *meso*-helicate and it additionally is

**Fig. 4** Parts of the X-ray structures of Li-**11a** Source: From Ref.<sup>[22]</sup>, Li-**11b** Source: From Ref.<sup>[23]</sup>, Na-**11c** Source: From Ref.<sup>[24]</sup>, and K-**11d** Source: From Ref.<sup>[25]</sup> showing the binding of alkali metal cations to dinuclear triple-stranded helicate-type complexes. DMF molecules are only indicated and only the cations that are bound to the interior of the complexes are shown.

**Scheme 4** NMR spectra of the formation of **11a** in the presence of Li, Na, or K.

coordinated by one DMF and one water molecule.<sup>[24]</sup> The cavity of **K-11d** is much too big to bind only one potassium cation in its interior. Consequently, in the solid state, two cations are found in the cavity and are additionally complexed by water and DMF.<sup>[25]</sup>

The results of the X-ray structural analyses of **11a-d** show that the counterions are not only innocent spectators but that they are parts of the self-assembled metallocryptand architecture (at least in the solid state). However, to enable templating of the cations, binding to the dinuclear complexes has to be present in solution, too.

To investigate the cation binding of the tetraanionic self-assembled metallacryptands in solution, heteronuclear nuclear magnetic resonance (NMR) studies were performed (e.g., <sup>7</sup>Li NMR spectroscopy of Li-**11a** in methanol-d<sub>4</sub> at variable temperature reveals that in contrast to the solid-state structure, only two lithium cations bind to the dinuclear complex **11a** in solution).<sup>[26]</sup> <sup>7</sup>Li NMR and <sup>23</sup>Na NMR of the Li salt and Na salt of **11b**, respectively, as well as of Na-**11c** also show binding of the cations. From competition experiments, it is deduced that potassium is encapsulated most effectively by metallacryptands followed by sodium and finally lithium.<sup>[25]</sup>

However, the question remains if the binding of the alkali metal cations in the solid state as well as in solution is really important for the self-assembly of helicate-type complexes (Scheme 4).

If the self-assembly of the small *meso*-helicate **11a** with only short methylene spacers is performed in the presence of potassium carbonate, no defined dinuclear complex is obtained. The <sup>1</sup>H NMR spectrum shows only broad bands that cannot be assigned. Electro-spray ionization mass spectrometry (ESI MS) reveals that a mixture of oligomers is present, with the dinuclear complex being one component of the mixture. However, if the same coordination experiment is performed with sodium or lithium carbonate, complexes **11a** are obtained, which show nicely resolved NMR spectra. Here, the templating influence of the cations is observed directly. The small dinuclear complex **11a** only assembles if small Li cations or Na cations are present, which can stabilize the complex by binding to internal oxygen atoms. The larger potassium cation is not able to bind to **11a** effectively and its presence might even destabilize the dinuclear titanium complex. Therefore a non-defined mixture of oligomers is formed. The addition of lithium or sodium salts as templates to the mixture of oligomeric potassium salts changes the NMR spectrum dramatically. Immediately

**Scheme 5** Imine-bridged dinuclear helicates.

**Scheme 6** Self- and hetero-recognition in the formation of helicates.

signals start to grow and, after some time, only the resonance of the dinuclear titanium complex **11a** can be observed. Effective templating takes place again.<sup>[22,26]</sup>

To enable the templating by cations in the self-assembly process, the cavities of the helicate-type complexes have to appropriately bind counteranions. Slight variations in the size as well as in the polarity of this cavity can disturb this binding already (Scheme 5).

Use of the two imine-bridged dicatchol ligands **12a** and **12b** leads to different results in a coordination study with titanium(IV) ions. The reaction of **12a** with titanium(IV) and alkali metal carbonate quantitatively leads to the phenyl-bridged dinuclear triple-stranded helicates **13a**. Ligand **12b** with a cyclohexyl spacer reduces the polarity of the cavity of **13b** compared to **13a**. Therefore no encapsulation of cations and no templating can take place. In the reaction of **12b** with titanium(IV) and alkali metal carbonate, only mixtures of oligomers can be observed. Electrospray ionization mass spectrometry shows that the dinuclear complex **13b** is one component of this mixture. But the dinuclear helicate Na-**13b** can be obtained in crystalline form by crystallization from the mixture. Indeed,

comparison of the X-ray structures of K-**13a** and Na-**13b** shows that in the solid state, **13a** binds counteranions in its interior, whereas no cations are encapsulated in **13b**. Only DMF molecules are located in the relatively apolar cavity.<sup>[27]</sup>

The templating of the cations in the formation of the triple-stranded helicate-type complexes **11** can be used for the self-recognition (or heterorecognition) of ligands during the complex formation.<sup>[28]</sup> The use of a 1:1 mixture of ligands **10a** and **10b** for the complex formation theoretically can lead to four different helicate-type complexes: two homoleptic ones with three similar ligands **10a** or **10b** per complex, and two heteroleptic compounds possessing one ligand **10a** and two of **10b**, or vice versa. In addition to this, oligomeric or polymeric material can be formed. However, if the coordination study with a 1:1 mixture of **10a** and **10b** is performed with titanium(IV) ions in the presence of potassium carbonate, only signals of the dinuclear helicate **11b** are observed by NMR on first sight. Having a closer look at the spectrum reveals that broad signals of oligomeric complexes of ligand **10a** are also present. In this experiment, ligand

Scheme 7 Induction of helicity by chiral templates.

self-recognition takes place, leading only to homoleptic complexes. Potassium cations are able to template the formation of complex **11b** but not of **11a**. Therefore the dinuclear complex **11b** is formed from **10b** but only oligomers from **10a**<sup>[29]</sup> (Scheme 6).

With sodium carbonate, a different result is obtained in this self-recognition experiment. Only the homoleptic triple-stranded complexes **11a** and **11b** are formed. Sodium cations are able to stabilize complexes of both ligands. However, because of the different binding modes of the cation to the coordination compounds, a sorting of the ligands takes place on complex formation and solely the homoleptic complexes are obtained.<sup>[29]</sup>

The compounds **11a** and **11b** are also observed in the presence of lithium carbonate as base. However, here, one of the two heteroleptic complexes **11e**,

bearing one ligand **10b** and two **10a**, is formed in addition. This is assumed to be because of the reduced size of lithium compared to sodium, which eventually enables a tight encapsulation of a lithium cation in the interior of **11e**.<sup>[29]</sup> (The cavity of **11b** is somewhat too big and the cavity of **11a** is too small for an effective binding of lithium.)

The discussed study on the self-recognition of ligands during complex formation shows how important the influence of the counterions is. The use of three different counteranions leads to three different outcomes in coordination studies. Hereby the templating of the cations strongly controls the assembly and recognition processes.

Further templating effects can be observed by the interaction of counteranions with helicates. If the helicate of ligand **14** is formed in the presence of *S-N*-methylnicotinium cations, an enantiomerically pure triple-stranded helicate **15** is obtained. Here the chiral cation interacts with the helicate and favors one helical twist over the other.<sup>[30]</sup> A similar induction of chirality occurs by addition of Lacour's chiral anion **16** to the triple-stranded dinuclear cobalt(II) helicate **17**<sup>[31,32]</sup> (Scheme 7).

Ligand **17** forms a triple-stranded dinuclear helicate **18** in the presence of potassium cations (Scheme 8). Addition of tetramethylammonium to **18** leads to a destabilizing templating effect, which results in a rearrangement of the dinuclear **18** into the tetranuclear complex **19**. By templating of the cation, the formation of the tetrahedral complex **19** is favored over the helicate **18**.<sup>[33]</sup>

The discussed results show that a strong templating effect is active in the formation of helicates and *meso*-helicates from dicatechol ligands. The investigation of this templating effect should be much easier if neutral helicates are formed without any counterions present. To study systems like this, a ligand unit other than catechol has to be chosen. The charge of the deprotonated catechol unit (2-) is too high to be compensated by a coordinated metal.

Scheme 8 Template-directed transformation of a helicate into a molecular tetrahedron.

**Fig. 5** Parts of the solid-state structures of **K-21b** Source: From Ref.<sup>[35]</sup>, **Cs-21c**, and **[NH<sub>4</sub>]-21c** Source: From Ref.<sup>[36]</sup>.

### 8-Hydroxyquinoline Ligands as Building Blocks for Helicate-Type Complexes

A ligand moiety, which is geometrically very similar to catechol but possesses only one negative charge (1<sup>-</sup>) in its deprotonated form, is 8-hydroxyquinoline. 8-Hydroxyquinoline forms neutral complexes with metals such as Ga(III), Al(III), Cr(III), or Fe(III).

Performing the reaction of the alkyl-bridged di(8-hydroxyquinoline) ligands **20a-d** with gallium nitrate (or aluminum(III) chloride, chromium(III) chloride, or iron(III) chloride) leads to an insoluble material. Elemental analysis shows that this material is composed of ligands and metals in a 3:2 ratio. If long alkyl chains are attached to **20b**, the material becomes soluble in apolar solvents. However, NMR as well as Maldi time-of-flight mass spectrometry (TOF MS) show that not a defined complex but a mixture of oligomers is present.<sup>[34-36]</sup>

Adding alkali metal salts and heating quantitatively transform the mixture of coordination compounds

obtained from ligands **20** into the desired dinuclear gallium(III) helicate-type complexes **21a-d** with the alkali metal cation bound in its interior. The same compounds **21a-d** are obtained directly if appropriate alkali metal salts are added during the complex formation of **20a-d** with gallium(III). The helicate-type complexes **21** are formed in a template-directed self-assembly process.<sup>[36]</sup>

Fig. 5 shows parts of the solid-state structures of **K-21b**, **Cs-21c**, and **[NH<sub>4</sub>]-21c**, with the cations encapsulated in the interior of the triple-stranded helicate **21b** or the *meso*-helicate **21c**.<sup>[35,36]</sup> From **[NH<sub>4</sub>]-21c**, it can be seen that ammonium ions also can template the formation of the dinuclear complexes by a combination of electrostatic and hydrogen bonding interactions.<sup>[36]</sup> In one case, it was even possible to show the encapsulation of ammonium in a dinuclear gallium complex by ROESY NMR spectroscopy in solution.<sup>[37]</sup>

In the formation of the complexes **21a-d**, a strong size dependence between the template and the ligand can be observed (see Scheme 9). The small complex **21a** is only formed in the presence of the small lithium cation. The next bigger complex **21b** is obtained in the presence of sodium cations, potassium cations, and rubidium cations, whereas the compound with C<sub>3</sub>-spacers **21c** is stabilized by potassium, rubidium, and

**Scheme 9** “Size-selectivity” in the template-directed formation of helicates.

**Scheme 10**

**Scheme 11** Template-directed formation of hexa-stranded helical complexes.

cesium. The biggest complex **21d** assembles only in the presence of the large cesium cation<sup>[36]</sup> (Scheme 10).

For comparison purposes, ligand **22** was synthesized, which does not possess internal oxygen atoms to bind templating cations in the interior of a dinuclear complex. Coordination studies of **22** with gallium again lead to an insoluble material with a correct elemental analysis for a 3:2 ligand/metal ratio. However, on addition of templating cations, no transformation of the mixture into a dinuclear gallium complex takes place.<sup>[34]</sup>

This shows that the stabilization of the helicate-type complexes occurs through binding of the cations to internal oxygen atoms of the complexes. Thus the template, in addition to the ligand spacer, connects the two complex units. The reaction of mono-8-hydroxyquinoline

derivatives **23**, possessing amide or urea moieties in the 7-position of the quinoline, with zinc(II) ions leads to trinuclear “hexa-stranded” complexes **24**. Here templating by the center of the three zinc ions is so strong that a covalent connection of the ligand unit is not necessary to obtain the “hexa”-helical complex **24**. In fact, some hydrogen bonding occurs between the amide or urea moieties and further stabilizes the complexes **24**. The X-ray structural analysis of **24** (R = NH-(S)-CH(CH<sub>3</sub>)Ph) in Scheme 11 reveals the hexa-stranded structure of the trinuclear complex. Because of the chiral substituent, the complex is formed in a stereoselective fashion with only the right-handed helix present.<sup>[38,39]</sup>

Compound **25** represents a very similar trinuclear complex, which is prepared by stepwise introduction of the two different kinds of metals. First, the mononuclear ruthenium(II) complex is formed, which then binds twice to the nickel(II) template to obtain the trinuclear complex **25**.<sup>[40]</sup>

**Scheme 12** The principle of dynamic combinatorial chemistry.

## CONCLUSION

Using the chemistry of dinuclear triple-stranded helicates as an example, it was shown that templating

often is very important in the self-assembly of supramolecular structures. It is an enthalpic driving force for the formation of defined supramolecular complexes. Hereby the templates influence the assembly of defined complexes as well as their structures and stereochemistry. With the discussed results, basic knowledge was gained, which now can be used to understand the formation of bigger, more complex, supramolecular coordination compounds.<sup>[41]</sup>

In the examples presented, very often an undefined mixture of complexes is formed by use of ligands and metal ions. However, because of the non-covalent character of the coordinative bond, the formation of the components of the mixture is reversible and, under appropriate conditions, all the components are in dynamic equilibrium with each other. When a template is added under “equilibration” conditions, it will select and bind the most appropriate compound of the mixture. In an ideal case, this leads to stabilization and the sole formation of the most stable complex-template aggregate<sup>[10]</sup> (Scheme 12).

Hereby, we strictly follow the principle of dynamic combinatorial chemistry<sup>[42]</sup> where, first, a dynamic combinatorial library of compounds is formed from building blocks, which bind to each other by non-covalent or labile covalent interactions. By addition of a template, one derivative is selected from the mixture under equilibration conditions. This method is used to find the most appropriate receptor or substrate of the library for the given template, which can be an ion,<sup>[35]</sup> a small molecular species, or even an enzyme.<sup>[43]</sup>

Templating seems to be even more important in supramolecular chemistry than in “classical” molecular chemistry. In the future, it will help us not only to find more fascinating new helicates, but also to prepare big supramolecular aggregates bearing supramolecular functionalities. It will enable the “bottom-up” approach to nanometer-dimensioned structures starting with simple molecules and using programmed information, which are embedded in the molecular components and which are controlled or “read out” by the template.<sup>[44]</sup>

## INTRODUCTION

The engineering of porosity, particularly at the meso-level, is expected to be of great scientific and technological significance in the 21st century where advances in nanoscience and technology are projected to catalyze major breakthroughs in biosciences and materials.

Aerogels are a class of highly porous buoyant materials that find use or show promise in many key products such as catalysts, thermal insulators, chemical adsorbers, sensors, fuel storage, energy absorbers, and aero capacitors. They may be in the form of particles, thin films, fibers, or monoliths. Some of the remarkable properties for the aerogels are high porosity, large pore volume, high surface area, and very good morphological stability during heat treatment at high temperatures. Recent discovery of surfactant-templated pathways enables better control over the properties of the porous materials. The advantages of the templating include high porosity, tunable unimodal or multimodal nanoporosity, and directional control. The new evaporation-induced self-assembly method that enables production of aerogel-like materials using soft chemistry and lower pressures further expands the spate of products that are possible in economically promising fashion. This porous structure can be further functionalized through doping and impregnation to host catalytic sites, conducting phases, or magnetic phases.

This review aims to address the issues of preparation of templated gels, removal of the solvent and template material, and subsequent functionalization of the surfactant-templated aerogels to further tune the porous structures.

## SOL-GEL SYNTHESIS

Most aerogels involve drying of gels synthesized using sol-gel chemistry. The sol-gel process involves the formation of a sol, which is a liquid suspension of solid particles ranging in size from 1 nm to 1  $\mu$ m. These materials can be obtained by the hydrolysis and partial condensation of a precursor such as a metal alkoxide.

The further condensation of sol particles into a multi-dimensional network produces a gel, which is a solid phase encapsulating a solvent. The gel materials are referred to as aquagel when water is used as the primary solvent and alcogel when alcohol is used instead. The encapsulated liquid can be removed from a gel by either evaporative drying or freeze-drying or processing at supercritical conditions. The resulting solid product is called as either xerogel or aerogel (if synthesized using supercritical processes). The advantages of sol-gel based synthesis of aerogels are their high purity, microstructure, homogeneity at molecular level, and low-temperature preparation.<sup>[1,2]</sup>

Since the introduction of M41S family of solids,<sup>[3]</sup> there has been an explosion of applications for templating applications and pore inducers. Templating is compatible with the sol-gel chemistry. Metal alkoxides have been the most extensively used precursor in sol-gel preparation because they are commercially available in high purity and their solution chemistry is well documented.<sup>[4]</sup> Sol-gel chemistry with metal alkoxides can be described in terms of two classes of reactions:

Hydrolysis reaction:

Condensation reactions:

where X can either be H or R (an alkyl group).

These two kinds of reactions capture the key phenomenon; a two-dimensional or three-dimensional gel network materializes from the condensation of partially hydrolyzed species. Any variables, such as the relative rates of hydrolysis and condensation, that affect either or both of these reactions are thus likely to have impact on the properties of the product. When the condensation reaction rate is relatively higher than the hydrolysis reaction rate, the resulting sol-gel

becomes highly branched and the corresponding primary gel structure is mesoporous. Whereas, if the hydrolysis reaction rate is relatively higher than that of condensation, then the resulting sol-gel is weakly branched and the corresponding gel structure is generally microporous.

Because hydrolysis and condensation are both nucleophilic displacement reactions, the reactivity of metal alkoxides is dependent on the positive partial charge of the metal atom and its coordination number. In general, the longer and bulkier the alkoxide group attached to a particular metal atom, the less reactive that precursor is in hydrolysis and condensation.<sup>[5]</sup> The choice of precursors and/or their concentrations is effective in controlling the hydrolysis and condensation reaction rates. The amount of water used in sol-gel preparation and the rate by which it is added also influence gel characteristics. The former is usually expressed in terms of the hydrolysis ratio  $h$ , defined as the moles of water per mole of metal alkoxide,  $M(OR)_m$ . The tendency of the precursor to condense is small when there is no local excess of water because there are few M-OH groups for cross-linking, gelation, or precipitation. If the hydrolysis ratio is marginally above 1, polymeric gels can form while sufficiently excess water leads to formation of cross-linked polymers, particulate gels, or precipitates. The rate of water addition is usually slow.

Two other important sol-gel parameters are temperature and solvent. Temperature is the most effective way to alter the relative rates of competing reactions and both high and low temperatures are used in practice. The solvent choice can change the nature of an alkoxide through solvent exchange as well as affecting the condensation reaction directly.

The effect of gelation time on gel properties is significant and should be part of the experimental design. Gel time is defined as the time it takes for a solution to undergo a rapid rise in viscosity. This corresponds to solution's transition from a viscous fluid to an elastic gel. At the gel point, there is a continuous solid phase with a structure where particles form and branch as dictated by the specific growth conditions. This particular phase has significant impact on the structural evolution these materials undergo in all subsequent processing steps.

Aging is the time between the formation of a gel network and the removal of solvent from that solid gel network. As long as the pore liquid remains in the matrix, a gel is not static and can undergo many changes. For alkoxide-derived gels, condensations between surface functional groups continue to occur even long after the gel point. This process can actually be desirable because it leads to a more cross-linked network that is mechanically stronger and easier to handle. However, extensive condensation causes a

phenomenon called syneresis, which is the solvent expulsion from the gel as the gel network shrinks. The shrinkage in alcoholic gel systems is attributed to formation of new bonds through condensation reactions, which increase the bridging bonds and cause contraction of the gel network.<sup>[6]</sup> Coarsening or ripening is a physical phenomenon driven by solubility differences associated with surfaces that have different radii of curvature. Coarsening basically involves the dissolution and reprecipitation of particles, resulting in an increase in the average pore size of the gel and a decrease in its specific surface area.

Parameters that affect these aging processes include temperature, time, and pH of the pore liquid. Common approaches to manipulating these parameters are soaking or washing the gel with another liquid, changing the humidity level of the gel environment, heating the gel, and using hydrothermal conditions. Although all these approaches have been demonstrated to change the gel characteristics, an understanding of the cause and effect is at best qualitative at present.

The fields of aerogels and sol-gel chemistry are not limited to metal oxides. Carbon aerogels<sup>[7]</sup> that find use in energetic applications are produced with the aid of sol-gel chemistry through aqueous polycondensation of resorcinol (1,3 dihydroxybenzene) with formaldehyde. This reaction under alkaline conditions proceeds through a sol-gel transition and results in the formation of a highly cross-linked polymer. Other precursors such as the phenol-furfural or melamine-formaldehyde system<sup>[8]</sup> are also possible.

The sol-gel chemistry is well covered in literature including a classic by Ref.<sup>[9]</sup>. The sol-gel gateway in the web provides<sup>[10]</sup> another pathway to vast amount of information.

## TEMPLATE MATERIALS

The chemical modifications aside, selection of the template material is of paramount importance in defining the final porosity, its distribution, orientation, and the surface texture. The general field of surfactant-templated materials and their applications has been the subject of intense work and many reviews.<sup>[11-17]</sup> They are generally classified as direct and mediated paths and involve cationic and anionic surfactants. However, for surfactant-templated aerogel synthesis, nonionic surfactants seem to be the current choice.

The template selection naturally dictates the processes that can be employed for its removal. While the primary removal path is thermal decomposition, extractive processes, particularly supercritical fluid-based ones, offer gentler and environmentally greener avenues, often with superior pore structure retention. Interplay between surfactant and solvent becomes

significant particularly at the drying stage. Question of to what extent the template material should be removed in the supercritical drying stage, along with the solvent, needs to be addressed at the design stage. In instances the surfactant or other templating material is to be removed supercritically, the available options, in decreasing order of desirability, are listed as follows:

- Template is soluble in supercritical carbon dioxide. The most popular supercritical solvent, carbon dioxide, has been used for many years for various applications including drying of aerogels. It is environmentally friendly and minimizes pore structure degradation. Unfortunately, CO<sub>2</sub> is non-polar, has low dielectric constant, and does not engage in van der Waals-type interactions. In other words, CO<sub>2</sub> is a poor solvent for highly polar and high molecular weight material. In the last decade, major strides in the design of CO<sub>2</sub>-philic and amphiphilic surfactants are made. A relevant review will possibly start with a look at the solubility<sup>[18]</sup> of commercial surfactants in carbon dioxide, include McClain et al.'s<sup>[19]</sup> work on design of fluorinated CO<sub>2</sub>-philic hydrocarbon-based surfactants, and focus on CO<sub>2</sub>-philic hydrocarbons composed of only C, H, and O molecules.<sup>[20]</sup> Although the aforementioned CO<sub>2</sub>-philic surfactants were synthesized for other purposes such as metal or protein extraction, cleaning, and polymerization reactions, their teachings will form a solid foundation for CO<sub>2</sub>-philic templating surfactants. The shape, orientation, and access to CO<sub>2</sub>-philic sites of surfactants are important in tuning the pore size distribution of the material synthesized with the aid of such templates.
- Template is soluble in a suitable entrainer plus supercritical carbon dioxide.<sup>[21–23]</sup> The advantages of supercritical fluids can be realized if entrainers (modifiers), such as alcohols, are used to enhance the solubility of the template material. The concern here is the recovery of liquid entrainer that has a tendency to preferentially adsorb within the porous matrix. Naturally, although less significant because of lower corresponding concentrations, the toxicity considerations that exist for liquid solvents are also applicable. If not removed, the indigenous solvent employed in sol-gel synthesis can serve as entrainer or co-solvent. This path for removal of surfactants has been successfully employed in removal of templated material in several applications, particularly nonionic ones.<sup>[21–24]</sup>
- Template soluble in other supercritical systems. In applications where intermediate or higher-temperature template removal is acceptable or desirable, other supercritical solvents may also be employed. The initial aerogel synthesis methods utilized alcohols indigenous within the sol.

The templates and supercritical fluids are two key technologies of self-assembly paths leading to unique materials.<sup>[25,26]</sup> It is also worth mentioning that supercritical fluids can be effectively used in a priori fractionation of surfactants for subsequent extractability.<sup>[27,28]</sup>

In many applications, removal of templating material using thermal means may be inevitable. These thermal operations may lead to sintering, e.g., alumina support. The sol-gel synthesis and template selection do affect the resulting support. This sintering problem can be addressed by adding mixed metal oxides. For example, addition of small concentrations of silica to alumina in the sol-gel formation stage expands the sintering free calcination temperature ranges.<sup>[29–31]</sup> Other attempts to aid preservation of the textural properties include addition of surfactants<sup>[32,33]</sup> and rare earth stabilization.<sup>[34]</sup>

## DRYING METHODS

The pore inducers, templates, and solvents should be removed from the wet gel before further functionalization or end use. The drying and extractive removal of the solvent and the template are discussed here, while thermal treatments and functionalization approaches are subsequently treated. The approaches to drying of wet porous material are evaporation, freeze drying, and supercritical drying. The approaches to drying are summarized in Fig. 1. Although traditionally, materials resulting from non-critical evaporative drying methods are called xerogels, the structural properties of such material are similar to that of aerogels because of recent advances such as use of templates and evaporative film formation through self-assembly.<sup>[35]</sup> Furthermore, evaporative processes inadvertently

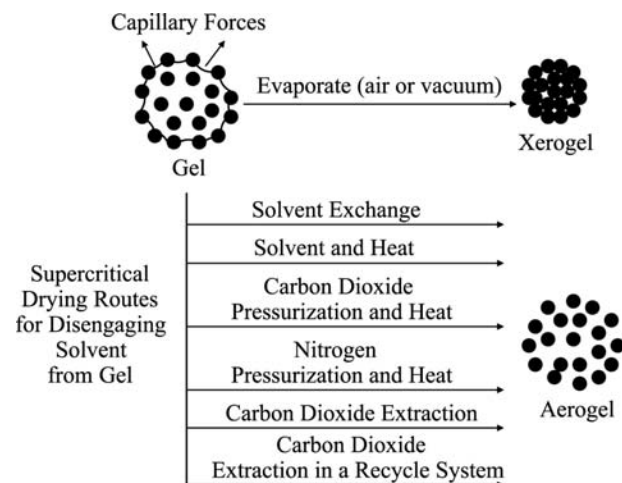

Fig. 1 Drying methods for gels.

become part of even supercritical drying and solvent extraction routes. Therefore evaporative drying is presented before supercritical routes that lead to aerogels are discussed.

### Evaporative Drying

The rate of evaporation,  $V_E$ , is proportional to the difference between vapor pressure of the evaporating fluid and the system pressure. Evaporation continues as long as vapor pressure is greater than bulk fluid pressure, a situation not likely in pressurized environments such as supercritical conditions. The vapor pressure at a surface composed of a large number of very small pores is influenced by the radii of the pores, as shown by the Gibbs–Kelvin equation.

$$\ln\left(\frac{p_s}{p_o}\right) = \frac{B\gamma}{RT} \frac{2}{r_m} \quad (1)$$

where  $p_s$  is the vapor pressure over the meniscus of the pore,  $p_o$  is the vapor over a flat surface (760 Torr),  $B$  is the molar volume of the liquid,  $R$  is the gas constant,  $\gamma$  is the difference between the solid–vapor and liquid–vapor interfacial energies,  $T$  is temperature, and  $r_m$  is the radius of curvature of the meniscus.

Because the pores of gels are generally small, capillary forces are generally dominant during drying and adsorption force and osmotic force are marginal when compared with the capillary forces because capillary force is a direct and strong function in capillary radius as suggested by equation below

$$P = \left(\frac{-2\gamma_{LV}}{r_m}\right) \quad (2)$$

where  $P$  is tension in the liquid inside the pores,  $\gamma_{LV}$  is the liquid–vapor interface energy, and  $r_m$  is radius of the curvature of the meniscus and is related to the cylinder pore radius as in Eq. (3)

$$r_m = \left(\frac{-r}{\cos(\theta)}\right) \quad (3)$$

where  $r$  is the cylindrical pore radius and  $\theta$  is the contact angle between the vapor and the solid gel phase.

Factors other than capillary pressure could affect the gel drying process. Adsorption forces bind solvent and surfactant into an ordered layer, a few molecules thick near a solid surface; the attractive force may drive flow of a film over an exposed solid surface and influence the curvature of the meniscus. However, if there were no capillary force ( $\gamma_{LV}$ ), no compressive force would be exerted on the network as evaporation emptied the pores and no shrinkage would result from

adsorption forces unless in those pores that have initial pore radius in the order of the film thickness of the adsorbed solvent. Removal of this adsorbed liquid can be sometimes difficult and will occur in the last stage of drying after the interparticle space is drained.

Osmotic pressure is also another factor that manifests some controlling effect on the drying process. It induces water to enter the interlayer space in some porous material particles to equalize the concentration of ions in that space and in the surrounding bulk liquid.

The drying behavior of porous solids has been classified into three different stages. The three stages of drying are stage 1, also referred to as constant rate period of drying, stage 2, referred to as first falling rate period, and stage 3, referred to as second falling rate period. The salient features of the rate of drying throughout the three stages are shown in Fig. 2.

This first stage is called “the constant rate period” because the evaporation rate per unit area (mass flux) of the drying surface is independent of time. The gel at the beginning of stage 1 drying has a surface area that is initially largely free liquid, separated by a relatively small area fraction of gel network with a transition zone of bound liquid. As the free liquid evaporates, the solid network contracts because of capillary stresses. The evolution of pore structure from the first stage into the second is depicted in Fig. 2A. During this stage, the decrease in the volume of the gel is equal to the volume of liquid lost by evaporation. The compliant gel network is deformed under the effect of the large capillary forces, which causes shrinkage of the gel and reduction of pore radii during drying. The greatest changes in volume, weight, density, and structure occur during stage 1 drying that ends when shrinkage ceases.

Stage 2, also known as first falling rate period, starts at the critical point as shown in Fig. 2. This stage is characterized with the highest capillary pressure imposed on the gel network during the drying process, hence causing shrinkage to the solid structure and affecting its permanent and final textural and structural properties.

The rate of drying in this stage decreases drastically from the rate of drying in the previous stage, and the temperature of the outer surface rises above the wet-bulb temperature. Liquid is driven to the outer surface by gradients in capillary vapor pressure, where it evaporates because of the ambient vapor pressure being lower than that inside the pores as shown in funicular section of Fig. 2B. The liquid in the pores near the surface remains in the funicular condition, so there are contiguous pathways along which flow can occur. Most of the evaporation is still occurring at the exterior surface, and the surface remains below the ambient temperature, and the rate of evaporation (on

Fig. 2 Stages of evaporative drying.

the outer surface of the gel) is sensitive to the ambient temperature and vapor pressure. At the same time, although some liquid evaporates within the unsaturated pores and the vapor is transported by diffusion, they are negligible when compared with the major liquid flow through the pore walls under capillary and tension forces. Fluid flow in stage 2 is driven by the gradient in capillary stress. Evaporation occurs at the outer surface because the vapor pressure is lower there than inside the humid pores. The vapor pressure gradient through the pores is associated with the capillary stress gradient in the pores. Therefore, the funicular liquid flows toward the exterior surface at all times. Since the vapor pressure and the surface tension are functions of temperature, the temperature affects the gradients in capillary pressure. Both acting forces (capillary and the surface tension) favor flow toward the outer surface. When there is a range of pore sizes in the body, the larger pores will empty first.

As in stage 1, the flow rate may also be influenced by adsorption forces in the same manner as shown in Fig. 2B to keep the surface under a few molecules-thick adsorbed layers of the liquid, and this causes flow of the film. This mechanism is most likely important when the vapor pressure at the surface is very low.

The transition from stage 2 to stage 3 and its inception is associated with a rise in the gel temperature because the temperature of the body is not as strongly suppressed as when evaporation rates were higher. The remaining liquid evaporates within the pores and is removed by diffusion of its vapor to the surface as shown in pendular section of Fig. 2B. This stage of drying is not affected by local changes in temperature,

ambient vapor pressure, or flow rate. At the start of stage 3, the gel is practically dry. It can be removed from the drying chamber and dehydrated under much more severe conditions (high temperature and under near vacuum pressure) without risk of cracking.

### Supercritical Drying

The supercritical drying methods evolved considerably since the pioneering work of Kistler<sup>[36]</sup> where excess alcohol was added to the autoclave and then heat was supplied so that supercritical conditions were reached. Subsequently, supercritical solvent was removed from the autoclave by depressurization above the critical temperature of the solvent.<sup>[36]</sup> These methods all have pressurization, heating, diffusion, and depressurization steps and may be easier to understand using the pressure-temperature (PT) diagram (Fig. 3) of the supercritical fluid. In these methods, the PT path is ABC as shown in Fig. 3. Van Lierop et al.<sup>[37]</sup> modified this method by pressurizing the system using an inert gas prior to heating; the path then corresponds to A'BC. A further improvement was carried out to the second method through the solvent exchange method in which the pore liquid was replaced with carbon dioxide that has a much lower critical temperature than alcohols. Carbon dioxide was then vented out of the system above its critical temperature. In some cases, an intermediate solvent miscible both with the pore liquid and carbon dioxide was pumped to the system to be subsequently replaced with carbon dioxide.<sup>[38]</sup> In yet another method, supercritical carbon

Fig. 3 Pressure–temperature diagram and drying paths.

dioxide was used to extract the pore liquid in a semi-continuous mode.<sup>[39]</sup> In the last method, the system was pressurized with carbon dioxide, and carbon dioxide–alcohol mixture was brought to supercritical conditions and the supercritical fluid was removed from the gel.<sup>[40]</sup>

Supercritical drying allows sustained single fluid phase where drying is free from liquid–vapor interfacial stresses. This facilitates the production of aerogels that have the same morphological properties as their alcogel precursors. On the other hand, production of crack-free monoliths still necessitates selection of best drying technology and the optimization of key processing variables such as heating and depressurization rates. In the heating and depressurization steps, high rates are expected to result in considerable stress formation. During heating, stress develops because of smaller thermal expansion of the solid network in comparison to the pore liquid. In addition, at high temperatures, solid network contracts because of the chemical bonds formed by condensation reactions. If the expanding pore liquid flows out of the body, stress is relieved. However, at high heating rates, limited time restricts the escape of the expanding liquid significantly.<sup>[41]</sup> The same analysis is valid for the depressurization rates. At high depressurization rates, the fluid outside the gel flows out of the reactor at a higher rate than the fluid flowing out of the gel network. Because of differential pressure, the fluid in the gel network expands and stress develops in the gel. Cracking occurs when the stress exceeds the strength of the gel network.<sup>[42]</sup> Scherer modeled the stress development during supercritical drying. The model for a cylindrical geometry with no radial constraint was applied to the heating step of the autoclave drying method assuming elastic behavior, and the analysis was extended to radially constrained viscous gel network for which an analytical solution is also obtained.<sup>[43]</sup>

We analyzed the stress formation in the heating steps of the autoclave drying and the carbon dioxide

exchange (solvent exchange) methods.<sup>[44]</sup> Stress forming in the pore liquid is a function of heating rate, viscosity, and thermal expansion coefficient of the liquid and mechanical properties of the gel network. For the autoclave drying and carbon dioxide exchange methods, the effects of different pore liquids with different thermal expansion coefficients, viscosities, critical temperatures, and critical pressures on the stress development were analyzed. The calculated radial stresses are compared with the modulus of rupture of the gel network to decide whether production of crack-free aerogels is possible as far as the heating steps in both autoclave drying and carbon dioxide exchange methods are concerned. The study showed the superiority of lower-temperature solvent extraction route.

### Removal of Template Material

The removal of the templating surfactant molecules occluded within the mesoporous materials after the synthesis step is often carried out through thermal means under air at temperatures between 500°C and 600°C. Although high-temperature calcinations allow removal of the surfactant completely, the decomposed surfactant cannot be used, the evolving gasses are often noxious, and the pore structures, particularly chemical integrity of the organic groups, are substantially altered.<sup>[45]</sup> At times, calcination is necessary part of the recipe. For example, in synthesis of alumina support, AlOOH is converted to Al<sub>2</sub>O<sub>3</sub> through calcination<sup>[24]</sup> and co-removal of template is feasible.

Alternative means include solvent extraction that allows surfactant removal without decomposition. The liquid extractions are carried under reflux, generate substantial amount of waste that are often toxic, and do require removal of the solvent from the porous matrix. The supercritical fluid extraction that has been used for drying is being increasingly applied to removal of the surfactant. The most popular supercritical solvent, carbon dioxide, has been used for many years for drying of aerogels, is environmentally friendly, and minimizes pore structure degradation.<sup>[24,46–48]</sup> Unfortunately, CO<sub>2</sub> is non-polar, has low dielectric constant, and does not engage in van der Waals-type interactions. In other words, CO<sub>2</sub> is a poor solvent for highly polar and high molecular weight materials.

The advantages of supercritical fluids can be realized if entrainers (modifiers), such as alcohols, are used to enhance the solubility of the template material. The concern here is the recovery of liquid entrainer that has a tendency to preferentially adsorb in the porous matrix.

Synthesis of thermally stable alumina supports has been the subject of intense effort for many years and is an excellent example of how synthesis method and

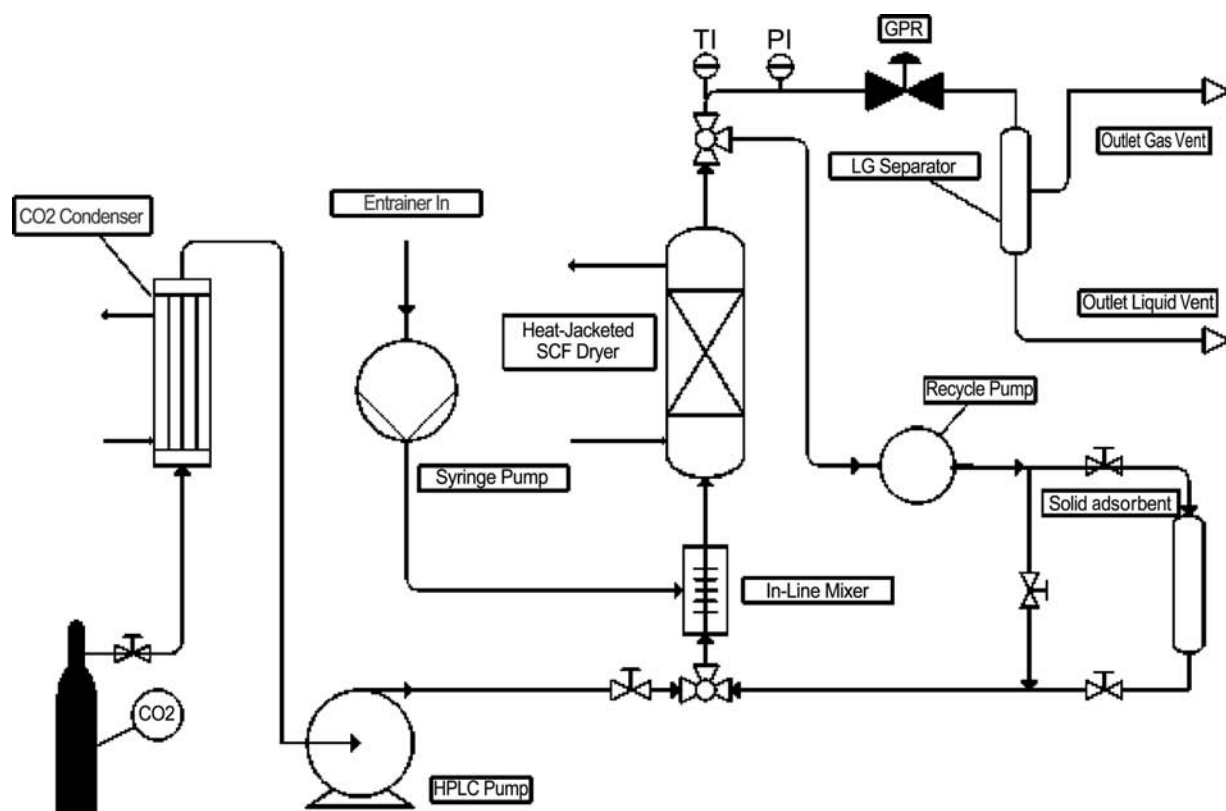

Fig. 4 Pilot plant flow sheet for supercritical drying and impregnation.

template removal technology can affect the pore structure. Fig. 4 shows the multipurpose pilot plant employed in drying as well as surface functionalization. Even after calcination at 773 K, BET pore areas over  $700 \text{ m}^2/\text{g}$  and unimodal pore sizes around 11 nm were achieved through non-ionic surfactant-templated (Triton X-114, a commercial surfactant) synthesis of alumina aerogels. Table 1 summarizes some key results.

## FUNCTIONALIZATION AND TAILORING NANOPOROUS MATERIAL

The approaches to chemical functionalization of porous matrices include impregnation, doping, and

self-assembly in the porous matrix. These approaches not only enable chemical functionalization of the surfaces, but also allow tuning of the surface texture and structure. In liquid-phase functionalizations, the shortcomings discussed in the context of drying, pore size reduction, and collapse are compounded by mass transfer limitations that hinder rate and access to the pores. Furthermore, capillary condensation and multilayer adsorption limit control and tunability. Therefore supercritical fluid-based impregnation and in situ processing offer a major advantage in instances where solubility-related issues are resolved. One of the earliest applications of the technology is simultaneous permeation of diffusion of monomers/polymers into porous wood matrix in the supercritical carbon dioxide

Table 1 Effect of surfactant and drying method on surface area and average pore diameter of alumina gels

Calcination temperature (K)	Without surfactant				With surfactant			
	Surface area ( $\text{m}^2/\text{g}$ )		Pore diameter (nm)		Surface area ( $\text{m}^2/\text{g}$ )		Pore diameter (nm)

for synthesis of wood polymer composites.<sup>[49]</sup> The same principle is applied by many for functionalization of mesoporous materials/aerogels.<sup>[50–53]</sup>

Naturally, physical means of functionalization such as etching are possible and widely used, particularly in two-dimensional situations.<sup>[54]</sup>

## CONCLUSION

Porosity of surfactant-templated aerogels can be tuned through judicious selection of sol–gel chemistry, surfactant, drying method employed, and the subsequent functionalization of the surface. The number of steps and manipulated variables are quite a few and are interrelated. The utility of the resulting porous matrix as particles, fiber, films, and monoliths as well as controllability at the nanolevel promise several advances and successful applications in the decades to come. The self-assembly and supercritical fluids are two key technologies that can enable these advances.

# Templating Polymer Crystal Growth Using Block Copolymers

Yueh-Lin Loo

Department of Chemical Engineering, University of Texas at Austin,  
Austin, Texas, U.S.A.

## INTRODUCTION

Block copolymers<sup>[1,2]</sup> can spontaneously self-assemble<sup>[3,4]</sup> to form periodic arrays of nanoscale domains.<sup>[5]</sup> Incorporating crystallizable moieties within block copolymers can further increase their morphological richness and kinetic complexity. Significant progress has been made in the last decade in understanding polymer crystallization within these semicrystalline materials. For example, we now have a good handle on how crystallization occurs and what the final solid state structures are in these materials. Through a combination of reciprocal space scattering and real space microscopy experiments, we now also understand the requirements for patterning and controlling polymer crystallization using nanoscale periodic domains. This entry will attempt to recount the progress in this field.

Familiarity with the concepts of phase separation in block copolymers will be important in the understanding of the nature of polymer crystallization *within* block copolymers. The section below provides a brief overview of block copolymer phase separation. It is further divided into two subsections for the ease of discussion. Phase separation and its resulting complexities in amorphous systems as well as semicrystalline block copolymers are discussed.

## BLOCK COPOLYMER PHASE SEPARATION—AMORPHOUS SYSTEMS

Block copolymers consist of chemically distinct polymer segments that are covalently strung together. Advances in polymerization techniques over the past four decades have enabled scientists to make model block copolymers of different architectures. Fig. 1 illustrates the architectural differences between a diblock, a triblock, and a starblock copolymer.<sup>[5]</sup> Because of the chemical incompatibility between the unlike polymer segments, block copolymers tend to phase separate; this phenomenon is analogous to oil and water. However, the presence of covalent junctions between the different segments restricts phase separation to a molecular-length scale ( $O \sim \text{nm}$ ). Thus phase separation in block copolymers

is generally known as *microphase separation* (as opposed to macrophase separation in polymer blends, where the domains are at least  $O \sim \mu\text{m}$ ).<sup>[1,2,5,6]</sup>

Minimization of free energy during microphase separation can lead to the formation of various interesting, thermodynamically-stable structures on a nanometer-length scale. With the advent of anionic polymerization, which permits the synthesis of model block copolymers with narrow molecular weight distribution (or narrow chain length distribution), phase separation of block copolymers containing flexible-chain, amorphous blocks has been explored extensively and is presently well understood.<sup>[1,2,5-7]</sup> Fig. 2 illustrates the different equilibrium structures that have been observed: body-centered cubic (BCC) array of spherical domains, hexagonally packed cylinders, cubic bicontinuous gyroid structure, and an alternating lamellar (layered) morphology. Because these structures result from block copolymer microphase separation, they are generally called *microdomains*. This entry focuses on using these microdomains to template or to pattern polymer crystallization. Before we discuss polymer crystallization in nanoscale domains, we should briefly review the phase behavior of amorphous block copolymers.

The equilibrium structure of block copolymers is determined by several factors:<sup>[5,6]</sup> the extent of “dislike” between blocks (or the Flory–Huggins interaction parameter,  $\chi$ ),<sup>[8,9]</sup> the total chain length  $N$  (or molecular weight), and the volume fraction of one block  $f$  (or composition). Fig. 3 contains a phase diagram for model block copolymers.<sup>[10]</sup> When the degree of chemical incompatibility between the dissimilar blocks is small—determined by the product  $\chi N$ <sup>[5]</sup>—the system is homogeneous; that is, microphase separation does not take place. However, if  $\chi N$  is large ( $\gg 10$ ; also known as being *strongly segregated*<sup>[11,12]</sup>), the system spontaneously undergoes microphase separation. The final structure that is adopted by the block copolymer system, e.g., spheres, cylinders, or lamellae, is determined by the block length ratio through  $f$ . Systems with approximately equal lengths of unlike blocks ( $f \approx 0.5$ ) form lamellae, while highly asymmetric systems form BCC spheres, with the short block comprising the

**Fig. 1** Schematic illustration of the architecture of a diblock (top), triblock (middle), and a starblock (bottom) copolymer. *Source:* From Ref.<sup>[5]</sup>, © 1990 Annual Reviews, Inc.

discrete phase. The characteristic spacing,  $d$  (Fig. 2), is determined by  $N$  and scales as<sup>[12]</sup>

$$d \sim N^{2/3} \quad (1)$$

Whether a block copolymer microphase separates, and what structure and microdomain size the block copolymer adopts, can thus easily be tuned during block copolymer synthesis by adjusting  $N$  and  $f$  accordingly.<sup>[5]</sup> Block copolymers with periodic microdomains  $O \sim 20\text{--}50$  nm can be routinely obtained by anionic polymerization.<sup>[13]</sup> The morphological richness and the nanoscale periodicity of block copolymers have been exploited for a variety of applications, ranging from components for car bumpers and shoe soles<sup>[1,2]</sup> to templates for optoelectronics research.<sup>[7,14,15]</sup> From a fundamental standpoint, the periodic nanoscale domains have also been exploited as a means to pattern and control polymer crystallization.<sup>[16]</sup> The latter shall be the focus of this entry.

## MICROPHASE SEPARATION IN SEMICRYSTALLINE SYSTEMS

Block copolymers containing one or more crystallizable segments are generally known as *semicrystalline block copolymers*.<sup>[1,16,17]</sup> Aside from microphase separation due to unlike block–block interactions, the incorporation of crystallizable moieties within a block copolymer architecture often lends additional morphological richness to the system. In semicrystalline block copolymers, phase separation can be driven by multiple forces, e.g., microphase separation and crystallization. As a consequence, the final solid-state structures adopted by semicrystalline block copolymers are more complex and, until recently, less predictable.<sup>[1]</sup>

Because our goal in this entry is to describe the phenomenon of templated crystallization in block copolymers, we shall limit our discussion to phase-separated (and not homogeneous) melts. We will examine the consequences of cooling microphase-separated semicrystalline block copolymers below the freezing temperature of the crystallizable block. Energetically, there are two possible outcomes: if microphase separation dominates the structure development process, the nanoscale domains that were created in the melt will remain on crystallization. However, if crystallization is the stronger driving force for phase separation, we expect semicrystalline block copolymers to behave like semicrystalline homopolymers (no amorphous block attached). Cooling from the melt would result in the formation of crystalline alternating lamellae and *spherulitic* superstructures.<sup>[17,18]</sup>

**Fig. 4** Hierarchical structures adopted by a semicrystalline homopolymer on crystallization. *Source:* Courtesy of Pratima Rangarajan and Richard A. Register.

Fig. 4 schematizes the structures that are formed on various length scales when a semicrystalline homopolymer crystallizes. From established calorimetric measurements, the energy associated with crystallization ( $O \sim 100 \text{ J/g}$ )<sup>[18,19]</sup> is much larger than the energy associated with microphase separation ( $O \sim 1 \text{ J/g}$ ).<sup>[20]</sup> Thus crystallization is expected to always dominate the structure development process in these materials; that is, semicrystalline block copolymers would always adopt a crystalline lamellar structure on cooling, regardless of block composition or existing melt structure.<sup>[1]</sup> This prediction also implies enormous structural rearrangement—simultaneous disruption of the melt structure and formation of spherulites—during crystallization. Therefore the final solid state structure of semicrystalline block copolymers would not be too different from that of semicrystalline homopolymers. We shall return to this topic later in this entry.

However, one can *kinetically force* crystallization to occur within the preformed nanoscale microdomains by employing a semicrystalline block copolymer where the amorphous block is *glassy* during crystallization. Vitrification of the amorphous block effectively freezes the microdomain structure in place; subsequent crystallization of the crystallizable block, if it occurs at

all, would have to take place within the prescribed microdomains. The following section examines the impact of crystallization in nanoscale environments in these semicrystalline-glassy systems. Following that, we shall discuss the complex structure development process in semicrystalline-rubbery systems, where the amorphous block remains *fluid* during crystallization.

## CRYSTALLIZATION IN NANOSCALE ENVIRONMENTS—SEMICRYSTALLINE-GLASSY BLOCK COPOLYMERS

Depending on the relative block lengths, the crystallizable component of the semicrystalline-glassy block copolymer can either form *discrete* domains, e.g., spheres and cylinders, or it can form the *continuous* phase, or the *matrix*. For ease of discussion, this section is divided into two subsections: The first subsection examines the crystallization behavior of semicrystalline-poor block copolymer systems where crystallization occurs in the discrete phase while the latter subsection describes how the presence of nanoscale glassy domains impacts crystallization in semicrystalline-rich block copolymers.

The presence of a vitreous component during crystallization strongly impacts the morphological structure of the semicrystalline block copolymer. Because the microphase-separated melt structure is effectively frozen in place, crystallization has to occur *within* the nanoscale domains (semicrystalline-poor systems) or around the nanoscale glassy domains (semicrystalline-rich systems). Not only does this influence the final solid-state structure (resulting in the preservation of the melt structure and preferential crystal orientation in the crystallized domains), it also drastically affects the crystallization kinetics and mechanism.

## SEMICRYSTALLINE-POOR BLOCK COPOLYMERS

In these block copolymers, the glass transition temperature of the amorphous matrix ( $T_{g,a}$ ) exceeds the freezing temperature ( $T_c$ ) of the crystallizable minority block. As the system is cooled from a microphase-separated melt, it first encounters  $T_{g,a}$ . Below  $T_{g,a}$ , the matrix is vitreous so the microphase-separated structure is effectively frozen. Subsequent cooling beyond  $T_c$  induces crystallization of the minor component. Because the melt structure had effectively been captured, crystallization is forced to occur *within* the microdomains prescribed by microphase separation. Thus the melt morphology is faithfully reproduced in the solid state. *Confined crystallization* in semicrystalline-glassy block copolymers was first demonstrated by

Lotz and Kovacs,<sup>[21]</sup> the researchers examined several compositionally asymmetric block copolymers of poly(ethylene oxide)-*b*-polystyrene, EO/S, where  $T_{g,S} > T_{c,EO}$ , and found the spherical melt structure to be preserved even after EO is fully crystallized. Cohen et al.<sup>[22]</sup> subsequently demonstrated the preservation of spherical polyethylene (E) microdomains in the solid state structure of an asymmetric polyethylene-*b*-polystyrene, E/S, diblock. However, if the E/S diblock was cast from a solution, the melt structure would be completely destroyed and a crystalline alternating lamellar morphology would result. This finding implies an important point: *Confined crystallization* in semicrystalline-glassy systems need not correspond to the equilibrium state—the structure with the lowest free energy—as the vitreous matrix kinetically restricts crystallization to occur within these nanoscale domains without substantial rearrangement of the domain structure.

More recently, Weimann et al.<sup>[23]</sup> examined a series of polyethylene-*b*-polyvinylcyclohexane, E/VCH, di- and triblock copolymers of varying compositions (and thus melt structures) and found crystallization to occur within the microdomains prescribed by microphase separation in all cases. Using a unique staining protocol, Loo, Register, and Adamson<sup>[24]</sup> were able to directly visualize these intricate solid state structures, for the first time, using transmission electron microscopy (TEM). Because of the differential uptake of ruthenium tetroxide, RuO<sub>4</sub> (staining agent), in different phases,<sup>[25–27]</sup> the researchers were able to observe individual 5-nm-thick E crystals within block copolymer spherical microdomains that span 16 nm.<sup>[24]</sup> In addition to disk-like crystals within spheres, they had also successfully imaged ribbon- and sheet-like crystals confined within nanoscale cylindrical<sup>[24]</sup> and lamellar<sup>[36]</sup> microdomains, respectively. Fig. 5 contains TEM micrographs reproduced from Ref.<sup>[24]</sup>. Thus a complex “structure-within-structure” type morphology can be routinely obtained in these semicrystalline-glassy systems where crystallization of the minor block is effectively trapped by the vitreous matrix. More recently, Zhu et al.<sup>[28,29]</sup> have demonstrated in a series of papers that crystallization of EO can also be patterned by a metastable perforated lamellar structure in EO/S block copolymers and blends. Block copolymers of various other chemistries, including polytetrahydrofuran-*b*-polystyrene, THF/S;<sup>[30]</sup> poly( $\epsilon$ -caprolactone)-*b*-polystyrene, CL/S;<sup>[31]</sup> as well as triblock copolymers of poly( $\epsilon$ -caprolactone)-*b*-polyethylene-*b*-polystyrene, CL/E/S,<sup>[32]</sup> where both CL and E are crystallizable, have also been examined.

Confining crystallization in an anisotropic environment induces the crystals to grow in a preferential direction. Indeed, Loo, Register, and Adamson<sup>[24]</sup> observed the formation of ribbon- and sheet-like crystals in cylindrical and lamellar domains. To quantify

**Fig. 5** Transmission electron micrographs of a fully crystallized E/VCH block copolymer where E comprises the cylindrical domains. The sample was flow aligned; top image reveals a projection along the cylinder axis while the bottom image shows a projection perpendicular to the cylinder axis. Individual ribbon-like crystals can be seen within the cylindrical microdomains. *Source:* From Ref.<sup>[24]</sup>, © 2000 Wiley & Sons, Inc.

the preferential crystal orientation, Hamley et al.<sup>[33]</sup> examined a prealigned lamellar-forming E/VCH diblock copolymer using simultaneous two-dimensional small- and wide-angle X-ray scattering (SAXS/WAXS) techniques. From the solid-state scattering patterns, the researchers inferred that the E crystals were preferentially oriented with their crystal stems *parallel* to the microdomain interface and their fast-growth axis (the *b* axis for polyethylene) randomly oriented in plane. More recently, compositionally asymmetric block copolymers where crystallization is confined within cylinders have also been examined in detail. Quiram<sup>[34]</sup> demonstrated, through simultaneous SAXS/WAXS on fully crystallized flow-aligned samples, that the E chains within cylindrical microdomains crystallize with their stems generally *perpendicular* to the cylinder axis. The preferential crystal orientations adopted by these systems are schematized in Fig. 6.

**Fig. 6** Schematic illustration of the orientation of the crystal stems in E-containing semicrystalline lamellar-forming (top) and cylinder-forming (bottom) block copolymers. *Source:* From Refs.<sup>[33]</sup> (top) and<sup>[34]</sup> (bottom), © 1996 (top) and 1998 (bottom) American Chemical Society.

The seemingly disparate orientations obtained in the different systems (and different morphologies) can be understood by noting that all these orientations align the fast growth axes of the crystals with the direction in which the crystals can grow unobstructed. In the lamellar samples, the fast growth axis is in the plane of the lamellae, while in the cylindrical samples, the fast growth axis is along the cylinder axis.

**Fig. 7** Crystallization temperature of E block as a function of block copolymer composition. The crystallization temperature monotonically decreases with E weight fraction. The dashed line represents the crystallization temperature of PE (no amorphous block attached).

Confining crystallization on a nanometer-length scale can also drastically affect the macroscopic properties of the material. For example, restricting crystallization in this manner suppresses spherulite formation so the polymer is optically clear (conventional semicrystalline homopolymers that form spherulites are typically opaque because the spherulites scatter light very intensely).<sup>[35]</sup> Confining crystallization within nanoscale domains also impacts the way by which crystallization occurs. Lotz and his coworkers<sup>[21]</sup> were among the first to notice big differences between the crystallization temperatures of semicrystalline-glassy block copolymers and semicrystalline homopolymers; the addition of an amorphous, glassy block greatly suppressed the crystallization temperatures. This was also observed in a series of E/VCH di- and triblock copolymers of varying compositions.<sup>[23]</sup> More recently, Loo et al.<sup>[36]</sup> found that the onset crystallization temperatures systematically decreased with the weight fraction of the crystallizable block (or as the domains become less connected) (Fig. 7).

In homopolymers, crystallization is typically initiated by *heterogeneous nucleation* on dust particulates or impurities present in the melt; the tendency to form micron-size spherulites suggests that only a small number of nuclei are required to fully crystallize the system.<sup>[17–19]</sup> However, in semicrystalline-glassy block copolymers where crystallization is isolated in nanoscale domains, the domains would need to be individually nucleated to fully crystallize the sample.<sup>[37,38]</sup> Because the number density of microdomains far exceeds the typical impurity density, researchers have

long speculated that *homogeneous nucleation*, a phenomenon not usually observed in bulk semicrystalline homopolymers, is responsible for initiating crystallization in the nanoscale domains of semicrystalline block copolymers. (A large energy barrier is associated with homogeneous nucleation and this is generally reflected by a large crystallization temperature depression.) To examine the mechanistic details of crystallization, high-resolution, time-resolved techniques are required to probe the structural changes that take place. Therefore, it took the development of synchrotron-based, time-resolved simultaneous SAXS/WAXS coupled with in situ differential scanning calorimetry (DSC; capable of excellent temperature control) to investigate the crystallization kinetics in these systems.<sup>[39–42]</sup> In a recent synchrotron study, Loo et al.<sup>[36]</sup> determined both the crystallization temperatures as well as the temperature dependence of the rate of crystallization for a series of E/VCH diblock copolymers of varying block ratios (and thus melt morphology). In sphere and cylinder formers (discrete crystallizable domains), the greatly suppressed crystallization temperature and the steep temperature dependence of crystallization indicated that crystallization in those systems is preceded by *homogeneous nucleation*. This is in stark contrast with bulk homopolymer crystallization where the process is almost always initiated by heterogeneous nucleation on impurities that are present in the system.<sup>[15,16]</sup> In the cubic bicontinuous gyroid-forming diblock, the extensive connection between the crystallizing domains dominated the crystallization kinetics; foreign nuclei that were already present in the melt were able to induce crystallization over large areas because the channels are highly connected. The lamellar samples exhibited peculiar two-step isothermal crystallization kinetics (Fig. 8), leading the researchers to conclude that there were two populations of lamellae within that particular sample: one that is highly interconnected at the grain boundaries so crystallization is preceded by heterogeneous nucleation at a relatively high temperature, and another that contains lamellae that are completely isolated so crystallization has to be induced by homogeneous nucleation.

Semicrystalline-glassy block copolymers remain an interesting subject of research, particularly because they serve as reference samples for studying crystallization behavior in semicrystalline-rubbery systems. This section highlighted recent experimental findings in block copolymers that contain an already-glassy matrix during crystallization. The glassy matrix can effectively preserve the melt structure in the crystalline solid state. This has enabled researchers to examine the impact of crystallization within nanoscale confinements. The following section highlights research on semicrystalline-glassy block copolymers where the semicrystalline block comprises the continuous phase.

**Fig. 8** Differential scanning calorimetry (top) and SAXS integrated intensity (bottom) indicating peculiar two-step crystallization in a lamellar E/VCH diblock copolymer. The atypical kinetics was attributed to the presence of two distinct populations of lamellar microdomains: one is highly interconnected—these domains are heterogeneously nucleated by dust particles at higher temperatures; the other consists of isolated domains—the individual domains are homogeneously nucleated at lower temperatures. *Source:* From Ref.<sup>[36]</sup>, © 2001, American Chemical Society.

### SEMICRYSTALLINE-RICH BLOCK COPOLYMERS

We previously discussed the possibility of imposing preferential crystal orientation in semicrystalline-glassy diblock copolymers when crystallization occurs within anisotropic nanoscale domains: In both lamellar-<sup>[33]</sup> and cylinder-forming<sup>[34]</sup> block copolymers, the fast growth axis is generally aligned so the crystals can grow unobstructed. As a result, the crystals tend to grow with their stems parallel to the lamellar interface and perpendicular to the cylinder axis in E-containing block copolymers. In semicrystalline-rich block copolymers where the crystallizable component comprises the matrix, we fully expect the presence of glassy anisotropic nanoscale domains to impose a preferential crystal orientation in the surrounding matrix as well. Here,

we highlight some recent work that examined crystal orientation in the continuous phase of semicrystalline-rich block copolymers.

Liu and Chu<sup>[43]</sup> were among the first to examine the possibility of inducing a preferential crystal orientation in the presence of glassy cylinders. The researchers looked at blends of polytetrahydrofuran (THF) with polytetrahydrofuran-*b*-poly(methyl methacrylate), THF/MMA, using synchrotron-based SAXS/WAXS. Despite the preservation of glassy MMA cylinders, the formation of spherulites was observed. This is expected because the crystallizable component comprises the matrix; the spherulites can easily develop around the glassy domains. Based on SAXS peak distortions on crystallization, Liu and Chu speculated that the presence of the cylinders can impart preferential crystal orientation to the matrix. In fact, they hypothesized that, under certain specific conditions, i.e., when the intercylinder spacing is comparable to the crystal long period, preferential packing of the THF crystals should be observed in the plane of the cylinder radii. Unfortunately, Liu and Chu did not directly observe the predicted preferential orientation because they had only examined isotropic samples (samples that were not prealigned). Subsequently, Park et al.<sup>[44]</sup> examined a prealigned polyethylene-*b*-poly(ethylene-propylene)-*b*-polystyrene, E/EP/S, triblock copolymer where crystallizable E comprises the matrix (S forms cylinders). While the preferential orientation of E crystals was observed along the cylinder axis—like crystallization inside cylinders, the crystals tend to grow with the fast growth axis generally aligned along the cylinder axis—preferential orientation was also *not* observed in the plane of the cylinder radii.

More recently, Loo, Register, and Adamson<sup>[45]</sup> examined a prealigned E-rich cylinder-forming semicrystalline block copolymer, E/VCH, using simultaneous two-dimensional SAXS/WAXS and discovered preferential crystal orientation in *two* dimensions. Fig. 9 contains SAXS/WAXS patterns collected with incident X-rays both parallel and perpendicular to the cylinder axis. As expected for unobstructed growth, the crystals are preferentially aligned with their fast growth axis along the cylinder axis. Additionally, preferential crystal orientation that is consistent with that inferred by Liu and Chu was recorded by Loo et al. Using a combination of SAXS and WAXS, the researchers showed that the crystals have their stems preferentially aligned along the (10) planes of the hexagonal microdomain lattice in the plane of the cylinder radii. The preferential orientation observed in the second dimension was subsequently attributed to the commensurability in length scales between the intercylinder spacing and the E crystal long spacing (as was speculated by Liu and Chu). The comparable length scales allow the crystals to

**Fig. 9** Two-dimensional SAXS (A and C) and WAXS (B and D) taken on an aligned, fully crystallized E/VCH diblock copolymer where VCH forms cylinders and E comprises the matrix. Patterns of SAXS and WAXS were simultaneously acquired with the X-ray beam perpendicular (A and B) and along (C and D) the cylinder axis. Preferential crystal orientation (arcs of nonuniform intensities in the WAXS patterns) is observed in both directions. *Source:* From Ref.<sup>[45]</sup>, © 2000 American Chemical Society.

adopt their equilibrium crystal thickness only when they are oriented in a particular direction with respect to the two-dimensional hexagonal microdomain lattice. Such crystal orientation is not observed when crystallization occurs inside cylinders. It was also not observed in the E/EP/S triblock copolymer by Park et al. because the intercylinder spacing was much greater than the E crystal long spacing. Thus the crystals can adopt their equilibrium thickness in any orientation relative to the microdomain lattice, as long as they are parallel to the cylinders.

The presence of glassy cylinders is effective at imparting preferential crystal orientation in the surrounding matrix. At the minimum, the crystals grow in a ribbon-like fashion with their fast growth axis preferentially aligned along the cylinder axis. Such orientation is also observed for crystallization inside cylinders. However, when the intercylinder spacing is comparable to the crystal long spacing, an additional preferential orientation in the plane of the cylinder radii is observed. Such orientation is only observed for crystallization around cylinders and not observed for crystallization inside cylinders. However, crystallization in these systems is almost always initiated by heterogeneous nucleation on impurities that are present in the melt and these crystals subsequently

grow in a three-dimensional fashion to fill space. As a result, micron-size spherulites are formed in the solid state; these materials are frequently opaque in appearance as a result of the presence of spherulites.

## SEMICRYSTALLINE-RUBBERY SYSTEMS

Thus far, we have covered the solid state structure development of semicrystalline-glassy block copolymers. In these materials, the ability to pattern or template crystallization arises purely from the fact that the amorphous component is glassy during crystallization. However, this ability to pattern crystallization becomes less clear when the amorphous block is *rubbery* at the onset of crystallization (recall the energetic argument presented earlier). Indeed, previous experiments conducted on semicrystalline-rubbery block copolymers reveal that the melt structure is typically eradicated on crystallization and a crystalline-alternating lamellar structure is formed. More recently, experiments on more strongly segregated systems have indicated that the melt structure of semicrystalline-rubbery block copolymers can be faithfully reproduced in the solid state.<sup>[37,38]</sup> This section summarizes experimental findings in semicrystalline-rubbery systems.

## MODERATELY-SEGREGATED SYSTEMS

We previously covered the energetics of the phase separation process: When the system is not kinetically frozen in the presence of a vitreous amorphous block, the final solid state structure development is complex and no longer as predictable. The details of the process now depend on the relative strengths of crystallization and microphase separation. In moderately-segregated block copolymers, crystallization generally dominates phase separation, always resulting in the formation of crystalline alternating lamellae (and spherulites) on cooling regardless of the melt structure.<sup>[39,40]</sup>

Many experiments on moderately-segregated block copolymer systems have verified that crystallization can disrupt the preexisting melt morphology on cooling, resulting in a crystalline lamellar structure. Douzinas, Cohen, and Halara<sup>[46]</sup> examined the melt and solid state morphologies of a series of polyethylene-*b*-poly(ethyl ethylene), E/EE, block copolymers of varying composition ( $f_E = 0.37-0.90$ ) using SAXS. Despite the presence of microphase-separated melts, lamellar structures always resulted on crystallization. Similar experiments were also conducted on microphase-separated E/EP diblocks ( $f_E = 0.30-0.70$ )<sup>[47]</sup> and E/EP/E triblocks ( $f_E = 0.30-0.70$ ).<sup>[48]</sup> When fully crystallized, all these materials exhibited alternating lamellar structures, and ultimately spherulites.

The disruption of melt structure (BCC spheres, hexagonally packed cylinders, alternating lamellae) and the simultaneous formation of a crystalline lamellar structure (and perhaps spherulites on a larger length scale) imply significant structural rearrangement during crystallization.<sup>[39,40]</sup> This speculation was verified by time-resolved scattering experiments on a moderately segregated E/EE block copolymer where the E blocks form cylinders in the melt.<sup>[41]</sup> On cooling, the cylindrical morphology is transformed to a lamellar structure with a larger domain spacing. The destruction of the melt morphology on crystallization had also been demonstrated with other block copolymer systems, including poly( $\epsilon$ -caprolactone)-*b*-poly(butadiene), CL/B,<sup>[49]</sup> poly( $\epsilon$ -caprolactone)-*b*-poly(dimethyl siloxane)-*b*-poly( $\epsilon$ -caprolactone), CL/DMS/CL,<sup>[50]</sup> and poly(ethylene oxide)-*b*-poly(butylene oxide), EO/BO.<sup>[51,52]</sup>

The solid-state structure of moderately-segregated semicrystalline-rubbery block copolymers is path dependent. Quiram et al.<sup>[35,53]</sup> examined a series of cylinder-forming polyethylene-*b*-poly(3-methyl-1-butene), E/MB, diblock copolymers and found that the final solid-state structure adopted by the moderately-segregated block copolymers depended on how the materials were crystallized: The cylindrical melt structure appeared to be preserved in the solid state when the sample was quenched in liquid nitrogen from the melt. However, if the diblocks were slowly cooled from the melt, a crystalline lamellar structure always resulted. This was the first demonstration that the melt structure can be *kinetically trapped* in the solid state even in presence of a fluid matrix provided that the cooling rates were sufficiently high. Such effects were also subsequently demonstrated by Loo, Register, and Ryan<sup>[54]</sup> with poly(ethylene)-*b*-poly(styrene-*r*-ethylene-*r*-butene), E/SEB. They were able to directly visualize the extent of structural rearrangement by imaging samples of moderately-segregated E/SEB after they were crystallized under different conditions. Chen et al.<sup>[55]</sup> also reported “crystallization-induced deformation” of the spherical microdomains when blends of EO and EO/B block copolymers were examined. In all these cases, the energetics of crystallization still overwhelms that of microphase separation, but templating crystal growth is achievable with the appropriate kinetic constraints.

The ability for crystallization to disrupt or *break out* of existing melt microdomains also impacts the crystallization kinetics. As expected, the crystallization kinetics are akin to those of semicrystalline homopolymers: The crystals are generally generated by heterogeneous nucleation, on impurities in the melt, and they subsequently grow in a three-dimensional fashion until all the crystallizable material is depleted. Spherulitic growth always results from such a process.

The combination of the energetics argument and well-documented experimental evidence of crystallization-

induced breakout has led researchers to believe that templating polymer crystallization is *not* possible without kinetic constraints in semicrystalline-rubbery systems.<sup>[1]</sup> However, recent experiments on strongly-segregated semicrystalline-rubbery block copolymers<sup>[37,38]</sup> have proven otherwise. By increasing block segregation, researchers have shown that crystallization can be effectively templated by the melt structure, despite the presence of a rubbery matrix at the onset of crystallization. The increase in interblock segregation can be achieved by the following methods: 1) increasing the molecular weight of the polymer ( $N$ ) and 2) tuning the unlike interactions (changing  $\chi$  by going to different chemistries). The section below highlights accomplishments in this area.

### STRONGLY-SEGREGATED SEMICRYSTALLINE-RUBBERY BLOCK COPOLYMERS

The motivation for examining strongly-segregated systems arises from the possibility that microphase separation may dominate over crystallization in the phase separation process. If this were true, the melt structure could be preserved without any kinetic constraints, even when the amorphous block is rubbery during crystallization. Therefore the confinement of crystallization on a nanoscale level would be achieved purely through unlike block segregation. The first evidence of melt structure preservation in a semicrystalline-rubbery block copolymer system was reported by Quiram, Register, and Marchend<sup>[35]</sup> Small-angle X-ray scattering experiments conducted on a high molecular weight (large  $\chi N$ ) E/MB cylinder-forming block copolymer, where  $T_{g,MB} = -17^\circ\text{C}$ , revealed that the melt structure is *generally* preserved on crystallization; that is, the characteristic lattice spacing remained the same even after crystallization. Because crystallization was effectively templated by microphase separation, the researchers may have anticipated the crystallization kinetics to resemble those for cylinder-forming semicrystalline-glassy block copolymers: homogeneous nucleation and instantaneous growth within discrete cylinders. Surprisingly, time-resolved SAXS/WAXS revealed crystallization kinetics that are not markedly different from those of semicrystalline homopolymers.

More recently, Loo, Register, and Ryan<sup>[37]</sup> examined a sphere-forming E/SEB semicrystalline-rubbery diblock and found crystallization of the minority component to be confined within the 25-nm spherical microdomains that are prescribed by microphase separation. Fig. 10 contains a TEM micrograph of the E/SEB sample that had been fully crystallized. Confined crystallization was observed at all cooling conditions, even at extremely slow cooling rates. Time-resolved SAXS/WAXS/DSC experiments conducted on the strongly segregated E/SEB diblock revealed

**Fig. 10** Transmission electron micrograph of a strongly segregated E/SEB diblock copolymer that exhibits *confined crystallization*. The spherical melt microdomains are exactly preserved on crystallization despite the presence of a rubbery matrix. *Source:* From Ref.<sup>[37]</sup>, © 2000 American Physical Society.

first-order crystallization kinetics similar to those observed in semicrystalline-glassy systems, where crystallization occurred in the discrete phase. Such crystallization kinetics are atypical compared to homopolymer crystallization and are indicative of homogeneous nucleation and isolated crystallization within individual spherical domains. Subsequent work on other systems, including EO/B,<sup>[56,57]</sup> have also indicated that the melt structure can be effectively preserved in the solid state without the presence of a glassy amorphous component.

To resolve the apparent disparity between the observed solid-state structure and its crystallization kinetics, Loo et al.<sup>[54]</sup> revisited the E/MB cylinder-forming diblock that had been examined by Quiram, Register, and Marchend<sup>[35]</sup> Using a block staining technique,<sup>[24]</sup> the researchers were able to image the solid state structure of the material. While the microphase-separated cylindrical structure is largely preserved, local distortions due to crystallization were observed. In particular, the crystals were able to traverse from one cylinder to its neighboring microdomain. Despite the general preservation of the melt structure, sigmoidal crystallization kinetics, which reflect the extensive connectivity and growth from a relatively small number of nuclei, was observed. While the E/MB diblock is strongly segregated, the interblock segregation strength during crystallization is

insufficient to effectively isolate crystallization within discrete microdomains. Therefore crystal growth in this material is merely *templated by*, but not *confined in*, nanoscale cylinders. By systematically quantifying the interblock segregation strength at crystallization, the isothermal crystallization kinetics, and the final solid state structures in a series of E-containing semicrystalline-rubbery block copolymers, Loo, Register, and Ryan<sup>[54]</sup> were able to come up with a “classification map” (Fig. 11) for identifying the crystallization modes in semicrystalline block copolymers with rubbery matrices.

The study of structure rearrangement in semicrystalline block copolymers have traditionally been carried out with scattering techniques; two-dimensional X-ray detectors have enabled the examination of preferential crystal orientation in aligned samples while synchrotron-based techniques have allowed us to access the kinetic and mechanistic details of crystallization. More recently, TEM has been employed to examine the melt and final solid state structures of these materials in real space.<sup>[24,54]</sup> With the advent of atomic force microscopy (AFM), direct imaging of the crystallization process is now also possible. For instance, Reiter et al.<sup>[58]</sup> were able to image the individual crystallizing domains in an asymmetric EO/B diblock copolymer during crystallization using AFM. By doing so, the researchers concluded that nanoscale crystallization within discrete domains of block copolymers is

**Fig. 11** Classification map for E-containing semicrystalline block copolymers with rubbery matrices. Three modes of crystallization were observed: “breakout” where the melt structure is completely destroyed on crystallization; “templated” where the melt structure is *generally* but not *faithfully* preserved in the solid state, and where indications of connectivity between crystallizing domains are present in the crystallization kinetics; and “confined” where crystallization occurs within the microdomains prescribed by microphase separation so the nanoscale domains are effectively preserved on cooling. *Source:* From Ref.<sup>[54]</sup>, © 2002 American Chemical Society.

independently stochastic; that is, crystallizing one nanoscale domain does not influence the probability of crystallizing its neighboring domains. By operating an optical microscope in reflection mode, Hong et al.<sup>[59]</sup> were also able to directly image the crystallization of a lamellar-forming EO/B diblock copolymer. In this case, the researchers observed crystallization between neighboring lamellae and attributed extended interdomain crystallization to the presence of defects, such as screw dislocations, in thin films.

## PATTERNING SEMICRYSTALLINE BLOCK COPOLYMERS OVER LARGE AREAS

So far in this entry, we have discussed how the self-assembly of block copolymers can be used to template or pattern polymer crystallization. The ability to control crystallization on a nanometer-length scale has in turn led to complex yet intriguing “structure-within-structure” type morphologies and new understanding of polymer crystallization kinetics and mechanisms. In this last section, we would like to highlight some of the more recent work on patterning semicrystalline block copolymers over large areas.

Block copolymers naturally self-assemble to form periodic nanoscale domains. We have addressed the increased complexity of the structures when block copolymers contain crystallizable segments. From an applications standpoint, the ability to locally pattern polymer crystallization is important, but so is the ability to control the formation of periodic nanoscale domains over large areas (long-range order). However, forming periodic patterns with block copolymers over long range remains a big challenge.<sup>[60]</sup> This is in large part because of the tendency for block copolymers to form micron-size grains. Thus significant research efforts have been dedicated to eliminating grain boundaries and increasing the long-range order in block copolymer thin films. These efforts have primarily relied on the application of external fields, such as electric fields<sup>[15,61]</sup> and temperature gradients,<sup>[62,63]</sup> as well as patterned<sup>[64,65]</sup> and epitaxially matched substrates.<sup>[66]</sup> More recently, De Rosa et al.<sup>[67]</sup> have demonstrated that they can produce large grains that span up to several hundred microns by rapid solidification of a semicrystalline E/S diblock copolymer from a crystallizable solvent. Cocrystallization of the crystallizable block with an epitaxially-matched solvent can effectively induce a preferential orientation of both the microdomains as well as the crystals over large areas.<sup>[67,68]</sup> Reiter et al.<sup>[69]</sup> found that, by combining dewetting with crystallization and microphase separation, the researchers were able to preferentially orient the crystalline lamellae in a poly(ethylene oxide)-*b*-poly(hydrogenated butadiene) diblock

copolymer perpendicular to the substrate over large areas. The ability for a block copolymer to crystallize has imparted an additional mechanism for manipulating long-range order. Furthermore, crystallization can be a fast process; the long-range order that is induced by cocrystallization of a solvent and a crystallizable block or a combination of dewetting and crystallization occurs over much shorter time scales compared to processes that require external fields. Long-range microdomain and crystal order induced by crystallization is straightforward and efficient, thereby making it highly attractive for advanced applications such as the parallel fabrication of quantum dots and memory bits, etc.

## CONCLUSION

Model block copolymers, synthesized by traditional anionic routes and containing only amorphous blocks, are presently considered well understood. Incorporating a crystallizable component in these materials has added morphological richness and kinetic complexity to the systems. We described in this entry the possibility of templating and controlling polymer crystallization in the presence of microphase-separated nanoscale domains. We discussed the crystallization behavior of semicrystalline-glassy block copolymers where the melt structure is exactly preserved as a result of the presence of an already-vitrified component. We also described the solid-state structure development of semicrystalline-rubbery systems; significant progress has been made in the last decade demonstrating that crystallization can also be effectively patterned in the absence of a glassy component. We concluded the entry by describing some recent experiments that pertain to achieving long-range order, both on the nanometer scale as well as on larger length scales. Work in this field continues to be exciting; with the advent of novel synthetic techniques, we are able to revisit and examine fundamental crystallization issues that were previously not addressable with semicrystalline homopolymers alone. Furthermore, with increasing prominence of patterning on a nanometer-length scale, understanding and having the ability to control polymer crystallization over several length scales may prove useful for the development of advanced applications such as lithographic masks, memory storage, as well as parallel fabrication of metal or semiconductor quantum dots.

# Thermal Effect on the Luminescence Properties of Quantum Dots

X. B. Zhang

R. D. Dupuis

*Microelectronics Research Center, University of Texas at Austin,

## INTRODUCTION

Semiconductor quantum dots (QDs) are similar to atoms in having a very sharp density of states distribution. However, what makes QDs such unusual objects are that we can control their shape, size, and hence the detailed characteristics of their energy levels and the number of confined states. The controllable shape, size, spatial distribution, and density of states endow the QDs with many novel properties, which have promising applications in optoelectronic devices. For example, QD-based injection lasers are predicted to have improved performance characteristics, such as a lower threshold current density, higher characteristic temperature, and higher differential gain in comparison with the conventional quantum well lasers.<sup>[1]</sup> The intersubband absorption of QDs can be used to design QD-based photodetectors operated in the mid-infrared spectral region. As compared to quantum wells, the reduced electron–phonon scattering in QDs provides the photoexcited carriers to be swept away as photocurrent before relaxing to the ground state and therefore makes the QDs to be more efficient in detection. Moreover, unlike the quantum-well photodetectors, QD photodetectors are intrinsically sensitive to normal photon incidence due to the breaking of the polarization selection rule.<sup>[2]</sup>

Because of these promising applications, the growth of semiconductor QDs has been extensively investigated in recent years. A major breakthrough in the fabrication of high-quality quantum dots is the growth of self-assembled quantum dots (SAQDs), typically formed by strained-layer epitaxy in systems having a large lattice-mismatch. The growth in such a system is usually through the Stranski–Krastanow (S–K) growth mode or by the Volmer–Weber (V–W) growth mode. For S–K growth, the growth is initially through a layer-by-layer mode, which results in a thin wetting layer; after the wetting layer exceeds a critical thickness, defect-free three-dimensional (3-D) islands nucleate coherently on top of the strained wetting layer. For V–W growth, 3-D islands nucleate directly

on the substrate without the formation of wetting layer. In the past years, laser diodes and photodetectors based on SAQDs with improved operation have been demonstrated. However, many factors, which fundamentally limit the performance of these devices, are still not well understood. Thermal effects have a great influence on the population of carriers in the energy states of QDs, and thus, such effects strongly influence the device performance. In order to realize room-temperature operation of the QD-based devices, the influence of temperature on their emission and absorption properties must be well understood. In this entry, we will review the impact of thermal effects on the optical properties of SAQDs. We first show how thermal excitation affects the optical properties of bulk semiconductors. We believe this knowledge for bulk semiconductors will be helpful for understanding the optical properties of QDs. After that, recent temperature-dependent emission studies of SAQDs are reviewed. In high-quality SAQDs, evidence of thermally excited carrier transfer between QDs is shown. An analytical model based on rate equations is used to interpret the emission properties. Finally, a conclusion and a brief future vision are given.

## THERMAL EFFECTS ON THE OPTICAL PROPERTIES OF BULK SEMICONDUCTORS

The luminescence spectra of high-purity bulk semiconductors at liquid helium temperature are often dominated by the near bandgap bound exciton and free exciton emission. An exciton is the electron–hole pair formed as a result of Coulomb attraction. When the exciton and an impurity atom form a complex, it is called a bound exciton. At low temperatures, electrons and holes are frozen in states associated with donor and acceptor impurities, respectively, and thus form neutral donors and acceptors. An exciton bound to a neutral donor is called a neutral donor-bound exciton, while an exciton bound to a neutral acceptor is called a

neutral acceptor-bound exciton. Sometimes, transitions between donor (or acceptor) and band states, or between donors and acceptors (i.e., donor–acceptor pairs or simply DAPs), are also observed in the emission spectra. The free exciton binding energy,  $E_X$ , depends on the Coulomb interaction between the electron and hole, which form the exciton. The binding energy of a free exciton bound to a neutral donor ( $E_{DX}$ ) or to a neutral acceptor ( $E_{AX}$ ) depends on the ionization energy of the donor ( $E_D$ ) and the acceptor ( $E_A$ ), respectively, and usually follows Hayne's rule:<sup>[3]</sup>

$$E_{DX} = \gamma_1 E_D \text{ and } E_{AX} = \gamma_2 E_A \quad (1)$$

where  $\gamma_1 \sim 0.2$  and  $\gamma_2 \sim 0.1$  were found for shallow donors and acceptors in Si. Similar values were also found in many other semiconductors. With an increase in temperature, the peak energies of the near bandgap emission usually follow the temperature-dependent bandgap and empirically the transition energies follow the Varshni equation:<sup>[4]</sup>

$$E(T) = E(0) - \alpha T^2 / (\beta + T) \quad (2)$$

where  $E(0)$  is emission energy at 0 K,  $\alpha$  and  $\beta$  are Varshni coefficients. The origin of the temperature-dependent bandgap is due to thermal expansion of the lattice and the changes in the electron–phonon interaction. Because of the nature of the electron–phonon interaction, the temperature-dependent bandgap is sometimes described in a Bose–Einstein-type expression:<sup>[4]</sup>

$$E(T) = E(0) - 2\alpha_B / [\exp(\hbar\omega_B/k_B T) - 1] \quad (3)$$

where  $\alpha_B$  represents the exciton–average phonon interaction,  $k_B$  is the Boltzmann constant, and  $\hbar\omega_B$  is the average phonon energy. The quenching of these emissions at high temperature is complicated and depends in detail upon the specific quenching channels involved in the emission. For a bound exciton, usually, each quenching channel is related to a thermal activation of the bound exciton from radiative state into a non-radiative state with a typical activation energy. The dynamic recombination and quenching processes can be described as:

$$\frac{dn}{dt} = -\frac{n}{\tau} - \sum_i \frac{n}{\tau_i} \exp(-\Delta E_i/k_B T) + G \quad (4)$$

where  $n$  is the density of bound exciton,  $\tau$  is the bound exciton radiative recombination lifetime,  $\tau_i$  is the effective scattering time from the radiative state to the  $i$ th non-radiative state,  $\Delta E_i$  is the thermal activation energy and is related to the energy difference between the radiative state and the  $i$ th nonradiative state, and

$G$  is the carrier generation rate. In steady-state conditions (i.e., the generation rate is uniform with time and  $dn/dt = 0$ ), we have:

$$n(T) = \frac{G\tau}{1 + \sum_i \frac{\tau}{\tau_i} \exp(-\Delta E_i/k_B T)} \quad (5)$$

The intensity of the bound exciton emission  $I(T)$  is proportional to  $n(T)$  and thus has the same equation as above. This equation has been widely used to fit the experimental results and gives valuable information related to the nonradiative channels. For example, a neutral acceptor bound exciton  $A^0X$  can be thermally dissociated into:<sup>[5]</sup> 1)  $A^0 + X$ , which has a typical activation energy  $E_{AX}$ ; or 2)  $A^0 + e + h$ , which has a typical activation energy of  $E_{AX} + E_X$ ; or to 3)  $A^-X + h$ , which has an activation energy of  $E_{AX} + E_X - E_{A^0e}$ ; or to 4)  $A^- + h + h + e$ , i.e., fully ionized which has a much larger activation energy. In a temperature-dependent photoluminescence (PL) study of the  $A^0X$  transition in GaAs, through fitting the PL intensity, two non-radiative channels were identified in different temperature regions. For free excitons, the quenching is mainly due to the thermal dissociation of excitons into free carriers. The intensity can be described with single activation energy:

$$I(T) = I(0) / [1 + C \exp(-\Delta E/k_B T)] \quad (6)$$

where  $I(0)$  is intensity at 0 K,  $C$  is related to  $\tau/\tau_n$ , where  $\tau_n$  is non-radiative recombination lifetime,  $\tau$  is radiative recombination lifetime and usually  $\propto T^{3/2}$  for free exciton in bulk materials.<sup>[6]</sup>  $\Delta E$  is the thermal activation energy and is related to the free excitonic binding energy. When both free and bound excitons contribute to the emission spectra, with an increase in temperature, the bound excitons may be dissociated into free excitons, in this case, the density of free excitons will increase and an increase in the intensity of the free exciton emission would be expected. This has been observed in some high-purity semiconductors.<sup>[7]</sup>

The line width of the excitonic emission (or absorption) contains two contributions: the inhomogeneous broadening and the homogeneous broadening.<sup>[8]</sup> This can be described as:

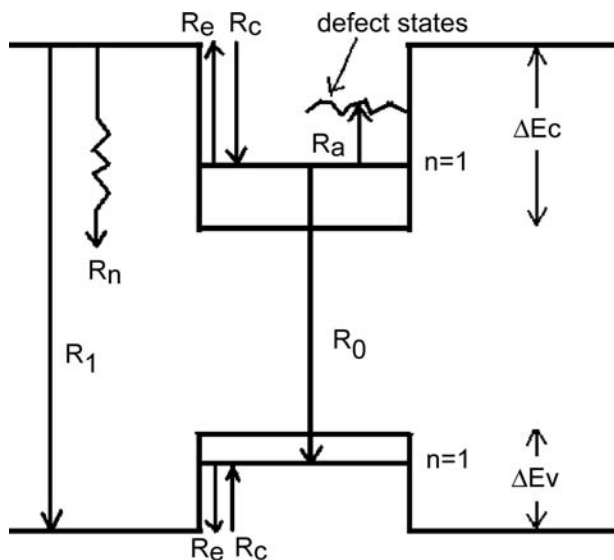

$$\Gamma(T) = \Gamma_0 + \gamma_{ph} T + \Gamma_{LO} N_{LO} \quad (7)$$

where  $\Gamma_0$  is the inhomogeneous line width due to the exciton–exciton, exciton–carrier interaction, and to scattering by defects and impurities, and, in alloy materials, by alloy composition fluctuations. The second term,  $\gamma_{ph} T$ , is due to acoustic phonon scattering. The quantity  $\gamma_{ph}$  represents the exciton–acoustic phonon

coupling strength. The  $T$  in  $\gamma_{\text{ph}}T$  is a result of the linear dependence of the acoustic phonon occupation number on the temperature  $T$ . The third term is the line width due to longitudinal-optical (LO) phonon scattering.  $\Gamma_{\text{LO}}$  is the exciton-LO phonon coupling strength, and  $N_{\text{LO}} = 1/[\exp(\hbar\omega_{\text{LO}}/kT) - 1]$  is the LO phonon occupation number. The values  $\gamma_{\text{ph}}$  and  $\Gamma_{\text{LO}}$  in quantum well or quantum-dot heterostructures are different because of the difference in the exciton-phonon coupling strength.

### THERMAL EFFECTS ON RECOMBINATIONS IN SIMPLE CONFINED SYSTEMS

In contrast to bulk materials, the thermal quenching of the emission in quantum-confined low-dimensional systems is more complicated. A schematic diagram of the emission and thermal activation processes is shown in Fig. 1. Usually, electrons and holes are created mainly in the barriers and are immediately captured into the confined electron and hole states in the quantum dot or quantum well with a large capture rate  $R_c$ . They also have a rate,  $R_1$ , to recombine radiatively, and  $R_n$  to recombine nonradiatively in the barriers. Once the electron and hole are captured in the confined states, they have several ways to recombine: 1) they

**Fig. 1** Schematic diagram of the emission and thermal activation processes in a single quantum confined system.  $\Delta E_c$  and  $\Delta E_v$  are the conduction and valence band offsets, respectively,  $n = 1$  is the first confined electron or hole states, and  $R_c$  is the electron or hole capture rate.  $R_e$  and  $R_a$  are the rates for thermal activation of carriers from  $n = 1$  confined states into barriers and defect states, respectively.  $R_1$  and  $R_n$  are the radiative and nonradiative recombination rates, respectively, in the barrier.  $R_0$  is the radiative recombination rate in the quantum-confined structure.

have a rate  $R_0$  to recombine radiatively; or 2) they have a rate  $R_e$  to be thermally activated back into barriers; or 3) they have a rate  $R_a$  to be thermally activated into a nonradiative defect state. Generally, Eqs. (4) and (5) can still be used to describe the radiative and non-radiative recombination in such low-dimensional systems. The non-radiative channel through the non-radiative defect states in the confined structures is different from that in bulk materials.<sup>[9]</sup> The reason is that the energy level of these defect states depends on the degree of localization, which is determined through the ratio between the extension of the defect wave function and the size of the confined structures. In case of weak localization, i.e., the extension of the defect wave function is comparable or larger than the size of the confined structures, the energy levels of the defect are quantized and depend on the size of the confined structures and also upon the position of the defect in the confined structures. On the other hand, in the strong localization case, the energetic difference in the conduction and valence bands of the bulk material is unchanged, and, as a consequence, the energetic distance between the defect energy level and the electron and hole subbands becomes a function of the size of confined structure as the quantization of the subbands depends on the size. For the thermal activation of carriers from confined states into the barrier states, two mechanisms have been reported. One is a bipolar activation process,<sup>[10]</sup> where the electron and hole are simultaneously activated into the barriers with a thermal activation energy equal to the energy difference between the emission peak and the barrier bandgap. The other is unipolar activation,<sup>[11]</sup> where the less-confined carrier electron (or hole) is thermally activated into the barrier with an activation energy close to the energy difference between the electron (or hole) confined state and the conduction (or valence) band states in barriers.

### THERMAL EFFECTS ON RECOMBINATIONS IN QUANTUM DOTS

The recombination and the thermal activation processes described above are very simple as the confined structures are isolated and carrier dynamics between ensembles of various-sized confined structures is not considered. Recently, successful fabrication of SAQDs through the S-K growth mode, typically with area density in the range of  $10^9$  to  $10^{11}$   $\text{cm}^{-3}$ , has been widely reported in many III/V, II/VI, and IV/IV semiconductor systems. However, because of the random statistical nature of the nucleation process, the grown QDs have a fluctuation in size. Gaussian distributions, bimodal distributions, or broad size distributions have been reported in different QD systems or under

different growth conditions. Such distributions in size have a great influence on the luminescence properties of QDs and make the carrier recombination in QDs difficult to understand. In the past years, temperature-dependent luminescence of SAQDs has been investigated in many semiconductor systems, such as InAs/AlGaAs,<sup>[12–18]</sup> ZnSe/ZnS,<sup>[19]</sup> CdTe/ZnTe,<sup>[20]</sup> and CdSe/ZnSe,<sup>[21–23]</sup> however, there is still no general agreement upon the thermal effects on the recombination processes in QDs. Generally, three characteristic features are observed in these QD systems: 1) the luminescence peak undergoes a red shift with temperature much faster than that of the bandgap of the bulk material; 2) the peak line width shows an unusual decrease with temperature in an intermediate temperature region; and 3) the luminescence at lower energies quenches much slower than that at higher energies, and in some cases, an enhancement in the luminescence of lower energies with temperature is observed. These features can be clearly seen in a temperature-dependent cathodoluminescence (CL) study of InP/In<sub>0.5</sub>Al<sub>0.5</sub>P QDs grown by low-pressure metal organic chemical vapor deposition (MOCVD).<sup>[24]</sup> The spectra are shown in Fig. 2. Obviously, a decrease in the CL intensity with temperature is observed. The inset of the figure shows an Arrhenius plot of the integrated CL intensity as a function of  $1000/T$ . By using Eq. (6), the thermal quenching at high temperature can be well fitted with an activation energy of  $\sim 150$  meV. This value is much smaller than the energy difference between the bandgap of In<sub>0.5</sub>Al<sub>0.5</sub>P and the CL peak ( $\sim 0.43$  eV) and is

very close to the difference in the conduction band energies, which suggests that unipolar escape of electrons from QDs is a likely mechanism being responsible for the thermal quenching of CL at high temperature.<sup>[11]</sup> Accompanying the quenching of the total CL emission, the CL intensity of the lower-energy tail is, in fact, on the increase with temperature until 200 K. This unusual increase will be discussed later below. Furthermore, the CL peak shows a large red shift and an unusual decrease in CL line width. The CL peak energy and the full width at half maximum vs. temperature are plotted in Fig. 3. The measured red shift amounts to about 160 meV in the temperature range of the experiment, significantly larger than that of bulk InP bandgap (dashed line in the figure). As shown in Fig. 3, the CL line width also shows an unusual behavior. Unlike the usually observed homogeneous broadening described by Eq. (7), the line width decreases first then increases with temperature with a dip around 200 K. These unusual properties were not observed in the temperature-dependent PL study of single QDs,<sup>[25,26]</sup> where the PL of a single QD is very narrow at low temperatures. With an increase in the temperature, the PL peak shifts as the bandgap does, the line width increases and can be described by Eq. (7).

The anomalous temperature-dependent PL was first observed in InAs/GaAs QDs.<sup>[12]</sup> Possibly because of the lower quality of InAs QDs on GaAs, an enhancement in the luminescence of lower energies was not observed in this report. The anomalous PL

**Fig. 2** Temperature-dependent CL spectra of InP/InAlP QDs. The electron beam current and voltage were 8 kV and 600 pA, respectively. The temperature for each spectrum is indicated in the figure. The inset of the figure shows an Arrhenius plot of the integrated CL intensity as a function of  $1000/T$ , where  $T$  is the temperature.

**Fig. 3** The energy and the full width at half maximum (FWHM) of the CL peak of InP/InAlP QDs as a function of temperature. The dashed line shows the temperature dependence of the InP bulk bandgap energy.

was interpreted as carrier tunneling between nearby dots. When the thermal energy becomes comparable to the exciton binding energy, the exciton will be ionized and the free electron and hole in small QDs will tunnel into large QDs very quickly. As a result, a large red shift and a narrowing line width would be expected. However, as the tunneling probability depends on the distance between QDs and the exciton binding energy depends on the QD size, there is no clear evidence to document the QD size and the QD density dependencies. This model was not considered in later studies. Instead of this model, a new model based upon the difference in the thermal activation energy between dots of different sizes was later proposed to interpret similar observations.<sup>[14,19]</sup> In this model, the quenching mechanism was thought to be the thermal activation of electrons and/or holes out of the QDs into barriers, or into the wetting layer (as a result of S-K growth mode), or into upper localized defect states, where they recombine non-radiatively. In this case, the thermal activation energy depends on the confining potential or the energy difference between the QD level and the defect level. With an increase in the temperature, the carriers in the smallest QDs, whose ground-state energies are the closest to that of the barrier or the defect states, would first be ionized. Indeed, this ionization would lead to a line width narrowing and a large red shift of the PL of QDs. In another report, a competition of recombination between the ground- and excited-electron and hole states<sup>[18]</sup> was thought to be the mechanism responsible for the anomalous temperature-dependent PL. In this model, instead of coming from the small QDs, the higher-energy part of the broad PL peak was assumed

to come from the electron- and hole-excited states transition. All these models cannot give rise to an increase in intensity of luminescence of large QDs with an increase in temperature. To account for this, a model of thermally activated carrier transfer from small dots to large ones was proposed.<sup>[15,16,22]</sup> The quenching mechanism is still the thermal activation of electrons and/or holes out of the QDs into barriers or wetting layer. The activation energy is therefore large for large QDs. Because of the high quality of the barrier material, those thermally activated carriers will not all recombine non-radiatively in barriers but have certain chance to be recaptured by the QDs. In an intermediate temperature range, the recapture process would overwhelm the thermal activation process in large QDs and an enhancement in luminescence of large QDs with temperature would be observed.

The fact that the thermal activation of carriers in smaller QDs is easier can be visualized in a temperature-dependent CL imaging study of InP/In<sub>0.5</sub>Al<sub>0.3</sub>Ga<sub>0.2</sub>P QDs grown by MOCVD with a high V/III precursor flow ratio.<sup>[27]</sup> The QDs grown under this condition show a distinct bimodal distribution in size with small QDs of height  $\sim 4$  nm and diameter  $\sim 50$  nm, and large QDs of height  $\sim 9$  nm and diameter  $\sim 70$  nm. The density of small QDs is  $\sim 100 \mu\text{m}^{-2}$  and of large QDs  $\sim 1 \mu\text{m}^{-2}$ . Fig. 4 shows the CL images measured at 75 and 295 K in a scanning electron microscope fitted with

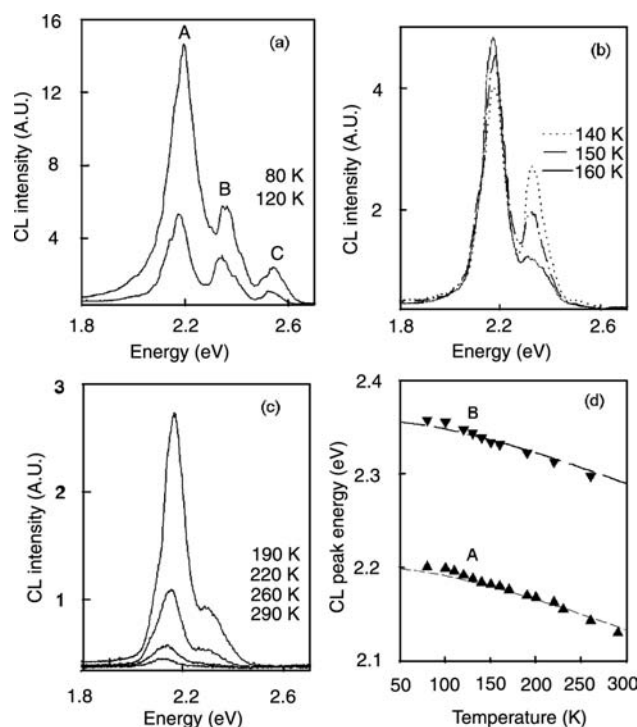

**Fig. 4** Cathodoluminescence images of an InP/InAlGaP QD sample. Images (A) and (B) are monochromatic images measured from the same area at 75 K, monitored at 1.87 and 1.73 eV, respectively. (C) and (D) are panchromatic and monochromatic CL images measured from the same area at 295 K. Image (D) is monitored at the CL peak 1.67 eV. Electron beam voltage was 8 kV and beam currents for images (A)–(D) were 300 pA, 600 pA, 100 pA, and 1 nA, respectively.

a CL system. Fig. 4A and 4B shows monochromatic CL images measured at 75 K, monitored at the CL peak 1.87 and 1.73 eV, respectively. Image (A) is very uniform, suggesting that the CL monitored at the peak comes mainly from the high-density small QDs, which are spatially uniformly distributed. Relatively, image (B) is non-uniform with some bright spots whose density is close to  $1 \mu\text{m}^{-2}$ . This suggests that the CL of lower energy comes from low-density large QDs. With an increase in temperature, the CL of small QDs gets weaker, while relatively, the CL of large QDs gets brighter. This can be clearly seen in a room-temperature panchromatic CL image (C), where the CL of large QDs is much brighter than the surrounding CL coming from high-density small QDs. Fig. 4D is a room-temperature monochromatic CL image, measured from the same area as image (C) and monitored at the peak 1.67 eV. A comparison of images (C) and (D) shows that the bright spots in the two images almost have the same corresponding positions. Therefore the room-temperature CL comes mainly from the low-density large QDs. Because of the large activation energy for these large QDs, the thermal activation of carriers out of the QDs is weak, and relatively, the CL of these large QDs is getting brighter and brighter with an increase in temperature.

## THERMALLY ACTIVATED CARRIERS TRANSFER BETWEEN QUANTUM DOTS

Evidence of thermally excited carrier transfer between QDs of different size comes from the temperature-dependent CL study of a few QDs. Fig. 5A to C shows the spot-mode CL spectra of CdSe QDs grown on ZnSe by MOCVD. The temperature for each spectrum is indicated in the figure. The calculated generation range, using the Kanaya–Okayama model,<sup>[28]</sup> is about  $0.8 \mu\text{m}$  in ZnSe, at the electron beam voltage of 10 kV used. Thus, in the spot-mode CL, the estimated excitation area is only  $0.5 \mu\text{m}^2$ . The number of dots examined by CL is estimated to be about 100. As this is much smaller than in the case of the area scan, the CL spectra are resolved into a series of sharp peaks now. As is labeled as peaks A, B, and C in Fig. 5A, the energies of the three prominent peaks are at roughly 2.20, 2.36, and 2.55 eV, respectively. A spot-to-spot CL measurement shows that the three peaks, A, B, and C, are most probably a result of the transitions in QDs of different sizes, and not of the transitions involving an excited state. An alternative origin of peak C is the CdSe flat islands<sup>[21]</sup> or the CdSe wetting layer<sup>[23]</sup> resulting from the S–K growth mode, as its energy is very close to what is expected.

**Fig. 5** (A)–(C) display the spot mode temperature-dependent CL spectra of the CdSe/ZnSe QDs. The temperature at which the spectrum was obtained is indicated in ascending order, corresponding to the top-down sequence of peak B in the spectra presented. The electron beam voltage and beam current were 10 kV and 1 nA, respectively. (D) shows the energies of peaks A and B as a function of temperature. The dash lines are lines that have the same temperature dependence as CdSe bulk band gap. *Source:* From Ref.<sup>[22]</sup>.

The evolution of the CL intensity with temperature can be divided into three characteristic regions. Below 140 K and above 170 K, the three peaks, A, B, and C, decrease in intensity with temperature. Between 140 and 170 K, peak A increases while peaks B and C decrease with temperature. Such an evolution of CL peaks with temperature is evidently responsible for the unusually large red shift and narrowing of the broad CL peak measured from a large area. The CL energies of peaks A and B, as a function of temperature, are shown in Fig. 5D. The two energies now follow the bandgap of bulk CdSe material very well. Peak C becomes too weak to follow, except at very low temperatures, and its energy is not plotted.

The above results strongly suggest that thermally activated carrier transfer between QDs of different sizes is important at intermediate temperatures (140–170 K). Such a transfer results in an increase in the intensity of the lower-energy peaks at the expense of the higher-energy ones. With an increase in the temperature, more and more of the photo-generated carriers in the QDs would be thermally activated into the barriers or the wetting layer. Before they recombine, either radiatively or non-radiatively, some of these activated carriers would be recaptured. A transfer of carrier results when the capturing is by another nearby QD. The difference in activation rates between QDs of different sizes causes a net transfer of carriers from small to large dots and results in a concurrent decrease in the intensities of the higher-energy CL peaks and an increase in those of the lower-energy peaks.

To better understand the carrier dynamics in CdSe QDs, we consider the rate Eq. (4). We assume that the carrier capture rate is large and independent of QD size. Furthermore, as the CL spectra in Fig. 5 are dominated by two peaks, A and B, a bimodal distribution in QD size is assumed here. Including the weaker peak C only adds to the complexity of the equations but does not change the physical outcome of the model. The modified rate equations are then given by:

$$\frac{dn_s}{dt} = N_s G - n_s(R_s + R_{se}) + n_l R_{le} \quad (8)$$

$$\frac{dn_l}{dt} = N_l G - n_l(R_l + R_{le}) + n_s R_{se} \quad (9)$$

where  $G$  is the generation rate,  $N$  the area density of QDs,  $n$  the density of carriers in QDs,  $R$  the recombination rate of carriers in QDs, and  $R_e$  the thermal activation rate of carriers from the QDs. The subscripts  $s$  and  $l$  refer to the small and large QDs, respectively. If we further assume that the carrier recombination rate does not depend on the size of QDs, i.e.,

$R_s = R_l = R$ , then the steady-state carrier density in the QDs becomes:

$$n_{s(l)} = \frac{GN_{s(l)}}{R} \frac{[R + (1 + N_{l(s)}/N_{s(l)})R_{le(se)}]}{R + R_{se} + R_{le}} \quad (10)$$

Although  $R$  is somewhat temperature dependent, especially through the non-radiative recombination processes, the temperature dependence of the carrier density is dominated by that of the activation rates  $R_{se(le)}$ , which can be taken as proportional to  $\text{Exp}(-\Delta E_{s(l)}/kT)$ , where  $\Delta E_s$  and  $\Delta E_l$  are the activation energies of the small and large QDs. Because of the quantum-confinement effect, activation from a state of a small QD would be easier than from a corresponding state of a large QD, so we expect  $\Delta E_s < \Delta E_l$ . The difference  $\Delta E = \Delta E_l - \Delta E_s$  is responsible for the temperature evolution of the CL peak intensities shown in Fig. 5A to C.

At low temperatures, such that  $\Delta E \gg kT$ , the activation rates are small compared to the recombination rate. Moreover, there is negligible transfer of carriers between the QDs of different sizes, and recombination occurs independently, so we have:

$$n_{s(l)} = \frac{GN_{s(l)}}{R} \quad (11)$$

An increase in temperature simply increases the non-radiative recombination rate, which is responsible for the slight decrease in the CL intensities of all peaks [Fig. 5A]. At intermediate temperatures, such that  $\Delta E \approx kT$ , the difference in transfer rates is large and a net transfer of carriers from small QDs to large ones occurs. We have:

$$n_s = \frac{GN_s}{R} \left( 1 - \frac{R_{se}}{R + R_{se}} \right) \text{ and} \\ n_l = \frac{GN_l}{R} \left( 1 + \frac{N_s R_{se}/N_l}{R + R_{se}} \right) \quad (12)$$

which clearly shows that the steady-state carrier density in the large QDs increases at the expense of the small ones. Moreover, the effect of this transfer on the steady-state carrier density depends strongly on the ratio  $R/R_{se}$ . When the activation rate is comparable to the recombination rate, the densities are strongly affected, resulting in an increase in the CL intensity of the low energy peak [Fig. 5B]. In cases where  $R/R_{se}$  are small, the luminescence would be dominated by radiative recombination within the large QDs only. At high temperatures, such that  $\Delta E \ll kT$ , the difference in activation rates is small, there is no net transfer, and we have:

$$n_{s(l)} = \frac{GN_{s(l)}}{R} \quad (13)$$

again. Just as in the low-temperature case, the intensities of the CL peaks from both the large and small QDs decrease as nonradiative recombination becomes increasingly important [Fig 5C].

The above model is very simple but can give a clear picture about thermally activated transfer of excited carriers between quantum dots. In the model, we have neglected the difference in carrier capture rates between the QDs. It has been shown that the strain-induced potential barrier at the QD/host semiconductor interface would slow down the capture of carriers into QDs.<sup>[29]</sup> Larger potential barrier would be expected at the interface of larger QDs.<sup>[30]</sup> The temperature-dependent capture rate  $C_{s(l)}$  may be taken as proportional to  $\text{Exp}(-\Delta E_{bs(b)}/kT)$ , where  $\Delta E_{bs}$  and  $\Delta E_{bl}$  are the potential barriers at the interface of small and large QDs, respectively. Considering the capture rate difference, the first and the last terms on the right side of the rate Eq. (8) should be multiplied by  $C_s$  and  $C_l$ , respectively [reversed in Eq. (9)]. As this potential barrier is found to be very small as compared to the activation energy, it is unimportant at high temperatures. At low temperatures, carriers would have more chance to be captured into the small QDs. In this way, the capture difference is similar to the activation difference at high temperatures.

## CONCLUSION

The growth of self-assembled QDs through the Stranski–Krastanow (S–K) growth mode has been realized in many III/V, IV/IV, and II/VI semiconductor systems, provided there is a large lattice mismatch in the heterostructures. Because of the defect-free nature and the strong 3-D quantum confinement effect, these SAQDs have promising applications in future optoelectronic devices such as laser diodes and photodetectors. However, most of these devices are limited to low-temperature operation. For better performance of these QD-based devices, thermal effects on the emission and absorption processes in QDs must be well understood. Therefore temperature-dependent luminescence studies of QDs have been reported in many semiconductor systems, which, generally, show the following three characteristic features in the luminescence spectra: 1) the luminescence peak undergoes a red shift with temperature much faster than that of the bandgap of bulk material; 2) the peak line width shows an unusual decrease with temperature in an intermediate temperature region; and 3) luminescence of lower energies quenches much slower than that of higher energies, and in some cases, an enhancement in the luminescence of lower energies with temperature is observed. To account for these features, various

models, such as carrier tunneling between nearby dots, difference in thermal activation energy between dots of different sizes, thermally activated carrier transfer between dots of different size, and a competition and redistribution of recombination between the ground- and excited-electron and hole states, have been proposed to interpret the observed anomalous temperature-dependent luminescence. Through the temperature-dependent CL study of high-quality InP/InAlP QDs and the spot-mode CL study of CdSe/ZnSe QDs, it has been shown that only the model of thermally activated carrier transfer between dots of different size can serve to interpret the experimental results well. The results show that with an increase in temperature, carriers in small QDs will be thermally activated into wetting layer (or barriers) first. Before they recombined, either radiatively or non-radiatively in barriers, some of these activated carriers would be recaptured by QDs. As the thermal activation of carriers in large QDs is relatively weak, a net transfer of carriers from small QDs into large ones results, which is eventually responsible for the above three features. The thermal activation process, which results in the large red shift of emission peak, the quenching of emission, and the dominant emission from large QDs at high temperatures, is not desired for device operations. How to suppress these features is very important in future studies. Temperature insensitive emission was reported in InGaAs/GaAs QDs by inserting a thin less-strained  $\text{In}_{0.3}\text{Ga}_{0.7}\text{As}$  layer just between the QDs and the upper GaAs layers.<sup>[31]</sup> The results were thought to be due to the temperature-dependent strain effect. Temperature insensitive emission was also reported in strain-engineered InGaAs quantum wire heterostructures.<sup>[32]</sup> Using strain to engineer the QD heterostructures is a promising way to develop temperature-insensitive QD emission. Recently, we found that the quantum-well and quantum-dot coupled structures, when employing optimized designs, show quite stable emission energy and line width with an increase in temperature.<sup>[33]</sup> Developing novel quantum-well and quantum-dot coupled structures is another way to stabilize the QD emission. Results have shown that the uniformity in QD size and shape is the main reason for the anomalous temperature-dependent luminescence. Obtaining QDs with a high uniformity in size, shape, and spatial distribution is very important in future work. This might be done after the growth is well understood and controlled. Relative to the emission studies, thermal effects on the intersubband absorption of QDs are quite less investigated, although it might have a great influence on the performance of QD-based infrared photodetectors. Carrier transfer between QDs of different size, and the thermal population of carriers in different energy levels in QDs are believed to have some effect on the intersubband

absorption process. This needs to be further explored in future work.

University of Maryland, College Park, Maryland, U.S.A.*

## INTRODUCTION

Thermodynamics is a keystone in engineering and science, bridging the gap between fundamentals and applications. However, when one compares the content of traditional courses in thermodynamics with what engineers often do in practice, one notices a gap and the gap is widening every year. New emerging technologies and products deal with subjects such as biomembrane and gene engineering, microreactor chemistry and microcapsule drug delivery, microfluids and porous media, nanoparticles and nanostructures, supercritical-fluid extraction and artificial organs. Engineers often must design processes for systems where classical thermodynamics (in particular, the Second Law) becomes insufficient, as in the case of strongly fluctuating and nanosize systems, or dissipative systems under conditions far away from equilibrium. Mesoscopic thermodynamics can be defined as a semiphenomenological approach to phenomena in systems where a length—intermediate between the atomistic scale and the macroscopic scale—emerges and where such a length explicitly affects the thermodynamic properties and phase behavior. Finite-size and fluctuation thermodynamics, critical phenomena in fluids and solids as well as in soft-matter materials (such as complex fluids), wetting and interfacial phenomena, self-organized criticality and dissipative structures, thermodynamics of pattern formation and fractals are examples of topics addressed in mesoscopic thermodynamics (equilibrium and non-equilibrium). While conventional methods of statistical mechanics remain the fundamental background of mesoscopic thermodynamics, coarse-grained approaches emphasizing universality rather than microscopic details, such as the Landau–Ginzburg local free-energy functional, can be successfully applied to describe what seem to be very different phenomena on mesoscales: from critical fluctuations to near-surface and interfacial density profiles, from micelles and microemulsions to porous media, from thin layers to nanoparticles. For this purpose, one can utilize a number of powerful theoretical concepts, such as renormalization-group theory, finite-size scaling, percolation theory, and coupling between

different order parameters so as to predict the properties at meso- and nanoscales.

## WHAT IS “MESOSCOPIC THERMODYNAMICS”?

Is traditional (macroscale) thermodynamics sufficient to deal with systems and processes mentioned above? Can one apply without restriction the laws and equations of classical thermodynamics to calculate chemical reaction equilibrium and design a microreactor with reaction space of only 100 nm thick, or describe the solubility of a protein molecule in a cell and its transport through a biomembrane? What is the definition of a phase in such systems? All biological cells are natural microreactors.<sup>[1]</sup> Can we still use the concepts of chemical potential, osmotic pressure, surface tension, etc. for such objects? A microchip can contain only hundreds of atoms. What is the limiting size for which thermodynamics is still applicable? In a microporous medium, not only does the surface energy dominate over the bulk energy, but also the surface itself can be poorly defined. Is still there room for thermodynamics there, beyond trivial mass and energy balances?

Classical thermodynamics is essentially macroscopic. To define thermodynamic states and thermodynamic properties, one needs systems with a huge number of individual particles, such as atoms or molecules. Statistical mechanics defines thermodynamic states and properties only in the so-called “thermodynamic limit”: the volume ( $V$ ) and the number of particles ( $N$ ) must tend to infinity, while the density of the substance,  $\rho = N/V$ , remains finite. Even 1 mm<sup>3</sup> of liquid water (1 mg) contains  $3 \times 10^{19}$  molecules. It is quite sufficient to regard such a small droplet of water as a macroscopic body and neglect surface effects in considering its bulk properties. If the characteristic size of the object is  $L$ , the surface energy is proportional to  $L^2$ , while the bulk energy is proportional to  $L^3$ . This is why one can measure the temperature of steam condensation and the vapor pressure in a small tube and use the data in design of an upscale distillation column that is 100 m high. Macroscopic thermodynamics eliminates

the size of the system by reducing the extensive thermodynamic properties, which depend on size, by the number of particles, number of kilograms, or by volume. Equations of thermodynamics usually operate with intensive properties, such as density, concentration, molar or specific volume, etc. which do not depend on size. The actual length scale is restored only in the stage of engineering design.

*Mesoscopic and nanoscale thermodynamics* is designed to fill the gap between the macroscopic and truly microscopic (atomistic) worlds. This field of science (“mesothermodynamics”) can be defined as a semiphenomenological approach to systems and phenomena in which a length—intermediate between the atomistic scale and the macroscopic scale—emerges and where such a length explicitly affects the thermodynamic properties. This science is still thermodynamics as its objects are still governed by statistical physics but, in contrast to “macrothermodynamics,” it explicitly contains a mesoscopic length scale associated with the structure of materials. It also includes thermal fluctuations, which emerge in the apparent violation of the Second Law. Typical models of mesothermodynamics are coarse-grained models that do not have to account for every detail on the atomic scale.<sup>[2]</sup> Instead, such models emphasize universality. For example, the behavior of many polymer solutions is often determined not by the particular structure of the monomer units, but by the fact that the polymer molecule is a long, flexible curve in three-dimensional space that cannot be crossed by other polymer molecules.

### “THINNER THAN A HAIR”

One can consider a length scale less than  $100\ \mu\text{m}$  as *mesoscopic*.  $100\ \mu\text{m}$  is a thickness of human hair (Fig. 1), and usually a microscope, optical or electronic, is needed to see objects smaller than that. Below  $1\ \mu\text{m}$ , one enters a *submicron* world. Between  $1$  and  $100\ \text{nm}$ , a size can be called *nanoscopic*. Any classification is conditional and approximate: sometimes “thinner-than-a-hair” objects can be treated macroscopically and some properties of larger objects may require a mesoscopic approach. There are three categories of popular objects in mesothermodynamics:

1. Soft condensed-matter materials such as complex fluids (polymer solutions, polymer melts, microemulsions, foams, gels, colloidal dispersions, liquid crystals).<sup>[2–7]</sup> Most food and cosmetics is soft matter. Humans (like other living organisms) are “soft machines.” The common feature of all soft condensed-matter systems is the existence of a (or more than one) *mesoscopic length scale*.

**Fig. 1** Scanning electron microscope (SEM) image of  $3.4\text{-}\mu\text{m}$  polystyrene particles on human hair. *Source:* Courtesy of Spherotech, Inc.

2. Systems that are essentially *finite* (practically speaking, of submicron- or nanosize) at least in one dimension.<sup>[8–10]</sup> Examples include nanoparticles (if the particle is considered as a separate system), pores, films and layers, strings and threads. Sometimes such systems can be truly microscopic (atomistic length scale) in a certain dimension and they can thus be treated as two- or even one-dimensional.
3. Systems in a *near-critical state* (i.e., in the vicinity of critical or second-order phase-transition points).<sup>[11–13]</sup> Such systems are mesoscopically inhomogeneous, i.e., like complex fluids, they possess a mesoscopic length scale, known as the “correlation length,” diverging at the critical point. As this correlation length is associated with spontaneous *thermal fluctuations*, the inhomogeneities are not real particles; they are loose clusters, statistically appearing and disappearing, and so have a finite (but diverging at the critical point) lifetime. As fluctuations exist in violation of the Second Law of thermodynamics, the near-critical state is close to instability and thus very fragile. Spectacular effects associated with diverging critical fluctuations are called “critical phenomena.”

The approach to introduce a mesoscale in thermodynamic properties goes back to van der Waals,<sup>[14]</sup> and is sometimes called “quasi-thermodynamics,” “local thermodynamics,” or “point-thermodynamics.”<sup>[15]</sup> Representation of a microheterogeneous system as an “ensemble” of small open systems was introduced and elaborated by Hill.<sup>[16]</sup> Many ideas and concepts of mesoscopic thermodynamics were developed and explored in colloid and interface science long ago.<sup>[17,18]</sup> However,

only recently has a high degree of *universality* (and thus “simplicity”), originating from the very existence of the mesoscopic length scale, been recognized. Furthermore, such powerful theoretical approaches as finite-size scaling, renormalization-group theory, percolation, and self-organized criticality have now become fully applicable to the variety of phenomena at mesoscales.

## ROLE OF FLUCTUATIONS

An important feature of a mesoscopic object that is commonly neglected in traditional thermodynamics is the effect of thermal fluctuations. Thermodynamics is based on two fundamental laws, the First Law and the Second Law. The First Law is the law of conservation of energy; it is exact and can be equally applied to any system regardless of size. The Second Law is a purely statistical law. It states that the entropy of an isolated system never decreases. The entropy always increases in irreversible processes and reaches its maximum in equilibrium. The asymmetric character of entropy is directly associated with the asymmetric nature of time: the past and the future of an isolated system are different if the entropy values are different. In statistical physics (see, e.g., Refs.<sup>[19,20]</sup>), entropy is defined as

$$S = k_B \ln W \quad (1)$$

where  $k_B = 1.381 \times 10^{-23}$  J/K is Boltzmann’s constant,  $W$  is the statistical weight—the number of possible microscopic states that realize the given macroscopic state (given volume, temperature, concentration, etc.). The larger the number of possible microscopic states—the larger the disorder—the higher the entropy. However, in any thermal (containing a large number of particles) system, the chaotic motion of particles leads to spontaneous deviations of locally defined properties (at any point of the system) from their average equilibrium values. Such deviations are known as *fluctuations*. As the fluctuations mean spontaneous deviations from equilibrium, they lead to local decrease of the entropy and thus exist in apparent violation of the Second Law of thermodynamics. A fluctuation will reduce the total entropy of the system, hence the probability,  $w$ , of fluctuation is

$$w \propto e^{\Delta S/k_B} \quad (2)$$

The mean square fluctuations of a density-like variable (“order parameter”)  $\varphi$  at temperature  $T$  are proportional to a generalized susceptibility  $\chi$ :

$$\langle(\Delta\varphi)^2\rangle = \frac{k_B T}{V} \chi \quad (3)$$

The smaller the volume,  $V$ , under consideration—the larger the fluctuations. In two-dimensional (planar)

systems, fluctuations are stronger. In one-dimensional (linear) systems, fluctuations are so strong that they destroy any long-range order.<sup>[19]</sup> The generalized susceptibility  $\chi$  is the inverse second derivative of the free energy with respect to  $\varphi$ . Depending on the system, it can be the isothermal compressibility (fluids), osmotic compressibility (fluid mixtures), magnetic or electric susceptibility, etc. while the order parameter will be associated with the density, concentration, magnetization, or polarization, respectively, or with another “density-like” variable. For example, the mean-square fluctuations of density,  $\rho$ , is given by

$$\langle(\Delta\rho)^2\rangle = \frac{k_B T}{V} \rho \left( \frac{\partial \rho}{\partial P} \right)_T \quad (4)$$

( $P$  denotes the pressure).

Another example is a fluctuation deviation from verticality in a micropendulum with a mass  $m = V\rho$ . The thermal collisions of the molecules in the medium with the pendulum cause random fluctuations in the angle  $\theta$  of suspension with length  $l$  (the equilibrium value of  $\theta$  is zero).<sup>[19]</sup>

$$\langle\theta^2\rangle = \frac{k_B T}{V\rho g l} \quad (5)$$

with  $g$  being the free-fall acceleration. The mean square fluctuation in the bending angle of the suspension thread is

$$\langle\gamma^2\rangle = \frac{l k_B T}{K} \quad (6)$$

with  $K$  being proportional to the bending elastic constant. In the above two examples, the susceptibilities are  $\chi = 1/(\rho g l)$  and  $\chi = (lV)/K$ , respectively.

## BUILDING A NANOPARTICLE

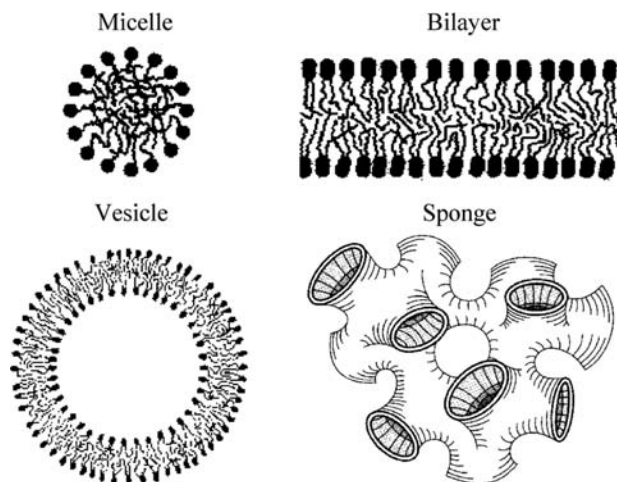

One of the ways to create a nanosize particle is to use amphiphilic molecules (surfactant) dissolved in water.<sup>[21]</sup> Two simple arrangements allow the tails to be away from the water: spherical *micelles* and a bilayer (Fig. 2). Biological membranes are double layers. A closed surface of a bilayer with the hydrophobic tails screened by the hydrophilic heads is known as a *vesicle*.

Suppose that we are interested in building a mono-disperse population of nanoparticles with a stable aggregation number  $m$ . The equilibrium fraction,  $\phi$ , of amphiphilic molecules in micelles or vesicles<sup>[2,18,22]</sup>

$$\phi = m[(x - \phi)f]^m \quad (7)$$

$$f = \exp\left(\frac{\mu_s(m=1) - \mu_s(m)}{k_B T}\right) \quad (8)$$

**Fig. 2** Possible arrangements of amphiphilic molecules in aqueous solutions.

(with  $x$  being the total concentration of amphiphilic molecules) assumes that all micelles (or vesicles) have the same (optimal) aggregation number. The fluctuation deviation of the surfactant chemical potential,  $\mu_s$ , from its optimal value may be written as

$$\Delta\mu_s = \mu_s(n) - \mu_s(m) = \frac{1}{2}K(n - m)^2 \quad (9)$$

The coefficient  $K$  is a response function ( $\chi = 1/\rho K$  serves as the susceptibility, similar to the compressibility or elasticity). For large  $m$ , Eq. (9) leads to a Gaussian mean-square fluctuation:

$$\langle (n - m)^2 \rangle = \frac{k_B T}{V} \chi = \frac{k_B T}{mK} \quad (10)$$

The larger the aggregation number—the sharper the micellization and more stable the aggregate. Spontaneously formed nanosize spherical vesicles [like those formed from some two-tailed amphiphilic molecules such as didodecyldimethylammonium bromide (DDAB)]<sup>[23]</sup> are usually more mono-disperse than spherical micelles, because the vesicle aggregation number is larger and the bilayer is less fragile (due to the two-tail structure,  $K$  is larger). At larger concentration of surfactant, aggregates of various shapes can be formed, such as worm-like micelles, onion-like bilayers (Fig. 3), or a bicontinuous “sponge” phase (Fig. 2). In such objects, fluctuations of the shape become important.

## CRITICAL PHENOMENA

Near a critical point of any kind (in fluids and fluid mixtures, near the Curie point in ferromagnetics, near the superfluid transition in liquid helium, near the

**Fig. 3** SEM micrographs of replicas from DDAB aqueous solutions: (A)  $5 \times 10^{-5}$  mol/L; (B)  $8 \times 10^{-4}$  mol/L. Source: From Ref.<sup>[23]</sup>.

second-order phase transitions in liquid and solid crystals), the fluctuations of the appropriate order parameter become so large and they live so long that they fully determine the macroscopic behavior, both of equilibrium and non-equilibrium properties. In other words, the macroscopic properties can be explained and calculated through the fluctuational mesoscopic length-scale. This is why the thermodynamics of critical phenomena is essentially mesoscopic.

Experimentally, it has been well established that asymptotically close to the critical point, all physical properties obey simple power laws (known as “scaling laws”)<sup>[11–13]</sup> (Fig. 4). The universal powers in these laws are called *critical exponents*. In all fluids and

**Fig. 4** Heat capacity at constant pressure,  $C_p$ , near the lower critical consolute point of 2,6-lutidine aqueous solution at the critical composition. (From Ref.<sup>[29]</sup>.) The solid curve corresponds to Eq. (13) with  $\alpha = 0.11$ . Note that in liquid mixtures,  $C_p$  has the same anomaly as  $C_v$  in one-component fluids. (From Ref.<sup>[13]</sup>.)

fluid mixtures, the critical exponents for analogous properties are the same numbers. The theory that explains the power laws is called *scaling theory*. The theory that calculates the universal critical exponents is known as *renormalization-group theory*.<sup>[12]</sup> The physical principle that governs the nature of critical phenomena is called the *critical point universality*. The physical background for the scaling and renormalization-group theory is the divergence of a mesoscopic characteristic length-scale—the size of fluctuations of the order parameter. Accurate scattering experiments have shown that the correlation length of fluctuations diverges at the critical point of a fluid as

$$\xi = \xi_0 \varepsilon^{-\nu} \text{ with } \nu = 0.63 \pm 0.01 \quad (11)$$

Here  $\xi_0$  is the range of intermolecular interactions and  $\varepsilon = (T - T_c)/T_c$ , the temperature distance to the critical temperature,  $T_c$ .

Let us assume that the near-critical state is a “gas” of fluctuational clusters with a mesoscopic size  $\xi$ . Then the fluctuational part of the Helmholtz energy,  $\Delta A$ , and the isochoric heat capacity per unit volume,  $\rho C_v = NC_v/V$ , read:<sup>[13]</sup>

$$\begin{aligned} \Delta A &\sim Nk_B T_c \sim \frac{Vk_B T_c}{\xi^3}, \quad \rho C_v \\ &= -T \left( \frac{\partial^2 (A/V)}{\partial T^2} \right)_V \end{aligned} \quad (12)$$

Along the critical isochore,  $\rho = \rho_c$ :

$$\rho C_v = A_0 \varepsilon^{-\alpha} \sim \frac{\varepsilon^{3\nu-2}}{\xi_0^3} \quad (13)$$

We conclude that the divergence of the correlation length is responsible for the divergence of the heat capacity, and that the critical amplitude of the heat capacity,  $A_0$ , is related to the amplitude of the correlation length (Fig. 4). Note that in the van der Waals theory, the isochoric heat capacity does not diverge at the critical point. The relations between the universal critical exponents for the space of any dimensionality,  $d$ ,

$$\alpha = 2 - d\nu \quad (14)$$

and between the system-dependent amplitudes

$$\rho_c A_0 \xi_0^d = \text{universal constant} \quad (15)$$

are known as *universal scaling relations*.

Another example of a property that can be estimated through the mesoscopic size of fluctuations scaling is the surface tension. As the surface tension vanishes at the critical point (Fig. 5), the interface

Fig. 5 Vapor–liquid surface tension of water.

becomes smooth and eventually disappears. The surface tension can be estimated as a product of the density of the Helmholtz energy

$$\frac{\Delta A}{V} \propto A_0 |\varepsilon|^{2-\alpha} \quad (16)$$

and the thickness of the interface, assumed to be equal to the correlation length,  $\xi = \xi_0 |\varepsilon|^{-\nu}$ .<sup>[13,15]</sup> Therefore taking into account Eqs. (14) and (15), we obtain

$$\sigma = \sigma_0 |\varepsilon|^{\vartheta} \propto \frac{\Delta A}{V} \xi \propto A_0 \xi_0 |\varepsilon|^{(d-1)\nu} \propto \frac{1}{\xi_0^2} |\varepsilon|^{\vartheta} \quad (17)$$

$$\vartheta = (d-1)\nu = 1.26 (\text{for } d=3) \quad (18)$$

$$\frac{\sigma_0 \xi_0^{d-1}}{k_B T_c} = \text{universal constant} \quad (19)$$

Note that in the van der Waals theory, that neglects fluctuations  $\vartheta = 3/2$ . The relations between other thermodynamic properties and the diverging correlation length can be obtained in a similar fashion.

## LANDAU–GINZBURG MESOSCOPIC FUNCTIONAL

The simplest way to introduce fluctuations or any other smooth heterogeneities in the mesoscopic thermodynamics is to consider a local (coordinate-dependent) density of an appropriate thermodynamic potential.<sup>[19]</sup> To be specific, consider the local density of the fluctuational part of the Helmholtz free energy

of a fluid with the local order parameter

$$\varphi(\vec{r}) = \frac{\rho(\vec{r}) - \rho_c}{\rho_c} \quad (20)$$

which is now spatially dependent on the position  $\vec{r}$ . In fluid binary mixtures, the order parameter will be associated with the partial density (molarity).<sup>[24]</sup> The part of the free-energy density, associated with the order parameter, thus will be defined as

$$\Delta(A/V) = \frac{k_B T}{v_0} \times \int \left[ \frac{1}{2} X[\varphi(\vec{r})]^2 + \frac{1}{2} c_0 (\nabla \varphi)^2 \right] d\vec{r} \quad (21)$$

where  $X$  is related to the inverse susceptibility as

$$\chi^{-1} = X + 2\varphi \frac{\partial X}{\partial \varphi} + \frac{1}{2} \frac{\partial^2 X}{\partial \varphi^2} \varphi^2$$

(inversely proportional to the second derivative of the free energy with respect to the order parameter),  $c_0$  is a constant associated with the range of intermolecular interactions, and  $v_0$  is the molecular volume. The expression

$$f[\varphi(\vec{r})] = \frac{1}{2} X[\varphi(\vec{r})]^2 + \frac{1}{2} c_0 (\nabla \varphi)^2$$

is known as *Landau–Ginzburg functional*. As the energy is scalar, the first non-vanishing gradient term is quadratic. Equation (21) simply states that not only a deviation from the equilibrium value of the order parameter will increase the free energy, but any fluctuational inhomogeneity represented by gradients of the order parameter will also increase the free energy and, thus, will not be thermodynamically favorable.

In mean-field (or van der Waals) approximation (valid for long-range interactions), the susceptibility is given by

$$\chi^{-1} = a_0 \varepsilon + 3u_0 \varphi^2 \quad (22)$$

and the correlation length reads

$$\xi = \sqrt{\frac{c_0}{a_0 \varepsilon}} = \xi_0 \varepsilon^{-1/2} \quad (23)$$

The constants  $a_0$  and  $u_0$  are order of unity. Note that the mean-field result ( $\nu = 0.5$ ) is in disagreement with the experimental fact ( $\nu = 0.63$ ) that is well described by the scaling theory.

## APPLICATIONS OF LANDAU–GINZBURG FUNCTIONAL

The Landau–Ginzburg functional can be used for description of a variety of phenomena on mesoscale such as interfacial phenomena, wetting transitions, near-surface density profile and adsorption, formation of microemulsions and liquid crystalline phases, spinodal decomposition, phase separation in polymer solutions and polymer blends, etc. This approach is more accurate when the local order parameter is not too much different from its macroscopic equilibrium value (smooth heterogeneities). As an example, consider the calculation of a smooth density profile in the fluid–fluid interface with the characteristic thickness  $\xi$ . The interfacial tension

$$\begin{aligned} \sigma &= \frac{d[\Delta(A/V)]}{dx dy} \\ &= \frac{k_B T}{v_0} \int \left[ \chi^{-1} \varphi^2 + \frac{1}{2} c_0 \left( \frac{d\varphi}{dz} \right)^2 \right] dz \\ &= \frac{k_B T}{v_0} \int_{-\infty}^{+\infty} \left[ c_0 \left( \frac{d\varphi}{dz} \right)^2 \right] dz \approx \frac{k_B T}{v_0} \int_{-\xi}^{+\xi} \left[ c_0 \left( \frac{\varphi_0}{\xi} \right)^2 \right] dz \\ &= 2 \frac{k_B T}{v_0} c_0 \frac{\varphi_0^2}{\xi} \end{aligned} \quad (24)$$

In this expression,  $\varphi_0$  is the equilibrium value of the order parameter in the bulk (the difference of densities or concentrations in the coexisting phases). Because of the conservation of mass through the interfacial profile:

$$\chi^{-1} \varphi^2 = \frac{1}{2} c_0 \left( \frac{d\varphi}{dz} \right)^2 \quad (25)$$

Thus in the Landau–Ginzburg functional approximation, also known as the Ornstein–Zernike approximation,

$$\chi \propto \xi^2 \text{ and } \varphi_0^2 \propto \frac{1}{\xi} \quad (26)$$

and we obtain the well-known result for the surface tension in the scaling theory [Eqs. (18) and (19)], which is valid even beyond this approximation.<sup>[15]</sup>

$$\sigma = \sigma_0 t^{\mathfrak{g}} \text{ with } \mathfrak{g} = 2\nu \text{ and } \sigma_0 \propto \frac{1}{\xi_0^2} \quad (27)$$

In the van der Waals approximation, which neglects effects of fluctuations on the macroscopic thermodynamic properties, the susceptibility is described by

Eq. (22). Hence in this approximation

$$\chi \propto \xi^2 \propto \varepsilon^{-1}, \quad \varphi_0 \propto \frac{1}{\xi} \propto \varepsilon^{1/2}, \quad \text{and } \sigma \propto \varepsilon^{3/2} \quad (28)$$

Nevertheless, the interfacial density profile obtained in the van der Waals theory,

$$\varphi(z) = \varphi_0 \tanh\left(\varphi_0 \sqrt{\frac{u_0}{2c_0}} z\right) = \varphi_0 \tanh(z/2\xi), \quad (29)$$

does not specify any particular temperature dependence and thus can serve as a reasonable approximation to describe the actual density profile (which is calculated properly only in the renormalization-group theory: see Fig. 6).

Another example of an application of the Landau–Ginzburg functional is the description of modulated and microheterogeneous phases.<sup>[25,26]</sup> If the coefficient  $c_0$  in the functional changes its sign, the next order term  $d_0(d^2\varphi/dz^2)^2$  must be added and a *modulated phase* (in  $z$  direction) with the wave number of modulation  $q_0 = (-c_0/d_0)^{1/2}$  may become stable. The inverse wave number of modulation serves as a new characteristic mesoscopic length in the system. The point where both  $c_0$  and  $\chi^{-1}$  vanish is known as the Lifshitz point (LP). If the density is “modulated” isotropically in all directions (like in the “sponge”

**Fig. 6** Landau–Ginzburg functional and order-parameter profile within the interface in van der Waals approximation. The thicker curve shows the profile calculated in renormalization-group theory. The correction to the classical result given by Eq. (29) reads:  $[1 + 1/2 \operatorname{sech}^2(z/2\xi)]^{-1/2}$ . Source: From Ref.<sup>[15]</sup>.

**Fig. 7** A schematic phase diagram of surfactant solution forming a modulated phase. The Lifshitz point (LP) separates the critical line of liquid–liquid phase separation (on the left) and the first-order phase separation (lower curve on the right). The transition between the homogeneous disordered phase and the modulated phase is second order. Source: From Ref.<sup>[27]</sup>.

phase of microemulsions), this point is known as the isotropic Lifshitz point<sup>[26,27]</sup> (Fig. 7).

## MESOSCALE SUSCEPTIBILITY

Mesoscale heterogeneities can be probed by the intensity of electromagnetic or neutron scattering at a selected wave number  $q = [(4\pi n)/\lambda] \sin(\theta/2)$  (where  $\lambda$  is the wave length of radiation,  $n$  is the refractive index, and  $\theta$  is the angle of scattering). With a static light-scattering experiment, one cannot probe inhomogeneities smaller than 30 nm, whereas dynamic light scattering enables one to measure the particle size as small as 3 nm through the diffusion coefficient of the Brownian motion. Neutron scattering can probe scales down to atomistic size.

The wave-number-dependent mesoscale susceptibility,  $\chi_q$ , is the correlation function in momentum space that can be obtained via the Fourier transformation of the coordinate-dependent correlation function. In the Ornstein–Zernike approximation

$$\chi_q = \int C(r) e^{-iqr} dV = \frac{\langle (\Delta\varphi)_q^2 \rangle V}{k_B T} = \frac{\chi}{1 + q^2 \xi^2} \quad (30)$$

In the limit of zero wave number and/or when the length  $\xi$  is small ( $q\xi \ll 1$ ), this formula becomes the usual thermodynamic expression (3) for the mean-square fluctuations. The susceptibility becomes spatially dependent and can diverge only in the zero wave-number limit (thermodynamic limit). It means that, at small scales,

**Fig. 8** Mesoscale osmotic compressibility (intensity of light scattering) measured at two different wave numbers in polystyrene ( $M = 2 \times 10^{-5}$ ) cyclohexane solution. The scattering angle  $150^\circ$  corresponds to the length scale of 36.3 nm. The solid curves are the scaling predictions in accordance with Eq. (30). The dashed curve denotes the osmotic compressibility in the thermodynamic limit (zero wave number). Source: From Ref.<sup>[28]</sup>.

the susceptibility is suppressed. For example, the compressibility of fluids or osmotic compressibility of binary mixtures near the critical point becomes smaller when one goes to shorter length scales (Fig. 8). At  $q\xi \gg 1$ , the mesoscopic susceptibility explicitly depends on the instrumental scale, being proportional to  $q^{-2}$ .

### FINITE-SIZE SCALING

The mesoscopic susceptibility is an example of a property restricted by a finite size (either by the instrumental probe like in a scattering experiment or by the inherent finite nature of the system).<sup>[7,8]</sup> If the isotropic system is restricted in three dimensions by a size  $L$ , the susceptibility

$$\chi(L, \xi) = \chi_\infty(\xi) \Upsilon(\xi/L) \quad (31)$$

The asymptotic behavior of the scaling function  $\Upsilon(\xi/L)$ :

$$\begin{aligned} (\xi/L) \ll 1 \quad \Upsilon(\xi/L) &\rightarrow 1 & \chi &= \chi_\infty(\xi) \sim \xi^{\gamma/\nu} \\ (\xi/L) \gg 1 \quad \Upsilon(\xi/L) &\rightarrow (\xi/L)^{-\gamma/\nu} & \chi &= \chi_L \sim L^{\gamma/\nu} \end{aligned} \quad (32)$$

The correlation length is replaced by the finite size. In a similar fashion, one can estimate the heat capacity near

**Fig. 9** Finite-size heat capacity at constant pressure near the lower critical consolute point of 2,6-lutidine aqueous solution at the critical composition. (+) In the bulk, (x) 250 nm porous nickel, (□) 100 nm porous glass, (▲) 10 nm porous glass. Source: From Ref.<sup>[29]</sup>.

the critical point in porous media:

$$C(L, \xi) = C_\infty(\xi) \Psi(\xi/L) \quad (33)$$

$$\begin{aligned} (\xi/L) \ll 1 \quad \Psi(\xi/L) &\rightarrow 1 & C &= C_\infty(\xi) \sim \xi^{\alpha/\nu} \\ (\xi/L) \gg 1 \quad \Psi(\xi/L) &\rightarrow (\xi/L)^{-\alpha/\nu} & C &= C_L \sim L^{\alpha/\nu} \end{aligned} \quad (34)$$

Experiments confirm the predictions of the finite-size scaling (see, e.g., Fig. 9 and Ref.<sup>[29]</sup>). If the size  $L$  is restricted in one dimension, we should expect a crossover from a three-dimensional system to a two-dimensional system and the finite scaling becomes affected by this crossover.

### COMPETITION OF MESOSCALES IN COMPLEX FLUIDS

Finite-size scaling is an example of competition between mesoscales. Another example is a polymer solution near the critical point of phase separation. In such a system, two mesoscopic lengths can be tuned independently: the correlation length of the critical

fluctuations by the proximity to the critical point of demixing and the size of the polymer molecules (radius of gyration,  $R_g$ ) by the molecular weight  $M$ . In dilute polymer solutions, the long polymer chain can exhibit a random walk or a self-avoiding walk. These two regimes are separated by the *theta* point, the limited point of polymer–solvent phase separation in the limit of the infinite degree of polymerization. The random walk is possible when the polymer chain and the solvent form either ideal or quasi-ideal solution. For the random walk, the radius of gyration of a chain (made up of  $N$  links with a length  $a$ ):

$$R_g = \sqrt{\langle R^2 \rangle} = aN^{1/2} \quad (35)$$

Real polymer solutions are not ideal. In the mean-field Flory–Hugging model, the virial expansion of the osmotic pressure,  $\Pi$ , reads:<sup>[30]</sup>

$$\frac{\Pi v_0}{k_B T} = \frac{\phi}{N} + B\phi^2 + C\phi^3 \dots$$

$$\left( \text{with } B = \frac{1}{2} - \frac{w}{k_B T} \text{ and } C = \frac{1}{3} \right) \quad (36)$$

Here  $v_0$  is the solvent molecular volume. The product  $v_0 B$  is called the *excluded volume*. The interaction parameter  $w$  determines the *theta* temperature:

$$w = \frac{k_B \Theta}{2} \quad (37)$$

When  $B > 0$ , the chain monomers repel each other and the chain swells in solution (good solvent). When  $B < 0$ , the chain monomers attract each other (poor solvent) and the chain collapses to form a compact globule. When  $B = 0$ , attractions and repulsions cancel each other and the chain exhibit a random walk (*theta* condition). The *theta* point is defined by the simultaneous vanishing of the first ( $1/N$ ) and second ( $B$ ) virial coefficients.

The fact that in a good solvent, the polymer chain is swollen means that the radius of gyration increases with degree of polymerization faster than in the ideal random-walk conditions. Instead of finding Eq. (35), we should expect in a good solvent

$$R_g = aN^\nu \text{ with } \nu > 1/2 \quad (38)$$

The chain cannot intersect itself; the monomer units have finite volume and two chains cannot be in the same place at the same time. This is a self-avoiding walk problem. Indeed, by minimization of the free energy, one can obtain for the self-avoiding chain

$$R_g = aN^{\frac{3}{d+2}} \text{ so that, } \nu = \frac{3}{d+2} \quad (39)$$

In three dimensions,  $\nu = 3/5$  in close agreement with scattering experiments<sup>[31]</sup> and renormalization group theory.<sup>[32]</sup>

The exponent  $\nu$  is similar to the critical exponent of the correlation length given by Eq. (11). Indeed, the radius of gyration can be regarded as the correlation length of fluctuations of a polymer–chain order parameter. According to de Gennes,<sup>[32]</sup> the polymer chain is characterized by the order parameter associated with the concentration of the chain ends (a probability for the ends to meet each other). This is a “vector” order parameter, while the square of the probability, the volume fraction of polymer, is the observable property. For the infinite chain, the probability tends to zero while the correlation length (radius of gyration) diverges. Such a state in infinite dilution (“self-avoiding walk singularity”) can be regarded as an analogue of a critical-point state. Tuning the second virial coefficient, one can drive this critical state to a first-order transition at which the chain collapses and the collapse is accompanied by phase separation. Such a singular point is known as a tricritical point, and it always originates from a coupling between two different order parameters. Phase separation means the emergence of a new order parameter—concentration. This is why the *theta* point is also a tricritical point.<sup>[32]</sup> A schematic phase diagram of a polymer solution is shown in Fig. 10. The *lambda*-line (vertical, at infinite dilution) is the line of self-avoiding walk singularities (analogous to a second-order transition line). The solid curve is the critical line of demixing. Asymptotically close to the critical point of phase separation, the correlation length of concentration fluctuations,  $\xi$ , eventually dominates, being much larger than the radius of gyration. In this (critical) regime, the polymer solution behaves like an ordinary fluid near its critical point. Close enough to the *theta* point, the radius of gyration

**Fig. 10** A schematic phase diagram of polymer solution. The dotted line shows the paths at critical compositions.

**Fig. 11** Molecular weight dependence of the correlation length in polystyrene-*n*-hexane solutions at the crossover temperature (circles). Crosses denote the normalized radius of gyration  $R_g/\sqrt{3}$ . Source: From Ref.<sup>[33]</sup>. From Ref.<sup>[34]</sup>. Dashed line denotes extrapolation as square root of  $M$ .

eventually dominates. It screens the concentration fluctuations and the polymer solution exhibits the theta-point tricritical (almost mean-field like) behavior. A regime where  $\xi$  and  $R_g$  are comparable is crossover between fluid criticality and theta-point tricriticality (Ref.<sup>[33]</sup> and Fig. 11).

The Landau–Ginzburg functional in the Flory–Huggins approximation reads.<sup>[35]</sup>

$$f(\varphi, N) = \frac{1}{2}\varepsilon\varphi^2 + \frac{1}{12}N^{-1/2}\varphi^4 + \frac{1}{2}N^{1/2}\nu_0^{2/3}(\nabla\varphi)^2 \quad (40)$$

Comparing Eq. (40) with Eqs. (22) and (23), we obtain the amplitude of the correlation length for polymer solutions in this approximation

$$\xi_0 = \nu_0^{1/3}N^{1/4} \quad (41)$$

Hence not only the radius of gyration, but also the effective range of “intermolecular” (including intra-chain) interactions diverge in the limit of infinite degree of polymerization.

## PERCOLATION

Another interesting example of a mesoscale structure is gel. Gel is a material composed of molecules or molecular aggregates that are able to form a macroscopic network with a non-zero shear modulus. The isolated subunits form usual liquid—a sol. Like

liquids, gels are structurally disordered and may contain a considerable fraction of liquid solvent. In a physical gel, heating can break the crosslinks while cooling can restore the links. Therefore the gel can be thermally reversible. Gelatin is an example of a thermo-reversible gel.

The change of macroscopic properties of gelatin solution changes at gelation point discontinuously, while the number of bonds changes continuously. It is similar to the symmetry break associated with phase transition points. The order parameter is the probability that a randomly chosen subunit belongs to the infinite network. A model, known as the *percolation* model, can describe generic features of the transition from sol to gel.<sup>[36]</sup> The percolation model emphasizes the geometrical features of network formation: the growth of the domain (“cluster”) in which all the subunits are interconnected. The correlation length is defined as the root mean square distance between the pair of sites that belong to the same cluster (proportional to the average size of cluster):

$$\xi = \xi_0|x - x_c|^{-\nu} \quad (42)$$

where  $x$  is the concentration of the bonds and  $x_c$  is the critical concentration (*percolation threshold*). For a simple three-dimensional cubic lattice  $\nu = 0.875$ .<sup>[37]</sup> The percolation model describes gelation as a “geometrical” phase transition and does not contain thermodynamics per se. However, in thermo-reversible gels, the temperature is coupled with geometry, making the configurational entropy and the percolation order parameter to be thermodynamic properties.<sup>[38]</sup>

## CONCLUSION

A variety of phenomena in condensed matter at submicron- and nanoscales, despite their diversity, demonstrate some generic features originating from the existence of a length scale intermediate between the size of atoms and the size one can see without a microscope. Mesoscopic thermodynamics is a semi-phenomenological approach that explicitly introduces this length scale into thermodynamics. The models of mesothermodynamics, such as the Landau–Ginzburg functional, emphasize a high degree of universality associated with a mesostructure and with the importance of fluctuations.

In this entry, only a few examples of mesoscale phenomena and systems have been discussed. Other promising objects of mesothermodynamics include polymer blends and melts, wetting transitions and critical adsorption, thermotropic and lyotropic liquid crystals, surface melting, and colloid crystals.

Meso- and nanoscales in non-equilibrium systems are the subject of non-equilibrium mesothermodynamics, which is still in its earliest stage. In particular, similar to thermodynamic properties, transport coefficients such as the diffusion coefficient or viscosity become spatially dependent at mesoscales (see, e.g., Ref.<sup>[39]</sup>). Moreover, away from equilibrium, generic long-range correlations emerge even in simple molecular fluids, making the famous concept of local equilibrium, at least, questionable.<sup>[40]</sup>

# Three-Dimensional Nanofabrication Using Multiphoton Absorption

John T. Fourkas  
Tommaso Baldacchini

*Eugene F. Merkert Chemistry Center, Boston College, Chestnut Hill, Massachusetts, U.S.A.*

## INTRODUCTION

One of the major goals of nanotechnology is to be able to fabricate complex, functional nanostructures at will. In recent years, there has been a tremendous effort from many groups to develop microfabrication techniques that can be adapted to the realm of nanostructures.<sup>[1–3]</sup> One driving force for such studies is the desire to break free from the constraints of conventional lithography. Although processes such as photolithography and electron beam lithography have been extremely successful in the production of electronic circuits with ever-decreasing feature sizes,<sup>[4]</sup> these techniques have significant limitations that preclude their use in many other contexts. These techniques are incompatible with many chemical and biological environments, can create sub-100-nm features only with difficulty, are not capable of fabricating structures with complex 3-D shapes, and generally require expensive facilities. Techniques such as nanoimprint lithography,<sup>[5]</sup> proximity probe lithography,<sup>[6]</sup> and soft lithography<sup>[7]</sup> are being developed to overcome these limitations. For instance, replica molding can be used to fabricate and replicate 2-D patterns with a resolution of 30 nm.<sup>[8]</sup> It has also been shown that intricate 3-D structures can be fabricated by soft lithography, although generally with feature sizes of 25  $\mu\text{m}$  or greater.

Microstereolithography allows for 3-D microfabrication with a feature size down to few micrometers.<sup>[9]</sup> UV lasers are focused on a thin layer of a liquid photoresist that undergoes solidification upon absorption of light. A second layer of photoresist is then added and another pattern is imposed over the first one. This process is repeated until the desired structure is completed. A developer solution is then used to wash away the unsolidified material, liberating the freestanding 3-D structure. Prototyping under these conditions is slow. For each layer, fresh resin must be spread flat on the polymerized object, which is the rate-determining step for the entire process. The wavelength of light and the film thickness are the major factors in determining the resolution limit of a few micrometers.

Since the first papers about microstereolithography appeared in 1993, many variations have been proposed

and demonstrated that improve resolution and production time.<sup>[10]</sup> Among these, the one that has allowed the fabrication of the smallest features is two-photon absorption polymerization (TPAP), which was introduced by Strickler and Webb<sup>[11]</sup> in 1991. It was the work of Maruo, Nakamura, and Kawata<sup>[12]</sup> in 1997 that first demonstrated the promise of this method for the fabrication of non-trivial 3-D structures with submicrometer resolution. In this entry, we will describe the basic principles of TPAP, illustrate how it can be applied to the fabrication of small 3-D structures with high accuracy, and discuss new developments that should bring this technique into the realm of nanofabrication.

## TWO-PHOTON ABSORPTION

All materials can be excited by a two-photon process when exposed to intense light. The only requirement is that the sum energy of the photons matches the energy required for the transition. The two-photon absorptivity is proportional to the imaginary part of the third-order susceptibility,  $\chi^{(3)}$ , which is non-zero in all materials.<sup>[13]</sup> Although Göppert-Mayer predicted this phenomenon in 1931,<sup>[14]</sup> the first experimental observation was not made until 1961.<sup>[15]</sup>

Two-photon absorption (TPA) is a rare event. For instance, Denk and Svoboda<sup>[16]</sup> calculated that under sunlight, a molecule of Rhodamine B, a good one- and two-photon absorber, undergoes one-photon excitation once per second, while the two-photon process occurs once every 10 million years. To increase the probability of TPA, intense sources of light (generally lasers) must be used.

The TPA cross sections of most molecules are small, usually on the order of  $10^{-50} \text{ cm}^4 \text{ sec photon}^{-1}$  (now defined as 1 GM in honor of Göppert-Mayer) or less. As a result, high local photon fluxes are needed to promote TPA. Commercially available Ti:sapphire lasers producing pulse durations  $\tau$  shorter than 100 fsec can meet this requirement. Each pulse has a peak power on the order of a kilowatt, while at a typical repetition

rate,  $f_p$ , of 80 MHz, the average power is on the order of hundreds of milliwatts. For comparison, a continuous wave laser must operate at a power  $(\tau f_p)^{-1/2}$  times higher than that required by an ultrafast-pulsed laser to achieve the same two-photon excitation efficiency.<sup>[17]</sup>

It has been shown that the probability  $n_a$  that a molecule will absorb two photons per pulse simultaneously when an objective of numerical aperture NA is used to focus the laser is given by

$$n_a \approx \frac{p_o^2 \delta}{\tau f_p^2} \left( \frac{(NA)^2}{2hc\lambda} \right)^2 \quad (1)$$

where  $p_o$  is the laser average power and  $\delta$  is the two-photon cross section of the molecule at wavelength  $\lambda$ .<sup>[18]</sup>

Because the probability of a TPA event is proportional to the square of the light intensity, excitation can be localized within the focal volume.<sup>[19]</sup> The higher the NA of the objective, the smaller the excitation volume. As shown above, the TPA efficiency falls off as the fourth power of the distance from the focal point.

In TPAP, the ability to excite a photoinitiator selectively within the focal volume allows for a spatial confinement of matter transformation. If upon TPA a liquid resin can be solidified, then with accurate positioning of the focal point, 3-D microstructures can be fabricated with submicron resolution. As long as the solubility properties of the solidified and unsolidified resins are different, the nonpolymerized material can be washed away to leave a freestanding structure.<sup>[20]</sup>

This fabrication process offers a unique combination of advantages. First, subdiffraction-limited resolution can be attained because chemical non-linearity results in a power threshold below which polymerization will not occur. Second, no topological constraints are present in the fabrication of 3-D structures. Third, the optical penetration depth is greatly increased with the use of near-IR light, which allows for the use of higher concentrations of photoinitiator than in one-photon polymerization. Fourth, movable components can easily be created without the use of sacrificial layers. Finally, the carbon-based nature of the materials can be used as a chemical handle to make polymers with tunable physical and chemical properties.

## MATERIALS AND EXPERIMENTAL SETUP

Two-photon absorption polymerization has been applied successfully to radical and cationic polymerization. In both cases, an initiator molecule plays a fundamental role. Its properties, such as the TPA cross section, the initiation efficiency, and the quantum yield, all influence the fabrication process.

Photoinitiators in radical polymerization are divided in two main groups.<sup>[21]</sup> Photoinitiators that

undergo unimolecular reaction are termed Type I. In these initiators, a bond breaks homolitically after excitation to form two radicals, at least one of which initiates the polymerization reaction. Photoinitiators that undergo a bimolecular reaction with a coinitiator to create radicals are termed Type II.

Lucirin TPO-L, Irgacure 369, and Irgacure 184 are all Type I photoinitiators and have been successfully used in TPAP.<sup>[22,23]</sup> Lucirin TPO-L is a member of the acylphosphine oxide photoinitiator family. Its absorption in the UV/visible region of the spectrum results from an  $n \rightarrow \pi^*$  transition that is red-shifted as a result of conjugation between a phosphonyl group and the carbon atom of the adjacent carbonyl group. Upon excitation, the carbon-phosphorus bond is cleaved, forming two radicals. The phosphinoyl radical has a tetrahedral structure with a single electron at one corner, which allows it to attack efficiently many substrates with no steric hindrance. As opposed to most acylphosphine oxide photoinitiators, Lucirin TPO-L is a liquid. The importance of this feature should not be underestimated, as most of the monomers and oligomers used in TPAP are highly viscous, but can form homogeneous solutions with Lucirin TPO-L readily.

Acylphosphine oxides are strongly inhibited by the presence of molecular oxygen. Although this represents a limitation to their use in curing thin films, it is an advantage in TPAP. By quenching the triplet state of the photoinitiator and by scavenging primary radicals efficiently, oxygen contributes to the formation of a threshold laser power below which fabrication is not possible. It is this threshold that allows for breaking of the diffraction limit, permitting fabrication with submicron resolution.

H-Nu 470 and Rose Bengal are Type II photoinitiators. They have been used in TPAP in the presence of a coinitiator, which is generally a bulky tertiary amine.<sup>[24,25]</sup> Upon excitation, the photoinitiator abstracts an  $\alpha$ -hydrogen atom from the amine.

All of the photoinitiators discussed so far are commercially available, and their properties have been optimized only for linear absorption. For this reason, some research groups have chosen a different approach, in which molecules with large two-photon-absorption cross sections are designed rationally and then synthesized.<sup>[26-29]</sup> It has been shown that molecules having electron-donating (D) and electron-withdrawing (A) groups separated by  $\pi$ -conjugated systems have large  $\delta$  values. An example is 4,4'-bis(*N,N*-di-*n*-butylamino)-*E*-stilbene. Starting with this structural motif, Cumpston et al. synthesized molecules with  $\delta$  values as large as 4400 GM, at least 3 orders of magnitude greater than those of most commercially available photoinitiators. Upon excitation by TPA, these molecules go through a large electronic reorganization and can undergo efficient electron

transfer with many substrates to initiate polymerization.<sup>[30]</sup> An appealing characteristic of this approach is the ability to shift the  $\lambda_{\max}$  of the TPA by small modifications in the molecular structure of the photoinitiator. Another structural motif characterized by large  $\delta$  values is a fluorenyl group intercalated between A and D groups. Molecules with this moiety have also successfully initiated radical polymerization induced by TPA.

A binary system consisting of 7-diethylamino-3-(2'-benzimidazolyl)coumarin and an iodonium salt has also been used in TPAP.<sup>[31,32]</sup> In this system, an electron transfer process occurs upon photoexcitation, leading to the formation of active aryl radicals.

Use of designer photoinitiators with TPA has allowed for fabrication with a low power threshold and wide dynamic range (defined as the ratio between the threshold and the damage powers).<sup>[33,34]</sup> Although these are desirable properties in TPAP, the scarce availability of these initiators makes their widespread use difficult.

Because of their high rate of polymerization, acrylates are the monomers and oligomers most widely used in radical TPAP.<sup>[35]</sup> Introducing chemical modifications in the ester group produces materials with different properties while having little effect on the polymerization rate. Because acrylates are used extensively in industry, a large variety of them are available commercially. To give the required stiffness to microstructures fabricated by TPAP, highly branched monomers incorporating cyclic structures are generally used.

Irgacure 369 has been used in the polymerization of an inorganic-organic hybrid material by TPA.<sup>[36]</sup> The organic portion consists of a methacrylate group, while the inorganic portion is an alkoxy- or perfluoroaryl silane whose length can be controlled via a hydrolysis/condensation reaction.<sup>[37]</sup> Changing the ratio between organic and inorganic groups changes the physical and chemical properties of the polymerized material.

Cationic photopolymerization employs initiators that generate strong Brønsted acids, which initiate chain reactions in substrates such as multifunctional epoxide and vinyl ether monomers.<sup>[21]</sup> It is important to note that cationic polymerization is not affected by the presence of molecular oxygen, and so the power threshold in this process is an intrinsic property of the materials used. Commercially available diaryliodonium and triarylsulfonium salts have been used successfully in TPAP.<sup>[29]</sup> In addition, a cationic photoinitiator with a large  $\delta$  value (690 GM at 705 nm) was synthesized by Kuebler et al.<sup>[38]</sup> The molecule, BSB-S<sub>2</sub>, consists of a bis[(diarylamino)styryl]benzene core with covalently attached sulfonium moieties and is an efficient photoacid.

Most of the resins used in TPAP are negative photoresists, in that the regions exposed to light harden, becoming insoluble in a postexposure development solvent. However, it has been shown that BSB-S<sub>2</sub>

can be used as a positive photoresist by inducing an ester-cleavage reaction in a solid polymer.<sup>[39]</sup> The newly formed polar groups make the volume in which they are present soluble in an aqueous base developer. This technique is promising for areas of microfabrication in which empty spaces have to be created, such as in microfluidics.

Microfabrication by TPAP can be performed by either moving the laser beam inside the photocurable resin or by moving the sample around a fixed laser beam. In the first case, a set of galvano mirrors is used to scan the focal spot in the  $x$ - $y$  plane and a piezo stage to move the sample or objective up and down. In the second scheme, the sample is moved in all three dimensions with the aid of a three-axis stage.

### 3-D Spatial Resolution

The ultimate resolution and complexity of 3-D microstructures fabricated by TPAP depend upon the factors influencing the shape and size of the smallest polymerized volume element or voxel. It is the accurate overlapping of these voxels that produces the desired surface topology of the final structure.

The square light intensity (SLI) distribution of the laser at the focal volume is an important determinant of voxel size. In this region, the highest concentration of active species is formed, thus inducing a state modification of the sample. Sun, Tanaka, and Kawata<sup>[40]</sup> have calculated that the near-focus SLI contour has a complicated distribution. Because an intensity threshold is present in TPAP, only the central portion is meaningful for microfabrication. As a consequence, the shape of a voxel resembles an ellipsoid with the two minor axes equal to each other and lying in the geometrical focal plane. The ellipsoid volume is proportional to the cube of the wavelength of the laser. Although shorter wavelengths will form smaller voxels, the choice of the excitation energy is dictated by the photoinitiator efficiency. In general, the working wavelength of choice optimizes the product of the photoinitiator two-photon cross-section ( $\sigma$ ) and quantum yield for radical generation ( $\eta$ ).

An analytical equation for the prediction of the photopolymerized voxel dimensions has been developed recently.<sup>[36]</sup> Assuming a Gaussian distribution of light intensity at the focal volume and a constant photon flux ( $I_0$ ) during the laser pulse, the expressions relating voxel diameter ( $d$ ) and length ( $l$ ) to the experimental parameters are

$$r(I_0, t) = r_0 \left[ \ln \frac{\sigma \eta I_0^2 f_p \tau_p t}{\ln \left( \frac{\rho_0}{\rho_0 - \rho_{th}} \right)} \right]^{\frac{1}{2}} \quad (2)$$

**Fig. 1** Truncated voxel fabricated using a 1.3-NA objective with a power of 2.0 mW at the sample and an exposure time of 500 msec.

and

$$l(I_o, t) = 2z_R \left[ \left( \frac{\sigma \eta I_o^2 f_p \tau_p t}{\ln \left( \frac{\rho_o}{\rho_o - \rho_{th}} \right)} \right)^{\frac{1}{2}} - 1 \right]^{\frac{1}{2}} \quad (3)$$

where  $t$  is the total processing irradiation time and  $\rho_o$  and  $\rho_{th}$  are the photoinitiator concentration and minimum concentration of radicals required to form a voxel, respectively. Thus knowledge of the radial ( $r_o$ ) and axial ( $z_R$ ) resolutions of the objective, which are given by the Abbe relations, is not sufficient to describe the voxel formation and growth in TPAP; correction factors involving the excitation light and the material properties have to be considered as well.

Experimentally, an accurate measurement of a photopolymerized voxel has to take into consideration the truncation effect.<sup>[40]</sup> To observe a single voxel using electron microscopy, it must be attached to a solid support so that it will not be washed away with the unpolymerized resin during the developing step. Consequently, a portion of each voxel is “truncated” by the substrate (Fig. 1), making the measurement of the complete voxel size impossible. An ascending scan technique overcomes this problem. At constant average power and exposure time, a series of voxels is fabricated, increasing the height of the laser beam focal point successively for each voxel starting from inside the solid support. Between voxels that are truncated and ones that are completely free to float away, some are barely attached to the solid support and will lie horizontally after washing. These voxels reveal their entire structure, allowing for the measurement of  $d(I_o, t)$  and  $l(I_o, t)$ .

In TPAP, the voxel size can be tuned by changing either the average power of the excitation light or the irradiation time. In the latter case, different groups

have experimentally confirmed the predictions of Eq. (2).<sup>[36,41]</sup> The lateral voxel dimension is proportional to the square root of the natural logarithm of the exposure time. Kawata et al.<sup>[42]</sup> have reported the best resolution to date in microfabrication by TPAP with a lateral voxel resolution of 120 nm. This value is roughly 4 times smaller than the diffraction limit predicted from the objective numerical aperture and the excitation wavelength. For such resolution, the intensity of the laser light must be set at a value that is just slightly higher than the intensity threshold for polymerization.

When the microfabrication conditions are optimized, the ratio between the axial and lateral dimensions ( $\mu$ ) of a photopolymerized voxel varies between 3 and 5, depending on the average power ( $p_o$ ) or the exposure time. In both cases,  $\mu$  increases with increasing  $p_o$  and  $t$ . This implies that the length of the voxel grows more rapidly than its diameter. This effect results from the fact that the SLI distribution is elongated along the optical axis of the laser beam.

Sun et al.<sup>[41]</sup> have elucidated the scaling laws for voxel growth in TPAP. They have observed that the rate with which  $\mu$  increases depends on whether  $p_o$  or  $t$  is varied. A change in average power produces a larger effect in  $\mu$  than does a change in exposure time. The same work highlighted an interesting phenomenon: at long exposure times,  $\mu$  saturates. Although such behavior is still not fully understood, it is believed that the diffusion of radicals plays an important role.

In microfabrication by TPAP, the most important characteristic of an objective is its numerical aperture. High-NA (1.3 to 1.4) objectives are generally employed because of their ability to reduce the excitation focal volume to a fraction of a femtoliter. When comparing voxels fabricated using different objectives under the same exposure conditions, unexpected results are observed. If the intensity of the laser beam is far from the intensity threshold, low NA objectives (e.g., 0.9) produce slimmer voxels than do high-NA objectives.<sup>[43]</sup> Near the intensity threshold, the smallest voxels are fabricated by high-NA objectives.

It has been suggested that high-NA objectives may break the symmetry of the focal field.<sup>[44]</sup> If this is true, then, when using linearly polarized light in TPAP, a polarization-dependent voxel shape will be observed. Sun et al.<sup>[43]</sup> have observed voxels with an ellipsoidal shape in which the two minor axes are no longer identical. The ratio between the two minor axes is approximately 1.1. This effect was eliminated with the use of circularly polarized light, which is consistent with asymmetry resulting from the high NA of the objective.

During microfabrication, the excitation laser beam has to traverse different interfaces before the sample.

**Fig. 2** Freestanding cantilevers fabricated using a  $40\times$  oil-immersion objective with an NA of 1.3 at a stage velocity of  $20\mu\text{m}/\text{sec}$  and average power of  $3.4\text{mW}$ . The index of refraction of the resin in (A) is 1.4930 while in (B) is 1.5222.

It is well known in TPA microscopy that refractive index mismatches among these interfaces produce aberrations at the focal volume that lead to a decrease in resolution, principally along the optical axis.<sup>[45]</sup> The same effect can be expected in TPAP, where the largest difference in indices of refraction is between the resin and the immersion oil used in combination with high-NA objectives. Scanning electron microscopic (SEM) images of two freestanding cantilevers fabricated by TPAP are shown in Fig. 2. Both structures were fabricated using a  $40\times$  oil-immersion objective (NA = 1.3) with identical stage velocity and power. The index of refraction of the resin used in (A) was lower than the one used in (B). In this second case, the resin was altered to render its refractive index similar to that of the immersion oil. The cantilever thickness in the index-matched system is approximately 20% smaller.

## MICROSTRUCTURES FABRICATED BY TWO-PHOTON ABSORPTION POLYMERIZATION WITH SUBMICRON RESOLUTION

In 1997, Maruo, Nakamura, and Kawata<sup>[12]</sup> first demonstrated that TPAP can be used to create complex 3-D microstructures. A spiral structure  $1.3\mu\text{m}$  wide,  $6.0\mu\text{m}$  in diameter, and  $10.3\mu\text{m}$  in axial pitch was fabricated as the first example of a 3-D microstructure created on such a small scale without employing a complicated layer-by-layer stacking process. Two-photon absorption fabrication techniques have continued to advance since this pioneering work, and it is now possible to create structures with intricate geometries and small dimensions. An example of such a microstructure is the microbull shown in Fig. 3.<sup>[42]</sup> It is interesting to note the fine reproduction of the complex surface topology of this object, the size of which is comparable to that of a human red blood cell. Fabrication of a solid bull required approximately 3 hr with a raster-scanning technique. However, this time was reduced to 13 min when only the exterior of the bull was polymerized using a vector-scanning method. Of course, the vector scan method provides a technical advantage exclusively when the microstructure exterior is self-supporting and when postcuring of the unpolymerized resin in its interior does not produce distortions.

Representative microstructures fabricated by TPAP in our laboratory are presented in Figs. 4–7. These images show 3-D structures that, because of their shape and size, cannot be produced using conventional lithographic techniques. For example, Figs. 5 and 6 show images of microstructures spanned by cables or bridges at different heights.

**Fig. 3** Microbull fabricated by TPA photopolymerization. Scale bar,  $2\mu\text{m}$ . Source: Prof. Hong-Bo Sun.

Fig. 4 Microcup with a diameter that increases with height.

The ultimate goal of any microfabrication/nanofabrication technology is the efficient production of devices that can deliver standard and non-standard functionality. Thus the analysis of materials performance on such small scales became of uttermost importance. It is a well-known fact in the world of semiconductor microfabrication that the scaling laws for many physical properties are not linear at small dimensions. Sun, Takada, and Kawata<sup>[46]</sup> have proven this point for a polymerized functional micromachine/

nanomachine as well. They fabricated a microspring with a feature size of 150 nm, a coil radius of 1 µm, and a pitch of 2 µm. One end of the spring was fixed to a polymerized anchor, and the other end had a polymerized bead of 1.5-µm diameter attached to it. The entire assembly was put in ethanol, and the microspring was mechanically activated by trapping the bead with optical tweezers. After being elongated without any elasticity failure, the bead was set free from the optical trap, letting the coil relax to its

Fig. 5 Pyramids interconnected by microcables at heights of 40 and 60 µm.

**Fig. 6** Overlapping microbridges at heights of 12, 24, and 42  $\mu\text{m}$ .

equilibrium point. The spring movement was overdamped and no oscillations around the equilibrium point was observed. The value of the spring constant was found to be 3 orders of magnitude smaller than that predicted from the bulk physical properties of the material. The main reason for the discrepancy between predicted and experimental values is presumed to be that the mechanical characteristics of the polymer are not the same for macroscopic and microscopic samples. In particular, the polymerization conversion percentage

induced by TPA is not known under the conditions used by the authors, and the Young's modulus depends critically on the degree of cross-linking. It is therefore dangerous to predict performance of microdevices/nanodevices by simply scaling down the properties of their macroscale counterparts.

One of the current trends in optoelectronics is the fabrication of 3-D periodic structures that have the ability to block the propagation of modes in certain region of the frequency spectrum. The geometry most

commonly used to create this photonic band gap (PBG) effect is a 3-D log-pile structure. It consists of layers of parallel rods in which the rod orientation in each layer is perpendicular to that in the adjoining layers. The center wavelength of the PBG is approximately the spacing between the rods. Thus submicron resolution in fabrication is a requirement for the creation of photonic crystals with PBG properties in the visible and near-IR region of the spectrum. Two-photon absorption polymerization presents an attractive alternative to semiconductor-based microfabrication for such devices, as complex geometries with resolutions reaching a few hundreds of nanometers are achievable. Log-pile microstructures with rod spacings of 1.2, 1.3, and 1.4  $\mu\text{m}$  were fabricated by TPAP, and their PBG properties verified experimentally.<sup>[47]</sup> As expected, the larger spacing created the more red-shifted PBG and the greater dip in transmission. In all three cases, the transmission dips were less than 50%. This limitation is a result of the poor refractive index contrast between polymer and air ( $\approx 0.5$ ), and it represents the main obstacle for applications. The appealing advantage of TPAP in the fabrication of microstructures with periodic modulation of refractive index was recently demonstrated. By connecting polymerized rods and sphere of 580 and 500 nm in diameter, respectively, Kaneko et al.<sup>[48]</sup> have fabricated a diamond-lattice microstructure that presents a strong PBG effect. In the race for the fabrication of 3-D microstructures with band gap at approximately the communication wavelength (1.55  $\mu\text{m}$ ), TPAP is surely a forerunner.

Objects with various other kinds of 3-D geometries have been made by TPA microfabrication. For example, a series of microgears was fabricated by TPAP.<sup>[49]</sup> They were fabricated around a shaft linked to the solid support and thus were able to rotate freely

under the flow of a solvent. With a similar procedure, Maruo, Ikuta, and Kovogi<sup>[50]</sup> have fabricated micro-scale/nanoscale manipulation tools that can be driven by light. An SEM image of a pair of microtweezers with submicron probe tips is shown in Fig. 8. Once in aqueous solution, laser trapping can optically drive the arms of the microtweezers. This type of remote control is promising in the realm of bionanotechnology, where electrostatic types of manipulators cannot be applied.

## CONCLUSION

The basic principles of TPAP have been described in this entry. Its ability to produce structures with any 3-D geometry at submicron resolution introduces a kind of freedom in microfabrication never before possible with other pattern formation techniques. For example, microstructures with curved surfaces and/or interconnected parts at different heights are easily fabricated.

In any fabrication process, resolution plays a fundamental role. In two-photon microfabrication, the achievement of sub-100-nm resolution will bring this technique into the realm of true nanofabrication. There are a number of clear steps that may be taken to achieve this goal. First, one might increase the order of the optical non-linearity. The volume excited by a three-photon absorption is smaller than that excited by a two-photon absorption. Perhaps more attractive, though, is the potential use of stimulated emission depletion (STED).<sup>[51]</sup> It has already been shown in fluorescence microscopy that the diffraction limit resolution can be broken by quenching excited chromophores at the rim of the focal spot through stimulated emission. The combination of the threshold effect and STED in TPAP should produce voxels with sub-100-nm sizes.

Although TPAP has been used to fabricate freely movable microparts and passive optic components, few functional devices have been made to date. To operate as actuators or sensors, microstructures fabricated by TPAP will greatly benefit from the optical, electrical, and magnetic properties of metals. Thus the fabrication of polymer/metal hybrid microstructure holds is a promising future direction of this technique for applications such as microelectrical mechanical systems and micrototal analytical systems.

## ACKNOWLEDGMENTS

The microstructures fabricated in our laboratory were created with support from the National Science Foundation (Grant ECS-0088438).

## INTRODUCTION

Titanium dioxide ( $\text{TiO}_2$ ) is a photosensitive semiconductor and its valence electrons are excited into the conduction band by high-energy radiation in the ultraviolet (UV) range (200–400 nm).<sup>[1,2]</sup>  $\text{TiO}_2$  has been used for diverse applications in various configurations as pellets, beads, powders, and immobilized films. The most frequently cited applications for  $\text{TiO}_2$  in a film configuration are as self-cleaning materials,<sup>[3,4]</sup> agents for heterogeneous photocatalysis,<sup>[5–7]</sup> solar cells,<sup>[8–10]</sup> gas sensors,<sup>[11,12]</sup> and corrosion-control coatings.<sup>[13–15]</sup>

Pure  $\text{TiO}_2$  pellets or beads tend to be brittle and susceptible to attrition or fragmentation under mild stress and shear forces.  $\text{TiO}_2$  powders are active because they have a high specific surface area, but removing the powder catalyst from the reaction bulk media can be troublesome.

Thus  $\text{TiO}_2$  film coatings have attracted considerable interest in the last decade. Film coatings make available the catalytic properties of  $\text{TiO}_2$  while benefiting from the mechanical properties of the substrate.  $\text{TiO}_2$  films are fabricated onto supporting materials (substrates) by a variety of different methods including the sol-gel method,<sup>[16]</sup> sputtering technique,<sup>[17]</sup> electrochemical process,<sup>[18,19]</sup> chemical vapor deposition (CVD),<sup>[20,21]</sup> and spray pyrolysis.<sup>[22,23]</sup>

## OVERVIEW

The substrate most commonly reported in the literature is quartz glass. This is because quartz glass coupons are easily available in many sizes and in different thickness sizes. In addition, studying the optical properties of the film is easier when the substrate is transparent and with known optical properties. Various other substrate materials used are silicon whiskers, ceramics, and stainless steel.

Stainless steel is an excellent substrate material for many reasons. It retains its structural integrity under

the high temperature required for heat treatment of the  $\text{TiO}_2$  films whereas quartz glass softens and deforms. Stainless steel also is not susceptible to attack during the coating process except under drastic conditions. Quartz and ceramics cannot be used in electrochemical processes because of their dielectric properties. Unlike quartz or ceramics, stainless steel can easily be worked into complex shapes and possesses excellent mechanical properties.

When substrates coated with  $\text{TiO}_2$  films are heat-treated, the ions from the substrate diffuse through the  $\text{TiO}_2$  layer.<sup>[24]</sup> Electron dispersive spectroscopy (EDS) studies show that when glass coated with  $\text{TiO}_2$  films is heat-treated near the melting point of glass (500–600°C), ions such as  $\text{Na}^+$ ,  $\text{Si}^+$ , and  $\text{Ca}^{2+}$  diffuse into the layer.<sup>[25]</sup> These cations act as sinks for the photogenerated electrons and inhibit the activity of the photocatalytic  $\text{TiO}_2$  film. Electron dispersive spectroscopy studies further show that when stainless-steel substrates coated with  $\text{TiO}_2$  are heat-treated,  $\text{Fe}^{3+}$  and  $\text{Cr}^{3+}$  ions diffuse into the  $\text{TiO}_2$  film<sup>[25]</sup> and these ions similarly inhibit the activity. However, the magnitude of diffusion is much smaller for stainless steel when compared with glass and the inhibitory effect is much lesser. Thus  $\text{TiO}_2$  photocatalytic coatings on stainless steel have higher photoactivity than  $\text{TiO}_2$  coatings on glass. For the above reasons, stainless steel is the material of choice for the purposes of fabricating practical process equipment such as  $\text{TiO}_2$  photocatalytic reactors for water and air treatment.

In this article, the first section focuses on the nanoscience of titanium dioxide by describing its crystal atomic structure and phase-transformation behavior and their influence on the observed photocatalytic and photosensitive properties of titanium dioxide. The nanotechnological methods used to fabricate  $\text{TiO}_2$  films on stainless-steel substrates are described with a brief discussion of their relative merits. Sol-gel methods to synthesize  $\text{TiO}_2$  films are discussed in detail because of their significant advantages over many other methods. The concluding section discusses the applications of  $\text{TiO}_2$  films on stainless steel.

## PHASES OF TiO<sub>2</sub> AND THEIR IMPACT ON PHOTOCATALYTIC AND PHOTSENSITIVE PROPERTIES

TiO<sub>2</sub> has an amorphous form and three crystalline phases: anatase, brookite, and rutile. At room temperature, the stable crystal phase is rutile. The anatase and brookite phases are metastable phases that can be converted, under suitable conditions, to the rutile phase. The brookite phase is rare and is rapidly converted to the rutile phase.

Anatase TiO<sub>2</sub> is composed of a tetragonal lattice forming octahedral structures.<sup>[26]</sup> Rutile TiO<sub>2</sub> is a hexagonal close-packed lattice also forming octahedral structures. It is characterized by the presence of the bridging oxygen on the 110 face.<sup>[27]</sup> The band gap for the anatase phase is 3.2–3.3 eV, while the band gap for the rutile phase is 3.0 ~ 3.1 eV. These energy levels correspond to UV radiation of 380–376 and 400 ~ 410 nm for anatase and rutile, respectively. When the surfaces of the crystals are illuminated with UV radiation of appropriate wavelength, electron-hole pairs are generated<sup>[2]</sup> by the excitation of an electron from the valence band to the conduction band. Some of these photogenerated pairs are destroyed by recombination either in the bulk or on the surface of the particle.

Other electron-hole pairs achieve charge separation and diffuse to the surface of the crystal to initiate and catalyze redox reactions with electron donors or acceptors.<sup>[28]</sup> The diffused electrons reduce Ti<sup>4+</sup> sites [Ti(IV)] on the surface of the crystals to Ti<sup>3+</sup> [Ti(III)]. The formation of the reduced Ti<sup>3+</sup> sites serves to lower the rate of recombination allowing the photogenerated holes to diffuse to the surface of the crystal to eventually generate the OH<sup>•</sup> radical that attack the organic compounds.<sup>[29,30]</sup>

For photocatalytic applications in the aqueous media, a number of studies have indicated that an increased fraction of the anatase phase increases the photoactivity.<sup>[31,32]</sup> Other studies<sup>[34,75,77]</sup> suggest that the ideal catalyst is a mixture of anatase and rutile phases. The proposed reason behind the enhanced photocatalytic activity is the transfer of electron between the crystal phases leading to lesser electron-hole recombination in the electron donor phase. Thus the more holes in the electron donor phase can diffuse to the surface of the crystal to take part in the radical generation step.

Some investigators have suggested that the electron transfer takes place from anatase to rutile. The removal of the hydroxyl group is easier from anatase 101 and 001 faces than the rutile 110 crystal face.<sup>[30]</sup> Since the hydroxyl groups are less strongly bound to the anatase phase than to the rutile phase, an increase in the number of holes diffusing to the anatase surface would

presumably increase the number of relatively easy to remove hydroxyl groups available for radical generation thus increasing the rate of attack on organic compounds.

Other investigators<sup>[75]</sup> have proposed that it is more likely that the electrons are transferred to lower energy anatase electron traps. The rate of generation of electronhole is higher in rutile than in anatase due to the lower band gap energy. However, the anatase is phase traps more electrons than the rutile phase. Hence there is less recombination in the anatase phase than in the rutile phase leading to more holes being available. Hurum et al.<sup>[76]</sup> suggest that the increased activity of the anatase-rutile mixed catalyst is due to transfer of electrons from rutile phase to lower energy anatase electron traps leading to a greater number of rutile originating holes diffusing to the surface and taking part in hydroxyl adsorption followed by radical generation.

In aqueous media, upon irradiation by UV light, the surface of TiO<sub>2</sub> undergoes a conversion from hydrophobic to hydrophilic state<sup>[29]</sup> by adsorbing hydroxyl groups from the dissociation of water molecules and by forming hydrogen bonds with the OH groups of undissociated water molecules.<sup>[34]</sup>

As suggested above, an ideal catalyst is possibly a mixture of anatase and rutile phases.

The following series of reactions for the photocatalytic pathway in aqueous media have been proposed:<sup>[35]</sup>

The superoxide radical then reacts with water

The final step is the radical generating step

The radicals subsequently react with the radical scavenging species.

## METHODS USED TO FABRICATE TiO<sub>2</sub> FILMS ON STAINLESS STEEL

Numerous methods have been used to fabricate TiO<sub>2</sub> films. Some of the published methods discussed here have been applied to produce films on substrates other

than stainless steel, but the techniques are equally applicable on stainless steel. The most widely used method is the sol-gel method because of its many advantages. It will be discussed in greater detail than the other methods.

Magnetron sputtering<sup>[36,77]</sup> is a process by which the substrate to be coated is placed in a low-pressure chamber. The chamber is evacuated and suitable sputtering gases are introduced. The commonly used gases are oxygen and argon. A source for the TiO<sub>2</sub> (also known as the target) is prepared by either compressing and sintering Ti powder or by using a Ti filament or bar. Magnets are placed on one side of the target. The distance between the target and the substrate is between 10 and 15 cm. A high d.c. voltage, usually in the order of a few thousand volts, is applied between the substrate and the target. A cyclical electromagnetic field (40 kHz–2.45 GHz)<sup>[36,77]</sup> is simultaneously applied to create plasma in the chamber. The Ti ions are transported from the target to the substrate under the effect of the applied potential.

Sputtered films are usually heat-treated at temperatures ranging from 500°C to 1000°C to convert the sputtered films to anatase and rutile phases<sup>[37,38]</sup> and thus improve their photocatalytic activity.

Sputtering is a technique limited to substrates that are small enough and can fit into a vacuum chamber. The coatings produced by sputtering are nonhomogeneous with respect to thickness. A more uniform coating can be produced by moving the target during deposition and by increasing the number of magnets used.<sup>[36]</sup> The roughness of the coatings is directly proportional to the deposition rate, which in turn is proportional to the applied voltage. Reducing the applied voltage results in smoother films. Reducing the O<sub>2</sub> partial pressure also produces smoother coatings.<sup>[39]</sup> Sputtered TiO<sub>2</sub> film catalysts have been used for photocatalysis both in the liquid phase and the gas phase.<sup>[17,38,40]</sup>

Spray pyrolysis is a method in which TiO<sub>2</sub> colloids or precursors are sprayed over a hot substrate using O<sub>2</sub> or air as a carrier gas. Some of the starting materials used for synthesis of the TiO<sub>2</sub> films are TiCl<sub>4</sub>,<sup>[41]</sup> titanium tetraisobutoxide,<sup>[22]</sup> and titanium tetraisopropoxide (TTIP).<sup>[42]</sup> The substrate temperature is maintained at 200–500°C by heating the substrate during the spraying process. Spraying is performed by means of spray guns, which may be computer-controlled to provide uniform spraying.<sup>[40]</sup> After the TiO<sub>2</sub> film is deposited, further heat treatment may be performed at temperatures up to 1050°C to convert TiO<sub>2</sub> into anatase or rutile phases.

Spray pyrolysis is a relatively simple technique that can be used for simple shapes including flat plate-like surfaces and the curved surfaces of tubes.<sup>[43]</sup> A major

advantage is that there is no limitation on the size of the substrate that can be coated by spraying. Thicker films may be obtained by increasing the spraying time or by repeating the spray process after heat treatment. However, precise control of the intrinsic film properties may be difficult to achieve.

Electrodeposition methods produce cathodic TiO<sub>2</sub> films on stainless steel. The source of the titanium can be a sacrificial anode<sup>[44]</sup> or titanium precursor salt such as TiO(SO<sub>4</sub>).<sup>[45]</sup> Titanium precursors are prone to hydrolysis and precipitation of titanium hydroxide gels catalyzed by the presence of very small amounts of water or other hydrolysis catalysts. Therefore acetone or acidic solvents are used as the bulk media.<sup>[44,46]</sup> A drawback of the electrodeposition method is the limitation on the thickness of the films that can be obtained as a result of backvoltage. Oxidation of the titanium metal to the oxide can occur in situ in the presence of water.<sup>[44]</sup> Alternatively, the deposited Ti films can be converted to the oxidized state by heat treatment in the presence of air. Heat treatment or annealing may also be performed to obtain phase transformation to the crystalline anatase or rutile phases. Electrodeposited TiO<sub>2</sub> films on stainless steel have been shown to have photocatalytic properties.<sup>[44]</sup>

Chemical vapor deposition (CVD) is a film synthesis process that utilizes a carrier gas to transport TiO<sub>2</sub> precursors onto a heated substrate. The typical precursor used is titanium tetraisopropoxide.<sup>[47]</sup> The substrate to be coated is placed in a closed chamber, which is then pumped out to a low pressure via vacuum pumps. The substrate is heated in this chamber at temperatures varying from 150°C to 750°C.<sup>[48–50]</sup> The carrier gas, usually N<sub>2</sub>, is bubbled through the precursor and transported into the chamber. The gases are adsorbed onto the heated substrate and deposition of the precursor takes place followed by oxidation. The coated substrate may be subsequently heat-treated to obtain crystalline TiO<sub>2</sub> films.<sup>[51]</sup> A variation of the basic CVD method is the laser-assisted CVD<sup>[47,52]</sup> in which a laser is used to provide the energy to convert the precursor to TiO<sub>2</sub>, thereby rendering the use of lower temperatures for the film coating and phase transformation process. The CVD process is subject to the same limitation as the sputtering process; the substrate must be small enough to be placed in the vacuum chamber. Furthermore, this technique is mainly useful for depositing very thin layers on smooth substrates. Precise control of film properties such as particle size and porosity is not achievable by this method.

Other methods of synthesizing TiO<sub>2</sub> films are through the use of binders to immobilize TiO<sub>2</sub> powder,<sup>[53,54]</sup> dip coating in reverse micellar<sup>[55]</sup> gels, and the hot wall technique.<sup>[56]</sup>

## SOL-GEL PROCESSES TO SYNTHESIZE TiO<sub>2</sub> FILMS ON STAINLESS-STEEL SUBSTRATES

Sol-gel processes are the most widely used methods to prepare TiO<sub>2</sub> photocatalytic films on substrates. A sol consisting of TiO<sub>2</sub> precursors is prepared and placed in a suitable container. The substrate to be coated is cleaned and placed in a lifting device. The substrate is then dipped into the sol container and pulled out (dip coating method). The obtained film is dried and heat-treated. The process can be repeated as desired to obtain thicker coatings.

A variety of titanium alkoxides have been used as starting materials for the sol. These include titanium tetraisopropoxide (TTIP),<sup>[16]</sup> titanium tetrabutoxide,<sup>[57]</sup> and titanium ethoxide.<sup>[58]</sup> The alkoxides are usually dissolved in ethanol, isopropanol, or 2-butanol.

Dip-coating produces uniform coats on substrates. However, to obtain uniform coats, the withdrawal speed of the substrate from the sol must be kept constant. Furthermore, the sol container must be large enough that the removal of the substrate causes negligible changes in liquid level. The thickness of the coating is directly dependent on the withdrawal speed up to a point.<sup>[66]</sup> The constant rate of removal is achieved by means of a simple lifting apparatus fitted with a variable speed controller. Removal of the substrate by hand is not recommended.

It is important to note the effect of solvent on the properties of the film derived from TTIP sols by dip coating. It has been reported that isopropyl alcohol is preferable than ethanol as a solvent for TTIP.<sup>[59]</sup> When ethanol is used as a solvent, oligomeric complexes of TTIP are formed. These oligomeric complexes are more slowly hydrolyzed because of steric hindrance. The lower rates of hydrolysis and condensation result in smaller particles of sol and produce a smooth surface.<sup>[59]</sup>

Formation of oligomeric complexes of TTIP is lesser when isopropyl alcohol is used as a solvent instead of ethanol.<sup>[59]</sup> The larger proportion of monomers of TTIP that remain in solution undergo hydrolysis and condensation faster and thus form larger particles. These larger particles of sol also produce a higher viscosity.<sup>[59]</sup> All other factors being constant, the film thickness is controlled by the viscosity. These larger particles produce a rough film. The use of isopropyl alcohol as solvent promotes crystallization of the anatase phase at a lower temperature than when ethanol is used as the solvent. Higher concentration of Ti<sup>3+</sup> sites is also obtained when isopropyl alcohol is used as the solvent. It is known that Ti<sup>3+</sup> sites are active sites for water decomposition during the photocatalytic process.<sup>[29,30]</sup>

Drying the dip-coated film on a substrate is essential prior to heat treatment. When the dip-coated liquid

film is heated, the rise in temperature decreases the viscosity. A simultaneous increase in viscosity occurs because of the loss of the solvent phase and the formation of cross-linked networks of polymers from the monomers. If the heating is rapid, the overall viscosity may decrease, leading to gravitational collapse of the dip-coated film. Drying at the same temperature as the dip-coating process allows for gradual loss of solvent and networking of the precursor monomers preventing a collapse of the film upon heat treatment.

Because the photocatalytic activity is intrinsically bound with the grain size and crystal phase fractions, controlling these parameters is essential to fabricate useful photocatalytic TiO<sub>2</sub> films. Grain size has an important effect on the transformation of anatase to rutile. It has been demonstrated for a system with water as the hydrolysis catalyst that pure anatase is formed between 225°C and 550°C.<sup>[60]</sup> At 550°C, the first peaks of rutile are observed. Above 800°C, anatase is entirely transformed into rutile. The phase transformation is accompanied by a grain-growth process.<sup>[60]</sup> The increase in grain size leads to a decrease in surface area. Phase transformation is a surface process as nucleation occurs on the surface and the decrease in surface area limits the number of available nucleation sites, thus tending to inhibit the transformation process. Grain growth is also driven by the surface energy. The decrease in surface area with the increase in grain size further slows down the growth of the grains. Smaller grains undergo the phase transformation from anatase to rutile easier than larger grains, which are more likely to be of mixed phase.

Diethanolamine (DEA)<sup>[61]</sup> may be added to stabilize the sol and increase the viscosity. It also promotes crystallization and increases the viscosity of the sol. Hydrolysis catalysts such as water or HCl are also added to the sol to facilitate the hydrolysis of the precursors. It has been demonstrated that the ratio of water/Ti alkoxide (denoted by  $w$ ) is crucial in determining the crystallization rate, the crystal structure of the crystals formed, the size of the crystal grains, and the phase-transformation temperatures.<sup>[61]</sup>

Water hydrolyzes titanium alkoxides and the extent of hydrolysis is directly dependent on the molecular ratio  $w$ . A  $w$  of 4 or above is needed for the complete hydrolysis of the alkoxide. The hydrolysis is followed by the polycondensation step. Gels with a lower  $w$  form linear polymer molecules in a weakly cross-linked network. This weakly cross-linked network allows for the relatively easy elimination of the organic components during heat treatment. Hence sols with a lower  $w$  form smaller anatase grains at a lower temperature and undergo phase transformation from anatase to rutile at a lower temperature. Gels with a higher  $w$  form a nonlinear three-dimensional polymer that is highly cross-linked. During heat treatment, the high

degree of cross-linking makes it relatively more difficult to eliminate the organic and water components.<sup>[61]</sup> The temperature of crystallization is observed to be higher and larger grains of anatase crystals are formed under the same conditions.<sup>[61]</sup> Because the stability of crystallites increases with grain size,<sup>[60]</sup> the larger grains formed also transform from anatase to rutile at a higher temperature.

The sols may be further modified by addition of components such as polyethylene glycol (PEG)<sup>[62]</sup> as discussed below. The objective is to improve the porosity of the anatase film obtained by the alkoxide sol-gel methods. An increase in porosity has a twofold effect on photocatalytic activity. Increased porosity means increased surface area for reaction and mass transfer. Pores of an optimum size also aid in capturing the incident radiation. It has been found that the porosity increases with an increase in the amount of polyethylene glycol. The pores are uniformly distributed over the surface of the film. The pore diameter also increases with an increase in the amount of polyethylene glycol. It has been demonstrated<sup>[61]</sup> that pores whose diameters are one-third to  $\frac{1}{2}$  the wavelength of the incident radiation are the most effective in capturing the incident radiation. For capturing radiation in the 200–400 nm range, intermediate pore sizes in the 100–150 nm range are the most effective.<sup>[61]</sup> When films were synthesized with pore sizes in the range 200–350 nm, they displayed a lower activity than films with 100–150-nm pore size.<sup>[61]</sup>

Another approach to increase the porosity is to use fine-powdered activated carbon as an additive to the sol.<sup>[63]</sup> Upon heat treatment, the carbon is eliminated, leading to the formation of very porous non-homogenous TiO<sub>2</sub> aggregates. Films formed by this technique, while exhibiting increased porosity, may be susceptible to mechanical problems such as flaking or fracture.

TiO<sub>2</sub> sol-gel-derived films also lend themselves to be easily doped by various materials to enhance their photocatalytic activity. Silicon has been used as a dopant for TiO<sub>2</sub> films.<sup>[64]</sup> Silicon in the form of silica (SiO<sub>2</sub>) suppresses the growth of crystal grain while also inhibiting the phase transformation from anatase to rutile. The surface area of the TiO<sub>2</sub> film increases with the increase in silica content, with mesopores being observed when the content was greater than 30%.<sup>[64]</sup> The crystal grain size does not increase after the silica content is greater than 10% by weight.<sup>[64]</sup> The resulting smaller grain size results in a large surface area. The surface area continues to increase with the increase in silica content even after the crystal-size increase tapers off as a result of the formation of mesopores and surface structures. It has been suggested<sup>[64]</sup> that while smaller pores may be more effective in absorption of light, larger pores may allow for better mass transfer,

and thus TiO<sub>2</sub> films with larger pores may be more effective as photocatalysts.

Platinum and iron have also been investigated as possible dopants for TiO<sub>2</sub> films.<sup>[65]</sup> TiO<sub>2</sub> doped with Pt displays about a third more photocatalytic activity than undoped TiO<sub>2</sub> films. Fe<sup>3+</sup> decreases the activity of the TiO<sub>2</sub> films possibly by acting as charge recombination site.

The sol-gel route of synthesis of TiO<sub>2</sub> films is the method of choice in many cases for several reasons: The sol-gel method does not need any special equipment other than a furnace for heat treatment. Dip-coating techniques for sol-gel methods allow complex-shaped substrates to be uniformly coated. Large substrates can be easily coated. The film properties can be precisely determined by controlling sol preparation parameters such as concentration and nature of precursors,<sup>[66]</sup> viscosity,<sup>[16]</sup> dipping temperature,<sup>[67]</sup> withdrawal speed,<sup>[16,68]</sup> and temperature and duration of heat treatment. The film thickness in sol-gel methods can be increased by repeating the dip-coating/drying/heat treatment cycle.<sup>[16,62,68]</sup>

## APPLICATIONS OF TiO<sub>2</sub> COATINGS ON STAINLESS STEEL

Most of the initial work in the area of TiO<sub>2</sub> photocatalysis focused on the use of TiO<sub>2</sub> powder slurries, pure beads, and pellets despite their obvious disadvantages as discussed earlier. With the realization that the photocatalytic activity is confined to a relatively shallow surface layer, the focus has shifted to the use of supported films of TiO<sub>2</sub>. The improvement and refinement of different techniques to support TiO<sub>2</sub> films on stainless steel and other substrates has resulted in a growing list of applications for TiO<sub>2</sub> photocatalytic films.

One of the primary areas of interest in TiO<sub>2</sub> photocatalysis is the destruction of organic contaminants in contaminated water and air. Supported TiO<sub>2</sub> films are illuminated by UV radiation of the appropriate wavelength. The contaminant to be destroyed is contacted with the catalyst surface either by immersion in the bulk phase or by a thin-film flow. Reaction takes place on the surface with the mass transfer of reactants occurring across the diffusive layer on the surface. The controlling step in TiO<sub>2</sub> photocatalysis is either the photogeneration of electrons-hole pairs via light absorption or the diffusion of reactants and products across the diffusive layer.

Plate photoreactors<sup>[69,70]</sup> utilize illuminated TiO<sub>2</sub> films on plates to degrade target compounds. Another type of photoreactor that has been used for degradation of organic pollutants is a rotating disk reactor.<sup>[71,72]</sup> The stainless-steel rotating disk is dip-coated with

titanium dioxide by a sol-gel process followed by heat treatment to obtain a mixed phase anatase-rutile film. As the disk rotates out of the aqueous phase, it carries up a thin layer of liquid on the surface. Several UV lamps mounted perpendicular to the surface provide UV illumination to the catalyst surface. Oxygen from the gas phase diffuses through the thin film to the catalyst surface and destruction of the contaminants takes place in the thin layer. A variation of this type of photoreactor is the use of a rotating cylinder instead of a rotating disk to enable the use of solar radiation instead of UV lamps.

## CONCLUSIONS

TiO<sub>2</sub> photocatalytic films immobilized on stainless steel show potential for use as anticorrosion agents.<sup>[13,73,74]</sup> The films exhibit self-cleaning properties against corrosive organic compounds.<sup>[15]</sup> Conventional paint and other anticorrosion coatings are passive agents. Photocatalytic TiO<sub>2</sub> films function as active agents, mineralizing organic deposits over time and thus cleaning themselves. This is a significant parameter for the reduction of maintenance costs. The same principle is used in the production of easily cleaned surgical tools for use in battlefield situations where the stainless-steel surgical tools coated with titanium dioxide are sterilized by UV irradiation in the presence of air.

Other emerging applications of TiO<sub>2</sub> films include solar-powered photoelectric cells, gas sensors for use in automobiles, and protective nonporous coatings for in vivo biomaterials.

## INTRODUCTION

Nanoparticles, arbitrarily defined as particles having particle sizes between 1 nm and 100 nm, have attracted significant interest due to their unique properties and are used in several revolutionary and important technological applications such as photocatalysis, sensors, solar cells, and memory devices. Nanosized semiconductors have become increasingly important in the world. Most organic pollutants consist of harmful constituent chemicals. Semiconductor photocatalysis uses light to activate nanoparticle catalysts in order to break down these chemicals. Photocatalysis works on the principle that positive charge carriers (holes) and negative charge carriers (electrons) are created when a semiconductor with an appropriate band gap, or energy difference between the conduction and the valance bands, is exposed to light. These carriers may then be used to initiate reactions at the catalyst surface. Electrons may be used for reducing metal ions ( $\text{As}^{+3}$ ,  $\text{Cr}^{+6}$ , etc.) while the positively charged holes can be used for the oxidation of organic chemicals (2-chlorophenol, trichloroethylene, etc.). However, several competing effects inherently limit the efficiency of a photocatalyst. The holes and electrons tend, by nature, to recombine through the emission of a photon (light) or a phonon (heat), yielding a neutral state. This recombination can occur in the bulk of the particle via volumetric recombination, as well as on the catalyst surface via surface recombination. Nanoparticles with a size of 20–30 nm provide the optimal balance between these effects and are thus best suited for photocatalysis.

Titanium dioxide is the most promising compound for photocatalysis applications.  $\text{TiO}_2$  is stable in aqueous media and is tolerant of both acidic and alkaline solutions. It is inexpensive, recyclable, reusable, and is relatively simple to produce. Most importantly its band gap is appropriate to initiate a variety of organic reactions as the redox potential of  $\text{H}_2\text{O}/\text{OH}\cdot$  lies within the bandgap.

The large bandgap of  $\text{TiO}_2$ ,  $\sim 3.2$  eV, lies in the UV range of the electromagnetic spectrum. This allows only 5–8% of sunlight that has the required energy to be useable for photocatalysis. Therefore, a visible-light activated catalyst would be much more efficient and effective. There are several known ways to increase the efficiency of a photocatalyst. Tailoring the bandgap of  $\text{TiO}_2$  to allow for visible light photocatalysis may be accomplished by reducing the particle size,<sup>[1]</sup> metal ion doping,<sup>[2–4]</sup> or electronegative atom doping.<sup>[5,6]</sup>

In 1972, Fujishima and Honda discovered the photocatalytic splitting of water on  $\text{TiO}_2$  electrodes<sup>[7]</sup> marking the beginning of heterogeneous photocatalysis. Since then, extensive research has been carried out to understand the fundamental processes and to enhance the photocatalytic efficiency of  $\text{TiO}_2$ . One of the most active areas of study for heterogeneous photocatalysis has been environmental cleanup applications owing to the fact that  $\text{TiO}_2$ -based photocatalysts cause total destruction of organic pollutants in wastewater.<sup>[8–14]</sup>

## EXCITON GENERATION AND RECOMBINATION

The first step in heterogeneous photocatalysis by semiconductors is the generation of electron-hole pairs in the semiconductor particles. Unlike metals, semiconductors possess an energy region where there are no electron energy levels. This region extends from the highest occupied molecular orbital (HOMO) of the filled valence band, to the lowest unoccupied molecular orbital (LUMO) of the vacant conduction band, and is called the band gap of the semiconductor. When a semiconductor absorbs light with energy equal to, or greater than its band gap, an electron is excited from the valance band to the conduction band leaving a hole in the valance band, thereby creating an electron-hole pair, as shown in Fig. 1. After excitation, the electrons

**Fig. 1** - Exciton generation by electron promotion from valance band to conduction band in semiconductors.

and holes generated can follow several pathways, as shown in Fig. 2. The migration of electrons and holes to the semiconductor surface allows for electron and/or holes to be transferred to the adsorbed organic or inorganic species. The semiconductor can donate electrons to reduce an electron acceptor (photocatalytic reduction).<sup>[15,16]</sup> Alternatively, when holes migrate to the surface and interact with an electron donor, oxidation of the donor (photocatalytic oxidation) occurs.<sup>[8-13]</sup> In competition with charge transfer to adsorbed species is electron/hole recombination. Excitons (electron/hole pairs generated in pure/bulk semiconductors) have a very short lifetime (nanoseconds) because of charge recombination.<sup>[17]</sup> Recombination of the separated electron and hole can occur in the volume of the semiconductor or on the surface, resulting in the emission of a photon (light) or phonon (heat). In order to reduce volume recombination, it is necessary to minimize the volume of the particle through the use of nanoparticles. However, nanoparticles have a very high surface to volume ratio. Therefore, surface recombination becomes more probable, offsetting the decrease in volumetric recombination. Therefore, the particle size must be optimized to minimize both surface and volume recombinations. Doping with metal ions (Nd, Pd, Co, Pt, etc.) or electronegative atoms (C, N, S, F, P, etc.) of TiO<sub>2</sub> offers a way to trap charge carriers and extend the lifetime of one or both of the charge carriers, enhancing the efficiency of the photocatalyst.<sup>[18-21]</sup>

**Fig. 2** Exciton recombination.

## PHOTOCATALYSIS ON NANOPARTICLES

### Photocatalyst Selection

When selecting a photocatalyst there are several characteristics that should be considered. It should be stable, inexpensive, non-toxic, highly photoactive and, for organic compound degradation, the redox potential of H<sub>2</sub>O/ $\cdot$ OH couple ( $\text{OH}^- \rightarrow \cdot\text{OH} + \text{e}^-$ ;  $E_0 = -2.8 \text{ eV}$ ) should be within the bandgap of the semiconductor. Table 1 shows a partial list of semiconductors that could be used as photocatalysts. However, only TiO<sub>2</sub> exhibits all of the factors listed above. It is chemically and biologically inert and it is found in such everyday products as paper, paint, sunscreen, food additives, etc. In addition, titanium dioxide is inexpensive (\$0.93/pound for micron size particles) and easy to produce in large amounts. The worldwide capacity for production of TiO<sub>2</sub> is estimated at 5,000,000 metric tons per year in over 16 countries.<sup>[22]</sup> Most importantly, the redox potential of H<sub>2</sub>O/ $\cdot$ OH ( $E_0 = -2.8 \text{ eV}$ ) falls within the bandgap of TiO<sub>2</sub> ( $E_g = 3.2 \text{ eV}$ ).

### CRYSTAL STRUCTURE OF TiO<sub>2</sub>

The two crystal structures of TiO<sub>2</sub> that are commonly used in photocatalysis are rutile and anatase. The structures of both rutile and anatase are tetrahedral differing in the number of atoms in the unit cell and the lattice constants  $a_0$  and  $c_0$ . A rutile unit cell contains six atoms, with lattice constants of  $a_0 = 4.593 \text{ \AA}$  and  $c_0 = 2.958 \text{ \AA}$ .<sup>[23]</sup> An anatase unit cell contains twelve atoms per unit cell with lattice parameters  $a_0 = 3.785 \text{ \AA}$  and  $c_0 = 9.511 \text{ \AA}$ .<sup>[24]</sup> Of the two phases, anatase shows relatively greater photocatalytic activity and is used more frequently for photocatalytic oxidation reactions.<sup>[25]</sup> However, the large band gap of anatase ( $E_g = 3.2 \text{ eV}$ ) only allows absorption of the UV portion of the solar spectrum. It would be desirable to alter the bandgap so that it could absorb in the visible range of the spectrum to increase the photocatalytic efficiency. Absorption in the visible range can

**Table 1** Band gap of some semiconductor photocatalysts

Semiconductor	Band Gap (eV)
TiO <sub>2</sub>	3.2
ZnO	3.2
ZnS	3.6
$\alpha$ -Fe <sub>2</sub> O <sub>3</sub>	2.8
WO <sub>3</sub>	2.8
SrTiO <sub>3</sub>	3.2

be improved by doping,<sup>[1–5]</sup> sensitization by surface modification,<sup>[26,27]</sup> and particle size modification.<sup>[28,29]</sup>

## PHOTOCATALYST SYNTHESIS

Currently, a variety of synthesis methods are being used for the preparation of semiconductor nanoparticles for photocatalytic uses. Ideally, the synthesis methods employed should form nanoparticles with a narrow size distribution and should allow easy control of particle properties (e.g., size, surface, doping, etc.). As will be seen later, these requirements are useful for the improvement of the photocatalytic properties of the semiconductor nanoparticles.

### Chemical Synthesis Methods

These methods utilize chemical precursors and/or chemical reactions to produce nanoparticles. They include chemical vapor deposition (CVD), sol-gel synthesis, chemical impregnation, co-precipitation, hydrothermal methods, and flame synthesis. There are several good review papers describing these techniques.<sup>[30–32]</sup> In the following sections, the two most commonly used techniques for nanoparticle synthesis, metallo-organic chemical vapor deposition (MOCVD) and sol-gel synthesis will be described.

### METALLO-ORGANIC CHEMICAL VAPOR DEPOSITION

The basic idea in MOCVD is that the chemical reactions among precursors occur at a certain temperature in a hot wall chamber so that no post-synthesis processes, like calcination, are required for crystallization or particle refinement. The size distribution of the particles can be achieved by controlling the temperature of the reactor or the flow rate of the precursors. Dopants can also be easily introduced into the reactor through a solid source, separated from the other liquid-precursor, or mixed in with the precursor. The formation of oxide nanoparticles is basically divided into four steps:

1. Introduction of precursor vapor (with carrier gas) and O<sub>2</sub> into the reactor.
2. Production of oxide monomers from the reaction of the precursor and O<sub>2</sub>.
3. Condensation of monomers to form larger oxide clusters by homogeneous nucleation in the gas phase based on a collision mechanism.
4. Formation of nanoparticles in the gas phase and on the substrates after attachment of large clusters to the substrate.

The reaction and condensation phases are two crucial steps in the formation of semiconductor nanoparticles by MOCVD as these determine the size and composition of the nanoparticles. Depending on the experimental conditions used (e.g., temperature, gas flow rates, and pressure) either thin films or free-standing nanoparticles can be created.

### SOL-GEL SYNTHESIS

The main advantage of this process is the ease of preparing nanocomposite materials such as organic-coated nanoparticles and nanoparticles in an organic network. The process starts by mixing a precursor solution and a solvent. The solvent is usually an alcohol such which has a low boiling point, such as ethanol. For the purpose of surface modification or doping, organic material or dopant precursor solutions can be mixed with the initial solution. The chemical reactions are carried out by dip-coating desired substrates in the precursor solution, usually at room temperature. The samples are required to rest with ventilation for enough time for gas-phase by-products to dissipate and to remove excess solvent. The as-grown nanoparticles are amorphous, and a calcination process is needed to form crystals. Thus, the sol-gel process is normally followed by heat treatment for crystallization.

## PHOTOCATALYST ENHANCEMENT

### Doping of Photocatalysts

The effects of doping semiconductors to increase the photocatalytic activity have been extensively studied.<sup>[1–5]</sup> Doping of semiconductors increases the efficiency of photocatalysts in two ways. First, doping of the TiO<sub>2</sub> solid with non-isovalent ions adds electron deficient sites (hole provider) or electron abundant sites (electron provider). These sites decrease recombination by trapping electrons or holes during their transportation from the interior of the particle to the surface. The trapping of electrons and holes at these sites effectively increase their lifetime and the probability that they will participate in the desired photocatalysis reaction at the surface.<sup>[3]</sup> Doping may also increase the efficiency by extending the absorption edge into the visible range. If the electronic coupling effect between dopant and semiconductor is strong enough to change the band structure, band gap narrowing becomes possible. The band gap narrowing can cause a small reduction of the photoredox potential energy of TiO<sub>2</sub>, but the increased photon absorption efficiency can compensate for this negative effect and overall greatly enhance photoreactivity of the

semiconductor. New molecular orbitals may form as a result of doping, effectively narrowing the band gap and lowering the absorption edge into the visible-light region.<sup>[2,4]</sup> Doping with various metal ions has been attempted in order to improve the photocatalytic activity and optical absorption of TiO<sub>2</sub>.<sup>[1-5,33,34]</sup> However, only in a few cases has doping led to noticeable absorption of visible light, such as in, Ti<sub>1-x</sub>Nd<sub>x</sub>O<sub>2</sub> (2), TiO<sub>2-x</sub>N<sub>x</sub> (4), TiO<sub>2-x</sub>S<sub>x</sub> (4) and Ti<sub>1-x</sub>Cr<sub>x</sub>O<sub>2</sub> (31). The effect of metal ion doping can be seen in Fig. 3.

### Sensitization by Surface Modification

A second semiconductor with a smaller band gap or other sensitizer is used to compensate the deficient charge generation of host semiconductor TiO<sub>2</sub>.<sup>[26,27]</sup> The photosensitization process expands the excitation wavelength range of the semiconductor through excitation of the sensitizer followed by charge transfer to the semiconductor. If the energy level of the excited state of the sensitizer is more negative than the conduction band energy level of the semiconductor, then the sensitizer molecule can transfer the electron to the conduction band of the semiconductor.<sup>[35]</sup> There are some problems associated with this method including the instability of the organic sensitizers, change of the selectivity of the host semiconductor, and the complexity of materials synthesis.

### Particle Size Modification

The quantum confinement effect was first proposed by Efros and Efros in 1982<sup>[36]</sup> based on the experimental findings by Ekimov and Onushchenko<sup>[37]</sup> of the size

**Fig. 3** Effect of dopants on the photocatalytic degradation of 2-chlorophenol.

effect on the blue shift in the main exciton absorption of CuCl (30 Å) nanocrystallites. The model was further modified by Lois Brus.<sup>[38]</sup> It has been shown that the bandgap of a semiconductor nanoparticle increases as the particle size decreases below the Bohr radius. The exciton Bohr radius for TiO<sub>2</sub> is about 10 nm.<sup>[33]</sup> It has been shown for TiO<sub>2</sub> nanoparticles that the band gap reduces between 23 nm and 10 nm.<sup>[28,29,33]</sup> At particles sizes smaller than the Bohr radius there is a sharp increase in the bandgap due to quantum confinement effect (Fig. 4).

### Photocatalytic Oxidation on TiO<sub>2</sub> Catalysts

When the charge carriers migrate to the surface of the catalyst the electrons may act as reducing agents while the holes act as oxidizing agents. The holes now located on the catalyst surface may react with adsorbed hydroxyl (OH<sup>-</sup>) groups to produce hydroxyl radicals (OH·) which are strong oxidizing agents.

The trapped electrons react with adsorbed molecular oxygen to produce the oxygen radicals, O<sub>2</sub><sup>-</sup> and O<sub>2</sub><sup>-2</sup>.<sup>[39]</sup>

Any organic species (R-H) present will either react directly with the holes at the surface<sup>[40]</sup> or with the hydroxyl radicals<sup>[41]</sup> and get oxidized. The possibility of the reaction of organic molecules with freely diffusing hydroxyl radicals has also been studied.<sup>[42]</sup>

**Fig. 4** Effect of particle size on a semiconductor band gap.

As long as an excess of oxygen is present and the reaction is allowed to continue (i.e., by exposing it to light), complete oxidation (mineralization) of the organic species will be achieved.<sup>[39]</sup>

Studies have shown that oxygen plays a more significant role during photocatalytic oxidation than simply scavenging the trapped electrons. It was found that degradation of 4-chlorophenol occurs at much lower rates, 20%, in the presence of an alternative electron acceptors or in oxygen depleted environments as compared to complete mineralization when the system is completely oxygen saturated.<sup>[43,44]</sup> It has also been shown that photocatalytic oxidation rates of organic compounds increase as the oxygen concentration is increased.<sup>[45]</sup>

### Photocatalytic Sterilization

Semiconductor photocatalysts may be used to kill bacteria. This allows for the creation of self-sterilizing surfaces. The first work of this type was carried out with *E. Coli* suspensions.<sup>[46,47]</sup> *E. Coli* suspensions exposed to UV illuminated TiO<sub>2</sub>-coated plates showed no surviving cells after only one hour of exposure. Suspensions exposed to UV light with no TiO<sub>2</sub> present showed that only 50% of the cells had been killed. Direct contact with the semiconductor is not a requirement for the cell destruction as it has been reported that when the cells and the TiO<sub>2</sub> were separated by a 50 μm PTFE film with 0.4 μm pores, all cells were destroyed when illuminated for four hours.<sup>[46]</sup> Photocatalysis has also been shown to be effective in the destruction of endotoxins such as O-157<sup>[47]</sup> that was the cause of a 1996 food poisoning outbreak in Japan.<sup>[48]</sup> After two hours of UV illumination most of the endotoxin was decomposed, with complete decomposition occurring in four hours.<sup>[46]</sup>

### Cancer Treatment Using Photocatalysis

In 1986, illuminated TiO<sub>2</sub> was used to kill tumor cells. TiO<sub>2</sub> film electrodes and colloidal suspensions were found to be effective in killing HeLa cells.<sup>[49]</sup> Various experimental conditions were studied including the effect of superoxide dismutase, that was found to enhance the effect due to the production of peroxide.<sup>[50–52]</sup> By using a UV illuminated TiO<sub>2</sub> microelectrode it was found possible to selectively kill a single cancer cell.<sup>[53]</sup> Animal experiments were carried out in a joint research between the University of Tokyo and the Yokohama City University School of Medicine where cancer cells were implanted under the skin

of mice to cause the formation of tumors. When the tumors grew to a size of 0.5 cm a titanium dioxide solution was injected. After a few days the skin was cut open exposing the tumor, that was subsequently irradiated with UV light. Thirteen days later the titanium dioxide treatment was repeated and a marked antineoplastic effect was observed.<sup>[54]</sup>

### CONCLUSION

When an aqueous suspension of a semiconductor, such as TiO<sub>2</sub>, is irradiated with light that has energy greater than the band gap of the semiconductor, an electron is promoted from the valance band to the conduction band. The holes generated in the semiconductor along with the radical species produced (i.e., OH·) and the activated oxygen species created by electron trapping (O<sub>2</sub><sup>-</sup> and O<sub>2</sub><sup>-2</sup>) are all strong oxidation agents for organic compounds. The oxidizing species generated have large enough oxidizing potential to completely transform any organic species to CO<sub>2</sub>, water, and mineral acids. The non-selective property of the system for complete oxidation/reduction has been applied to water purification for the photodegradation of organic and reduction of heavy metal pollutants.

## INTRODUCTION

Recent years have witnessed an unprecedented growth in research in the area of nanoscience and nanotechnology. The applications of nanotechnology will affect and improve almost every aspect of our lives from information technology to fabrics, finishes and materials generally. Most of these involve nanotechnological applications where there is no tangible direct health risk from exposure to the nanomaterial during manufacture or use. For instance, there is an increasing optimism that use of nanoparticles (NPs) in medicine will bring significant advances in the diagnosis and treatment of major diseases such as cancer and cardiovascular (CV) diseases.<sup>[1,2]</sup> Anticipated applications include use of NP (particles <100 nm in diameter) for drug delivery and diagnosis, and in nutraceuticals and production of biocompatible materials. The reason why NPs are attractive for such purposes is based on important and unique features, such as their surface-to-mass ratio, which are much larger than that of other particles, their quantum properties, and their ability to adsorb and carry other compounds. NPs have a large (functional) surface, which is able to bind, adsorb, and carry other compounds such as drugs, probes, and proteins.

Engineered NPs are important tools to realize a number of these applications in nanotechnology but may have the potential to get airborne resulting in human exposure or spread into the environment. As little is known about the hazards of these new materials, the emergence of nanotechnology has also initiated the debate on how these materials should be classified, tested, and used. The specific challenge for toxicologists is to understand the hazards associated with NP exposure and use this to determine and manage the risk to individuals who are exposed, to minimize adverse effects on health.

This entry first concentrates on the health hazards of NPs upon different exposure routes (lung, skin, and oral). Subsequently, it anticipates to translate the

know-how on effects of combustion-derived NPs (CDNPs) in ambient atmosphere to testing strategies that may be used for engineered NPs.

## DESCRIPTION OF RELEVANT PARTICLES

### Particle Definitions

Particle toxicology has developed along the lines of industrial development and has experience with particles down to the NP size range.<sup>[3]</sup> As shown in [Table 1](#), there have been decades of human exposure to NPs in the form of diesel soot and bulk NPs from industrial processes. Toxicological research has produced a database that is quite extensive for certain NPs, like diesel soot and carbon black, but less so for others such as fumed silica and alumina. The similarity or differences of these “traditional” NP to the new engineered NP is important since we have some concept of the hazard that these provide and so they may act as “benchmarks.” This database on CDNP [previously ultrafine particles (UFP)] demonstrates that exposure to these particles is associated with pulmonary inflammation,<sup>[4]</sup> immune adjuvant effects<sup>[5]</sup> and adverse systemic effects including blood coagulation and CV effects.<sup>[6,7]</sup> The meeting of the worlds of Nanoscience, with its engineered NP, and that of toxicology, with its know-how of ultrafines, has led to an impressive series of workshops and meetings over the past several years. However, so far little exchange of methods and concepts has occurred although both disciplines are expected to benefit from an exchange of methods and know-how.

Previously NPs were referred to by the toxicology community as UFPs, which are denominated as the fraction of ambient particulate matter (PM), which is smaller than 100 nm. Nowadays the denomination of the term NP is more frequent, and in this entry, we use the term NP for particles being intentionally produced with the same cutoff size of 100 nm.

**Table 1** Nomenclature of NPs: each class of NPs is described by source, exemplar particle, target exposure group, and toxicological knowledge at the time of writing

Nomenclature	Source	Example	Who is exposed?	Toxicological knowledge
CDNPs (ultrafine)	Combustion	Diesel soot	Everyone	+++
Bulk-manufactured NP (ultrafine)	Combustion	Carbon black	Occupational	++
	Synthesis	Amorphous silica	Occupational	+
Engineered NP	Geological/synthesis	Alumina	Occupational	-/+
	Nanotubes	Combustion	Occupational	-/+
	Q-dots	Synthesis	Patients	-/+

+++ = substantial toxicology database; ++ = some toxicology data available; + = limited toxicology database; -/+ = virtually no data available on toxicology.

NPs therefore include both bulk products such as carbon blacks and titanium dioxide (TiO<sub>2</sub>), but also particles that are engineered and produced in low quantities such as quantum dots and polymer carriers for imaging and drug delivery. This terminology is also illustrated in Fig. 1, which shows the different particles, their sources, and the evidence for potential health effects. In Table 2, a brief summary of the above definitions is given. Some specific groups of NP are described in the paragraphs below and concern CDNPs, bulk-manufactured NPs, and nanotubes.

### PM<sub>10</sub> and CDNPs

CDNPs are a component of environmental PM, which is measured by mass-based sampling conventions such as PM<sub>10</sub> and PM<sub>2.5</sub>. CDNPs are a small mass fraction of total anthropogenic particulate emissions but constitute a very large proportion of the particle number in the urban cloud. CDNPs are primary particles or agglomerates with a diameter smaller than 100 nm, although they tend to aggregate further with time and enter the accumulation mode of fine particles. The impact of PM on health has been extensively addressed in epidemiological studies across the globe; increased participation of PM in chronic and acute scenarios is associated with deaths and adverse health

effects in susceptible groups. These susceptible groups comprise patients with chronic lung disease and CV disease. From these studies, it is estimated that a 10 µg/m<sup>3</sup> increase in the concentration of PM<sub>2.5</sub> causes an overall mortality increase of 0.9%, while deaths from specific respiratory diseases can increase by as much as 2.7%. Epidemiological studies do not readily allow associations of adverse effects with subcomponents of PM, dependent as they usually are on mass measures of PM. However, several epidemiological studies have been able to identify combustion-derived particles as an important component in driving adverse effects of PM.<sup>[8]</sup> Toxicology can more easily study the components of PM, and there has been considerable amount of research on the combustion-derived particles component.

### Bulk-manufactured NPs

Most of the experimental, toxicological insights and hazards of NP have been explored with a small set of CDNP and bulk-manufactured NPs. Bulk-manufactured NPs have been used in industry for some decades and are produced in many tons/year; in 2004, the largest production volumes were recorded for colloidal silica, TiO<sub>2</sub>, and various iron oxides. All these bulk NPs were previously considered to be so-called nuisance dusts until it was observed that upon prolonged exposure in rats inflammation and lung tumors (Fig. 3) can occur.<sup>[4,6,7,9]</sup> In summary, these findings (Table 3) set the stage for the current discussion on risks of NPs illustrated in Fig. 1. A key question is whether the different pieces of toxicological and epidemiological evidence on different NP can be mutually used or whether a more sophisticated approach is necessary.

### Nanotubes

Carbon nanotubes (CNTs) comprise entirely carbon; they can be viewed as formed by rolling a single sheet

**Fig. 1** Illustration of the different sources and applications of NP. Epidemiology and toxicology have demonstrated acute effects of anthropogenic NP in humans, as well chronic effects of existing, manufactured NP in animals. It remains an open issue whether the hazards and risks found with those types of NP can be extrapolated to newly developed, engineered NP.

**Table 2** Definitions of particles in relation to their sources and application

Particle type	Description
PM <sub>10</sub> , PM <sub>2.5</sub>	Particle mass fraction in ambient air with a mean diameter of 10 or 2.5 μm, respectively. Basis of current standards for ambient particles in Europe and U.S.A.
Coarse particles	The mass fraction of PM <sub>10</sub> , which is bigger than 2.5 μm
UFP (PM <sub>0.1</sub> )	The fraction of PM <sub>10</sub> with a size cutoff at 0.1 μm. Contains primary particles and agglomerates smaller than 100 nm
PSP	Poorly soluble particles with low specific toxicity. Terminology used in relation to bulk synthetic UFP
NPs	Primary particles of intentionally produced material smaller than 100 nm
Liposomes	Particles, not strictly NP, consisting of fatty acids and derivatives
Carriers conjugates	Polymer-protein or polymer-drug conjugates with a size below 100 nm used in drug delivery

of graphite into a seamless cylinder. There are two classes of CNTs: single-walled and multiwalled. Multiwalled nanotubes are larger and consist of many single-walled tubes stacked one inside the other. Single-walled tubes can be as much as 10 times as strong as steel and 1.2 times as stiff as diamond, so they find many applications in the industry for reinforcing materials. They have a needle-like shape and are commonly a few nanometers wide but can be several millimeters in length. They therefore have some commonality with asbestos and other fibers used in industry. The harmful effects of fibers are driven by three properties: by length, thinness and biopersistence (i.e., resistance to breakdown in the lungs). A typical long, thin, biopersistent fiber that causes lung disease is amphibole asbestos. The experience with asbestos-related lung disease suggests that CNTs should be treated as a special case, and that their toxicity testing and possibly their regulation should be benchmarked against asbestos and not conventional NPs. Another reason to specifically address this group is the anticipated increase in production and use in the next few years.<sup>[10]</sup>

## TOXICOLOGICAL EFFECTS OF NPs

### Lung Exposure

The largest database on the potential toxicity of NPs has originated from the PM<sub>10</sub> literature, where the “NP hypothesis” has proved to be a powerful force for research. Therefore we consider it relevant to discuss this evidence in the expectation that it will shed light on the toxicity of engineered NP. The idea that CDNPs are an important component that drives the adverse effects of environmental particulate air pollution or PM<sub>10</sub> comes from several sources:

1. Much of the mass of PM<sub>10</sub> is considered to be non-toxic and so there has arisen the idea that there is a component(s) of PM<sub>10</sub> that actually drives the proinflammatory effects and CDNPs seem a likely candidate.
2. CDNPs are the dominant particle type by number suggesting that they may be important and their small size means that they have a large

**Table 3** Important findings on the biological activity in the toxicity of NPs between 1990 and now

Description of finding
NP TiO <sub>2</sub> causes pulmonary inflammation. Later studies show that inflammation is mediated by surface-area dose
NPs cause more lung tumors than fine particles in rat chronic studies. Effect is surface-area mediated
NPs inhibit macrophage phagocytosis, mobility, and killing
NPs affect immune response to common allergens
NPs are related to lung function decline in asthmatics
NPs cause oxidative stress in vivo and in vitro, by inflammatory action and generation of surface radicals
NP exposure adversely affects cardiac function and vascular homeostasis
NPs have access to systemic circulation upon inhalation and instillation
NPs interfere with Ca-transport and cause increased binding of proinflammatory transcription factor nuclear factor (NF)-κB
NPs cause progression of plaque formation
NPs can affect mitochondrial function
NPs can translocate to the brain from the nose
NPs do affect rolling in hepatic tissue

surface area/unit mass. Particle toxicology suggests that, in general, for toxic particles, more particle surface equals more toxicity.

3. Substantial toxicological data and limited data from epidemiological sources support the contention that NPs in PM<sub>10</sub> are important drivers of adverse effects.

Toxicological studies with inhaled NP have suggested several major mechanisms by which this CDNP component of PM may cause responses that explain mortality in those with existing pulmonary and CV diseases.<sup>[11,12]</sup>

1. First, inhalation exposure to NP can invoke bronchoalveolar inflammation in susceptible individuals and exacerbate existing airways disease such as COPD leading to death.<sup>[12]</sup>
2. Bronchoalveolar inflammation may also cause the release of inflammatory mediators that can trigger systemic hypercoagulability of the blood thereby increasing the risk for CV events such as those observed when PM levels increase.<sup>[13]</sup>
3. A second mechanism is the progression and destabilization of atheromatous plaques by inhalation of PM.<sup>[14]</sup> NP properties are likely to promote plaque destabilization through their documented effects such as inflammation and oxidative stress causing LDL oxidation and lipid peroxidation.
4. A third mechanism is provided by recent observations that NP upon inhalation deposits to a large extent in the nose, and may pass through the olfactory epithelium in the upper nose and reach the brain.<sup>[15]</sup> Little is known about the effects of the uptake, but one could imagine disturbance in the central nervous system (CNS) control of the autonomic nervous system as a possible consequence.
5. Finally, NP may translocate from various deposition sites [lung, gastrointestinal (GI) tract, and dermis] to the systemic circulation and distribute to secondary organs (vascular wall, heart, liver, and spleen) and affect organ function directly. However, quantitative estimates of translocation range between 50% of lung-deposited <sup>13</sup>C NP (26 nm size) within 24 hr in a rat model to less than 1% using 18 nm Iridium particles in vivo or in isolated perfused lung; further research in this area is clearly warranted.

A large series of molecular epidemiological studies in combination with animal studies have supported aspects of the plausibility of the above mechanisms. A multinational trial on CV risks (MONICA), performed between 1984 and 1988, reported a higher

blood viscosity and C-reactive protein (CRP)<sup>[16]</sup> during an air pollution episode in 1985. Recent studies from the same research group in Erfurt (Germany) have identified combustion NP as an important variable explaining cardiac deaths owing to increased ambient particle exposure. In fact, the association became stronger with smaller particles, and individuals with CV diseases were more likely to die than others. Clearly further research is needed, but the research reported to date has direct relevance to public-health policy, because both coal-burning and traffic emissions continue to be major sources of NP exposure worldwide. Recent studies in the Netherlands and Ireland have demonstrated the importance of regulating combustion-derived particle emissions.<sup>[17,18]</sup>

### Intravenous Exposure

Studies on effects of injected engineered NP have been performed with particles developed for therapeutic purposes such as polymers, liposomes, and engineered inorganic NPs. For intravenous (IV) administration, the choice of an appropriate NP is crucial with regard to many chemical and biological properties that determine biocompatibility. The toxicology of NPs that are used in drug delivery is now well understood thanks to extensive studies on cytotoxicity, hemotoxicity, complement activation, and cellular or humoral immunogenicity of many candidate NP.<sup>[19]</sup> Polycationic particles are in general cytotoxic, hemolytic, and can activate complement. On the other hand, polyanionic particles are less cytotoxic, but can cause procoagulant activity, and can also stimulate cytokine release from lymphocytes and mononuclear cells. Polymeric macromolecules (including polyaminoacids or polysaccharides) can elicit a humoral response characterized by increased total or specific immunoglobulin E (IgE) or immunoglobulin M (IgM) levels. All biological responses seem to be molecular-weight dependent for polymers and also depend on size when considering (in)organic NP. It has to be realized that the potential biological interactions of the NP can change when drugs or complementary antibodies are attached.

Toxicokinetics, usually described as absorption, distribution, metabolism and excretion (ADME), can change when new chemical entities are attached or other properties are modified. Ideally, the NP or the skeleton should be biodegradable or soluble. If the skeleton is not degradable at all, the molecular weight of the copolymers should be limited to <40,000 Da to ensure renal elimination as a backup for clearance. All these elements and toxicological concepts are developed and demonstrated in the use of surface-engineered iron oxide NPs, which have been used to pioneer the biocompatibility of nanomaterials.

Magnetite, because of its strong magnetic properties, was used first in biology and then in medicine for cell separation and magnetic guidance of particles for site-specific drug delivery. Nowadays, a whole series of compounds is known [e.g., polyethylene glycol (PEG)] that can be used for coating of iron oxide particles to allow drug delivery applications.

### GI Uptake and Effects of NP

NPs (<0.1  $\mu\text{m}$ ) and microparticles (0.1–3  $\mu\text{m}$ ) are ingested at high levels/person/day, and it is estimated that  $10^{12}$ – $10^{14}$  particles, mainly silicates and  $\text{TiO}_2$ , are ingested/person/day in the Western world.<sup>[20]</sup> After entering the GI tract, NPs are scavenged by M-cells overlying the Peyer's patches lymphoid follicles and in this way circumvent active uptake by intestinal epithelium. Some studies have shown that NPs ( $\text{TiO}_2$  and silicates) can accumulate locally in the GI tract in the Peyer's patches and have suggested that this may be related to exacerbation of inflammation in Crohn's disease, but the evidence is weak.

Translocation of ingested NP from the GI tract to the blood is suggested by studies in rats and humans, which have shown that ingested  $\text{TiO}_2$  particles (150–500 nm) can translocate to the blood and accumulate in liver and spleen.<sup>[21]</sup> Earlier studies described a mechanism of "persorption" by GI tract epithelial cells, whereby even larger particles are taken up into lymphatic and blood circulation and translocated to the liver and other organs.<sup>[22]</sup> Recently, nanocrystals have become the subject of intense investigation for oral administration of drugs and functional food components. Nanocrystals of drugs or food constituents, produced by precipitation or other processes, are 100% pure. As they are very efficiently taken up in vivo, and easy to produce, their production for oral application is expected to increase considerably. Interestingly, studies with ultrafine metal particles did not show a significant translocation to the blood circulation from the GI tract and thereby to other organs.<sup>[23]</sup> In the latter study after esophageal administration of 18 nm  $^{192}\text{Ir}$  particles in suspension, virtually the whole of the  $^{192}\text{Ir}$  dose was found in fecal excretion within 2–3 days. During the six-day observation period, no detectable  $^{192}\text{Ir}$  was observed in urine. Six days after administration, there was no detectable  $^{192}\text{Ir}$  in any organ or tissue of the body. Hence, it was concluded that for these particles, there was no uptake and/or absorption from the GI tract.

### Dermal Uptake and Effects of NP

The skin is one of the major exposure routes to NPs because of its large surface (well over  $2\text{m}^2$ ) and

Administration	Surface	Secondary targets
INTRAVENOUS		All organs
SKIN	$2\text{m}^2$	Liver
GI-Tract	$40\text{m}^2$	
<u>Respiratory tract</u>		
• Olfactory epithelium	$5\text{cm}^2$	Brain
• Bronchial epithelium		Heart
• Alveolar epithelium	$90\text{m}^2$	Circulation
		Liver

**Fig. 2** NP uptake routes and secondary target organs. The primary route of exposure to NP is determined by the type of exposure and preventive actions. However, upon uptake, the secondary target of NP differs substantially between routes of uptake. For example, uptake of NP through the small epithelial surface ( $5\text{cm}^2$ ) maybe a small quantitative route, but on the other hand, the target organ brain is directly accessed.

frequent application of consumer products that contain NP (Fig. 2). Particles with a size of approximately 50–500 nm are widely used in cosmetic products, to improve the homogeneity of the formulations applied to the skin surface, or to act as a UV filter against sun radiation. In the latter case, the

**Fig. 3** Relationship between lung tumor responses and particle surface area. Various poorly soluble low toxicity particles including nanoparticles have been shown to cause inflammation and lung tumors after intratracheal administration in rats. Fine and UFP were administered by intratracheal instillation in rats, and lung tumors were evaluated after 129 weeks. In both cases, straight line is obtained with a threshold between 0.2 and  $0.3\text{m}^2$  for lung cancer and  $200\text{cm}^2$  for inflammation in the rat. Source: Reproduced with permission from Ref.<sup>[9]</sup>.

smallest particles act as “nanomirrors” on the skin and partly reflect the sunlight. Because of their scattering properties, they increase the optical pathway of UV photons entering the upper part of the horny layer, and energy is absorbed by the stratum corneum and by the other organic components of the sunblock. Paradoxically, TiO<sub>2</sub>, one of the mostly prevalent NP found in cosmetics, has considerable photocatalytic activity. To prevent potential adverse effects caused by this property, the TiO<sub>2</sub> used in cosmetic preparations is often coated. The usual concentration of the NPs in the formulations is usually less than 3%. Sunscreens are usually applied to the skin at a concentration of 2 mg/cm<sup>2</sup>, which means that if 1 m<sup>2</sup> of skin is treated, the total external amount of NP applied is ~600 mg of NP. There is considerable discussion about the uptake of NP through the skin. In principle, there are three possible penetration pathways of topically applied substances through the skin: intercellular penetration, intracellular penetration, and follicular penetration. In the past, the penetration was described as a diffusion process through the lipid layers of the stratum corneum. Liposomes with a diameter between 20 nm and 200 nm have been found to be active carriers of topically applied drugs into the living epidermis via the intercellular penetration route.<sup>[24]</sup>

The penetration of native and coated TiO<sub>2</sub> NP into the stratum corneum of living human skin has been investigated by tape stripping and biopsy in combination with spectroscopic measurements. Penetration of NPs through the horny layer could not be detected by x-ray fluorescence in sections of the biopsy.<sup>[25]</sup> These data also confirmed the results of earlier work, which detected no percutaneous absorption of particles in skin samples from humans treated with a microfine titanium oxide-containing sunscreen. A more recent study on the percutaneous penetration of micronized TiO<sub>2</sub> preparations in sunscreens used two different samples, one containing primary particles of 10 to 15 nm present as aggregates of approximately 100 nm, and another sample with primary particles of approximately 100 nm. Both of these particle types remained on the surface of the stratum corneum, and did not penetrate into the stratum corneum or living compartments of the skin.<sup>[26]</sup> It cannot be excluded that some physical properties of NP may enhance the absorption/penetration of certain substances applied to the skin such as reported for methanol or octanol. However, the results of available studies suggest that, although small particles may be deposited on the follicle orifice, they do not penetrate the skin via the follicle. This was confirmed by the results of a recent study, which showed that polystyrene NP (20 to 200 nm) accumulated in the

follicle orifices but did not penetrate into the skin or the follicle.<sup>[27]</sup>

### Effects of NP in the CNS

NPs might gain access to the brain by two different mechanisms:

- Trans-synaptic transport after deposition on the olfactory epithelium
- Uptake from the blood through the blood–brain barrier (BBB)

The first pathway has been studied primarily with model particles such as carbon, Au, and MnO<sub>2</sub> in experimental inhalation models.<sup>[15]</sup> The second pathway has been the result of extensive research and particle surface manipulation in drug delivery, as an approach to try to deliver drugs to the brain.<sup>[28]</sup> The latter studies suggest that the physiological obstacle that the BBB provides may limit the distribution of some proteins and viral particles after transvascular delivery to the brain, suggesting that the healthy BBB contains defense mechanisms protecting it from being breached by blood-borne NPs. A number of pathologies, including hypertension and allergic encephalomyelitis, however have been associated with experimental increases in permeability of the BBB to NPs. Conversely, the NP surface charge has been shown to alter the blood–brain integrity<sup>[29]</sup> and so warrant consideration for brain toxicity and brain distribution profiles.

Paramagnetic NPs have been used for magnetic resonance imaging (MRI) of different cell types within neural tissue. This has proved efficacious, and it has been suggested that this might be useful in humans for tracking the development of stem cell grafts used to treat neurodegenerative diseases. However, the potential impact of NPs on human neuronal tissue has not yet been investigated in detail. NPs have, however, been shown to induce the production of reactive oxygen species (ROS) and oxidative stress. Oxidative stress has been implicated in the pathogenesis of neurodegenerative diseases such as Parkinson’s and Alzheimer’s.<sup>[30]</sup> Therefore it is conceivable that the long-term effects of NP exposure might include a decrease in cognitive function. Evidence for such effects is presented by studies in biopsies from city dwellers and Alzheimer’s-like pathology have demonstrated increased markers of inflammation and AB42-accumulation in frontal cortex and hippocampus in association with the presence of NPs. Chronic (four months) exposure to concentrated airborne particles caused degeneration in dopaminergic neurons in a specific area of brains of mice.<sup>[31]</sup>

## SCREENING-ENGINEERED NP FOR TOXICOLOGICAL HAZARDS

From the above it is clear that a range of end points should be considered for the testing of NP for potential hazards. Some engineered NP, which becomes airborne, may pose inhalation hazards, but cosmetics containing NP normally provide only dermal exposures. Therefore hazards should be tested appropriately, to their mode of exposure and portal of entry. Other engineered NPs are being used as devices to target drugs to specific tissues, to increase their biological half-time, or for imaging purposes such as extravasation and tumor treatment. The testing of engineered NP for these purposes follows guidelines such as defined in European union (EU) or Food and Drug Administration (FDA) medical device regulations, which are based on their biocompatibility as measured by platelet adhesion and activation, neutrophil attachment, angiogenesis, and cell spreading.<sup>[19]</sup> However regulatory bodies start to realize that current guidelines or classification may not be valid. In addition, important questions remain such as the following:

Which components should be tested?

The following should all be considered: Native particle, native particle with surface modification, stability of the surface coating, effects of the NP and surface coating, and materials used for synthesis of NP.

What type of tests should be used? A range of in vitro and in vivo tests should provide information that can contribute to hazard assessment. Both classical tests and newer models reflecting current insights into the mechanisms of NP toxicity should be employed.

### Relevant Particle Properties and Mechanisms

The present data indicate that apart from particle size, particle surface chemistry and particle surface charge are important parameters determining NP toxicity, translocation and subsequent effects. Apart from particle characteristics, the permeability of several cellular barriers is considered to play a role.<sup>[32]</sup> Toxicological studies have shown that oxidative stress is a central mechanism that may be responsible for the inflammatory effects of PM and NP causing pulmonary responses.<sup>[6,33]</sup> On the other hand, inflammation is known to amplify the burden of ROS to the lung, and thereby causes a persistent oxidative stress. For several reasons, NPs are particularly able to generate oxidative stress when the particles deposit on the epithelium of the respiratory tract:

1. NP surface area: The surface area of particles is known to be a major factor in driving inflammation<sup>[6,34]</sup> as well as lung carcinogenicity in

experimental systems (Fig. 3).<sup>[9]</sup> NPs of low-toxicity, low-solubility materials have a very high surface area/unit mass. They are also highly inflammogenic by virtue of this high surface area and oxidative stress, generated through mechanisms that are not well understood. NPs typically form aggregates both in the air and upon deposition, which are aerodynamically larger than the classical definition of a NP, i.e., they can be larger than 100 nm. However, these NPs in aggregates still express toxicity consistent with their geometric surface area and not in relation to their surface area as deduced from their aerodynamic diameter as an aggregate.

2. Carrier function: NPs may contain or adsorb components that have the ability to generate free radicals and cause oxidative stress. These components include polycyclic aromatic hydrocarbons (PAHs), *n*-alkanes, nitro-PAHs and quinones formed by combustion or derived from unburnt fuel. Interaction of these organics with enzyme systems can result in oxidative stress via the production of oxidants such as superoxide anion. Absorbed or soluble metals can typically generate ROS in acellular and cellular systems<sup>[35]</sup> and is related to the inflammatory response to NPs in vivo.<sup>[36]</sup>
3. Surface modification and coatings: Whatever test will be used or developed, it needs to be appreciated that most suppliers apply postproduction strategies to modify NPs to prevent aggregation or stimulate disaggregation. In both industrial and life sciences applications, different coatings are employed (Table 4). There is now a body of evidence from the drug delivery and toxicological literature that surface modification as well as surface charge can have major impacts on biological response to particles, including phagocytosis, genotoxicity, and inflammation. Particle coating with PEG or dextran is commonly used to prevent recognition by the reticuloendothelial system and increase the half-life of particle-conjugated drugs.<sup>[37]</sup> A clear example, albeit not in NP, demonstrating the crucial role of particle surface comes from work with respirable, quartz samples. Coating with aluminum lactate or the polymer polyvinyl-pyridine-*N*-oxide (PVNO) has a dramatic impact on the various adverse effects of the native quartz, including phagocytosis/endocytosis, oxidative deoxy ribonucleic acid (DNA) damage, and inflammation following instillation into rat lung.<sup>[38]</sup> In sunscreens, NP TiO<sub>2</sub> is often used as “nanomirrors” to partly reflect the sunlight from the skin. To reduce potential photocatalytic adverse effects,

**Table 4** Surface modifications of NP used for technical (polysynthetic route) and drug delivery applications. Whereas most coatings for medical applications have been designed or tested to prevent adverse effects, most industrial coatings serve technological purposes

Postsynthetic modification or coating of NP	Specific properties
<i>Industrial applications</i>	<i>Dispersable in</i>
4-Dimethylaminopyridine	Water
Mercaptoundecane acid	Water
Thiols (e.g., Dodecanethiol)	Non-polar solvents like hexane, toluene, chloroform, acetone
Fluoroalkanes	Non-polar solvents like hexane, toluene, chloroform, acetone
Trialkoxysilanes and derivatives thereof	Water, alcohol
Phosphorous-containing substances like $\text{Ph}_2\text{PC}_6\text{H}_4\text{SO}_3\text{Na}$	pH dependent in water or non-polar solvents
Aminoalkanes and derivatives	Dependent on functionalization in non-polar solvents or alcohol
<i>Medical applications (ferrofluids)<sup>a</sup></i>	<i>Biological/physical properties</i>
PEG	Improves biocompatibility
Dextran	Enhances blood circulation time
Fatty acids	Colloidal stability
Polyvinyl alcohol (PVA)	Monodisperse particles
Polyacrylic acid	Helps bioadhesion, improves stability
Poly (D,L-lactide)	Biocompatible, low cytotoxicity
Phosphorylcholine	Prevents complement activation
Chitosan	Natural biocompatible, hydrophilic and widely employed on agricultural, cosmetics, foods and medicine
Gelatin	Hydrophilic emulsifier, natural

<sup>a</sup>Modified from Gupta & Gupta (2005) as applied to iron oxide particles.

the  $\text{TiO}_2$  is often coated. Surface modified  $\text{TiO}_2$  has been the subject of considerable toxicological investigation and has shown that the hydrophobic coatings usually tend to lower the inflammatory response after inhalation or instillation. However, one study reported very substantial acute toxicity after instillation of doses around 1 mg/rat. It is crucial to know-how the surface modification has been achieved and if this can be released from the NP in biological media (e.g., low pH in macrophages). In the case of sunscreen-grade coated titanium oxide NPs, the stability of the coating was investigated by laser-induced plasma spectroscopy. No changes in the mechanical stability of the coated micro-particles could be detected during the manufacturing of the sunscreen.

### Tests for Toxicity of Engineered NP

Considering the large amount of research on effects and mechanisms of CDNP, it is surprising to note that little has been done to screen engineered NP for potential adverse health effects. There are different opinions as to whether existing tests may pick up all of the

hazards. Existing tests detecting toxicological hazards of NP may not be sensitive enough, or may not look in the correct place, e.g., blood or brain. Lessons can be learned from animal research with CDNP failing to reproduce the effects of PM seen in epidemiological studies. Although the reasons for this are somewhat understood (e.g., poor models of susceptibility and variability in exposure), this underscores the need to develop and validate new test models as well as to evaluate and validate existing methods for testing of engineered NP.<sup>[39]</sup>

Currently there is no alternative to the approach used in the pharmaceutical industry, i.e., a case-by-case approach. There is a clear need to develop concepts of testing, which can be achieved through bridging studies with appropriate regard to dosimetry. The dosimetry should be related to the anticipated application of the nanostructured materials and to the metric, which is chosen or investigated. Another reason for the right dosimetry is that often only small amounts of nanomaterials are available, and for instance, inhalation studies are virtually impossible. With regard to testing of the toxicity of engineered NPs, a variety of tests may be used that were applied to particles of highly contrasting size and dimension such as asbestos and man-made fibers, quartz and coal mine dust, fly ashes,

and diesel exhaust particles. In response to the “NP hypothesis,” a number of *in vitro* and *in vivo* tests have been introduced for comparative toxicity testing at equal mass of commercial particles of fine vs. ultrafine size (e.g., carbon black and TiO<sub>2</sub>). Tests for NP toxicity can be arbitrarily subdivided into four levels:

1. Testing of the (re)activity of NP in acellular or subcellular systems (e.g., dissolution, radical generation, protein/DNA oxidation, lipid peroxidation enzyme inactivation/immobilization, and action on isolated mitochondria).
2. Testing of NP *in vitro*, using intact cells or cell systems (e.g., lung epithelial cells, skin cells, gut cells, vascular endothelium, and macrophages).
3. Testing of NP in isolated organ culture systems (e.g., intact skin models, whole blood, isolated perfused lung, and heart).
4. *In vivo* testing.

#### Short-term tests for reactivity and toxicity

Very rapid and basic acellular approaches that have been used to predict particle reactivity include testing of plasmid DNA unwinding or oxidation of calf thymus DNA. Electron paramagnetic resonance (EPR) combined with a spin trap has been used to determine the radical generation properties of particulate materials well above the nanosize range such as quartz and asbestos in relation to (surface) modification, as well as of ambient PM. With a few exceptions, these EPR studies showed positive associations with toxicity *in vitro* and/or *in vivo*.

#### Cellular tests

Cellular tests are very common in particle toxicology because little material is required, they have short-term readouts, and microscopical techniques are easy to apply concomitantly. A classic test is the hemolysis assay, which is based on properties of reactive constituents to elicit hemoglobin leakage upon red blood cell membrane damage. Nowadays, toxicity testing of particles *in vitro* mainly uses primary cells and/or immortalized cell lines. End points for toxicity include membrane-damaging properties (e.g., LDH leakage) or changes in mitochondria-associated metabolic competence [e.g., MTT assay and adenosine triphosphate (ATP)], reflecting necrosis and/or apoptosis. Various cell types can be tested, with due regard to the route of entry and/or target tissue or organ of concern (e.g., pulmonary type II cells, colon cells, keratinocytes, and endothelial cells). Notably, alveolar epithelial cells are often used to screen for markers of proinflammatory pathways and or toxicity of inhaled NP, but other assays can be chosen based on the application of the NP. Differential cell adhesion and toxicity (fibroblast) are often used as a screening test to optimize surface modification in NP for drug delivery of coatings of biocompatible materials.

#### Isolated organ and *in-vivo* testing

**CV Effects.** Patients with CV diseases are the principal vulnerable group with respect to effects of inhaled CDNP. Therefore it is recommended that *in vivo* screening of engineered NP will concentrate on CV end points using appropriate animal models. An overview of end points and models that can be used is given in Table 5.

**Table 5** Test methods and models that can be used to explore potential hazards of NP particles for the CV system

Test System	End point	Interpretation
<i>Cardiomyocytes</i>		
Primary	Beating frequency, Ca <sup>2+</sup> -response Ca-dependent channels, cytoskeletal behaviour	Basic effects on cardiac metabolism
Cell lines	Ca <sup>2+</sup> -response, ATP response, apoptosis	
<i>Aorta rings (in vitro)</i>	Contraction-relaxation with epinephrine-carbachol	Autonomic innervation
Langendorf perfusion ( <i>ex vivo</i> )	Coronary flow, left ventricular developing pressure, heart rate	Heart function
<i>Telemetry (whole animal)</i>	Heart rate variability, ECG, blood pressure, vessel diameter	Cardiac and vascular function
Biomarkers in plasma/blood	Fibrinogen, CRP	Acute phase response
	Factor VII	Blood coagulation
	Viscosity, clotting time	
	Plasminogen activator inhibitor	
	Endothelin, angiotensin converting enzyme (ACE)	Endothelial damage/activation

Broadly the CV effects of NPs that need to be considered include the following:

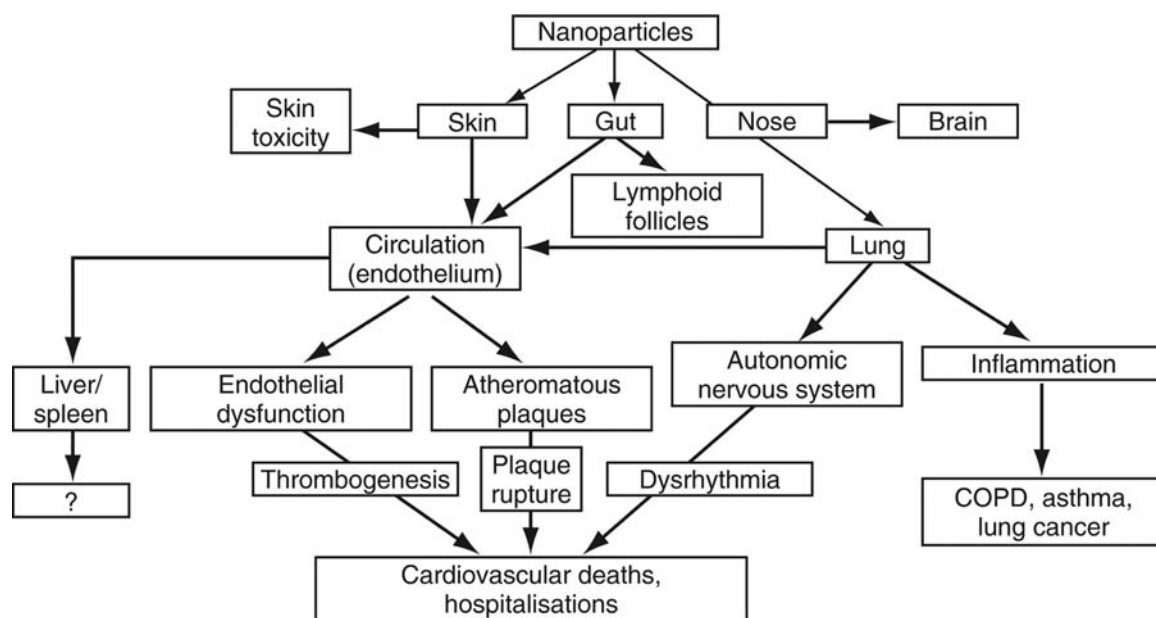

1. Effects on clotting homeostasis: Several toxicological studies have demonstrated that CDNPs and model NPs can gain access to the blood following inhalation or instillation. There is also evidence that NP introduced into the bloodstream or lung can enhance experimental thrombosis.<sup>[40]</sup>
2. Effects on neural control of CV function: Humans, dogs, rats, and mice have been used to study heart rate variability after inhalation of combustion NP and significant effects seen.<sup>[31]</sup>
3. Effects in models of coronary artery disease: Progression/worsening of plaques has been demonstrated in animal models of coronary artery disease. In Watanabe hyperlipidemic rabbits, instilled PM caused both development and activity in the plaques compared with controls. In ApoE mice, which spontaneously develop atheromatous plaques, chronically inhaled CAPS also caused worsening of the plaques.
4. Effects on vascular function: Both in vivo and ex-vivo experiments have been conducted after pulmonary exposure to NP. For example, arterial diameters decreased and blood pressure increased when measured in vivo. Isolated aorta rings or hearts can also be used to study autonomic innervation and function of the heart and vascular tissue<sup>[41]</sup> but show outcomes

physiologically different from in vivo findings. Telemetric procedures can be applied in most animals to measure cardiac function and vascular function.

**Uptake and Effects in the CNS.** It has been recently reported that inhaled UFPs translocate into the CNS via the olfactory epithelium nerve,<sup>[15]</sup> and NP drugs have been shown to cross the BBB under certain conditions.<sup>[28]</sup> Routine tests of uptake into the CNS by various NPs, as well as assays to predict their possible adverse consequences for this organ, need to be developed. For such tests, one may consider neuroimaging techniques in exposed animals, in vitro tests with glial cells and astrocytes, and the use of non-invasive quantitative electroencephalogram (QEEG).

## CONCLUSIONS

Building on data on the known behavior and toxicity of CDNPs and the few data that exist on other NP, the potential fate and adverse effects of engineered NPs is shown diagrammatically in Fig. 4. Presently, it is unknown whether the hazard, the specificity to vulnerable groups, the translocation, or the mechanism of adverse effects induced by CDNP in epidemiological studies can be extrapolated to hazard and risk estimation of the immense variety of engineered NP. In addition, we are unsure whether inhalation studies with bulk NP (carbon black and TiO<sub>2</sub>) can be used

**Fig. 4** The potential fate and adverse effects of engineered NPs is diagrammatically illustrated. NPs may use different uptake routes (gut, nose, skin, and lung) and exert different toxicity or reach different secondary targets after uptake or deposition. The major known health effects (of UFP) affect patients with pulmonary and cardiovascular diseases.

for direct comparison with engineered NP (Fig. 1). Paradoxically, whereas toxicology is trying to understand the mechanisms of NP translocation and how these minute amounts of NP might invoke response, pharmacology involves the injection of large numbers of NP into the blood for the systemic delivery of drugs or for imaging and therapy. Clearly these different concepts need to be reconciled. In this review, we have indicated what effects of NP toxicologists have found, and how this know-how could be used to develop new screening procedures for safe NP for industrial and nanomedical purposes.

Where possible, we have tried to indicate where nanoscience and toxicology should connect, communicate, and exchange methods. An even more favorable approach is to include toxicological testing in early phase of development, as has been generated for man-made mineral fibers to prevent a repeat of the asbestos experience. In producing numerous engineered NPs at low volume, a conceptual understanding of biological actions of materials is an obligatory. Such a conceptual understanding would provide an umbrella to protect society and consumers against low amounts of potentially toxic materials.

## ACKNOWLEDGMENTS

The authors are indebted to many collaborators in the development of their know-how in this area. In particular, collaboration with Roel Schins (IUF), Wolfgang Kreyling (GSF), Lang Tran (IOM), Vicki Stone (Napier University), and Detleff Müller-Schulte (Magnamedics GmbH) has generated a lot of the thinking that is included in this article. In addition, the authors thank Catrin Albrecht, Doris Hoehr, and Welf Mahlke for the use of their work on lung microscopy.

# Tribology of Inorganic Nanoparticles

Lev Rapoport

*Tribology Laboratory, Holon Academic Institute of Technology,  
Holon, Israel*

## INTRODUCTION

One of the main tribological properties of rubbed pairs is self-lubrication. The key to self-lubricating materials is the rapid and easy shear and transfer of thin films from one surface to another. The solid lubricants assure a “self-lubrication” of oils, greases, coatings, polymer composites, bearing powder materials, etc.

In the present work, a novel brand of nanomaterials—inorganic fullerene (IF)-like solid lubricant nanoparticles of  $WS_2$  and  $MoS_2$  (IF)—is considered. Friction and wear properties of IF nanoparticles are compared with commercially available layered  $WS_2$  and  $MoS_2$  solid lubricants. IF solid lubricant nanoparticles were added to oil, grease, and impregnated into the pores of powdered materials. Polymer nanocomposite with IF nanoparticles and alumina covered by thin IF film showed superior tribological properties in comparison to the reference materials. The mechanisms of IF self-lubrication are discussed.

## INORGANIC FULLERENE-LIKE SOLID LUBRICANT MATERIALS

Inorganic layered compounds are abundant, in particular, among the transition-metal chalcogenides (sulfides, selenides, and tellurides), halides (chlorides, bromides, and iodides), oxides (hydroxides), and numerous ternary and quaternary compounds. Layered materials such as graphite,  $MoS_2$  and  $WS_2$  (platelets of the 2H polytype) are used both as solid lubricants<sup>[1,2]</sup> and as additives in liquid lubricants.<sup>[3,4]</sup> Minimum tangential resistance is commonly associated with shearing of the weak interlayer (typically van der Waals) bonds in these materials.<sup>[5,6]</sup> Unfortunately, the 2H platelets tend to stick to the mating metal pieces through the reactive dangling bonds on the prismatic edges (10 $\bar{1}0$ ), which lead to their rapid annihilation through burnishing and oxidation. The friction coefficient of  $MoS_2$  solid lubricant particles is more than 0.1 at humid and oxygen-containing environments.

Recently, the tribological properties of  $C_{60}$  and  $C_{70}$  fullerenes were described.<sup>[7–9]</sup> It was speculated that the nearly spherical fullerenes might behave as nanoscale

ball bearings. Intuitively, fullerene molecules are thought to be too small to separate between asperities of the mating metal surfaces and, therefore, they tend to enter into crevices or valleys. Experiments by Campbell et al.<sup>[10]</sup> with  $C_{60}$  molecules dissolved in dry toluene tend to substantiate this hypothesis, but comparison of this result with macroscopic friction measurements does not yield a conclusive outcome. Further work of this group has demonstrated that, whereas the adhesion energy of smooth  $C_{60}$  films is very low, the friction coefficient is rather high in this case. The tendency of the fullerene powders to clump and compress into a high shear strength layer was demonstrated to be a main cause of the high friction coefficient.<sup>[11]</sup>

Using a reasoning similar to that of carbon fullerenes<sup>[12]</sup> and carbon nanotubes,<sup>[13]</sup> several groups proposed<sup>[14–16]</sup> that their formation is not unique to carbon and is, in fact, a genuine property of 2-D (layered) compounds, such as  $WS_2$  and  $MoS_2$ . However, in contrast to graphite, each molecular sheet consists of multiple layers of different atoms chemically bonded to each other. The initial discovery of IF materials elicited a substantial effort of many groups, which has been recently reviewed by a number of authors.<sup>[17,18]</sup> These nanomaterials were termed under the generic name inorganic fullerene-like (IF) materials. The results of a detailed study of inorganic fullerene-like nanomaterials are considered in this book, in a separate chapter.<sup>[19]</sup>

The analysis of IF nanoparticles showed that the most, if not all, nanoparticles were closed and hollow, and their shape was found to be irregular with a small fraction of the particles (<10%) having nearly spherical shape. The hollow cage structure of the IF imparts a high elasticity, which augments their resilience in a specific loading range.<sup>[20]</sup> Dislocations, which have deleterious influence on the chemical stability and the tribological behavior, were abundant in these nanoparticles. A typical assortment of such nanoparticles is shown in Fig. 1. The tilting of the samples in the TEM suggests that the IF- $WS_2$  nanoparticles have a spherical shape. Atomic force microscopic (AFM) image of an IF- $WS_2$  nanoparticle, confirming a spherical shape, is presented in Fig. 2. The average size of

**Fig. 1** Transmission electron microscopic (TEM) image of typical IF-WS<sub>2</sub> nanoparticles at different tilt angles. Results demonstrate the spherical shape of these nanoparticles.

the IF-WS<sub>2</sub> particles was close to 120 nm, while it was about 50 nm for IF-MoS<sub>2</sub>. High elasticity of the IF-WS<sub>2</sub> nanoparticles was confirmed by the analysis of the IF-WS<sub>2</sub> nanoparticle ensemble under hydrostatic compression.<sup>[21]</sup> This experiment was performed to evaluate the behavior of IF solid lubricant nanoparticles as a self-lubricating medium. It was found that these nanoparticles are capable of withstanding a severe hydrostatic pressure, caused by compression. Detailed structural studies revealed that no phase changes were observed during compression. With increasing load, some IF-WS<sub>2</sub> nanoparticles were found to be damaged (Fig. 3). Frequently observed defects can be associated with the breakout of the outer shells of the nanoparticles. The layer-to-layer distance of 0.62 nm was preserved in the broken sheets. The inner layers of these nanoparticles seem to remain intact. The broken outer layers are expected to be transferred to friction surfaces, providing superior tribological properties of rubbed surfaces. The 2H-WS<sub>2</sub> particles with platelet shape suffered severe damage under the same loading conditions.

The behavior of the IF nanoparticles has been compared with layered 2H-WS<sub>2</sub> and 2H-MoS<sub>2</sub>. Preliminary friction experiments showed that IF added to oil possess lubricating properties superior to those of 2H platelets in a definite range of operating conditions.<sup>[22]</sup> The weak van der Waals forces operating between the

layers leading to easy shear of the films likely cannot control the tribological properties of spherical IF-WS<sub>2</sub> nanoparticles. We attributed the recently reported outstanding tribological behavior of IF-WS<sub>2</sub> to its chemical inertness and to the hollow cage structure, which leads to high elasticity and allows the particles to roll, rather than slide (rolling friction), in appropriate loading regimes. It was realized that the addition of small amounts of quasi-spherical WS<sub>2</sub> or MoS<sub>2</sub> nanoparticles with fullerene-like structure to various kinds of lubricant greatly improves their tribological characteristics. Thus a systematic study of the tribological behavior of such nanoparticles under different contact conditions was undertaken. Based on this study, some applications for these nanoparticles are offered. Hereinafter, some recent highlights of this progress will be delineated.

### THE EFFECT OF THE IF NANOPARTICLES IN OIL

Ring-block test of a steel pair at sliding velocities  $V = 0.22$ – $1$  m/sec and loads of 150–1200 N was performed.<sup>[23]</sup> To simulate typical industrial conditions,

**Fig. 2** AFM image of spherical IF-WS<sub>2</sub> nanoparticles.

**Fig. 3** Scanning electron microscopic (SEM) micrograph of ensemble of the IF-WS<sub>2</sub> nanoparticles after compression with a pressure of 500 MPa.

only 5 wt.% of the solid lubricants (IF or 2H-WS<sub>2</sub>) were dispersed in oil. It was observed that IF showed superior friction and wear properties under relatively low values of the loads and sliding velocities. Analysis of the solid lubricant particles showed that a substantial number of the 2H platelets were destroyed, whereas IF particles were found to remain undamaged under these conditions. With increasing load, three mechanisms of IF particle damage could be discerned: plastic deformation of the quasi-spherical nanoparticles into ovoid shape; peeling-off of external sheaths; and splitting.<sup>[23]</sup> The quantity of damaged particles increased with increasing load. The amount of the oxide was found to be substantially larger on the surface of the wear track in contact with the 2H-WS<sub>2</sub> platelets compared to IF nanoparticles. The chemical reactions that are relevant to the wear of platelet materials occurred predominantly at the prismatic edges, where reactive dangling bonds exist. The presence of unsaturated or dangling bonds in metal dichalcogenides led to oxidation of the surface in the surrounding environment, especially at elevated temperatures which may occur as a result of friction. For instance, a switch from an environment of dry nitrogen to humid air led to an increase of the friction coefficient of 2H-WS<sub>2</sub> from 0.03–0.04 to 0.15–0.20, and a decrease in its resistance to oxidation by several orders of magnitude.<sup>[24]</sup> Therefore, the absence of dangling bonds may be one of the prime advantages of IF nanoparticles over the crystalline platelet (2H) particles for reduction of friction and wear.

Mixed lubrication is an extremely important regime of liquid lubrication when both fluid film and boundary lubrication take place.<sup>[25]</sup> Mixed lubrication region is the transition to scuffing and seizure. The behavior of IF-WS<sub>2</sub> solid lubricant in oil has been compared with pure oil.<sup>[26]</sup> The kinetic of the friction force change between two feedings of lubricants has been analyzed. Based on this analysis, it was concluded that the addition of IF nanoparticles to oil induces protection for the contact surface, decreases the fraction of straight asperity contact, and thus improves the tribological properties of pin-on-disk contact pair under mixed lubrication. It was found that the wear of the pin rubbed with oil + IF lubricant is lower in comparison to the pin lubricated by a pure oil. This effect grows with increasing load, suggesting that the favorable role of the IF increases with the load. Damage and destruction of IF-WS<sub>2</sub> was usually observed over a pressure of 0.5 GPa. The main damage incurred to the IF nanoparticles was the exfoliation (delamination) of external sheets (Fig. 4). Thin nanosheets of delaminated IF are also observed. Usually, only a few external molecular sheets of the IF are damaged. Appreciable damage occurred for the small number of fullerene-like nanoparticles. The surface of the pin

**Fig. 4** TEM image of the IF nanoparticles after the pin-on-disk test.

rubbed with oil + IF was found to be covered by a film. X-ray photoelectron spectroscopy (XPS) analysis revealed that this film consisted of WS<sub>2</sub>.

IF agglomerates are compressed and penetrate into the surface layers of the soft pin (Fig. 5). As a result of this effect, the surfaces rubbed with oil + IF were rougher compared to the surfaces lubricated with a pure oil. The main friction mechanism for IF nanoparticles in the range of mixed lubrication is the transfer of exfoliated thin sheets to the contact surface. The transfer is probably responsible for the self-lubrication of the IF solid lubricant nanoparticles in the mixed range of lubrication.

After the friction test, the loaded pin was etched lightly with 3% HNO<sub>3</sub> in alcohol, which dissolved the wear debris impregnated onto the metal surface and

**Fig. 5** Penetration of the IF nanoparticles and their agglomerates into the surface layers of hard disk.

revealed the wear damage. SEM analysis of the etched surface showed that, while the oil-lubricated surface was heavily damaged with deep scratches and grooves occurring, the surface of the metallic pin lubricated with oil + IF remained almost unchanged.

The thickness of the lubricant film depends on contact conditions (viscosity of lubricant, load, and sliding velocity). Using the analysis of mixed lubrication for the surface with a real roughness,<sup>[25]</sup> the mean film thickness was found to be smaller than the size of IF nanoparticles. When film thickness is smaller than the size of nanoparticles, IF-WS<sub>2</sub> have to delaminate or, they can be preserved in the valleys of the roughened surfaces, or the two processes can occur together. Identification of WS<sub>2</sub> on the contact surface (XPS and etching), preservation of the full shape of IF nanoparticles (TEM analysis), and the formation of a rough surface under steady friction prove that a part of the IF-WS<sub>2</sub> is preserved in valleys of the contact surface while another portion of the IF nanoparticles is delaminated and transferred to the rubbed surfaces.

IF nanoparticles in the valleys and delaminated transferred nanosheets on the surface decrease the straight asperity contact under mixed lubrication. Thus the IF-WS<sub>2</sub> film protects the contact surface and enhances the wear resistance of contact surfaces. We suppose that sliding/rolling of the IF nanoparticles in the interface between rubbed surfaces is the main friction mechanism under loads, when the shape of nanoparticle is preserved. It was found that the efficacy of IF nanoparticles was increased with the load. It may be expected that, under friction with very high loads (>1 GPa), a considerable number of nanoparticles will be delaminated and consequently, transfer of thin nanosheets a few nanometers in size may be a dominant friction mechanism. Recent results confirm this assumption.<sup>[27]</sup> Also, this study underscores the importance of size control for the IF nanoparticles.

Using the surface force apparatus, the friction behavior of IF nanoparticles was investigated in detail.<sup>[28–30]</sup> It was revealed that IF nanoparticles are gradually exfoliated, leaving molecular sheets of WS<sub>2</sub> on the mica surface, thereby reducing the shear resistance of the matting pairs in tetradecane suspension. Therefore the interplay between the rolling/sliding of the nanoparticles and their slow exfoliation seem to play an important role in the self-lubricating of mating tribological surfaces with IF. In contrast, 2H-WS<sub>2</sub> particles did not show favorable tribological properties.<sup>[30]</sup>

## IMPREGNATION OF IF NANOPARTICLES INTO POWDER MATERIALS

Modern powder metallurgy (PM) technologies are used to produce low-cost, high-quality bearings and

gears with long-term performance and reliability in critical applications (high loads and sliding velocities). Interconnected system of pores renders the supply of oil impregnated throughout the entire metal piece, thereby providing self-lubrication of these bearings. The lubricating fluid flows through the porous structure and is furnished to the metal surface. However, the addition of oil is prohibitive for various applications, such as aerospace, vacuum systems, and electrical motors. The impregnation of solid lubricants platelets, such as powders of WS<sub>2</sub> and MoS<sub>2</sub>, into the powder matrix allows for an increased loading of the bearings. Unfortunately, the friction coefficients encountered in bearings stuffed with solid lubricants are invariably higher (0.1–0.3) than in oil-impregnated bearings.

For most applications, the porosity of self-lubricating bearings lie between 25% and 35%. It is clear that such high porosity diminishes the mechanical properties of the porous material. On the other hand, reducing the porosity to increase the strength of the matrix would restrict the permeation of the solid lubricant into the pores. It was hypothesized that IF-WS<sub>2</sub> nanoparticles will benefit self-lubricating bearing technology in a number of ways. First, being small (0.005–0.2 μm), they could be easily impregnated into bearings of substantially smaller porosity. Such bearings will have appreciably higher mechanical strength combined with an improved tribological behavior, especially under extreme loads and velocities. Second, their seamless character and spherical shape will allow their facile impregnation throughout the entire bearing matrix. Also, being stocked in microscopic pores, these slippery nanoparticles would not be removed at once from the contact area. Instead, a slow release of the nanoparticles from the matrix pores will provide steady flux of lubricants and easy shearing of the metal–metal interface, even under extreme loads. It was also expected that the spherical shape of IF nanoparticles impregnated inside a porous solid matrix will lead to an easy flow from the pores to the contact surface, thus alleviating both friction losses and wear. The continuous supply of solid lubricant nanoparticles to the sliding contact is of great importance in this case. Therefore, it is expected that impregnation of spherical nanoparticles into the densified powder matrix will lead to a nanocomposite with superior mechanical and self-lubricating properties. Porous metal pieces, which are similar in size and shape to commercially available sliding bearings, were manufactured according to a standard PM procedure. The details of preparation PM parts were described in Ref.<sup>[31]</sup> Bronze, iron, and iron–nickel matrices were been used in this work. Subsequently, impregnation of oil–2H-WS<sub>2</sub> and oil–IF-WS<sub>2</sub> (10 wt.%) suspensions into the porous metal parts was carried out under low vacuum. IF-WS<sub>2</sub>

nanoparticles and layered platelets 2H-WS<sub>2</sub> with size close to 4 μm were used as solid lubricants. The density of IF nanoparticles is about 15–20% smaller than that of the bulk (2H) particles. Afterward, the samples were dried at 150°C (2 hr), under a vacuum of 10<sup>-2</sup> Torr, in order to release the fluid lubricant from the porous metal piece. The hollow IF nanoparticles were 5 wt.% of the powder bronze, compared with 6% for the 2H-WS<sub>2</sub>.

Fig. 6A shows SEM micrographs of the virgin bronze surfaces after impregnation of the 2H-WS<sub>2</sub> platelets has taken place. As shown by the micrograph, the surface of the metal matrix is non-uniform, and the 2H-WS<sub>2</sub> platelets are “glued” edge-on onto the metal surface through their reactive prismatic (10 $\bar{1}$ 0) faces (Fig. 6B). This orientation is unfavorable for the tribological action of this lubricant, and is, in fact, expected to “glue” the asperities of the two mating metal surfaces. Contrarily, the IF-WS<sub>2</sub> nanoparticles are scattered quite randomly on the porous metal matrix surface. Spherical agglomerates of the IF nanoparticles, which are trapped in the cavities on the metal

block surface, are discernible. The SEM image of the powder nanocomposite showed that the penetration of IF-WS<sub>2</sub> nanoparticles is close to 150–250 μm, and it depends on the matrix density.

The study of friction and wear was performed by using a ring-block tester at wide range of sliding velocities and load.<sup>[32]</sup> Samples that were oil-impregnated and dried (hereafter designated as reference) were studied first. It was established that the surface pores of this sample are rapidly filled with agglomerated wear particles already under the low load. The agglomeration and compaction of the wear particles in the pores led to a formation of smooth surfaces. With increasing load, severe plastic deformation of the surface layers was obtained. In this case, delamination of thin surface plates was observed. The fast agglomeration and compaction of the wear particles within the pores and the severe plastic deformation of the surface layers led to an increase of the friction coefficient, contact temperature, and wear rate. With increased loading, the pores became completely closed, and a smooth surface of the densified powdered block is obtained. Upon transition to seizure, the wear particles adhere to the contact surface, leading to the formation of a rough surface. The friction coefficient and temperature increase abruptly, which finally leads to seizure of the matting surfaces.

The friction coefficient and temperature for bronze part impregnated with oil + IF and reference sample were very low ( $\mu = 0.006$ ) over a large range of contact conditions, while it was higher ( $\mu = 0.06$ ) for reference sample. In this case, a lot of small pores were preserved on the surface of powdered bronze impregnated with IF under steady friction conditions. With increasing load the detached and trapped wear particles fill the pores, but a fraction of the pores nevertheless remained opened. Friction and wear of the samples impregnated with IF nanoparticles associated with their release from the interconnected system of pores in the metal matrix and a furnishing to the contact interface. Supply of the solid lubricant from the pores to the surface requires the preservation of an open porosity at the surface. Furthermore, IF nanoparticles facilitate the dislodging of the agglomerated wear particles from the pores and thus preserve the porosity and the supply of IF nanoparticles to contact surfaces. Thus the impregnation of IF nanoparticles into the pores enables the improvement of the self-lubricating properties of powder materials, thereby considerably decreasing the friction coefficient and wear rate. Diminution of the friction coefficient with the IF nanoparticles can be attributed to the following effects:<sup>[33–36]</sup>

1. The slow release and furnishing of nanoparticles from the open pores to the contact surface prevent the direct contact between the first bodies.

**Fig. 6** SEM micrographs of the virgin bronze surfaces after the impregnation of the solid lubricant particles: A) IF-WS<sub>2</sub> nanoparticles distributed in the pores; B) 2H particles glued onto the metal surface (noted by arrow).

2. The sliding/rolling of IF nanoparticles in the boundary of the first bodies and in between the wear particles (third body) facilitate the shear of the lubrication film.
3. The adhesion of IF nanoparticles to the agglomerated wear particles facilitates their dislodging from the pores, keeping the pores to remain open during loading.

It was shown that 2H particles are “glued” edge-on to the underlying metal surface through their reactive prismatic faces (10 $\bar{1}$ 0).<sup>[32]</sup> The sticking (“gluing”) of the prismatic edges of the 2H platelets to the metal surface averts their permeation deep into the metal piece and leads to their accumulation at the metal surface. The accumulation of 2H particles in the superficial pores leads to the formation of a thin WS<sub>2</sub> film on the surface of the sample. Under low load, this film provides the low friction coefficient and a reduced wear rate. However, with increasing load, the WS<sub>2</sub> film is cracked and its favorable tribological properties are diminished. The transition to seizure occurs under a load much lower than with IF nanoparticles.

The supply of solid lubricant from the pores to the surface requires the preservation of an open porosity at the surface. In the case of powdered materials impregnated with 2H-WS<sub>2</sub>, the large delaminated wear debris filled the pores. This effect led to smoothing of the rubbed surface and clogging of the pores. In contrast, the IF-WS<sub>2</sub> nanoparticles, which are dispersed throughout the entire porous metal reservoir, are forced to proceed gradually to the metal surface, and some of them are even picked up by the disk.

The efficacy of the IF is considerably increased when an oil film is supplied to the interface. The application of oil allowed the considerable increase in the load-bearing capacity of powdered bearing samples impregnated with oil + IF nanoparticles.<sup>[34]</sup> It is likely that the release and furnishing of the solid lubricant from the interconnected system of pores to the contact surface is also facilitated by the oil.

#### ADDITION OF THE IF NANOPARTICLES INTO THE GREASE

The effect of IF nanoparticles added to a heavy-duty (lithium-based) grease was studied by using a ring-block tester.<sup>[37]</sup> Here, the friction behavior of the base grease (containing 5 wt.% IF-WS<sub>2</sub> nanoparticles) and a commercial grease [containing 5 wt.% 2H-MoS<sub>2</sub> particles (platelets) as additives] were compared. SEM examination of the tested grease shows that IF nanoparticles remained intact, but partially agglomerated. The fibrelous structure of the grease is preserved after the tribological experiments with the added IF

nanoparticles, suggesting that grease does not decompose, or react, with either the nanoparticles or the metal surfaces, even under the heavy loads employed in the present experiment (Fig. 7A). The delamination of thin layers is observed on the surface of the 2H-MoS<sub>2</sub> (Fig. 7B). The friction and wear behavior of the base grease, the same state-of-the-art grease formulated with 2H MoS<sub>2</sub> platelets, and the grease formulated with IF tungsten disulphide nanosphere material were compared. Notably, the addition of only a small amount (5 wt.%) of the IF-WS<sub>2</sub> nanoparticles to the grease leads to very low friction coefficient under very high loads, largely surpassing the critical loads for seizure of the pristine grease, or the grease with 5 wt.% 2H-MoS<sub>2</sub>, added. While the temperature of the grease with 2H-MoS<sub>2</sub> particles rises to 75°C under high load of 2700 N load, it does not

Fig. 7 SEM micrograph showing the thickener fibers with IF A) and 2H B) particles of solid lubricant.

exceed 55°C under 3300 N for the grease with added IF nanoparticles. The effect of IF nanoparticles in greases on the friction, wear, and the temperature of powdered iron samples was studied. Under low loads, friction coefficients for greases with IF and 2H were close. However, with increasing load, the IF became more effective. Under load of 2700 N, a transition to seizure occurred with 2H particles, while the test with IF was continued up to the maximum possible load of the tester (3300 N). It was found that, in analogy to the friction coefficient, the effect of IF increases with the load. Thus it may be concluded that all the tribological parameters studied were considerably improved for the grease with IF nanoparticles in comparison to commercially available grease with 2H-MoS<sub>2</sub> particles. A large part of the pores was preserved on the surface of the powdered sample lubricated with grease + IF, while most of the pores were found to be clogged on the surface of the sample rubbed with a virgin grease. The study of friction and wear of powdered materials with greases showed high efficacy of the IF in comparison to commercial grease with 2H-MoS<sub>2</sub> particles and the base grease. IF nanoparticles were transferred from the grease to the contact surface. Energy-dispersive X-ray (EDS) and XPS analyses demonstrated that IF nanoparticles are confined in the pores of powdered matrix and are released to the interface even over high contact conditions.

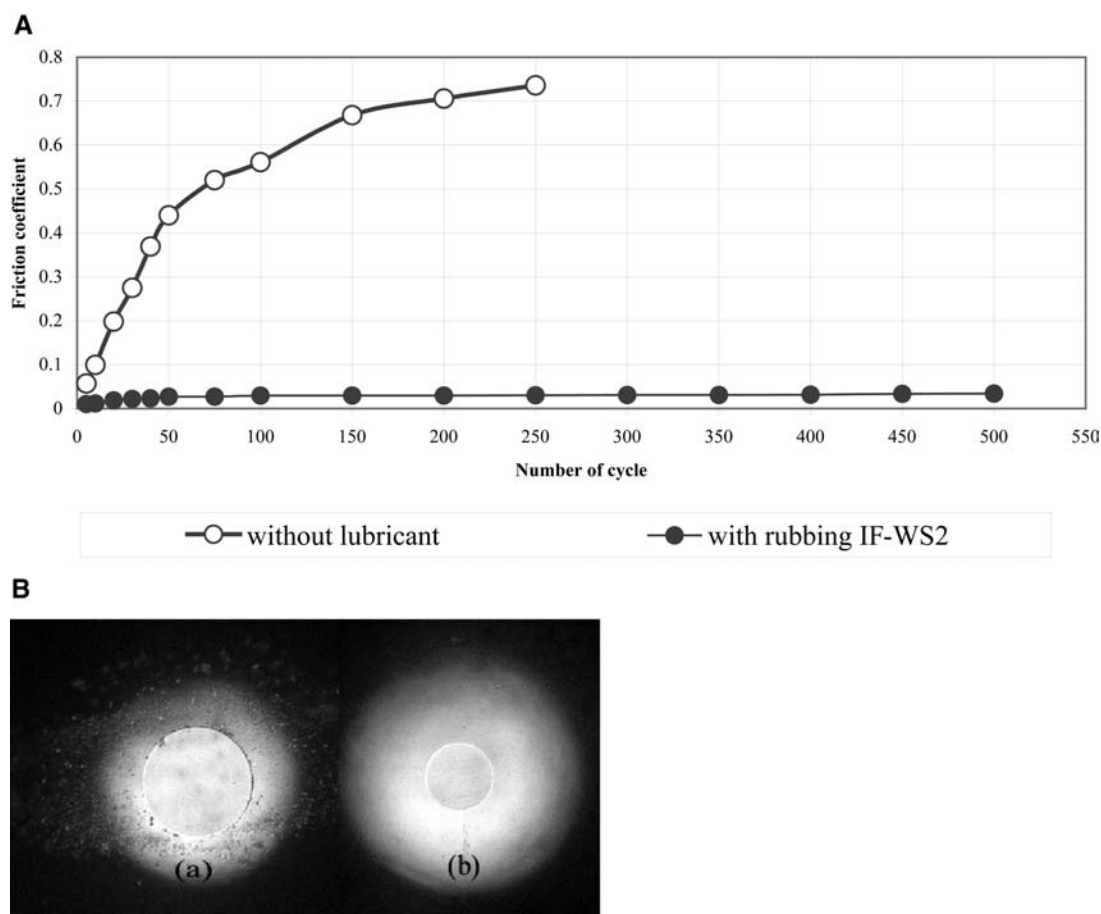

### NEW APPLICATIONS OF IF SOLID LUBRICANT NANOPARTICLES

Thin films of IF nanoparticles were deposited on metal substrates, either in the pure form or embedded in electroless coatings,<sup>[30,38,39]</sup> and were found to confer low friction and wear to the substrate, even under very high loads, ultrahigh vacuum (UHV), and in a humid atmosphere. It was shown that the frictional and wear properties of MoS<sub>2</sub> thin films deposited by ablating a solid MoS<sub>2</sub> target can be improved by the incorporation of fullerene-like nanoparticles.<sup>[38]</sup> IF-MoS<sub>2</sub> nanoparticles were tested under boundary lubrication and ultrahigh vacuum (UHV) and were found to yield an ultralow friction coefficient in both cases compared to hexagonal 2H-MoS<sub>2</sub> material.<sup>[30]</sup> The friction coefficient under high pressure (maximum pressure above 1.1 GPa in oil and 400 MPa in high vacuum) and slow sliding velocities (1.7 mm/sec in oil test and 1 mm/sec in high vacuum), and decreased and stabilized at about 0.04 for 800 cycles in both cases. It was found that 2H-MoS<sub>2</sub> particles are flattened and then break because of the contact pressure. The lamellar structure discovered in wear particles, MoS<sub>2</sub>, leads to ultralow friction.

Ceramic materials are very ionic and consequently, are rather tough and brittle, notoriously known for

exhibiting very poor tribological behavior. This poor behavior can be also attributed to the high surface roughness of ceramic materials. When rubbed against another surface, asperities of the rough ceramic surface detach and small wear particles are formed, which scratch and damage the mating surface, leading to its rapid deterioration. The surface of an alumina wafer was coated with a thin dry layer of IF-WS<sub>2</sub> nanoparticles, which was stressed under pressure applied by the reciprocating action of a ceramic ball. The added IF nanoparticles were found to decorate the irregularities and scratches on the surface of ceramic materials. Fig. 8A shows the results of a tribological experiment with Si<sub>3</sub>N<sub>4</sub> ball and a flat alumina wafer. Here a 1 order-of-magnitude reduction of the friction coefficient is obtained by adding IF-WS<sub>2</sub> to the interface in comparison to a dry friction test. Furthermore, severe wear damage occurs to the surface of the ceramic ball rubbed against alumina (a) in Fig. 8B. Contrarily, almost no wear was incurred to the ceramic ball that was rubbed against the alumina surface coated with IF film (b) in Fig. 8B. This remarkable behavior could potentially be very useful for machine parts in the textile, food, and microelectronic industries, where ceramic components take part in the manufacturing processes. Under very high pressure (>1 GPa), nanoparticles suffer a severe plastic deformation and they gradually exfoliate, producing a continuous film 3–5 nm thick on the underlying surface, which has been studied by AFM.<sup>[36]</sup> This film is expected to provide easy shear of thin exfoliated sheets of IF nanoparticles under such extreme circumstances. This observation was, in fact, preceded by a theoretical calculation, which predicted that IF nanoparticles 60 nm in diameter will plastically deform under pressures exceeding 1 GPa.<sup>[39]</sup>

A polymer-fullerene-like-WS<sub>2</sub> nanocomposite was developed by impregnating the epoxy resin with IF-WS<sub>2</sub> nanoparticles. Polymer pin-steel disk test has been performed to evaluate the self-lubricating properties of this composite.<sup>[40]</sup> The friction coefficient of a disk-pin impregnated with IF-WS<sub>2</sub> is shown to be three times lower than for a pair: epoxy resin-steel disk. The wear rate of the polymer nanocomposite is found to be 10 times lower than for the virgin polymer. It is shown that polymer nanocomposites are transferred to the hard metal surface, releasing slowly the IF nanoparticles, which provides easy shear for the mating surfaces. Analysis of the contact surfaces of the steel disk rubbed with the polymer nanocomposite identified a transferred black film on the surface. To prepare the samples for TEM analysis, the transferred film was carefully delaminated from the surface of the disk. Using EDS analysis, it was observed that, apart from the epoxy matrix, the delaminated particles contain WS<sub>2</sub>. It is likely that increasing the strength of

**Fig. 8** A) The friction coefficient of a  $\text{Si}_3\text{N}_4$  ball loaded against  $\text{Al}_2\text{O}_3$  flat wafer; B) micrographs demonstrating the wear damage on the surface of the balls loaded against alumina wafer: a) without IF film and b) with thin film of IF nanoparticles.

nanocomposite, as a result of impregnation of stiff and elastic spherical particles and the formation of the transfer films containing the IF solid lubricant nanoparticles, are the main factors leading to lowering of the friction of the nanocomposite with solid lubricant nanoparticles. The wear coefficient,  $K_w$ , for nanocomposites was  $0.5 \times 10^{-11}$  vs.  $4.6 \times 10^{-11} \text{ mm}^3/\text{mmN}$  for the epoxy samples.<sup>[40]</sup>

## CONCLUSION

This description shows a plethora of somewhat unrelated tests and disparate set of data, whereby different interfaces lubricated with IF nanoparticles exhibited invariably significantly better tribological behavior compared with the reference systems, especially under heavy loads. It suggests that the beneficial self-lubricating properties of IF nanoparticles cannot be attributed to a single mechanism alone. Under low loads, the film thickness is close to the size of nanoparticles. In this case, the shape of the nanoparticles is preserved and sliding/rolling of the spherical IF

nanoparticles at the interface seems to be the dominant friction mechanism. The agility of IF nanoparticles in the contact region also depends on their shape and size, underscoring the importance of their synthesis. The quasi-spherical shaped nanoparticles produced by the fluidized bed reactor are very suitable in this respect. When the film thickness is smaller than the size of the solid lubricant nanopowder (high contact pressures), deformation and destruction of IF nanoparticles leads to the exfoliation of thin external sheets. The self-lubricating behavior of IF solid lubricant nanoparticles is probably provided by shear of the thin transfer film. Note, that the distorted IF nanoparticles were found to be both in the valleys of contact surface and as transferred sheets at the summits of the asperities. The IF- $\text{WS}_2$  film serves to protect the contact surface and thus enhances the wear resistance of contact surfaces. Nanoparticles confined in the surface irregularities are unable to slide freely away from the contact area and are gradually released from the grooves and furnished to the mating surface, providing easy shearing, temporarily, until they are trapped again in another groove. This mechanism explains the

beneficial role of surface roughness on the performance of the IF nanoparticles in tribological contacts. Self-lubricating properties of the powder materials impregnated with IF solid lubricant nanoparticles are explained by their easy furnishing and slow release to the contact surface. Stiffness of IF nanoparticles and their self-lubricating properties impart superior tribological properties to ceramic surfaces coated by IF and polymer nanocomposites with embedded solid lubricant nanoparticles.

## INTRODUCTION

The moving contact of two solid surfaces results in friction and wear. Annually, friction and wear are estimated to cost the United States 6% of the gross national product,<sup>[1]</sup> or over half a billion dollars per year. Friction is a familiar concept that many people assume is well understood. Students often learn in high school or introductory college physics that friction can be described by a simple expression  $-F_f = \mu F_N$ , where  $F_f$  is the magnitude of frictional force,  $\mu$  is the (constant) coefficient of friction, and  $F_N$  is the magnitude of the normal force between two surfaces—and that there is a different coefficient of friction for initial motion (i.e., beginning at rest) and for two surfaces already moving (sliding friction), with tabulations of the coefficients of friction available for various pairs of surfaces. However, these relatively simple concepts—which often fail in practice, because the phenomenological coefficient of friction turns out to be a function of the details of the preparation of the two surfaces in contact, the operating conditions, the sliding velocity, and so on—hide the fact that friction is a very complicated phenomenon, little understood fundamentally, and dependent on processes taking place at the nanoscale.

Lubrication—defined by Webster's dictionary as the "application of a substance capable of reducing friction, heat, and wear when introduced as a film between solid surfaces"—is necessary to reduce damage to the moving surfaces and to enable reliable operation. Fundamentally, the phenomena of friction, wear, and lubrication involve molecular mechanisms occurring on a nanometer scale, and hence a good understanding of lubricant behavior on this scale is critical to developing new technologies for reduction of loss due to friction. Practical examples are many and range from applications at the leading edge of lubrication technology [microelectromechanical systems (MEMS) and next generation magnetic disk drives] to the

superficially more mundane area of automotive lubrication (where the distances between asperities in moving metal surfaces can be in the range of nanometers or less).

In recent years, the goal of understanding lubrication at the nanoscale, and the related concepts of friction and wear, has resulted in the emergence of the field of nanotribology as both an experimental and a theoretical discipline. Experimentally, the development of versions of the surface force apparatus that permitted the controlled oscillatory sliding motion of two surfaces (typically mica) at measurable gaps of the order of nanometers opened up the possibility of studying friction and lubrication at the nanoscale.<sup>[2–4]</sup> Similarly, around the same time, the ever-increasing availability of computing power made it possible to perform molecular-level simulations of the tribology of nanoconfined systems.<sup>[5,6]</sup> For more details, several recent reviews of various aspects are available.<sup>[7–12]</sup> In this entry, we will focus on a relatively small set of nanotribological experiments and related theoretical calculations. However, before doing so, we briefly comment on some applications of nanotribology to provide some perspective on the range of situations encountered.

## POTENTIAL APPLICATIONS

Nanoscale lubrication is ubiquitous in lubrication scenarios, even in such apparently large-scale applications as automotive lubrication. As a result of the asperities on the moving surfaces in an automobile engine and gears, extreme shear rates in excess of  $10^7 \text{ sec}^{-1}$  are found,<sup>[13]</sup> when gears come together in automotive lubrication, extreme pressures can result in elastohydrodynamic lubrication (EHL), in which the surfaces deform elastically with a thin lubricant film trapped between them. EHL is not necessarily associated with high strain rates, and is, in fact, usually an issue when

two rolling curved surfaces come together; however, the distances between the surfaces can be in the nanometer range (e.g., 25 nm for some ball bearings). The usual phenomenological explanation for EHL behavior is that, under extreme pressures, the confined lubricant undergoes a transition to a solid or glassy state. Other examples of nanoscale lubrication include magnetic disk drive lubrication, the operation of which relies on the relative motion of the magnetic head and the recording media with a spacing on the scale of nanometers,<sup>[14]</sup> producing shear in the fluid between the surfaces. Current air-bearing designs have a spacing of about 10 nm,<sup>[15]</sup> to achieve higher linear recording density and thus high data storage, this spacing needs to be reduced even further. With an ultrathin lubricant film (composed of fluorinated compounds) of  $L = 10$  nm and an operation speed  $V = 10$  m sec<sup>-1</sup> (typical for 30-mm disk drive), the shear rate  $\dot{\gamma} = V/L$  when the slider comes into contact with the lubricant would be  $\approx 10^9$  sec<sup>-1</sup> and higher. Similar nanoscale lubrication considerations arise in many microelectromechanical systems (MEMS), including micromotors. Finally, the nascent field of nanobiotribology<sup>[16]</sup> seeks to understand the nanoscale processes involved in lubrication in biological systems (e.g., the lubricants in joints are predominantly water), as well as utilize the principles of biological lubrication to engineer biomimetic lubricants.

### Experimental Characterization of Nanotribological Behavior

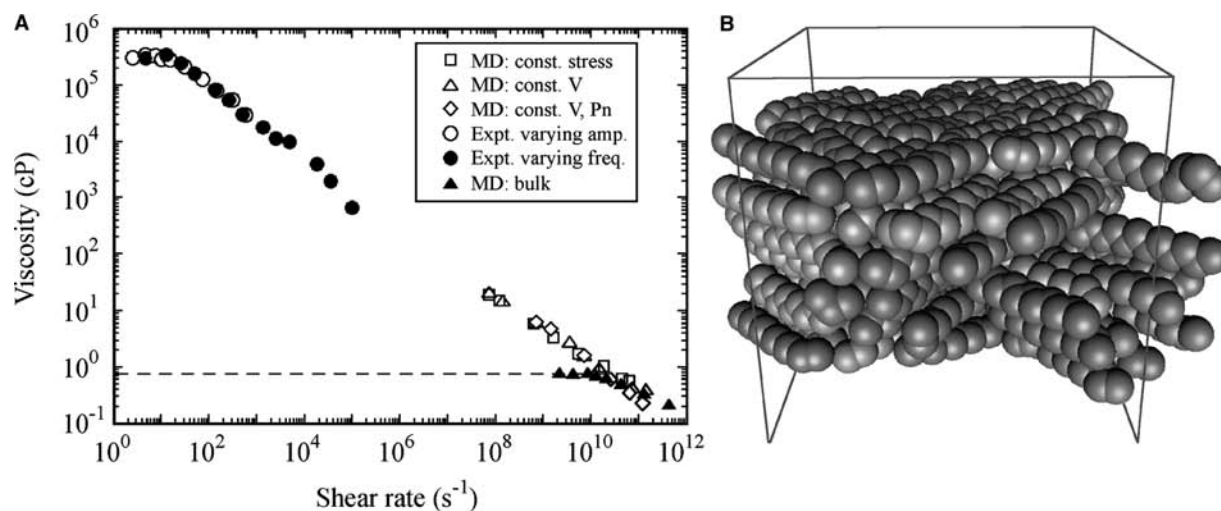

Much of the recent progress in experimental characterization of nanotribology has been made possible by the relatively recent development of instruments capable of maintaining two surfaces at fixed nanometer-scale spacing while applying a lateral force to move the surfaces with respect to each other. The instruments used most frequently are the atomic force microscope (AFM) and its frictional counterpart, the lateral force microscope (LFM),<sup>[8,17,18]</sup> the surface forces apparatus (SFA),<sup>[7,19]</sup> and the closely related surface force balance (SFB).<sup>[20–22]</sup> In the AFM, a cantilever tip (radius of about 30 nm, corresponding to a contact area of  $\sim 10^{-15}$  m<sup>2</sup>) is passed over the surface of interest; by measuring the deflection of the tip in both the horizontal and vertical directions, the surface morphology and the friction can be simultaneously measured.

Much of what we know about the rheology of nanoconfined liquids comes from the laboratories of Granick and Klein, and we briefly describe them here. In Granick et al.'s SFA experiments,<sup>[23,24]</sup> the lubricant of interest is confined between atomically smooth, step free single crystals of muscovite mica. Changes in the surface separation are measured by optical

interferometry. Surface forces are applied and the resulting motion detected using piezoelectric bimorphs. The contact region results from two crossed curved surfaces; hence, the contact region is circular with a diameter on the order of 100  $\mu$ m (corresponding to a contact area of  $\sim 10^{-8}$  m<sup>2</sup>). The diameter is measured by viewing flattened interference fringes through an optical microscope. In Klein and Kumacheva's SFB,<sup>[20–22]</sup> the contact region is also formed by crossed mica cylinders with a contact area of  $\sim 10^{-10}$  m<sup>2</sup>. The normal and lateral (or shear) forces between the two curved mica sheets are measured by monitoring the bending of two orthogonal sets of leaf springs.

We now briefly review the findings from Granick's and Klein's experimental studies. For non-polar fluids, such as short alkanes and octamethylcyclotetrasiloxane (OMCTS), which is approximately spherical with diameter  $\sim 9$  Å, the low-shear-rate (i.e., Newtonian) viscosity is many orders of magnitude greater than that of the same fluid in the bulk. Moreover, the fluid makes the transition to non-Newtonian shear thinning behavior at strain rates that are orders of magnitude lower than those of the corresponding bulk fluid. A case in point is dodecane, shown in Fig. 1A. The experimental results are from Granick's group<sup>[19]</sup> and correspond to six layers of dodecane confined between mica sheets. Note that the Newtonian viscosity is 6 orders of magnitude greater than bulk dodecane at the same temperature and pressure, and that transition to non-Newtonian shear thinning is observed for a strain rates of  $\sim 10^3$  sec<sup>-1</sup>, compared with  $\sim 10^{10}$  sec<sup>-1</sup> for bulk dodecane (derived from simulations) at the same temperature and at a pressure equal to the normal pressure in the confined experiment. As the transition to non-Newtonian behavior takes place at strain rates approximately equal to the inverse of the slowest relaxation time in the system, these results suggest that under nano-confinement, relaxation times are increasing by many orders of magnitude, perhaps indicating the onset of an ordered or glassy state. A stronger conclusion is made by Klein, who, for nano-confined OMCTS, finds a transition from fluid-like behavior (when the distance between the confining surfaces accommodates seven layers or more of OMCTS) to solid-like behavior for six layers or less. "Solid-like" behavior, in this context, means the existence of a measurable yield stress, the stress below which no sliding motion takes place. A liquid has zero yield stress, as the application of any amount of stress causes flow. The measured yield stress in Klein's experiment is less than that of a typical bulk solid, suggesting the formation of a "soft" solid (or certainly one with a different structure than a bulk).

However, for nano-confined water, strikingly different results are found.<sup>[25]</sup> Klein's experiments show no dramatic increase in viscosity under nanoconfinement—the

**Fig. 1** (A) Log–log plot of viscosity as a function of shear rate for six layers of dodecane confined between mica sheets. The open and filled circles are experimental results; the open square, triangle, and diamond are molecular dynamics (MD) simulations of this system performed in different ways (constant applied stress, constant applied sliding velocity and the latter at fixed normal pressure); the filled triangles show non-equilibrium MD results for dodecane in the bulk at the same temperature and pressure. Note that there is quite good agreement between experiment and simulation, although there remains a gap between the highest strain rate in experiment and the lowest addressable by straightforward MD. (B) Structure of six-layer dodecane system in the absence of shear. The structure evolves from a disordered structure over a period of nanoseconds, and exhibits a nonzero yield stress. *Source:* From Ref.<sup>[29]</sup>. From Ref.<sup>[27]</sup>.

increase in viscosity is not directly measurable, but can be shown to increase by less than a factor of 3. Even at extreme nanoconfinement (three water layers), water does not exhibit many orders of magnitude increase in viscosity nor does it exhibit properties associated with an ordered solid-like phase (such as sustaining a yield stress).

As we shall see below, computer simulations of nanotribological behavior exhibit many of the features of the above experiments, and there has been general satisfaction that discrepancies between experimental measurements (or their interpretation) would be resolved over time. However, at the time of writing this entry (2003), a controversy has arisen over the impact of surface impurities on the measured rheological responses of nanoconfined fluids. Christenson and coworkers<sup>[26,27]</sup> have shown that cleaved mica sheets cut with a white-hot platinum wire (as used in surface force apparatus experiments) are contaminated by platinum nanoparticles. Their explanation for the strikingly different behavior of water and non-polar fluids is as follows: in the presence of water, they assert that platinum particles leave the surface, while in the presence of non-polar fluids, the platinum particles remain on surface. This raises the possibility that some of the reported experiments may be producing artifacts resulting from platinum surface contamination. Granick has responded with a careful analysis of his own experiment, confirming the presence of platinum

nanoparticles<sup>[28]</sup> in the usually employed procedures. He has followed up with experiments using a protocol that eliminates Pt nanoparticle contamination.<sup>[29]</sup> These new experiments reproduced much of the behavior reported previously by Granick's group, but adds a new twist: the viscosity of the confined fluid is found to be dependent on the speed at which the two surfaces are brought together. In the case of so-called "rapid quenches" (surfaces brought together at speeds of the order of nm/sec), the viscosity of nanoconfined OMCTS is orders of magnitude above the bulk; in the case of "quasistatic quenches" (surfaces brought together at speeds of  $<10^{-2}$  nm/sec), the degree of viscosity enhancement is experimentally unresolvable, but is certainly not in the many-orders-of-magnitude range. Given that the rapid-quench Pt-nanoparticle-free experiments confirm his earlier results, Granick concludes that the Pt nanoparticles do not play a dominant role in determining the rheology of the nanoconfined system. Granick also reasserts the absence of an order–disorder transition in the nanoconfined fluid, similar to his previous findings. As of the writing of this entry, Klein has not responded in print to the issues raised by Christenson et al. However, from discussions with Klein and members of his group, it appears that, long before any questions were raised about Pt nanoparticle contamination, the Klein group adopted experimental protocols to minimize the presence of Pt nanoparticles on their mica surfaces.

## Computer Simulations of Nanotribological Behavior

The existence of experimental data (such as that reviewed above) and the importance of nanotribology have inspired many molecular simulation studies of nanotribological systems. The simulations have attempted to model both the AFM and SFA/SFB experiments; in the former case, it is reasonable to simulate the experiment fully because the size of the AFM tip is small enough to be accessible to simulation. Simulations of the SFA/SFB experiments have usually involved treating the contact surface as essentially infinite in two dimensions and nanoscopic in the direction of confinement. The brevity of this entry does not permit a thorough discussion of the molecular simulations; instead, we refer the interested reader to several overview papers.<sup>[9,30–34]</sup>

Rather, we focus our discussion here on computer simulations<sup>[35–37]</sup> directly relevant to the experimental measurements described above. In these simulations, nanoconfined mica was studied by classical molecular dynamics using standard united-atom alkane force fields and an approximation to the mica surface consisting of a Lennard–Jones (LJ) solid with the LJ energy determined by experimental values for the surface energy of mica. The nanoconfined systems were prepared by beginning with an equilibrated bulk system of dodecane (i.e., in periodic boundary conditions); the mica-like surfaces were then introduced into the simulations (thus eliminating periodic boundary conditions in one direction) and slowly (on simulation time scales) brought together until the normal pressure was of the same order of magnitude as the normal pressure in the experiment, resulting in compression of the nanoconfined dodecane. [Note that according to the definition introduced by Zhu and Granick,<sup>[29]</sup> this corresponds to a rapid quench.] The major conclusions from this work are as follows: first, although we are currently unable to simulate down to the strain rates at which experiments can be performed because of the very long relaxation times in the system, the sliding behavior of nanoconfined dodecane (as can be seen in Fig. 1A) is similar to that measured experimentally by Granick and coworkers.<sup>[37]</sup> Second, a transition from disordered fluid (for seven or more layers of confined dodecane) to an ordered solid-like phase (for six layers or less, see Fig. 1B), in agreement with the findings of Klein and Kumacheva<sup>[21,38]</sup> for similar non-polar fluids. For wall–fluid interactions that are attractive, the density of the confined fluid increases above the bulk density at the same density and pressure. The transition to a solid-like phase occurs when the confined density exceeds the bulk solidification density.<sup>[35]</sup> For branched alkanes, we observe an enhancement in the confined density, but

it is insufficient to exceed the solidification density for the branched alkane, and so no solidification is observed.<sup>[36]</sup> This insight between the densification of the confined fluid and the conditions under which a transition can take place to an ordered phase was used by Klein and coworkers in understanding the striking difference between the behavior of water under nanoconfinement<sup>[25]</sup> and non-polar fluids such as alkanes noted above. Klein and Kumachera attributed this to the fact that the expected densification on nanoconfinement, when interpreted in terms of bulk behavior, pushes water *away* from the bulk solidification density (owing to the density maximum in water).

## CONCLUSION

Nanotribology and nanoscale lubrication are fields that are still at an early stage, with ongoing experimental and theoretical controversies. The importance of nanoscale lubrication in fields as diverse as automobiles, hard disk drives, and biology, as well as the difficulty of simulating and performing experiments on these systems, will ensure that it will continue to be a very active area of research in the years to come.

## INTRODUCTION

Over the past decade, substantial research efforts have been directed toward the synthesis of nanostructured powders and thin films, which raise the prospects of advanced materials with dramatically improved properties based on nanoscale grain structure. It would be particularly advantageous to exploit these improved properties to extend the lifetime and robustness of tungsten carbide tools. As a result of this industrial significance, intensive efforts are being made to produce these tungsten carbide-based materials with finer and nanoscale grain size.

Many differing process technologies have been introduced to produce both nanostructured tungsten carbide and tungsten carbide–cobalt composite powders. Process technologies range from improvements to the conventional solid-state synthesis to more radical techniques such as spray conversion and vapor deposition methods.

For many applications, nanocrystalline powders have to be consolidated and sintered to make *bulk* materials and engineering components. However, most nanostructured powders lose their nanoscale characteristics after sintering because of extremely rapid rate of grain growth during sintering. Controlling grain growth during sintering and producing bulk nanocrystalline hard materials remain a critical technology challenge.

For those materials, especially metallic structural materials, the inability to achieve nanoscale grain sizes at sintered state also hinders efforts to characterize and understand their mechanical behavior as nanostructured materials. Cemented tungsten carbide is one of those materials. There are strong indications of dramatic shift in the mechanical behavior when the grain sizes of tungsten carbide cobalt (WC–Co) become progressively finer. But the potential of fully consolidated cemented tungsten carbide with true nanoscale grain sizes (<30 nm) remains unexplored.

## PRODUCTION TECHNOLOGY

The potential benefits of such finer grain size materials sparked keen interest in toolmakers, and work in this area was initiated as early as 1929.<sup>[1]</sup> While numerous techniques to produce nanostructured tungsten carbide (WC) and WC–Co powders have been developed, only a few have been proven capable at the industrial level. Production challenges include economic considerations, powder properties, powder handling, and processability. These preparation techniques cover a diverse array of processes as evident from the discussion below.

Thermochemical processing, involving spray conversion technology, was first introduced in the early 1990s for the production of these WC–Co powders and subsequently scaled up to produce the powders at an industrial level. This is a simple three-step process involving aqueous solution formation, spray drying to form an amorphous powder, and gas-phase carburization with carbon containing gases to form phase pure WC–Co powders.<sup>[2,3]</sup> The dissolution of soluble salts of tungsten, cobalt, and other additives allows uniform mixing at the molecular level. This phase uniformity is maintained in the spray drying process that yields large, porous, and flowable precursor powder particles. These particle features facilitate a uniform and complete gas phase conversion to the WC–Co cermet. The process has been demonstrated at the industrial level and is also amenable to the incorporation of grain growth inhibitors, such as vanadium carbide and chromium carbide, while facilitating recycling capabilities. As shown in Figs. 1 and 2, each large micron-sized particle contains millions of nanograin WC particles distributed in the binder matrix. The large particles reduce both powder-handling difficulties and reactivity as the discrete nanograin particles are all contained in a larger body in a type of hierarchical structure. The powders have been processed and consolidated into finished tooling parts, and significant improvements in printed circuit board drills were reported by

**Fig. 1** Etched nanocomposite WC–Co particle, showing the substructure containing WC nanograins.

Eason et al.<sup>[4]</sup> Dramatic changes in the properties of sintered parts prepared from these nanostructured WC–Co powders have also been demonstrated, as evident from the scratch test data shown in Fig. 3.

Gao, Kear, and Seegopaul<sup>[5]</sup> have reported a direct gas phase process to produce nanophase WC from the tungsten precursor, ammonium metatungstate. It is felt that the carbide formation is possible at low temperatures through a substitution of carbon for oxygen in the matrix. The authors have also demonstrated a recycling process in which spent carbide tools of various compositions and grain sizes are recycled into nanostructured tungsten–carbide–cobalt composite powders.<sup>[6]</sup>

Kim et al.<sup>[7,8]</sup> varied the thermochemical process by introducing a mechanical milling treatment of the spray-dried powder that contained added carbon to assist in the carburization phase. The milled powder is then converted to nanophase composite powder by gas phase reduction and carburization. It was also shown that grain growth inhibitors could be incorporated into the composite powders to assure a uniform dispersion for improved grain growth control.

Another variation of the spray conversion process involves the coprecipitation of cobalt with salts of tungsten, such as ammonium paratungstate.<sup>[9]</sup> As in the spray conversion process, the hardmetal constituents are mixed at the atomic level. Low-temperature hydrogen reduction together with the catalytic activity of cobalt facilitated the production of the nanostructured powders. W–Co powders (20–50 nm) were also produced by a similar process.<sup>[10]</sup>

High-energy milling has been shown to possess the capability to produce nanoscale WC and WC–Co nanocomposites.<sup>[11]</sup> In one such example, the synthesis of the WC–Co composite is completed by the process of mechanical alloying driven principally by the interdiffusion reactions and the high densities of defects and interfaces. Tan and Wu<sup>[12]</sup> varied the classical high-energy milling process by using magnesium-containing graphite mixtures. The graphite provided the carbon for carbide formation, while the magnesium facilitated the reactive synthesis. Acid dissolution is required for the magnesium removal from the 4–20 nm sized tungsten carbide product.

Vapor phase techniques have also been reported to prepare these nanocarbides, but scale-up to industrial levels would be problematic. Direct-current arc plasma was used to synthesize 40-nm WC–Co powders from a cobalt tungstate precursor, using ethylene as a carbon source.<sup>[13]</sup>

Another approach, termed integrated mechanical and thermal activation (IMTA) process, was reported by Ban and Shaw.<sup>[14]</sup> Nanoscale WC–Co powders were prepared from mixtures of cobalt, tungsten oxides, and graphite. Use of a polymer precursor as an in situ carbon source was also shown to produce phase pure WC–Co nanocomposites.<sup>[15]</sup>

## SINTERING OF NANOCRYSTALLINE WC–CO CERMETS

Cemented tungsten carbide is usually sintered via liquid phase sintering (LPS) under vacuum, or the so-called sinter hot isostatic pressing (HIP), where a low-pressure HIP is applied following vacuum sintering. Hot pressing and standard HIP can also be used to consolidate WC–Co, but they are normally not used unless there are special needs. Typical pressures for HIP and HIP are 10–70 and 100–350 MPa, respectively.

The consolidation of nanostructured WC–Co powder has been studied using a variety of means including the standard liquid phase sintering (LPS),<sup>[16–24]</sup> hot isostatic pressing (HIP),<sup>[25]</sup> and unconventional processes such as microwave<sup>[26]</sup> and spark plasma sintering (SPS).<sup>[27]</sup> In all cases of high-temperature conditions during sintering, grains grow rapidly. The finest grain size of sintered WC–Co reported in the literature to date, using nanostructured powders, is approximately 100 nm; grain size of 70 nm<sup>[42,43]</sup> was also reported by measuring the same group of samples as in Ref.<sup>[16]</sup>

Studies of the grain growth behavior have found that grain growth occurs extremely rapidly during the early stages of sintering. Fang and Eason<sup>[16]</sup> documented the densification and grain size vs. the LPS time and temperature. It was found that at the first data point ( $t = 5$  min), the grain sizes of the samples were already dramatically increased from their initial nanometer sizes, as shown in the Fig. 4. McCandlish, Kear, and Kim<sup>[9]</sup> observed that the WC grain size in a WC–10 wt.% Co alloy sintered using nanostructured WC–Co powder manufactured by Nanodyne, Inc. was 200 nm after 30 sec at 1400°C, and it became 2  $\mu$ m (2000 nm) after additional 30 sec of sintering.

Schubert<sup>[28]</sup> pointed out that grain growth started during heating up to the temperature, which is attributed to the high degree of “metastability” of the powder. Specifically, it was reported<sup>[28]</sup> that up to 85% of densification is accomplished below 1280°C when grain sizes are <0.3  $\mu$ m, while up to 70% of densification is accomplished at the same temperature when grain size is 0.7  $\mu$ m, which suggests that the onset of sintering is a function of the temperature. Experimental evidence of the sintering and grain growth at solid state provided by Goren-Muginstein<sup>[29]</sup> and Porat, Berger, and Rosen<sup>[23]</sup> indicated that large amount of grain growth

**Fig. 4** Grain size vs. sintering time comparing WC–Co materials made from nanocrystalline powders to those from conventional fine grain powders and the effects of VC grain growth inhibitor.

is already widespread at 1200°C, while liquid phase is not expected to form until 1280°C. In summary, when grain sizes of WC powder are <100 nm, significant sintering and densification will occur at solid state.

## Grain Growth Inhibitors

Grain growth inhibitors have been used to mitigate grain growth during sintering. It was found that 100–150 nm grain sizes at full density could be obtained with the addition of 1.5 wt.% vanadium carbide via standard LPS.<sup>[16,22,30]</sup> In the same study, 100–200 nm grain sizes were achieved without grain growth inhibitors at 99% relative density by employing a plasma-activated sintering (PAS) technique. The use of grain growth inhibitors is widely practiced for sintering fine grain and ultrafine grain WC–Co materials in the industry. Commonly used grain inhibitors include chromium carbide ( $\text{Cr}_3\text{C}_2$ ), tantalum carbide (TaC), and vanadium carbide (VC). Their relative effectiveness in mitigating grain growth can be ranked in the order  $\text{VC} > \text{Cr}_3\text{C}_2 > \text{NbC} > \text{TaC}$ , although other considerations such as corrosion resistance and hot hardness may also affect the choice of grain growth inhibitors.

The mechanisms of growth inhibition are the subject of many research reports.<sup>[31]</sup> Sadangi<sup>[32]</sup> carried out an in-depth study on the effects of VC addition on grain growth in WC–Co, which suggested that VC or  $\text{Cr}_3\text{C}_2$  are more effective in inhibiting grain growth because they have higher solubility and diffusivity in cobalt binder phase. The dissolution of VC and  $\text{Cr}_3\text{C}_2$  in the binder phase mitigates the solution–reprecipitation of

tungsten carbide, which is the mechanism of grain growth during sintering of WC–Co materials. Based on this theory of mechanism, grain growth inhibitors are incorporated in a solid solution of cobalt phase. These solid solution grain growth inhibitors form low melting point ternary liquids(s) at temperatures in the range of 1200–1250°C. Because these low melting point solid solutions are saturated with grain growth-inhibiting elements, the dissolution of W and C in the binder phase is prevented and grain growth is minimized.

### Pressure-Assisted Sintering

Pressure-assisted sintering is another approach for controlling grain growth. Published microstructures showed WC grains to be ~200 to 500 nm after HIP.<sup>[17,25]</sup> In particular, Azcona et al.<sup>[25]</sup> investigated the sintering of nanostructured WC–Co powder by conducting HIP at solid state. But even when grain growth inhibitors were used in combination with HIP at solid state, the final sintered grain sizes were reported to be between 200 and 600 nm.

In particular, it has been demonstrated that nanoscale grain sizes after sintering can be achieved with ultrahigh-pressure processes such as hot pressing using ultrahigh-pressure cells with >1 GPa pressure,<sup>[33]</sup> explosive compaction,<sup>[34]</sup> or severe plastic deformation methods.<sup>[35]</sup> However, all current high-pressure processes (>1 GPa) are laboratory techniques that are not suitable for mass production.

A fundamental reason for using external pressure during sintering is to promote densification. Externally applied pressure adds a driving force for densification. It is a particularly important factor for sintering nanostructured powder because it does not directly contribute to the driving force for grain growth. The effects of pressure are constrained by the pores and any gases in the pores. With conventional pressure-assisted sintering techniques, such as hot pressing and HIP, a longer holding time is required to allow diffusion and creep flow-controlled mechanisms to contribute to the final densification. The longer holding time, however, leads to significant grain growth. Higher pressures are capable of collapsing pore structures and inducing plastic flow and rapid bonding in powder compacts at elevated temperatures. This eliminates the need for long holding times at high temperatures and hence prevents grain growth to occur.

Mechanisms of grain growth during the sintering of nanoscale powders are of great interest. It is reasonable to assume that there are new mechanisms that are unique to nanocrystalline particles. There have been numerous suggestions that the grain growth occurs by coalescence of grains. Coalescence is initiated by

contact between particles. It can occur via several mechanisms including grain rotation. Another mechanism is the faceted WC crystal growth along preferential orientations, which could happen in solid state because of localized chemical inhomogeneity.<sup>[36]</sup> To date, however, there is no experimental confirmation of such mechanisms nor is there any method for controlling coalescence.

The behavior of nanocrystalline WC–Co powder during sintering is consistent with published research on sintering of other nanocrystalline powders. An excellent review on the consolidation of nanostructured powders was presented by Groza and Dowding.<sup>[37]</sup> Based on many sintering studies of mostly ceramic powders, the following viewpoints are summarized. The onset of sintering is reported to be consistently and significantly lower in nanoparticulates compared with conventional materials. Sintering of both metal and ceramic nanoparticles was found to start at temperatures of 0.2–0.4 T<sub>m</sub> compared with 0.5–0.8 T<sub>m</sub> for conventional powders. Oxides densify without significant grain growth until the density reaches approximately 90% of the bulk density. Then the grain growth becomes very rapid.<sup>[38,39]</sup> This phenomenon is attributed to the effects of pores on grain growth. There are unique and different mechanisms operating during the sintering of nanopowders because of the low apparent activation energy for early-stage sintering of nanopowders. When nanosizes are approached, atomic mechanisms become more obvious. For example, the rotation and alignment of nanosized grains may be easier. Although these possibilities have not been experimentally proved, a simple scaling down of the conventional sintering equations is not applicable.

In summary, the published data show that no true nanocrystalline (<50 nm) *bulk* WC–Co materials have been produced to date. Grain growth occurs extremely rapidly during the early stages of sintering. Grains grow significantly in solid state during sintering of nanocrystalline powders. The extreme rapid rate of grain growth cannot be explained by the mechanisms of densification and grain growth known for the sintering of micron- or submicron-sized particles. Mechanisms for grain growth in solid state may include coalescence by grain rotation. Experimental observations suggest that ~100 nm is the low limit of grain size refinement for WC–Co materials given the currently available knowledge and technologies. The need to fully densify the material and limit grain growth at the same time causes opposing considerations in process design. However, there is little published research that focuses on the interactions between densification and grain growth during sintering.

Finally, it is noted that sintered grain sizes between 0.6 and 0.9 μm can be, and are being, manufactured commercially by using conventional ultrafine tungsten

carbide powders. The initial grain size of commercial ultrafine WC powder ranges between 0.3 and 0.5  $\mu\text{m}$ . Recently, Gille et al.<sup>[30]</sup> reported a new grade of sintered hardmetal with a 100-nm mean linear intercept length using 1% total of a VC/Cr<sub>3</sub>C<sub>2</sub> additive.

## MECHANICAL PROPERTIES OF BULK NANOCRYSTALLINE WC–Co

Cemented tungsten carbide, consisting of large volume fractions of WC particles in a cobalt metal matrix, is a cermet composite material. It is well understood that the hardness of cermet materials is inversely proportional to its grain size and that the fracture toughness is inversely proportional to the hardness. Therefore finer grain size usually results in lower fracture toughness. But for nanostructured metal alloys and ceramics, it has been noted that the mechanisms of strengthening are different because of the large volume fractions of grain boundaries. The deformation mechanisms depend on grain boundary sliding and diffusion-controlled processes.<sup>[40,41]</sup> Grain boundaries in polycrystalline metals also impede the motion of cracks, which contributes to better fracture toughness. Therefore it is hypothesized that the fracture toughness of WC–Co composite will improve when WC grain sizes reach nanoscale.

### Hardness and Fracture Toughness

Hardness and fracture toughness are the two most important mechanical properties of cemented tungsten carbide and other cermets. Other mechanical properties, such as flexural strength, wear resistance, and impact resistance, are fundamentally dependent on the hardness and fracture toughness and their relationship.

The mechanical properties of nanostructured WC–Co composites were reported in several studies.<sup>[16,17,42–44]</sup> As expected, very high hardness was achieved with the ultrafine-grained microstructure. Data show that the fracture toughness of the sintered WC–Co using nanostructured powder decreases as the hardness increases. Denseley and Hirth<sup>[43]</sup> studied the fracture toughness of sintered WC–Co with an average grain size of 70–100 nm and 6.7% of cobalt using modified compact tension method. They suggested that the mode I and mode I/III fracture toughness of nanoscale tungsten carbide grains (70 nm) in cobalt was less than the toughness of mesoscale WC–6.7%Co alloys with similar cobalt volume fractions. Although this is consistent with the general trend for the conventional WC–Co, it was disappointing for many in the field because the toughness

improvement is much more highly needed than the increase in hardness.

However, several other reported data in literature indicate that the mechanical behavior of bulk WC–Co deviates significantly from its coarser grain counterpart when the grain sizes approach 100 nm. Fang and Eason<sup>[16]</sup> showed that the surface crack resistance of sintered bulk WC–Co using nanostructured powder by the Palmquist method is higher than that using conventional fine powder when they are compared at the same hardness level, as shown in Fig. 5.

Jia, Fisher, and Gallers<sup>[42]</sup> further showed that the reduction in toughness vs. hardness levels off when grain size reaches nanoscale as shown in Fig. 6. It was suggested that the toughness decreases with increasing hardness in conventional composites, but the increase of hardness in nanostructured composites does not decrease their bulk fracture toughness. The difference between the fracture toughness of WC–Co using nanostructured powder and that using conventional ultrafine powder has also been shown to depend on the cobalt contents (Fang, unpublished). For example, when a sample was sintered using nanostructured WC–10%Co powder, the sintered hardness was  $R_a = 92.0$  and the fracture toughness  $K_{Ic}$  was  $12.0 \text{ MPa} \cdot \text{m}^{1/2}$ , while the fracture toughness of the conventional WC–Co is approximately  $9.0 \text{ MPa} \cdot \text{m}^{1/2}$  when  $R_a = 92.0$ . This indicates over 30% increase in the fracture toughness.

A similar result is reported by Bartha et al.<sup>[17]</sup> as shown in Fig. 7. It shows an isolated case in which the fracture toughness is higher for samples made from

**Fig. 5** Surface crack resistance vs. hardness comparing WC–Co materials made from nanocrystalline powders with those from conventional fine grain powders and commercial products.

**Fig. 6** Fracture toughness vs. hardness of WC–Co materials comparing nanophase composite samples to conventional composite samples.

nanocrystalline powders than those from conventional powders when compared at a similar hardness level.

Based on these data, it is clear that the mechanical behavior deviates from the normal trend for hardness vs. toughness for *bulk* WC–Co when grain sizes approach nanoscale. In addition, the trend of deviation is toward the improvement of hardness vs. toughness relationship. Because all these data are based on samples that have submicron grain sizes at sintered state, the mechanical behavior of WC–Co with truly nanoscale grain sizes (<30 nm) remains unexplored. A breakthrough in sintering technologies based on in-depth research is needed to enable one to manufacture *bulk* materials with nanoscale grain structure

**Fig. 7** Fracture toughness vs. hardness of WC–Co sintered from nanocrystalline powders at various temperatures.

before the true mechanical behavior of nanoscale WC–Co can be studied.

There are three categories of possibilities by which the mechanical properties of WC–Co with nanoscale grain sizes may be improved over those of the conventional WC–Co materials. The first is based on the effects of flaws. It is expected that the flaw sizes, for example, pore sizes, in the sintered material starting with nanocrystalline WC–Co powder are drastically reduced when compared with that in the conventional *bulk* WC–Co. If the grain size is preserved at < 30 nm, the flaw size will then be a few nanometers or less. This is beneficial for the fracture toughness, independent of the hardness of the material.

The second possibility is based on the effects of interfaces. At the nanoscale level, there will be a tremendous increase in the amount of interfaces between the WC grains and the Co binder compared with coarser-grained counterparts. The partition of the crack path through binder/carbide (B/C) interfaces as opposed to other interfaces or transgranular cracks will increase dramatically in nanocrystalline WC–Co. It has been shown<sup>[45]</sup> that the crack does not advance exactly along the interface but proceeds in the binder, forming closely spaced shallow dimples in conventional WC–Co. There is an appreciable amount of plastic deformation of the binder involved in fracturing through B/C. The increase in the fractions of crack path through B/C will contribute a significant amount of fracture energy to the process, which would in turn enhance the overall toughness of the material.

The third possibility is also related to the effects of interfaces involving the deformation mechanisms. As pointed out by Gleiter<sup>[40]</sup> and Siegel,<sup>[41]</sup> the conventional dislocation generation and migration become increasingly difficult as the scale is reduced into the nanometer range. The more likely mechanisms for deformation will be grain boundary sliding and short-range, diffusion-assisted events such as grain rotation and grain shape accommodation. Both of the above interface-dependent mechanisms will be possible particularly at a relatively high cobalt content when the nano-WC particles are enclosed by the cobalt phase, the grain size of which is also at a nanoscale. When the nanocrystalline cobalt becomes the controlling phase, the behavior of the composite will also change.

It should be noted that for conventional bulk WC–Co, the fracture toughness is a function of mean free path (MFP) between the WC grains. It is dependent on the plastic deformation and tearing of cobalt metal binder. A finer grain size results in a smaller MFP at a given constant volume fraction of cobalt and a smaller plastic zone and therefore lower fracture toughness. For nanocrystalline WC–Co, the effect of

the plastic mechanisms of Co will no doubt be reduced from the viewpoint of MFP. Therefore all the possible grain boundary mechanisms including sliding and rotation are critical for its toughness. The question is whether the fracture energy through grain boundaries will be enough to compensate the loss of plastic deformation of binder phase, and what would be the final relationship between the hardness and the fracture toughness. The answers to these questions will have far-reaching scientific significance not only with respect to WC–Co cermet materials, but also many other material systems including other metal matrix composites (MMCs).

### Wear Resistance and Performance

The sliding wear resistance of nanostructured WC–Co materials was studied in detail by Jia and Fisher<sup>[46]</sup> using a carefully constructed pin-on-disc method without lubricant at room temperature. A series of grades of WC–Co with varying grain sizes and cobalt contents were made into pins with polished hemispherical shape, with the radius of the tip being about 3.5 mm. During the tests, the pins slid under modest load (9.8 N) on commercially ground silicon nitride plates. The results showed that the wear resistance of nanostructure WC–Co is higher than that of conventional cermets in proportion to their hardness as shown in Fig. 8. The sliding wear of the conventional and nanostructured WC–Co composites is, in first approximation, expressed by a Blok–Archard equation with

**Fig. 8** The dependence of wear rate of WC–Co composites sliding against silicon nitride at 9.8-N applied load and 31.4 mm/s sliding speed.

wear coefficient  $k = 6.9 \times 10^{-6}$ . The Blok–Archard equation is given as follows.

$$V = kPs/H$$

where  $k$  is the wear coefficient,  $H$  is the hardness,  $P$  is the load, and  $s$  is the sliding distance. However, a more detailed analysis found that the wear coefficient  $k$  as functions of grains sizes and cobalt content does not follow the same trend as that of conventional WC–Co composites as shown in Fig. 9, which suggests that the general trend of increasing wear with decreasing WC grain size does not extend to nanostructured materials.

The wear resistance of WC–Co materials is a functional property that depends on the hardness and fracture toughness of the material and the wear environment/mechanisms. It is particularly important to note the effects of wear mechanisms. Different wear applications, i.e., wear environment, have different mechanisms of wear. The ranking of the wear resistance of WC–Co materials and the effects of grain size and cobalt content differ depending on specific applications. Therefore the results obtained from sliding wear tests may not be directly applied to sand abrasion or cutting tool applications. To the best knowledge of the authors, to date, there are no studies on the wear resistance of nanostructured WC–Co materials in machining or sand abrasion applications that are available in public literature.

Applications of nanostructured cemented tungsten carbide include all areas where conventional WC–Co materials are used. However, industrial interests have been focused on the manufacturing of printed circuit board (PCB) drills. Printed circuit board drills can have drill tip as fine as 40  $\mu\text{m}$  as shown in Fig. 10. The grain size of the material that the drills are made of becomes a significant portion of the tip. Extremely fine grain sizes are required to achieve long and reliable tool life. Fig. 11

**Fig. 9** The variation of wear coefficient  $k$  with the carbide grain size in WC–Co composites sliding against silicon nitride at 9.8-N applied load and 31.4 mm/s sliding speed. Triangles: nanocomposites; squares: cermets with 6%Co; circles: other commercial grades of WC–Co with 10%Co, 15%Co, and 20%Co respectively.

**Fig. 10** A printed circuit board drill with a tip diameter of 0.25 mm.

compares the tool life of a PCB drill made of nanocrystalline powders with that of conventional powders. The result is consistent with the higher hardness of the nanocrystalline WC–Co composites. But it also demonstrates the effectiveness of using nanocrystalline powder in preventing premature tool failures.

Another area of application for nanocrystalline WC–Co powder that attracted active research interests

**Fig. 11** The primary wear of printed circuit board drills vs. the number of holes drilled.

is the use of nanocrystalline WC–Co powders for thermal spray coatings. The availability of nanostructured WC–Co composites sparked interest in preparing nanostructured coatings to exploit enhanced hardness, toughness, abrasion, and corrosion properties. While extensive efforts have been made to produce WC–Co hard coatings by use of conventional thermal spray techniques and despite the maturity of thermal spray technology, difficulties were still encountered in preparing dense non-porous coatings, with limited decarburization.<sup>[47]</sup> As a result, the expected increases in the hardness of the coatings were not obtained. The authors recommended that improvements in the powder feedstock or better thermal spray conditions be required to achieve the advanced properties. Skandan et al.<sup>[48]</sup> reported a unique approach to limit the decarburization during thermal spray. The nanophase WC–Co powders were mixed with larger grain size tungsten carbide to create a multimodal coating that yielded improved wear resistance in the absence of decarburization. Improvements were expected by the use of lower-temperature cold spray process, and Lima et al.<sup>[49]</sup> have reported such improved properties by using the cold spray process to prepare nanostructured WC–Co coatings.

## CONCLUSION

The advent of nanotechnology has been heralded as the “new industrial revolution.” Nanostructured materials, a subset of nanotechnology, are expected to have major impact across all industries, improving our everyday lives. The cutting tool industry has already seen the benefits of fine grain tungsten carbide cobalt cermets, and significant improvements over the existing performance are expected from finished tools with a nanograin structure.

Many powder production technologies have been developed over the years, with a few of these reaching commercial-scale levels. More work is needed, however, both to improve the processability of the powders and attain acceptable production economics. As these powders are then consolidated into tooling parts, the major challenge involves the retention of the nanograin structures after the required sintering of the parts made from the nanoscale powders. Many sintering processes have been presented, but in all cases, the basic grain growth mechanism becomes the limiting factor in attaining a true nanograin WC–Co tool.

# Ultrathin Polymer Films: Nanoparticle Nucleation

Pieter Stroeve

Department of Chemical Engineering and Materials Science, University of California–Davis, Davis, California, U.S.A.

## INTRODUCTION

In recent years, the fabrication of nanostructured materials and exploration of their properties have attracted the attention of physicists, chemists, biologists, and engineers.<sup>[1–4]</sup> Interest in such systems arises from the fact that the mechanical, chemical, electrical, optical, magnetic, electrooptical, and magneto-optical properties of these particles are different from their bulk properties and depend on the particle size.<sup>[5–9]</sup> There are numerous areas where nanoparticulate systems are of scientific and technological interest. To produce these systems in appropriate matrices is a significant challenge. This entry considers nanoparticles in nanofilms of polyelectrolyte. First, we will briefly review some key areas of applications of nanoparticle systems, with an emphasis on nanoparticles in matrices, and then we will address the area of layer-by-layer deposition of polyelectrolytes. Finally, nucleation and growth of nanoparticles in nanofilms of polyelectrolytes will be discussed.

## OVERVIEW

### Semiconducting Nanoparticles

Nanoparticulate systems are deemed technologically important in the design of miniaturized, ultrahigh density integrated circuits and information storage devices of the future and in some sense an alternate route to overcoming the 100-nm barrier in conventional electronics and develop nanodimensional molecular electronic devices.<sup>[10–13]</sup>

Owing to their semiconducting properties, group II–VI and IV–VI compounds have been intensively examined by various authors.<sup>[14]</sup> The size-dependent optoelectronic properties of nanoparticles (diameter 1–100 nm) are attributed to quantum confinement effects.<sup>[1–13]</sup> Briefly, electronic excitation in semiconductors arises from an exciton (an electron and hole bound pair) localized in a potential well. Theoretical calculations<sup>[6–13]</sup> have demonstrated that when particle sizes corresponding to the De Broglie wavelength of the free charge carriers are approached, quantum

confinement effects become dominant. One manifestation of such an effect is an increase in the optical band gap energy with decreasing particle size that is readily manifested as sharp changes in color visible to the naked eye. Depending on the particle size, the color of CdS colloids may vary from blue to red, whereas PbS nanoparticles may appear pale yellow, orange, red, or black.

Nanoparticles has been studied in micelles,<sup>[15–17]</sup> vesicles,<sup>[18,19]</sup> sol–gel glasses,<sup>[20,21]</sup> zeolites,<sup>[22,23]</sup> Langmuir–Blodgett (LB) films,<sup>[24,25]</sup> and polymers.<sup>[26,27]</sup> In most cases the clusters have poorly defined surfaces and a broad distribution of particle sizes. Empedocles et al.<sup>[28]</sup> have demonstrated control in preparing monodisperse CdSe clusters using a synthesis medium consisting of trioctylphosphine and its oxide. While size exclusion chromatography permits a narrow size distribution of particle sizes, only minute quantities of the materials are obtained, which is unsuitable for any large-scale applications. On the contrary, the synthetic route used by Empedocles, Norris, and Bawendi<sup>[28]</sup> permits the production of gram quantities of nanoparticulate solids. Chemical reactions initiated within the microscopic cavities of zeolites, glasses, polymers, and micelles provide another process of preparing nanoparticles. The shape and sizes of the nanoparticles in these “microreactors” are largely controlled by the restricted geometry of the cavities in which nucleation and growth of these particles occur. Thermodynamic and entropic requirements also play a crucial role in determining the size of these clusters.

### Iron Oxide Nanoparticles

In the attempt to improve magnetic recording technology, great effort has been made for obtaining high-density recording media. For this purpose, the production of nanoparticles that are uniform, highly dispersible, and oriented in a matrix is essential. Controlled coercivity (between 500 and 1500 Oe) and high saturation magnetization are important tasks. Increasing the coercivity to an applicable level has been fulfilled by doping or coating the maghemite particles with Co.<sup>[29]</sup> The production of nanoparticles has been

achieved on the basis of a mimetic approach, i.e., with the utilization of an organic support that plays an essential role in crystal nucleation and in its growth control.

Nguyen and Diaz reported a simple synthesis of bulk poly(pyrrole-*N*-propylsulfonate) polymer composites containing nanosized magnetite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>) particles.<sup>[30]</sup> Using FeCl<sub>3</sub>, they polymerized pyrrole-*N*-propylsulfonate, resulting in a black polymeric powder. Using sulfonate groups as nucleation sites for the growth of nanoparticles was a new technique introduced by Ziolo et al.<sup>[31,32]</sup> when they reported a matrix-mediated synthesis of maghemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>). The bulk magnetic material that they synthesized, a  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>/polymer nanocomposite, was optically active at room temperature. Using FeCl<sub>3</sub> and FeCl<sub>2</sub> they ion-exchanged sulfonated polystyrene cross-linked with divinylbenzene which yielded a polymer with iron cations ionically bonded to sulfonate groups. Washing with NaOH, then heating to 60°C, while adding aqueous H<sub>2</sub>O<sub>2</sub> solution, oxidized the iron to  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>. Ziolo et al. proposed that the sulfonate groups of the polymer matrix provide spatially located sites for the growth of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, while the void volume in the cross-linked resin imposes a limit on the maximum size of the crystals grown, thereby minimizing aggregation of the iron oxide particles. Particles ranged in size from 5 to 10 nm, as determined by transmission electron microscopy (TEM).

A similar technique was used to prepare a superparamagnetic form of goethite in pores of sulfonated, highly cross-linked poly(divinylbenzene) microspheres.<sup>[33]</sup> The synthesized iron oxide had a calculated magnetic susceptibility, which was about 3 orders of magnitude larger than bulk goethite. Chemically, ferrous ion oxidation reaction leads to the formation of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>/polymer composites, using a commercial ion exchange resin consisting of sulfonated, lightly cross-linked polystyrene. The use of polymers with different pore diameters and grade of cross-linkage lead to the oxidation of ferrous chloride to different iron oxides. In this behavior it could be shown that organic matrices have a dramatic influence on the crystallization product.

## Biom mineralization

Biom mineralization occurs naturally in many biological systems including bacteria.<sup>[4]</sup> In the presence of a supersaturated solution, minerals may form on the surface of a living organism. The formed structures are characterized by a high degree of regularity and the supramolecular architectures are finely controlled. Although biom mineralization had been widely

studied,<sup>[4,34–36]</sup> the mechanisms of growth are not always understood. The supramolecular organization of the organic support seems to have an essential role in the process; these organized architectures (such as vesicles, micelles, polymeric networks) provide functionalized surfaces that act as templates and assist in the interfacial molecular recognition. In many cases the organic matrix provides precise sites for oriented nucleation.

## LAYER-BY-LAYER DEPOSITION

The layer-by-layer deposition technique of building supramolecular multilayers on solid substrates by adsorbing polyelectrolytes has emerged as a simple means of producing templates of controlled thickness. Decher<sup>[37,38]</sup> has established that such multilayers may be reproducibly built and the resultant structure is mechanically and thermally stable. Such films have been utilized in the preparation of electroluminescent devices, zener diodes, and the possibility of their use in flat screen displays has been suggested.<sup>[13]</sup> The porous and supramolecular structure of these films provides opportunities for studying chemical reactions in the nanoscale regime. Fig. 1 shows pictorially an example of the layer-by-layer deposition technique for sequential deposition of a polyanion followed by a polycation on a positively charged surface.

The procedure of layer-by-layer deposition is simple. For example, poly(diallyldimethylammoniumchloride) (PDDA), a polycation, and poly(styrene-sulfonate) (PSS), a polyanion, can be deposited sequentially on a negatively charged surface as follows. The polyionic solutions of PDDA and PSS can be prepared separately in 20-mM concentrations: the former is dissolved in deionized water, whereas the latter is dissolved in a 0.1-M NaOH solution, and then adjusted to a pH of 4.5 by drop wise addition of 0.1 M HCl. All concentrations are calculated based on the monomer molecular weights. Polymer films can be assembled on negatively charged substrates if one starts with PDDA. A PDDA/PSS deposition cycle is termed the deposition of one layer-pair. For nanoparticle nucleation, deposition is preferably ended with the first half of a layer-pair in order to terminate the film with a PDDA layer, as will be discussed later. The deposition of the layer-by-layer films can be followed by UV-visible spectroscopy as shown in Fig. 2, and the absorbance is linear with the number of layer-pairs deposited. For the above conditions each layer-pair is approximately 4–5 nm thick, so that a 10.5-layer-pair-thick nanofilm is about 50 nm in total thickness.

Fig. 1 Schematic representation of layer-by-layer deposition for a positively charged surface.

### NUCLEATION OF NANOPARTICLES IN NANOFILMS OF POLYELECTROLYTES

It has been demonstrated by Stroeve and coworkers<sup>[39–43]</sup> that divalent and trivalent ions can bind to the negatively charged sulfonate groups in layer-by-layer polyelectrolyte nanofilms and that the absorbed ions can be oxidized to form nanoparticles of oxides, or reduced to form nanoparticles or other compounds. For example, nucleation of metal oxide nanoparticles within a nanofilm of polyelectrolyte occurs by cycling the polymer-coated substrates first in  $\text{M}^{2+}$  and then in  $\text{NaOH}$  or  $\text{NH}_4\text{OH}$  solutions (absorption–oxidation cycles or oxidative hydrolysis cycles). The  $\text{M}^{2+}$  solutions can be prepared in concentrations of 4–40 mM by dissolving a  $\text{M}^{2+}$  salt [e.g.,  $\text{MCl}_2$  or  $\text{M}(\text{NO}_3)_2$ ] in purified water. The solutions of 0.1–1.0 M base are made using purified water. Before cycling, all solutions are vigorously sparged for 45 min with nitrogen gas to remove any

dissolved oxygen in solution. In Schlenken tubes, under nitrogen gas, the polymer nanofilm on a substrate can be exposed to the  $\text{M}^{2+}$  solution for a few minutes. Typical substrates can be quartz, silicon wafers, ZnSe wafers, membranes, or more complex-shaped substrates such as catalytic particles. The substrates are rinsed with degassed and purified water to remove excess ions absorbed in the film, and then exposed to  $\text{NaOH}$  or  $\text{NH}_4\text{OH}$  solution for several minutes. Substrates are then rinsed with degassed and purified water and dried completely before the absorption–oxidation cycle is repeated. Fig. 3 shows that the process of oxidative nucleation and growth can be followed by UV–visible spectroscopy.<sup>[39]</sup> Fig. 3B shows that the nucleation of nickel hydroxide nanoparticles with the number of oxidative hydrolysis cycles is linear. The resulting nickel hydroxide nanoparticles after  $x$  cycles is shown in Fig. 4. Each oxidative hydrolysis cycle nucleates new nanoparticles, while nanoparticles from previous cycles grow in size.

**Fig. 2** A) UV-visible absorption for a number of layer-pair (LP) deposition (without absorption-oxidation cycles); B) absorbance at 225 nm with respect to the number of layer-pairs deposited. *Source:* From Fojas et al. [Ref.<sup>[39]</sup>], with permission.

Dante et al.<sup>[40]</sup> demonstrated the formation of akaganéite ( $\beta$ -FeOOH) in multilayered, polymer films of PDDA and PSS produced by the layer-by-layer technique. Ferrous chloride was used as the starting metal ion solution. Uniform, needlelike nanoparticles of  $\beta$ -FeOOH were obtained inside the nanofilm. Transmission electron microscopy showed uniform needles with a diameter of 10 nm and a length of 100 nm. Deposition of the nanofilms had to be terminated with the last layer being PDDA. In the case that the last layer was PSS, two types of nanoparticles were obtained:  $\beta$ -FeOOH and  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>. The  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles were spherical and 10 nm in size. Presumably, the mechanism of oxidation of iron ions on the outermost PSS surface layer was different from the oxidation of the iron ions bound to the inner PSS layers.

Dutta et al.<sup>[41]</sup> studied the nucleation and growth of lepidocrocite ( $\gamma$ -FeOOH) crystals in a nanofilm generated as a result of a layer-by-layer adsorption of PDDA and PSS. Interest in lepidocrocite stems from the fact that it is paramagnetic at room temperature having a low Neel temperature of 77 K and is easily

**Fig. 3** A) UV-visible absorption spectra for 6.5 layer-pairs cycled in a 40-mM NiCl<sub>2</sub>·6H<sub>2</sub>O solution and in 1.0 M NaOH solution; B) absorbance at 300 nm with respect to number of oxidative cycles. *Source:* From Fojas et al. [Ref.<sup>[39]</sup>], with permission.

converted into other industrially important magnetic oxides, namely, maghemite and hematite upon heating. Nanofilm films were formed by the layer-by-layer deposition technique on a quartz substrate. Nucleation of nanoparticles in the nanofilm of polyion was initiated by adsorbing ferric nitrate and its subsequent hydrolysis with ammonium hydroxide. Repeating the above process resulted in an increase in the density of the nanoparticles initially formed followed by the appearance of crystallites that grow in dimensions with the number of adsorption and hydrolysis cycles. The size of the crystals can be controlled by the number of cycles used. Analysis of the steady-state UV-visible absorption spectra of the films revealed the formation of lepidocrocites, which was confirmed by FTIR and selected area electron diffraction (SAED) studies. An important feature of this work was that lepidocrocite ( $\gamma$ -FeOOH) is formed instead of akaganéite, which was generated when ferrous chloride was used as the starting material as reported in the work of Dante et al.<sup>[40]</sup> It therefore appears likely that the initial

**Fig. 4** TEM image of 2.5 layer-pairs with eight oxidative hydrolysis cycles using 4 mM  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$  and ammonia base ( $50 \text{ K} \times$  magnification). The smaller particles are about 50 nm in length, while the larger particles are about 300 nm in length. The smaller nanoparticles are generated with each cycle, whereas existing particles continue to grow in size with each cycle. *Source:* From Fojas et al. [Ref.<sup>[39]</sup>], with permission.

starting material plays a key role in determining the structural and morphological characteristics of iron oxyhydroxides although their chemical compositions are the same.

Nucleation and growth of lead sulfide (PbS) nanoparticles in a PDDA–PSS film produced by the layer-by-layer deposition technique has been studied by Dutta et al.<sup>[42]</sup> Interest in PbS arises from the fact that it is a semiconductor having a small band gap (0.41 eV) and large exciton diameter (18 nm) that permits size-quantization effects to be observable even for large-sized particles or crystallites. Moreover, the non-linear optical (NLO) properties of PbS nanoparticles show large differences in their optical limiting behavior below and above the absorption edge, suggesting that such systems may be utilized in high-speed switching.<sup>[43]</sup> Chemical reaction within the polymer film was initiated by Dutta et al.<sup>[42]</sup> by absorbing  $\text{Pb}^{2+}$  from an aqueous solution of  $\text{Pb}(\text{NO}_3)_2$  followed by exposing the film to  $\text{H}_2\text{S}$  gas. Electron microscopic examination of the films revealed that while nanoparticles are formed in films that were subject to one or two reaction cycles, large crystallites were formed when these films were exposed to a large number<sup>[10]</sup> of reaction cycles. In the latter case a broad distribution of particle sizes is observed and may

perhaps be attributed to a form of Ostwald ripening. Detailed studies show the nucleation and growth of the PbS nanoparticles into larger crystallites. UV–visible absorption studies reveal that the absorption spectral profiles of the films are dependent on the size of the PbS crystallites. The broadened absorption spectral profile observed for films subject to a large number of reaction cycles may be attributed to the superposition of the spectral profiles of the small clusters that tend to be blue shifted due to quantum confinement effects and the large clusters that are red shifted. Crystal size can be controlled by the number of cycles. Essentially, a single cycle only gives nanoparticles that continue to grow in size with more cycles. Instead of using a reducing reaction, it was also possible to oxidize the Pb ions to make  $\text{PbSO}_4$  particles.<sup>[42]</sup>

Zhang et al.<sup>[44]</sup> reported the oxidative hydrolysis of  $\text{Co}^{2+}$  ions absorbed in organized, multilayered, polymer films to form cobalt hydroxide nanocrystals. It was found in this study that using more polymer layer-pairs result in more crystal growth. Hydrolysis of the  $\text{Co}^{2+}$  ions in a nitrogen-rich environment gave rise to mainly needlelike crystallites of  $\alpha\text{-Co}(\text{OH})_2$  that were initially about 100 nm in length and then increased in size with the number of absorption–hydrolysis cycles. However, in an oxygen-rich micro-environment, hexagonal crystallites were found to be predominant. X-ray diffraction (SAED) and TEM studies revealed that these hexagonal crystallites are mainly that of  $\beta\text{-Co}(\text{OH})_2$ . Fig. 5 shows the transition from the alpha to the beta form as observed by TEM. These studies suggest that by varying the nitrogen-to-oxygen ratio the formation of  $\alpha\text{-Co}(\text{OH})_2$  and  $\beta\text{-Co}(\text{OH})_2$  may be controlled.

Rubner and colleagues<sup>[45,46]</sup> have further improved the method of Dante et al.<sup>[40]</sup> by using weak polyelectrolytes, such as poly(acrylic acid) (PAA), instead of a strong polyelectrolyte such as PSS. The advantage of their technique is that the linear charge density can be varied with pH. Thus it is possible to control the charge density of the adsorbing polyelectrolyte and the charge of the previously adsorbed polymer. This technique allows the control of the thickness of the nanofilm, the composition, surface properties, and the level of polymer interpenetration. Rubner and colleagues synthesized layer-by-layer nanofilms containing silver nanoparticles and semiconductor nanoparticles. They showed that it was possible to stratify the nanofilm in layers with nanoparticles and layers without nanoparticles. Dai and Bruening used postreduction of metal ions to obtain layer-by-layer films of catalytic metal nanoparticles with a size range of 4 to 30 nm.<sup>[47]</sup> Recently, Rubner and colleagues nucleated palladium nanoparticles as catalytic seeds for further growth of electroless nickel on the nanoparticle seeds.<sup>[48]</sup> The size of the seeded nickel nanoparticles could be controlled

**Fig. 5** TEM micrographs of a 3.5 layer pairs of PDDA-PSS films at different stages of the absorption-hydrolysis process in a nitrogen-enriched environment: (A) two cycles, and in an oxygen-enriched microenvironment panels; (B) four cycles; (C) eight cycles. The concentrations of cobalt chloride and sodium hydroxide solutions were 4 and 10 mM, respectively. Source: From Zhang et al. [Ref.<sup>[44]</sup>], with permission.

and up to 14-nm-diameter nanoparticles were obtained inside the nanofilms.

## CONCLUSION

The layer-by-layer technique of depositing polyions on substrates to build nanofilms of specific thickness, composition, and surface charge can be used to carry out nanoreaction inside the films to form nanoparticle-polymer complexes. Nanofilms of nanoparticle-polymer are useful in coatings, catalysis, electrical, optical, magnetic, electrooptical, and magneto-optical applications. Manipulation of film type and reaction conditions allows for control of the nanoparticle product, distribution, and size inside the polymer matrix.

# Virus Nanoparticles: Adsorption and Organization on Substrates

Jiyu Fang

*Advanced Materials Processing and Analysis Center, University of Central Florida,  
Orlando, Florida, U.S.A.*

## INTRODUCTION

Virus particles are supramolecular structures containing a nucleic acid [either deoxyribonucleic acid (DNA) or ribonucleic acid (RNA)] core surrounded by a protein layer, known as the capsid. They are important entities in biological systems and useful templates for the synthesis of inorganic nanocrystals. Recently, studies regarding the interfacial behavior of virus particles have begun to emerge from the understanding of two-dimensional (2-D) protein crystallization, the immobilization for studying their structures with atomic force microscopy (AFM) and the preparation of scaffolds for assembling mesoscale materials. The adsorption and organization of virus particles on surfaces are the topic of this entry.

## BACKGROUND

Adsorption and self-organization of biological molecules on surfaces have attracted considerable interest because of their biological implications and potential applications. Viruses are architectural biological assemblies containing two basic units:<sup>[1]</sup> a core of nucleic acid plus a capsid. The viral capsid consists of a large number of protein subunits. Highly monodispersed virus particles with specific shapes are useful templates for the synthesis of inorganic materials. For example, Shenton et al.<sup>[2]</sup> demonstrated that the external surface of tobacco mosaic virus (TMV) particles, consisting of repeated patterns of charged amino acid residues, could be used as nucleation sites for surface-controlled deposition of inorganic materials. The TMV-templated sol-gel condensation of tetraethoxysilane led to the formation of SiO<sub>2</sub> rods. Douglas and Young<sup>[3]</sup> synthesized inorganic nanoparticles within the spherical cage of the well-defined cowpea chlorotic mottle virus (CCMV), devoid of nucleic acid. In this system, the positively charged inner compartment provided a suitable interface for inorganic crystal nucleation. The resulting nanoparticles of paratungstate and decavanadate showed a uniform size

distribution, which is determined by the dimensions of the viral cage. Mao et al.<sup>[4]</sup> genetically engineered M13 particles by binding specific peptides to the particle surfaces. They found that the modified M13 particles could be used to directly synthesize magnetic and semiconducting nanowires. We expect that the organization of these virus templates on substrates will lead to the ordered arrays of the dots and nanowires, which are essential for the next generation of nanodevices. The immobilization of virus particles on substrates will provide an opportunity for us to study their structures with AFM. However, the interfacial behaviors of virus particles are poorly understood due to their complicated structures, variegated electrostatic surfaces, and conformational dynamics. The goal of this entry is to highlight studies on the adsorption and organization of virus particles on substrate surfaces.

## ADSORPTION OF VIRUS NANOPARTICLES ON SUBSTRATES

Recently, a number of methods have been developed to control the adsorption of virus particles on substrates and immobilize them on the substrate surfaces with the goal of studying their structures with AFM. Kuznetsov et al.<sup>[5]</sup> studied the adsorption of several virus particles on substrates using AFM. They found that brome mosaic virus (BMV) and cauliflower mosaic virus (CaMV) adhered well to mica and were stable to repeated AFM scanning. The appearance and organization of capsomere structures on the surface of single BMV particles are clearly visible in the AFM image shown in Fig. 1A. The capsomere consists of either five or six protein capsid subunits. Each has a depression at the center. The capsomeric units on the CaMV surface organize into a hexameric lattice with a spacing ranging from 10 to 12 nm (Fig. 1B).

Knez et al.<sup>[6]</sup> studied the adsorption of TMV on chemically modified substrates with AFM. They found that the TMV particles adsorbed on hydrophobic graphite surfaces showed a cylindrical shape with a height of 18 nm. While on the chemically modified,

**Fig. 1** AFM images of A) bromo mosaic virus and B) cauliflower mosaic virus immobilized mica. Capsid substructures are clearly visible. *Source:* From Ref.<sup>[4]</sup>.

hydrophilic surfaces, the TMV particles were flattened to a height of 15 nm. The conformation change was suggested to be a result of the strong hydrogen binding of the carboxylate or acyl chloride termini of the hydrophilic surfaces with the TMV particles.

We reported the selective adsorption of bacteriophage T4 and its tail on a patterned organosilane monolayer consisting of  $\text{CH}_3$ -terminated islands surrounded by a  $\text{CF}_3$ -terminated continuous phase.<sup>[7]</sup> As can be seen from the AFM image, which is shown in Fig. 2A, the tail tubes are preferentially adsorbed on the  $\text{CF}_3$ -terminated surface. The strong affinity of the tubes for the  $\text{CF}_3$ -terminated continuous phase allows detailed imaging by AFM. It is known that T4 tubes are 9.8 nm wide and 98 nm long. The average width of the tubes measured in the AFM image is  $43 \pm 2$  nm. Much of the difference in the widths is

**Fig. 2** AFM images of tail tubes and tube baseplates adsorbed on a patterned silane monolayer consisting  $\text{CH}_3$ -terminated islands surrounded by a  $\text{CF}_3$ -terminated continuous phase.

attributed to the geometrical effect of the AFM tip. The measured height of the tube is unaffected by the tip size, and we find that it ranges from 9.4 to 10.3 nm. Although broadening by the AFM tip affects the image resolution, there is an evidence of the final bulge, an increase of the radius by about 4 nm on one end of the tubes. Tube dimers, which are formed by linking two fibers that project from one end of the tubes, are also clearly visible. The angle between the tubes in a dimer varies from  $80^\circ$  to  $180^\circ$ .

Fig. 2B shows the adsorption of T4 tail tubes with baseplates on patterned organosilane monolayers. The characteristic T-shaped tube baseplates selectively adsorb on the  $\text{CF}_3$ -terminated surface. The baseplates are flexible. For example, baseplates are negatively stained baseplates can undergo a transition from a dish shape to a knob-shaped configuration under the influence. We find that most of the baseplates adsorbed on the  $\text{CF}_3$ -terminated surface exhibit a knob configuration (Fig. 2C), but dish-shaped baseplates are also observed (Fig. 2D). Tail tubes joined to baseplates are stable when the loading force applied on the tip is  $<4$  nN; however, if the force is  $>5$  nN, the tubes can be gradually removed from the baseplates during repeated scans although the baseplates are not displaced (Fig. 3). In this situation, the AFM tip acts like a knife to cut the tube from the baseplate.

An AFM image of a complete T4 is shown in Fig. 4A. The  $\text{CH}_3$ -terminated surface resists T4 adsorption. The T4 adsorbed on  $\text{CF}_3$ -terminated continuous phase can be repeatedly imaged if the loading

**Fig. 3** AFM images of tube baseplates adsorbed on the  $\text{CF}_3$ -terminated surface. The images were taken after A) 2, B) 4, C) 6, and D) 10 scans.

**Fig. 4** A) AFM and B) FFM images of individual T4 on a patterned silane monolayer consisting  $\text{CH}_3$ -terminated islands surrounded by a  $\text{CF}_3$ -terminated continuous phase. The two images were taken simultaneously during scanning.

force is  $<4\text{ nN}$ . The head, tail, and probably three fibers of the phage are observed in the AFM image. The head height measured from the cross-sectional profile is about 71 nm, which is close to the known value of 75 nm. Fig. 4B is a frictional force microscopy (FFM) image of the T4 that was taken simultaneously with the AFM image shown in Fig. 4A. The resolution in the FFM image of the T4 is better than that of the AFM image. Although the apparent dimensions of the head (120-nm length and 100-nm width) are affected by tip broadening, the ratio of the head length to width is close to the expected value. The tail structures (neck and baseplate), which are not detected by the AFM, are better resolved by the FFM. The better resolution may be attributed to the high sensitivity of the frictional force to the chemical nature of the T4 surface. Occasionally, the leaking of DNA from the T4 tail is observed. This can be seen

**Fig. 5** AFM image of a collapsed T4 with the ejected DNA on the  $\text{CF}_3$ -terminated surface.

from the AFM image shown in Fig. 5 in which the empty head collapses. The measured height of the collapsed head is about 43 nm. The leaked DNA spreads onto the  $\text{CF}_3$ -terminated surface.

Fig. 6A shows a FFM image of a giant T4 (a T4 phage with a normal tail but an elongated head), immobilized on the  $\text{CF}_3$ -terminated surface. The giant head is 250 nm long and is flatter than a normal head. It is known that the sheath around the tail tubes consists of the 144 copies of gp18 protein arranged in 24 annuli of six subunits each. These sheath annuli are visible on the tail surface (Fig. 6A). The measured spacing of the annuli from the high-resolution FFM image (Fig. 6B) is about 8.9 nm, which from transition electron microscopy is expected to be 4.1 nm. The doubling of the periodicity may perhaps be explained by a pairing of the annuli as a result of drying. A higher-resolution image of the head surface is shown in Fig. 6C. The characteristic hexagonal capsid lattice of the head is evident. The lattice spacing from the FFM image is about 15.8 nm. This value agrees with the known lattice.

High-resolution AFM images of individual virus particles can be obtained when the particles are strongly immobilized on substrates. This allows us to study their structures in great details. For the T4 particles immobilized on the  $\text{CF}_3$ -terminated surface, structural features, such as head, neck, tail, baseplate, and fibers, as well as detailed organization on a scale smaller than 8 nm have been resolved by AFM. Now we know how to use genetic and chemical approaches to bind functional groups to the specific sites of the virus surfaces.<sup>[8,9]</sup> Anisotropic immobilization of the virus particles on surfaces will open up new avenues for the structural investigation of the selected sites.

## ORGANIZATION OF VIRUS NANOPARTICLES ON SUBSTRATES

Virus particles are highly monodispersed in size and well defined in shape. Their ability of self-assembly on substrates has attracted considerable interest in forming organized structures and patterned surfaces. Maeda<sup>[10]</sup> studied the organization of TMV particles on a glass substrate. The TMV particles were found to organize into birefringent crack and zigzag patterns during the drying of 50 mg/mL suspension on the glass substrate (Fig. 7). In the ordered region of the crack pattern, TMV particles appear as a hard rod and are uniaxially oriented. While in the zigzag pattern, TMV particles act as a semiflexible rod rather than a hard rod and were bent by  $60^\circ$ . Wadu-Mesthrige et al.<sup>[11]</sup> showed that the drying of 75  $\mu\text{g/mL}$  suspension on mica substrate could lead to the formation of 2-D

**Fig. 6** A) FFM image of a giant T4 on the  $\text{CF}_3$ -terminated surface, B) FFM image of the tail sheath, and C) FFM image of the head lattice.

spindle patterns, in which TMV particles branch and fuse to form a 2-D networks (Fig. 8A). They also demonstrated that the 2-D organization of the TMV particles could be controlled by adding bovin serum albumin (BSA) in the suspension. In this system, the attachment of BSA proteins on TMV particles changes the interparticle interactions and eliminates the organization of TMV particles on mica (Fig. 8B).

Nam et al.<sup>[12]</sup> reported the genetically driven assembly of M13 virus. The M13 virus is a rodlike particle, which is coated by 2700 copies of polypeptides that cover the interior single-stranded, circular DNA, giving the virion with a length of 880 nm and a diameter of 6.6 nm.<sup>[13]</sup> In this system, M13 particles were genetically modified by binding an anti-streptavidin peptide at one end of the M13 and a hexahistidine peptide at the other end. A nanoring could be assembled using the streptavidin–NiNTA molecule as a link to bridge both ends of the M13 particle. Li et al.<sup>[14]</sup> reported the self-assembly of ZnS-nanocrystal modified M13 particles on substrates during the drying of 30 mg/mL suspension; the modified M13 particles were found to organize into a smectic structure, in which the M13 particles orient parallel to the substrate surface and share a long-range positional order. The ZnS nanocrystals, which link at one end of the M13 particles, showed an ordered array within the self-assembled

smectic structure. The ordered films of nanocrystal functionalized M13 particles are expected to have potential applications in photonic bandgap materials and microelectronics.

Work carried out in my laboratory showed the drying-induced 2-D organization of M13 particles on substrates. Fig. 9A shows a typical AFM image of a self-organized structure of M13 particles on mica by the drying of 0.1 mg/mL suspension. The morphologies of the organized structures are reminiscent of the dewetting process and thought to be dried droplets. A higher-resolution AFM image (Fig. 9B) shows that the dried droplets contain a 2-D lateral condensation of the M13 particles. They are slightly bent and gradually change their orientation to form singular points at which the M13 particles gather.

We also studied the organization of icosahedral cowpea mosaic virus (CPMV) particles on substrates.<sup>[15]</sup> The CPMV particle has a picornalike  $T = 1$  protein shell with an asymmetric unit containing three  $\beta$ -sandwich folds formed by two polypeptides.<sup>[16]</sup> When a droplet of 0.08 mg/mL suspension is dried on mica, the CPMV particles organize into a 2-D hexagonal array that has some degree of crystalline order (Fig. 10). The measured height, and therefore the diameter of the CPMV particles, is about 28 nm, consistent

**Fig. 8** AFM images of TMV particles organized on mica without (left) and with (right) the presence of BSA in solution. Source: From Ref.<sup>[8]</sup>.

**Fig. 9** A) Low and B) high resolution tapping AFM images of dried droplets of 0.1 mg/mL M13 solution on mica.

**Fig. 10** Tapping AFM image of 2-D ordered structures of CPMV particles on mica. *Source:* From Fang, J.Y., Soto, C.M., Ratna, B., Lin, T., Johnson, J.E., unpublished data.

with data from X-ray crystallography. This suggests that the CPMV particles are not distorted by drying. The center-to-center distance along the nearest neighbor direction is about 29 nm. Voids are also visible within this hexagonal lattice. The 2-D organization

process of the CPMV particles, which is visualized here, can be speculated as thus: When the solvent evaporates from a droplet of the virus solution, the solubility limit exceeded and a lattice of viruses nucleates on the mica surface due to the particle–particle and particle–substrate interactions.

As the concentration of the CPMV particles increases, we can expect that the virus–virus interactions become strong. The CPMV particles are found to organize into parallel and orthogonal lines as a droplet of 0.15 mg/mL suspension is dried on mica in air (Fig. 11A). More details of the self-organized lines can be seen from the AFM image shown in Fig. 11B. There is slight distortion in the width of the lines near the connections. The height profile along the lines drawn in Fig. 11B shows that these parallel lines have almost the same height, 250 nm, which is closed to nine virus layers. The average width of the lines is about  $600 \pm 40$  nm. The typical distance between the parallel lines is about  $7 \mu\text{m}$ . It is important to point out that the Tris buffer used in our experiments does not show line formation in the absence of CPMV particles. The parallel and orthogonal lines are only observed by drying a droplet of CPMV-containing solution on mica. Fig. 11C shows a fluorescence microscopy image of the organized structures of the CPMV particles, in which the RNA was labeled with SYTO 13. This dye fluoresces only when it is bound to RNA. This confirms that the parallel and orthogonal lines are indeed a result of the self-organization of the CPMV particles.

Recently, a new approach based on the combination of genetic engineering and chemical modification has been developed to organize and pattern virus particles on substrates. For example, Smith et al.<sup>[17]</sup> used dip-pen nanolithography to write self-assembled monolayers (SAMs) into nanoscale patterns presenting functional maleimide groups. They found that the genetically engineered CPMV particles with cysteine (Cys) inserted at the specific locations selectively adsorb on the patterned SAMs through the specific

**Fig. 11** A) Optical microscopy, B) tapping AFM, and C) fluorescence microscopy images of self-organized CPMV patterns on mica. RNA within the CPMV shown in Fig. 8C was labeled with a probe.

**Fig. 12** Tapping-mode AFM images and high profile of a wt-VCP nanoarray. *Source:* From Ref.<sup>[14]</sup> ©2003 American Chemical Society.

binding between the maleimide and cysteine groups (Fig. 12). In order to prevent interparticle cross-linking via disulfide bond formation during the adsorption process, Klem et al.<sup>[18]</sup> used a solid-phase synthetic approach to break the symmetry of the genetically engineered cysteine-rich CCMP particles. The CCMP particles with asymmetric functional groups were found to form a 2-D array on Au surfaces.

## CONCLUSION

The immobilization of virus particles on substrates allows detailed imaging by scanning force microscopy in air and solution. Structural features and surface lattices of single virus particles (T4 and BMV) immobilized on substrates can be resolved at the nanometer scale. Future directions involve the site-specific immobilization of virus particles for presenting selected sites for structural investigation.

Self-organization of virus particles from a concentrated suspension onto substrates can lead to the formation of complex ordered structures over a large area, providing not only new insights regarding a variety of complex biological structures at interfaces but also new prospects in the field of patterning on surfaces. Recently, there has been a growing interest in the use of virus particles as templates to synthesize inorganic nanocrystals on the outer surface or in the inner surface of the capsids.<sup>[2–4,19–21]</sup> Future efforts include exploring the self-assembly capability of nanocrystal-modified viruses to organize the resulting nanocrystals into ordered arrays, which are essential for the next generation of nanodevices. Undoubtedly, the development of virus building blocks that can self-assemble into well-ordered structures will stimulate our interest in nanotechnology.

# Yttria-Tetragonally Stabilized Zirconia

R. Allen Kimel

Materials Science and Engineering Department, Pennsylvania State University,  
University Park, Pennsylvania, U.S.A.

## INTRODUCTION

In the field of structural ceramics, yttria-tetragonally stabilized zirconia (Y-TZP) is of great interest because of its high strength and toughness and good wear resistance.<sup>[1-3]</sup> Previous studies have demonstrated that wet processing routes provide the best possible mechanism for obtaining “bulk” nanocrystalline ceramics because wet processing does not call for extremely high pressures for consolidation as are needed with conventional dry forming techniques.<sup>[4-6]</sup> The chief problem with wet processing is aqueous attack on Y-TZP.<sup>[7-21]</sup> Aqueous degradation can lead to processing dilemmas as the dissolution of yttrium ions from the surface of the powder changes the surface chemistry of the powder while leading to a lack of control over suspension pH values. Furthermore, dissolution of the yttrium-stabilizing agent can lead to catastrophic degradation of the ceramic in service as a result of the tetragonal to monoclinic phase change which leads to spallation of the ceramic because of stresses produced by the 5–6 vol.% expansion associated with the phase change. It is the aim of this review to summarize the current scientific understanding about the aqueous chemistry of Y-TZP and the implications toward synthesis, dispersion, and processing of nanosized Y-TZP. After reviewing the wealth of knowledge in the literature, elucidation of the techniques that will allow for the aqueous synthesis and processing of nanosized Y-TZP will be apparent. Improvement and utilization of these techniques will lead to the accomplishment of a universal goal in structural ceramics which is the production of bulk ceramics from nanosized ceramic powders.

## AQUEOUS CHEMISTRY OF YTTRIA-TETRAGONALLY STABILIZED ZIRCONIA

Several research groups have investigated aqueous attack of Y-TZP ceramics.<sup>[7-21]</sup> There are two major theories for the reaction of Y-TZP in water. The first theory comes from work performed by Lange,

Dunlop, and Davis<sup>[7]</sup> They performed a study on sintered, polycrystalline Y-TZP with yttrium content ranging from 2 to 6 mol%. The aging experiments in this study were performed at 250°C in a tube furnace in a humid environment. From this study, Lange, Dunlop, and Davis concluded that water attacks a tetragonal grain on the surface of the ceramic. Lange, Dunlop, and Davis hypothesized that during aqueous attack, water leaches a sufficient amount of yttrium such that the surface tetragonal grain transforms into the monoclinic phase. Further depletion of yttrium causes the monoclinic structure to grow until a critical size is reached. At this critical size, the monoclinic structure will grow spontaneously until the entire grain is transformed to the monoclinic phase. If this new monoclinic grain is greater than a critical size, then microcracks will form exposing more virgin surface from which yttrium can be leached. Lange, Dunlop, and Davis further showed that transformation of tetragonal phase to monoclinic phase decreases with increasing yttrium content. Conclusions by Lange, Dunlop, and Davis were reached through the use of high-resolution transmission electron microscopy (HRTEM) and X-ray diffraction (XRD), but no solution analysis or kinetic studies were performed. Therefore no direct measurement of yttrium in solution was made nor was the rate at which the proposed leaching mechanism took place measured. Yoshimura et al.<sup>[8]</sup> have also performed studies on the aqueous attack of sintered, polycrystalline Y-TZP. The aging experiments in this study were performed over a range of temperatures from 250°C to 800°C under hydrothermal conditions. It was concluded by Yoshimura et al. that water chemically adsorbs to the surface of the ceramic. Then hydroxide groups migrate through the oxygen vacancies in the Y-TZP lattice leading to the formation of zirconium and yttrium hydroxides. The increase in the size of the hydroxide groups with respect to the oxygen vacancy gives rise to stressed sites at the oxygen vacancies within the lattice. The stressed site defect, in turn, acts as a site for the nucleation of the monoclinic phase. The transformation of tetragonal to monoclinic then

leads to microcracking and macrocracking. The major difference between the mechanisms proposed by Lange, Dunlop, and Davis and Yoshimura et al. is that in the Yoshimura et al. model, hydroxide transport into the material, not yttrium leaching, contributes to the failure of the ceramic seen in aqueous environments. Studies on oxygen diffusion in Y-TZP and the effect of oxygen on the tetragonal to monoclinic transformation pose problems for the Yoshimura et al. theory in the temperature range at which Yoshimura et al. conducted aging experiments.<sup>[22,23]</sup> Research has demonstrated that as the yttrium content increases, oxygen diffusion rates increase.<sup>[22]</sup> Thus one might expect that OH<sup>-</sup> diffusion rates would also increase which would lead to the presence of many stressed sites in the ceramic according to the degradation model proposed by Yoshimura et al. These stressed sites, which would lead to degradation of properties in the ceramic, have not been observed in other studies. Research has also been shown that simply replacing <sup>16</sup>O in Y-TZP with <sup>18</sup>O leads to a decrease in the amount of tetragonal to monoclinic transformation.<sup>[23]</sup> If such a small mass change leads to such a significant change in transformation, it is reasonable to expect that replacing <sup>16</sup>O with OH<sup>-</sup> would have a similar effect, but such has not been observed in the literature.

Beyond these two aforementioned studies, a recent publication has shown that at room temperature, a diffusion-controlled leaching model is supported by data from kinetic studies of the aqueous degradation of 3 mole percent yttria tetragonally stabilized zirconia (3Y-TZP).<sup>[21]</sup> Experiments performed by Kimel and Adair allowed for leaching kinetics of yttrium to be measured and the effects of the aqueous degradation to be established. Interestingly, it was shown that the leaching of yttrium from 3Y-TZP did not have an adverse effect on the crystal structure of the 3Y-TZP powder within the sensitivity of XRD. However, it was also shown that yttrium leaching has significant effects on the surface chemistry of 3Y-TZP powder which can have a deleterious effect on the stability of 3Y-TZP aqueous suspensions.

In addition to characterizing the mechanism behind the aqueous degradation of 3Y-TZP, the work by Kimel and Adair showed that the addition of a surface passivation agent could trivialize the effects of aqueous degradation. It was determined that the addition of oxalic acid to the aqueous suspension of 3Y-TZP led to the formation of a passivation layer, suspected to be yttrium oxalate, that reduced yttrium ions in solution beyond detection. Furthermore, the formation of the passivation layer led to the development of significant surface charge that could be used to facilitate dispersion of the 3Y-TZP powder in aqueous suspension.

## SYNTHESIS METHODS FOR YTTRIA-TETRAGONALLY STABILIZED ZIRCONIA

There are a variety of ways to produce nanosized Y-TZP powder including, but not limited to, polymerization/sol-gel, coprecipitation, and hydrothermal synthesis.<sup>[24-42]</sup> Synthesis by polymerization or sol-gel methods typically takes on a procedure similar to that of Pechini.<sup>[24]</sup> In the Pechini process, a complexing agent, such as citric acid, chelates cationic precursors. This suspension is then reacted with a glycol to form organic ester monomers, which polymerize with the addition of heat to form a sol of homogeneously distributed metal ions in an organic matrix. This sol is further heated to produce a resin, which is further heated to remove organic residuals producing the desired stoichiometric oxide powder. Coprecipitation involves the precipitation of individual amorphous metal hydroxides from solutions of metal salts in a solvent. Precipitation is typically achieved by changing the suspension pH or by the addition of heat to evaporate solvent which leads to a supersaturated environment that facilitates precipitation. The metal hydroxides are then calcined to form the desired stoichiometric metal oxide. Hydrothermal synthesis is precipitation with the addition of heat in excess of the boiling point of the solvent in a pressure vessel.

In some instances, precipitation occurs out of a homogeneous solution.<sup>[31,34,43,44]</sup> The homogeneous solution is produced by keeping the participating metal ions in solution by some complexation chemistry. Precipitation takes place when the complex is broken and large amounts of nuclei are dumped into solution. The complex is usually broken by the addition of a reagent, a change in the solution pH, or heat is added to the homogeneous solution causing a physical breaking of the complex as opposed to the chemical breaking that occurs with the addition of a reagent. The method of precipitation by the addition of heat takes advantage of nucleation/growth ideas to produce ultrafine particles. With the addition of a complexing agent, the critical limit of supersaturation is increased. When the complex is broken, the time available for self-nucleation is increased. After the complex is broken at temperature, the temperature is decreased. When the suspension temperature reaches the point at which the complex is stable again, any metal ions present in solution are recomplexed and thus not available for growth after self-nucleation. As a consequence, no growth occurs because of the decrease in the time available for growth and the resulting particles are ultrafine in size.

The choice of complexing agent is made based on several considerations. First, the complexing agent needs to form a stable complex with the metal ions

over a wide range of pH values. Second, a complexing agent is chosen such that it will impart some sort of surface passivation to the precipitated particles to prevent aggregation of the as-synthesized particles. The surface passivation or colloid protection of the particles by the complexing agent can be accomplished by electrostatic repulsion, steric repulsion, or both occurring simultaneously. Beyond those two considerations, a complexing agent with simple chemistry (i.e., requiring least amount of reagents, time for formation of homogeneous solution, lowest cost, etc.) is desirable for ease in preparing solutions and for future processing steps. Complexing agents have been studied in detail for many years.<sup>[45–49]</sup> Intorre and Martell<sup>[45–47]</sup> had a series of papers in which they studied complexes for zirconium in aqueous solution. The complexing agents were based on structures having multidentate ligands.

Recent research has been performed on the aqueous synthesis of sub-10-nm Y-TZP using a metal ligand approach.<sup>[42]</sup> In this study by Kimel, sub-10-nm 1.7 mole percent yttria tetragonally stabilized zirconia (1.7Y-TZP) powder was produced hydrothermally by precipitation from homogeneous solution. Bicine was used as the metal ligand complexing agent. The powder was precipitated after hydrothermal treatment of the homogeneous solution at 200°C for 8 hr. This treatment yielded 2-wt.% solids with a nominal particle size of 7–8 nm. The as-precipitated powder was crystalline and did not require further calcinations. In addition, it was found that the bicine provided a form of surface protection that would allow for dispersion of the as-precipitated powder.

## WET PROCESSING OF NANOSIZED PARTICLES

To pursue wet processing techniques for the fabrication of bulk ceramics from nanoparticles, obtaining well-dispersed nanoparticles suspensions is essential. However, obtaining well-dispersed nanoparticle suspensions proves to be a mountainous challenge. This challenge is primarily because of the fact that as particle size decreases, surface area increases. In nature, a system will evolve to the lowest energy state, so too it is with nanoparticles. With an increase in surface area generally comes an increase in surface energy, thus nature will try to lower the energy of a nanoparticles system in a way that will be detrimental to developing a well-dispersed suspension for wet processing.

The detrimental result of lowering the energy of a nanoparticle system will be agglomeration, which effectively increases the particle size and lowers the surface area. Generally, agglomeration will occur by the collision of two particles in suspension. Particles

collide via random motion caused by thermal energy present in the system. Upon collision, two scenarios can occur—the particles can stick together or the particles can repel each other. Which scenario occurs depends on the interaction energy between the two particles. The theory of the interaction energy between two-particle double layers is described by Derjaguin, Landau, Verwey, and Overbeek (DLVO).<sup>[50,51]</sup> The DLVO theory predicts the interaction of two-particle double layers by accounting for the repulsive forces present. The presence of repulsive forces leads to colloidal stability as these forces prevent particles from sticking together.

In terms of colloidal stability, there are generally three ways in which a colloid can be stabilized.<sup>[52,53]</sup> The three general types of colloid stability are known as steric, electrostatic, and electrosteric. The third type of stability, electrosteric, is a combination of both electrostatic and steric stabilization. In the realm of polymeric stabilization of colloids, electrosteric stabilization is also associated with the term protective or association colloid. The coinage of the term of “protective colloid” is given to Zsigmondy, who conducted experiments with gold colloids and gelatin around the turn of the 20th century.<sup>[54]</sup> The idea of protective or association colloid has been discussed thoroughly in the literature.<sup>[54–63]</sup> Some of the benefits of this type of protection are insensitivity to electrolyte concentration, applicability in both aqueous and nonaqueous systems, and effectiveness in a large range of solid loading. In a research by Kimel,<sup>[64]</sup> it was found that complexing agent, bicine, formed a protective colloid around the as-precipitated 1.7Y-TZP powder. The 1.7Y-TZP powder was dispersed, recovered, and concentrated to a 50-wt.% (14 vol.%) aqueous suspension by centrifugation and ultracentrifugation. The bicine was found to flocculate the powder but prevents particle to particle contact. The flocculation was reversed by displacing the bicine on the surface of the 1.7Y-TZP powder with the oxalate anion by washing the suspension in an oxalic acid solution using centrifugation. Centrifugation then allowed for concentration of the aqueous suspension by forming a pellet, followed by redispersion in a smaller volume of an oxalic acid solution.

Once a well-dispersed suspension is in place, a forming technique needs to be chosen. A majority of ceramic components made from powders containing a nominal particle size of 1 μm or greater are generally formed using dry-pressing techniques such as uniaxial or isostatic compression. However, use of these techniques with nanosized powders is inherently difficult because of consolidation and energy issues.<sup>[4,65–67]</sup> Nanosized powders are significantly affected by hydration forces which lead to aggregation which, in turn, can lead to the problems of poor powder flow

and poor packing of the powder particles in the die. The high surface area associated with nanosized powders can lead to friction problems along the die and also lead to poor flow and powder packing. These problems also contribute to the need for forces larger than the capabilities of most conventional presses and also greatly inhibit the ability to make large bulk samples.

Wet processing techniques avoid the problems of dry forming techniques by keeping the powder in a suspension. Using a well-dispersed suspension circumvents the issues of powder flow and powder packing, leaving only the problem of consolidation to overcome. Consolidation during wet processing can be addressed by drying techniques and/or the application of a load.

Drying without application of a load is a technique used in evaporation, sol-gel drying, and slip casting. Evaporation has problems as applied to nanoparticles because of agglomeration and phase separation while driving off solvent with the application of heat.<sup>[68,69]</sup> Evaporation without stringent control of heating can also lead to the development of drying stresses in the body which can result in internal defects and cracking. Sol-gel drying is similar to evaporation in terms of producing drying stresses because of the large amount of solvent that has to be removed for consolidation.<sup>[70]</sup> As a consequence, sol-gel drying is typically only applied to bodies that are thin and have low dimensionality such as thin films and fibers.

Slip casting is performed by placing a suspension into a porous mold, where drying and consolidation then take place by water being removed from the suspension into the porous mold via capillarity forces resulting from the mold having a finer pore structure than the suspension body.<sup>[52,53]</sup> However, suspensions of well-dispersed nanosized particles will have nanosized pore structures which will result in capillarity forces much greater than those found in a typical mold material. Thus there will be no driving force for drying of the nanosize particle body, and as a result, poor consolidation and low green densities will be obtained.

Wet processing techniques using the application of force for consolidation include centrifugation and filter pressing. Centrifugation uses centrifugal forces to pack powder particles by pulling them out of suspension. Submicron alumina powders have been consolidated in this manner as well as being used in this research for recovery of the well-dispersed as-synthesized Y-TZP powder.<sup>[70]</sup> However, a wide particle size distribution can lead to mass separation in the final compact and conventionally, centrifuge tubes are limited in size, thus limiting the size of the bulk body to be made.

Filter pressing consolidates the powder by pressing the suspension into the bottom of a die where a membrane is located. The membrane allows the water to pass through leaving behind a consolidated powder

compact. Because the powder is in suspension, friction between the die walls and the powder is negated and as such, much lower pressures are needed for compaction as compared with dry pressing. Most studies on filter pressing in literature were performed on alumina powders.<sup>[65,68,69,71-74]</sup> While many of these studies resulted in well-packed green bodies, none of the studies was performed with nanosized powders on the order of 20 nm or less as is the case with this thesis work. Also, while the use of zirconia was discussed, there is a lack of literature on drying and sintering of such as-pressed pellets. Furthermore, cracking issues associated with drying filter-pressed pellets have not been satisfactorily addressed. Despite the lack of literature and the drying issues, filter pressing provides an excellent opportunity for forming bulk bodies from nanosized particles.<sup>[75]</sup> Transparent pellets of 1.7Y-TZP with a nominal thickness of 2-3 mm were produced by filter pressing by Kimel.<sup>[76]</sup> The green pellets were found to have a 48% theoretical density and average grain size of 18 nm after drying to 120°C.

## CONCLUSION

A goal of aqueous processing of nanosized Y-TZP powders is the production of bulk Y-TZP ceramics. To accomplish this goal, several issues will be addressed. First is determining the nature of aqueous degradation of Y-TZP and finding a method for the controlling degradation such that it becomes a non-issue. Surface passivation provides a mechanism by which such control can be found. However, as particle sizes decrease below 10 nm, conventional dispersants will need to be replaced by much smaller organic molecules. Once familiarity with the degradation issues is gained, a suitable synthesis technique to produce nanosized particles and allow for future aqueous processing of the nanosized particles must be developed. From the literature review, precipitation from homogeneous solution is a promising technique that provides for control over particle size as well as the surface chemistry of the particles. Upon the production of nanosized Y-TZP, recovery and dispersion of the powder must take place. From the literature review of processing techniques, the production of a well-dispersed suspension is imperative for the use of wet processing techniques to consolidate the nanosized Y-TZP powder into a bulk Y-TZP ceramic body.

## INTRODUCTION

Zeolites are three-dimensional, microporous, crystalline solids with well-defined structures that contain aluminum, silicon, and oxygen in their regular framework. When zeolite crystals are intergrown to form continuous layers, the resulting membranes can separate gas mixtures with high selectivities because their pore sizes are comparable to the molecular dimensions. Separation is possible by molecular sieving, preferential adsorption, or differences in diffusion rates. Zeolitic membranes can be classified as either symmetric membranes (self-supported) or asymmetric membranes (supported). Different from the mesoporous inorganic membranes used in gas diffusion process for uranium isotope separation, zeolite membranes consist of many crystallites packed together without crystallite boundary gap in ideal cases. Different types of membranes have varying crystal structure, pore size, and surface properties, thus exhibiting different separation and/or catalytic properties.

Up to date, some zeolite membranes such as the MFI type have been well developed in the last decade since some early works in this area.<sup>[1,2]</sup> Preparation techniques have been developed and fine-tuned in recent years, which makes it possible to fabricate a large and pinhole-free zeolite membrane. Zeolite-membrane-based separations<sup>[3]</sup> and reactions<sup>[4]</sup> have generated much interest in recent years. They are attractive for a variety of reasons, including steady state operation, tailored selectivity, low energy consumption, compatibility to high-temperature and high-pressure conditions, and potential for effective separation and combined reaction-separation systems. Such merits offer the opportunity to solve problems associated with high production costs. Zeolite

membranes have been the highlight in the separation technology and novel reactor engineering fields, and is widely expected to find commercial applications in the near future. Some excellent reviews on the preparation and application of zeolite membranes have appeared in the last several years.<sup>[5,6]</sup> However, the rapid development of this field necessitates a timely update on this topic, particularly on preparation of zeolite membrane and its application to environmental separation and reactions.

## TYPES OF ZEOLITE MEMBRANES

Zeolite, with its well-defined, nanometer-sized pore structure, is an attractive material for inorganic membrane separation and reactions. Small (i.e., 0.3–0.4 nm with 6- and 8-membered ring), medium (i.e., 0.5–0.6 nm with 10-membered ring), and large pore (i.e., 0.7–0.8 nm with 12-membered ring) zeolites have been successfully made into membranes.

SAPO-34 and NaA, having pore size windows of 0.38 and 0.43 nm, respectively, are examples of small-pore zeolite membranes. SAPO-34 zeolite membranes were reported by Poshusta et al.<sup>[7]</sup> to separate CO<sub>2</sub>/CH<sub>4</sub>, CO<sub>2</sub>/N<sub>2</sub>, N<sub>2</sub>/CH<sub>4</sub>, H<sub>2</sub>/CH<sub>4</sub>, H<sub>2</sub>/CO<sub>2</sub>, and H<sub>2</sub>/N<sub>2</sub> binary mixtures. NaA membrane has been intensively studied for dehydration of solvents and alcohols.<sup>[8]</sup> Their use in hybrid membrane reactor has been demonstrated for esterification reaction.<sup>[9]</sup> Recently, Xu et al.<sup>[10]</sup> and Dong, Xu, and Shi<sup>[11]</sup> used a novel process to synthesize a high-quality NaA membrane from clear solution. Besides, Xu and other researchers<sup>[12,13]</sup> investigated the effects of microwave heating on the synthesis of NaA zeolite membrane. Their results indicated that the microwave

synthesis has the advantages of very short time, small zeolite particle size and narrow particle size distribution, and large permeance. Shah et al.<sup>[14]</sup> applied the NaA zeolite membrane to separate methanol/water, ethanol/water, and dimethylformamide/water mixtures with selectivities of 140, 2140, and 330, respectively.

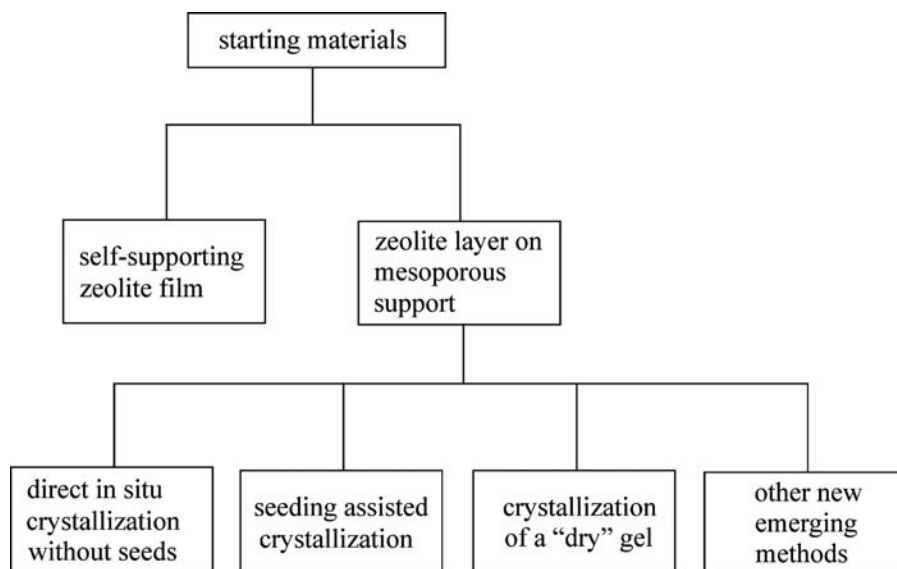

The MFI structure (i.e., silicalite or its aluminosilicate analog, ZSM-5) has been most intensively investigated experimentally and theoretically and often employed in laboratory membrane devices. Owing to its medium-size (~0.55 nm) pore network, which are close to the dimensions of industrial gases, it has been applied in many areas such as hydrocarbons separation, recycling of valuable gases<sup>[15]</sup> and novel metal complexes,<sup>[16]</sup> natural gas cleaning,<sup>[17]</sup> membrane reactor, and so on. With their three-dimensional pore channel network, MFI zeolites are fairly robust and have been a main subject of research in zeolite membrane. Separations of light gases, close-boiling hydrocarbons, organic-water solution, and butane or xylene isomers have been reported in the literature using MFI zeolite membranes. MFI zeolites have an anisotropic pore structure consisting of straight channels along the 010 crystallographic orientation intersected by sinusoidal channels along the 100 direction. This structural anisotropy is expected to influence the transport properties along the different zeolite crystallographic orientations. Foreign atoms can be easily substituted for Si in the MFI zeolite framework.<sup>[18]</sup> These include aluminum for ZSM-5, titanium for TS-1, and vanadium for VS-1.<sup>[19]</sup> This renders MFI zeolites a wider range of chemical and catalytic properties as compared to other zeolite families. Silicon-rich silicalite membrane is inert and hydrophobic, whereas the addition of Al in ZSM-5 transforms the zeolite into acidic catalyst with hydrophilic property. Similarly, the incorporation of titanium and vanadium in TS-1 and VS-1 impart the zeolites with unique catalytic properties. Besides modifying the zeolite chemistry, the presence of these foreign atoms in the framework also perturbs the size and shape of the zeolite pores affecting the transport of molecules through the channel. It also alters the chemical interaction between the diffusing molecule and the zeolite pore wall. The unsaturated charges caused by the insertion of foreign atoms are balanced by counterions, whose presence can further physically restrict and chemically modify the pore channels. Ge,<sup>[20]</sup> B,<sup>[21]</sup> V,<sup>[22]</sup> and Fe<sup>[23]</sup> atoms have been incorporated into the framework of MFI zeolite membrane with interesting properties exhibited.

Faujasite zeolites including zeolite NaY and NaX are representatives of large-pore zeolite (0.74 nm) membranes. Hence it can be used in applications involving larger molecules. Depending on their Si/Al

ratios, faujasites are categorized into X (Si/Al  $\approx$  1–1.5) and Y (Si/Al  $>$  2) although they both have topologically the same framework. Furthermore, modification of the faujasite crystals, either by ion exchange or by dealumination, can be used to control the adsorption or intracrystalline diffusion properties, providing a way of tailoring the membranes to specific applications. Hasegawa et al.<sup>[24]</sup> prepared ion-exchanged faujasite membranes that can separate CO<sub>2</sub>/N<sub>2</sub> with a separation factor of 40. They also synthesized an NaY-type zeolite membrane on the inner surface of a porous  $\alpha$ -alumina support tube by a hydrothermal technique. The synthesized Y-type zeolite membranes were stable at temperatures up to 400°C. Kita et al.<sup>[25]</sup> employed an NaY pervaporation membrane for the separation of methanol and methyl-*tert*-butyl ether (MTBE) mixtures. Nikolakis et al.<sup>[26]</sup> applied faujasite zeolite membrane to successfully separate benzene/cyclohexane, benzene/*n*-hexane, toluene/*n*-heptane, propylene/propane, and ethylene/methane with the separation factors of 160, 144, 45, 6.2, and 8.4, respectively. Lassinantti, Hedlund, and Sterte<sup>[27]</sup> described the preparation of FAU zeolite membrane on polished, seeded alumina wafers. The film thickness was found to be a linear function of synthesis duration up to a certain point. Further treatment reduced the film thickness. Continuous and crack-free films with thicknesses in the range 210–2670 nm were synthesized in their work. Jeong et al.<sup>[28]</sup> and Kobayashi et al.<sup>[29]</sup> studied the application of the NaY-type zeolite membrane to separate C<sub>6</sub> hydrocarbon mixtures both experimentally and theoretically. Another large-pore zeolite, mordenite,<sup>[30–32]</sup> has also been used for H<sub>2</sub>/N<sub>2</sub> and water/alcohol separation. Mordenite's unidimensional, straight pore channels provide easy access and transport through the membrane, but make it more susceptible to fouling.

## PREPARATION OF ZEOLITE MEMBRANES

In general, there are two categories of zeolite membranes mainly related to their preparation processes, i.e., self-supported membranes and composite membranes. The first type of membrane is constituted by a pure zeolitic phase, while a zeolitic thin film formed on a support is the composite type. The preparation of self-supported zeolitic films easily introduces some drawbacks in terms of lack of homogeneous thickness and mechanical instability. So far, zeolitic films have been synthesized in the presence of momentary support (therefore removed after the preparation) or permanent support (to form zeolite composite membranes). A momentary support can be a poly(tetrafluoroethylene) slab, a Teflon sleeve, a Vycor frit, a silver, nickel, or stainless-steel plate. A permanent support can be

**Fig. 1** Preparation strategy for zeolite membrane.

any of the numerous available materials such as amorphous silica, silicon wafers, glass, aluminum platelets, stainless steel, porous ceramics, or porous  $\alpha$ -Al<sub>2</sub>O<sub>3</sub>,  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> membranes.

Freestanding zeolite layers larger than a few square centimeters are difficult to form, and the resulting structures are fragile. Therefore zeolite membranes are typically deposited on mechanically robust porous supports (alumina, stainless steel, etc.). The technical challenge developing supported zeolitic membranes lies in how to decrease the large thickness (typically 50  $\mu$ m) of the membrane required to obtain defect-free samples, because defects are easily presented in very thin layers. Several methods have been reported to grow zeolite films on porous supports by the in situ approach. Among the different strategies for the preparation of zeolite membranes, as shown in Fig. 1, the preparation of the so-called composite membranes seems to be the most frequently used and most promising technique.

The thin zeolite top layer can be hydrothermally crystallized in one step on the top of the support or inside the pores of the support, which can be called "direct in situ crystallization." The essence of the in situ approach is to bring the surface of a porous support in contact with a zeolite synthesis solution (sol or gel) and keep the system under controlled conditions so zeolite can nucleate and grow to a continuous film on the support surface. If the zeolite layer is formed in several steps using seed crystals that grow together to a continuous supported zeolite layer in a subsequent hydrothermal synthesis, the process is referred to as "seeding supported crystallization." In addition to the hydrothermal crystallization as the main technique to prepare supported zeolite layers, defect-free zeolite layers can be synthesized by a vapor-phase method

called "dry synthesis." An amorphous dry gel can be crystallized on a porous alumina support by a vapor-phase transport method. Other new preparation concepts, such as pulsed-laser deposition,<sup>[33,34]</sup> microwave assisting synthesis,<sup>[12,13]</sup> and substrate heating method,<sup>[35]</sup> have been proposed in recent years.

## ZEOLITIC MEMBRANES USED IN ENVIRONMENTAL SEPARATION

Zeolites have been conventionally used as catalysts, ion exchangers, and adsorbents. Molecules with different sizes and shapes can be discriminated or separated by zeolites through their channels. Generally, separation or purification of gases by zeolites is carried out by pressure swing adsorption. High capital costs and energy consumption characterizes the limitations of such process, and continuous operation is not easily realized. In a membrane configuration, both equipment and operation costs can be dramatically reduced, and continuous operation is possible. Since the 1990s, much research effort has been devoted to the synthesis of zeolite membrane. The potential of using zeolitic materials for membrane-based separations has been realized only in recent years. Uses of zeolite membranes in environment-friendly separations such as the production of clean fuel and energy-efficient processes are emerging. Among them, H<sub>2</sub> separation from light gas mixtures and alcohol from aqueous solutions have received increasing attention. Some researchers have also studied other environment-relating separations. For example, Turlan et al.<sup>[16]</sup> applied silicalite membrane to recover a palladium homogeneous catalyst from its mixture with solvent and product. Piera et al.<sup>[36]</sup> used MFI-type zeolite membranes to

separate CO/air at very low CO concentrations (160 ppbv). At 245 K, a CO/air separation factor of 3.14 was achieved, which shows that it is possible to use zeolite membranes for the removal of pollutants from air, especially where these gases are present in trace concentrations. This is the first work in the open literature dealing with gas separations at trace concentration levels using zeolite membranes.

## H<sub>2</sub> Separation from Gas Mixtures

Hydrogen as a clean energy carrier has attracted increasing attention worldwide because of their higher energy content, environmental advantages, and potential market. The greatest potential use for hydrogen is as an energy carrier for fuel cell vehicles. Moreover, the use of hydrogen presents a totally clean energy use without any emissions of NO<sub>x</sub>, CO, and CO<sub>2</sub>. However, H<sub>2</sub> usually coexists with other light gases when it is produced from industrial processes such as gasification reactions and steam reforming reactions. Therefore it is highly desirable to separate hydrogen from other gases from hydrogen-rich gas streams. Membrane separation has been demonstrated to be superior than the present PSA technology. Studies in separation of H<sub>2</sub> from light gases have been performed by many groups in recent years. Some key findings related to hydrogen separation are summarized in Table 1.

Smaller-pore zeolites such as zeolite A (0.38-nm pore diameter) and SAPO-34 (about 0.43-nm pore diameter) have the potential to improve light gas separation by exploiting differences in size between light gases. Several research groups<sup>[7,37,42]</sup> have explored the synthesis of small-pore zeolite membranes for the separation of light gas mixtures. They reported that H<sub>2</sub>/CH<sub>4</sub> mixture was separated primarily by differences in molecular size, and the selectivity was about 4–25. Aoki, Kusakabe, and Morooka<sup>[38]</sup> reported that H<sub>2</sub>/N<sub>2</sub> selectivities through NaA zeolite membranes were 3.7. Masuda et al.<sup>[39]</sup> develop a silane-cracking

method to modify the pore size of MFI-type membrane, which was applied to H<sub>2</sub> separation from mixture gases containing H<sub>2</sub> and N<sub>2</sub> or O<sub>2</sub> in a flow system. The permeances of N<sub>2</sub> and O<sub>2</sub> of the modified membrane were markedly reduced to about 1/500 of those of a fresh membrane, whereas the permeance of H<sub>2</sub> decreased to only 1/10 of that of a fresh membrane. Consequently, the separation factor of H<sub>2</sub>, which is 1.5–4.5 for a fresh membrane, could be enhanced to about 100. Illgen et al.<sup>[40]</sup> fabricated H<sub>2</sub>-selective MFI zeolite membranes on a porous ceramic tube. At 500°C, this membrane separate H<sub>2</sub> from isobutane with separation factors of 70 and H<sub>2</sub> permeances of ca. 1 m<sup>3</sup> (STP)/m<sup>2</sup> hbar. The high temperature is applied to eliminate the adsorption effects on the permeation. Lai and Gavalas<sup>[41]</sup> prepared the supported ZSM-5 membranes using a TPA-free synthesis gel on asymmetric  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> tubular supports. The membranes have Si/Al ratio much greater than the membranes prepared using TPA<sup>+</sup> in the synthesis gel. Gas permeation measurements yielded high selectivities based on the molecular size. At room temperature, the selectivities of H<sub>2</sub> over N<sub>2</sub>, CH<sub>4</sub>, and *n*-butane were 38, 61, and 10<sup>4</sup>, respectively.

## Membranes for Energy-Efficient Alcohol/Water Separations

Alcohol/water separations are conventionally achieved by distillation, which is apparently inferior to membrane separation both in operating costs and energy consumption. Besides, membrane separation between alcohol and water usually exhibits quite high selectivities because of the strong affinity between zeolites and water. Fruitful results in this area have been achieved in recent years and are summarized in Table 2.

Mitsui Engineering and Ship-Building Co. first installed a commercial plant using 16 zeolite A tubular membrane modules and produced 600 L/hr of dehydrated solvents (ethanol, 2-propanol, acetone, etc.)

**Table 1** H<sub>2</sub> separation data from gas mixtures

Gases	Membrane type	Permeance [10 <sup>-8</sup> mol/(m <sup>2</sup> s Pa)]	Selectivity	Reference
H <sub>2</sub> /CH <sub>4</sub>	SAPO-34	5.0–17/0.48–3.8	4.5–13.5	[7]
H <sub>2</sub> /CH <sub>4</sub>	SAPO-34	3.2/0.13	24.6	[37]
H <sub>2</sub> /N <sub>2</sub>	A type	5.0/1.3	3.7	[38]

<i>t</i> -BuOH/water	Silicalite	3.5	144	[44]
<i>t</i> -BuOH/water	A type	1.5	16,000	[44]
<i>t</i> -BuOH/water	Polymeric	0.5	3,615	[44]

containing less than 0.2% of water from feeds at 120°C containing 10% of water.<sup>[8]</sup> Shah et al.<sup>[14]</sup> explored the commercial zeolite NaA membranes for the pervaporation separation of binary solvent/water systems in a broad range of concentrations and temperatures. Tuan et al.<sup>[43]</sup> separated liquid mixtures by pervaporation using metal ion-substituted ZSM-5 zeolite membranes. Their results indicate that substituted ZSM-5 membranes had higher methanol/water separation factors than silicalite-1. The B-ZSM-5 membrane had a methanol/water separation factor of 49. The separation factors and fluxes in pervaporation through substituted ZSM-5 membranes (except Ge-ZSM-5) were in the order methanol > ethanol > propanol. Gallego-Lizon et al.<sup>[44]</sup> compared the commercially available polymeric, microporous silica and zeolite (NaA type) membranes by pervaporation with respect to the dehydration of binary mixtures of *t*-butanol and water. They showed that the microporous silica membrane resulted in the highest flux (3.5 kg m<sup>-2</sup> h<sup>-1</sup>) and the NaA zeolite membrane exhibited the highest selectivity (16,000).

## ZEOLITIC MEMBRANES FOR MEMBRANE REACTORS

Zeolite membranes are thermally stable and well adapted to high-temperature applications because they can be used as separators only and/or as active contactors if they are catalytically active. The use of zeolite membranes in reactors has many advantages in terms of the several unique functions: to separate the products formed, to remove inhibitors, or to add reactants in a variety of reaction scenarios. In addition, the zeolite materials that constitute the membranes often

have intrinsic catalytic properties, which makes it possible to conceive reactors where the membrane itself performs the reaction and separation functions. Integration of reaction and separation at the microscopic level has numerous potential advantages in applications, such as the increase of selectivity in situations where a short-lived valuable intermediate product is generated. It has demonstrated an increase in conversion of the reactants and, in some situations, increase in selectivities. Membrane reactors are now widely used in reaction processes.

Generally, there are two configurations in the membrane reactor. The first is that the membrane performs the exclusive separating function, and does not take part in the reactions. The other is an integrated system with the membrane simultaneously performing the functions of separation and catalysis in the reaction. In the former case, the products formed on the catalyst must desorb, diffuse to the membrane surface, and transport to the opposite side. Obviously, this introduces a supplementary transport resistance compared to the case where reaction and separation are carried out in the absence of catalytic materials other than the membrane itself.

## Membrane Reactors with Separation Functions

In this case, zeolite membranes are used as separation membranes and not as catalytic membranes. The use of zeolite membranes for the dehydrogenation of hydrocarbons is a typical example for this configuration. Ciavarella et al.<sup>[45]</sup> showed that the isobutene yields were increased to four times higher than that observed in a conventional reactor. The possibility of using membrane reactors to increase the removal of hydrogen in dehydrogenation reactions or in other processes

**Fig. 2** Comparison of ZMR (zeolite membrane reactor) and FBR (fixed-bed reactor) performances. The *i*-octene yield as a function of temperature. *Source:* From Ref.<sup>[46]</sup>.

producing hydrogen, such as decomposition ( $H_2S$ ,  $H_2O$ ) and synthesis gas production, will significantly promote the conversion of reactants. Illgen et al.<sup>[40]</sup> fabricated  $H_2$ -selective, MFI zeolite membranes on a porous ceramic tube, which was used to support the packed bed inside. The conversion of isobutane dehydrogenation was increased by almost a factor of 2.

Piera et al.<sup>[46]</sup> investigated the use of an MFI (silicalite) zeolite membrane reactor (ZMR) in the liquid-phase oligomerization of *i*-butene. The membrane was used for the selective removal of *i*-octene from the reaction environment, thus reducing the formation of unwanted  $C_{12}$  and  $C_{16}$  hydrocarbons. Reaction experiments were then carried out over an acid resin catalyst bed located on the membrane tube side. Seen from Fig. 2, the ZMR (zeolite membrane reactor) produced a very significant increase in the selectivity, and as a consequence also in the yield of *i*-octenes (intermediate product in the oligomerization of *i*-butene), compared to a conventional fixed-bed reactor (FBR), while maintaining the similar *i*-butene conversion.

Salomon et al.<sup>[47]</sup> employed some different hydrophilic membranes (mordenite or NaA zeolite) to selectively remove water from the reaction atmosphere during the gas-phase synthesis of methyl-*tert*-butyl ether (MTBE) from *tert*-butanol and methanol. This reaction was carried out over a bed of catalyst packed on the inside of this zeolite tubular membrane. Their results indicate that MTBE yields were obviously higher than the traditional fixed-bed reactor. Farrusseng, Julbe, and Guizard<sup>[48]</sup> applied three different porous ceramic membranes (microporous MFI zeolite, mesoporous  $SiO_2$ , and meso-macroporous  $AlPO_4$  membranes) to distribute  $O_2$  for the partial oxidation of  $C_3H_8$  in an inert membrane reactor. The performance of the three membranes as  $O_2$  distributors were evaluated by their ability 1) to control the  $O_2$  partial pressure in the tube side and 2) to limit the back-diffusion of

$C_3H_8$  to the shell side by application of a transmembrane pressure. The  $AlPO_4$  membrane was shown to be the most efficient membrane as a porous  $O_2$  distributor. Jafar, Budd, and Hughes<sup>[9]</sup> applied zeolite A membranes to the esterification of lactic acid with ethanol to give ethyl lactate. Experimental results demonstrated the removal of water by pervaporation or vapor permeation enhanced the yields of ethyl lactate by about 20%. Liu, Gao, and Au<sup>[49]</sup> applied the NaA membrane in a membrane reactor ( $NiO/La_2O_3-\gamma-Al_2O_3$  as catalyst) for  $CH_4/CO_2$  reforming.  $CH_4$  and  $CO_2$  conversions, and  $CO$  and  $H_2$  selectivities were significantly higher than the values observed over a traditional fixed-bed reactor by more than 10%, especially for the increase of  $CO_2$  conversion by 30%.

### Membrane Reactors with Combined Separation and Catalytic Functions

Zeolite membrane, with its intrinsic or incorporated catalytic properties, can be applied in zeolite membrane reactors, combining the reaction and separation functionalities at the same time. Oxidative dehydrogenation of alkanes is a good case in point. The potential use of catalytic membrane reactors in this case appears to be of particular interest for 1) controlling the oxygen feeding to limit the highly exothermic total combustion and 2) improving the contact between the reactant and the catalytic sites. Immobilizing transition metal ions in zeolites by ion exchange or by incorporation into the lattice leads to stable, isolated, and well-defined, redox-active catalytic sites. Julbe et al.<sup>[22]</sup> tested the oxidative dehydrogenation of propane on V-free MFI membranes and V-MFI zeolite membranes. Both MFI and V-MFI membranes were found to produce propene with about 40% selectivity but with higher  $O_2$  and  $C_3H_8$  conversions for the V-MFI. Hasegawa et al.<sup>[50,51]</sup> applied noble metal-impregnated Y-type zeolite membranes for the selective oxidation of  $CO$ , which was present at concentrations of several 100 ppm in a stream of hydrogen. Ciavarella et al.<sup>[52]</sup> separated  $H_2$  and isobutene mixture using composite alumina-MFI-zeolite with a separation factor of 25 at 723 K, a typical temperature of the isobutane dehydrogenation in membrane reactor, which indicates a good commercial prospect. Takata et al.<sup>[53]</sup> applied the ion-exchanged H-type MFI zeolite membranes to the alkylation of toluene with methanol. A *p*-xylene selectivity of 80% were attained using H-MFI zeolite membranes at 450–500°C, as illustrated in Fig. 3, providing the possible application of an MFI zeolite membrane for use in a catalytic membrane reactor (CMR).

Bernal et al.<sup>[54]</sup> used a catalytically active zeolite membrane to shift the reaction equilibrium by selective water permeation during ethanol esterification.

Fig. 3 Toluene conversion Source: From Ref.<sup>[53]</sup>.

The H-ZSM-5 membrane used in their work had sufficient catalytic activity to carry out the esterification of ethanol with acetic acid, and at the same time was selective for water permeation. As a consequence, the reaction and separation functions could be very efficiently coupled, and the conversion obtained (63.1%) at the same feed rate and catalyst loading was greater than in conventional fixed-bed reactors (49.4%), or in reactors where the zeolite membrane was kept separated from the catalyst (56.9%). Zhang et al.<sup>[23]</sup> fabricated the crack-free Fe-MFI zeolite that was used for the conversion of ethylbenzene to styrene and obtained 15% of conversion increase over the conventional fixed-bed reactor.

## CONCLUSION

Successful synthesis of high-quality microporous zeolite membranes has opened up new fields of membrane applications in environmental separation and reactions. Some separation applications such as  $H_2$  from mixtures and water/alcohol separation have great commercial potential. Zeolite membranes permit the integration of reaction and effective separation in a single stage. Some reactions have been tested in zeolitic membrane reactors and showed promising results. Extending the catalytic zeolite membrane to more reactions is currently the focus of many industrial and research groups around the world.

However, many challenges exist in zeolite membranes. A typical example is the low flux through the zeolite membrane because of the fact that relatively thick zeolite layers on the order of a few micrometers to 50  $\mu\text{m}$  are necessary to ensure a pinhole-free and crack-free zeolite layer. Decreasing the membrane thickness while keeping its compactness will dramatically

increase its flux, thus resulting to more throughputs in practical applications. Some researchers have reported some significant advances in increasing the gas flux through the membrane by reducing the membrane thickness or by fabricating the membrane with higher surface area. However, reproducibility for thick zeolite membrane fabrication is always a challenge. In this regard, the search for optimal zeolite membrane materials and novel synthesis methods for improved chemical and structural stability will require continuing efforts of researchers.

Many catalytic processes of industrial importance involve the combination of high-temperature and chemically harsh environments, two factors that strongly favor zeolite membranes. They can be integrated in broad arrays of membranes in membrane reactors for separation and reaction applications, ranging from biochemical through environmental to petrochemical applications. The zeolite membranes can be employed for the permeation of the products to shift equilibrium limitations or the distribution of reactants for the control of concentration of selected species, or to carry out catalysis and separation at the same time. Hence conversion enhancement can be significantly achieved in several reaction processes such as hydrogenation, dehydrogenation, and esterification. Therefore the employment of zeolite membrane reactors for several industrial applications is envisioned. However, scale-up problems are still the main limitations of this technology, in particular that large, crack-free zeolite membrane surface areas are required for membrane reactors in industrial application. This area requires major research and development efforts to take the technology to the industrial application stage.

## ACKNOWLEDGMENTS

Financial support from the Australian research council is gratefully acknowledged and thanks are also due to Prof. Feng-shou Xiao, Jilin University, China, for some useful discussions and suggestions.
