

Volume I-VI

DEKKER  
Encyclopedia of  
Nanoscience  
and  
Nanotechnology

Second Edition

# Encyclopedias from Taylor & Francis Group

## Agriculture Titles

- Dekker Agropedia Collection (Eight Volume Set)**  
ISBN: 978-0-8247-2194-7      Cat. No.: DK803X
- Encyclopedia of Agricultural, Food, and Biological Engineering**  
Edited by Dennis R. Heldman  
ISBN: 978-0-8247-0938-9      Cat. No.: DK9381
- Encyclopedia of Animal Science**  
Edited by Wilson G. Pond and Alan Bell  
ISBN: 978-0-8247-5496-9      Cat. No.: DK2206
- Encyclopedia of Pest Management**  
Edited by David Pimentel  
ISBN: 978-0-8247-0632-6      Cat. No.: DK6323
- Encyclopedia of Pest Management, Volume II**  
Edited by David Pimentel  
ISBN: 978-1-4200-5361-6      Cat. No.: 53612
- Encyclopedia of Plant and Crop Science**  
Edited by Robert M. Goodman  
ISBN: 978-0-8247-0944-0      Cat. No.: DK1190
- Encyclopedia of Soil Science, Second Edition (Two Volume Set)**  
Edited by Rattan Lal  
ISBN: 978-0-8493-3830-4      Cat. No.: DK830X
- Encyclopedia of Water Science, Second Edition (Two Volume Set)**  
Edited by Stanley W. Trimble  
ISBN: 978-0-8493-9627-4      Cat. No.: DK9627

## Chemistry Titles

- Encyclopedia of Chromatography, Second Edition (Two Volume Set)**  
Edited by Jack Cazes  
ISBN: 978-0-8247-2785-7      Cat. No.: DK7851
- Encyclopedia of Supramolecular Chemistry (Two Volume Set)**  
Edited by Jerry L. Atwood and Jonathan W. Steed  
ISBN: 978-0-8247-5056-5      Cat. No.: DK056X
- Encyclopedia of Surface and Colloid Science, Second Edition (Eight Volume Set)**  
Edited by P. Somasundaran  
ISBN: 978-0-8493-9615-1      Cat. No.: DK9615

## Engineering Titles

- Encyclopedia of Chemical Processing (Five Volume Set)**  
Edited by Sunggyu Lee  
ISBN: 978-0-8247-5563-8      Cat. No.: DK2243
- Encyclopedia of Corrosion Technology, Second Edition**  
Edited by Philip A. Schweitzer, P.E.  
ISBN: 978-0-8247-4878-4      Cat. No.: DK1295
- Encyclopedia of Energy Engineering and Technology (Three Volume Set)**  
Edited by Barney L. Capehart  
ISBN: 978-0-8493-3653-9      Cat. No.: DK653X
- Dekker Encyclopedia of Nanoscience and Nanotechnology, Second Edition (Six Volume Set)**  
Edited by Cristian I. Contescu and Karol Putyera  
ISBN: 978-0-8493-9639-7      Cat. No.: DK9639
- Encyclopedia of Optical Engineering (Three Volume Set)**  
Edited by Ronald G. Driggers  
ISBN: 978-0-8247-0940-2      Cat. No.: DK9403

## Business Titles

- Encyclopedia of Library and Information Science, Second Edition (Four Volume Set)**  
Edited by Miriam Drake  
ISBN: 978-0-8247-2075-9      Cat. No.: DK075X
- Encyclopedia of Library and Information Science, First Update Supplement**  
Edited by Miriam Drake  
ISBN: 978-0-8493-3894-6      Cat. No.: DK8948
- Encyclopedia of Public Administration and Public Policy, Second Edition (Three Volume Set)**  
Edited by Evan M. Berman  
ISBN: 978-0-4200-5275-6      Cat. No.: AU5275
- Encyclopedia of Wireless and Mobile Communications (Three Volume Set)**  
Edited by Borko Furht  
ISBN: 978-0-4200-4326-6      Cat. No.: AU4326

This book contains information obtained from authentic and highly regarded sources. Reasonable efforts have been made to publish reliable data and information, but the author and publisher cannot assume responsibility for the validity of all materials or the consequences of their use. The authors and publishers have attempted to trace the copyright holders of all material reproduced in this publication and apologize to copyright holders if permission to publish in this form has not been obtained. If any copyright material has not been acknowledged please write and let us know so we may rectify in any future reprint.

Except as permitted under U.S. Copyright Law, no part of this book may be reprinted, reproduced, transmitted, or utilized in any form by any electronic, mechanical, or other means, now known or hereafter invented, including photocopying, microfilming, and recording, or in any information storage or retrieval system, without written permission from the publishers.

For permission to photocopy or use material electronically from this work, please access [www.copyright.com](http://www.copyright.com) (<http://www.copyright.com/>) or contact the Copyright Clearance Center, Inc. (CCC), 222 Rosewood Drive, Danvers, MA 01923, 978-750-8400. CCC is a not-for-profit organization that provides licenses and registration for a variety of users. For organizations that have been granted a photocopy license by the CCC, a separate system of payment has been arranged.

*To the lasting memory of the Founding Editor,  
Professor James A. Schwarz,  
who shaped our lives;  
and to the enduring patience of our wives,  
Adriana and Ildiko, who understood so  
well and always supported us.*

*Cristian I. Contescu  
Karol Putyera  
Oak Ridge, TN and Syracuse, NY  
July 2008*

**Cristian I. Contescu**

*Materials Science and Technology Division,  
Oak Ridge National Laboratory, Oak Ridge, Tennessee, U.S.A.*

**Karol Putyera**

*EAG New York Shiva Technologies, Syracuse, New York, U.S.A.*

**Founding Editor James A. Schwarz**

*Syracuse University, Syracuse, New York, U.S.A.*

***Editorial Advisory Board***

**Frank Armatis**

*Advanced Materials Technology Center,  
3M Corporation, St. Paul,  
Minnesota, U.S.A.*

**R. Terry K. Baker**

*Catalytic Materials Ltd., Holliston,  
Massachusetts, U.S.A.*

**Robert Birge**

*Department of Chemistry,  
University of Connecticut, Storrs,  
Connecticut, U.S.A.*

**Vijoleta Braach-Maksvytis**

*CSIRO Executive Management Council,  
Australian Government, Lindfield,  
New South Wales, Australia*

**Gianfranco Cerofolini**

*Department of Materials Science,  
University of Milano-Bicocca,  
Milan, Italy*

**Stephen Y. Chou**

*Department of Electrical Engineering,  
Princeton University, Princeton,  
New Jersey, U.S.A.*

**Morinobu Endo**

*Faculty of Engineering, Shinshu University,  
Nagano-city, Japan*

**Toshiaki Enoki**

*Department of Chemistry,  
Tokyo Institute of Technology,  
Tokyo, Japan*

**Gerhard Ertl**

*Department of Physical Chemistry,  
Fritz Haber Institute of the Max Planck  
Society, Berlin, Germany*

**Robert Glass**

*Lawrence Livermore National Laboratory,  
Livermore, California, U.S.A.*

**D. Wayne Goodman**

*Department of Chemistry,  
Texas A&M University,  
College Station, Texas, U.S.A.*

**Elias Greenbaum**

*Chemical Sciences Division,  
Oak Ridge National Laboratory,  
Oak Ridge, Tennessee, U.S.A.*

**Hans-Joachim Güntherodt**

*Institut für Physik der Universität Basel,  
Basel, Switzerland*

**Norbert Hampp**

*Department of Chemistry,  
Philipps Universität,  
Marburg, Germany*

**Tim Harper**

*CMP-Cientifica S.L., Madrid, Spain*

**Arthur Hubbard**

*Santa Barbara Science Project,  
Santa Barbara, California, U.S.A.*

**Enrique Iglesia**

*Department of Chemical Engineering,  
University of California, Berkeley,  
California, U.S.A.*

**Mietek Jaroniec**

*Department of Chemistry,  
Kent State University, Kent,  
Ohio, U.S.A.*

**Andy Kaldor**

*ExxonMobil Research and Engineering,  
Annandale, New Jersey, U.S.A.*

**Jürgen Kirschner**

*Max-Planck-Institut für  
Mikrostrukturphysik,  
Halle, Germany*

**Laszlo B. Kish**

*Department of Electrical Engineering,  
Texas A&M University,  
College Station, Texas, U.S.A.*

**Kenneth Klabunde**

*Department of Chemistry,  
Kansas State University,  
Manhattan, Kansas, U.S.A.*

**James Leckie**

*Department of Civil and Environmental  
Engineering, School of Engineering,  
Stanford University, Stanford,  
California, U.S.A.*

**Charles M. Lieber**

*School of Engineering and Applied Science,  
Harvard University, Cambridge,  
Massachusetts, U.S.A.*

**Chad Mirkin**

*Department of Chemistry,  
Northwestern University,  
Evanston, Illinois, U.S.A.*

**Shuming Nie**

*Department of Biomedical Engineering,  
Emory University School of Medicine,  
Atlanta, Georgia, U.S.A.*

**Jens K. Norskov**

*Department of Physics,  
Technical University of Denmark,  
Lyngby, Denmark*

**Mark Reed**

*Department of Electrical Engineering and  
Applied Physics, Yale University,  
New Haven, Connecticut, U.S.A.*

**David C. Rees**

*Astex Technology Ltd., Cambridge, U.K.*

**Stacey L. Ristinmaa-Sörensen**

*Department of Physics,  
University of Lund,  
Lund, Sweden*

**John A. Rogers**

*Department of Chemistry, University of  
Illinois at Urbana-Champaign,  
Urbana, Illinois, U.S.A.*

**Debra R. Rolinson**

*Advanced Electrochemical Materials,  
Naval Research Laboratory, Washington,  
District of Columbia, U.S.A.*

**Jurgen Ruhe**

*Institute for Microsystem Technology,  
Albert-Ludwig University,  
Freiburg, Germany*

**Purnesh Seegopaul**

*Pangaea Ventures, Jersey City,  
New Jersey, U.S.A.*

**Stu Soled**

*ExxonMobil Research and  
Engineering, Annandale,  
New Jersey, U.S.A.*

**Stephan J. Stranick**

*National Institute of Standards and  
Technology (NIST), Gaithersburg,  
Maryland, U.S.A.*

**Arthur ten Wolde**  
*Confederation of Netherlands  
Industry and Employers VNO-NCW,  
The Hague, The Netherlands*

**Frederick Tepper**  
*Argonide Corp., Sanford, Florida, U.S.A.*

**Gary Tompa**  
*Structured Materials Industries, Inc.,  
Piscataway, New Jersey, U.S.A.*

**Robert Trew**  
*Department of Electrical and Computer  
Engineering, North Carolina*

*State University, Raleigh,  
North Carolina, U.S.A.*

**Etienne F. Vansant**  
*Department of Chemistry, University of  
Antwerp (UIA), Wilrijk, Belgium*

**Younan Xia**  
*Department of Biomedical Engineering,  
Washington University, Saint Louis,  
Missouri, U.S.A.*

**Peidong Yang**  
*Department of Chemistry,  
University of California, Berkeley,  
California, U.S.A.*

## Volume I

<b>Aberration-Corrected Z-Contrast STEM: Semiconducting Nanocrystals</b> / James R. McBride, Andrew R. Lupini, Stephen J. Pennycook, and Sandra J. Rosenthal .....	1
<b>Adhesion: Cell on a Substrate</b> / Frédéric Pincet .....	22
<b>Adhesion: Coated Surfaces, Effect of Humidity</b> / Joan E. Curry and Sungsoo Kim .....	32
<b>Adsorption on Heterogeneous Surfaces</b> / Vinay K. Gupta and Yu-Wen Huang .....	41
<b>Aerosol Nanoparticles: Coagulation Theory</b> / Ken Won Lee and Soon-Bark Kwon .....	53
<b>AFM: Biopolymers</b> / Nehal I. Abu-Lail and Terri A. Camesano .....	63
<b>AFM: Hydrogen-Bonded Nanostructures</b> / Holger Schönherr, Mercedes Crego-Calama, G. Julius Vancso, and David N. Reinhoudt .....	76
<b>AFM: Imaging Artifacts</b> / Stephanie Butler Velegol .....	88
<b>AFM: Imaging and Force Spectroscopy on Cell Surfaces</b> / Yves F. Dufrêne .....	99
<b>AFM: Metal Ion Sorption</b> / Viriya Vithayaveroj, Sotira Yiacoumi, and Costas Tsouris .....	109
<b>AFM: Nanolithography on Organized Films</b> / Seunghyun Lee and Haiwon Lee .....	119
<b>AFM: Protein Adsorption</b> / David T. Kim, Harvey W. Blanch, and Clayton J. Radke .....	129
<b>AFM: Simulation of Interaction Forces</b> / Ivan U. Vakarelski, Scott C. Brown, Bahar Basim, and Brij M. Moudgil .....	153
<b>Amphiphilic Block Copolymer Monolayer at Air–Water Interface</b> / Emiko Mouri and Hideki Matsuoka .....	168
<b>Anion-Templated Self-Assembly: Inorganic Compounds</b> / Louise S. Evans and Philip A. Gale .....	178
<b>Anion-Templated Self-Assembly: Organic Compounds</b> / Paul D. Beer and Mark R. Sambrook .....	191
<b>Anodization Patterned on Aluminum Surfaces</b> / Juchao Yan, G. V. Rama Rao, Plamen B. Atanassov, and Gabriel P. López .....	203
<b>Antidot Lattices: Chaotic Transport</b> / Tsuneya Ando .....	210
<b>Atmospheric Nanoparticles: Formation and Physicochemical Properties</b> / James N. Smith .....	228
<b>Automotive Parts: Impact of Nanotechnology</b> / Ganesh Skandan, Amit Singhal, and Damian Sobrevilla .....	241
<b>Axle Molecules Threaded through Macrocycles</b> / Daryle H. Busch and Thomas Clifford .....	249
<b>Barcoded Nanowires</b> / Rebecca L. Stoermer and Christine D. Keating .....	259
<b>Barrier Properties of Ordered Polymer Nanocomposites</b> / Bon-Cheol Ku, Alexandre Blumstein, Jayant Kumar, Lynne A. Samuelson, and Dong Wook Kim .....	267

<b>Basic Nanostructured Catalysts</b> / Robert J. Davis	278
<b>Bimetallic Layered Nanocomposites</b> / Amit Misra and Richard G. Hoagland	288
<b>Bio-Microarrays</b> / Günter E.M. Tovar and Achim Weber	298
<b>Biocatalytic Single-Enzyme Nanoparticles</b> / Jay W. Grate and Jungbae Kim	307
<b>Biological and Chemical Decontamination</b> / Peter K. Stoimenov and Kenneth J. Klabunde	312
<b>Biomaterials: Mechanical Characterization</b> / Eunice Phay Shing Tan and Chwee Teck Lim	317
<b>Biomedical Applications: Implants</b> / Jeremiah Ejiolor and Thomas J. Webster	327
<b>Biomedical Applications: Novel Materials and Devices</b> / J. Zachary Hilt and Mark E. Byrne	339
<b>Biomedical Magnetic Nanoparticles</b> / Ian Robinson, Le Duc Tung, and Nguyen T.K. Thanh	354
<b>Biomimetic Design of Self-Assembling Systems</b> / Mila Boncheva and George M. Whitesides	364
<b>Biomimetic Receptors for Carboxylate Recognition</b> / Rocco Ungaro, Alessandro Casnati, and Francesco Sansone	372
<b>Bionanoparticles</b> / Krishnaswami S. Raja, Sukanta Dolai, Wei Shi, and Qian Wang	386
<b>Bioremediation of Environmental Contaminants</b> / Xiomara C. Kretschmer and Russell R. Chianelli	397
<b>Biosensor Applications: Porous Silicon Microcavities</b> / Benjamin L. Miller, Philippe M. Fauchet, Scott R. Horner, and Selena Chan	408
<b>Biosensor Applications: Surface Engineering</b> / Genady Zhavnerko and Kwon-Soo Ha	416
<b>Biosensors Based on Carbon Nanotubes</b> / Yuehe Lin, Wassana Yantasee, Fang Lu, Joseph Wang, Mustafa Musameh, Yi Tu, and Zhifeng Ren	428
<b>Biosensors: Fractal Analysis of Binding Kinetics</b> / Harshala Butala and Ajit Sadana	441
<b>Biosurfaces: Water Structure at Interfaces</b> / Yan-Yeung Luk	453
<b>Block Copolymer Nanoparticles</b> / Sandrine Pensec, Daniel Portinha, Laurent Bouteiller, and Christophe Chassenieux	467
<b>Cadmium Selenide Quantum Dots</b> / Kenzo Maehashi and Hisao Nakashima	477
<b>Cadmium Selenide Quantum Rods: Anisotropy</b> / Liang-shi Li and A. Paul Alivisatos	487
<b>Cadmium Sulfate Nanocrystals: Computational Analysis</b> / Stacie Nunes, Zhigang Zhou, Jeffrey D. Evanseck, and Jeffry D. Madura	498
<b>Capsules: Polymer Microcapsules</b> / Gleb B. Sukhorukov	508
<b>Capsules: Specific Layer Structures</b> / Lars Dähne and Claire S. Peyratout	522
<b>Carbon-Based Nanostructures: Hydrogen Storage</b> / Xianxian Wu and Nidia C. Gallego	535
<b>Carbon Forms Structured by Energetic Species</b> / Yeshayahu Lifshitz	553
<b>Carbon Nanotransistors</b> / Po-Wen Chiu and Siegmund Roth	563
<b>Carbon Nanotube-Conducting Polymer Composites in Supercapacitors</b> / Mark Hughes	574
<b>Carbon Nanotube Electrodes</b> / Valentina Lazarescu	586
<b>Carbon Nanotube Interconnects</b> / Alain E. Kaloyeros, Kathleen A. Dunn, Autumn T. Carlsen, and Anna W. Topol	596
<b>Carbon Nanotube-Metal Matrix Composites</b> / Efraín Carreño-Morelli	611
<b>Carbon Nanotubes: Electrochemical Modification</b> / Kannan Balasubramanian, Marko Burghard, and Klaus Kern	620
<b>Carbon Nanotubes: Flow Control in Membranes</b> / Scott A. Miller and Charles R. Martin	630
<b>Carbon Nanotubes: Functionalization</b> / Bin Zhao, Hui Hu, Elena Bekyarova, Mikhail E. Itkis, Sandip Niyogi, and Robert C. Haddon	640
<b>Carbon Nanotubes: Gas Adsorption Properties</b> / Juan Manuel Diez Tascón and Eduardo J. Bottani	653
<b>Carbon Nanotubes: Hydrogen Storage</b> / Masashi Shiraishi, Taishi Takenobu, Hiromichi Kataura, and Masafumi Ata	662
<b>Carbon Nanotubes: Modeling of Hydrogen Chemisorption</b> / Ronald C. Brown	671

<b>Carbon Nanotubes: Optical Properties</b> / R. Saito, Mildred S. Dresselhaus, G. Dresselhaus, A. Jorio, A. G. Souza Filho, and M. A. Pimenta . . . . .	679
<b>Carbon Nanotubes and Other Carbon Materials</b> / Morinobu Endo, Yoong Ahm Kim, Takuya Hayashi, Mauricio Terrones, and Mildred S. Dresselhaus . . . . .	691
<b>Carbon Nanotubes for Storage of Energy: Supercapacitors</b> / Elzbieta Frackowiak . . . . .	707
<b>Carbon Nanotubes: Supramolecular Mechanics</b> / Boris I. Yakobson and Luise S. Couchman . . . . .	722
<b>Carbon Nanotubes: Thermal Properties</b> / J. Hone . . . . .	736
<b>Catalysis by Supported Gold Nanoclusters</b> / D. Wayne Goodman . . . . .	744

---

## Volume II

<b>Catalyst Nanostructures: X-Ray Absorption</b> / Jeffrey T. Miller, M. K. Neylon, C. L. Marshall, and Arthur Jerome Kropf . . . . .	753
<b>Catalysts by Nanoscale Design</b> / Chaitanya Kumar Narula . . . . .	772
<b>Catalytic Processes: Nanoscale Simulations</b> / Vladimir I. Elokhin and Aleksandr V. Myshlyavtsev . . . . .	782
<b>Ceramic Nanocomposites: Self-Diagnostic Ability of Catastrophic Damage</b> / Pavol Šajgalík and Zoltán Lenčés . . . . .	794
<b>Charge Carrier Dynamics of Nanoparticles</b> / Fanxin Wu and Jin Z. Zhang . . . . .	804
<b>Charge Transfer in Metal–Molecule Heterostructures</b> / Debasish Kuila, David B. Janes, and Clifford P. Kubiak . . . . .	819
<b>Charge Transport in Multilayer Nanostructures</b> / Daniel M. Schaadt . . . . .	834
<b>Chemical Warfare Agents: Biosensors for Detection</b> / Elias Greenbaum, Miguel Rodriguez, Jr., and Charlene A. Sanders . . . . .	842
<b>Colloid Systems: Micelles and Nanocrystals</b> / B.L.V. Prasad and Savka I. Stoeva . . . . .	856
<b>Colloidal Nanometals as Fuel Cell Catalyst Precursors</b> / Helmut Bönnemann and K. S. Nagabhushana . . . . .	863
<b>Colloidal Nanoparticles: Aggregation Patterns at Surfaces</b> / Hamidou Haidara and Karine Mougín . . . . .	882
<b>Colloidal Nanoparticles: Electrokinetic Characterization</b> / Kunio Furusawa and Hideo Matsumura . . . . .	893
<b>Colloidal Structures on Patterned Surfaces</b> / Aránzazu del Campo, Anne-Sophie Duwez, Charles-André Fustin, and Ulrich Jonas . . . . .	907
<b>Computational Analysis Using Normal and Multibody Modes</b> / Bryan C. Hathorn, Donald W. Noid, Bobby G. Sumpter, Chao Yang, and William A. Goddard III . . . . .	921
<b>Computational Analysis of Switchable Catenanes</b> / Xiang Zheng and Karl Sohlberg . . . . .	930
<b>Computational Analysis of Switchable Rotaxanes</b> / Xiang Zheng and Karl Sohlberg . . . . .	939
<b>Conducting Polymer Nanopatterns</b> / Shaun F. Filocamo and Mark W. Grinstaff . . . . .	954
<b>Conducting Polymer Nanotubes</b> / Seung Il Cho and Sang Bok Lee . . . . .	965
<b>Controlled Size and Shape Supramolecular Aggregates on Solid Surfaces</b> / Takashi Yokoyama, Toshiya Kamikado, Shiyoshi Yokoyama, and Shinro Mashiko . . . . .	974
<b>Coordination Framework Topology</b> / Neil R. Champness and Neil S. Oxtoby . . . . .	984
<b>Core–Shell Hydrogel Nanoparticles</b> / Clinton D. Jones and L. Andrew Lyon . . . . .	993
<b>Core–Shell Nanospheres, Hollow Capsules, and Bottles</b> / Gang Zhang, Kai Zhang, Yi Yu, and Bai Yang . . . . .	1003
<b>Cubosomes: Bicontinuous Liquid Crystalline Nanoparticles</b> / Patrick T. Spicer . . . . .	1018
<b>Cyanogels: Processing by Spin Coating</b> / Shu Zhu and Andrew B. Bocarsly . . . . .	1029
<b>Cyclic Peptides: Self-Assembly in Hydrogen-Bonded Nanotubes</b> / Roberto J. Brea and Juan R. Granja . . . . .	1037
<b>Dendritic Nanocatalysts</b> / Kiyotomi Kaneda, Masahiko Ooe, Makoto Murata, Tomoo Mizugaki, and Kohki Ebitani . . . . .	1054

<b>Dimensionally Graded Semiconductor Nanoparticle Films</b> / Arif A. Mamedov, Nicholas A. Kotov, and Nataliya N. Mamedova	1062
<b>Dip-Pen Nanolithography: Applications and Functional Extensions</b> / Björn T. Rosner and Linette M. Demers	1070
<b>Dip-Pen Nanolithography: Optical Inks</b> / Brandon L. Weeks, Aleksandr Noy, Abigail E. Miller, Jennifer E. Klare, Bruce W. Woods, and James J. De Yoreo	1084
<b>Dissymmetrical Nanoparticles</b> / Stéphane Reculosa, Christophe Mingotaud, Etienne Duguet, and Serge Ravaine	1093
<b>DNA-Based Nanoinstrument Design</b> / Alexander Hillisch and Stephan Diekmann	1102
<b>DNA-Conjugated Metal Nanoparticles: Chip Detection Applications</b> / Wolfgang Fritzsche	1114
<b>DNA Hybridization: Electronic Control</b> / Kimberly Hamad-Schifferli	1122
<b>DNA Interactions with Functionalized Emulsions</b> / Thierry Delair	1134
<b>Dynamic AFM on Heterogeneous Surfaces</b> / Ijeoma M. Nnebe and James W. Schneider	1144
<b>Electrical Double-Layer Formation</b> / Kun-Lin Yang, Sotira Yiacoumi, and Costas Tsouris	1157
<b>Electrically Functional Nanostructures</b> / Orlin D. Velev and Simon O. Lumsdon	1171
<b>Electrochemical Langmuir Trough</b> / Natalia Varaksa, Thomas F. Magnera, and Josef Michl	1189
<b>Electrochemical Sensors: Functionalized Silica</b> / Yuehe Lin, Wassana Yantasee, and Glen E. Fryxell	1196
<b>Electrochemical Toxicity Sensors</b> / James F. Rusling	1207
<b>Electron Microscopy at Very High Resolution</b> / Klaus van Benthem and Stephen J. Pennycook	1217
<b>Electronic Switches</b> / Richard J. Nichols, David J. Schiffrin, and Wolfgang Haiss	1230
<b>Enantioselectivity on Surfaces</b> / David M. Rampulla and Andrew J. Gellman	1242
<b>Environmental Electron Microscopy Imaging</b> / Satoshi Utsunomiya, Christopher S. Palenik, and Rodney C. Ewing	1252
<b>Environmental Nanoparticles</b> / Alexandra Navrotsky	1262
<b>Enzymatic Synthesis of Nanostructured Polymers and Composites</b> / Christy Ford, Vijay T. John, Gary McPherson, Jibao He, Joseph Akkara, David Kaplan, and Arijit Bose	1271
<b>Epoxy-Layered Silicate Nanocomposites</b> / Chenggang Chen and Tia Benson Tolle	1284
<b>Ethane-Preferred Conformation</b> / Lionel Goodman and Vojislava Pophristic	1294
<b>Fluorescence-Voltage Single Molecule Spectroscopy</b> / Young Jong Lee, Andre J. Gesquiere, So-Jung Park, and Paul F. Barbara	1300
<b>Fluorofullerenes</b> / Olga V. Boltalina and Steven H. Strauss	1307
<b>Fullerenes and Carbon Nanotubes</b> / Laszlo Mihalý	1322
<b>Fullerenes: Chemistry</b> / Mark S. Meier	1331
<b>Fullerenes: Isomer Identification</b> / Guangyu Sun	1340
<b>Fullerenes: Magnetic Behavior</b> / T. L. Makarova	1352
<b>Fullerenes: Topology and Structure</b> / G. Benedek and M. Bernasconi	1360
<b>Functionalization of Surface Layers on Ceramics</b> / Toshihiro Ishikawa	1375
<b>Gecko-Inspired Adhesives: Nanofabrication</b> / Aránzazu del Campo and Eduard Arzt	1384
<b>Gene Delivery via Polymer Nanoparticles</b> / Jie Wen and Kam W. Leong	1394
<b>Germanium Nanoparticles</b> / Boyd R. Taylor and Louisa J. Hope-Weeks	1405
<b>Gold Nanoclusters: Structural Disorder</b> / Ignacio L. Garzón	1412
<b>Gold Nanoparticles on Titania: Activation and Behavior</b> / Jose A. Rodriguez	1422
<b>Guests within Hydrophobic Pockets: Conventional Synthesis</b> / Bruce C. Gibb	1429
<b>Guests within Hydrophobic Pockets: Self-Assembly</b> / Bruce C. Gibb	1451
<b>Halide Transport through Biological Membranes</b> / Lars-Oliver Essen	1476

## Volume III

<b>Heterogeneous Catalysts: Atomic Scale Studies</b> / Robert F. Klie, Kai Sun, Mark M. Disko, Jingyue Liu, and Nigel D. Browning	1491
<b>Heterogeneous Catalytic Reactions by Mass Spectrometry</b> / Steven M. Thornberg and Deborah E. Hunka	1505
<b>Heterogeneous Surfaces with Nanosized Channel Lattices</b> / Lifeng Chi, Michael Gleiche, Steven Lenhart, and Nan Lu	1515
<b>Hierarchically Imprinted Nanostructures for Separation</b> / Sheng Dai, Zongtao Zhang, and Chengdu Liang	1525
<b>High-Strength Alloys: Nanogranular Phases</b> / Dmitri Valentinovich Louzguine and Akihisa Inoue	1536
<b>Hydrogel Nanoparticles Made of Cross-Linked Polyvinylpyrrolidone</b> / Susmita Mitra, Dhruva Jyoti Bharali, and Amarnath Maitra	1546
<b>Ice Nanotubes inside Carbon Nanotubes</b> / Kenichiro Koga and Hideki Tanaka	1558
<b>In-Situ Electron Microscopy</b> / Charles W. Allen	1568
<b>Indium Arsenide Islands on Silicon</b> / P. C. Sharma and Kang L. Wang	1582
<b>Infrared Spectroscopy: Biomolecular Structure at Interfaces</b> / Curtis W. Meuse	1590
<b>Inorganic Nanotubes</b> / Reshef Tenne	1598
<b>Inorganic Nanotubes: Synthesis by Chemical Transport Reaction</b> / Maja Remskar	1606
<b>Inorganic Sulfide Nanotubes: Mechanical Behavior</b> / Ifat Kaplan-Ashiri, H. Daniel Wagner, Gotthard Seifert, and Reshef Tenne	1617
<b>Integrated Methods in Quantum Chemistry</b> / Stephan Irle and Keiji Morokuma	1627
<b>Intercalated Polypropylene Nanocomposites</b> / Michael J. Solomon and Anongnat Somwangthanaroj	1642
<b>Interfacial Forces: Colloidal Particle-Liquid</b> / Sarah A. Nespolo and Geoffrey W. Stevens	1650
<b>Interfacial Phenomena: Chemical Selectivity</b> / Vinay K. Gupta	1662
<b>Ionic Strength Effects: Tunable Nanocrystal Distribution in Colloidal Gold Films</b> / E. Stefan Kooij, E.A. Martijn Brouwer, Herbert Wormeester, and Bene Poelsema	1672
<b>Iron Nanoparticles</b> / Dale L. Huber	1681
<b>Iron Oxide Nanoparticles</b> / Mamoru Senna	1688
<b>Island Nucleation: Predictions</b> / Maria C. Bartelt	1696
<b>Island Surfaces: Fabrication on Self-Assembled Monolayers</b> / Hongjie Liu, Charles Maldarelli, M. Lane Gilchrist, and Alexander Couzis	1708
<b>Lab-on-a-Chip Microreactors</b> / Paul D.I. Fletcher, Stephen J. Haswell, Paul Watts, and Xunli Zhang	1721
<b>Langmuir-Blodgett Films</b> / Ursula Mazur	1738
<b>Laser-Based Deposition: Patterning</b> / Edward M. Nadgorny and Jaroslaw Drelich	1749
<b>Layer-by-Layer Assembly of Electroactive Thin Films to Layered Carbon Electrodes</b> / Tarek R. Farhat	1764
<b>Layer-by-Layer Assembly of Gold Nanoclusters with Self-Assembled Monolayers</b> / Kohei Uosaki, Wenbo Song, Masayuki Okamura, and Toshihiro Kondo	1773
<b>Layer-by-Layer Assembly of Polyelectrolyte Films: Membranes and Catalysts</b> / Bernd Tieke and Ali Toutianoush	1784
<b>Layer-by-Layer Assembly of Semiconducting and Photoreactive Bolaform Amphiphiles</b> / Jason Locklin, Derek Patton, Chuanjun Xia, Xiaowu Fan, and Rigoberto C. Advincula	1798
<b>Layer-by-Layer Assembly of Thin Films of Mixed Nanoparticles</b> / Jianchang Guo, Encai Hao, and Tianquan Lian	1813
<b>Layer-by-Layer Electrostatic Self-Assembly</b> / Michael J. McShane and Yuri M. Lvov	1823
<b>Layered Double Hydroxides: Self-Assembly and Multiple Phases</b> / Zhi Ping Xu and Paul S. Braterman	1841

<b>Ligand–Receptor Systems with Infinite Binding Affinity</b> / <i>Claude F. Meares</i> . . . . .	1853
<b>Lipid Membranes: Nanostructure and Dynamic Organization</b> / <i>J. Gaudioso and D. Y. Sasaki</i> . . . . .	1859
<b>Liposomes: Direct Force Measurement by AFM</b> / <i>Guangzhao Mao, Xuemei Liang, and K.Y. Simon Ng</i> . . . . .	1869
<b>Liquid Crystals and Nanostructured Surfaces: Detecting Protein Binding</b> / <i>Yan-Yeung Luk</i> . . . . .	1878
<b>Litho-to-Nano Link</b> / <i>Gianfranco Cerofolini, Dario Narducci, and Elisabetta Romano</i> . . . . .	1890
<b>Low-Dielectric Constant Materials</b> / <i>Robert D. Miller</i> . . . . .	1901
<b>Luminescence of Nanoparticle-Labeled Antibodies and Antigens</b> / <i>Shaopeng Wang and Nicholas A. Kotov</i> . . . . .	1915
<b>Magnetic Ferrofluids</b> / <i>Carlos Rinaldi, Thomas Franklin, Markus Zahn, and Tahir Cader</i> . . . . .	1922
<b>Magnetic Nanocarbon</b> / <i>T. L. Makarova</i> . . . . .	1939
<b>Magnetic Nanomaterials: Conventional Synthesis and Properties</b> / <i>Dajie Zhang</i> . . . . .	1951
<b>Magnetic Nanomaterials: Nonconventional Synthesis and Chemical Design</b> / <i>Luminita Patron, Ioana Mindru, and Gabriela Marinescu</i> . . . . .	1968
<b>Magnetic Nanoparticles</b> / <i>Valérie Cabuil</i> . . . . .	1985
<b>Magnetic Nanoparticles for Granular Recording Media</b> / <i>David E. Nikles and J. W. Harrell</i> . . . . .	2001
<b>Membrane-Coated Nanoparticles: Photochemistry</b> / <i>Ulrich Siggel, Guangtao Li, and Jürgen-Hinrich Fuhrhop</i> . . . . .	2012
<b>Mesoporous Materials</b> / <i>James C. Vartuli, Wielsaw J. Roth, and Thomas F. Degnan, Jr.</i> . . . . .	2029
<b>Metal Clusters on Oxides</b> / <i>Ivan Stensgaard</i> . . . . .	2044
<b>Metal Nanoparticle Catalysts</b> / <i>Naoki Toshima</i> . . . . .	2052
<b>Metal Nanoparticle Ensembles: Collective Optical Properties</b> / <i>Alexander Wei</i> . . . . .	2064
<b>Metal Nanoparticles Prepared in Supercritical Carbon Dioxide</b> / <i>Harry W. Rollins</i> . . . . .	2072
<b>Metal Nanoparticles: Self-Assembly into Electronic Nanostructures</b> / <i>Venugopal Santhanam and Ronald P. Andres</i> . . . . .	2079
<b>Metal Nanostructures: Synthesis Controlled by Photoexcitation</b> / <i>Kei Murakoshi and Yoshihiro Nakato</i> . . . . .	2091
<b>Metal Nanostructures: Synthesis by Soft Chemical Methods</b> / <i>Yugang Sun and Younan Xia</i> . . . . .	2105
<b>Metal–Oxide Interfaces: Design via Control of Defect Density</b> / <i>A. Bogicevic</i> . . . . .	2116
<b>Metal Oxide Nanoparticles</b> / <i>Ryan M. Richards</i> . . . . .	2126
<b>Metal Oxide Nanoribbons and Carbon Nanotubes: Modeling</b> / <i>Amitesh Maiti</i> . . . . .	2140
<b>Metallic Nanopowders</b> / <i>Frederick Tepper, Marat I. Lerner, and David S. Ginley</i> . . . . .	2153
<b>Metallic Nanopowders: Rocket Propulsion</b> / <i>Leonid Kaledin and Frederick Tepper</i> . . . . .	2165
<b>Metallic Quantum Dots</b> / <i>J. P. Wilcoxon</i> . . . . .	2176
<b>Metallomacrocyclic Selective Ion Receptors</b> / <i>Kay Severin</i> . . . . .	2202

## Volume IV

<b>Mica Surfaces: Charge Nucleation and Wear</b> / <i>James M. Helt and James D. Batteas</i> . . . . .	2211
<b>Micro- and Mesoporous Nanomaterials: Catalytic Properties</b> / <i>Johannes A. Lercher and Andreas Jentys</i> . . . . .	2229
<b>Microgel Dispersions: Colloidal Forces and Phase Behavior</b> / <i>Jianzhong Wu and Zhibing Hu</i> . . . . .	2243
<b>Microweighing in Supercritical Carbon Dioxide</b> / <i>You-Ting Wu and Christine S. Grant</i> . . . . .	2253
<b>Mineral Nanoparticles: Electrokinetics</b> / <i>Mehmet S. Celik and Bahri Ersoy</i> . . . . .	2266
<b>Mixed Metal Oxide Nanoparticles</b> / <i>Pramesh N. Kapoor, Ajay Kumar Bhagi, Ravichandra S. Mulukutla, and Kenneth J. Klabunde</i> . . . . .	2280
<b>Molecular Computing Machines</b> / <i>Yaakov Benenson and Ehud Shapiro</i> . . . . .	2291
<b>Molecular Electronics: Logic and Memory</b> / <i>Dustin K. James and James M. Tour</i> . . . . .	2303

<b>Molecular Electronics: Models of Switchable and Programmable Devices</b> / <i>Pedro A. Derosa, Vandana R. Tarigopula, and Jorge M. Seminario</i> . . . . .	2317
<b>Molecular Manipulator: Dynamic Design Criteria</b> / <i>Andrés Jaramillo-Botero</i> . . . . .	2336
<b>Molecular Motor-Powered Nanodevices: Control Mechanisms</b> / <i>Jacob J. Schmidt and Carlo D. Montemagno</i> . . . . .	2347
<b>Molecular Orientation at Interfaces: Vibrational Spectroscopy</b> / <i>Zhan Chen</i> . . . . .	2357
<b>Molecular Probes of Cation–Arene Interactions</b> / <i>George W. Gokel</i> . . . . .	2369
<b>Molecular Receptor-Modified Metal Nanoparticles</b> / <i>Jian Liu</i> . . . . .	2377
<b>Molecular Self-Assembly: Environmental and Sensing Applications</b> / <i>Glen E. Fryxell, R. Shane Addleman, S. V. Mattigod, Yuehe Lin, T. S. Zemanian, H. Wu, Jerome C. Birnbaum, J. Liu, and X. Feng</i> . . . . .	2387
<b>Molecular Simulations of DNA Counterion Distributions</b> / <i>Alexander Lyubartsev</i> . . . . .	2398
<b>Molecular Switches</b> / <i>Jean-Pierre Launay, Christophe Coudret, and Christian Joachim</i> . . . . .	2411
<b>Molecular Switches and Motors</b> / <i>Richard A. van Delden and Ben L. Feringa</i> . . . . .	2424
<b>Molecular Wires</b> / <i>Dustin K. James and James M. Tour</i> . . . . .	2441
<b>Monolayer-Protected Metal Nanoparticles: Chemical Sensing and Gas Chromatography</b> / <i>Jay W. Grate, David A. Nelson, Rhonda Skaggs, Robert E. Synovec, and Gwen M. Gross</i> . . . . .	2460
<b>Monolayer-Protected Metal Nanoparticles: Synthesis</b> / <i>Young-Seok Shon</i> . . . . .	2469
<b>Moore’s Law: Performance and Power Dissipation</b> / <i>Laszlo B. Kish</i> . . . . .	2480
<b>Motor Proteins in Synthetic Materials and Devices</b> / <i>Henry Hess, George Bachand, and Viola Vogel</i> . . . . .	2484
<b>Nano–Mesoscopic Interface: Hybrid Devices</b> / <i>Gianfranco Cerofolini</i> . . . . .	2493
<b>Nanoarrays: Electrochemically Self-Assembled</b> / <i>S. Bandyopadhyay</i> . . . . .	2502
<b>Nanobiological Sensors</b> / <i>Nathaniel Cady, Anand Gadre, and Alain E. Kaloyeros</i> . . . . .	2514
<b>Nanobridges: Thermal Properties</b> / <i>Jeong Won Kang and Ho Jung Hwang</i> . . . . .	2522
<b>Nanoceramics</b> / <i>Abbas Khaleel</i> . . . . .	2531
<b>Nanoceramics: Thermal Conductivity</b> / <i>Paul G. Klemens</i> . . . . .	2539
<b>Nanocolloidal Gold Films: Self-Assembly</b> / <i>E. Stefan Kooij, E.A. Martijn Brouwer, Agnes A. Mewe, Herbert Wormeester, and Bene Poelsema</i> . . . . .	2545
<b>Nanocomposite Magnetic Materials: Shock-Induced Synthesis</b> / <i>N. N. Thadhani and Z. Q. Jin</i> . . . . .	2556
<b>Nanocrystal Arrays: Self-Assembly and Physical Properties</b> / <i>Xiao-Min Lin, Raghuv eer Parthasarathy, and Heinrich M. Jaeger</i> . . . . .	2568
<b>Nanocrystals Synthesized in Colloidal Self-Assemblies</b> / <i>M. P. Pileni</i> . . . . .	2581
<b>Nanocrystalline Magnesia and Alumina: Surface Chemistry</b> / <i>Richard M. Narske</i> . . . . .	2592
<b>Nanocrystalline Materials: Fatigue</b> / <i>Alexie Yu. Vinogradov and Sean R. Agnew</i> . . . . .	2602
<b>Nanocrystalline Materials: Synthesis and Properties</b> / <i>Alexandr I. Gusev</i> . . . . .	2621
<b>Nanocrystalline Oxides: Surfactant-Assisted Growth</b> / <i>Claudia L. Bianchi, Silvia Ardizzone, and Giuseppe Cappelletti</i> . . . . .	2637
<b>Nanocrystalline Zeolites</b> / <i>Vicki H. Grassian and Sarah C. Larsen</i> . . . . .	2646
<b>Nanocrystallization</b> / <i>John H. Perepezko</i> . . . . .	2655
<b>Nanocrystals: Size-Dependent Properties and Emerging Applications</b> / <i>G. U. Kulkarni, P. John Thomas, and C.N.R. Rao</i> . . . . .	2665
<b>Nanocrystals: Synthesis and Mesoscalar Organization</b> / <i>G. U. Kulkarni, P. John Thomas, and C.N.R. Rao</i> . . . . .	2676
<b>Nanodiamonds</b> / <i>Jean-Yves Raty and Giulia Galli</i> . . . . .	2697
<b>Nanoencapsulation of Bioactive Substances</b> / <i>Yury E. Shapiro</i> . . . . .	2707
<b>Nanofibers and Carbon Nanotubes: Novel Metal Catalyst Supports</b> / <i>Mark A. Keane</i> . . . . .	2723

<b>Nanofilms in Giant Magnetoresistance Heads</b> / Edward Grochowski and Robert E. Fontana, Jr. . . . .	2737
<b>Nanofiltration Separations</b> / Eric M.V. Hoek and Anna Jawor . . . . .	2749
<b>Nanofriction and Nanowear of Sliding Systems: Simulations</b> / W.C.D. Cheong . . . . .	2763
<b>Nanolithography: Length Scale Limitations</b> / Takashi Ito . . . . .	2779
<b>Nanomaterials: Advances in Technology and Industry</b> / Ganesh Skandan and Amit Singhal . . . . .	2788
<b>Nanomaterials: Manufacturing, Processing, and Applications</b> / Pramod K. Sharma, Weifang Miao, Anit Giri, and Srikanth Raghunathan . . . . .	2799
<b>Nanomaterials and Molecular Devices: De Novo Design Theory</b> / Kwang S. Kim, P. Tarakeshwar, and Han Myoung Lee . . . . .	2815
<b>Nanomaterials and Nanodevices: Ion-Beam Technology</b> / Dmitri Litvinov and Sakhrat Khizroev . . . . .	2825
<b>Nanomaterials: Trends</b> / Richard Silbergliitt . . . . .	2836
<b>Nanomechanical Resonant Devices: Surface Chemistry</b> / Joshua A. Henry, Debodhonyaa Sengupta, and Melissa A. Hines . . . . .	2848
<b>Nanoparticle Arrays: Optical and Electronic Applications</b> / Ilona Kretschmar and Mark A. Reed . . . . .	2856
<b>Nanoparticle Assemblies: Magnetic Properties</b> / Xiangcheng Sun . . . . .	2868
<b>Nanoparticle Suspensions: Phase Behavior</b> / Subramanian Ramakrishnan and Charles F. Zukoski . . . . .	2878
<b>Nanoparticle Synthesis: Biological Path</b> / Kenji Iwahori and Ichiro Yamashita . . . . .	2890
<b>Nanoparticles: Generation, Functionalization, and Ion Sensing</b> / Jason J. Davis and Paul D. Beer . . . . .	2898
<b>Nanoparticles: Synthesis in Polymer Substrates</b> / Bai Yang and Junhu Zhang . . . . .	2912

## Volume V

<b>Nanophase Powders: Mechanosynthesis</b> / F. Miani, F. Maurigh, and F. Delogu . . . . .	2923
<b>Nanoporosity Evolution on Dealloying</b> / Jonah Erlebacher . . . . .	2938
<b>Nanoporous Anodic Alumina: Structural and Optical Anisotropy</b> / E. Stefan Kooij, Aurelian C. Gâlcă, Herbert Wormeester, and Bene Poelsema . . . . .	2947
<b>Nanostructured Alloys: Cryomilling Synthesis and Behavior</b> / David Witkin, Piers Newbery, Bing Q. Han, and Enrique J. Lavernia . . . . .	2958
<b>Nanostructured Catalysts</b> / Ravichandra S. Mulukutla . . . . .	2967
<b>Nanostructured Catalysts: Design and Synthesis</b> / Hua Chun Zeng . . . . .	2974
<b>Nanostructured Composites: Carbon-Derived Fibers</b> / Peter M.A. Sherwood . . . . .	2986
<b>Nanostructured Composites: Titanium-Based Alloys</b> / Jürgen Eckert, Jayanta Das, and Ki Buem Kim . . . . .	2996
<b>Nanostructured Materials: Metals on Microtubule Supports</b> / Silke Behrens and Eberhard Unger . . . . .	3012
<b>Nanostructured Materials: Synthesis by Mechanical Attrition</b> / Carl C. Koch . . . . .	3019
<b>Nanostructured Materials: Synthesis by Mechanical Means</b> / H.-J. Fecht . . . . .	3030
<b>Nanostructured Materials: Synthesis in Supercritical Fluids</b> / Yuehe Lin, Xiang-Rong Ye, and Chien M. Wai . . . . .	3040
<b>Nanostructured Multilayers: Applications in X-Ray Optics</b> / Michael Störmer, Carsten Michaelsen, Jörg Wiesmann, Paulo Ricardo, and Rüdiger Bormann . . . . .	3052
<b>Nanostructured Silica and Silica-Derived Materials</b> / Ho-Cheol Kim and Geraud Dubois . . . . .	3063
<b>Nanostructured Ultrastrong Materials</b> / Nicholas A. Kotov, Arif A. Mamedov, Dirk M. Guldi, Zhiyong Tang, Maurizio Prato, James Wicksted, and Andreas Hirsch . . . . .	3072

<b>Nanostructures Based on Layered Transition-Metal Chalcogenides</b> / <i>Russell R. Chianelli and Myriam Perez de la Rosa</i> .....	3080
<b>Nanostructures Derived from Phase-Separated Polymers</b> / <i>Michael R. Bockstaller and Edwin L. Thomas</i> .....	3093
<b>Nanotube Sensors</b> / <i>Marc Wirtz and Charles R. Martin</i> .....	3109
<b>Nanotubes: Functionalization</b> / <i>Stanislaus S. Wong and Sarbajit Banerjee</i> .....	3119
<b>Nanowires: Molecular Assembly</b> / <i>Tomoyuki Akutagawa, Takayoshi Nakamura, and Jan Becher</i> .....	3136
<b>Nanowires and Nanobelts: Mechanical Properties</b> / <i>Zhong Lin Wang</i> .....	3146
<b>Near-Field Microscopy</b> / <i>Björn T. Rosner and Daniel W. van der Weide</i> .....	3159
<b>Near-Field Raman Spectroscopy</b> / <i>Eric Ayars</i> .....	3169
<b>Near-Field Raman Spectroscopy: Resolution Enhancement</b> / <i>Satoshi Kawata and Yasushi Inouye</i> .....	3177
<b>Near-Field Scanning Optical Microscopy: Chemical Imaging</b> / <i>Bogdan Dragnea</i> .....	3185
<b>Noble Metal Nanoparticles on Carbon Fibers</b> / <i>Dmitri A. Bulushev and Igor Yuranov</i> .....	3195
<b>Nonlinear Optical Materials from Self-Assembled Organic Films</b> / <i>Matthew Guzy, Richey M. Davis, Patrick J. Neyman, Charles Brands, J. R. Heflin, Harry W. Gibson, and Kevin E. Van Cott</i> .....	3206

## Volume VI

<b>Scanning Near-Field Photolithography</b> / Graham J. Leggett . . . . .	3709
<b>Scanning Probe Lithography: Polymeric and Biomolecular Nanostructures</b> / Stefan Zauscher . . . . .	3721
<b>Scanning Single-Electron Transistor Microscopy</b> / N. B. Zhitenev and T. A. Fulton . . . . .	3731
<b>Self-Assembled Monolayers: Adsorption and Desorption from Alkanethiols on Gold</b> / Pieter Stroeve . . . . .	3738
<b>Self-Assembled Monolayers: Chemical and Physical Modification under Vacuum</b> / Jessica Torres, Anthony J. Wagner, Christopher C. Perry, Glenn M. Wolfe, and D. Howard Fairbrother . . . . .	3747
<b>Self-Assembled Monolayers: Surface Nanostructure Effect on Wetting</b> / Jun Yang, Jingmin Han, Kelvin Isaacson, and Daniel Y. Kwok . . . . .	3762
<b>Self-Assembled Quantum Dots: Atomic Scale Engineering</b> / S. Oktyabrsky and Alain E. Kaloyeros . . . . .	3775
<b>Self-Assembled Quantum Dots: Electronic Structures and Optical Properties</b> / Andrew Williamson . . . . .	3789
<b>Self-Assembled Silane Monolayers: Cyano-to-Carboxylic Termination Conversion</b> / Chandra Sekhar Palla and Alexander Couzis . . . . .	3801
<b>Self-Assembled Structures</b> / Anna Cristina Samia and Xiao-Min Lin . . . . .	3816
<b>Self-Assembled Thin Films: Optical Characterization</b> / Herbert Wormeester, E. Stefan Kooij, and Bene Poelsema . . . . .	3829

<b>Self-Assembly and Chirality of Molecules at Interfaces</b> / <i>Dalia G. Yablon</i> . . . . .	3840
<b>Self-Assembly of Coordination Cages</b> / <i>Laura Pironcini and Enrico Dalcanale</i> . . . . .	3848
<b>Self-Assembly Directed by NH-O Hydrogen Bonding</b> / <i>Katrina A. Jolliffe and Leonard F. Lindoy</i> . . . . .	3864
<b>Self-Formed Quantum Dots: Structural and Optical Characterization</b> / <i>Shun-ichi Gonda and Hajime Asahi</i> . . . . .	3877
<b>Self-Organized Superstructures: Molecular Design</b> / <i>Makoto Tadokoro</i> . . . . .	3886
<b>Semiconductor Nanowires: Macroelectronics Applications</b> / <i>Yugang Sun and John A. Rogers</i> . . . . .	3896
<b>Semiconductor Nanowires: Nanoscale Electronics and Optoelectronics</b> / <i>Yu Huang, Xiangfeng Duan, and Charles M. Lieber</i> . . . . .	3910
<b>Semiconductor Nanowires: Rational Synthesis</b> / <i>Xiangfeng Duan and Charles M. Lieber</i> . . . . .	3941
<b>Semiconductor Quantum Dots: Atomic Ordering over Time</b> / <i>Peter Moeck</i> . . . . .	3954
<b>Semiconductor Quantum Dots: Site-Controlled Self-Organization</b> / <i>S. Kohmoto, H. Nakamura, S. Nishikawa, T. Yang, and K. Asakawa</i> . . . . .	3965
<b>Sensors Based on Chemicurrents</b> / <i>B. Roldan Cuenya and E. W. McFarland</i> . . . . .	3973
<b>Silane Self-Assembled Monolayers: Nanoscale Domains by Sequential Adsorption</b> / <i>Nitin Kumar</i> . . . . .	3984
<b>Silica Nanotubes: Wetting and Diffusion</b> / <i>Kenji Okamoto, Karthik Jayaraman, Sang Jun Son, Sang Bok Lee, and Douglas S. English</i> . . . . .	3995
<b>Silica Surfaces Functionalization</b> / <i>V. A. Tertykh</i> . . . . .	4001
<b>Silicon Functionalization for Molecular Electronics</b> / <i>Gianfranco Cerofolini, Dario Narducci, and Elisabetta Romano</i> . . . . .	4009
<b>Silicon Nanoclusters: Simulations</b> / <i>Aaron Puzder</i> . . . . .	4021
<b>Silicon Nanocrystals: Quantum Confinement</b> / <i>James R. Chelikowsky</i> . . . . .	4033
<b>Single-Cell Level Mass Spectrometric Imaging</b> / <i>Sara G. Ostrowski, Andrew G. Ewing, and Nicholas Winograd</i> . . . . .	4046
<b>Single Molecule Spectroscopy for Nanomaterials Characterization</b> / <i>Daniel A. Higgins and Yanwen Hou</i> . . . . .	4057
<b>Single-Walled Carbon Nanotubes: Field Emission Properties</b> / <i>Xiaofeng F. Duan, Brahim Akdim, and Ruth Pachter</i> . . . . .	4078
<b>Single-Walled Carbon Nanotubes: Geometries, Electronic Properties, and Actuation</b> / <i>Guangyu Sun, Marc Nicklaus, and Miklos Kertesz</i> . . . . .	4085
<b>Single-Walled Carbon Nanotubes: Separation Using Capillary Electrophoresis</b> / <i>Stephen K. Doorn</i> . . . . .	4096
<b>Single-Walled Carbon Nanotubes: Structures and Symmetries</b> / <i>Carter T. White and John W. Mintmire</i> . . . . .	4108
<b>Small Amplitude AFM</b> / <i>Peter M. Hoffmann</i> . . . . .	4119
<b>Smallest Size Regime: Control of Ultrafast Dynamics</b> / <i>Stefan Vajda and Ludger Wöste</i> . . . . .	4132
<b>Smart Nanotubes for Biotechnology and Biocatalysis</b> / <i>Charles R. Martin and Punit Kohli</i> . . . . .	4147
<b>Soft Materials: AFM Investigations and Nanophysics</b> / <i>J. P. Aimé, R. Boisgard, S. Marsaudon, and G. Couturier</i> . . . . .	4158
<b>Stability of Nanostructures on Surfaces</b> / <i>Karsten Pohl</i> . . . . .	4167
<b>STEM of Chiral Pair Self-Assembled Monolayers</b> / <i>Yuguang Cai and Steven L. Bernasek</i> . . . . .	4176
<b>STEM: Self-Assembly on Graphite</b> / <i>Thomas Müller</i> . . . . .	4185
<b>Structural Color</b> / <i>Pete Vukusic</i> . . . . .	4195
<b>Structural Nanomaterials</b> / <i>Joanna R. Groza and Jeffrey C. Gibeling</i> . . . . .	4205
<b>Structural Transitions in Thin Films</b> / <i>Rajarshi Banerjee, Gregory B. Thompson, and Hamish L. Fraser</i> . . . . .	4217
<b>Superconductor Nanowires: Templated by Single Molecules</b> / <i>Alexey Bezryadin, Anthony Bollinger, David Hopkins, Michael Murphey, Mikas Remeika, and Andrey Rogachev</i> . . . . .	4228

<b>Supramolecular Networks Synthesized in Nanoparticle–Polymer Mixtures</b> / <i>Anna C. Balazs and Gavin A. Buxton</i> . . . . .	4240
<b>Surface-Enhanced Raman Scattering</b> / <i>Adam M. Schwartzberg and Jin Z. Zhang</i> . . . . .	4250
<b>Surface Forces on Nanoparticles Determined by Direct Measurement</b> / <i>Jeong-Min Cho, Georgios Pyrgiotakis, and Wolfgang M. Sigmund</i> . . . . .	4260
<b>Surface Plasmon Spectra of Silver and Gold Nanoparticle Assemblies</b> / <i>Mondona Zangeneh and Roger Terrill</i> . . . . .	4271
<b>Template-Directed Assembly of Dinuclear Triple-Stranded Helicates</b> / <i>Markus Albrecht</i> . . . . .	4283
<b>Templating Aerogels for Tunable Nanoporosity</b> / <i>Aydin K. Sunol and Sermin G. Sunol</i> . . . . .	4294
<b>Templating Polymer Crystal Growth Using Block Copolymers</b> / <i>Yueh-Lin Loo</i> . . . . .	4303
<b>Thermal Effect on the Luminescence Properties of Quantum Dots</b> / <i>X. B. Zhang and R. D. Dupuis</i> . . . . .	4316
<b>Thermodynamics at the Meso- and Nanoscale</b> / <i>Mikhail A. Anisimov</i> . . . . .	4326
<b>Three-Dimensional Nanofabrication Using Multiphoton Absorption</b> / <i>John T. Fourkas and Tommaso Baldacchini</i> . . . . .	4338
<b>Titania Coatings on Stainless Steel</b> / <i>Ganesh Balasubramanian, Dionysios D. Dionysiou, and Makram T. Suidan</i> . . . . .	4348
<b>Titania Nanoparticles: Photocatalytic Properties</b> / <i>Scott Buzby and S. Ismat Shah</i> . . . . .	4356
<b>Toxicological Effects and Screening of Engineered Nanoparticles</b> / <i>Paul Borm and Ken Donaldson</i> . . . . .	4363
<b>Tribology of Inorganic Nanoparticles</b> / <i>Lev Rapoport</i> . . . . .	4375
<b>Tribology at the Nanoscale</b> / <i>Peter T. Cummings and Clare McCabe</i> . . . . .	4385
<b>Tungsten Carbide–Cobalt Nanocomposites</b> / <i>Purnesh Seegopaul and Zhigang Zak Fang</i> . . . . .	4390
<b>Ultrathin Polymer Films: Nanoparticle Nucleation</b> / <i>Pieter Stroeve</i> . . . . .	4400
<b>Virus Nanoparticles: Adsorption and Organization on Substrates</b> / <i>Jiyu Fang</i> . . . . .	4407
<b>Yttria-Tetragonally Stabilized Zirconia</b> / <i>R. Allen Kimel</i> . . . . .	4414
<b>Zeolite Membranes</b> / <i>Wei Xing, João C. Diniz da Costa, Gao Qing (Max) Lu, and Z. F. Yan</i> . . . . .	4421

# Topical Table of Contents

---

## Analytical Methods and Characterization Techniques

---

### *Atomic Force Microscopy*

<b>AFM: Biopolymers</b> / Nehal I. Abu-Lail and Terri A. Camesano . . . . .	63
<b>AFM: Hydrogen-Bonded Nanostructures</b> / Holger Schönherr, Mercedes Crego-Calama, G. Julius Vancso, and David N. Reinhoudt . . . . .	76
<b>AFM: Imaging and Force Spectroscopy on Cell Surfaces</b> / Yves F. Dufrêne . . . . .	99
<b>AFM: Imaging Artifacts</b> / Stephanie Butler Velegol . . . . .	88
<b>AFM: Metal Ion Sorption</b> / Viriya Vithayaveroj, Sotira Yiacoumi, and Costas Tsouris . . . . .	109
<b>AFM: Nanolithography on Organized Films</b> / Seunghyun Lee and Haiwon Lee . . . . .	119
<b>AFM: Protein Adsorption</b> / David T. Kim, Harvey W. Blanch, and Clayton J. Radke . . . . .	129
<b>AFM: Simulation of Interaction Forces</b> / Ivan U. Vakarelski, Scott C. Brown, Bahar Basim, and Brij M. Moudgil . . . . .	153
<b>Biomaterials: Mechanical Characterization</b> / Eunice Phay Shing Tan and Chwee Teck Lim . . . . .	317
<b>Dip-Pen Nanolithography: Applications and Functional Extensions</b> / Björn T. Rosner and Linette M. Demers . . . . .	1070
<b>Dynamic AFM on Heterogeneous Surfaces</b> / Ijeoma M. Nnebe and James W. Schneider . . . . .	1144
<b>Liposomes: Direct Force Measurement by AFM</b> / Guangzhao Mao, Xuemei Liang, and K.Y. Simon Ng . . . . .	1869
<b>Mica Surfaces: Charge Nucleation and Wear</b> / James M. Helt and James D. Batteas . . . . .	2211
<b>Self-Formed Quantum Dots: Structural and Optical Characterization</b> / Shun-ichi Gonda and Hajime Asahi . . . . .	3877
<b>Small Amplitude AFM</b> / Peter M. Hoffmann . . . . .	4119
<b>Soft Materials: AFM Investigations and Nanophysics</b> / J. P. Aimé, R. Boisgard, S. Marsaudon, and G. Couturier . . . . .	4158
<b>Surface Forces on Nanoparticles Determined by Direct Measurement</b> / Jeong-Min Cho, Georgios Pyrgiotakis, and Wolfgang M. Sigmund . . . . .	4260

---

### *Electron Microscopy*

<b>Aberration-Corrected Z-Contrast STEM: Semiconducting Nanocrystals</b> / James R. McBride, Andrew R. Lupini, Stephen J. Pennycook, and Sandra J. Rosenthal . . . . .	1
<b>Catalysts by Nanoscale Design</b> / Chaitanya Kumar Narula . . . . .	772
<b>Controlled Size and Shape Supramolecular Aggregates on Solid Surfaces</b> / Takashi Yokoyama, Toshiya Kamikado, Shiyoshi Yokoyama, and Shinro Mashiko . . . . .	974
<b>Electron Microscopy at Very High Resolution</b> / Klaus van Benthem and Stephen J. Pennycook . . . . .	1217

---

**Analytical Methods and Characterization Techniques (*cont'd.*)**

---

**Electron Microscopy (*cont'd.*)**

<b>Environmental Electron Microscopy Imaging</b> / Satoshi Utsunomiya, Christopher S. Palenik, and Rodney C. Ewing	1252
<b>Heterogeneous Catalysts: Atomic Scale Studies</b> / Robert F. Klie, Kai Sun, Mark M. Disko, Jingyue Liu, and Nigel D. Browning	1491
<b>In-Situ Electron Microscopy</b> / Charles W. Allen	1568
<b>Molecular Switches</b> / Jean-Pierre Launay, Christophe Coudret, and Christian Joachim	2411
<b>Nanoparticle Assemblies: Magnetic Properties</b> / Xiangcheng Sun	2868
<b>Nanostructures Based on Layered Transition-Metal Chalcogenides</b> / Russell R. Chianelli and Myriam Perez de la Rosa	3080
<b>Nanowires: Molecular Assembly</b> / Tomoyuki Akutagawa, Takayoshi Nakamura, and Jan Becher	3136
<b>Polymer Nanowires Conjugated by Controlled Chain Polymerization</b> / Yuji Okawa and Masakazu Aono	3501
<b>Scanning Single-Electron Transistor Microscopy</b> / N. B. Zhitenev and T. A. Fulton	3731
<b>Semiconductor Quantum Dots: Atomic Ordering over Time</b> / Peter Moeck	3954
<b>Semiconductor Quantum Dots: Site-Controlled Self-Organization</b> / S. Kohmoto, H. Nakamura, S. Nishikawa, T. Yang, and K. Asakawa	3965
<b>Stability of Nanostructures on Surfaces</b> / Karsten Pohl	4167
<b>STEM of Chiral Pair Self-Assembled Monolayers</b> / Yuguang Cai and Steven L. Bernasek	4176
<b>STEM: Self-Assembly on Graphite</b> / Thomas Müller	4185

---

**Mass Spectrometry**

<b>Fluorofullerenes</b> / Olga V. Boltalina and Steven H. Strauss	1307
<b>Heterogeneous Catalytic Reactions by Mass Spectrometry</b> / Steven M. Thornberg and Deborah E. Hunka	1505
<b>Single-Cell Level Mass Spectrometric Imaging</b> / Sara G. Ostrowski, Andrew G. Ewing, and Nicholas Winograd	4046

---

**Near-Field Microscopy Techniques**

<b>Near-Field Microscopy</b> / Björn T. Rosner and Daniel W. van der Weide	3159
<b>Near-Field Raman Spectroscopy</b> / Eric Ayars	3169
<b>Near-Field Raman Spectroscopy: Resolution Enhancement</b> / Satoshi Kawata and Yasushi Inouye	3177
<b>Near-Field Scanning Optical Microscopy: Chemical Imaging</b> / Bogdan Dragnea	3185
<b>Scanning Near-Field Photolithography</b> / Graham J. Leggett	3709

---

**Optical Characterization Methods**

<b>Barcoded Nanowires</b> / Rebecca L. Stoermer and Christine D. Keating	259
<b>Nanoporous Anodic Alumina: Structural and Optical Anisotropy</b> / E. Stefan Kooij, Aurelian C. Gâlcă, Herbert Wormeester, and Bene Poelsema	2947
<b>Self-Assembled Silane Monolayers: Cyano-to-Carboxylic Termination Conversion</b> / Chandra Sekhar Palla and Alexander Couzis	3801
<b>Self-Assembled Thin Films: Optical Characterization</b> / Herbert Wormeester, E. Stefan Kooij, and Bene Poelsema	3829
<b>Smallest Size Regime: Control of Ultrafast Dynamics</b> / Stefan Vajda and Ludger Wöste	4132

<b>Structural Color</b> / <i>Pete Vukusic</i> . . . . .	4195
<b>Surface Plasmon Spectra of Silver and Gold Nanoparticle Assemblies</b> / <i>Mondona Zangeneh and Roger Terrill</i> . . . . .	4271

### **Other Techniques**

<b>Colloidal Nanoparticles: Electrokinetic Characterization</b> / <i>Kunio Furusawa and Hideo Matsumura</i> . . . . .	893
<b>Fluorescence-Voltage Single Molecule Spectroscopy</b> / <i>Young Jong Lee, Andre J. Gesquiere, So-Jung Park, and Paul F. Barbara</i> . . . . .	1300
<b>Fullerenes: Isomer Identification</b> / <i>Guangyu Sun</i> . . . . .	1340
<b>Single Molecule Spectroscopy for Nanomaterials Characterization</b> / <i>Daniel A. Higgins and Yanwen Hou</i> . . . . .	4057
<b>Single-Walled Carbon Nanotubes: Separation Using Capillary Electrophoresis</b> / <i>Stephen K. Doorn</i> . . . . .	4096

### **Vibrational Spectroscopy**

<b>Infrared Spectroscopy: Biomolecular Structure at Interfaces</b> / <i>Curtis W. Meuse</i> . . . . .	1590
<b>Molecular Orientation at Interfaces: Vibrational Spectroscopy</b> / <i>Zhan Chen</i> . . . . .	2357
<b>Raman Spectroscopy of Carbon Nanotube–Polymer Composites</b> / <i>Bin Chen</i> . . . . .	3682
<b>Surface-Enhanced Raman Scattering</b> / <i>Adam M. Schwartzberg and Jin Z. Zhang</i> . . . . .	4250

### **X-Ray Spectroscopy Techniques**

<b>Biomedical Magnetic Nanoparticles</b> / <i>Ian Robinson, Le Duc Tung, and Nguyen T.K. Thanh</i> . . . . .	354
<b>Catalyst Nanostructures: X-Ray Absorption</b> / <i>Jeffrey T. Miller, M. K. Neylon, C. L. Marshall, and Arthur Jerome Kropf</i> . . . . .	753
<b>Nanostructured Composites: Carbon-Derived Fibers</b> / <i>Peter M.A. Sherwood</i> . . . . .	2986
<b>Nanostructured Multilayers: Applications in X-Ray Optics</b> / <i>Michael Störmer, Carsten Michaelsen, Jörg Wiesmann, Paulo Ricardo, and Rüdiger Bormann</i> . . . . .	3052
<b>Self-Assembled Monolayers: Chemical and Physical Modification under Vacuum</b> / <i>Jessica Torres, Anthony J. Wagner, Christopher C. Perry, Glenn M. Wolfe, and D. Howard Fairbrother</i> . . . . .	3747

## **Bionanotechnology and Biomedical Nanotechnology**

### **Adsorption, Adhesion, and Binding at Interfaces**

<b>Adhesion: Cell on a Substrate</b> / <i>Frédéric Pincet</i> . . . . .	22
<b>AFM: Biopolymers</b> / <i>Nehal I. Abu-Lail and Terri A. Camesano</i> . . . . .	63
<b>AFM: Imaging Artifacts</b> / <i>Stephanie Butler Velegol</i> . . . . .	88
<b>AFM: Protein Adsorption</b> / <i>David T. Kim, Harvey W. Blanch, and Clayton J. Radke</i> . . . . .	129
<b>Bio-Microarrays</b> / <i>Günter E.M. Tovar and Achim Weber</i> . . . . .	298
<b>Biosurfaces: Water Structure at Interfaces</b> / <i>Yan-Yeung Luk</i> . . . . .	453
<b>Electrochemical Sensors: Functionalized Silica</b> / <i>Yuehe Lin, Wassana Yantasee, and Glen E. Fryxell</i> . . . . .	1196
<b>Halide Transport through Biological Membranes</b> / <i>Lars-Oliver Essen</i> . . . . .	1476
<b>Infrared Spectroscopy: Biomolecular Structure at Interfaces</b> / <i>Curtis W. Meuse</i> . . . . .	1590
<b>Liposomes: Direct Force Measurement by AFM</b> / <i>Guangzhao Mao, Xuemei Liang, and K.Y. Simon Ng</i> . . . . .	1869
<b>Liquid Crystals and Nanostructured Surfaces: Detecting Protein Binding</b> / <i>Yan-Yeung Luk</i> . . . . .	1878

---

## Bionanotechnology and Biomedical Nanotechnology (*cont'd.*)

---

### *Adsorption, Adhesion, and Binding at Interfaces (cont'd.)*

<b>Protein Adsorption Kinetics under an Applied Electric Field</b> / Paul R. Van Tassel . . . . .	3569
<b>Proteins: Structure and Interaction Patterns to Solid Surfaces</b> / Thomas J. Webster . . . . .	3590
<b>Virus Nanoparticles: Adsorption and Organization on Substrates</b> / Jiyu Fang . . . . .	4407

---

### *Biomimetic Devices and Sensors*

<b>Biomimetic Receptors for Carboxylate Recognition</b> / Rocco Ungaro, Alessandro Casnati, and Francesco Sansone . . . . .	372
<b>Biosensor Applications: Porous Silicon Microcavities</b> / Benjamin L. Miller, Philippe M. Fauchet, Scott R. Horner, and Selena Chan . . . . .	408
<b>Biosensor Applications: Surface Engineering</b> / Genady Zhavnerko and Kwon-Soo Ha . . . . .	416
<b>Biosensors Based on Carbon Nanotubes</b> / Yuehe Lin, Wassana Yantasee, Fang Lu, Joseph Wang, Mustafa Musameh, Yi Tu, and Zhifeng Ren . . . . .	428
<b>Biosensors: Fractal Analysis of Binding Kinetics</b> / Harshala Butala and Ajit Sadana . . . . .	441
<b>Motor Proteins in Synthetic Materials and Devices</b> / Henry Hess, George Bachand, and Viola Vogel . . . . .	2484
<b>Nanobiological Sensors</b> / Nathaniel Cady, Anand Gadre, and Alain E. Kaloyeros . . . . .	2514
<b>Nanoparticle Synthesis: Biological Path</b> / Kenji Iwahori and Ichiro Yamashita . . . . .	2890
<b>Nucleoside- and Nucleobase-Substituted Oligopyrrolic Macrocycles</b> / Vladimír Král, Martin Valík, Tatiana V. Shishkanova, and Jonathan L. Sessler . . . . .	3216
<b>Optical Nanosensors and Nanobiosensors</b> / Brian M. Cullum . . . . .	3258

---

### *Biomolecular Substrates*

<b>Biocatalytic Single-Enzyme Nanoparticles</b> / Jay W. Grate and Jungbae Kim . . . . .	307
<b>Bionanoparticles</b> / Krishnaswami S. Raja, Sukanta Dolai, Wei Shi, and Qian Wang . . . . .	386
<b>Nanostructured Materials: Metals on Microtubule Supports</b> / Silke Behrens and Eberhard Unger . . . . .	3012
<b>Nanostructured Silica and Silica-Derived Materials</b> / Ho-Cheol Kim and Geraud Dubois . . . . .	3063
<b>Scanning Probe Lithography: Polymeric and Biomolecular Nanostructures</b> / Stefan Zauscher . . . . .	3721
<b>Single-Cell Level Mass Spectrometric Imaging</b> / Sara G. Ostrowski, Andrew G. Ewing, and Nicholas Winograd . . . . .	4046
<b>Smart Nanotubes for Biotechnology and Biocatalysis</b> / Charles R. Martin and Punit Kohli . . . . .	4147

---

### *DNA-Based Technologies*

<b>DNA Hybridization: Electronic Control</b> / Kimberly Hamad-Schifferli . . . . .	1122
<b>DNA-Conjugated Metal Nanoparticles: Chip Detection Applications</b> / Wolfgang Fritzsche . . . . .	1114
<b>Electrochemical Toxicity Sensors</b> / James F. Rusling . . . . .	1207
<b>Gold Nanoclusters: Structural Disorder</b> / Ignacio L. Garzón . . . . .	1412
<b>Molecular Computing Machines</b> / Yaakov Benenson and Ehud Shapiro . . . . .	2291

---

### *Drug and Gene Delivery*

<b>Biomedical Magnetic Nanoparticles</b> / Ian Robinson, Le Duc Tung, and Nguyen T.K. Thanh . . . . .	354
<b>Capsules: Specific Layer Structures</b> / Lars Dähne and Claire S. Peyratout . . . . .	522
<b>Gene Delivery via Polymer Nanoparticles</b> / Jie Wen and Kam W. Leong . . . . .	1394
<b>Ligand-Receptor Systems with Infinite Binding Affinity</b> / Claude F. Meares . . . . .	1853

<b>Lipid Membranes: Nanostructure and Dynamic Organization</b> / <i>J. Gaudioso and D. Y. Sasaki</i> . . . . .	1859
<b>Luminescence of Nanoparticle-Labeled Antibodies and Antigens</b> / <i>Shaopeng Wang and Nicholas A. Kotov</i> . . . . .	1915
<b>Nanoencapsulation of Bioactive Substances</b> / <i>Yury E. Shapiro</i> . . . . .	2707
<b>Polyelectrolyte–Surfactant Complex Nanoparticles</b> / <i>Hans-Peter Hentze</i> . . . . .	3403

### ***Environmental and Health Implications***

<b>Atmospheric Nanoparticles: Formation and Physicochemical Properties</b> / <i>James N. Smith</i> . . . . .	228
<b>Biological and Chemical Decontamination</b> / <i>Peter K. Stoimenov and Kenneth J. Klabunde</i> . . . . .	312
<b>Bioremediation of Environmental Contaminants</b> / <i>Xiomara C. Kretschmer and Russell R. Chianelli</i> . . . . .	397
<b>Chemical Warfare Agents: Biosensors for Detection</b> / <i>Elias Greenbaum, Miguel Rodriguez, Jr., and Charlene A. Sanders</i> . . . . .	842
<b>Electrochemical Toxicity Sensors</b> / <i>James F. Rusling</i> . . . . .	1207
<b>Environmental Nanoparticles</b> / <i>Alexandra Navrotsky</i> . . . . .	1262
<b>Nanomaterials: Manufacturing, Processing, and Applications</b> / <i>Pramod K. Sharma, Weifang Miao, Anit Giri, and Srikanth Raghunathan</i> . . . . .	2799
<b>Toxicological Effects and Screening of Engineered Nanoparticles</b> / <i>Paul Borm and Ken Donaldson</i> . . . . .	4363

### ***Supramolecular Chemistry***

<b>Biomimetic Design of Self-Assembling Systems</b> / <i>Mila Boncheva and George M. Whitesides</i> . . . . .	364
<b>Cyclic Peptides: Self-Assembly in Hydrogen-Bonded Nanotubes</b> / <i>Roberto J. Brea and Juan R. Granja</i> . . . . .	1037
<b>Hierarchically Imprinted Nanostructures for Separation</b> / <i>Sheng Dai, Zongtao Zhang, and Chengdu Liang</i> . . . . .	1525
<b>Nanomaterials: Trends</b> / <i>Richard Silbergliitt</i> . . . . .	2836
<b>Phase Transfer of Monosaccharides through Noncovalent Interactions</b> / <i>Elizabeth K. Auty and Anthony P. Davis</i> . . . . .	3347
<b>Protein Nanotubes as Building Blocks</b> / <i>Hiroshi Matsui</i> . . . . .	3578

### ***Tissue Engineering***

<b>Biomaterials: Mechanical Characterization</b> / <i>Eunice Phay Shing Tan and Chwee Teck Lim</i> . . . . .	317
<b>Biomedical Applications: Implants</b> / <i>Jeremiah Ejiofor and Thomas J. Webster</i> . . . . .	327
<b>Biomedical Applications: Novel Materials and Devices</b> / <i>J. Zachary Hilt and Mark E. Byrne</i> . . . . .	339
<b>Layer-by-Layer Electrostatic Self-Assembly</b> / <i>Michael J. McShane and Yuri M. Lvov</i> . . . . .	1823

## **Catalysts and Catalytic Properties at the Nanoscale**

### ***Metal Clusters and Nanoparticles on Supports***

<b>Catalysis by Supported Gold Nanoclusters</b> / <i>D. Wayne Goodman</i> . . . . .	744
<b>Catalyst Nanostructures: X-Ray Absorption</b> / <i>Jeffrey T. Miller, M. K. Neylon, C. L. Marshall, and Arthur Jerome Kropf</i> . . . . .	753
<b>Catalysts by Nanoscale Design</b> / <i>Chaitanya Kumar Narula</i> . . . . .	772
<b>Catalytic Processes: Nanoscale Simulations</b> / <i>Vladimir I. Elokhin and Aleksandr V. Myshlyavtsev</i> . . . . .	782

---

**Catalysts and Catalytic Properties at the Nanoscale (cont'd.)**

---

**Metal Clusters and Nanoparticles on Supports (cont'd.)**

<b>Colloidal Nanometals as Fuel Cell Catalyst Precursors</b> / Helmut Bönnemann and K. S. Nagabhushana .....	863
<b>Dendritic Nanocatalysts</b> / Kiyotomi Kaneda, Masahiko Ooe, Makoto Murata, Tomoo Mizugaki, and Kohki Ebitani .....	1054
<b>Gold Nanoparticles on Titania: Activation and Behavior</b> / Jose A. Rodriguez .....	1422
<b>Heterogeneous Catalysts: Atomic Scale Studies</b> / Robert F. Klie, Kai Sun, Mark M. Disko, Jingyue Liu, and Nigel D. Browning .....	1491
<b>Metal Clusters on Oxides</b> / Ivan Stensgaard .....	2044
<b>Metal Nanoparticle Catalysts</b> / Naoki Toshima .....	2052
<b>Nanofibers and Carbon Nanotubes: Novel Metal Catalyst Supports</b> / Mark A. Keane .....	2723
<b>Noble Metal Nanoparticles on Carbon Fibers</b> / Dmitri A. Bulushev and Igor Yuranov .....	3195
<b>Palladium Nanoclusters</b> / Kiyotomi Kaneda, Kwang-Min Choi, Tomoo Mizugaki, and Kohki Ebitani .....	3309
<b>Platinum Nanoparticles: Synthesis and Catalytic Properties</b> / Ioan Balint and Akane Miyazaki .....	3386

---

**Molecular Sieves and Mesoporous Materials**

<b>Basic Nanostructured Catalysts</b> / Robert J. Davis .....	278
<b>Heterogeneous Catalytic Reactions by Mass Spectrometry</b> / Steven M. Thornberg and Deborah E. Hunka .....	1505
<b>Mesoporous Materials</b> / James C. Vartuli, Wielsaw J. Roth, and Thomas F. Degnan, Jr. ....	2029
<b>Micro- and Mesoporous Nanomaterials: Catalytic Properties</b> / Johannes A. Lercher and Andreas Jentys .....	2229
<b>Nanocrystalline Zeolites</b> / Vicki H. Grassian and Sarah C. Larsen .....	2646
<b>Zeolite Membranes</b> / Wei Xing, João C. Diniz da Costa, Gao Qing (Max) Lu, and Z. F. Yan .....	4421

---

**Nanotechnology Methods for Catalyst Synthesis**

<b>Biocatalytic Single-Enzyme Nanoparticles</b> / Jay W. Grate and Jungbae Kim .....	307
<b>Enzymatic Synthesis of Nanostructured Polymers and Composites</b> / Christy Ford, Vijay T. John, Gary McPherson, Jibao He, Joseph Akkara, David Kaplan, and Arijit Bose .....	1271
<b>Layer-by-Layer Assembly of Polyelectrolyte Films: Membranes and Catalysts</b> / Bernd Tieke and Ali Toutianoush .....	1784
<b>Mixed Metal Oxide Nanoparticles</b> / Pramesh N. Kapoor, Ajay Kumar Bhagi, Ravichandra S. Mulukutla, and Kenneth J. Klabunde .....	2280
<b>Nanocrystalline Oxides: Surfactant-Assisted Growth</b> / Claudia L. Bianchi, Silvia Ardizzone, and Giuseppe Cappelletti .....	2637
<b>Nanostructured Catalysts</b> / Ravichandra S. Mulukutla .....	2967
<b>Nanostructured Catalysts: Design and Synthesis</b> / Hua Chun Zeng .....	2974
<b>Polymer-Mediated Self-Assembly of Nanoparticles</b> / Tyler B. Norsten, Amitav Sanyal, Roy Shenhar, and Vincent M. Rotello .....	3443
<b>Polymer-Nanoparticle Composites</b> / Kevin Sill, Seunghoo Yoo, and Todd Emrick .....	3487
<b>Titania Coatings on Stainless Steel</b> / Ganesh Balasubramanian, Dionysios D. Dionysiou, and Makram T. Suidan .....	4348

<b>Titania Nanoparticles: Photocatalytic Properties</b> / Scott Buzby and S. Ismat Shah .....	4356
--------------------------------------------------------------------------------------------------	------

## Colloidal Phenomena

### *Adsorption, Adhesion, Surface Interactions*

<b>Aerosol Nanoparticles: Coagulation Theory</b> / Ken Won Lee and Soon-Bark Kwon .....	53
<b>AFM: Metal Ion Sorption</b> / Viriya Vithayaveroj, Sotira Yiacoymi, and Costas Tsouris .....	109
<b>AFM: Simulation of Interaction Forces</b> / Ivan U. Vakarelski, Scott C. Brown, Bahar Basim, and Brij M. Moudgil .....	153
<b>Colloidal Nanoparticles: Aggregation Patterns at Surfaces</b> / Hamidou Haidara and Karine Mougín .....	882
<b>Colloidal Structures on Patterned Surfaces</b> / Aránzazu del Campo, Anne-Sophie Duwez, Charles-André Fustin, and Ulrich Jonas .....	907
<b>Heterogeneous Surfaces with Nanosized Channel Lattices</b> / Lifeng Chi, Michael Gleiche, Steven Lenhert, and Nan Lu .....	1515
<b>Ionic Strength Effects: Tunable Nanocrystal Distribution in Colloidal Gold Films</b> / E. Stefan Kooij, E.A. Martijn Brouwer, Herbert Wormeester, and Bene Poelsema .....	1672
<b>Nanocolloidal Gold Films: Self-Assembly</b> / E. Stefan Kooij, E.A. Martijn Brouwer, Agnes A. Mewe, Herbert Wormeester, and Bene Poelsema .....	2545
<b>Protein Adsorption Kinetics under an Applied Electric Field</b> / Paul R. Van Tassel .....	3569
<b>Self-Assembled Monolayers: Surface Nanostructure Effect on Wetting</b> / Jun Yang, Jingmin Han, Kelvin Isaacson, and Daniel Y. Kwok .....	3762
<b>Surface Forces on Nanoparticles Determined by Direct Measurement</b> / Jeong-Min Cho, Georgios Pyrgiotakis, and Wolfgang M. Sigmund .....	4260
<b>Yttria-Tetragonally Stabilized Zirconia</b> / R. Allen Kimel .....	4414

### *Electrically Charged Particles*

<b>Carbon Nanotubes: Flow Control in Membranes</b> / Scott A. Miller and Charles R. Martin .....	630
<b>Colloidal Nanoparticles: Electrokinetic Characterization</b> / Kunio Furusawa and Hideo Matsumura .....	893
<b>DNA Interactions with Functionalized Emulsions</b> / Thierry Delair .....	1134
<b>Electrical Double-Layer Formation</b> / Kun-Lin Yang, Sotira Yiacoymi, and Costas Tsouris .....	1157
<b>Electrically Functional Nanostructures</b> / Orlin D. Velev and Simon O. Lumsdon .....	1171
<b>Electrochemical Langmuir Trough</b> / Natalia Varaksa, Thomas F. Magnera, and Josef Michl ...	1189
<b>Hierarchically Imprinted Nanostructures for Separation</b> / Sheng Dai, Zongtao Zhang, and Chengdu Liang .....	1525
<b>Hydrogel Nanoparticles Made of Cross-Linked Polyvinylpyrrolidone</b> / Susmita Mitra, Dhruba Jyoti Bharali, and Amarnath Maitra .....	1546
<b>Mineral Nanoparticles: Electrokinetics</b> / Mehmet S. Celik and Bahri Ersoy .....	2266
<b>Molecular Simulations of DNA Counterion Distributions</b> / Alexander Lyubartsev .....	2398
<b>Polyion Complex Micelles</b> / Atsushi Harada and Kazunori Kataoka .....	3409
<b>Polymer Colloids and Their Metallation</b> / Lyudmila M. Bronstein .....	3430

### *Nucleation and Crystal Growth*

<b>Atmospheric Nanoparticles: Formation and Physicochemical Properties</b> / James N. Smith .....	228
<b>Germanium Nanoparticles</b> / Boyd R. Taylor and Louisa J. Hope-Weeks .....	1405
<b>Interfacial Forces: Colloidal Particle-Liquid</b> / Sarah A. Nespolo and Geoffrey W. Stevens .....	1650

---

**Colloidal Phenomena (cont'd.)**

---

***Nucleation and Crystal Growth (cont'd.)***

- Nanocrystals Synthesized in Colloidal Self-Assemblies** / *M. P. Pileni* . . . . . 2581
- Nanoparticle Suspensions: Phase Behavior** / *Subramanian Ramakrishnan and Charles F. Zukoski* . . . . . 2878
- 

***Spontaneous Organization of Matter***

- Adhesion: Coated Surfaces, Effect of Humidity** / *Joan E. Curry and Sungsoo Kim* . . . . . 32
- Amphiphilic Block Copolymer Monolayer at Air–Water Interface** / *Emiko Mouri and Hideki Matsuoka* . . . . . 168
- Biomimetic Design of Self-Assembling Systems** / *Mila Boncheva and George M. Whitesides* . . . . . 364
- Capsules: Polymer Microcapsules** / *Gleb B. Sukhorukov* . . . . . 508
- Colloid Systems: Micelles and Nanocrystals** / *B.L.V. Prasad and Savka I. Stoeva* . . . . . 856
- Cubosomes: Bicontinuous Liquid Crystalline Nanoparticles** / *Patrick T. Spicer* . . . . . 1018
- Enzymatic Synthesis of Nanostructured Polymers and Composites** / *Christy Ford, Vijay T. John, Gary McPherson, Jibao He, Joseph Akkara, David Kaplan, and Arijit Bose* . . . . . 1271
- Microgel Dispersions: Colloidal Forces and Phase Behavior** / *Jianzhong Wu and Zhibing Hu* . . . . . 2243
- Self-Assembled Structures** / *Anna Cristina Samia and Xiao-Min Lin* . . . . . 3816
- Self-Assembled Thin Films: Optical Characterization** / *Herbert Wormeester, E. Stefan Kooij, and Bene Poelsema* . . . . . 3829
- 

**Computational Analysis, Simulations, and Theoretical Modeling**

---

***Electronic Structures, Optical, and Transport Properties***

- Antidot Lattices: Chaotic Transport** / *Tsuneya Ando* . . . . . 210
- Carbon Nanotransistors** / *Po-Wen Chiu and Siegmur Roth* . . . . . 563
- Carbon Nanotubes: Gas Adsorption Properties** / *Juan Manuel Diez Tascón and Eduardo J. Bottani* . . . . . 653
- Carbon Nanotubes: Optical Properties** / *R. Saito, Mildred S. Dresselhaus, G. Dresselhaus, A. Jorio, A. G. Souza Filho, and M. A. Pimenta* . . . . . 679
- Carbon Nanotubes: Thermal Properties** / *J. Hone* . . . . . 736
- Fullerenes and Carbon Nanotubes** / *Laszlo Mihaly* . . . . . 1322
- Fullerenes: Topology and Structure** / *G. Benedek and M. Bernasconi* . . . . . 1360
- Photonic Crystal Fibers** / *P. St. J. Russell, J. C. Knight, T. A. Birks, and P. J. Roberts* . . . . . 3356
- Self-Assembled Quantum Dots: Electronic Structures and Optical Properties** / *Andrew Williamson* . . . . . 3789
- Silicon Nanocrystals: Quantum Confinement** / *James R. Chelikowsky* . . . . . 4033
- Supramolecular Networks Synthesized in Nanoparticle–Polymer Mixtures** / *Anna C. Balazs and Gavin A. Buxton* . . . . . 4240
- Thermodynamics at the Meso- and Nanoscale** / *Mikhail A. Anisimov* . . . . . 4326
- 

***First Principles Analysis and Density Functional Theory***

- Carbon Nanotubes: Modeling of Hydrogen Chemisorption** / *Ronald C. Brown* . . . . . 671
- Ethane-Preferred Conformation** / *Lionel Goodman and Vojislava Pophristic* . . . . . 1294

<b>Metal Oxide Nanoribbons and Carbon Nanotubes: Modeling</b> / Amitesh Maiti . . . . .	2140
<b>Metal–Oxide Interfaces: Design via Control of Defect Density</b> / A. Bogicevic . . . . .	2116
<b>Molecular Electronics: Models of Switchable and Programmable Devices</b> / Pedro A. Derosa, Vandana R. Tarigopula, and Jorge M. Seminario . . . . .	2317
<b>Silicon Nanoclusters: Simulations</b> / Aaron Puzder . . . . .	4021
<b>Single-Walled Carbon Nanotubes: Field Emission Properties</b> / Xiaofeng F. Duan, Brahim Akdim, and Ruth Pachter . . . . .	4078
<b>Single-Walled Carbon Nanotubes: Geometries, Electronic Properties, and Actuation</b> / Guangyu Sun, Marc Nicklaus, and Miklos Kertesz . . . . .	4085
<b>Single-Walled Carbon Nanotubes: Structures and Symmetries</b> / Carter T. White and John W. Mintmire . . . . .	4108

---

### ***Molecular Dynamics, Monte Carlo, and Hybrid Simulation Methods***

<b>Cadmium Sulfate Nanocrystals: Computational Analysis</b> / Stacie Nunes, Zhigang Zhou, Jeffrey D. Evanseck, and Jeffrey D. Madura . . . . .	498
<b>Catalytic Processes: Nanoscale Simulations</b> / Vladimir I. Elokhin and Aleksandr V. Myshlyavtsev . . . . .	782
<b>Computational Analysis of Switchable Catenanes</b> / Xiangge Zheng and Karl Sohlberg . . . . .	930
<b>Computational Analysis of Switchable Rotaxanes</b> / Xiangge Zheng and Karl Sohlberg . . . . .	939
<b>Computational Analysis Using Normal and Multibody Modes</b> / Bryan C. Hathorn, Donald W. Noid, Bobby G. Sumpter, Chao Yang, and William A. Goddard III . . . . .	921
<b>Electrical Double-Layer Formation</b> / Kun-Lin Yang, Sotira Yiaccoumi, and Costas Tsouris . . . . .	1157
<b>Integrated Methods in Quantum Chemistry</b> / Stephan Irle and Keiji Morokuma . . . . .	1627
<b>Island Nucleation: Predictions</b> / Maria C. Bartelt . . . . .	1696
<b>Molecular Simulations of DNA Counterion Distributions</b> / Alexander Lyubartsev . . . . .	2398
<b>Nanofriction and Nanowear of Sliding Systems: Simulations</b> / W.C.D. Cheong . . . . .	2763
<b>Tribology at the Nanoscale</b> / Peter T. Cummings and Clare McCabe . . . . .	4385

---

## **Design Methods at the Nanoscale**

---

### ***Bioinspired Materials***

<b>Biomimetic Design of Self-Assembling Systems</b> / Mila Boncheva and George M. Whitesides . . . . .	364
<b>DNA-Based Nanoinstrument Design</b> / Alexander Hillisch and Stephan Diekmann . . . . .	1102
<b>Gecko-Inspired Adhesives: Nanofabrication</b> / Aránzazu del Campo and Eduard Arzt . . . . .	1384
<b>Nanomaterials: Trends</b> / Richard Silbergliitt . . . . .	2836
<b>Nanoparticle Synthesis: Biological Path</b> / Kenji Iwahori and Ichiro Yamashita . . . . .	2890
<b>Nanostructured Materials: Metals on Microtubule Supports</b> / Silke Behrens and Eberhard Unger . . . . .	3012

---

### ***Controlled Assembly Strategies***

<b>Layer-by-Layer Assembly of Semiconducting and Photoreactive Bolaform Amphiphiles</b> / Jason Locklin, Derek Patton, Chuanjun Xia, Xiaowu Fan, and Rigoberto C. Advincula . . . . .	1798
<b>Layer-by-Layer Assembly of Thin Films of Mixed Nanoparticles</b> / Jianchang Guo, Encai Hao, and Tianquan Lian . . . . .	1813
<b>Layered Double Hydroxides: Self-Assembly and Multiple Phases</b> / Zhi Ping Xu and Paul S. Braterman . . . . .	1841
<b>Molecular Probes of Cation–Arene Interactions</b> / George W. Gokel . . . . .	2369
<b>Nanocrystals Synthesized in Colloidal Self-Assemblies</b> / M. P. Pileni . . . . .	2581

---

**Design Methods at the Nanoscale (cont'd.)**

---

**Controlled Assembly Strategies (cont'd.)**

<b>Nanostructured Ultrastrong Materials</b> / Nicholas A. Kotov, Arif A. Mamedov, Dirk M. Guldi, Zhiyong Tang, Maurizio Prato, James Wicksted, and Andreas Hirsch	3072
<b>Self-Assembly Directed by NH-O Hydrogen Bonding</b> / Katrina A. Jolliffe and Leonard F. Lindoy	3864
<b>Self-Assembly of Coordination Cages</b> / Laura Pirondini and Enrico Dalcanale	3848
<b>Semiconductor Nanowires: Macroelectronics Applications</b> / Yugang Sun and John A. Rogers	3896
<b>Semiconductor Nanowires: Nanoscale Electronics and Optoelectronics</b> / Yu Huang, Xiangfeng Duan, and Charles M. Lieber	3910
<b>Surface Plasmon Spectra of Silver and Gold Nanoparticle Assemblies</b> / Mondona Zangeneh and Roger Terrill	4271
<b>Template-Directed Assembly of Dinuclear Triple-Stranded Helicates</b> / Markus Albrecht	4283
<b>Templating Aerogels for Tunable Nanoporosity</b> / Aydin K. Sunol and Sermin G. Sunol	4294
<b>Templating Polymer Crystal Growth Using Block Copolymers</b> / Yueh-Lin Loo	4303

---

**Interfacial Engineering**

<b>Carbon Nanotubes: Functionalization</b> / Bin Zhao, Hui Hu, Elena Bekyarova, Mikhail E. Itkis, Sandip Niyogi, and Robert C. Haddon	640
<b>Metal-Oxide Interfaces: Design via Control of Defect Density</b> / A. Bogicevic	2116
<b>Nanolithography: Length Scale Limitations</b> / Takashi Ito	2779
<b>Nano-Mesoscopic Interface: Hybrid Devices</b> / Gianfranco Cerofolini	2493
<b>Nanostructured Catalysts: Design and Synthesis</b> / Hua Chun Zeng	2974
<b>Nanostructured Multilayers: Applications in X-Ray Optics</b> / Michael Störmer, Carsten Michaelsen, Jörg Wiesmann, Paulo Ricardo, and Rüdiger Bormann	3052
<b>Nanostructured Silica and Silica-Derived Materials</b> / Ho-Cheol Kim and Geraud Dubois	3063
<b>Nanotube Sensors</b> / Marc Wirtz and Charles R. Martin	3109
<b>Polyelectrolyte Films with Incorporated Carbon Nanotubes</b> / Jason H. Rouse and Peter T. Lillehei	3396
<b>Ultrathin Polymer Films: Nanoparticle Nucleation</b> / Pieter Stroeve	4400

---

**Structure Control**

<b>Colloidal Nanometals as Fuel Cell Catalyst Precursors</b> / Helmut Bönnemann and K. S. Nagabhushana	863
<b>Coordination Framework Topology</b> / Neil R. Champness and Neil S. Oxtoby	984
<b>Metal Oxide Nanoparticles</b> / Ryan M. Richards	2126
<b>Nanomaterials and Molecular Devices: De Novo Design Theory</b> / Kwang S. Kim, P. Tarakeshwar, and Han Myoung Lee	2815
<b>Organofullerenes in Water</b> / Eiichi Nakamura and Hiroyuki Isobe	3277
<b>Polymer Nanowires Conjugated by Controlled Chain Polymerization</b> / Yuji Okawa and Masakazu Aono	3501
<b>Self-Organized Superstructures: Molecular Design</b> / Makoto Tadokoro	3886
<b>Semiconductor Nanowires: Rational Synthesis</b> / Xiangfeng Duan and Charles M. Lieber	3941
<b>Structural Transitions in Thin Films</b> / Rajarshi Banerjee, Gregory B. Thompson, and Hamish L. Fraser	4217

<b>Superconductor Nanowires: Templated by Single Molecules</b> / Alexey Bezryadin, Anthony Bollinger, David Hopkins, Michael Murphey, Mikas Remeika, and Andrey Rogachev .....	4228
<b>Zeolite Membranes</b> / Wei Xing, João C. Diniz da Costa, Gao Qing (Max) Lu, and Z. F. Yan .....	4421

---

## Energy Storage Devices and Energy-Directed Applications

<b>Automotive Parts: Impact of Nanotechnology</b> / Ganesh Skandan, Amit Singhal, and Damian Sobrevilla .....	241
<b>Carbon Nanotube Electrodes</b> / Valentina Lazarescu .....	586
<b>Carbon Nanotube–Conducting Polymer Composites in Supercapacitors</b> / Mark Hughes .....	574
<b>Carbon Nanotubes for Storage of Energy: Supercapacitors</b> / Elzbieta Frackowiak .....	707
<b>Carbon Nanotubes: Electrochemical Modification</b> / Kannan Balasubramanian, Marko Burghard, and Klaus Kern .....	620
<b>Carbon Nanotubes: Gas Adsorption Properties</b> / Juan Manuel Diez Tascón and Eduardo J. Bottani .....	653
<b>Carbon Nanotubes: Hydrogen Storage</b> / Masashi Shiraishi, Taishi Takenobu, Hiromichi Kataura, and Masafumi Ata .....	662
<b>Carbon Nanotubes: Modeling of Hydrogen Chemisorption</b> / Ronald C. Brown .....	671
<b>Carbon-Based Nanostructures: Hydrogen Storage</b> / Xianxian Wu and Nidia C. Gallego .....	535
<b>Nanomaterials: Advances in Technology and Industry</b> / Ganesh Skandan and Amit Singhal .....	2788
<b>Oxide Nanoparticles: Electrochemical Performance</b> / Dominique Larcher and Jean-Marie Tarascon .....	3299
<b>Photovoltaics: Organic-Based Solar Cells</b> / Sean E. Shaheen and David S. Ginley .....	3370
<b>Porous Alumina Templates for Nanofabrication</b> / Latika Menon .....	3525

---

## Environmental Applications and Societal Implications

<b>Atmospheric Nanoparticles: Formation and Physicochemical Properties</b> / James N. Smith .....	228
<b>Automotive Parts: Impact of Nanotechnology</b> / Ganesh Skandan, Amit Singhal, and Damian Sobrevilla .....	241
<b>Biological and Chemical Decontamination</b> / Peter K. Stoimenov and Kenneth J. Klabunde .....	312
<b>Bioremediation of Environmental Contaminants</b> / Xiomara C. Kretschmer and Russell R. Chianelli .....	397
<b>Chemical Warfare Agents: Biosensors for Detection</b> / Elias Greenbaum, Miguel Rodriguez, Jr., and Charlene A. Sanders .....	842
<b>Electrochemical Toxicity Sensors</b> / James F. Rusling .....	1207
<b>Environmental Nanoparticles</b> / Alexandra Navrotsky .....	1262
<b>Gold Nanoparticles on Titania: Activation and Behavior</b> / Jose A. Rodriguez .....	1422
<b>Molecular Self-Assembly: Environmental and Sensing Applications</b> / Glen E. Fryxell, R. Shane Addleman, S. V. Mattigod, Yuehe Lin, T. S. Zemanian, H. Wu, Jerome C. Birnbaum, J. Liu, and X. Feng .....	2387
<b>Moore's Law: Performance and Power Dissipation</b> / Laszlo B. Kish .....	2480
<b>Nanocrystalline Zeolites</b> / Vicki H. Grassian and Sarah C. Larsen .....	2646
<b>Nanofiltration Separations</b> / Eric M.V. Hoek and Anna Jawor .....	2749
<b>Nanomaterials: Advances in Technology and Industry</b> / Ganesh Skandan and Amit Singhal .....	2788
<b>Patents and Inventions</b> / Jeffrey A. Lindeman .....	3318

---

**Environmental Applications and Societal Implications (*cont'd.*)**

<b>Photovoltaics: Organic-Based Solar Cells</b> / Sean E. Shaheen and David S. Ginley . . . . .	3370
<b>Platinum Nanoparticles: Synthesis and Catalytic Properties</b> / Ioan Balint and Akane Miyazaki . . . . .	3386
<b>Risk Assessment and Benefits</b> / Douglas Mulhall . . . . .	3702
<b>Titania Nanoparticles: Photocatalytic Properties</b> / Scott Buzby and S. Ismat Shah . . . . .	4356
<b>Toxicological Effects and Screening of Engineered Nanoparticles</b> / Paul Borm and Ken Donaldson . . . . .	4363
<b>Zeolite Membranes</b> / Wei Xing, João C. Diniz da Costa, Gao Qing (Max) Lu, and Z. F. Yan . . . . .	4421

---

**Fullerenes and Carbon Nanotubes**

---

**Chemistry and Functionalization**

<b>Biosensors Based on Carbon Nanotubes</b> / Yuehe Lin, Wassana Yantasee, Fang Lu, Joseph Wang, Mustafa Musameh, Yi Tu, and Zhifeng Ren . . . . .	428
<b>Carbon Nanotubes: Electrochemical Modification</b> / Kannan Balasubramanian, Marko Burghard, and Klaus Kern . . . . .	620
<b>Carbon Nanotubes: Flow Control in Membranes</b> / Scott A. Miller and Charles R. Martin . . . . .	630
<b>Carbon Nanotubes: Functionalization</b> / Bin Zhao, Hui Hu, Elena Bekyarova, Mikhail E. Itkis, Sandip Niyogi, and Robert C. Haddon . . . . .	640
<b>Fullerenes: Chemistry</b> / Mark S. Meier . . . . .	1331
<b>Ice Nanotubes inside Carbon Nanotubes</b> / Kenichiro Koga and Hideki Tanaka . . . . .	1558
<b>Nanotubes: Functionalization</b> / Stanislaus S. Wong and Sarbajit Banerjee . . . . .	3119
<b>Organofullerenes in Water</b> / Eiichi Nakamura and Hiroyuki Isobe . . . . .	3277
<b>Smart Nanotubes for Biotechnology and Biocatalysis</b> / Charles R. Martin and Punit Kohli . . . . .	4147

---

**Composite Materials**

<b>Nanoceramics: Thermal Conductivity</b> / Paul G. Klemens . . . . .	2539
<b>Nanofibers and Carbon Nanotubes: Novel Metal Catalyst Supports</b> / Mark A. Keane . . . . .	2723
<b>Nanostructured Composites: Carbon-Derived Fibers</b> / Peter M.A. Sherwood . . . . .	2986
<b>Nanostructured Materials: Synthesis in Supercritical Fluids</b> / Yuehe Lin, Xiang-Rong Ye, and Chien M. Wai . . . . .	3040
<b>Nanostructured Ultrastrong Materials</b> / Nicholas A. Kotov, Arif A. Mamedov, Dirk M. Guldi, Zhiyong Tang, Maurizio Prato, James Wicksted, and Andreas Hirsch . . . . .	3072
<b>Noble Metal Nanoparticles on Carbon Fibers</b> / Dmitri A. Bulushev and Igor Yuranov . . . . .	3195
<b>Polyelectrolyte Films with Incorporated Carbon Nanotubes</b> / Jason H. Rouse and Peter T. Lillehei . . . . .	3396
<b>Polymer Nanocomposites with Nanoparticle and Carbon Nanotube Fillers</b> / B. J. Ash, A. Eitan, and L. S. Schadler . . . . .	3466
<b>Raman Spectroscopy of Carbon Nanotube–Polymer Composites</b> / Bin Chen . . . . .	3682

---

**Energy-Related Applications**

<b>Carbon Nanotube Electrodes</b> / Valentina Lazarescu . . . . .	586
<b>Carbon Nanotubes for Storage of Energy: Supercapacitors</b> / Elzbieta Frackowiak . . . . .	707
<b>Carbon Nanotubes: Gas Adsorption Properties</b> / Juan Manuel Diez Tascón and Eduardo J. Bottani . . . . .	653

<b>Carbon Nanotubes: Hydrogen Storage</b> / Masashi Shiraishi, Taishi Takenobu, Hiromichi Kataura, and Masafumi Ata	662
<b>Carbon Nanotubes: Modeling of Hydrogen Chemisorption</b> / Ronald C. Brown	671
<b>Carbon-Based Nanostructures: Hydrogen Storage</b> / Xianxian Wu and Nidia C. Gallego	535

### **Structures and Properties**

<b>Carbon Forms Structured by Energetic Species</b> / Yeshayahu Lifshitz	553
<b>Carbon Nanotube Interconnects</b> / Alain E. Kaloyeros, Kathleen A. Dunn, Autumn T. Carlsen, and Anna W. Topol	596
<b>Carbon Nanotubes and Other Carbon Materials</b> / Morinobu Endo, Yoong Ahm Kim, Takuya Hayashi, Mauricio Terrones, and Mildred S. Dresselhaus	691
<b>Carbon Nanotubes: Optical Properties</b> / R. Saito, Mildred S. Dresselhaus, G. Dresselhaus, A. Jorio, A. G. Souza Filho, and M. A. Pimenta	679
<b>Carbon Nanotubes: Supramolecular Mechanics</b> / Boris I. Yakobson and Luise S. Couchman	722
<b>Carbon Nanotubes: Thermal Properties</b> / J. Hone	736
<b>Fluorofullerenes</b> / Olga V. Boltalina and Steven H. Strauss	1307
<b>Fullerenes and Carbon Nanotubes</b> / Laszlo Mihaly	1322
<b>Fullerenes: Isomer Identification</b> / Guangyu Sun	1340
<b>Fullerenes: Magnetic Behavior</b> / T. L. Makarova	1352
<b>Fullerenes: Topology and Structure</b> / G. Benedek and M. Bernasconi	1360
<b>Integrated Methods in Quantum Chemistry</b> / Stephan Irle and Keiji Morokuma	1627
<b>Magnetic Nanocarbon</b> / T. L. Makarova	1939
<b>Nanodiamonds</b> / Jean-Yves Raty and Giulia Galli	2697
<b>Single-Walled Carbon Nanotubes: Field Emission Properties</b> / Xiaofeng F. Duan, Brahim Akdim, and Ruth Pachter	4078
<b>Single-Walled Carbon Nanotubes: Geometries, Electronic Properties, and Actuation</b> / Guangyu Sun, Marc Nicklaus, and Miklos Kertesz	4085
<b>Single-Walled Carbon Nanotubes: Separation Using Capillary Electrophoresis</b> / Stephen K. Doorn	4096
<b>Single-Walled Carbon Nanotubes: Structures and Symmetries</b> / Carter T. White and John W. Mintmire	4108
<b>Superconductor Nanowires: Templated by Single Molecules</b> / Alexey Bezryadin, Anthony Bollinger, David Hopkins, Michael Murphey, Mikas Remeika, and Andrey Rogachev	4228

### **Functional Nanomaterials**

#### **Catalysts and Adsorbents**

<b>Catalysis by Supported Gold Nanoclusters</b> / D. Wayne Goodman	744
<b>Dendritic Nanocatalysts</b> / Kiyotomi Kaneda, Masahiko Ooe, Makoto Murata, Tomoo Mizugaki, and Kohki Ebitani	1054
<b>Layer-by-Layer Assembly of Polyelectrolyte Films: Membranes and Catalysts</b> / Bernd Tieke and Ali Toutianoush	1784
<b>Mesoporous Materials</b> / James C. Vartuli, Wielsaw J. Roth, and Thomas F. Degnan, Jr.	2029
<b>Mixed Metal Oxide Nanoparticles</b> / Pramesh N. Kapoor, Ajay Kumar Bhagi, Ravichandra S. Mulukutla, and Kenneth J. Klabunde	2280
<b>Molecular Receptor-Modified Metal Nanoparticles</b> / Jian Liu	2377
<b>Nanocrystalline Magnesia and Alumina: Surface Chemistry</b> / Richard M. Narske	2592

---

**Functional Nanomaterials (cont'd.)**

---

**Catalysts and Adsorbents (cont'd.)**

- Silica Surfaces Functionalization** / V. A. Tertykh ..... 4001
- Titania Coatings on Stainless Steel** / Ganesh Balasubramanian, Dionysios D. Dionysiou,  
and Makram T. Suidan ..... 4348
- 

**Electronic and Photonic Materials**

- Carbon Nanotransistors** / Po-Wen Chiu and Siegmund Roth ..... 563
- Carbon Nanotube Electrodes** / Valentina Lazarescu ..... 586
- Carbon Nanotube Interconnects** / Alain E. Kaloyeros, Kathleen A. Dunn, Autumn T. Carlsen,  
and Anna W. Topol ..... 596
- Charge Carrier Dynamics of Nanoparticles** / Fanxin Wu and Jin Z. Zhang ..... 804
- Conducting Polymer Nanopatterns** / Shaun F. Filocamo and Mark W. Grinstaff ..... 954
- Conducting Polymer Nanotubes** / Seung Il Cho and Sang Bok Lee ..... 965
- Electrically Functional Nanostructures** / Orlin D. Velev and Simon O. Lumsdon ..... 1171
- Low-Dielectric Constant Materials** / Robert D. Miller ..... 1901
- Membrane-Coated Nanoparticles: Photochemistry** / Ulrich Siggel, Guangtao Li and  
Jürgen-Hinrich Fuhrhop ..... 2012
- Nanofilms in Giant Magnetoresistance Heads** / Edward Grochowski and  
Robert E. Fontana, Jr. .... 2737
- One-Dimensional Electrically Conducting Polymeric Nanostructures** / Andrew D.W. Carswell  
and Brian P. Grady ..... 3243
- Oxide Nanoparticles: Electrochemical Performance** / Dominique Larcher and  
Jean-Marie Tarascon ..... 3299
- Photonic Crystal Fibers** / P. St. J. Russell, J. C. Knight, T. A. Birks, and  
P. J. Roberts ..... 3356
- Photovoltaics: Organic-Based Solar Cells** / Sean E. Shaheen and David S. Ginley ..... 3370
- Semiconductor Nanowires: Macroelectronics Applications** / Yugang Sun and  
John A. Rogers ..... 3896
- Semiconductor Nanowires: Rational Synthesis** / Xiangfeng Duan and Charles M. Lieber ..... 3941
- Silicon Functionalization for Molecular Electronics** / Gianfranco Cerofolini,  
Dario Narducci, and Elisabetta Romano ..... 4009
- 

**Functionalized Surfaces and Molecular Recognition**

- Anodization Patterned on Aluminum Surfaces** / Juchao Yan, G. V. Rama Rao,  
Plamen B. Atanassov, and Gabriel P. López ..... 203
- Capsules: Specific Layer Structures** / Lars Dähne and Claire S. Peyratout ..... 522
- Core-Shell Nanospheres, Hollow Capsules, and Bottles** / Gang Zhang, Kai Zhang,  
Yi Yu, and Bai Yang ..... 1003
- Dip-Pen Nanolithography: Applications and Functional Extensions** / Björn T. Rosner and  
Linette M. Demers ..... 1070
- Dip-Pen Nanolithography: Optical Inks** / Brandon L. Weeks, Aleksandr Noy, Abigail E. Miller,  
Jennifer E. Klare, Bruce W. Woods, and James J. De Yoreo ..... 1084
- Dissymmetrical Nanoparticles** / Stéphane Reculosa, Christophe Mingotaud, Etienne Duguet,  
and Serge Ravaine ..... 1093
- Gecko-Inspired Adhesives: Nanofabrication** / Aránzazu del Campo and Eduard Arzt ..... 1384
- Gene Delivery via Polymer Nanoparticles** / Jie Wen and Kam W. Leong ..... 1394

<b>Monolayer-Protected Metal Nanoparticles: Chemical Sensing and Gas Chromatography</b> / <i>Jay W. Grate, David A. Nelson, Rhonda Skaggs, Robert E. Synovec, and Gwen M. Gross</i> . . .	2460
<b>Nanoporous Anodic Alumina: Structural and Optical Anisotropy</b> / <i>E. Stefan Kooij, Aurelian C. Gâlcă, Herbert Wormeester, and Bene Poelsema</i> . . . . .	2947
<b>Polymer Colloids and Their Metallation</b> / <i>Lyudmila M. Bronstein</i> . . . . .	3430
<b>Self-Assembled Monolayers: Chemical and Physical Modification under Vacuum</b> / <i>Jessica Torres, Anthony J. Wagner, Christopher C. Perry, Glenn M. Wolfe, and D. Howard Fairbrother</i> . . . . .	3747

### ***Magnetism-Based Utilization***

<b>Iron Oxide Nanoparticles</b> / <i>Mamoru Senna</i> . . . . .	1688
<b>Magnetic Ferrofluids</b> / <i>Carlos Rinaldi, Thomas Franklin, Markus Zahn, and Tahir Cader</i> . . . . .	1922
<b>Magnetic Nanomaterials: Conventional Synthesis and Properties</b> / <i>Dajie Zhang</i> . . . . .	1951
<b>Magnetic Nanomaterials: Nonconventional Synthesis and Chemical Design</b> / <i>Luminita Patron, Ioana Mindru, and Gabriela Marinescu</i> . . . . .	1968
<b>Magnetic Nanoparticles</b> / <i>Valérie Cabuil</i> . . . . .	1985
<b>Magnetic Nanoparticles for Granular Recording Media</b> / <i>David E. Nikles and J. W. Harrell</i> . . . . .	2001
<b>Nanoparticle Assemblies: Magnetic Properties</b> / <i>Xiangcheng Sun</i> . . . . .	2868

### ***Nanopowders and Nanocomposites***

<b>Automotive Parts: Impact of Nanotechnology</b> / <i>Ganesh Skandan, Amit Singhal, and Damian Sobrevilla</i> . . . . .	241
<b>Bimetallic Layered Nanocomposites</b> / <i>Amit Misra and Richard G. Hoagland</i> . . . . .	288
<b>Carbon Nanotube–Conducting Polymer Composites in Supercapacitors</b> / <i>Mark Hughes</i> . . . . .	574
<b>Carbon Nanotube–Metal Matrix Composites</b> / <i>Efraín Carreño-Morelli</i> . . . . .	611
<b>Carbon Nanotubes: Flow Control in Membranes</b> / <i>Scott A. Miller and Charles R. Martin</i> . . . . .	630
<b>Carbon Nanotubes: Functionalization</b> / <i>Bin Zhao, Hui Hu, Elena Bekyarova, Mikhail E. Itkis, Sandip Niyogi, and Robert C. Haddon</i> . . . . .	640
<b>Ceramic Nanocomposites: Self-Diagnostic Ability of Catastrophic Damage</b> / <i>Pavol Šajgalík and Zoltán Lenčéš</i> . . . . .	794
<b>Functionalization of Surface Layers on Ceramics</b> / <i>Toshihiro Ishikawa</i> . . . . .	1375
<b>Intercalated Polypropylene Nanocomposites</b> / <i>Michael J. Solomon and Anongnat Somwangthanaroj</i> . . . . .	1642
<b>Iron Nanoparticles</b> / <i>Dale L. Huber</i> . . . . .	1681
<b>Metallic Nanopowders</b> / <i>Frederick Tepper, Marat I. Lerner, and David S. Ginley</i> . . . . .	2153
<b>Metallic Nanopowders: Rocket Propulsion</b> / <i>Leonid Kaledin and Frederick Tepper</i> . . . . .	2165
<b>Metallic Quantum Dots</b> / <i>J. P. Wilcoxon</i> . . . . .	2176
<b>Nanotubes: Functionalization</b> / <i>Stanislaus S. Wong and Sarbjit Banerjee</i> . . . . .	3119

### ***Inorganic Nanowires***

<b>Barcoded Nanowires</b> / <i>Rebecca L. Stoermer and Christine D. Keating</i> . . . . .	259
<b>Inorganic Nanotubes</b> / <i>Reshef Tenne</i> . . . . .	1598
<b>Inorganic Nanotubes: Synthesis by Chemical Transport Reaction</b> / <i>Maja Remskar</i> . . . . .	1606
<b>Inorganic Sulfide Nanotubes: Mechanical Behavior</b> / <i>Ifat Kaplan-Ashiri, H. Daniel Wagner, Gotthard Seifert, and Reshef Tenne</i> . . . . .	1617
<b>Molecular Wires</b> / <i>Dustin K. James and James M. Tour</i> . . . . .	2441
<b>Nanobridges: Thermal Properties</b> / <i>Jeong Won Kang and Ho Jung Hwang</i> . . . . .	2522

---

**Inorganic Nanowires (*cont'd.*)**

<b>Nanostructured Materials: Metals on Microtubule Supports</b> / <i>Silke Behrens and Eberhard Unger</i> .....	3012
<b>Nanostructures Based on Layered Transition-Metal Chalcogenides</b> / <i>Russell R. Chianelli and Myriam Perez de la Rosa</i> .....	3080
<b>Nanowires and Nanobelts: Mechanical Properties</b> / <i>Zhong Lin Wang</i> .....	3146
<b>Nanowires: Molecular Assembly</b> / <i>Tomoyuki Akutagawa, Takayoshi Nakamura, and Jan Becher</i> .....	3136
<b>Semiconductor Nanowires: Rational Synthesis</b> / <i>Xiangfeng Duan and Charles M. Lieber</i> .....	3941
<b>Silica Nanotubes: Wetting and Diffusion</b> / <i>Kenji Okamoto, Karthik Jayaraman, Sang Jun Son, Sang Bok Lee, and Douglas S. English</i> .....	3995
<b>Superconductor Nanowires: Templated by Single Molecules</b> / <i>Alexey Bezryadin, Anthony Bollinger, David Hopkins, Michael Murphey, Mikas Remeika, and Andrey Rogachev</i> .....	4228

---

**Magnetic Nanoparticles**

<b>Antidot Lattices: Chaotic Transport</b> / <i>Tsuneya Ando</i> .....	210
<b>Biomedical Magnetic Nanoparticles</b> / <i>Ian Robinson, Le Duc Tung, and Nguyen T.K. Thanh</i> .....	354
<b>Charge Transport in Multilayer Nanostructures</b> / <i>Daniel M. Schaadt</i> .....	834
<b>Fullerenes: Magnetic Behavior</b> / <i>T. L. Makarova</i> .....	1352
<b>Iron Oxide Nanoparticles</b> / <i>Mamoru Senna</i> .....	1688
<b>Magnetic Ferrofluids</b> / <i>Carlos Rinaldi, Thomas Franklin, Markus Zahn, and Tahir Cader</i> .....	1922
<b>Magnetic Nanocarbon</b> / <i>T. L. Makarova</i> .....	1939
<b>Magnetic Nanomaterials: Conventional Synthesis and Properties</b> / <i>Dajie Zhang</i> .....	1951
<b>Magnetic Nanomaterials: Nonconventional Synthesis and Chemical Design</b> / <i>Luminita Patron, Ioana Mindru, and Gabriela Marinescu</i> .....	1968
<b>Magnetic Nanoparticles</b> / <i>Valérie Cabuil</i> .....	1985
<b>Magnetic Nanoparticles for Granular Recording Media</b> / <i>David E. Nikles and J. W. Harrell</i> .....	2001
<b>Nanocomposite Magnetic Materials: Shock-Induced Synthesis</b> / <i>N. N. Thadhani and Z. Q. Jin</i> ..	2556
<b>Nanocrystals: Size-Dependent Properties and Emerging Applications</b> / <i>G. U. Kulkarni, P. John Thomas, and C.N.R. Rao</i> .....	2665
<b>Nanofilms in Giant Magnetoresistance Heads</b> / <i>Edward Grochowski and Robert E. Fontana, Jr.</i> .....	2737
<b>Nanomaterials and Nanodevices: Ion-Beam Technology</b> / <i>Dmitri Litvinov and Sakhrat Khizroev</i> .....	2825
<b>Nanoparticle Assemblies: Magnetic Properties</b> / <i>Xiangcheng Sun</i> .....	2868
<b>Permanent Magnets Based on Nanostructured Intermetallic Alloys</b> / <i>Paul McGuinness, Andraž Kocjan, and Spomenka Kobe</i> .....	3328
<b>Permanent Nanocomposite Magnets</b> / <i>Satoshi Hirosawa</i> .....	3336
<b>Porous Alumina Templates for Nanofabrication</b> / <i>Latika Menon</i> .....	3525

---

**Mechanical Properties at the Nanoscale**
***Alloys and Composites***

<b>Bimetallic Layered Nanocomposites</b> / <i>Amit Misra and Richard G. Hoagland</i> .....	288
<b>Carbon Nanotube–Metal Matrix Composites</b> / <i>Efraín Carreño-Morelli</i> .....	611

<b>Ceramic Nanocomposites: Self-Diagnostic Ability of Catastrophic Damage</b> / Pavol Šajgalík and Zoltán Lenčés . . . . .	794
<b>Epoxy-Layered Silicate Nanocomposites</b> / Chenggang Chen and Tia Benson Tolle . . . . .	1284
<b>High-Strength Alloys: Nanogranular Phases</b> / Dmitri Valentinovich Louzguine and Akihisa Inoue . . . . .	1536
<b>Intercalated Polypropylene Nanocomposites</b> / Michael J. Solomon and Anongnat Somwangthanaroj . . . . .	1642
<b>Nanostructured Alloys: Cryomilling Synthesis and Behavior</b> / David Witkin, Piers Newbery, Bing Q. Han, and Enrique J. Lavernia . . . . .	2958
<b>Nanostructured Composites: Titanium-Based Alloys</b> / Jürgen Eckert, Jayanta Das, and Ki Buem Kim . . . . .	2996
<b>Polypropylene and Thermoplastic Olefins Nanocomposites</b> / Francis M. Mirabella, Jr. . . . .	3509

**Friction, Deformations, and Wear**

<b>AFM: Simulation of Interaction Forces</b> / Ivan U. Vakarelski, Scott C. Brown, Bahar Basim, and Brij M. Moudgil . . . . .	153
<b>Mica Surfaces: Charge Nucleation and Wear</b> / James M. Helt and James D. Batteas . . . . .	2211
<b>Nanocrystalline Materials: Fatigue</b> / Alexie Yu. Vinogradov and Sean R. Agnew . . . . .	2602
<b>Nanofriction and Nanowear of Sliding Systems: Simulations</b> / W.C.D. Cheong . . . . .	2763
<b>Nanophase Powders: Mechanosynthesis</b> / F. Miani, F. Maurigh, and F. Delogu . . . . .	2923
<b>Nanostructured Materials: Synthesis by Mechanical Attrition</b> / Carl C. Koch . . . . .	3019
<b>Nanostructured Materials: Synthesis by Mechanical Means</b> / H.-J. Fecht . . . . .	3030
<b>Structural Nanomaterials</b> / Joanna R. Groza, and Jeffrey C. Gibeling . . . . .	4205
<b>Tribology at the Nanoscale</b> / Peter T. Cummings and Clare McCabe . . . . .	4385
<b>Tribology of Inorganic Nanoparticles</b> / Lev Rapoport . . . . .	4375

**Nanomechanical Devices**

<b>Magnetic Ferrofluids</b> / Carlos Rinaldi, Thomas Franklin, Markus Zahn, and Tahir Cader . . . . .	1922
<b>Microweighing in Supercritical Carbon Dioxide</b> / You-Ting Wu and Christine S. Grant . . . . .	2253
<b>Molecular Motor-Powered Nanodevices: Control Mechanisms</b> / Jacob J. Schmidt and Carlo D. Montemagno . . . . .	2347
<b>Nanomechanical Resonant Devices: Surface Chemistry</b> / Joshua A. Henry, Deborahonyaa Sengupta, and Melissa A. Hines . . . . .	2848

**Soft Materials and Weak Interfacial Forces**

<b>AFM: Biopolymers</b> / Nehal I. Abu-Lail and Terri A. Camesano . . . . .	63
<b>AFM: Imaging Artifacts</b> / Stephanie Butler Velegol . . . . .	88
<b>Biomaterials: Mechanical Characterization</b> / Eunice Phay Shing Tan and Chwee Teck Lim . . . . .	317
<b>Dynamic AFM on Heterogeneous Surfaces</b> / Ijeoma M. Nnebe and James W. Schneider . . . . .	1144
<b>Interfacial Forces: Colloidal Particle-Liquid</b> / Sarah A. Nespolo and Geoffrey W. Stevens . . . . .	1650
<b>Langmuir-Blodgett Films</b> / Ursula Mazur . . . . .	1738
<b>Liposomes: Direct Force Measurement by AFM</b> / Guangzhao Mao, Xuemei Liang, and K.Y. Simon Ng . . . . .	1869
<b>Small Amplitude AFM</b> / Peter M. Hoffmann . . . . .	4119
<b>Soft Materials: AFM Investigations and Nanophysics</b> / J. P. Aimé, R. Boisgard, S. Marsaudon, and G. Couturier . . . . .	4158
<b>Surface Forces on Nanoparticles Determined by Direct Measurement</b> / Jeong-Min Cho, Georgios Pyrgiotakis, and Wolfgang M. Sigmund . . . . .	4260

---

**Mechanical Properties at the Nanoscale (*cont'd.*)**

---

***Supramolecular Mechanics of Nanotubes and Nanowires***

<b>Carbon Nanotubes: Supramolecular Mechanics</b> / Boris I. Yakobson and Luise S. Couchman . . . . .	722
<b>Inorganic Nanotubes</b> / Reshef Tenne . . . . .	1598
<b>Inorganic Sulfide Nanotubes: Mechanical Behavior</b> / Ifat Kaplan-Ashiri, H. Daniel Wagner, Gotthard Seifert, and Reshef Tenne . . . . .	1617
<b>Nanostructured Ultrastrong Materials</b> / Nicholas A. Kotov, Arif A. Mamedov, Dirk M. Guldi, Zhiyong Tang, Maurizio Prato, James Wicksted, and Andreas Hirsch . . . . .	3072
<b>Nanowires and Nanobelts: Mechanical Properties</b> / Zhong Lin Wang . . . . .	3146
<b>Nanowires: Molecular Assembly</b> / Tomoyuki Akutagawa, Takayoshi Nakamura, and Jan Becher . . . . .	3136

---

**Molecular Electronics and Nanoscale Devices**

---

***Molecular Electronics and Nanocomputing***

<b>Barcoded Nanowires</b> / Rebecca L. Stoermer and Christine D. Keating . . . . .	259
<b>Carbon Nanotransistors</b> / Po-Wen Chiu and Siegmund Roth . . . . .	563
<b>Charge Transfer in Metal–Molecule Heterostructures</b> / Debasish Kuila, David B. Janes, and Clifford P. Kubiak . . . . .	819
<b>DNA Hybridization: Electronic Control</b> / Kimberly Hamad-Schifferli . . . . .	1122
<b>DNA-Conjugated Metal Nanoparticles: Chip Detection Applications</b> / Wolfgang Fritzsche . . . . .	1114
<b>Electronic Switches</b> / Richard J. Nichols, David J. Schiffrin, and Wolfgang Haiss . . . . .	1230
<b>Litho-to-Nano Link</b> / Gianfranco Cerofolini, Dario Narducci, and Elisabetta Romano . . . . .	1890
<b>Metal Nanoparticles: Self-Assembly into Electronic Nanostructures</b> / Venugopal Santhanam and Ronald P. Andres . . . . .	2079
<b>Molecular Computing Machines</b> / Yaakov Benenson and Ehud Shapiro . . . . .	2291
<b>Molecular Electronics: Logic and Memory</b> / Dustin K. James and James M. Tour . . . . .	2303
<b>Molecular Electronics: Models of Switchable and Programmable Devices</b> / Pedro A. Derosa, Vandana R. Tarigopula, and Jorge M. Seminario . . . . .	2317
<b>Molecular Switches</b> / Jean-Pierre Launay, Christophe Coudret, and Christian Joachim . . . . .	2411
<b>Molecular Wires</b> / Dustin K. James and James M. Tour . . . . .	2441
<b>Nano–Mesoscopic Interface: Hybrid Devices</b> / Gianfranco Cerofolini . . . . .	2493
<b>Optical Molecular Devices</b> / A. Prasanna de Silva and Nathan D. McClenaghan . . . . .	3251
<b>Semiconductor Nanowires: Nanoscale Electronics and Optoelectronics</b> / Yu Huang, Xiangfeng Duan, and Charles M. Lieber . . . . .	3910
<b>Silicon Functionalization for Molecular Electronics</b> / Gianfranco Cerofolini, Dario Narducci, and Elisabetta Romano . . . . .	4009

---

***Molecular Mechanical Devices***

<b>Computational Analysis of Switchable Catenanes</b> / Xiang Zheng and Karl Sohlberg . . . . .	930
<b>Computational Analysis Using Normal and Multibody Modes</b> / Bryan C. Hathorn, Donald W. Noid, Bobby G. Sumpter, Chao Yang, and William A. Goddard III . . . . .	921
<b>Molecular Manipulator: Dynamic Design Criteria</b> / Andrés Jaramillo-Botero . . . . .	2336
<b>Molecular Motor-Powered Nanodevices: Control Mechanisms</b> / Jacob J. Schmidt and Carlo D. Montemagno . . . . .	2347

<b>Molecular Switches and Motors</b> / <i>Richard A. van Delden and Ben L. Feringa</i> . . . . .	2424
<b>Motor Proteins in Synthetic Materials and Devices</b> / <i>Henry Hess, George Bachand, and Viola Vogel</i> . . . . .	2484

**Colloidal Chemistry Methods**

<b>Colloid Systems: Micelles and Nanocrystals</b> / B.L.V. Prasad and Savka I. Stoeva . . . . .	856
<b>Colloidal Structures on Patterned Surfaces</b> / Aránzazu del Campo, Anne-Sophie Duwez, Charles-André Fustin, and Ulrich Jonas . . . . .	907
<b>Dimensionally Graded Semiconductor Nanoparticle Films</b> / Arif A. Mamedov, Nicholas A. Kotov, and Nataliya N. Mamedova . . . . .	1062
<b>Enzymatic Synthesis of Nanostructured Polymers and Composites</b> / Christy Ford, Vijay T. John, Gary McPherson, Jibao He, Joseph Akkara, David Kaplan, and Arijit Bose . . . . .	1271
<b>Gecko-Inspired Adhesives: Nanofabrication</b> / Aránzazu del Campo and Eduard Arzt . . . . .	1384
<b>Germanium Nanoparticles</b> / Boyd R. Taylor and Louisa J. Hope-Weeks . . . . .	1405
<b>Hydrogel Nanoparticles Made of Cross-Linked Polyvinylpyrrolidone</b> / Susmita Mitra, Dhruba Jyoti Bharali, and Amarnath Maitra . . . . .	1546
<b>Ionic Strength Effects: Tunable Nanocrystal Distribution in Colloidal Gold Films</b> / E. Stefan Kooij, E.A. Martijn Brouwer, Herbert Wormeester, and Bene Poelsema . . . . .	1672
<b>Island Surfaces: Fabrication on Self-Assembled Monolayers</b> / Hongjie Liu, Charles Maldarelli, M. Lane Gilchrist, and Alexander Couzis . . . . .	1708
<b>Layer-by-Layer Assembly of Electroactive Thin Films to Layered Carbon Electrodes</b> / Tarek R. Farhat . . . . .	1764
<b>Layered Double Hydroxides: Self-Assembly and Multiple Phases</b> / Zhi Ping Xu and Paul S. Braterman . . . . .	1841
<b>Monolayer-Protected Metal Nanoparticles: Synthesis</b> / Young-Seok Shon . . . . .	2469
<b>Nanocrystalline Materials: Synthesis and Properties</b> / Alexandr I. Gusev . . . . .	2621
<b>Nanomaterials: Advances in Technology and Industry</b> / Ganesh Skandan and Amit Singh . . . . .	2788
<b>Nanomaterials: Manufacturing, Processing, and Applications</b> / Pramod K. Sharma, Weifang Miao, Anit Giri, and Srikanth Raghunathan . . . . .	2799
<b>Nanoparticles: Synthesis in Polymer Substrates</b> / Bai Yang and Junhu Zhang . . . . .	2912

---

**Dissolution and Etching**

<b>Anodization Patterned on Aluminum Surfaces</b> / Juchao Yan, G. V. Rama Rao, Plamen B. Atanassov, and Gabriel P. López . . . . .	203
<b>Metal Nanostructures: Synthesis Controlled by Photoexcitation</b> / Kei Murakoshi and Yoshihiro Nakato . . . . .	2091
<b>Nanoporosity Evolution on Dealloying</b> / Jonah Erlebacher . . . . .	2938
<b>Nanotube Sensors</b> / Marc Wirtz and Charles R. Martin . . . . .	3109
<b>Porous Alumina Templates for Nanofabrication</b> / Latika Menon . . . . .	3525

---

**Lithography**

<b>AFM: Nanolithography on Organized Films</b> / Seunghyun Lee and Haiwon Lee . . . . .	119
<b>Conducting Polymer Nanopatterns</b> / Shaun F. Filocamo and Mark W. Grinstaff . . . . .	954
<b>Dip-Pen Nanolithography: Optical Inks</b> / Brandon L. Weeks, Aleksandr Noy, Abigail E. Miller, Jennifer E. Klare, Bruce W. Woods, and James J. De Yoreo . . . . .	1084
<b>Laser-Based Deposition: Patterning</b> / Edward M. Nadgorny and Jaroslaw Drelich . . . . .	1749
<b>Litho-to-Nano Link</b> / Gianfranco Cerofolini, Dario Narducci, and Elisabetta Romano . . . . .	1890
<b>Nanolithography: Length Scale Limitations</b> / Takashi Ito . . . . .	2779

<b>Nanomaterials and Nanodevices: Ion-Beam Technology</b> / Dmitri Litvinov and Sakhrat Khizroev	2825
<b>Polymer Molding: Nanostructure Replication</b> / Daniel B. Wolfe, J. Christopher Love, and George M. Whitesides	3456
<b>Printed and Molded Nanostructures: Photonic Applications</b> / John A. Rogers	3559
<b>Scanning Near-Field Photolithography</b> / Graham J. Leggett	3709
<b>Scanning Probe Lithography: Polymeric and Biomolecular Nanostructures</b> / Stefan Zauscher	3721

### ***Mechanosynthesis***

<b>Nanocrystallization</b> / John H. Perepezko	2655
<b>Nanophase Powders: Mechanosynthesis</b> / F. Miani, F. Maurigh, and F. Delogu	2923
<b>Nanostructured Alloys: Cryomilling Synthesis and Behavior</b> / David Witkin, Piers Newbery, Bing Q. Han, and Enrique J. Lavernia	2958
<b>Nanostructured Materials: Synthesis by Mechanical Attrition</b> / Carl C. Koch	3019
<b>Nanostructured Materials: Synthesis by Mechanical Means</b> / H.-J. Fecht	3030

### ***Sol-Gel Synthesis***

<b>Cyanogels: Processing by Spin Coating</b> / Shu Zhu and Andrew B. Bocarsly	1029
<b>Metal Oxide Nanoparticles</b> / Ryan M. Richards	2126
<b>Mixed Metal Oxide Nanoparticles</b> / Pramesh N. Kapoor, Ajay Kumar Bhagi, Ravichandra S. Mulukutla, and Kenneth J. Klabunde	2280
<b>Nanomaterials: Manufacturing, Processing, and Applications</b> / Pramod K. Sharma, Weifang Miao, Anit Giri, and Srikanth Raghunathan	2799
<b>Polymer Nanofibers Prepared by Electrospinning</b> / Roland Dersch, Andreas Greiner, and Joachim H. Wendorff	3480

### ***Synthesis in Supercritical Fluids***

<b>Metal Nanoparticles Prepared in Supercritical Carbon Dioxide</b> / Harry W. Rollins	2072
<b>Microweighing in Supercritical Carbon Dioxide</b> / You-Ting Wu and Christine S. Grant	2253
<b>Nanostructured Materials: Synthesis in Supercritical Fluids</b> / Yuehe Lin, Xiang-Rong Ye, and Chien M. Wai	3040
<b>Templating Aerogels for Tunable Nanoporosity</b> / Aydin K. Sunol and Sermin G. Sunol	4294

## **Nanostructures and Nanophase Structures**

### ***Advanced Ceramics***

<b>Functionalization of Surface Layers on Ceramics</b> / Toshihiro Ishikawa	1375
<b>Iron Oxide Nanoparticles</b> / Mamoru Senna	1688
<b>Magnetic Nanomaterials: Nonconventional Synthesis and Chemical Design</b> / Luminita Patron, Ioana Mindru, and Gabriela Marinescu	1968
<b>Nanoceramics</b> / Abbas Khaleel	2531
<b>Nanoceramics: Thermal Conductivity</b> / Paul G. Klemens	2539
<b>Nanostructured Silica and Silica-Derived Materials</b> / Ho-Cheol Kim and Geraud Dubois	3063
<b>Tungsten Carbide–Cobalt Nanocomposites</b> / Purnesh Seegopaul and Zhigang Zak Fang	4390
<b>Ytria-Tetragonally Stabilized Zirconia</b> / R. Allen Kimel	4414

---

**Nanostructures and Nanophase Structures (*cont'd.*)**

---

**Arrays and Superlattices**

<b>Bio-Microarrays</b> / Günter E.M. Tovar and Achim Weber	298
<b>Colloidal Nanoparticles: Aggregation Patterns at Surfaces</b> / Hamidou Haidara and Karine Mougin	882
<b>Conducting Polymer Nanopatterns</b> / Shaun F. Filocamo and Mark W. Grinstaff	954
<b>Nanocrystals: Synthesis and Mesoscale Organization</b> / G. U. Kulkarni, P. John Thomas, and C.N.R. Rao	2676
<b>Nanoparticle Arrays: Optical and Electronic Applications</b> / Ilona Kretzschmar and Mark A. Reed	2856
<b>Printed and Molded Nanostructures: Photonic Applications</b> / John A. Rogers	3559
<b>Quantum Dot Arrays: Electromagnetic Properties</b> / Sergey A. Maksimenko and Gregory Ya. Slepyan	3606
<b>Quantum Dots: Phonons in Self-Assembled Multiple Germanium Structures</b> / Jianlin Liu, Aleksandr Khitun, and Kang L. Wang	3673
<b>Supramolecular Networks Synthesized in Nanoparticle–Polymer Mixtures</b> / Anna C. Balazs and Gavin A. Buxton	4240

---

**Core–Shell and Asymmetric Nanostructures**

<b>Capsules: Polymer Microcapsules</b> / Gleb B. Sukhorukov	508
<b>Capsules: Specific Layer Structures</b> / Lars Dähne and Claire S. Peyratout	522
<b>Core–Shell Hydrogel Nanoparticles</b> / Clinton D. Jones and L. Andrew Lyon	993
<b>Core–Shell Nanospheres, Hollow Capsules, and Bottles</b> / Gang Zhang, Kai Zhang, Yi Yu, and Bai Yang	1003
<b>Dissymmetrical Nanoparticles</b> / Stéphane Reculosa, Christophe Mingotaud, Etienne Duguet, and Serge Ravaine	1093
<b>Metal Nanostructures: Synthesis by Soft Chemical Methods</b> / Yugang Sun and Younan Xia	2105
<b>Nanobridges: Thermal Properties</b> / Jeong Won Kang and Ho Jung Hwang	2522
<b>Nanoencapsulation of Bioactive Substances</b> / Yury E. Shapiro	2707
<b>Oil-Filled Nanocapsules</b> / Royale S. Underhill	3234

---

**Layered Nanostructures**

<b>Bimetallic Layered Nanocomposites</b> / Amit Misra and Richard G. Hoagland	288
<b>Charge Transport in Multilayer Nanostructures</b> / Daniel M. Schaadt	834
<b>Dimensionally Graded Semiconductor Nanoparticle Films</b> / Arif A. Mamedov, Nicholas A. Kotov, and Nataliya N. Mamedova	1062
<b>Epoxy-Layered Silicate Nanocomposites</b> / Chenggang Chen and Tia Benson Tolle	1284
<b>Nanostructures Based on Layered Transition-Metal Chalcogenides</b> / Russell R. Chianelli and Myriam Perez de la Rosa	3080
<b>Structural Transitions in Thin Films</b> / Rajarshi Banerjee, Gregory B. Thompson, and Hamish L. Fraser	4217

---

**Metal Nanoparticles**

<b>Catalysis by Supported Gold Nanoclusters</b> / D. Wayne Goodman	744
<b>Colloidal Nanometals as Fuel Cell Catalyst Precursors</b> / Helmut Bönnemann and K. S. Nagabhushana	863
<b>Gold Nanoclusters: Structural Disorder</b> / Ignacio L. Garzón	1412

<b>Iron Nanoparticles</b> / Dale L. Huber	1681
<b>Metal Nanoparticle Catalysts</b> / Naoki Toshima	2052
<b>Metal Nanoparticles Prepared in Supercritical Carbon Dioxide</b> / Harry W. Rollins	2072
<b>Metallic Nanopowders</b> / Frederick Tepper, Marat I. Lerner, and David S. Ginley	2153
<b>Nanoporosity Evolution on Dealloying</b> / Jonah Erlebacher	2938
<b>Nanostructured Composites: Titanium-Based Alloys</b> / Jürgen Eckert, Jayanta Das, and Ki Buem Kim	2996
<b>Noble Metal Nanoparticles on Carbon Fibers</b> / Dmitri A. Bulushev and Igor Yuranov	3195
<b>Palladium Nanoclusters</b> / Kiyotomi Kaneda, Kwang-Min Choi, Tomoo Mizugaki, and Kohki Ebitani	3309

---

### ***Nanocrystals and Nanopowders***

<b>Cubosomes: Bicontinuous Liquid Crystalline Nanoparticles</b> / Patrick T. Spicer	1018
<b>Metal Oxide Nanoparticles</b> / Ryan M. Richards	2126
<b>Nanocrystal Arrays: Self-Assembly and Physical Properties</b> / Xiao-Min Lin, Raghuvver Parthasarathy, and Heinrich M. Jaeger	2568
<b>Nanocrystalline Materials: Fatigue</b> / Alexei Yu. Vinogradov, and Sean R. Agnew	2602
<b>Nanocrystalline Materials: Synthesis and Properties</b> / Alexandr I. Gusev	2621
<b>Nanocrystallization</b> / John H. Perepezko	2655
<b>Nanocrystals Synthesized in Colloidal Self-Assemblies</b> / M. P. Pileni	2581
<b>Nanodiamonds</b> / Jean-Yves Raty and Giulia Galli	2697
<b>Nanomaterials: Advances in Technology and Industry</b> / Ganesh Skandan and Amit Singhal	2788
<b>Nanomaterials: Manufacturing, Processing, and Applications</b> / Pramod K. Sharma, Weifang Miao, Anit Giri, and Srikanth Raghunathan	2799
<b>Nanoparticles: Generation, Functionalization, and Ion Sensing</b> / Jason J. Davis and Paul D. Beer	2898
<b>Permanent Magnets Based on Nanostructured Intermetallic Alloys</b> / Paul McGuinness, Andraž Kocjan, and Spomenka Kobe	3328

---

## **Optical Properties and Optoelectronic Devices**

---

### ***Photonic Crystals and Nonlinear Optical Media***

<b>Nanoparticle Arrays: Optical and Electronic Applications</b> / Ilona Kretschmar and Mark A. Reed	2856
<b>Nanoporous Anodic Alumina: Structural and Optical Anisotropy</b> / E. Stefan Kooij, Aurelian C. Gâlcă, Herbert Wormeester, and Bene Poelsema	2947
<b>Nanostructures Derived from Phase-Separated Polymers</b> / Michael R. Bockstaller and Edwin L. Thomas	3093
<b>Nonlinear Optical Materials from Self-Assembled Organic Films</b> / Matthew Guzy, Richey M. Davis, Patrick J. Neyman, Charles Brands, J. R. Heflin, Harry W. Gibson, and Kevin E. Van Cott	3206
<b>Photonic Crystal Fibers</b> / P. St. J. Russell, J. C. Knight, T. A. Birks, and P. J. Roberts	3356
<b>Porphyritic Materials: Self-Assembly on Surfaces</b> / Charles Michael Drain, James D. Batteas, Gabriela Smeureanu, and Sandeep Patel	3539
<b>Printed and Molded Nanostructures: Photonic Applications</b> / John A. Rogers	3559
<b>Structural Color</b> / Pete Vukusic	4195

---

**Optical Properties and Optoelectronic Devices (*cont'd.*)**

---

**Quantum Confinement Effects**

<b>Cadmium Selenide Quantum Dots</b> / Kenzo Maehashi and Hisao Nakashima . . . . .	477
<b>Cadmium Selenide Quantum Rods: Anisotropy</b> / Liang-shi Li and A. Paul Alivisatos . . . . .	487
<b>Core-Shell Hydrogel Nanoparticles</b> / Clinton D. Jones and L. Andrew Lyon . . . . .	993
<b>Indium Arsenide Islands on Silicon</b> / P. C. Sharma and Kang L. Wang . . . . .	1582
<b>Luminescence of Nanoparticle-Labeled Antibodies and Antigens</b> / Shaopeng Wang and Nicholas A. Kotov . . . . .	1915
<b>Membrane-Coated Nanoparticles: Photochemistry</b> / Ulrich Siggel, Guangtao Li, and Jürgen-Hinrich Fuhrhop . . . . .	2012
<b>Metallic Quantum Dots</b> / J. P. Wilcoxon . . . . .	2176
<b>Optical Molecular Devices</b> / A. Prasanna de Silva and Nathan D. McClenaghan . . . . .	3251
<b>Quantum Dot Lasers</b> / Mikhail V. Maximov and Nikolai N. Ledentsov . . . . .	3617
<b>Quantum Dots: Electronic Coupling and Structural Ordering</b> / Glenn S. Solomon . . . . .	3634
<b>Self-Assembled Quantum Dots: Electronic Structures and Optical Properties</b> / Andrew Williamson . . . . .	3789
<b>Self-Formed Quantum Dots: Structural and Optical Characterization</b> / Shun-ichi Gonda and Hajime Asahi . . . . .	3877
<b>Semiconductor Nanowires: Nanoscale Electronics and Optoelectronics</b> / Yu Huang, Xiangfeng Duan, and Charles M. Lieber . . . . .	3910
<b>Silicon Nanoclusters: Simulations</b> / Aaron Puzder . . . . .	4021
<b>Silicon Nanocrystals: Quantum Confinement</b> / James R. Chelikowsky . . . . .	4033
<b>Thermal Effect on the Luminescence Properties of Quantum Dots</b> / X. B. Zhang and R. D. Dupuis . . . . .	4316

---

**Surface Plasmons and Raman Scattering**

<b>Carbon Nanotubes: Optical Properties</b> / R. Saito, Mildred S. Dresselhaus, G. Dresselhaus, A. Jorio, A. G. Souza Filho, and M. A. Pimenta . . . . .	679
<b>Metal Nanoparticle Ensembles: Collective Optical Properties</b> / Alexander Wei . . . . .	2064
<b>Metal Nanostructures: Synthesis Controlled by Photoexcitation</b> / Kei Murakoshi and Yoshihiro Nakato . . . . .	2091
<b>Nanocrystals: Size-Dependent Properties and Emerging Applications</b> / G. U. Kulkarni, P. John Thomas, and C.N.R. Rao . . . . .	2665
<b>Optical Nanosensors and Nanobiosensors</b> / Brian M. Cullum . . . . .	3258
<b>Quantum Dots: Inelastic Light Scattering from Electronic Excitations</b> / Christian Schüller . . . . .	3661
<b>Surface-Enhanced Raman Scattering</b> / Adam M. Schwartzberg and Jin Z. Zhang . . . . .	4250
<b>Surface Plasmon Spectra of Silver and Gold Nanoparticle Assemblies</b> / Mondona Zangeneh and Roger Terrill . . . . .	4271

---

**Polymer Nanomaterials**

---

**Electronic Materials and Nanocomposites**

<b>Conducting Polymer Nanotubes</b> / Seung Il Cho and Sang Bok Lee . . . . .	965
<b>Fluorescence-Voltage Single Molecule Spectroscopy</b> / Young Jong Lee, Andre J. Gesquiere, So-Jung Park, and Paul F. Barbara . . . . .	1300

<b>Litho-to-Nano Link</b> / Gianfranco Cerofolini, Dario Narducci, and Elisabetta Romano . . . . .	1890
<b>Low-Dielectric Constant Materials</b> / Robert D. Miller . . . . .	1901
<b>Polymer Nanocomposites with Nanoparticle and Carbon Nanotube Fillers</b> / B. J. Ash, A. Eitan, and L. S. Schadler . . . . .	3466
<b>Polymer–Clay Nanocomposites and Polymer Brushes</b> / Xiaowu Fan, Chuanjun Xia, and Rigoberto C. Advincula . . . . .	3417

<b>Quantum Dots: Phonons in Self-Assembled Multiple Germanium Structures</b> / Jianlin Liu, Aleksandr Khitun, and Kang L. Wang . . . . .	3673
<b>Self-Assembled Quantum Dots: Electronic Structures and Optical Properties</b> / Andrew Williamson . . . . .	3789
<b>Silicon Nanoclusters: Simulations</b> / Aaron Puzder . . . . .	4021
<b>Silicon Nanocrystals: Quantum Confinement</b> / James R. Chelikowsky . . . . .	4033
<b>Thermal Effect on the Luminescence Properties of Quantum Dots</b> / X. B. Zhang and R. D. Dupuis . . . . .	4316

## Sensors and Actuators

### *Biosensors and Biomimetic Chemistry*

<b>Biomedical Applications: Novel Materials and Devices</b> / J. Zachary Hilt and Mark E. Byrne . . . . .	339
<b>Biomimetic Receptors for Carboxylate Recognition</b> / Rocco Ungaro, Alessandro Casnati, and Francesco Sansone . . . . .	372
<b>Biosensor Applications: Porous Silicon Microcavities</b> / Benjamin L. Miller, Philippe M. Fauchet, Scott R. Horner, and Selena Chan . . . . .	408
<b>Biosensor Applications: Surface Engineering</b> / Genady Zhavnerko and Kwon-Soo Ha . . . . .	416
<b>Biosensors Based on Carbon Nanotubes</b> / Yuehe Lin, Wassana Yantasee, Fang Lu, Joseph Wang, Mustafa Musameh, Yi Tu, and Zhifeng Ren . . . . .	428
<b>Biosensors: Fractal Analysis of Binding Kinetics</b> / Harshala Butala and Ajit Sadana . . . . .	441
<b>Chemical Warfare Agents: Biosensors for Detection</b> / Elias Greenbaum, Miguel Rodriguez, Jr., and Charlene A. Sanders . . . . .	842
<b>DNA-Based Nanoinstrument Design</b> / Alexander Hillisch and Stephan Diekmann . . . . .	1102
<b>Layer-by-Layer Electrostatic Self-Assembly</b> / Michael J. McShane and Yuri M. Lvov . . . . .	1823
<b>Ligand–Receptor Systems with Infinite Binding Affinity</b> / Claude F. Meares . . . . .	1853
<b>Lipid Membranes: Nanostructure and Dynamic Organization</b> / J. Gaudioso and D. Y. Sasaki . . . . .	1859
<b>Liquid Crystals and Nanostructured Surfaces: Detecting Protein Binding</b> / Yan-Yeung Luk . . . . .	1878
<b>Nanobiological Sensors</b> / Nathaniel Cady, Anand Gadre, and Alain E. Kaloyeros . . . . .	2514
<b>Optical Nanosensors and Nanobiosensors</b> / Brian M. Cullum . . . . .	3258

### *Chemical Imaging and Molecular Sensing*

<b>Near-Field Raman Spectroscopy: Resolution Enhancement</b> / Satoshi Kawata and Yasushi Inouye . . . . .	3177
<b>Near-Field Scanning Optical Microscopy: Chemical Imaging</b> / Bogdan Dragnea . . . . .	3185
<b>Optical Molecular Devices</b> / A. Prasanna de Silva and Nathan D. McClenaghan . . . . .	3251
<b>Surface-Enhanced Raman Scattering</b> / Adam M. Schwartzberg and Jin Z. Zhang . . . . .	4250

### *Chemical Sensors*

<b>Electrically Functional Nanostructures</b> / Orlin D. Velev and Simon O. Lumsdon . . . . .	1171
<b>Metallomacrocyclic Selective Ion Receptors</b> / Kay Severin . . . . .	2202
<b>Molecular Probes of Cation–Arene Interactions</b> / George W. Gokel . . . . .	2369
<b>Molecular Receptor-Modified Metal Nanoparticles</b> / Jian Liu . . . . .	2377

---

**Sensors and Actuators (cont'd.)**

---

**Chemical Sensors (cont'd.)**

- Molecular Self-Assembly: Environmental and Sensing Applications** / Glen E. Fryxell,  
R. Shane Addleman, S. V. Mattigod, Yuehe Lin, T. S. Zemanian, H. Wu,  
Jerome C. Birnbaum, J. Liu, and X. Feng . . . . . 2387
- Monolayer-Protected Metal Nanoparticles: Chemical Sensing and Gas Chromatography** /  
Jay W. Grate, David A. Nelson, Rhonda Skaggs, Robert E. Synovec, and  
Gwen M. Gross . . . . . 2460
- Phase Transfer of Monosaccharides through Noncovalent Interactions** / Elizabeth K. Auty  
and Anthony P. Davis . . . . . 3347
- Sensors Based on Chemicurrents** / B. Roldan Cuenya and E. W. McFarland . . . . . 3973
- 

**Electrochemical Sensors**

- Carbon Nanotubes: Electrochemical Modification** / Kannan Balasubramanian,  
Marko Burghard, and Klaus Kern . . . . . 620
- Electrochemical Sensors: Functionalized Silica** / Yuehe Lin, Wassana Yantasee, and  
Glen E. Fryxell . . . . . 1196
- Electrochemical Toxicity Sensors** / James F. Rusling . . . . . 1207
- Nanoparticles: Generation, Functionalization, and Ion Sensing** / Jason J. Davis and  
Paul D. Beer . . . . . 2898
- Nanotube Sensors** / Marc Wirtz and Charles R. Martin . . . . . 3109
- 

**Molecular Motors, Switches and Actuators**

- Electronic Switches** / Richard J. Nichols, David J. Schiffrin, and Wolfgang Haiss . . . . . 1230
- Molecular Motor-Powered Nanodevices: Control Mechanisms** / Jacob J. Schmidt and  
Carlo D. Montemagno . . . . . 2347
- Motor Proteins in Synthetic Materials and Devices** / Henry Hess, George Bachand, and  
Viola Vogel . . . . . 2484
- Single-Walled Carbon Nanotubes: Geometries, Electronic Properties, and Actuation** /  
Guangyu Sun, Marc Nicklaus, and Miklos Kertesz . . . . . 4085
- 

**Spontaneous Self-Organization of Matter**

---

**Architecture and Growth Modes**

- Indium Arsenide Islands on Silicon** / P. C. Sharma and Kang L. Wang . . . . . 1582
- Nanoarrays: Electrochemically Self-Assembled** / S. Bandyopadhyay . . . . . 2502
- Nanocrystalline Zeolites** / Vicki H. Grassian and Sarah C. Larsen . . . . . 2646
- Nanocrystals: Synthesis and Mesoscale Organization** / G. U. Kulkarni,  
P. John Thomas, and C.N.R. Rao . . . . . 2676
- Porphyritic Materials: Self-Assembly on Surfaces** / Charles Michael Drain,  
James D. Batteas, Gabriela Smeureanu, and Sandeep Patel . . . . . 3539
- Ring Structures from Nanoparticles and Other Nanoscale Building Blocks** /  
Zhen Liu and Rastislav Levicky . . . . . 3694
- 

**Arrays and Superlattices**

- Bio-Microarrays** / Günter E.M. Tovar and Achim Weber . . . . . 298
- Colloid Systems: Micelles and Nanocrystals** / B.L.V. Prasad and Savka I. Stoeva . . . . . 856

<b>Metal Nanoparticle Ensembles: Collective Optical Properties</b> / Alexander Wei	2064
<b>Molecular Electronics: Logic and Memory</b> / Dustin K. James and James M. Tour	2303
<b>Nanocolloidal Gold Films: Self-Assembly</b> / E. Stefan Kooij, E.A. Martijn Brouwer, Agnes A. Mewe, Herbert Wormeester, and Bene Poelsema	2545
<b>Nanocrystal Arrays: Self-Assembly and Physical Properties</b> / Xiao-Min Lin, Raghuvver Parthasarathy, and Heinrich M. Jaeger	2568
<b>Nanoparticle Arrays: Optical and Electronic Applications</b> / Ilona Kretzschmar and Mark A. Reed	2856
<b>Self-Assembled Thin Films: Optical Characterization</b> / Herbert Wormeester, E. Stefan Kooij, and Bene Poelsema	3829
<b>Stability of Nanostructures on Surfaces</b> / Karsten Pohl	4167
<b>Virus Nanoparticles: Adsorption and Organization on Substrates</b> / Jiyu Fang	4407

### **Host-Guest Chemistry**

<b>Guests within Hydrophobic Pockets: Conventional Synthesis</b> / Bruce C. Gibb	1429
<b>Guests within Hydrophobic Pockets: Self-Assembly</b> / Bruce C. Gibb	1451
<b>Interfacial Phenomena: Chemical Selectivity</b> / Vinay K. Gupta	1662
<b>Metallomacrocyclic Selective Ion Receptors</b> / Kay Severin	2202

### **Intermolecular Association and Phase Behavior**

<b>Block Copolymer Nanoparticles</b> / Sandrine Pensec, Daniel Portinha, Laurent Bouteiller, and Christophe Chassenieux	467
<b>Microgel Dispersions: Colloidal Forces and Phase Behavior</b> / Jianzhong Wu and Zhibing Hu	2243
<b>Nanoparticle Suspensions: Phase Behavior</b> / Subramanian Ramakrishnan and Charles F. Zukoski	2878
<b>Nanostructures Derived from Phase-Separated Polymers</b> / Michael R. Bockstaller and Edwin L. Thomas	3093

### **Langmuir-Blodgett Films**

<b>AFM: Nanolithography on Organized Films</b> / Seunghyun Lee and Haiwon Lee	119
<b>Biosensor Applications: Surface Engineering</b> / Genady Zhavnerko and Kwon-Soo Ha	416
<b>Electrochemical Langmuir Trough</b> / Natalia Varaksa, Thomas F. Magnera, and Josef Michl	1189
<b>Heterogeneous Surfaces with Nanosized Channel Lattices</b> / Lifeng Chi, Michael Gleiche, Steven Lenhart, and Nan Lu	1515
<b>Langmuir-Blodgett Films</b> / Ursula Mazur	1738
<b>Nanowires and Nanobelts: Mechanical Properties</b> / Zhong Lin Wang	3146
<b>Organosilanes: Molecular Assembly</b> / Atsushi Takahara	3287
<b>Polyelectrolyte Films with Incorporated Carbon Nanotubes</b> / Jason H. Rouse and Peter T. Lillehei	3396
<b>Self-Assembled Silane Monolayers: Cyano-to-Carboxylic Termination Conversion</b> / Chandra Sekhar Palla and Alexander Couzis	3801

### **Layer-by-Layer Assembly**

<b>Barrier Properties of Ordered Polymer Nanocomposites</b> / Bon-Cheol Ku, Alexandre Blumstein, Jayant Kumar, Lynne A. Samuelson, and Dong Wook Kim	267
<b>Layer-by-Layer Assembly of Electroactive Thin Films to Layered Carbon Electrodes</b> / Tarek R. Farhat	1764

---

**Spontaneous Self-Organization of Matter (cont'd.)**

---

**Layer-by-Layer Assembly (cont'd.)**

<b>Layer-by-Layer Assembly of Gold Nanoclusters with Self-Assembled Monolayers</b> / <i>Kohei Uosaki, Wenbo Song, Masayuki Okamura, and Toshihiro Kondo</i> . . . . .	1773
<b>Layer-by-Layer Assembly of Semiconducting and Photoreactive Bolaform Amphiphiles</b> / <i>Jason Locklin, Derek Patton, Chuanjun Xia, Xiaowu Fan, and Rigoberto C. Advincula</i> . . . . .	1798
<b>Layer-by-Layer Assembly of Thin Films of Mixed Nanoparticles</b> / <i>Jianchang Guo,</i> <i>Encai Hao, and Tianquan Lian</i> . . . . .	1813
<b>Layer-by-Layer Electrostatic Self-Assembly</b> / <i>Michael J. McShane and Yuri M. Lvov</i> . . . . .	1823
<b>Layered Double Hydroxides: Self-Assembly and Multiple Phases</b> / <i>Zhi Ping Xu and</i> <i>Paul S. Braterman</i> . . . . .	1841
<b>Metal Nanostructures: Synthesis by Soft Chemical Methods</b> / <i>Yugang Sun and Younan Xia</i> . . . . .	2105
<b>Nanoparticles: Synthesis in Polymer Substrates</b> / <i>Bai Yang and Junhu Zhang</i> . . . . .	2912

---

**Self-Assembled Monolayers**

<b>Adhesion: Coated Surfaces, Effect of Humidity</b> / <i>Joan E. Curry and Sungsoo Kim</i> . . . . .	32
<b>Magnetic Nanoparticles for Granular Recording Media</b> / <i>David E. Nikles and J. W. Harrell</i> . . . . .	2001
<b>Metal Nanoparticles: Self-Assembly into Electronic Nanostructures</b> / <i>Venugopal Santhanam</i> <i>and Ronald P. Andres</i> . . . . .	2079
<b>Monolayer-Protected Metal Nanoparticles: Synthesis</b> / <i>Young-Seok Shon</i> . . . . .	2469
<b>Nonlinear Optical Materials from Self-Assembled Organic Films</b> / <i>Matthew Guzy,</i> <i>Richey M. Davis, Patrick J. Neyman, Charles Brands, J. R. Heflin,</i> <i>Harry W. Gibson, and Kevin E. Van Cott</i> . . . . .	3206
<b>Scanning Near-Field Photolithography</b> / <i>Graham J. Leggett</i> . . . . .	3709
<b>Self-Assembled Monolayers: Adsorption and Desorption from Alkanethiols on Gold</b> / <i>Pieter Stroeve</i> . . . . .	3738
<b>STEM of Chiral Pair Self-Assembled Monolayers</b> / <i>Yuguang Cai and Steven L. Bernasek</i> . . . . .	4176

---

**Self-Assembled Quantum Dots**

<b>Cadmium Selenide Quantum Dots</b> / <i>Kenzo Maehashi and Hisao Nakashima</i> . . . . .	477
<b>Quantum Dots: Inelastic Light Scattering from Electronic Excitations</b> / <i>Christian Schüller</i> . . . . .	3661
<b>Quantum Dots: Phonons in Self-Assembled Multiple Germanium Structures</b> / <i>Jianlin Liu,</i> <i>Aleksandr Khitun, and Kang L. Wang</i> . . . . .	3673
<b>Self-Assembled Quantum Dots: Atomic Scale Engineering</b> / <i>S. Oktyabrsky and</i> <i>Alain E. Kaloyeros</i> . . . . .	3775
<b>Self-Assembled Quantum Dots: Electronic Structures and Optical Properties</b> / <i>Andrew Williamson</i> . . . . .	3789
<b>Thermal Effect on the Luminescence Properties of Quantum Dots</b> / <i>X. B. Zhang and</i> <i>R. D. Dupuis</i> . . . . .	4316

---

**Supramolecular Structure Control**

<b>AFM: Hydrogen-Bonded Nanostructures</b> / <i>Holger Schönherr, Mercedes Crego-Calama,</i> <i>G. Julius Vancso, and David N. Reinhoudt</i> . . . . .	76
<b>Biomimetic Design of Self-Assembling Systems</b> / <i>Mila Boncheva and George M. Whitesides</i> . . . . .	364
<b>Controlled Size and Shape Supramolecular Aggregates on Solid Surfaces</b> / <i>Takashi Yokoyama,</i> <i>Toshiya Kamikado, Shiyoshi Yokoyama, and Shinro Mashiko</i> . . . . .	974
<b>Cyclic Peptides: Self-Assembly in Hydrogen-Bonded Nanotubes</b> / <i>Roberto J. Brea and</i> <i>Juan R. Granja</i> . . . . .	1037

<b>Inorganic Nanotubes: Synthesis by Chemical Transport Reaction</b> / Maja Remskar	1606
<b>Nanoencapsulation of Bioactive Substances</b> / Yury E. Shapiro	2707
<b>Polyelectrolyte–Surfactant Complex Nanoparticles</b> / Hans-Peter Hentze	3403
<b>Polymer-Mediated Self-Assembly of Nanoparticles</b> / Tyler B. Norsten, Amitav Sanyal, Roy Shenhar, and Vincent M. Rotello	3443
<b>Self-Assembled Structures</b> / Anna Cristina Samia and Xiao-Min Lin	3816
<b>Self-Assembly Directed by NH–O Hydrogen Bonding</b> / Katrina A. Jolliffe and Leonard F. Lindoy	3864
<b>Self-Assembly of Coordination Cages</b> / Laura Pirondini and Enrico Dalcanale	3848
<b>Self-Organized Superstructures: Molecular Design</b> / Makoto Tadokoro	3886

### **Surface-Mediated Assembly**

<b>Adsorption on Heterogeneous Surfaces</b> / Vinay K. Gupta and Yu-Wen Huang	41
<b>Biosurfaces: Water Structure at Interfaces</b> / Yan-Yeung Luk	453
<b>Charge Transfer in Metal–Molecule Heterostructures</b> / Debasish Kuila, David B. Janes, and Clifford P. Kubiak	819
<b>Colloidal Structures on Patterned Surfaces</b> / Aránzazu del Campo, Anne-Sophie Duwez, Charles-André Fustin, and Ulrich Jonas	907
<b>Island Surfaces: Fabrication on Self-Assembled Monolayers</b> / Hongjie Liu, Charles Maldarelli, M. Lane Gilchrist, and Alexander Couzis	1708
<b>Liquid Crystals and Nanostructured Surfaces: Detecting Protein Binding</b> / Yan-Yeung Luk	1878
<b>Molecular Self-Assembly: Environmental and Sensing Applications</b> / Glen E. Fryxell, R. Shane Addleman, S. V. Mattigod, Yuehe Lin, T. S. Zemanian, H. Wu, Jerome C. Birnbaum, J. Liu, and X. Feng	2387
<b>Self-Assembled Monolayers: Chemical and Physical Modification under Vacuum</b> / Jessica Torres, Anthony J. Wagner, Christopher C. Perry, Glenn M. Wolfe, and D. Howard Fairbrother	3747
<b>Self-Assembled Monolayers: Surface Nanostructure Effect on Wetting</b> / Jun Yang, Jingmin Han, Kelvin Isaacson, and Daniel Y. Kwok	3762
<b>Self-Assembly and Chirality of Molecules at Interfaces</b> / Dalia G. Yablon	3840
<b>Silane Self-Assembled Monolayers: Nanoscale Domains by Sequential Adsorption</b> / Nitin Kumar	3984
<b>STEM: Self-Assembly on Graphite</b> / Thomas Müller	4185

### **Templated Assembly**

<b>Oil-Filled Nanocapsules</b> / Royale S. Underhill	3234
<b>Protein Nanotubes as Building Blocks</b> / Hiroshi Matsui	3578
<b>Template-Directed Assembly of Dinuclear Triple-Stranded Helicates</b> / Markus Albrecht	4283
<b>Templating Aerogels for Tunable Nanoporosity</b> / Aydin K. Sunol and Sermin G. Sunol	4294

## **Supramolecular Chemistry**

### **Molecular Recognition**

<b>Biosensor Applications: Porous Silicon Microcavities</b> / Benjamin L. Miller, Philippe M. Fauchet, Scott R. Horner, and Selena Chan	408
<b>DNA Hybridization: Electronic Control</b> / Kimberly Hamad-Schifferli	1122
<b>Interfacial Phenomena: Chemical Selectivity</b> / Vinay K. Gupta	1662
<b>Ligand–Receptor Systems with Infinite Binding Affinity</b> / Claude F. Meares	1853

---

**Supramolecular Chemistry (cont'd.)**

**Molecular Recognition (cont'd.)**

<b>Lipid Membranes: Nanostructure and Dynamic Organization</b> / J. Gaudioso and D. Y. Sasaki . . . . .	1859
<b>Molecular Probes of Cation–Arene Interactions</b> / George W. Gokel . . . . .	2369
<b>Molecular Receptor-Modified Metal Nanoparticles</b> / Jian Liu . . . . .	2377
<b>Nanomaterials and Molecular Devices: De Novo Design Theory</b> / Kwang S. Kim, P. Tarakeshwar, and Han Myoung Lee . . . . .	2815
<b>Nucleoside- and Nucleobase-Substituted Oligopyrrolic Macrocycles</b> / Vladimír Král, Martin Valík, Tatiana V. Shishkanova, and Jonathan L. Sessler . . . . .	3216
<b>Phase Transfer of Monosaccharides through Noncovalent Interactions</b> / Elizabeth K. Auty and Anthony P. Davis . . . . .	3347

---

**Selective Self-Assembly**

<b>AFM: Hydrogen-Bonded Nanostructures</b> / Holger Schönherr, Mercedes Crego-Calama, G. Julius Vancso, and David N. Reinhoudt . . . . .	76
<b>Anion-Templated Self-Assembly: Inorganic Compounds</b> / Louise S. Evans and Philip A. Gale . . . . .	178
<b>Controlled Size and Shape Supramolecular Aggregates on Solid Surfaces</b> / Takashi Yokoyama, Toshiya Kamikado, Shiyoshi Yokoyama, and Shinro Mashiko . . . . .	974
<b>Cyclic Peptides: Self-Assembly in Hydrogen-Bonded Nanotubes</b> / Roberto J. Brea and Juan R. Granja . . . . .	1037
<b>Porphyric Materials: Self-Assembly on Surfaces</b> / Charles Michael Drain, James D. Batteas, Gabriela Smeureanu, and Sandeep Patel . . . . .	3539
<b>Self-Assembly Directed by NH–O Hydrogen Bonding</b> / Katrina A. Jolliffe and Leonard F. Lindoy . . . . .	3864
<b>Template-Directed Assembly of Dinuclear Triple-Stranded Helicates</b> / Markus Albrecht . . . . .	4283

---

**Supramolecular Networks and Templates**

<b>Anion-Templated Self-Assembly: Organic Compounds</b> / Paul D. Beer and Mark R. Sambrook . . . . .	191
<b>Axle Molecules Threaded through Macrocycles</b> / Daryle H. Busch and Thomas Clifford . . . . .	249
<b>Block Copolymer Nanoparticles</b> / Sandrine Pensec, Daniel Portinha, Laurent Bouteiller, and Christophe Chassenieux . . . . .	467
<b>Carbon Nanotubes: Supramolecular Mechanics</b> / Boris I. Yakobson and Luise S. Couchman . . . . .	722
<b>Coordination Framework Topology</b> / Neil R. Champness and Neil S. Oxtoby . . . . .	984
<b>Guests within Hydrophobic Pockets: Conventional Synthesis</b> / Bruce C. Gibb . . . . .	1429
<b>Guests within Hydrophobic Pockets: Self-Assembly</b> / Bruce C. Gibb . . . . .	1451
<b>Metallomacrocyclic Selective Ion Receptors</b> / Kay Severin . . . . .	2202
<b>Organofullerenes in Water</b> / Eiichi Nakamura and Hiroyuki Isobe . . . . .	3277
<b>Self-Assembled Structures</b> / Anna Cristina Samia and Xiao-Min Lin . . . . .	3816
<b>Self-Assembly of Coordination Cages</b> / Laura Pirondini and Enrico Dalcanale . . . . .	3848
<b>Self-Organized Superstructures: Molecular Design</b> / Makoto Tadokoro . . . . .	3886
<b>Supramolecular Networks Synthesized in Nanoparticle–Polymer Mixtures</b> / Anna C. Balazs and Gavin A. Buxton . . . . .	4240

---

## Surface and Interfacial Chemistry

---

### *Adhesion and Interfacial Forces*

<b>Adhesion: Cell on a Substrate</b> / <i>Frédéric Pincet</i> . . . . .	22
<b>Dynamic AFM on Heterogeneous Surfaces</b> / <i>Ijeoma M. Nnebe and James W. Schneider</i> . . . . .	1144
<b>Interfacial Forces: Colloidal Particle–Liquid</b> / <i>Sarah A. Nespolo and Geoffrey W. Stevens</i> . . . . .	1650
<b>Self-Assembled Monolayers: Surface Nanostructure Effect on Wetting</b> / <i>Jun Yang, Jingmin Han, Kelvin Isaacson, and Daniel Y. Kwok</i> . . . . .	3762
<b>Tribology of Inorganic Nanoparticles</b> / <i>Lev Rapoport</i> . . . . .	4375

---

### *Adsorption and Porous Materials*

<b>Adsorption on Heterogeneous Surfaces</b> / <i>Vinay K. Gupta and Yu-Wen Huang</i> . . . . .	41
<b>AFM: Metal Ion Sorption</b> / <i>Viriya Vithayaveroj, Sotira Yiacoumi, and Costas Tsouris</i> . . . . .	109
<b>AFM: Protein Adsorption</b> / <i>David T. Kim, Harvey W. Blanch, and Clayton J. Radke</i> . . . . .	129
<b>Biological and Chemical Decontamination</b> / <i>Peter K. Stoimenov and Kenneth J. Klabunde</i> . . . . .	312
<b>Biosurfaces: Water Structure at Interfaces</b> / <i>Yan-Yeung Luk</i> . . . . .	453
<b>Hierarchically Imprinted Nanostructures for Separation</b> / <i>Sheng Dai, Zongtao Zhang, and Chengdu Liang</i> . . . . .	1525
<b>Interfacial Phenomena: Chemical Selectivity</b> / <i>Vinay K. Gupta</i> . . . . .	1662
<b>Micro- and Mesoporous Nanomaterials: Catalytic Properties</b> / <i>Johannes A. Lercher and Andreas Jentys</i> . . . . .	2229
<b>Microweighing in Supercritical Carbon Dioxide</b> / <i>You-Ting Wu and Christine S. Grant</i> . . . . .	2253
<b>Nanoporosity Evolution on Dealloying</b> / <i>Jonah Erlebacher</i> . . . . .	2938
<b>Protein Adsorption Kinetics under an Applied Electric Field</b> / <i>Paul R. Van Tassel</i> . . . . .	3569
<b>Proteins: Structure and Interaction Patterns to Solid Surfaces</b> / <i>Thomas J. Webster</i> . . . . .	3590
<b>Self-Assembled Monolayers: Adsorption and Desorption from Alkanethiols on Gold</b> / <i>Pieter Stroeve</i> . . . . .	3738
<b>Single-Walled Carbon Nanotubes: Field Emission Properties</b> / <i>Xiaofeng F. Duan, Brahim Akdim, and Ruth Pachter</i> . . . . .	4078
<b>Virus Nanoparticles: Adsorption and Organization on Substrates</b> / <i>Jiyu Fang</i> . . . . .	4407

---

### *Catalysts and Catalytic Processes*

<b>Catalytic Processes: Nanoscale Simulations</b> / <i>Vladimir I. Elokhin and Aleksandr V. Myshlyavtsev</i> . . . . .	782
<b>Metal Clusters on Oxides</b> / <i>Ivan Stensgaard</i> . . . . .	2044
<b>Nanofibers and Carbon Nanotubes: Novel Metal Catalyst Supports</b> / <i>Mark A. Keane</i> . . . . .	2723
<b>Nanostructured Catalysts</b> / <i>Ravichandra S. Mulukutla</i> . . . . .	2967
<b>Nanostructured Catalysts: Design and Synthesis</b> / <i>Hua Chun Zeng</i> . . . . .	2974

---

### *Electrically Charged Surfaces*

<b>Electrical Double-Layer Formation</b> / <i>Kun-Lin Yang, Sotira Yiacoumi, and Costas Tsouris</i> . . . . .	1157
<b>Electrochemical Langmuir Trough</b> / <i>Natalia Varaksa, Thomas F. Magnera, and Josef Michl</i> . . . . .	1189
<b>Mica Surfaces: Charge Nucleation and Wear</b> / <i>James M. Helt and James D. Batteas</i> . . . . .	2211
<b>Mineral Nanoparticles: Electrokinetics</b> / <i>Mehmet S. Celik and Bahri Ersoy</i> . . . . .	2266
<b>Oxide Nanoparticles: Electrochemical Performance</b> / <i>Dominique Larcher and Jean-Marie Tarascon</i> . . . . .	3299

---

**Surface and Interfacial Chemistry (cont'd.)**

---

**Phase Separation and Self-Organization**

<b>Metal–Oxide Interfaces: Design via Control of Defect Density</b> / A. Bogicevic	2116
<b>Nanocrystalline Oxides: Surfactant-Assisted Growth</b> / Claudia L. Bianchi, Silvia Ardizzone, and Giuseppe Cappelletti	2637
<b>Nanoparticles: Synthesis in Polymer Substrates</b> / Bai Yang and Junhu Zhang	2912
<b>Nanostructures Derived from Phase-Separated Polymers</b> / Michael R. Bockstaller and Edwin L. Thomas	3093
<b>Ordered Vesicles at the Silicon–Water Interface</b> / Duncan J. McGillivray	3269
<b>Polyelectrolyte–Surfactant Complex Nanoparticles</b> / Hans-Peter Hentze	3403
<b>Polyion Complex Micelles</b> / Atsushi Harada and Kazunori Kataoka	3409
<b>Templating Polymer Crystal Growth Using Block Copolymers</b> / Yueh-Lin Loo	4303

---

**Surface Reactivity**

<b>Biosensors: Fractal Analysis of Binding Kinetics</b> / Harshala Butala and Ajit Sadana	441
<b>Enantioselectivity on Surfaces</b> / David M. Rampulla and Andrew J. Gellman	1242
<b>Lab-on-a-Chip Microreactors</b> / Paul D.I. Fletcher, Stephen J. Haswell, Paul Watts, and Xunli Zhang	1721
<b>Molecular Orientation at Interfaces: Vibrational Spectroscopy</b> / Zhan Chen	2357
<b>Nanocrystalline Magnesia and Alumina: Surface Chemistry</b> / Richard M. Narske	2592
<b>Nanomechanical Resonant Devices: Surface Chemistry</b> / Joshua A. Henry, Debodhonyaa Sengupta, and Melissa A. Hines	2848
<b>Nano–Mesoscopic Interface: Hybrid Devices</b> / Gianfranco Cerofolini	2493
<b>Nanotubes: Functionalization</b> / Stanislaus S. Wong and Sarbajit Banerjee	3119
<b>Sensors Based on Chemicurrents</b> / B. Roldan Cuenya and E. W. McFarland	3973
<b>Silica Surfaces Functionalization</b> / V. A. Tertykh	4001
<b>Stability of Nanostructures on Surfaces</b> / Karsten Pohl	4167
<b>Yttria-Tetragonally Stabilized Zirconia</b> / R. Allen Kimel	4414

---

**Symmetry and Patterns on Solid Surfaces**

<b>Anodization Patterned on Aluminum Surfaces</b> / Juchao Yan, G. V. Rama Rao, Plamen B. Atanassov, and Gabriel P. López	203
<b>Colloidal Nanoparticles: Aggregation Patterns at Surfaces</b> / Hamidou Haidara and Karine Mougin	882
<b>Dissymmetrical Nanoparticles</b> / Stéphane Reculosa, Christophe Mingotaud, Etienne Duguet, and Serge Ravaine	1093
<b>Heterogeneous Surfaces with Nanosized Channel Lattices</b> / Lifeng Chi, Michael Gleiche, Steven Lenhart, and Nan Lu	1515
<b>Laser-Based Deposition: Patterning</b> / Edward M. Nadgorny and Jaroslaw Drelich	1749
<b>Self-Assembly and Chirality of Molecules at Interfaces</b> / Dalia G. Yablon	3840
<b>Silica Nanotubes: Wetting and Diffusion</b> / Kenji Okamoto, Karthik Jayaraman, Sang Jun Son, Sang Bok Lee, and Douglas S. English	3995

---

**Thin Films and Monolayers at Surfaces**

<b>AFM: Nanolithography on Organized Films</b> / Seunghyun Lee and Haiwon Lee	119
<b>Amphiphilic Block Copolymer Monolayer at Air–Water Interface</b> / Emiko Mouri and Hideki Matsuoka	168

<b>Biosensor Applications: Surface Engineering</b> / <i>Genady Zhavnerko and Kwon-Soo Ha</i> . . . . .	416
<b>Charge Transfer in Metal–Molecule Heterostructures</b> / <i>Debasish Kuila, David B. Janes, and Clifford P. Kubiak</i> . . . . .	819
<b>Cyanogels: Processing by Spin Coating</b> / <i>Shu Zhu and Andrew B. Bocarsly</i> . . . . .	1029
<b>Functionalization of Surface Layers on Ceramics</b> / <i>Toshihiro Ishikawa</i> . . . . .	1375
<b>Infrared Spectroscopy: Biomolecular Structure at Interfaces</b> / <i>Curtis W. Meuse</i> . . . . .	1590
<b>Island Nucleation: Predictions</b> / <i>Maria C. Bartelt</i> . . . . .	1696
<b>Island Surfaces: Fabrication on Self-Assembled Monolayers</b> / <i>Hongjie Liu, Charles Maldarelli, M. Lane Gilchrist, and Alexander Couzis</i> . . . . .	1708
<b>Langmuir-Blodgett Films</b> / <i>Ursula Mazur</i> . . . . .	1738
<b>Layer-by-Layer Assembly of Electroactive Thin Films to Layered Carbon Electrodes</b> / <i>Tarek R. Farhat</i> . . . . .	1764
<b>Organosilanes: Molecular Assembly</b> / <i>Atsushi Takahara</i> . . . . .	3287
<b>Polyelectrolyte Films with Incorporated Carbon Nanotubes</b> / <i>Jason H. Rouse and Peter T. Lillehei</i> . . . . .	3396
<b>Self-Assembled Silane Monolayers: Cyano-to-Carboxylic Termination Conversion</b> / <i>Chandra Sekhar Palla and Alexander Couzis</i> . . . . .	3801
<b>Silane Self-Assembled Monolayers: Nanoscale Domains by Sequential Adsorption</b> / <i>Nitin Kumar</i> . . . . .	3984
<b>STEM: Self-Assembly on Graphite</b> / <i>Thomas Müller</i> . . . . .	4185
<b>Titania Coatings on Stainless Steel</b> / <i>Ganesh Balasubramanian, Dionysios D. Dionysiou, and Makram T. Suidan</i> . . . . .	4348

# Preface

The science of the “ultra small”—nanoscience—has dramatically exploded during the last few years, and the technologies operating with “ultra small things”—the nanotechnologies—acquired quickly a firm position in today’s world of business, technological development, and public perception. Several factors contributed to the acceleration of scientific knowledge and technological progress in the last decades, among which the rapid development of fast computers, availability of high-resolution analytical techniques, and the progress of molecular biology and genetics are probably the most important. The result was an unprecedented expansion of the frontiers of science, which empowered the human genius with unlimited options of top-down and bottom-up methods for manipulation of materials structure and control of properties at multiple levels, from atomic to molecular, supramolecular, and biomolecular. Already a distinctive mark of 21st century, nanoscience and nanotechnology will certainly have a steadily increasing influence on the quality of life and the environment of this Planet for centuries to come.

*Dekker Encyclopedia of Nanoscience and Nanotechnology, Second Edition* provides a comprehensive and detailed review, from multiple angles, of major developments in the human’s quest for understanding and mastering of physical, chemical and biological objects and structures having at least one dimension smaller than about 100 nm.

Under the expert supervision of the late Professor James A. Schwarz, Marcel Dekker, Inc. published the first edition in 2004 to great acclaim. The success of first edition, the development of the title through online updates, and the dynamics of this continuously growing field has created a high demand for a second edition only four years after the first edition. The second edition offers updated and revised entries, along with many additions that reflect the focus towards energy and environmental issues currently in the news. The new edition is expanded to six volumes. All entry titles have been revised to better reflect to the entry’s content, while optimized for alphabetical listing. In addition, a comprehensive (though not exhaustive) topical table of contents has been designed, structured on 24 major topics and almost 100 subtopics. With a robust and efficient indexing system and staggered bleed tabs, this second print edition will be a useful reference tool for scientists in academia and national laboratories, engineers, students, as well as entrepreneurs, policy makers, and opinion builders. The online version of the Encyclopedia offers quick access to individual entries in HTML or PDF format, enriched graphical content, hundreds of color illustrations and photographs, and an efficient keyword search engine.

# Preface to the First Edition

Nanoscience encompasses all scientific phenomena that transpire in dimensions spanning the range of multiple atom clusters, molecular aggregates, supermolecular structures, polymers and biomolecules. In other words, nanoscience is the science of the nanoscale—or the very, very minute. Nanotechnology, the technological use of these properties and phenomena, has the potential to revolutionize a breathtaking range of fields, across practically all domains of human activity. The intense interest in using nanostructures stems from the promise that they boast superior electrical, optical, mechanical, chemical, or biochemical properties. There is little doubt that the use of these new materials and systems will lay the ground for the new technological revolution of 21st century. Research in nanoscience is exploding as scientists from chemistry, physics, and biology, including colloid and polymer chemistry, materials and surface science, and biochemistry, biophysics and molecular biology have begun to examine the superior properties that characterize materials and phenomena at the nanoscale.

The Dekker Encyclopedia of Nanoscience and Nanotechnology is a vehicle by which scientists and the interested public can explore the most recent developments in today's nanomaterials, and preview several of their foreseen applications of tomorrow. The subject areas of this five volume collective work include, but are not limited to, chemistry, physics, molecular and quantum biology, materials science and engineering and computer science. The topics include fullerenes and carbon nanotubes, quantum dots and inorganic nanowires, interfacial chemistry, nanostructures, analytical and characterization methods, design and fabrication techniques of nanocomposites, properties of functional nanomaterials, nanostructured catalysts, molecular electronics, optical devices, bionanotechnology, colloidal phenomena—even future and environmental considerations about nanotechnology. In short, the reference strives to encompass, document, and organize the enormous proliferation of information that has emerged from the revolution at the nanoscale.

It is the editors' hopes that the Dekker Encyclopedia of Nanoscience and Nanotechnology will help researchers, graduate students, undergraduate students, and non-professionals all better understand and participate in this remarkable emerging field. To keep the reference accessible, the Encyclopedia is published in both online and print formats. The print version consists of multiple traditional hardbound volumes with articles arranged alphabetically. The front matter to each volume provides an alphabetical Table of Contents and a Topical Table of Contents. An index at the back of each volume is intended as a further guide.

The online version of the Encyclopedia has been created by coupling the content of the print edition with a powerful search engine and user-friendly interface. The online database is dynamic, with additional articles added each quarter. As with the print edition, users will be able to browse the alphabetical and topical Table of Contents, but they will also be able to search for entries by keywords.

The editors of the Dekker Encyclopedia of Nanoscience and Nanotechnology could not have accomplished their feat without the help of many. We first thank the authors of more than 300 articles which, as recognized experts in their fields, lend their credibility and prestige to the Encyclopedia. In addition, the editors were joined by an esteemed International Editorial Advisory Board whose input was crucial to shaping the reference. Success in the coordination of the activities that has resulted in this final product is due to the remarkable staff at Marcel Dekker, Inc. We are indebted to the direction provided to us by Ellen Lichtenstein, Carolyn Hall, Oona Schmid, Susan Lee, Joanne Jay, and Jeeran Ok.

In particular, the creative ideas and boundless energy that Oona Schmid has demonstrated is greatly acknowledged by the three of us. We also thank Anita Lekhwani for her confidence in us as editors and Russell Dekker for his support and encouragement.

# Acknowledgment

This Encyclopedia is the result of a relentless and enthusiastic effort of hundreds of scientists from all over the world. Although from different backgrounds—physicists and chemists, biologists and software engineers, mathematicians and materials scientists—and speaking different languages, they all share a devouring passion for discovery and scientific knowledge, and an immense dedication to their profession. We cannot be more grateful to all and every one of the reputed scientists who wrote this Encyclopedia, chapter by chapter, almost “layer by layer”. Our thanks go also to all members of the Editorial Advisory Board who improved this collective work. Built upon the first edition published at Marcel Dekker, Inc., this Second Edition could not be finalized without the dedication and professionalism of the staff at Taylor & Francis Group. In particular we appreciate the remarkable direction and creativity of Claire Miller, Director of Encyclopedia Programs at Taylor & Francis, and of her assistants, Alasdair Denvil, Elif Kaynak, Susan Lee, and Laura Sylvest.

## A Note on Terminology

New terms, based on the prefix nano, have gained broad circulation, unified the older terminology, and defined the topics of newly found disciplines. Just as the research community has struggled to restrict when and where the prefix nano can be appropriately used, we too struggled with the *Dekker Encyclopedia of Nanoscience and Nanotechnology* to avoid puncturing every sentence with the prefix nano. As this terminology develops, the online edition of the Encyclopedia will be able to incorporate these new conventions.

But at the time of publication of the first edition of the Encyclopedia these questions are still unresolved. One definition that has been proposed in order to remove the ambiguity would limit the use of the nano prefix to research and development of objects having the key property that they have at least one dimension in the range of 1 to 100 nanometers. New advances in synthetic methods for making such structures, combined with new analytical and manipulation tools, made it possible to refine methods to the point where de novo designed objects with nanoscopic dimension can, in many cases, be assembled in molecule-pure form or spatially organized structures. These systems, designed through processes that exhibit fundamental control over the physical and chemical attributes of molecular-scale structures, can be combined to form larger structures.

However, the *Dekker Encyclopedia of Nanoscience and Nanotechnology* has numerous entries that include the words micro and meso. Thus the use of the term nano, which, according to one broadly circulated definition, only limits research and technology to development in the length scale of approximately 1–100 nanometer range, is not simply a metric of length. Science at the nanoscale does not accept rigid limits on dimensionality. Indeed the very utility of nanoscience may be compromised by arbitrarily circumscribing its reach. After all, for ancient Greeks, the term “nanos” meant a dwarf. Keeping this in mind, we attempted in this reference to use the term nano to refer to objects and their subsequent processing into newly created structures, devices, or systems that have novel properties and functions because of their small and/or intermediate size. In other words, size and performance are the critical parameters that provide the requisite conditions to justify the use of the term nano.

By adopting a more elastic definition, which on one hand spans sizes from a few nanometer(s) to one (or a few) hundred(s) nanometers, but at the same time recognizes that the properties and performance of nanoobjects are rooted in their nanoscopic size, we believe that we made justice to all views that currently shape this field of continuous development and hope that other investigators—at universities, state laboratories, and in industries—will follow our lead.

## About the Editors-in-Chief

**Cristian I. Contescu** is Senior Staff Member of Materials Science and Technology Division at Oak Ridge National Laboratory, in Oak Ridge, Tennessee (USA). A former Senior Scientist of the Institute of Physical Chemistry in Bucharest, Romania (1971–1992), he later became an Adjunct Assistant Professor at Syracuse University, Syracuse NY, and served as Senior Scientist at HITCO Carbon Composites (Gardena, CA) and Material Methods, LLC (Newport Beach, CA). His scientific interests include surface and interface processes, adsorption and catalysis, gas and energy storage. Dr. Contescu is author or coauthor of over 50 peer-reviewed publications, book chapters, and patents. He is member of the Editorial Board of CARBON journal, and served as co-chair of the Colloid and Surface Chemistry Division of the American Chemical Society symposia on nanoscience and nanotechnology. He is a member of the American Carbon Society and the American Chemical Society. He received the M.Sc. degree (1971) in physical chemistry from Bucharest University, Romania, and the Ph.D. degree (1979) in physical chemistry from Bucharest Polytechnic Institute, Romania.

- Editorial Board, CARBON journal (2007)
- “Gheorghe Spacu” National Award of the Romanian Academy Division of Chemical Sciences (1991)
- International Research & Exchanges Board (IREX) fellowship (1990)
- Special Merit Diploma (Summa cum Laudae) from Bucharest University (1971)

**Karol Putyera** is Director of Analytical Services, Evans Analytical Group (EAG) Shiva Technologies, Syracuse, New York (USA). He started to work for Shiva Technologies, Inc. in 1992 as a part-time GDMS analyst while being a Research Associate in the L.C. Smith College of Chemical Engineering and Materials Science at Syracuse University NY, from 1992-1995. After completing his JSPS fellowship at Chiba University in Japan Dr. Putyera joined Shiva full-time as Technical Manager and subsequently held positions in the company as Director of Advanced Technology Group, General Manager Shiva West, Laboratory Director, Vice President for Business and Technology Development and most recently President of Shiva Technologies, Inc. and Shiva Technologies Europe. Dr. Putyera completed his BS and M.S. degrees in Physical Chemistry at Charles University, Prague, Czech Republic in 1983 and 1985, respectively. He received his Ph.D. degree in Inorganic Chemistry in 1991 at the Institute of Inorganic Chemistry, Slovak Academy of Sciences, Slovak Republic.

- Japanese Society for Promotion of Science Fellowship (1996)
- Slovak Academy of Sciences “Golden Plaque” for young research scientists from the Slovak Academy of Sciences (1990)

**Founding Editor James A. Schwarz** (deceased, 2004) was Professor of Chemical Engineering and Materials Science at Syracuse University, Syracuse, New York (USA). The author or coauthor of numerous professional publications, presentations, and patents, Prof. Schwarz had unanimously recognized contributions in surface science, catalysis, carbon science, and colloid science. He was President of the California Catalysis Society and a member of the American Vacuum Society, the American Chemical Society, and the American Institute of Chemical Engineers. He was the 2004 Chair of the Colloid and Surface Chemistry Division of the American Chemical Society. He received the

B.S. degree (1965) in science and the M.S. degree (1966) in chemistry from Stevens Institute of Technology, Hoboken, New Jersey, and the Ph.D. degree (1969) in chemistry from Stanford University, California.

- Chair of Colloid Division of the American Chemical Society (2004)
- Senior Fulbright Fellow to Romania (1997)
- American Chemical Society Langmuir Award (2001)
- Chancellor's Citation for Academic Excellence at Syracuse University (2002)

## Abstract

The development of aberration-corrected scanning transmission electron microscopy (STEM) has provided new insight in the development of nanomaterials. Specifically, atomic number contrast STEM, or Z-STEM, has been applied to elucidate the structure of cadmium-based semiconductor nanocrystals. With sub-angstrom detail, the images obtained elucidated the effects of surfactants on the nanocrystal shape, showed the precise coverage of epitaxial shells for core/shell quantum dots, as well as provided the first images of the atomic structure of alloy nanocrystals.

Semiconducting nanocrystals are one of the most beautiful examples of how new and fascinating physical properties arise in the nano-regime. As first demonstrated by Louis Brus, the band gap, and in essence, the color of a semiconductor becomes size-dependent when the diameter is reduced to below the bulk Bohr exciton diameter.<sup>[1]</sup> This allows for precise tuning of the absorption and emission properties by simply controlling the nanocrystal's diameter. In 1993, Murray, Norris, and Bawendi published the synthesis that would form the basis of the production of monodisperse, colloidal nanocrystals.<sup>[2]</sup> This has become the foundation of the nanocrystal field, which has since grown to not only include fundamental investigations into the properties of the nanocrystals themselves, but also the development of practical applications. Efforts are currently focused on the use of colloidal nanocrystals or “quantum dots” for the development of fluorescent probes for biological imaging, phosphors for solid-state lighting, and light harvesters for photovoltaics.<sup>[3–10]</sup> Although great strides have been made towards the development of these applications, much more basic research is needed to develop them into powerful, reliable, and competitive technologies.

One of the most useful properties of nanocrystals is their large surface-to-volume ratio. For example, in a 1.2 nm diameter nanocrystal, nearly all of the atoms are surface atoms. This results in the surface dominating the chemical and physical properties of the nanocrystal. The surface consists of a mixture of unpassivated atoms with dangling bonds and atoms that are passivated with surfactants. The electronic, optical, and physical

properties of the nanocrystal are extremely sensitive to the surface conditions. Dangling bonds can act as charge traps, reducing the emission efficiency. They are also able to easily take part in chemical reactions. For example, oxygen can bind to the unpassivated atoms forming an oxide, which can cause photo-brightening and eventually quenching.<sup>[11]</sup> The presence and type of passivating ligand can also be chosen to tailor the properties of the nanocrystal in controlled ways, such as improving the emission efficiency, or quenching the emission completely, if desired. The surface can also be affected by “shelling”; core/shell quantum dots have an outer coating of a wide bandgap semiconductor to passivate the surface and confine electrons and holes to the core. The thickness and total coverage of the shell dictates the quantum yield and resistance to photobleaching of core/shell quantum dots.

The importance of the surface structure has driven the application of aberration-corrected, atomic number contrast scanning transmission electron microscopy (Z-STEM) to characterize nanocrystals. This technique allows for direct imaging the nanocrystal's core and surface structure with sub-angstrom resolution. Additionally, the image intensity is dependent on chemical composition and thickness affording an unparallel view of the nanocrystal. This entry will review our recent work in utilizing this technique to study colloidal cadmium-based semiconductor nanocrystals. Specifically, Z-STEM was used for (1) observing the effect of surfactant on the nanocrystal shape; (2) guiding the development of near unity quantum

yield core/shell nanocrystals; and (3) the characterization of homogeneous nanocrystal alloys. These applications rely on the unique capability of Z-STEM to simultaneously provide sub-angstrom resolution, allowing individual atoms to be imaged, and chemical identification of the elements present.

## SYNTHESIS OF CdSe NANOCRYSTALS

The current methods for synthesizing CdSe nanocrystals follow procedures similar to those of Bowen-Katari, Colvin, and Alivisatos, which eliminated the need for size-selective precipitation to produce monodisperse samples.<sup>[12]</sup> In this preparation, 99% trioctylphosphine oxide (TOPO) and tri-*n*-butylphosphine (TBP) is used as received from Aldrich. Se (60 mesh powder) is dissolved in TBP and followed by the addition of dimethylcadmium. The injection solution of cadmium and selenium in TBP is then diluted 4:1 with TBP and injected into the reaction vessel of TOPO at ~350°C. The solution is removed from heat and allowed to cool under argon, which prevents oxidation of the nanocrystal surface. To recover nanocrystals from the solid, room temperature TOPO mixture, methanol is added to dissolve the TOPO and precipitate the nanocrystals, which are then recovered by filtration. To make nanocrystals with an absorption maximum larger than 580 nm, the reaction is cooled from 350°C to 320°C and the nanocrystals are allowed to grow while the size is monitored by drawing aliquots from solution and monitoring the absorption spectra. Using this growth method, the initial tight size distribution is lost. This can be overcome by the addition of additional reagent solution to “focus” the size distribution.

The use of dimethylcadmium to produce high-quality nanocrystals is still common. However, Peng and Peng demonstrated the use of CdO as a benign source of cadmium.<sup>[13]</sup> In this one-pot approach, CdO, TOPO and either hexylphosphonic acid (HPA) or tetradecylphosphonic acid (TDPA) are loaded into a three-neck flask. At temperatures above 270°C, the phosphonic acid complexes with the CdO forming a clear and colorless solution. After the formation of the colorless cadmium phosphonate complex, Se:TBP is injected into the reaction, which initiates the formation of nanocrystals. This method can also be used to produce high-quality CdS and CdTe nanocrystals by replacement of the anion solvated by TBP.<sup>[14]</sup>

Weller and co-workers developed a similar synthetic methodology using cadmium acetate  $\text{Cd}(\text{CH}_3\text{CO}_2)_2$  as the precursor.<sup>[15]</sup> In this method, a stock selenium solution of trioctylphosphine:Se (TOP:Se) is added to a mixture of TOPO:hexadecylamine (HDA):TDPA at 120°C. This is then heated to 300°C to which a stock solution of cadmium acetate and selenium dissolved in

TOP is rapidly injected. Both the cadmium and selenium stock solutions are stored inside a glove box under nitrogen atmosphere. Additionally, efforts to reduce the use of phosphine in the chemistry has led to the development of the use of oleic acid and octadecene as the surfactants, in place of TOPO and the phosphonic acids.<sup>[16]</sup>

## TEM EXPERIMENTAL

Nanocrystal sample preparation for electron microscopy is, in general, simple. The as-synthesized nanocrystal powder or liquid need to be purified to remove any excess starting materials and surfactants. It is critical to develop a methodology that removes the unbound surfactants as they will deposit with the nanocrystals onto the TEM grid, making the overall sample thicker than desired, and they may also cause contamination. Contamination is believed to be beam-induced polymerization of carbonaceous materials on the carbon support. This polymer can continue to grow until the beam can no longer penetrate the specimen. The cleaning steps typically used to remove this unwanted material depend on the surfactants used during synthesis. TOPO-coated nanocrystals need only three methanol washes, TOPO-HDA nanocrystals require an inverse precipitation step in octanol, while oleic acid-coated nanocrystals require three washes with a careful mixture of chloroform and acetone.<sup>[17]</sup> Once clean, the powdered nanocrystals should be brought into solution with an appropriate solvent. For TOPO-coated nanocrystals, toluene or hexanes work well. Ultrathin carbon on formvar TEM grids purchased from Ted Pella, Inc. (part no. 01822-F) are ideal for imaging nanocrystal samples. They have an average thickness of 30 nm and are fairly resilient to sample preparations due to the formvar support. The formvar support can be removed to minimize the film thickness and subsequently the carbon background in the TEM images. For Z-STEM, lacey carbon coated with ultrathin carbon, also from Ted Pella, is used to provide the least amount of background for imaging.

After the film is cleaned, a drop of a nanocrystal solution with an optical density of less than 0.1 is placed onto the grid. Anticapillary tweezers should prevent premature drawing up of, or wicking, of the solution. A Kimwipe™ can be used to “wick” the solvent off in a controllable fashion, leaving the nanocrystals on the carbon film. Alternatively, the solvent can be allowed to evaporate, helping the nanocrystals to array and limit nanocrystal stacking and bunching. The higher the boiling point of the solvent, the longer the nanocrystals will have to order themselves on the grid. However, leaving the solvent to dry also allows for

more of the excess surfactants to accumulate on the grid, increasing the chance for contamination under the electron beam.

Since the electron beam is focused to a point in STEM, it is more susceptible to contamination and requires extra care during sample preparation. Even samples that do not contaminate under conventional TEM conditions can be problematic in STEM. To combat this, samples on ultra-thin carbon grids can be plasma cleaned for up to 20 sec in an argon/oxygen plasma cleaner. More effectively, yet more damaging to the nanocrystals, the sample can be exposed to a high intensity light bulb, either outside the microscope, or in the air lock under vacuum. Twenty minutes of the “light bulb” treatment can effectively eliminate contamination and allow for sustained imaging over a single area for an extended period of time.

## THE MICROSCOPES

Conventional high-resolution transmission electron microscopy (HRTEM) images were obtained using a Phillips CM20 operating at 200 kV, located at Vanderbilt University. Z-STEM images were taken using the VG HB603u 300 kV aberration-corrected STEM located at Oak Ridge National Laboratories, in collaboration with Stephen J. Pennycook. Fitted with a Nion  $C_s$  corrector, the HB603u has a record-setting 0.78 Å resolution, allowing for several pixels in an image to be devoted to a single angstrom.<sup>[18]</sup> Images are collected using a high-angle annular dark field detector (HAADF), which allows for simultaneous collection of dark field (Z-STEM) and bright field images. The dark field images are formed by the highly scattered electrons, resulting in image intensities that are dependent on sample thickness and the atomic number ( $Z$ ) of the atom or atomic column being imaged. Images are collected and processed using Gatan’s Digitalmicrograph software. Unless otherwise noted, images are “smoothed” to remove any high frequency shot noise from the images. Color has been added to emphasize that the intensity is important in image interpretation.

## CONVENTIONAL HIGH-RESOLUTION TRANSMISSION ELECTRON MICROSCOPY (HRTEM) FOR CHARACTERIZATION OF NANOCRYSTALS

Conventional HRTEM is the standard technique for measuring the size, dispersity, and overall quality of a nanocrystal sample. Owing to the ability of nanocrystals to freely rotate under the electron beam, obtaining lattice resolved images of them requires quick reflexes and often a bit of luck. Unlike thin films of solids, whose crystallographic orientation is dependent on how it is sliced, nanocrystals are free to rotate on the carbon film and align themselves randomly. Fringe patterns in phase contrast imaging are used to determine the size, shape, and the crystal structure of the object being imaged. Because of the relatively small number of properly aligned nanocrystals, finding nanocrystals that are not in contact with others and facing with the zone axis towards the electron beam can be a difficult task. Using solutions with a low concentration of nanocrystals and allowing the solvent to evaporate, allowing the nanocrystals to array, is best for producing the highest number of isolated nanocrystals per area of carbon film. The difference between evaporating and “wicking” the nanocrystal solution can be seen in the TEM images in Fig. 1. The nanocrystals in the wicked sample, Fig. 1A, are clumped together, while those of the evaporated sample, Fig. 1B, are evenly separated into a two-dimensional array, with the distance between them dictated by sample concentration and surfactant. Highly concentrated solutions of nanocrystals form extremely dense arrays that are not useful for imaging individual nanocrystals, as shown in Fig. 1C. Figure 2 shows the three distinct fringe patterns that can be assigned to different orientations of the nanocrystal.<sup>[19]</sup> The pattern labeled “B” is consistent with the [100] orientation. This is the most common orientation found, since the largest face of the nanocrystal is in contact with the carbon film. The zigzag pattern labeled “C” is that of the [010] orientation. To achieve this orientation, the nanocrystal must be resting on a corner

**Fig. 1** TEM sample preparation. TEM images of samples that were wicked (A), not wicked (B) and overcrowded (C) are shown.

**Fig. 2** Fringe patterns. (A) TEM image of randomly orientated CdSe nanocrystals. (B–D) [100], [010], [001] fringe patterns and their associated lattice spacing.

facet. The orientation labeled “D” corresponds to [001] direction and requires the nanocrystal to be sitting on end. This orientation clearly shows the hexagonal shape of wurtzite CdSe. From images like these, it is not only possible to determine the average nanocrystal size but also determine the average shape. The size of the nanocrystal can be determined either by counting the number of lattice fringes and multiplying that number times the fringe spacing or by simply determining the scale of the image and then measuring the diameter of the particle. The latter, however, requires that the microscope be precisely calibrated. Approximately 200 measurements of individual nanocrystals are needed to determine a size distribution.<sup>[19]</sup>

Large shape morphologies can be easily seen under HRTEM conditions. Fig. 3 contains HRTEM images of CdSe nanocrystal prepared under different reaction conditions. Fig. 3A is a CdSe nanorod. Figure 3D are images of nanorods with small outgrowths, and Fig. 3E and F are TEM images of a bipod and tetrapod, respectively. The odd shapes of the nanocrystals in Fig. 3 could be the result of the large number of stacking faults [a stacking fault is a break in the regular crystal pattern,<sup>[20]</sup>] or the result of the mixture of surfactants used in the synthesis. Wurtzite CdSe nanocrystals often have zinc blende stacking faults in them due to the small energetic difference between the two phases. The nanocrystal in 3A shows several sections of zinc blende in the top half while the bottom half

exhibits the normal alternating pattern of a wurtzite crystal lattice oriented in the [010] direction. From the fringes, it can be presumed that the growth is along the *c*-axis, since this is the long axis of the nanocrystal. It is also known from the CdSe nanocrystal structure that there are Cd and Se rich facets, which should create surfaces with different chemical reactivities. However, in which direction growth occurs, whether towards the Se face or the Cd face, cannot be determined. This unidirectional growth, if understood, could lead to control of facet-specific growth mechanisms such as those that formed the tetrapods in Fig. 3E and F.<sup>[14,21]</sup> Unfortunately, phase contrast imaging does not yield enough detail to differentiate the Cd- and Se-terminated facets.<sup>[11,22,23]</sup> However, Z-STEM can directly probe the chemical structure with atomic level precision. A general description of the technique is described in the following section.

### ATOMIC NUMBER CONTRAST SCANNING TRANSMISSION ELECTRON MICROSCOPY (Z-STEM)

Atomic number contrast scanning transmission electron microscopy uses an atom-sized probe that scans across the sample to form an image. The electrons scattered at low angles are used to form a bright field image while those scattered at high angles are used to

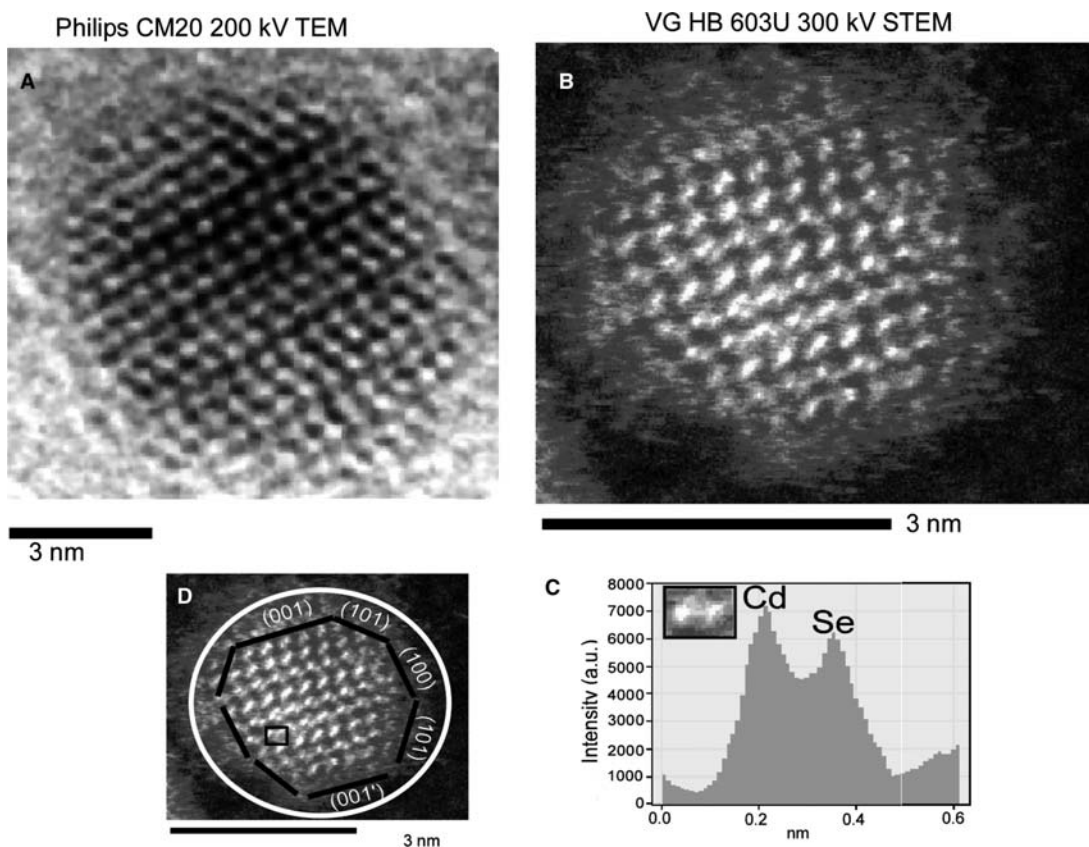

**Fig. 3** TEM images of various shapes of CdSe nanocrystals. Depending on the growth conditions, nanocrystals can form shapes such as rods (A), rods with growths (B–D) and bi-pods and tetrapods (E and F). G is a cartoon illustrating the tetrapod in (F) with the fourth arm pointing in the Z direction, out of the sample plane.

form a dark field image. The bright field image is a coherent phase contrast image, similar to that formed in a comparable high-resolution TEM. High-angle scattering is generated incoherently, and leads to an incoherent image, the resolution of which is directly related to electron probe diameter. The electron probe size in STEM is limited by the beam energy, its energy spread, and by aberrations in probe-forming lenses.<sup>[24]</sup> Also, high-angle scattered electrons show a strong atomic number contrast, hence the term Z-STEM, or Z-contrast imaging, also known as HAADF imaging.<sup>[25–27]</sup> These electrons can be compared with the He ions in Rutherford Backscattering in that their energy and intensity are dependent on the material with which they interact. Electrons impinging upon a heavy atom will scatter more frequently to higher angles than those that encounter a lighter atom. Therefore, scattered electrons detected from atoms with differing atomic weights appear as intensity variations in the image, yielding elemental information directly from the image. Unlike coherent imaging techniques such as phase contrast imaging (conventional HRTEM), there are no complicated contrast changes with focus or specimen thickness.<sup>[28]</sup> This allows for direct interpretation of the images; a bright spot in the image plane corresponds directly to a scattering center in the object plane, i.e. an atom. Additionally, the intensity of the scattered electrons depends on the square of the atomic number of the scattering atom, yielding spatially resolved chemical information.<sup>[25]</sup>

As a result of the sub-angstrom probe and its imaging design, Z-STEM provides an unmatched ability to achieve structural and chemical information from individual nanostructures at the atomic level.<sup>[18,29]</sup> For example, Z-STEM tomography was recently used to determine the 3D structure of less than 10 nm Sn quantum dots embedded in Si with cubic nanometer resolution.<sup>[30]</sup> Z-STEM has been used for many years to directly image the atomic structure of grain boundaries and interfaces, even revealing specific impurity segregation sites.<sup>[31–33]</sup> A key advantage of Z-STEM is that it can be easily combined with electron energy loss spectroscopy (EELS) to achieve elemental identification with atomic resolution.<sup>[34]</sup> Today, with the successful correction of lens aberrations, Z-STEM has demonstrated 0.78 Å spatial resolution by directly imaging Si [112] atomic dumbbells.<sup>[18]</sup> The higher resolution and image contrast also results in a greatly improved sensitivity for EELS, opening many opportunities for materials science research.<sup>[35]</sup> For example, it was shown using these two techniques that rare earth dopant atoms, such as La, preferentially segregate to the amorphous crystal interfaces of Si<sub>3</sub>N<sub>4</sub>.<sup>[36]</sup> This level of precise information is critical for the development of nanomaterials where the placement of a single atom can drastically affect the desired properties.

A comparison between two similarly orientated CdSe nanocrystals, imaged under HRTEM and Z-STEM, is shown in Fig. 4. False color has been added to the Z-STEM image to emphasize the

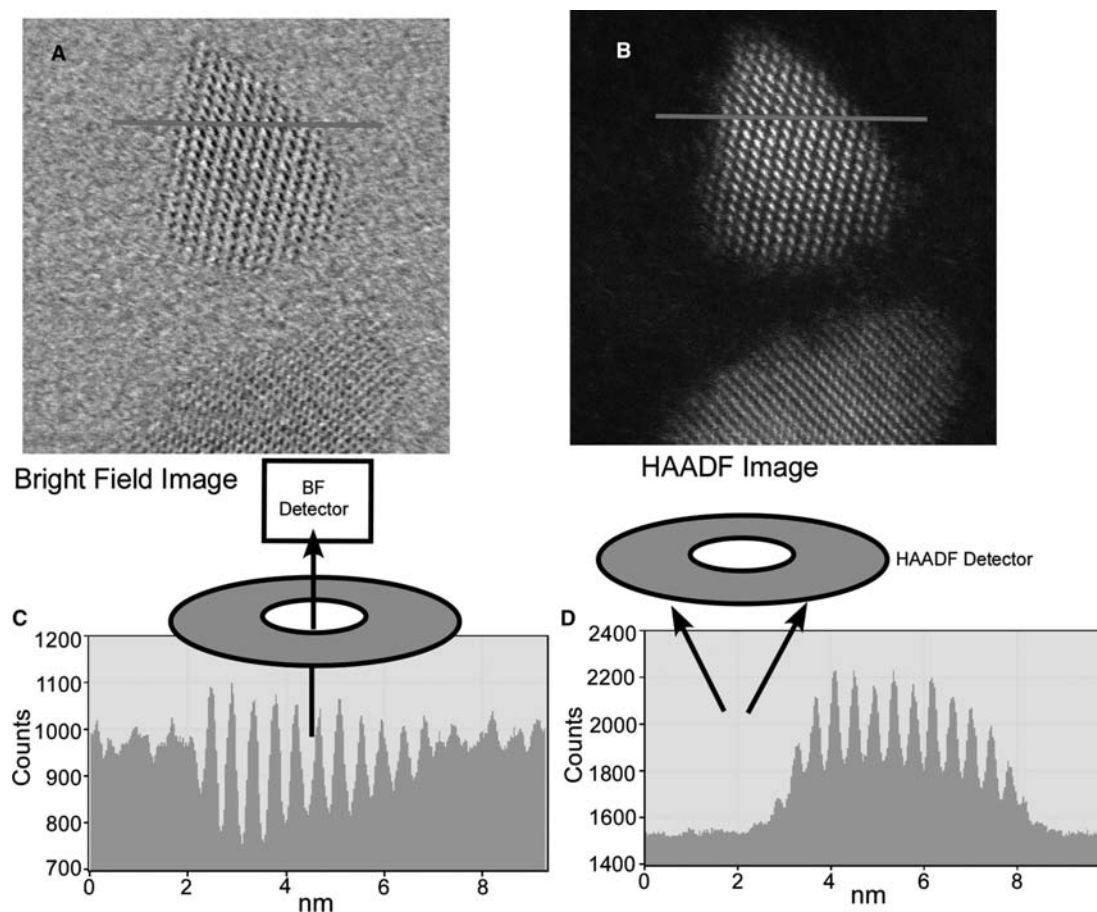

**Fig. 4** TEM-Z-STEM comparison. (A) and (B) are TEM and Z-STEM images of similarly orientated CdSe nanocrystals. (C) is a line profile taken from (D) (black box) showing intensity contrast from the Cd and Se atomic columns. The intensity contrast can be used to assign specific facets in the image (D). The white circle in (D) highlights the amorphous oxide coating. *Source:* Reprinted with permission from *Nano Lett.*, **2004**, 4 (7) 1279–1283. © 2004 American Chemical Society.

importance of the image intensity. Unlike the conventional HRTEM image in Fig. 4A, chemical and structural information can be obtained directly from the intensities in the raw Z-STEM image. For example, the Cd and Se columns in Fig. 4B can be assigned from the intensity difference found in the raw image, as indicated by the intensity profile in Fig. 4C. With this information, the Cd-rich (001) and the Se-rich (001') surfaces can be then assigned by following the alternating intensities to the surface, as shown in Fig. 4D. Additionally, since the electrons that are detected are incoherently scattered, phase contrast that produces the speckle pattern in bright field images of amorphous carbon is not present. As a result, single atoms can be imaged on the surface of an amorphous carbon film, and nanocrystal edges are clearly visible in cases where the nanocrystal is not susceptible to oxidation.<sup>[37]</sup> In the images in Fig. 4, the nanocrystal edges are oxidized owing to exposure to air, and the resultant amorphous oxide layer, which has been enclosed by a white circle, can be clearly seen in the Z-STEM image in Fig. 4D. The spots seen in the oxide are the remains of the outer surface of the nanocrystal. Individual atoms and

atomic clusters can readily be found in this region; these atoms and clusters would not be visible using conventional HRTEM since there is no contrast between amorphous materials and the amorphous carbon support.

Besides the smaller probe size, an additional advantage of aberration correction is that the STEM Bright Field (BF) has about two orders of magnitude more current, enhancing the signal-to-noise resolution, making it a practically useful additional channel of information. It is obtained simultaneously with the Z-STEM image, and is equivalent to an aberration-corrected HRTEM image by the principle of reciprocity (reversing ray directions). Fig. 5 shows the simultaneous BF and Z-STEM images of a triangular shaped CdSe/CdS core/shell nanocrystal taken after the installation of the aberration corrector.<sup>[38]</sup> The BF image shows the edge of the nanocrystal more clearly, because of the reduced image delocalization, but it is still not able to detect individual atoms on the amorphous carbon support because of the lack of strong Z-contrast. The Z-STEM image does show individual atoms and small clusters on the carbon film. The

**Fig. 5** Bright field vs. dark field STEM. The STEM images A (bright field) and B (dark field) are obtained simultaneously during imaging. The line profiles (C and D) show the reduction in back ground intensity afforded by dark field imaging. *Source:* Reprinted with permission from *Surf. Sci. Rep.*, **2007**, 62, 111–157. © 2007 Elsevier B. V.

line profiles in Figs. 5C and D illustrate how the bright field image is formed by constructive and destructive interference on top of the contrast from the carbon support, whereas the Z-STEM image exhibits a sharp increase in intensity between the carbon film and the nanocrystal, indicating the precise location of the surface. However, the bright field image is still particularly useful for finding focus and for manually adjusting for astigmatism, although it should be noted that optimum focus for a bright field image is not exactly the same as optimum focus for the Z-STEM image.<sup>[28]</sup>

### Z-STEM OF CdSe NANOCRYSTALS

The following figures show how easily Z-STEM images can be interpreted. There are three main orientations that allow lattice-resolved images. Examples of these are shown in Figs. 6 and 7. The images can be interpreted simply by comparison to a computer generated “ball-and-stick” CdSe nanocrystal model and rotating it in three dimensions to match the atomic arrangement

in the Z-STEM image. This particular model was developed by Andreas Kadavanich using Crystal Maker.<sup>[39]</sup> It is interesting to note that in the image of the nanocrystal in the [100] orientation, Fig. 6A, the Cd and Se columns are nearly resolved. The spacing between the atomic columns in this orientation is 0.67 Å, just beyond the resolution of the microscope. The nanocrystal in Fig. 6B is in the [001] orientation, showing no mass contrast as the Se and Cd atomic columns are overlapped. Alternatively, the nanocrystal in Fig. 7A is in the [010] orientation where the Cd and Se atomic columns are separated, showing mass contrast. Also, a new orientation that had not been resolved prior to use of the aberration corrector is seen in Fig. 7B; it is the [111] orientation with a column separation of 2.75 Å.

Figs. 8A and B show two Z-STEM images of the TOPO/HDA nanocrystals with a zinc blende crystal structure. These nanocrystals do not exhibit the alternating “zigzag” pattern of a wurtzite nanocrystal. Also, these images exhibit a larger coating of the oxide layer, probably due to the light bulb treatment applied

**Fig. 6** Z-STEM images and model. The images obtained (A and B) can be directly compared to a traditional ball and stick model to determine orientation. The larger, orange atoms represent Cd while the smaller, blue atoms are Se. *Source:* Reprinted with permission from *Surf. Sci. Rep.*, **2007**, 62, 111–157. © 2007 Elsevier B. V.

prior to imaging. Fig. 8A is a CdSe nanocrystal in the [010] orientation. This position shows the clearest mass contrast between the Cd and Se columns. However, a crystallographic defect can be seen in the image as there is an extra intensity source in between the atomic columns, probably indicating a stacking fault or twin boundary in the nanocrystal. The nanocrystal in Fig. 8B is also in the [010] orientation, but has a stacking fault parallel to the beam direction, indicated by the black line. In the case of the nanocrystal in Fig. 8B, two zinc blende phases are separated by a wurtzite stacking fault, forming a twin boundary. These low-energy defects in the crystal lattice are common for semiconducting nanocrystal systems.<sup>[40–42]</sup>

The nanocrystal in Fig. 8C shows the typical [001] pattern, but with faint “spots” situated directly in the center of the hexagons, as can be seen in the intensity profile (8F). The intensity profile shows that these peaks, marked by black arrows, are above the noise level in the image and appear perfectly spaced between the other atomic columns. This particular pattern is the result of a stacking fault midway through the nanocrystal that causes a shift of half of the crystal lattice. Figs. 8D and E show a model CdSe nanocrystal with a stacking fault that can reproduce the experimental image from the [001] and [010] orientations, respectively. The yellow arrow indicates the direction of the stacking fault.

The nanocrystal shown in Fig. 9A shows a relatively symmetrical intensity along its C-axis as would be expected for a traditional nanocrystal. The 3D cartoon

(Fig. 9B) is helpful for visualizing the 3D shape of the nanocrystal. However, the nanocrystal in Fig. 9C clearly shows a large decrease in intensity for half of the nanocrystal, giving the impression that it is only partially completed or that a possible defect formation prevented further growth. An artist’s conception of the approximate 3D shape is shown in Fig. 9D. From the 3D shape, it appears that the growth occurs in a stepwise manner, starting at a surface edge and then moving across while building upward along the C-axis. This most likely occurs due to the higher number of dangling bonds on the edges of the nanocrystal. With the surface clearly visible in these images, it should be feasible to observe subtle differences in surface structure caused by varying the surfactants, as illustrated in the following section.

## SURFACTANT EFFECTS ON NANOCRYSTAL SURFACE STRUCTURE

It has been reported previously that CdSe nanocrystals prepared by the TOPO-only method are Cd rich.<sup>[43]</sup> It is believed that the excess Cd found in the TOPO-only nanocrystals resides in the elongated [101] facets, where there are two Se dangling bonds at each Se surface site. However, when an HDA was used as a co-surfactant, improvements in fluorescence quantum yield and narrower size distribution were also accompanied by a reduction in the excess cadmium measured. Z-STEM was used to image the CdSe

**Fig. 7** Z-STEM images and model. (A) is a Z-STEM image of a CdSe nanocrystal showing atomic contrast with its associated model. (B) shows a peculiar spot pattern that can be obtained by tilting a nanocrystal to the [111] orientation. *Source:* Reprinted with permission from *Surf. Sci. Rep.*, **2007**, *62*, 111–157. © 2007 Elsevier B. V.

nanocrystals produced under these two conditions and to determine any difference in surface structure.

The images in Fig. 10 are the first aberration-corrected Z-STEM images of CdSe nanocrystals ever taken, obtained shortly after the installation of the spherical aberration ( $C_s$ ) corrector. The optimum probe size just after installation was around 0.8 Å, later demonstrated with the direct imaging of the 0.78 Å spacing in an Si [112] foil.<sup>[18]</sup> The striking detail of the surface of these nanocrystals prepared with TOPO as the only surfactant clearly shows the precise shape of the nanocrystals. Several of the nanocrystals in Fig. 10A appear elongated, while most exhibit an ovoid shape. The Z-STEM images clearly show a lack of shape distribution control. It was proposed that this might be the result of a “magic” impurity that exists in technical grade TOPO causing an increase in growth along the  $C$ -axis.<sup>[44]</sup> However, CdSe nanocrystals with a good size distribution cannot be grown without this “magic” impurity. Additionally, having too much of this impurity leads to uncontrolled growth. Prior to the Z-STEM reported here, it was determined by Peng and Peng that the magic ingredient was a phosphonic acid impurity in the TOPO that was necessary to control the shape and growth of the nanocrystals.<sup>[14]</sup> In addition to the phosphonic acid, a long-chain, primary

amine, such as HDA, was also added to obtain superb size distribution without the need for size selective precipitation.<sup>[23]</sup> Atomic number contrast scanning transmission electron microscopy images of CdSe nanocrystals prepared with the mixture of TOPO/HDA and dodecylphosphonic acid, are shown in Fig. 10B. In both images, the large number of lattice-resolved nanocrystals illustrates the benefit of the  $C_s$  corrector and the small probe size. Since the nanocrystals are free to rotate, obtaining a good lattice-resolved image is dependent on the orientation of the nanocrystal during image capture. As the probe size decreases, the number of lattice-resolved nanocrystals increases due to improved ability to image nanocrystals off axis, and the higher number of zone-axis orientations that are resolvable. The small features seen near the surface would be very difficult to detect using conventional HRTEM.

Interestingly, a striking difference between the two images can be seen. Although the sizes of the nanocrystal samples differ only by 0.3 nm on average, their overall shape is markedly different. The TOPO-prepared CdSe nanocrystals in Fig. 10A appear to be elongated, compared with those of the TOPO/HDA-prepared nanocrystals in Fig. 10B. For example, the nanocrystal circled in Fig. 10C shows a definite

**Fig. 8** (A) and (B) show Z-STEM images of CdSe nanocrystals with stacking faults perpendicular to the image plane. (C) is a Z-STEM image of a CdSe nanocrystal with a stacking fault in the image plane, adding intensity in the center of hexagons (D–F). *Source:* Reprinted with permission from *Surf. Sci. Rep.*, **2007**, *62*, 111-157. © 2007 Elsevier B. V.

narrowing along the  $c$ -axis, which is parallel to the surface plane. The inhomogeneous faceting of this sample is most likely the result of preferential growth along this axis. From this image, the orientation of the Cd and Se dumbbells can be determined, illustrated by the line profile in Fig. 10D, allowing us to assign the narrow end of the nanocrystal as the Se-rich (001') face. This directly assigns the Se-rich face as the primary growth face and allows the direct determination of the remaining faces as shown in Fig. 10C. The growth direction and growth mode matches what was seen in more detail in the Z-STEM image of an “incomplete” nanocrystal in Fig. 9.

### CHARACTERIZATION OF THE SHELL STRUCTURE OF CdSe-BASED CORE/SHELL NANOCRYSTALS

The ability of Z-STEM to simultaneously collect chemical information with structural position makes it an ideal tool for studying core/shell nanocrystals. The mass difference between the core and shell material manifests itself as a clear change in intensity in the raw images. Core-less, or “dark,” particles are

easily identified in the same manner. We chose to study CdSe-based cores/shell systems since they have been previously characterized extensively. The purpose of the shell material is to passivate surface trap sites and to energetically confine the electron and hole. For high photoluminescence yields, ideally every absorbed photon will lead to the emission of a photon. To ensure radiative electron and hole recombination, a material with a wider band gap than the core is used to coat the surface. ZnS satisfies this requirement for CdSe cores, and is typically used as the shell material due. CdSe/ZnS is also an ideal test-bed for Z-STEM because of the large mass difference between the ZnS shell and the CdSe core. This work was performed in collaboration with Quantum Dot Corporation (now part of Invitrogen) to develop core/shell nanocrystals into commercially viable fluorescent probes.

Fig. 11A shows the first Z-STEM image of a CdSe/ZnS core/shell nanocrystal, prepared using the standard literature preparation by Quantum Dot Corp. with a core size of 3.0 nm and a measured fluorescence quantum yield of 34%.<sup>[11]</sup> The nanocrystal in the center of the raw Z-STEM image features a bright core, with a fainter shell encircling it. Lattice fringes seen on the shell indicate that it is crystalline; however,

**Fig. 9** Z-STEM and shape. The intensity contrast can be used to judge the overall nanocrystal shape. (A) is a regularly shaped nanocrystal with uniform intensity, illustrated by the cartoon (B). 7C shows a drastic decrease in intensity suggesting that the nanocrystal may not be complete, as illustrated by the cartoon (D). *Source:* Reprinted with permission from *Surf. Sci. Rep.*, **2007**, *62*, 111–157. © 2007 Elsevier B. V.

the shell is not spherical in shape and coats the core unevenly. From this image, the existence of core-less particles, presumably ZnS nanocrystals that nucleated during shell growth, are also seen. These dark particles can be clearly identified by their uniform intensity across the particle. Additionally, a large amount of excess starting material can be seen associated with the core/shell nanocrystals. This is surprising to find, given that the nanocrystals were washed several times. Finally, an amorphous or semicrystalline shell can be seen on the outermost surface of the core/shells, which is most likely an oxide coating on the ZnS shell.

**Fig. 11B** shows an extreme case where the ZnS shell only grew in one direction. This could be the result of the 11% lattice mismatch between CdSe and ZnS.<sup>[20]</sup> However, a more likely cause is the varied reactivity of the different nanocrystal surfaces. The Se rich, (001') face of CdSe is unpassivated and typically the most reactive, and therefore it is the most likely place for shell growth to initiate. It is quite likely that this surface remains the most chemically reactive, since as the shell grows it remains the least passivated. This leads to a competitive growth process that often leaves the remainder of the core with little or no shell coverage, **Fig. 11C** shows a line profile along the *C*-axis of the core/shell in **Fig. 11B**, illustrating the intensity change going from shell to core due to the mass difference between the CdSe core and the ZnS shell. The interface between core and shell has been marked with a black arrow. The shell can be seen only covering one surface of the core. The large number of ZnS particles found is most

likely due to the extreme excess of ZnS precursors that were used in an attempt to force the shell to grow on all the surfaces.

In general, the problem of growing a lattice-mismatched material onto a surface has been addressed before.<sup>[45–47]</sup> When a material is grown onto another material with different lattice spacing, strain energy is created as the chemical bonds are bent and stretched. For a cubic system, the strain energy areal density,  $E_e$ , is given by Eq. (1).

$$E_e = \varepsilon^2 B h \quad (1)$$

$\varepsilon$  is defined as the in-plane strain,  $B$  is the bulk modulus for a thin film (for bulk CdSe,  $B$  is  $5.5 \times 10^{11}$  dyn/cm<sup>2</sup> at room temperature), and  $h$  is the film thickness. This thickness dependence leads to an important parameter called the critical thickness,  $h_c$ . In equilibrium, there is a maximum thickness of material that can be grown on a lattice-mismatched substrate before a dislocation forms. For growth on (100) cubic substrates,  $h_c$  is defined by Eq. (2).

$$h_c = \frac{b(1 - \nu \cos^2 \Theta_{db}) [\ln(\frac{h_c}{b}) + 1]}{8\pi(1 + \nu)f(\cos \lambda)} \quad (2)$$

In this equation,  $b$  is the Burgers vector, or the lattice constant of the defect,  $\nu$  is Poisson's ratio,  $f$  is the lattice mismatch,  $\Theta$  is the angle between the dislocation and its Burgers vector, and  $\lambda$  is the angle between the slip direction, the direction that the defect propagates

**Fig. 10** TOPO vs. TOPO/HDA. (A) and (B) are Z-STEM images of CdSe nanocrystals prepared with TOPO and a mixture of TOPO and HDA, respectively. The TOPO only nanocrystals exhibit elongated facets (C). The relative intensity differences between atomic columns (D) seen in the images was used to identify the elongated facet as the (101) facet. *Source:* Reprinted with permission from *Nano Lett.*, **2004**, 4 (7) 1279–1283. © 2004 American Chemical Society.

and a line in the interface plane.<sup>[20]</sup> The important result of this relationship is that the critical thickness is inversely related to the lattice mismatch between the materials. Since the lattice mismatch between ZnS and CdSe is nearly 11%,  $h_c$  is less than 1 nm, so only a very thin ZnS shell can be grown before dislocations form. These dislocations could act as potential recombination centers, degrading the effectiveness of the shell. To obtain thicker shells, a shell material that has a smaller lattice mismatch with CdSe can be grown initially, followed by a thin coating of the material with a larger lattice mismatch. Two potential intermediate shell materials for the CdSe/ZnS core/shell system are CdS and ZnSe, which have lattice constants that reside between those of CdSe and ZnS.

Quantum Dot Corporation chose to introduce Cd in the shelling process to “dope” the shell to improve shell coverage. This method could produce either a  $Zn_{(1-x)}Cd_xS$  shell or a CdSe/CdS/ZnS graded-shelled nanocrystal. Rutherford backscattering spectroscopy (RBS). RBS was used to confirm the addition of Cd to the shell, with an atomic ratio of Zn to Cd of 3:1, reduced from the 8:1 ratio found in the literature prepared sample.<sup>[44]</sup> This indicates that the majority of the shell contains Cd. Although the images (such as Fig. 11D) obtained do not clearly indicate an outer ZnS shell, owing to the varied reactivities of the cation precursors, it is quite likely that the majority of the zinc is coating the surface. Atomic number contrast scanning transmission electron microscopy images were

**Fig. 11** Z-STEM of core/shell nanocrystals. (A) and (B) are images of CdSe/ZnS core/shell nanocrystals showing intensity contrast between core and shell (C). The black arrow in B and C indicates the interface between core and shell. (D) has cadmium doped into the shell, which improved shell coverage but reduced the amount of intensity contrast between core and shell. (E) shows a ZnS nanocrystal along side a core/shell nanocrystal with the associated intensity profile (F). Since the ZnS nanocrystal does not have a shell, the intensity remains uniform over its entirety. The dashed arrows indicate the position where the intensity profiles (C and F) were obtained. Reprinted with permission from *Nano Lett.*, **2006**, 6 (7) 1496–1501. Source: © 2006 American Chemical Society.

obtained from the 3 nm core/shell/shell sample. This was the first core/shell/shell sample examined after the microscope was fitted with the  $C_s$  corrector. Fig. 11D shows the first lattice resolved image of a graded core/shell nanocrystal.

The square shape of the core/shell nanocrystal in 11D suggests that all sides are being coated. In comparison with the CdSe/ZnS quantum dot in Fig. 11B, the mass contrast between core and shell has diminished. This is most likely due to the structure being that of a core with a double shell of CdS/ZnS. The CdS acts

as an intermediate layer, which improved total shell coverage when compared with that of a shell consisting of only ZnS. The increased ease of coating the quantum dot surface with CdS is manifested in the fact that the majority of the nanocrystals imaged in this sample are core/shells and not CdS or ZnS nanoparticles. Although the image in Fig. 11E was not typical of the sample, it does afford a unique opportunity to show the mass contrast difference between a core/shell nanocrystal and ZnS nanocrystal. This image features a core/shell nanocrystal associated with a long ZnS

**Fig. 12** Z-STEM of Qdot 655 core/shell nanocrystals. The core/shells (A and B) have a graded CdS/ZnS shell coating and exhibit a “nano-bullet” shape. Despite the graded shell, the overall coverage continues to prefer one particular surface over the others. 12C is the intensity profile taken along the c-axis showing a fairly uniform intensity profile until it begins to decrease near the tip. (D and E) are conventional TEM images of the same material with markers indicating contrast that can be misinterpreted as the result of the core/shell structure and is typical for nanocrystal rods. *Source:* Reprinted with permission from *Nano Lett.*, **2006**, 6 (7) 1496–1501. © 2006 American Chemical Society and from *Surf. Sci. Rep.*, **2007**, 62, 111–157. © 2007 Elsevier B. V.

nanocrystal. The line profile, Fig. 11F, illustrates how easily ZnS particles can be identified by the image intensity. Since there is no change in the chemical composition, the ZnS particle has a nearly flat intensity profile, while the neighboring core/shell nanocrystal has a gaussian intensity profile. The intensity changes dramatically across the core/shell nanocrystal since the intensity is not only affected by the change in the amount of material but also by the change in chemical composition.

The double-shell method was also applied to the coating of CdSe nanorods with aspect ratios (length : width) near 2 : 1. The resulting core/shell/shell rods routinely have quantum efficiencies of 100% and are now commercially available from Invitrogen under the product names 655 and 605 AMP Quantum Dots. The initial number is the wavelength in nanometers of the emission maximum. These core/shells were coated with an AMP

polymer that makes them water-soluble.<sup>[48]</sup> AMP stands for a generalized group of amphiphilic polymers, which have hydrophobic and hydrophilic end groups. The hydrophobic tails are used to interact with the hydrophobic surfactants on the surface of the nanocrystal. In the presence of water, the polymer forms a micelle around the quantum dot with the hydrophilic head groups forming the outer surface. These groups can then be cross-linked, essentially sealing the quantum dot in a “plastic bag.”

The Z-STEM images in Fig. 12A and B show very little contrast between core and shell, since the shell is nearly all CdS. However, clear contrast can be seen between the intensities of the selenium and sulfur from the atomic dumbbells in the images. This is illustrated by the noticeable change in the appearance of the alternating dumbbells going from the center of the particle to the tip. The lesser intensity of the peaks in the atomic

dumbbell is from the anion, which in this case is the Se and S atomic columns. As the material transitions from predominantly CdSe/CdS to CdS, the anion intensity decreases to the point where only intensity from the Cd column can be seen. The abruptness of the loss of the anion intensity suggests that these particular nanorods may have a layered structure and are not an alloy.

Interestingly, the overall morphology deviates strongly from a homogeneous shell coating. The core/shell shape is that of a “bullet,” capped with a flat surface on one end while forming a point on the other. The line profile in Fig. 12C indicates very little intensity difference between core and shell. The sloping nature of the intensity profile near the tip of the nanorod is most likely due to a convolution of the lower atomic number of the shell material and the nanorod narrowing to a point. For comparison, Fig. 12D and E show two HRTEM images of the 655 AMP nanorods. The core/shell rod marked with an arrow in Fig. 12D appears to have some intensity

contrast that could be attributed to the core/shell structure. However, none of the other rods in the same image show similar of contrast. This suggests that the contrast change is more likely a chromatic aberration effect, or the result of lattice strain, than actual contrast between different materials. Further evidence that the contrast change is not related to a core/shell structure is that similar contrast changes have been seen in nanorods that do not have a shell. The arrow in Fig. 12E points to a zinc blende stacking fault similar to the ones seen in the Z-STEM images (Fig. 12A and B).

Surprisingly, the Z-STEM images of the 605 AMP core/shell nanorods, Fig. 13A and B, appear narrower and more elongated in comparison with the 655 AMP “nano-bullets.” The shell covering the (001') facet is nearly as thick as the core nanocrystal, as illustrated by the intensity profile in Fig. 13C. Additionally, this intensity profile shows a three-tiered structure that suggests three different chemical compositions. We can

**Fig. 13** Z-STEM of 605 Qdots. (A) and (B) are Z-STEM images of graded core/shell nanocrystals with the shell material predominantly coating one surface. The graded structure can be seen in the intensity profile (C). (D–F) are conventional TEM images of the same material, with F having the c axis perpendicular to the image plane. *Source:* Reprinted with permission from *Nano Lett.*, **2006**, 6 (7) 1496–1501. © 2006 American Chemical Society and from *Surf. Sci. Rep.*, **2007**, 62, 111–157. © 2007 Elsevier B. V.

assign the highest-intensity region to the CdSe core, the intermediate region to the CdS inner shell and the edges to the ZnS outer shell. The other possibility is that the final two rows are also CdS but only covering a small portion of the surface. The filling of the  $\{101\}$  facets is not as evident in the majority of the 605 emitting core/shell rods; however, the shell material still covers the Se-rich faces preferentially. For comparison, Fig. 13D–F shows three HRTEM images of the 605 AMP core/shell nanorods. Figure 13D and E are typical TEM images of this nanorod sample, showing a rounded end and a pointed end on each of the core/shell rods. Fig. 13F is a HRTEM image of a 605 AMP nanorod aligned with the (001) face perpendicular to the TEM grid. Although the surface is not well defined, the overall shape appears asymmetrical, which is most likely due to the shell coating certain surfaces preferentially. Unfortunately, no Z-STEM images of an on-end core/shell rod have been obtained owing to the extremely low occurrence of this orientation for rod-shaped nanocrystals.

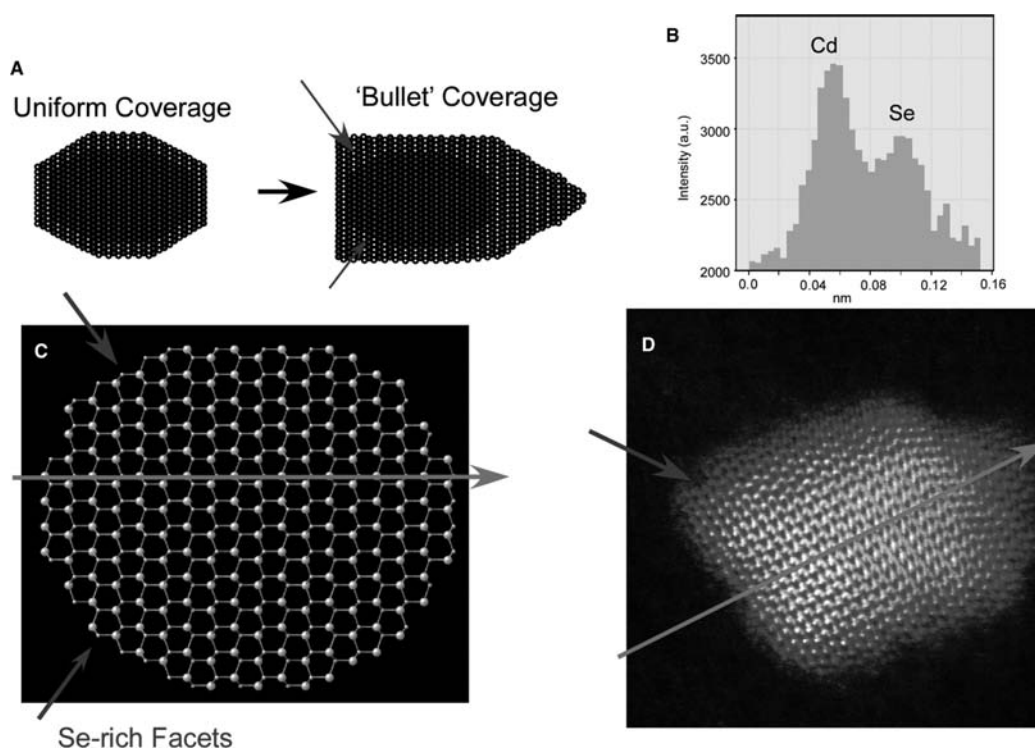

Fig. 14 shows Z-STEM images of the 605 AMP core/shell rods whose shell surfaces are clearly resolved. Several gaps and outgrowths, marked with a white oval can be seen, showing that the shell is not perfect at its surface. If tunneling of charges through the shell occurs, these defects would serve as potential trap sites due to the presence of unsatisfied bonds. However, this sample has a quantum yield of nearly 100%, indicating that the ability of an electron

or hole to tunnel to the shell surface is limited. This means that the shell surface need not be perfect, but instead that the shell only needs to cover the entire surface of the core, to effectively passivate the core.

The level of atomic detail afforded by Z-STEM can be used to identify specific nanocrystal faces of core/shell nanocrystals. This is important because the CdSe nanocrystal facets are not chemically equivalent, which may explain why the coating of the shell is not uniform. As illustrated by the cartoon in Fig. 15, once the alternating intensity pattern of the Cd and Se dumbbells is identified (Fig. 15B), we can then assign one end of the rod as the Se-rich (001') face and the other as the Cd-rich (001) face. A comparison of the image to a model of the CdSe core (Fig. 15C) can then be used to identify the remaining surfaces. The image in Fig. 15D exhibits the typical "nano-bullet" shape, with a near perfectly flat end opposite a pointed end. Using the atomic dumbbells, we can definitively assign the pointed end of the nanorod as the anion rich (001') face. This supports predictions in the literature stating that the Se-rich face is the primary growth face for the CdSe core.<sup>[23]</sup> The facets with the next highest concentration of Se surface sites are the (101') facets, located near the flat end of the "nano-bullet" (marked with a blue arrow). Interestingly, to achieve the unique bullet shape, these corner (101') facets must also grow at a faster rate than the side (100) faces. The shell appears to be at its thinnest on the Cd-rich (001) and the  $\{100\}$  surfaces, with an average coverage of a

**Fig. 14** Z-STEM images of core/shell surface. Defects such as missing atomic columns can be seen on the shell surface (circled). *Source:* Reprinted with permission from *Surf. Sci. Rep.*, **2007**, *62*, 111–157. © 2007 Elsevier B. V.

**Fig. 15** Shell Growth Model. (A) shows a cartoon illustration of the difference between the predicted core/shell structure and the obtained “nano-bullet” shape. From atomic dumbbell contrast (B) one can orientate a model (C) to an image of a core/shell nanocrystal (D). With this simple comparison, it would appear that the shell is preferentially growing on the anion rich surfaces. *Source:* Reprinted with permission from *Nano Lett.*, **2006**, 6 (7) 1496–1501. © 2006 American Chemical Society.

monolayer or two, while the Se-rich  $\{101'\}$  facets have about 4–5 monolayers and the  $(001')$  facet has anywhere from 6 to 15 monolayers. Thus, the shell-growth mechanism appears to select the anion surface sites preferentially.

Fig. 16 shows a CdSe/CdS core/shell nanorod oriented with the  $(010)$  face parallel to the TEM grid. The atomic dumbbells are clearly resolved in the raw image and can easily be assigned by their mass contrast. In Fig. 16B, a Fourier filter has been used to reduce the amount of noise in the image to better show the mass contrast. This rod was resting on an edge, as illustrated by the model in Fig. 16D and provides a unique opportunity to illustrate how structure in the  $z$ -direction (out of the image plane) can be obtained from the raw image. The intensity profile in Fig. 16C beautifully outlines the faceted shape of the nanocrystal surface that coincides with this orientation. Lastly, the intensity profile in Fig. 16E shows how cleanly the individual atomic columns are resolved in the image. In this single image, we can see the atomic structure, identify specific facets, and determine the core/shell rod's 3D shape.

The Z-STEM images and the near unity quantum yield of the AMP-coated core/shell nanorods suggest that shell coverage free of interfacial defects is more important than electron and hole confinement.

Presumably, in the case of ZnS, defects in the shell or a lack of complete shell coverage provide tunneling sites or surface sites for non-radiative recombination. This is supported by the result that the largest improvement in fluorescence quantum yield was realized by choosing a better lattice-matched material at the expense of electron confinement. Elimination of dark particles is also important, resulting in another 20% increase in fluorescence quantum yield. However, the role of Zn in the core/shell/shell system remains important. Core/shell rods made with only a CdS shell were found to be far less photostable than those containing Zn. The role of ZnS as a photostabilizing layer has been supported by previous work, in which CdSe cores with ZnS shells demonstrated an improved photostability over cores with a CdS shell.<sup>[22]</sup> This is most likely due to the CdS shell absorbing at 366 nm, which is the wavelength commonly used for fluorescence imaging. Since bulk ZnS absorbs at 345 nm and below, a ZnS shell should only absorb at even lower wavelengths (due to quantum confinement), making it less susceptible to photodegradation under typical experimental conditions. In this system, the benefit of a lattice-matched CdS shell has been combined with the photostability of the ZnS shell to make very bright and stable core/shell nanocrystals.

**Fig. 16** Nanocrystal Hand-stand. (A) (raw) and (B) (Fourier filtered) are Z-STEM images of a core/shell rod in the (010) orientation. The intensity profile (C) shows the shape of the nanocrystal with a facet rising out of the image plane. (D) illustrates the nanocrystal orientation relative to the electron beam (green) and scan direction (green arrow). ### Z-STEM OF $\text{CdSe}_x\text{S}_{(1-x)}$ ALLOYS

$\text{CdSe}_x\text{S}_{(1-x)}$  alloys have the potential for use as fluorescent probes when multiple emission colors are needed without resorting to changing the diameter of the nanocrystals. For example, work by Bawendi et al. illustrates the need to consider the effects of the nanocrystal's hydrodynamic radius when conducting a fluorescence imaging experiment in vivo.<sup>[49]</sup> By changing the relative amounts of the two anions, the band gap can be adjusted while maintaining the nanocrystal diameter.

Alloy nanocrystals were synthesized by using the method of Swafford, where the composition was controlled by adjusting the relative amounts of the anions found in the injection solution.<sup>[17]</sup> The composition of the nanocrystal was determined by RBS analysis on purified aliquots pulled during growth. However, although the RBS data suggests that the relative amounts of sulfur and selenium remained constant during growth, sequestering of one the anions or the nucleation of non-alloyed nanocrystals could not be

ruled out from the RBS analysis alone. Z-STEM was employed to demonstrate uniform distribution of the anions throughout the nanocrystals. If the nanocrystals exhibited a core/shell structure in the Z-STEM images, this would indicate that the elements were sequestering during growth.

Figure 17A and B show the Z-STEM images of  $\text{CdS}_{0.55}\text{Se}_{0.45}$ . Unlike the core/shell images shown earlier, there is no noticeable change in intensity across the nanocrystal. However, the nanocrystals exhibit a zinc blende structure with a large number of stacking faults that can be seen on nearly every nanocrystal. To determine whether this was a result of the alloying process or an affect of the oleic acid surfactant, CdSe nanocrystals prepared using oleic acid as the surfactant were also imaged. Figure 17C shows Z-STEM images of CdSe prepared in oleic acid. The CdSe nanocrystals are also zinc blende, unlike those produced in TOPO and appear to have the same large number of stacking faults as seen for the alloys. This suggests that the zinc blende structure and number of stacking faults is the result of the surfactant and not the alloying process.

**Fig. 17** Z-STEM of CdS<sub>0.55</sub>Se<sub>0.45</sub> alloyed nanocrystal. (A) and (B) are Z-STEM images of alloyed nanocrystals showing large number of stacking fault but no contrast due to sequestering or core/shell structures. (C) is an image of CdSe nanocrystals prepared using oleic acid. In contrast to nanocrystals synthesized in TOPO/HDA, there are a large number of stacking faults and twinning, the result of the oleic acid surfactant.

## CONCLUSION

The use of aberration-corrected Z-STEM has provided a clearer understanding of the surface structure of nanocrystals and its importance in growth. For the first time, it was possible to image, with atomic-scale precision, the surface of a nanocrystal. The result of this has allowed for the accurate assignment of the nanocrystal surfaces and uses that to formulate a mechanism for nanocrystal growth and, in a similar fashion, shell growth.

From the Z-STEM images obtained and the chemistry employed, our current understanding of nanocrystal growth involves a dynamic competition between the different reactivities of the nanocrystal surface. Growth is predominantly along the C-axis

from the anion terminated surface, with a rate dependent on the amount of phosphonic acid and aliphatic amine used in the reaction. The growth of a symmetrical epitaxial shell is also hindered by the highly reactive anion-rich facets leading to certain surfaces with very little shell and others with a large excess. Homogeneous nanocrystal alloys are possible; however, the use of oleic acid produces nanocrystals with large numbers of stacking faults.

# Adhesion: Cell on a Substrate

Frédéric Pincet

Laboratoire de Physique Statistique de l'Ecole Normale Supérieure, Paris, France

## INTRODUCTION

Life would not exist if the molecules involved did not interact in a very dynamical way. An equilibrium situation must not be reached and evolution has to be continual. This implies that life originates from interactions and bonds that are weak and have a short lifetime (1  $\mu$ sec to several days) because of thermal fluctuations. Living systems endure a constant competition among these molecules that bind to each other. These molecular bonds, called ligand–receptor bonds or keylock bonds, define what is known as specific interactions. All molecules interact with each other, but, if possible, will form the strongest possible bond. It can be considered that two molecules that tend to bind in many situations are able to recognize each other. This can be observed in cell adhesion when two cells adhere because of specific molecules that they express at their surfaces. In real cells, this adhesion is usually difficult to quantify because of their complex physical properties and the high number of molecules that are present at their surfaces. However, for model cells, it is possible to quantify the adhesion and to deduce molecular properties of the bonds, even for very weak bonds. Here such a model of a cell adhering to a substrate will be presented. This model will be experimentally checked by the vesicle micromanipulation technique and applied to a bond involved in embryogenesis.

## MODEL OF A CELL ADHERING ON A SUBSTRATE

Let us consider the following model where a “cell” of constant total area  $A_t$  will be seen as a capsule bearing  $N$  freely diffusing recognition sites (ligands) on its surface (Fig. 1). This cell adheres to a substrate containing complementary sites (receptors) that are not able to diffuse. The density of receptors is therefore fixed and will be called  $\rho_0$ . Apart from the ligand–receptor interactions, the cell and the substrate do not exhibit either significant repulsion (polymer-like, for instance) or attraction (van der Waals, for instance). During the adhesion process, the ligands tend to move toward the contact region to bind to receptors on the substrate.

This leads to an enrichment of ligands in the contact area  $A_c$ , where their density becomes higher than in the rest of the cell, therefore creating a bidimensional osmotic pressure that pushes the ligands away from the contact. Qualitatively, equilibrium will be reached when the attraction of the sites toward the contact zone is perfectly balanced by this osmotic repulsion.

More quantitatively, when the cell adheres to the substrate, the mechanical equilibrium represents the balance between the specific energy associated with contact formation and the cellular deformation work. For a variation  $\delta A_c$  of the contact area, it can be written:

$$W_{\text{adh}}\delta A_c + \delta w = 0 \quad (1)$$

where  $\delta w$ ,  $W_{\text{adh}}$  is the adhesion energy (positive), namely, the free energy to create a unit contact area, and  $\delta w$  is the cellular deformation work associated with the variation of contact  $\delta A_c$ . One has to be aware that the  $W_{\text{adh}}$  is not the energy necessary to bring one unit area of the initial cell surface to contact. It is more subtle: it represents the energy gained by taking an adapted area of the part of the cell that is not in contact with the substrate, concentrating the ligands to their final concentration in the contact area (this must give a unit final area), and bringing it to contact with the substrate where bonds can form.

Because the differential of the free energy  $F$  is  $dF = \delta w - SdT$  and the reaction is isothermic, one obtains  $dF = \delta w$ .

This means that at mechanical equilibrium:

$$W_{\text{adh}} = \left( \frac{\partial F}{\partial A_c} \right)_{v,T} = k_B T \left( \frac{\partial \ln Z}{\partial A_c} \right)_{v,T} \quad (2)$$

where  $Z$  is the partition function.

To obtain the value of the adhesion energy, it is therefore required to differentiate the free energy as a function of  $A_c$ .<sup>[1]</sup>

In the contact area, the ligands can be in two states, unbound or bound to a receptor. As they are energetically in the same configurations, the unbound ones and the ligands in the rest of the cell must have the same concentration,<sup>[2]</sup>  $n_u$ . The concentration of bound ligands will be noted  $n_b$ .

**Fig. 1** Schematic view of the model of a cell adhering to a substrate: the cell is a capsule containing freely diffusing sites, ligands, on its membrane. These sites can bind to complementary sites, receptors, on the substrate, where they are immobile.

### ADHESION ENERGY AND BIDIMENSIONAL OSMOTIC PRESSURE AT EQUILIBRIUM

To relate the adhesion energy and the bidimensional osmotic pressure, the same approach as that taken by Evans<sup>[3]</sup> will be used. The Gibbs free energy can be written  $G = \mu_b N_b + \mu_u N_u$ , where  $\mu_b$  and  $N_b$  ( $\mu_u$  and  $N_u$ ) are the chemical potential and number of the bound (unbound) ligands.

This leads directly to:

$$\delta G = \mu_b \delta N_b + N_b \delta \mu_b + \mu_u \delta N_u + N_u \delta \mu_u \quad (3)$$

Since  $\mu_b = \mu_b^0 + k_B T \ln(n_b/n_0)$  and  $\mu_u = \mu_u^0 + k_B T \ln(n_u/n_0)$ , where  $n_b = N_b/A_c$ ,  $n_u = N_u/A_t$  and  $n_0 = N/A_t$ ,

$$N_b \delta \mu_b = k_B T N_b (\delta n_b)/n_b = k_B T A_c \delta n_b \quad (4)$$

and, similarly,

$$N_u \delta \mu_u = k_B T N_u (\delta n_u)/n_u = k_B T A_t \delta n_u \quad (5)$$

Also, the chemical equilibrium can be written:

$$\mu_u = \mu_b \quad (6)$$

and the conservation of the total number of ligands  $N = N_u + N_b = A_t n_u + A_c n_b$ . Differentiating these last two expressions gives

$$\delta N_u = -\delta N_b \quad (7)$$

and

$$n_b \delta A_c + A_c \delta n_b + A_t \delta n_u = 0 \quad (8)$$

Inserting Eqs. (4)–(8) into Eq. (3) considerably simplifies  $\delta G$ :  $\delta G = -n_b k T \delta A_c$ . The expression of  $W_{adh}$  follows:

$$W_{adh} = n_b k T \quad (9)$$

This relation was derived in the mid-80s<sup>[3,4]</sup> and means that the adhesion energy equals the bidimensional osmotic pressure. This kind of relation between these two quantities could be expected because, as mentioned above, the adhesion energy tends to pull the ligands toward the contact area and the osmotic pressure (entropy) pushes them away. At equilibrium, the induced incoming and outgoing fluxes must balance each other and therefore the adhesion energy must be related to the osmotic pressure.

From Eq. (6), one gets

$$n_f = n_b \exp((\mu_b^0 - \mu_u^0)/kT) \quad (10)$$

$(\mu_b^0 - \mu_u^0)$  has to depend on the binding energy  $e_b$ . Thus, it would seem at first sight that using Eq. (9), one can deduce  $e_b$  from  $W_{adh}$ . This turns out to be incorrect because to know the exact expression of  $(\mu_b^0 - \mu_u^0)$ , other information about the interaction is needed. For instance, the naive approach where  $\mu_b^0 - \mu_u^0 = e_b$  is wrong (it can be seen that Eqs. (9) and (10) are then not compatible for  $e_b = 0$ ).

To circumvent this problem, a simple model of the ligand–receptor interaction is needed.

### MACROSCOPIC ADHESION ENERGY AND MOLECULAR BINDING ENERGY

To schematize the interaction, it will be considered that around each receptor of the substrate, there is a molecular trapping area  $\alpha$ , meaning that a ligand will be bound only if it is within this area  $\alpha$  surrounding the receptor (Fig. 2).<sup>[5]</sup> It will also be assumed that the trapping areas of the different receptors cannot overlap. The total number of receptors in the contact zone is  $\rho_0 A_c$ , which means that the area of the total trapping zone is  $A_b = \alpha \rho_0 A_c$ . The ligands within  $A_b$  are bound to a receptor, those in the rest of the cell, no matter whether or not they are in the contact zone, are unbound. The internal energy of a given configuration

**Fig. 2** Model of the ligand–receptor interaction: if the ligand is within the attraction area  $\alpha$  of the receptor, it is bound (left ligand). Otherwise, it is unbound (right ligand).

with  $n$  ( $0 \leq n \leq N$ ) ligands in the trapping zone and  $N - n$  ligands in the rest of the cell is  $-ne_b$ . Therefore, the partition function of the system can be written:

$$\begin{aligned}
 Z &= \sum_{n=0}^N \frac{N!}{n!(N-n)!} A_b^n (A_t - A_b)^{N-n} e^{ne_b/k_B T} \\
 &= (A_t + A_b(e^{e_b/k_B T} - 1))^N \quad (11)
 \end{aligned}$$

where  $k_B T$  is the thermal energy.

Hence, the free energy is:

$$F = -Nk_B T \ln(A_t + A_b(e^{e_b/k_B T} - 1)) \quad (12)$$

$W_{adh}$  is directly derived from Eq. (2):

$$W_{adh} = N\alpha\rho_0 k_B T \frac{(e^{e_b/k_B T} - 1)}{(A_t + \alpha\rho_0 A_c(e^{e_b/k_B T} - 1))} \quad (13)$$

Results that could have been intuitively anticipated can be deduced from Eq. (13):

1.  $W_{adh}$  decreases when the contact zone increases because the “reservoir” made by the outer part of the cell becomes relatively smaller as compared to  $A_c$ .
2. When the number of receptors in the contact zone is small,  $W_{adh}$  is independent of  $A_c$ . This is the linear regime where the fraction of bound ligands is small.
3. When  $e_b$  is large, all the ligands are bound to receptors and, as expected from Eq. (9),  $W_{adh} = Nk_B T/A_c$ .

One may note that there is a strong limitation of this model, which is to allow several ligands to be bound to the same receptor. In practice, this is usually not a problem, but it can happen that when there are too few receptors and the binding energy is large, the number of bound ligands and therefore  $W_{adh}$  will be overestimated. Also, any cooperative effects among the ligand molecules have been neglected. In a system where these problems arise, numerical simulations seem to be the best way to relate  $W_{adh}$  and  $e_b$ .

This second approach (model of a trapping area) is compatible with Eq. (9) because the latter can be derived from Eq. (13). The average number of bound ligands  $\langle n \rangle$  is:

$$\begin{aligned}
 \langle n \rangle &= \frac{\left( \sum_{n=0}^N n \frac{N!}{n!(N-n)!} A_b^n (A_t - A_b)^{N-n} e^{ne_b/k_B T} \right)}{Z} \\
 &= \frac{NA_b e^{e_b/k_B T}}{A_t + A_b(e^{e_b/k_B T} - 1)} = \frac{A_c W_{adh}}{k_B T} \quad (14)
 \end{aligned}$$

Since  $n_b = \langle n \rangle/A_c$ , Eq. (14) is the same as Eq. (9).

Therefore, Eqs. (9) and (13) give a complete description of the ligand distribution at equilibrium and allow one to directly deduce the molecular binding energy from the total adhesion energy if the trapping area  $\alpha$ , the total number of ligands  $N$ , and the density of receptors  $\rho_0$  are known.

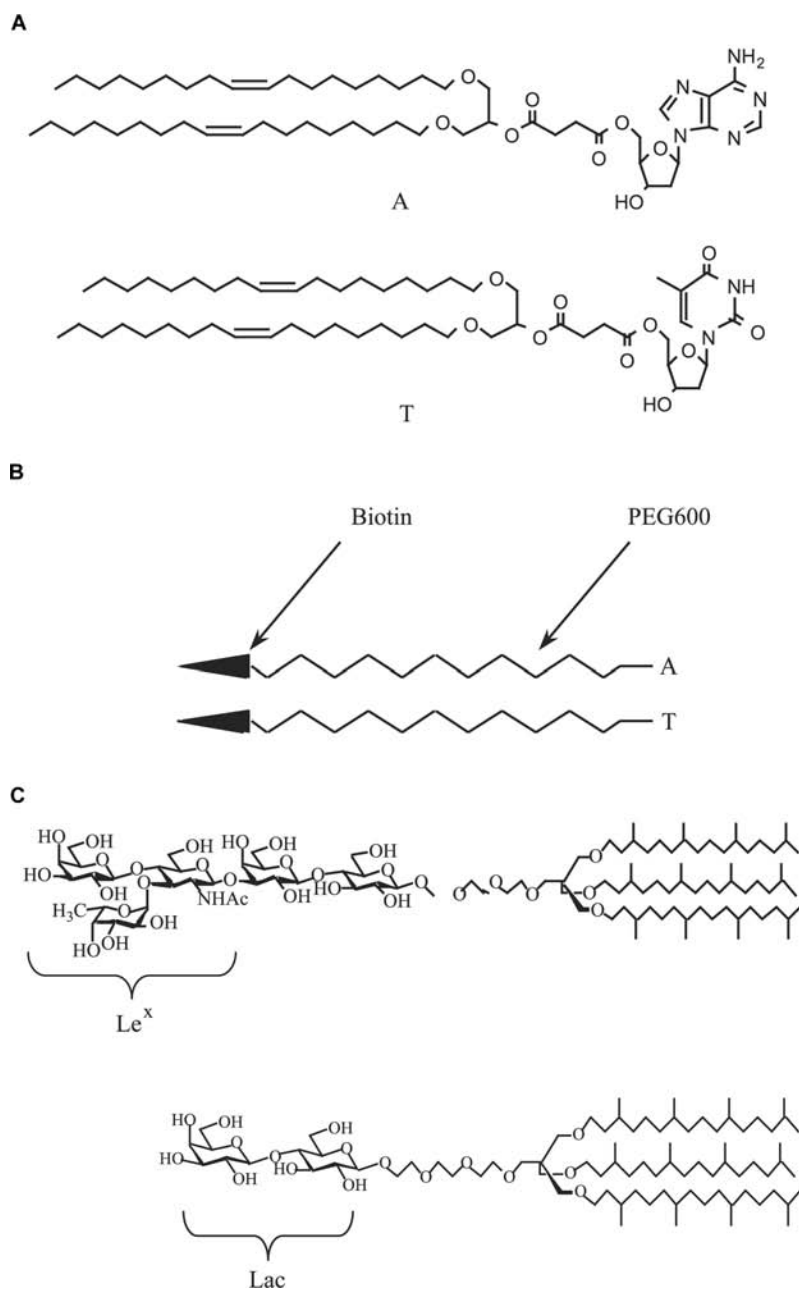

## EXPERIMENTAL VERIFICATION OF THE MODEL

To test this model, a suitable technique is based on vesicle adhesion measurement by micromanipulation.<sup>[6]</sup> It consists in holding a slightly deflated 10- to 30- $\mu\text{m}$  vesicle in a micropipette with a controlled aspiration. At the start of the experiment, the shape of the vesicle is a segment of sphere outside of the pipette and a cylindrical portion inside the pipette (which ends in an hemisphere of radius equal to the inner radius of the pipette,  $r_p$ ). The knowledge of the initial diameter of the vesicle, the length of cylindrical part, and the pipette inner diameter allows one to determine the surface and volume of the vesicle. Facing the vesicle is the substrate with a known geometry. For instance, in Fig. 3 is shown the case of a vesicle facing a bead. The vesicle is then moved and placed in tangential contact with the substrate. If adhesion occurs, e.g., through weak ligand–receptor bonds, the vesicle will stretch following the shape of the substrate in order to increase the contact area. The volume and surface of the vesicle remain essentially constant throughout the whole process. Therefore, adhesion requires the volume and surface of the vesicle outside the pipette to be larger than it originally was. This is achieved by a decrease of the projected length inside the pipette. The adhesion energy can then be deduced through the Young–Dupr  equation:

$$W_{adh} = \gamma(1 - \cos \theta) \quad (15)$$

**Fig. 3** Micromanipulated vesicle in contact with a bead held by a micropipette. The bar represents 5  $\mu\text{m}$ . The measurement of the contact angle  $\theta$  directly gives the adhesion energy through the Young–Dupr  equation [Eq. (15)].

**Fig. 4** Structures of the functionalized molecules used in the adhesion experiments. (A) Lipids with two unsaturated chains with 18 carbons to ensure the fluidity of the vesicle membranes and either adenosine (top) or thymidine (bottom) in the polar head. Vesicles containing 10% of either of these lipids and 90% of a common neutral lipid (SOPC) were used in the vesicle-bead adhesion experiments. (B) Heterofunctional molecules containing a PEG chain with a biotin at one end and either adenosine (top) or thymidine (bottom) at the other end. These molecules were grafted on superavidin-coated beads that were used for the vesicle-bead adhesion experiments. (C) Top: The Lewis X ( $Le^x$ ) determinant is a trisaccharide ( $Gal\beta 1 \rightarrow 4 [Fuc\alpha 1 \rightarrow 3] GlcNAc$ ). In this lipid, it is covalently bound to three hydrophobic chains. To ensure good accessibility of the  $Le^x$  groups for interaction, they were provided with translational and orientational mobilities by branching the chains (this keeps the layers in a fluid state by hindering their crystallization) and by means of a flexible spacer between the chains and the  $Le^x$ . Bottom: the same lipid without the  $Le^x$  group.

where  $\theta$  is the contact angle,  $W_{adh}$  is the adhesion energy as defined above, and  $\gamma$  is the tension of the vesicle, which is obtained by applying the Laplace equation to the outer part of the vesicle and to the hemisphere at the tip of the cylinder inside the pipette:

$$\gamma = \frac{r_p \Delta P}{2(1 - r_p c)} \quad (16)$$

Here  $c$  is the average curvature of the vesicle and  $\Delta P$  is the aspiration (i.e., the difference in pressure between the outside and inside of the pipette).

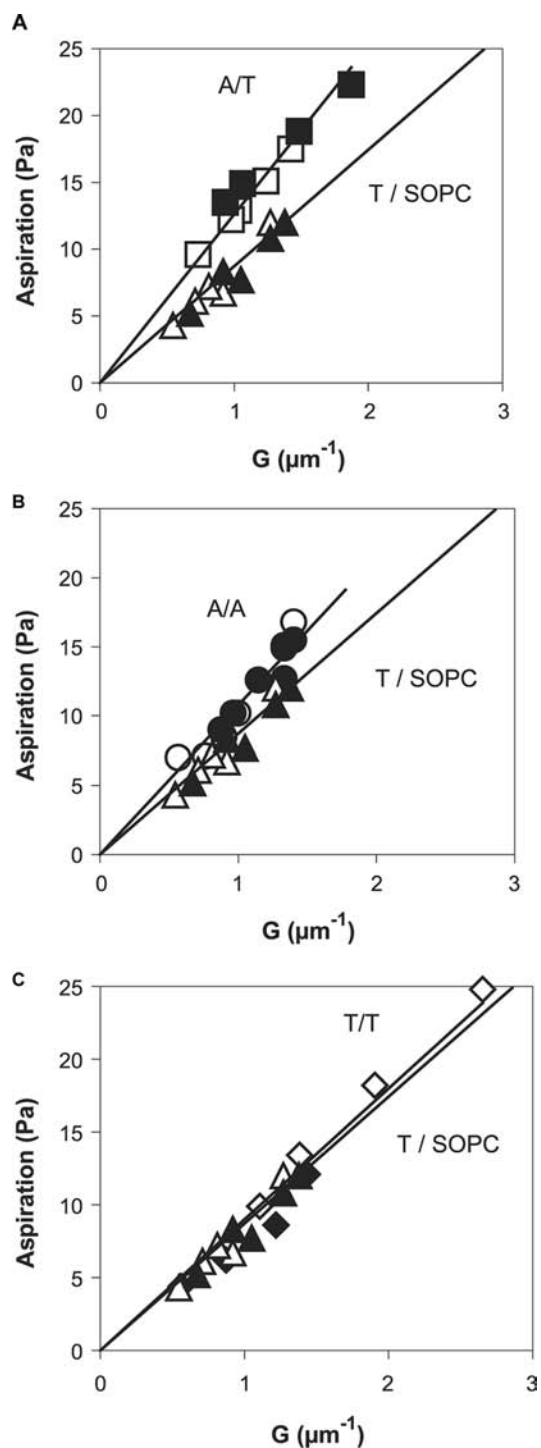

Combining Eqs. (15) and (16) gives:

$$W_{adh} = \frac{r_p \Delta P}{2(1 - r_p c)} (1 - \cos \theta) \quad (17)$$

It is possible to obtain an accurate value of  $W_{adh}$  by plotting  $\Delta P$  as a function of  $G$ :

$$G = \frac{r_p (1 - \cos \theta)}{2(1 - r_p c)} \quad (18)$$

The slope of the graph is then exactly  $W_{adh}$ . To make sure the adhesion process is reversible, it is necessary to make cycles of decreasing-increasing aspiration

**Fig. 5** Aspiration pressure as a function of  $G$  [cf. Eq. (18)] for a specific interaction and comparison with the non-specific case T/SOPC (control). According to Eq. (3), the slopes are equal to  $W_{adh}$ . The solid lines are fits forced through zero and they roughly represent the adhesion energy. However, the values reported in Table 1 are averages from fits not forced through zero and in which the increasing pressure is treated separately from the decreasing one. Closed (open) symbols correspond to the increase (decrease) of the aspiration pressure. (A) A bead–T vesicle, (B) A bead–A vesicle, (C) T bead–T vesicle.

pressure. It will not work in the case of strong bonds with lifetimes longer than the experimental characteristic time: the membrane is then pinned on the substrate and the receding contact angle will be larger than the advancing one. Therefore, to test the model, it is necessary to use weak bonds with well-known binding energies. Nucleosides such as adenosine and thymidine are good examples of such bonds.<sup>[7,8]</sup> For this purpose, lipids carrying one nucleoside (adenosine, A, or thymidine, T) as a polar headgroup were synthesized (Fig. 4A). Giant vesicles were formed by hydrating a lipid mixture of stearyl-oleoylphosphatidylcholine (SOPC)/nucleoside lipid (9/1) (after evaporation from chloroform solution) in 320 mOsm sucrose solution.<sup>[9]</sup> The vesicle suspension was added to an aqueous glucose solution chamber of a slightly higher osmolarity (360 mOsm) than that of the vesicle in order to deflate it and make it micromanipulable.

The substrates were superavidin-coated polystyrene beads purchased from Bangs Labs. The average area per attachment site for biotin was of a few hundreds of nanometers squared per effective binding site. To coat them with nucleosides, a polyethylene glycol (PEG) spacer arm was dissymmetrically functionalized at one end with biotin, and at the other end with a nucleoside (A or T) (Fig. 4B). The beads were incubated in water (50  $\mu\text{g}/\text{ml}$ ) with one of these heterobi-functionalized PEG arms (1 mg/mL) for 1 day. The contact angle was measured for several tension values of the flaccid vesicle membrane by decreasing the aspiration and then increasing it to check for the reversibility of the adhesion. This decreasing/increasing aspiration process was repeated several times on the same vesicle/bead couple, and, as expected, it was observed that this adhesion was reversible within the experimental error.

Four adhesion situations were investigated: A bead–A vesicle, T bead–T vesicle, T bead–A vesicle, and A bead–T vesicle. A control experiment was performed in which the vesicle was made of only SOPC and adhered to a T-coated bead. It turns out that the adhesion measured in the control experiment cannot be neglected, meaning that there is a non-specific adhesion that has to be subtracted from the measurements to obtain the actual value of  $W_{adh}$  due to the bonds. Fig. 5 shows the aspiration pressure as a function of  $G$  for the different cases. The resulting values for  $W_{adh}$ , reported in Table 1, are independent of the vesicle size.

Given the experimental error, the A bead–T vesicle and T bead–A vesicle systems have the same adhesion energy, as expected. It may be observed that the specific adhesion energies follow the increasing order:  $W_{adh}(T/T) < W_{adh}(A/A) < W_{adh}(A/T)$ . This is consistent with the data reported in the literature.<sup>[7,8]</sup>

**Table 1** Adhesion energy values ( $W$ ) averaged, as indicated in Fig. 5, from at least two separate experiments and six cycles

	A bead–T vesicle	T bead–A vesicle	A bead–A vesicle	T bead–T vesicle	T bead–SOPC vesicle
$W$ ( $\mu\text{J}/\text{m}^2$ )	12.0	12.9	9.9	9.3	8.6
$W_{\text{adh}}$ ( $\mu\text{J}/\text{m}^2$ )	3.4	4.3	1.3	0.7	

The error is  $\pm 1 \times 10^{-6} \text{ J m}^{-2}$ .  $W_{\text{adh}}$  is equal to  $W - W_{\text{nspe}}$ , where  $W_{\text{nspe}}$  is the T bead–SOPC vesicle adhesion energy.

The short lifetime of the bonds is illustrated by the small fraction of occupied bead sites (5%) that can be estimated from the specific adhesion energy, the known bond energy, and the bead site density.

By using Eq. (13) one directly obtains  $e_b$  from the measured specific adhesion energy values if  $\rho_o\alpha$  is known. As the same grafting technique was used for the A and T beads,  $\rho_o\alpha$  should also be the same in all the cases and is expected to be of the order of  $10^{-4}$ . We can therefore try to find a value that conciliates the four types of adhesion data (A/T, T/A, A/A, T/T).  $\rho_o\alpha = 2.4 \times 10^{-4}$  gives values that are in closest agreement with the known binding energy values.<sup>[7,8]</sup> This value for  $\rho_o\alpha$  seems reasonable because the  $\alpha$  should be of the order of a fraction of the polar head of the lipid (a few tenths of nanometers squared) and of the  $\rho_o$  order of  $10^{15}$  molecules/ $\text{nm}^2$ . The accuracy on  $\rho_o\alpha$  can be estimated from Table 2 where the binding energy values assuming different values of  $\rho_o\alpha$  near the best one are given.

Experimentally, the equilibrium seems to be reached in less than a minute for each change of aspiration pressure. This result may seem surprising because it generally takes about 15 min for lipids to diffuse around a giant vesicle. Given  $W_{\text{adh}}$  and Eq. (10), the enrichment is around 1% at the true equilibrium obtained within 15 min. This negligible amount is within the experimental error of  $W_{\text{spe}}$ . This was fully checked experimentally as the measured contact angle did not vary significantly for 20 min at a given aspiration pressure. In this approximation, equilibrium can be obtained locally because of the excess of sites on the vesicle, and lateral diffusion does not bring significant change. The local equilibrium time is typically the one needed for a lipid to explore an area  $1/\rho_o$ , which is less than a second. This explains the fast

equilibrium and why the observed hysteresis is not stronger than for non-functionalized vesicles.<sup>[10]</sup> In contrast, if there were more sites on the bead or less sites on the vesicle, the diffusion of the vesicle sites toward the contact region would noticeably change the equilibrium time.

Therefore, the description relating adhesion energy measurements to binding energies through Eq. (13) is satisfactory and can be applied to other systems. The main limitation is the requirement to know  $\rho_o\alpha$  because it is not easy to obtain, but numerical simulations may provide good estimates in some cases. The vesicle micromanipulation technique is also a good approach to measure binding energies in this way. The precision of the technique is given by the dispersion of the adhesion energy data. In the case of weak bonds like A/T where this dispersion is seen in Table 2, the error is about  $0.5k_B T$ .

## A BIOLOGICALLY RELEVANT APPLICATION OF THE APPROACH

Molecular features governing the selectivity in cell–cell recognition and adhesion are key elements to understand morphogenesis and organogenesis. All living organisms are characterized by the presence of glycoproteins and glycosphingolipids (GSLs) on the cytoplasmic membrane. Carbohydrate chains, being exposed structures at the cell surface, should play an essential role in early events of cell–cell recognition. Indeed, they have firmly been recognized as interaction sites in cell adhesion processes such as leukocyte recruitment or host–pathogen interaction. Such events are commonly attributed to lectin or lectinlike proteins and the corresponding specific carbohydrate ligands. It has been suggested only a decade ago that specific carbohydrate–carbohydrate interactions may also play this important role.<sup>[11]</sup> Several direct measurements of adhesion between surfaces decorated with glycolipids have been reported in the past.<sup>[12–18]</sup> These strong adhesions, obtained through various techniques (surface force apparatus, osmotic stress method, and vesicle micromanipulation), were due to van der Waals or other non-specific forces. However, some carbohydrate–carbohydrate interactions found in biological processes, have been proposed to be specific.<sup>[11,19,20]</sup> One of them, the Lewis<sup>x</sup> determinant

**Table 2** Binding energy values ( $e_b$ ) as deduced from Eq. (17) for different values of  $\rho_o\alpha$ 

$\rho_o\alpha$	$1.9 \times 10^{-4}$	$2.4 \times 10^{-4}$	$3.1 \times 10^{-4}$	Literature values
A/T	2.9	3.2	3.4	3.6
T/A	3.1	3.4	3.6	3.6
A/A	2.0	2.3	2.5	1.9
T/T	1.5	1.7	1.9	1.5

The binding energy values can be compared to the literature values (right column).

(Le<sup>x</sup>) has been identified as presumably playing a biological role by means of intermembrane interactions. According to current hypothesis, it has a calcium-mediated specific interaction with itself.

Le<sup>x</sup> has been shown to be involved in murine and human embryogenesis. This carbohydrate is present on the cell membrane in the polar headgroup of glycolipids. It is not expressed at the cell surface until the eight-cell stage, shows maximal expression at the morula stage of mouse embryogenesis, and declines after compaction.<sup>[21,22]</sup> This compaction stage could be inhibited either by anti-Le<sup>x</sup> antibodies, Le<sup>x</sup> itself, or by inactivating the calcium with Ethylenediaminetetraacetic Acid (EDTA). As Le<sup>x</sup> is not charged, the role of the calcium is not of an electrostatic nature. These results<sup>[23,24]</sup> led the authors to propose a calcium-mediated Le<sup>x</sup>–Le<sup>x</sup> specific homotypic interaction as a basis of cell adhesion in preimplantation embryos and in various tumour cells. Other observations also strongly suggest that Le<sup>x</sup>–Le<sup>x</sup> interactions exist in the presence of Ca<sup>2+</sup>.<sup>[25–28]</sup>

The approach described above made it possible to conduct the first direct quantitative measurements of this putative interaction in a physicochemically well-defined system and in conditions similar to the natural environment of the glycolipid, i.e., lipid bilayers. This was done through the adhesion between two giant vesicles functionalized with synthetic glycolipids.

The Le<sup>x</sup> determinant is a trisaccharide, which, in classical natural sphingolipids, is attached to the ceramide through a lactose group. For this study, a lipid<sup>[29]</sup> with a Le<sup>x</sup> headgroup attached to hydrophobic chains via a “spacer” group to ensure its mobility was synthesized (Fig. 4C). In this synthetic glycolipid, a rather low solubility in water together with good bilayer cohesion was obtained by using three hydrophobic chains instead of two as in ceramide. To ensure good accessibility of the Le<sup>x</sup> groups for interaction, they were provided with translational mobility by branching the chains. This hinders the bidimensional crystallization of the chains and keeps the layers in a fluid state. Orientational mobility was provided by a flexible spacer between the chains and the Le<sup>x</sup>. This allowed the Le<sup>x</sup> groups to take the exact orientation and position for which the specific interaction can occur.

For the controls, a glycolipid with the same features but without Le<sup>x</sup> was synthesized (Fig. 4C) that will be referred to as Lac lipid.

Giant vesicles were formed exactly in the same way as for the A and T vesicles by lipid hydration (after evaporation from chloroform solution) in 320 mOsm sucrose solution. The Le<sup>x</sup>-functionalized vesicles, hereinafter referred to as Le<sup>x</sup> vesicles, were made from a mixture of SOPC and the synthetic Le<sup>x</sup> lipid (90 : 10 mol ratio). Control vesicles were made of SOPC and Lac lipid (90 : 10 mol ratio) and will be called Lac vesicles.

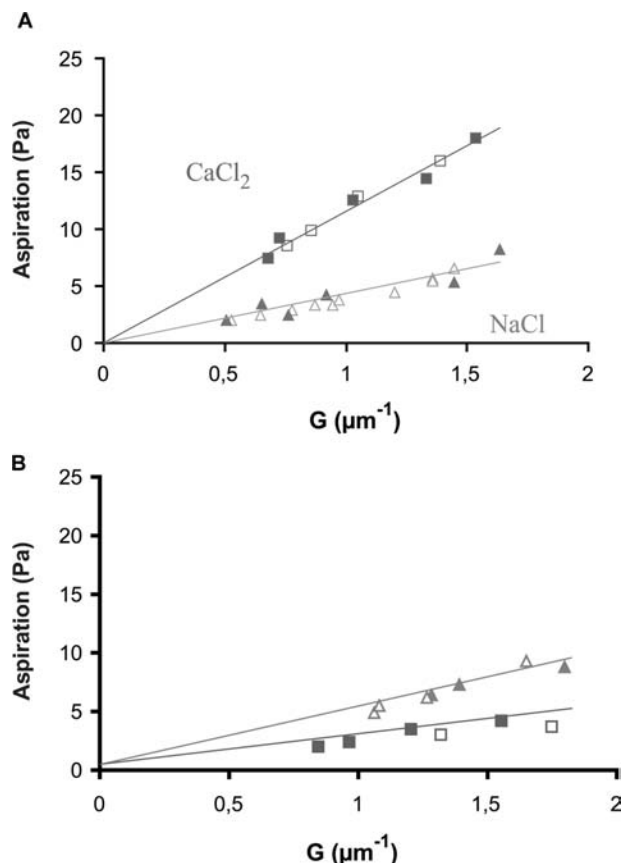

Two vesicles were transferred into another chamber filled with salt solution (either NaCl or CaCl<sub>2</sub> at 360 mOsm). As in the previous experiment, both vesicles were micromanipulated into tangential contact. One of the vesicles represents the substrate. It is strongly aspirated so that its spherical shape is not modified throughout the whole process. The contact angle was measured for several tension values of the other vesicle membrane by decreasing the aspiration and then increasing it to check the reversibility of the adhesion.

The experiments consisted in comparing the adhesion of two Le<sup>x</sup> vesicles in NaCl and in CaCl<sub>2</sub> (Le<sup>x</sup>/Le<sup>x</sup> experiments). As calcium is sometimes known to produce peculiar effects on bilayer interactions,<sup>[30]</sup> it was necessary to compare Le<sup>x</sup>/Le<sup>x</sup> experiments with experiments in which the Le<sup>x</sup> groups from one of the vesicles were absent (Le<sup>x</sup>/Lac experiments).

Fig. 6 shows the aspiration pressure as a function of  $G$  [cf. Eq. (17)] for the controls and Le<sup>x</sup>/Le<sup>x</sup> experiments. As before, the slopes are equal to the vesicle adhesion free energies and are independent of the vesicle size. Adhesion energy values for the controls and for the Le<sup>x</sup>/Le<sup>x</sup> experiments are given in Table 3. The effect of adding calcium on the Le<sup>x</sup> vesicles is clearly seen in Table 3 and in Fig. 6. The adhesion energy in CaCl<sub>2</sub> is 2.5 times higher than in NaCl whereas the Le<sup>x</sup>/Lac experiments showed a small decrease of the adhesion energy with calcium ( $3 \times 10^{-6} \text{ J m}^{-2}$ ). These results unambiguously show that Le<sup>x</sup> groups are necessary on both vesicles for the calcium-induced adhesion enhancement to occur. This is in agreement with the specific interaction scheme advocated by Hakomori.<sup>[11]</sup>

The adhesion, in the case of NaCl and for both types of vesicles, is the result of a balance between van der Waals attractions and short-range repulsions that include entropic and structural contributions.<sup>[15,31]</sup> Therefore, the higher adhesion in NaCl in the Le<sup>x</sup>/Lac system as compared to Le<sup>x</sup>/Le<sup>x</sup> may seem surprising. However, one may note that the sugar groups are bound to the lipid chains by a flexible spacer (Fig. 4C). The thermal fluctuations of this spacer can cause steric repulsions as polymer brushes do.<sup>[32]</sup> This difference between Le<sup>x</sup>/Le<sup>x</sup> and Le<sup>x</sup>/Lac experiments is not relevant for our purpose because van der Waals forces do not play a significant role in cell membrane interactions. Usually, the adhesions are governed by cell adhesion molecules such as proteins or lipids given that there are many steric repulsions produced by the glycocalix. For this reason, two biomembranes will not adhere in the absence of specific adhesion sites.

The specific contribution  $W_{\text{adh}}$  of the Le<sup>x</sup> groups to the adhesion energy of our vesicles is equal to the difference between the effects of calcium on adhesion

**Fig. 6** Aspiration pressure as a function of parameter  $G$  given in Eq. (18): (A)  $\text{Le}^x/\text{Le}^x$  experiment (two vesicles with SOPC/ $\text{Le}^x$ , 90:10); (B)  $\text{Le}^x/\text{Lac}$  experiment (one vesicle is SOPC/ $\text{Le}^x$ , 90:10, and the other is SOPC/Lac, 90:10); The closed symbols represent decreasing aspiration, and open ones are for increasing aspiration. Triangles are for NaCl solution and squares for  $\text{CaCl}_2$ . The straight lines are least square fits.

energy in the  $\text{Le}^x/\text{Le}^x$  and in the  $\text{Le}^x/\text{Lac}$  experiments. Table 3 shows that  $W_{\text{adh}} = 10 \pm 5 \mu\text{J m}^{-2}$ . This adhesion is weak for the density of sugar that was used. This indicates that the interactions must be weak and therefore that the lifetime of the bonds is small. Thus, the case of  $\text{Le}^x$  is favorable for the use of the model of

**Table 3** Adhesion energy of vesicles ( $10^{-6} \text{J/m}^2$ ) in aqueous media between  $\text{Le}^x$ - or Lac-functionalized vesicles in NaCl and in  $\text{CaCl}_2$

Left vesicle/right vesicle	Adhesion energy ( $\mu\text{J/m}^2$ )	
	In 0.2 M NaCl	In 0.11 M $\text{CaCl}_2$
$\text{Le}^x/\text{Le}^x$	$4.5 \pm 2$	$11 \pm 2$
$\text{Le}^x/\text{Lac}$	$5.4 \pm 2$	$2.5 \pm 2$

$\text{Le}^x$  means that the vesicle composition is SOPC/ $\text{Le}^x$  90:10; same for Lac.

a cell adhering to a substrate. This is confirmed by the fact that a single slope for the contact formation and separation of the vesicles are identical, meaning that the adhesion is continuous and reversible. Eq. (9) gives an enrichment smaller than 2%. Therefore, the density can be considered as constant. This has the consequence that the density of sites on the substrate can be taken as the initial density of  $\text{Le}^x$  in the vesicles, which is  $1.4 \times 10^{17}$  molecules/ $\text{m}^2$ . In addition,  $\alpha\rho_0A_c$  will be much smaller than  $A_t$ . Therefore, Eq. (13) can be rewritten here:

$$W_{\text{adh}} = A_t\rho_0^2\alpha k_B T(e^{e_b/k_B T} - 1) \quad (19)$$

Because the  $\text{Le}^x$  are in the polar head of the lipids,  $\alpha$  should be of the order of the polar head of the lipid. A good estimate seems to take the same value as that measured with two membranes made of A and T lipids:<sup>[33]</sup>  $0.3 \times 10^{-18} \text{m}^2$ . With these values,  $e_b$  ranges between  $0.17$  and  $0.5k_B T$  (i.e.,  $0.1$  and  $0.3$  kcal/mol). Previous glycolipid studies showed strong van der Waals interactions.<sup>[12–16,18]</sup> In the present work, the calcium-induced interaction is specific and comes in addition to van der Waals forces. Note that these molecules are neutral and therefore this interaction is not intrinsically electrostatic.

This ultraweak interaction energy validates the assumption that the binding energy is substantially below  $k_B T$ . A rough estimate of the bond lifetime can be obtained by comparison with the streptavidin/biotin system ( $30k_B T$  bond energy and lifetime of several days) and assuming an Arrhenius law. It is well below  $1 \mu\text{sec}$ . It is most unusual to measure molecular interaction energies well below the thermal energy. This only shows that cell–cell adhesion will require a large number of these molecules as is indeed observed during the morula stage of mouse embryogenesis. The molecular mechanism of the  $\text{Le}^x$  interaction still remains mysterious. The mediation by  $\text{Ca}^{2+}$  could result from the setting up of an appropriate coordination shell around the cation.<sup>[34]</sup>

These measurements with synthetically tailored  $\text{Le}^x$  containing neoglycolipids could be analyzed with the model of a cell adhering to a substrate presented above. It directly confirms the involvement of neutral cell surface oligosaccharides in cell–cell adhesion and illustrates why, when the  $\text{Le}^x$  sites are blocked, the compaction stage of the embryo does not occur.<sup>[23]</sup>  $\text{Le}^x$  is capable, in the presence of  $\text{Ca}^{2+}$ , to substantially enhance the deformation and adhesion of lipid vesicles, i.e., objects with mechanical features akin to those of the cell membranes. The interaction scaled down to one molecule is well below thermal energy. It produces transient and dynamic adhesion that is indeed what cell differentiation requires.

This direct measurement of biologically relevant carbohydrate/carbohydrate interaction shows that it is now possible to quantify such ultraweak bonds with the presented model. It opens up a new promising field in biology.

## CONCLUSION

The simple model that describes cell adhesion on a substrate gives quantitatively good results and allows one to relate the adhesion energy to the excess of ligand in the contact zone and to the molecular binding energy. The experimental approach that is presented can be used to describe the properties of adhesion molecules that produce weak bonds. In contrast, for vesicles bearing stronger binding sites, Eq. (9) is not valid anymore. However, some information about the ligand receptor information can still be obtained.<sup>[35]</sup> The adhesion molecules are expected to diffuse toward the contact zone, which therefore should contain a higher density of adhesion molecules, leaving the non-contacting part of the vesicle depleted, especially for large contact areas.

Also, this model deals only with adhesion at equilibrium. With the same kind of approach, it is possible to try to understand the formation dynamics of the contact zone. More precisely, the nucleation of patches can appear during the spreading of the contact. This has been discussed elsewhere.<sup>[36]</sup>

Finally, the case of real biological cells is much more complicated to quantify, as there are many more parameters involved such as the glycocalyx, the cytoskeleton, and many adhesion molecules acting at the same time. The role of the glycocalyx has been included in another approach by Bell, Dembo, and Bongrand<sup>[4]</sup> The mechanical properties of a cell are very different from that of a vesicle and, although it has been tried in the past,<sup>[37,38]</sup> the measurement of the contact angle does not give very satisfactory results.

## INTRODUCTION

Self-assembled monolayers (SAMs) are monomolecular layers that are spontaneously formed on immersing a solid substrate into a solution containing active surfactant molecules. The best studied examples are silanes, which are used to modify, for example, silica and mica surfaces, and alkylthiols, which have an affinity for coinage metals.<sup>[1]</sup> Organic SAMs can be used to alter and control the chemical nature of surfaces. For instance, SAMs provide a robust base layer for immobilizing biological molecules in biosensors. The bonding of enzymes to alkanethiol SAMs on gold has received attention as a method of constructing enzyme electrodes.<sup>[2]</sup> Lee et al.<sup>[3]</sup> are developing a surface plasmon resonance-based monosaccharide sensor by immobilizing a small thiol-based receptor molecule on gold containing a boronic acid group that is known to covalently bind the 1,2 or 1,3-diol of sugars. The success of SAM-based sensor applications depends on the stability of the underlying SAM as a function of aging and on environmental conditions such as humidity and temperature.

Self-assembly is simple and widely applicable in areas such as coatings, lubrication, templating, optoelectronics, and microelectromechanical systems/nanoelectromechanical systems (MEMS/NEMS). MEMS offers great promise for system integration of sensors, actuators, and signal processing. The miniaturization and integration offered by MEMS devices is attractive in applications where smaller size and weight are desirable. However, as devices become smaller, the surface area-to-volume ratio becomes larger and surface forces become more important. Factors determining the performance, reliability, and durability of MEMS devices are not well understood. In many applications, it will be impractical or impossible to protect MEMS devices from the operating environment. For instance, robust MEMS actuators must operate in a variety of conditions, some of which may be extreme (e.g., high temperature, a wide range of climatic conditions, and

high vacuum).<sup>[4]</sup> In MEMS, nanoscale dimensions potentially separate device components where water can capillary condense, giving rise to stiction. Many applications for MEMS/NEMS are not really practical, as many studies have revealed the profound negative influence of stiction, friction, and wear on the efficiency, power output, and steady-state speed of microdynamic/nanodynamic devices.<sup>[5,6]</sup> Komvopoulos and Yan<sup>[7]</sup> have shown that liquid bridging at intermediate humidity is the dominating short-range attraction mechanism prevailing at MEMS interfaces. It is also known that head/disk stiction occurs at humidities greater than 80%.<sup>[8]</sup> The ubiquitous presence of water vapor makes the study of the effect of relative humidity (RH) on the performance and reliability of MEMS devices crucial. Depositing a hydrophobic SAM on a hydrophilic surface can reduce surface wettability. Organosilane SAMs are being investigated as boundary lubricants and antiwetting coatings in MEMS devices to reduce the effect of humidity on friction and wear.

In order for SAMs to be useful as boundary lubricants, in biosensors, as MEMS coatings, and in a variety of other applications, it is important to understand the effect of environmental conditions such as humidity and temperature on SAM robustness and stability. In this entry, we present current research on the effect of humidity on the adhesiveness of alkyl-based SAM coatings on gold, silica, and mica. The wide variety of SAMs designed to be immersed in water (for instance functionalized SAMs for sensor applications) is not specifically discussed here, but this information should be pertinent for those interested in the effect of water on underlying SAM stability and adhesion.

## CAPILLARY CONDENSATION AND ADHESION

In studies of physisorbed surfactant monolayers on mica, Chen and Israelachvili<sup>[9]</sup> found that adhesion increased with RH and was dependent on the

hydrophilicity of headgroups and the phase state of hydrocarbon chains. Humidity has also been shown to increase the mobility of surfactant molecules on the surface by penetrating into the headgroup region and by weakening the attraction between the surfactant molecules and the mica.<sup>[10,11]</sup> Humidity affects adhesion between surfaces because when the surfaces are close enough, water capillary condenses around the contact zone as long as the sum of the water contact angles on the two surfaces is less than  $180^\circ$ .<sup>[12]</sup> This annulus gives rise to an attractive capillary force in addition to any direct solid–solid adhesion that must be overcome to separate the surfaces. The capillary pressure depends on the relative vapor pressure according to the Kelvin equation:

$$\frac{kT}{v_m} \ln \frac{p}{p_0} = \gamma_{LV} \left( \frac{1}{r_1} + \frac{1}{r_2} \right) \quad (1)$$

where  $r_1$  and  $r_2$  are the meniscus radii of curvature,  $k$  is the Boltzmann constant,  $T$  is the temperature,  $\gamma_{LV}$  is the liquid–vapor surface tension,  $p/p_0$  is the vapor pressure, and  $v_m$  is the molar volume of the condensed liquid. It is assumed that the vapor is ideal, the liquid is incompressible, and the molar volume of the vapor is much larger than the molar volume of the liquid. More complicated expressions can be used to account for these assumptions.<sup>[13,14]</sup>

The adhesive force because of capillary condensation is simply:

$$F_{\text{cap}} = \Delta p A \quad (2)$$

where  $\Delta p$  is the pressure difference across a curved interface acting on an area  $A$ . The Young–Laplace equation relates the Laplace pressure to the surface tension and local meniscus curvature as follows:

$$\Delta p = \gamma_{LV} \left( \frac{1}{r_1} + \frac{1}{r_2} \right) \quad (3)$$

Considering the general case of a rigid sphere of radius  $R$  interacting with a rigid, flat plate (no surface deformations because of adhesive forces), the capillary pressure is given by:

$$F_{\text{cap}} = \Delta p A = 2\pi\gamma_{LV} \left( \frac{1}{r_1} + \frac{1}{r_2} \right) R^2 \sin^2 \phi \quad (4)$$

where  $\phi$  is the filling angle, as shown in Fig. 1A.<sup>[12]</sup> In the limit of vanishing filling angle, the capillary pressure is given by:

$$F_{\text{cap}} = 2\pi R \gamma_{LV} (\cos \theta_1 + \cos \theta_2) \quad (5)$$

**Fig. 1** Schematic illustration of capillary condensation between a sphere of radius  $R$  and a flat plate. In panel (A), both the sphere and the flat are rigid.  $\phi$  is the filling angle and  $d$  is the sphere–plate separation. In panel (B), the sphere is deformable.  $a$  is the radius of the flattened contact zone and  $\rho$  is the distance from the contact center to the edge of the capillary condensate.

where  $\theta_1$  and  $\theta_2$  are the water contact angles on the two surfaces. If the filling angle is large, such as the tip of an atomic force microscope (AFM) in contact with a surface at high humidity, more complicated expressions are required, as detailed by Orr, Scriven, and Rivas.<sup>[12]</sup> If the meniscus is assumed to be circular, the capillary force can be approximated as:<sup>[15]</sup>

$$F_{\text{cap}} = \pi R \gamma_{LV} \times \left( -\sin \phi + \frac{\cos(\theta_1 + \phi) + \cos \theta_2}{\frac{d}{R} + 1 - \cos \phi} \sin^2 \phi \right) \quad (6)$$

where the filling angle is fixed by the vapor pressure according to the Kelvin equation:

$$\begin{aligned} \frac{kT}{\gamma_{LV} v_m} \ln \frac{p}{p_0} &= \frac{\Delta p}{\gamma_{LV}} = \left( \frac{1}{r_1} + \frac{1}{r_2} \right) \\ &= \frac{1}{R \sin \phi} - \frac{\cos(\theta_1 + \phi) + \cos \theta_2}{d + R(1 - \cos \phi)} \end{aligned} \quad (7)$$

and  $d$  is the sphere–flat separation at the point of closest approach. In the case of an AFM tip, the resolved surface tension force may also be important

and should be added. It is given as:

$$F_S = 2\pi\gamma_{LV}R \sin \phi \sin(\theta_1 + \phi) \quad (8)$$

If the sphere and flat are elastic and adhesive, the theory of Johnson, Kendall, and Roberts (JKR)<sup>[16]</sup> is frequently used to explain surface deformation and adhesion in dry conditions. The JKR theory predicts a finite contact diameter even under zero load. The adhesive force is given by:

$$F = \frac{3}{2}\pi RW = 3\pi R\gamma \quad (9)$$

where  $W$  is the Dupré energy of adhesion given by:

$$W = \gamma_1 + \gamma_2 - \gamma_{12} \quad (10)$$

where  $\gamma_1$  and  $\gamma_2$  are the surface energies of the contacting materials, and  $\gamma_{12}$  is the interfacial energy between the two surfaces. If the materials are identical, then  $\gamma_{12} = 0$  and  $W = 2\gamma$ . The JKR theory only takes into account the adhesive interactions inside the contact zone and neglects interactions between the surfaces outside the contact zone. Derjaguin, Muller, and Toporov (DMT)<sup>[17]</sup> approached the problem from a different point of view by treating the contact as Hertzian but taking into account the interactions outside the contact zone. Their theory predicts an adhesive force of:

$$F = 2\pi RW = 4\pi R\gamma \quad (11)$$

Maugis<sup>[18]</sup> showed that these two theories are actually special cases of a theory derived using linear elastic fracture mechanics with an adhesive “Dugdale” zone outside the contact area. In the Dugdale model, a constant adhesive stress is assumed to act between the surfaces in a region just outside the contact zone. Outside this region, the adhesive force falls to zero.

Maugis and Gauthier-Manuel<sup>[19]</sup> pointed out that capillary condensation is the perfect example of a Dugdale zone outside the contact area. The condensate occupies an annulus in which the adhesive stress is constant and is given by the Laplace pressure. Maugis took the stress outside the contact zone to be:

$$\begin{aligned} \sigma_0 &= \Delta p & a > r > \rho \\ &= 0 & r > \rho \end{aligned} \quad (12)$$

where  $a$  is the radius of the contact zone,  $\rho$  is the radius of the area covered by the condensate, and  $r$  is the radial coordinate (Fig. 1B). Maugis derived the

following equations:

$$\begin{aligned} \frac{W}{\sigma_0} &= \frac{a^2}{\pi R} ((x^2 - 1)^{1/2} + (x^2 - 2) \tan^{-1} \\ &\quad \times (x^2 - 1)^{1/2}) + \frac{16\sigma_0 a}{3\pi K} ((x^2 - 1)^{1/2} \tan^{-1} \\ &\quad \times (x^2 - 1)^{1/2} - x + 1) \end{aligned} \quad (13)$$

$$\begin{aligned} F &= \frac{a^3 K}{R} - 2\sigma_0 a^2 ((x^2 - 1)^{1/2} + x^2 \tan^{-1} \\ &\quad \times (x^2 - 1)^{1/2}) \end{aligned} \quad (14)$$

where  $x = \rho/a$  and  $F$  is the load on the system. Although it is not possible to simplify these equations further to obtain one equation that gives the load as a function of the contact radius, it is possible to solve these two equations using an iterative procedure. As shown in Maugis,<sup>[18]</sup> as  $p/p_0 \rightarrow 0$ , JKR results are recovered and as  $p/p_0 \rightarrow 1$ , DMT results are recovered.

The effect of humidity on the stability, wettability, and adhesion of SAM-coated surfaces depends on the ability of water to favorably interact with the monolayer. The contact angle of water on a SAM surface gives a good indication of SAM wettability. SAMs with hydrophilic terminal groups have low contact angles and adhesion is strongly affected by humidity because of capillary condensation. On highly hydrophobic SAMs, advancing contact angles are generally very high ( $\sim 110^\circ$ ) with receding angles slightly lower.<sup>[20]</sup> The hysteresis between advancing and receding angles provides a measure of the degree of surface roughness or heterogeneity.<sup>[1]</sup> Large contact angle hysteresis or contact angles that decrease with time indicate that water interacts somewhat favorably with the SAM. In the case of alkylsilane SAMs, it is likely that water changes the monolayer by penetrating to the SAM–substrate interface and by hydrolyzing the siloxane bonds. In these cases, humidity will affect adhesion near saturation.

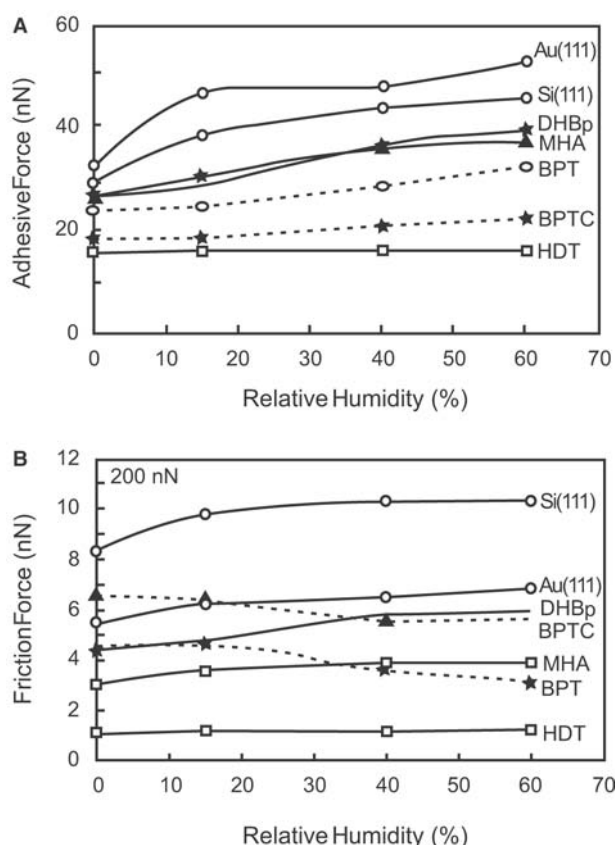

## ALKYLTHIOL SAMs ON GOLD

SAMs that are particularly effective in repelling water are alkanethiol SAMs deposited on gold. These SAMs are packed very tightly and are covalently bound to the gold substrate through the metal–sulfur bond. The alkyl chains of the thiols are in the all-trans conformation, tilted at an angle of  $\sim 20\text{--}30^\circ$  from normal to the metal surface.<sup>[21]</sup> In general, these SAMs have very high advancing and receding contact angles, indicating that water is unable to disrupt the layer at least on the time scale of the experiment. Liu and Bhushan<sup>[5]</sup> used the AFM to measure adhesion between a silicon nitride tip and SAMs with different

terminal groups deposited on Au(111) and Si(111) as a function of humidity up to 60% RH. Fig. 2 shows the adhesive force as a function of RH for bare gold and silicon, a carboxylic acid-terminated SAM (16-mercapto-hexadecanoic acid) on gold (MHA), a hydroxyl-terminated biphenyl SAM (4,4'-dihydroxybiphenyl) on silicon (DHBp), a biphenyl SAM (1,1'-biphenyl-4-thiol) on gold (BPT), a cross-linked version of the biphenyl SAM (BPTC), and a hydrophobic SAM (hexadecane thiol) (HDT). Adhesion increases with RH for the uncoated and the hydrophilic SAM-coated surfaces. It increases less dramatically for phenyl-terminated SAM coatings and it is independent of humidity for the hydrophobic coating. This suggests that at least for humidities up to 60%, the methyl-terminated thiol SAM affords protection against capillary-induced adhesion.

Li, Chen, and Jiang<sup>[22]</sup> found that the friction of a silicon nitride AFM tip on an alcohol-terminated

**Fig. 2** The influence of RH on the adhesive force between a silicon nitride AFM tip and Si(111), Au(111), and five SAMs: a carboxylic acid-terminated SAM (16-mercapto-hexadecanoic acid) on gold (MHA), a hydroxyl-terminated biphenyl SAM (4,4'-dihydroxybiphenyl) on silicon (DHBp), a biphenyl SAM (1,1'-biphenyl-4-thiol) on gold (BPT), a cross-linked 1,1'-biphenyl-4-thiol (BPTC), and a hydrophobic SAM (hexadecane thiol) (HDT). *Source:* From Fig. 9 of Ref.<sup>[5]</sup>.

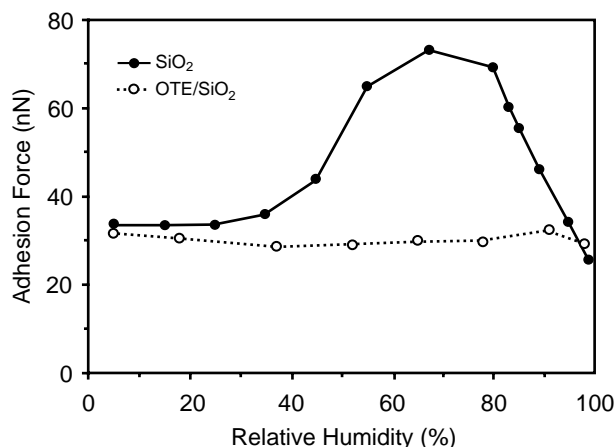

**Fig. 3** Pull-off forces (mN/m) as a function of RH. Separate SAMs were prepared for each data point: square symbols are for the alcohol-terminated SAM; circles are for the methyl-terminated SAM. *Source:* From Fig. 1 of Ref.<sup>[24]</sup>.

SAM ( $C_{11}OH$ ) on gold is high at 10% RH but decreases with increasing humidity because water acts as a lubricant. Friction on a methyl-terminated SAM ( $C_{12}$ ) is independent of humidity even for immersion in pure water. However, as pointed out by Yoshizawa, Chen, and Israelachvili<sup>[23]</sup> there is no fundamental relationship between friction and adhesion even though they are sometimes highly correlated.

In contrast to AFM studies, Quon, Ulman, and Vanderlick<sup>[24]</sup> measured the effect of humidity on the adhesion between a SAM-coated gold surface [root mean square (rms) roughness 20 Å] and a molecularly smooth mica surface using a surface forces apparatus (SFA).<sup>[25]</sup> In the SFA, the force is measured between cross-cylinders with radii of curvature of approximately 2 cm. Because water wets mica ( $\theta = 0$ ), according to Eq. (5), it is expected that humidity will affect adhesion through capillary condensation. As shown in Fig. 3, for both alcohol- and methyl-terminated alkylthiol SAMs, adhesion increased with increasing RH. The magnitude of the adhesion at a particular RH was always higher for the alcohol-terminated SAM because the water contact angle is very small. Interestingly, near saturation, the adhesive force for the methyl-terminated SAM is much greater (643 mN/m) than is predicted by Eq. (5) (335 mN/m) if the SAM is assumed to be very hydrophobic ( $\theta \sim 105^\circ$ ). The reason for this unexpectedly large adhesion is not clear. However, it suggests that water interacts with the hydrophobic surface to a greater extent than expected for an alkanethiol on gold.

## ALKYLSILANE SAMs ON SILICA

The effect of humidity on the adhesion of alkylsilane SAMs deposited on Si/SiO<sub>2</sub> surfaces has been more thoroughly investigated compared with alkylthiols on

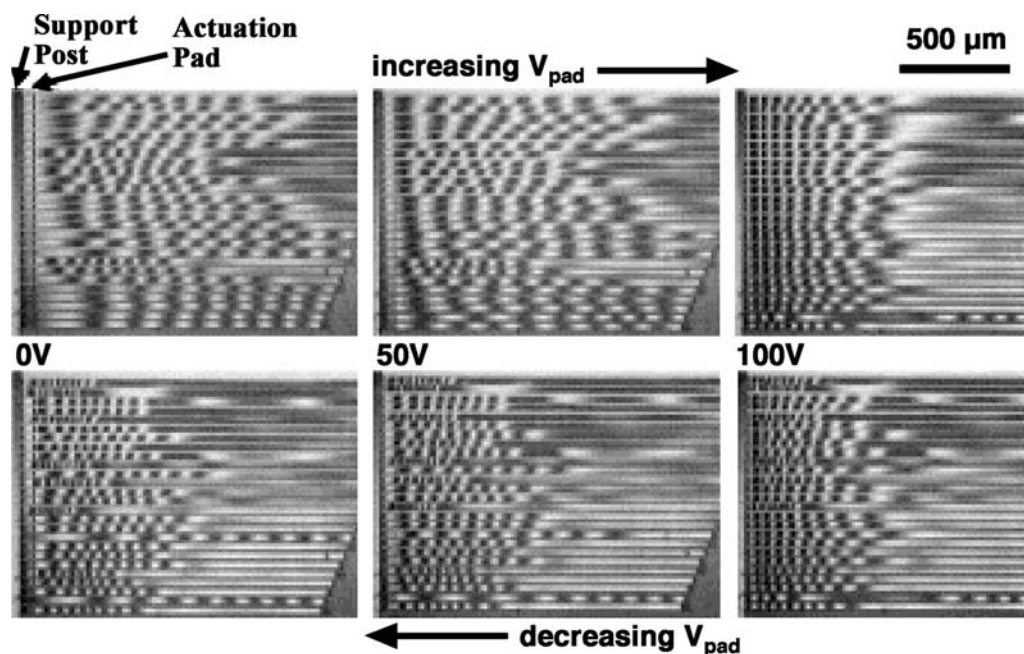

**Fig. 4** Measured adhesion force as a function of humidity for SiO<sub>2</sub> and OTE/SiO<sub>2</sub> against a Si<sub>3</sub>N<sub>4</sub> AFM tip. Source: From Fig. 2 of Ref.<sup>[15]</sup>.

gold in part because of the importance of antiadhesive coatings in silicon-based MEMS devices. An important difference between SAMs formed by alkylthiols and organosilanes is the possibility for the formation of cross-linked siloxane bridges (Si–O–Si) between adjacent molecules. It is commonly assumed that this cross-linking stabilizes these SAMs.<sup>[26]</sup> However, it is not clear as to what extent this actually occurs because the cross-linking should be sterically hindered.<sup>[27]</sup> Zhang et al.<sup>[28]</sup> investigated the effect of humidity (up to 80%) on the adhesive force between an AFM silicon nitride tip and organosilane SAMs with different terminal groups (–CH<sub>3</sub>, –COOCH<sub>3</sub>, and –COOH) deposited on hydrogen-terminated silica Si(111). Adhesion to hydrophilic SAMs increased at the highest humidities because of capillary condensation, whereas there was no change in the adhesive force between the tip and the methyl-terminated SAM. He et al.<sup>[29]</sup> also found that the adhesive force between an AFM tip rendered hydrophobic by coating with *n*-octadecyltrichlorosilane (OTS) and a silicon surface did not change for humidities up to 80%. Xiao and Qian<sup>[15]</sup> examined the adhesion between an AFM silicon nitride tip and an *n*-octadecyltriethoxysilane (OTE)-coated silicon surface, and found essentially no dependence on humidity up to 98%, as shown in Fig. 4. Interestingly, adhesion between the tip and a bare hydrophilic silica surface first increases with increasing humidity because of capillary condensation and then decreases close to saturation. Because the tip radius is small, the filling angle becomes large near saturation. According to Eq. (6), the effect of an increasing filling angle is a decreasing adhesive force, as is observed. The net effect is that the adhesive forces on the bare silica surface and the OTE-coated silicon surface are the same near saturation. For practical purposes, the AFM experiments discussed here show that the hydrophobic SAM affords

protection against capillary-induced adhesion even at high humidity.

With a specific focus on MEMS, some workers have developed an in situ microcantilever beam technique for measuring adhesion using an as-fabricated MEMS test structure constructed from polycrystalline silicon (polysilicon) that exhibits nanometer-scale rms roughness.<sup>[30–32]</sup> Capillary condensation complicates the fabrication as well as the operation of MEMS, so much effort is being directed at antiadhesive strategies. Hydrophobic SAMs are being investigated as coatings for MEMS devices as these coatings reduce adhesion. De Boer et al.<sup>[30]</sup> studied the effect of humidity on the adhesion of perfluorotrichlorosilane (FDTS)-coated (from solution in isooctane) cantilever beams to an FDTS-coated substrate. For humidities up to 80%, adhesion of the beams was not observed to change significantly. After a 4-hr exposure at 90% RH, a mild adhesion increase was observed, and a much more significant increase was observed after 7 hr of exposure (Fig. 5). AFM topographic images showed mounds, strongly suggesting that increased adhesion correlates with this structural change of the surface. The authors hypothesized that the mounds are the result of humidity-induced restructuring from a surface monolayer phase to a lyotropic bulk phase. Mayer et al.<sup>[32]</sup> coated cantilever beams with monolayer films of tridecafluoro-1,1,2,2-tetrahydrooctyltrichlorosilane (FOTS) in a chemical vapor deposition process. These coatings are hydrophobic, and adhesion tests on coated and uncoated MEMS test structures demonstrate superior performance of FOTS coatings. Cleaned, uncoated, cantilever beam structures exhibit high adhesion energies in a high-humidity environment (100 mJ/m<sup>2</sup> for >90% RH) because of capillary condensation. FOTS-coated beams exhibit negligible adhesion at low humidity and ≤20 mJ/m<sup>2</sup> adhesion energy at >90% RH. No obvious film degradation was observed for films exposed to >90% RH at room temperature for ~24 hr. The authors suggest that chemical vapor deposition of FOTS affords greater stability in high-humidity environments compared with solution-based deposition.

Patton et al.<sup>[4]</sup> evaluated the effect of an OTS SAM coating on the tribological performance of a MEMS electrostatic lateral output motor. For uncoated motors, excessive wear of sliding contacts and permanent adhesion of static contacts were observed at 0.1% RH. Degradation of electrostatic force and high stiction forces limited dynamic performance and reliability, and caused device sticking at and above 70% RH because of capillary condensation. Around 50% RH, uncoated motors exhibited negligible wear, low adhesion, and a wear life at least three orders of magnitude longer than in dry conditions. Water vapor behaved as a gas-replenishable lubricant. The OTS

**Fig. 5** Interferograms of adhesion hysteresis observed at RH = 90% after a 7-hr exposure. The images are compressed by a factor of three in the horizontal direction relative to the vertical. Twenty-five beams run horizontally, are 10  $\mu\text{m}$  wide, and are spaced 5  $\mu\text{m}$  apart. Their lengths are from 1500  $\mu\text{m}$  (bottom of each image) to 2000  $\mu\text{m}$  (top). Beams longer than 1700  $\mu\text{m}$  are cut off because of the charge-coupled device (CCD) camera field limit. The voltage was increased up to 160 V before decreasing. *Source:* From Fig. 5 of Ref.<sup>[30]</sup>.

coating broadened the operating envelope to 30–50% RH and reduced stiction, which allowed better dynamic performance at high RH. At high RH, stiction problems recurred when the OTS coating was worn away. By controlling and optimizing the amount of adsorbed water with the OTS coating, excellent performance, low friction and wear, and excellent durability were attained with the lateral output motor.

It is generally thought that organosilane SAMs covalently bind to silica, imparting enhanced stability.<sup>[33]</sup> However, infrared spectroscopic studies indicate that few, if any, bonds are formed and that with exposure to water over time, siloxane bonds hydrolyze.<sup>[34]</sup> It is difficult to determine how water vapor interacts with the SAM on the molecular level from the AFM and cantilever beam studies. Ohnishi, Yaminsky, and Christenson<sup>[35]</sup> measured the force between heptadecafluoro-1,1,2,2,-tetrahydrodecyltriethoxysilane (FTE) SAMs deposited on identical fused glass surfaces (radius of curvature  $\sim 2\text{mm}$ ) using the interfacial gauge.<sup>[36]</sup> The force as a function of surface separation was measured in dry conditions, near saturation, and in water. In humid air, the force curve obtained as the surfaces were brought together was shifted toward larger distances compared with dry conditions, presumably because layers of water were adsorbed between the substrate and the

**Fig. 6** Measured forces on approach to saturated water vapor of fluorinated surfaces prepared by three different methods: ( $\circ$ ) Langmuir–Blodgett deposition; ( $\diamond$ ) FTE adsorbed from  $\text{CHCl}_3$ ; ( $\blacksquare$ ) FTE adsorbed from the neat solution. In the inset of the lower figure, the force profile of Langmuir–Blodgett in humid air (shifted to larger distances) is compared with that in dry air ( $\cdots \cdots \bullet \cdots \cdots$ ). The solid line is a fit obtained with the equation for the capillary force [Eq. (4)] *Source:* From Ref.<sup>[35]</sup>, with  $V = 3 \times 10^{-15} \text{ cm}^3$ . From Fig. 5 of Ref.<sup>[37]</sup>.

fluorocarbon layer (Fig. 6). No capillary condensation forces were detected with increasing humidity even though SAM thickness increased.<sup>[37]</sup> This suggests that in this case, the silane SAM is not covalently bound to the silica surface. The response to humidity is reversible in that if the water vapor is removed, the forces measured in dry conditions are recovered.

## ALKYLSILANE SAMS ON MICA

Alkylsilanes have attracted attention because they are capable of cross-polymerization and covalent attachment to SiO<sub>2</sub>-based oxide surfaces such as oxidized silicon wafers. Mica also contains Si–O bonds, but there are no inherent functional groups on the surface to serve as attachment sites. SAMs on mica are potentially useful in non-linear optics because mica can be prepared as relatively large, molecularly smooth sheets.<sup>[1]</sup>

Several research groups have investigated the deposition of alkylsilanes, mostly OTS and OTE, on mica.<sup>[38–42]</sup> These monolayers are hydrophobic as judged by the contact angle of water, but in some cases, the contact angle decreases with prolonged exposure to water.<sup>[42,43]</sup> Tian et al.<sup>[39]</sup> investigated the effect of humidity on the friction force on OTE SAMs on mica. On bare mica, water acts as a lubricant and the friction force decreases gradually as humidity increases. At low humidities, an OTE SAM coating also serves as a good lubricant, reducing friction. As humidity increases, friction increases, indicating that water in contact with the OTE SAM decreases its lubricating effectiveness. Above ~30% RH, the film breaks down at a critical load and the tip contacts bare mica. The load required to cause breakdown decreases as humidity increases, indicating that the presence of water makes it easier to remove the SAM. Because the OTE SAM is not fully compact because of long-range disordering, condensed water can penetrate through the film to the OTE–mica interface. The accumulation of water at the interface weakens the OTE–mica links as well as the links between OTE molecules; therefore the film quality deteriorates.

Kim, Christernson, and Curry<sup>[42]</sup> used the SFA to study OTE SAMs on mica. In this case, the OTE SAM was deposited on both bare mica and plasma-pretreated mica. Because mica has no functional groups to which the OTE can bond covalently, plasma treatment was used to break surface Si–O–Si bonds to create an opportunity for covalent attachment between the OTE SAM and mica. In this work, OTE SAMs deposited on both untreated and plasma-treated mica were initially highly hydrophobic, but contact angle hysteresis indicated that water interacts favorably with the monolayers on prolonged exposure. Defects in the monolayer most likely make it possible for the water to

reach the hydrophilic region between the silane head-groups and the mica. More water was adsorbed by the monolayers on untreated mica compared with the plasma-treated case. This work strongly indicated that if the SAM is not firmly anchored to the substrate, water can accumulate in the region between the SAM and the substrate. Near saturation, water droplets also condensed on the surface presumably as monolayer defects regardless of how well the SAM was anchored. At very high humidities, a capillary condensed annulus of water was observed around the contact zone.

In a further study, Kim, Christernson, and Curry<sup>[44]</sup> used the SFA to investigate the effect of humidity on surface deformation and adhesion of untreated and plasma-treated mica surfaces coated with OTE SAMs. In general, when two solid bodies come into contact, they deform in a way that is determined by their elastic or viscoelastic properties, by the surface forces between them, and by any externally applied load.<sup>[45]</sup> Because of the practical importance of understanding interparticle adhesion, the relationship between surface deformation and adhesion has been studied extensively.<sup>[18]</sup> Capillary condensation acts outside the contact area and modifies the adhesive force in two interrelated ways: first, by altering the surface deformation; and, second, by increasing the adhesive force because of the Laplace pressure in the annulus. In the presence of a capillary condensed liquid bridging the two surfaces, the measured adhesive force has contributions both from the direct solid–solid adhesion and from the Laplace pressure arising from the liquid–vapor interface.<sup>[46]</sup> In this study, the size of the contact area was measured as a function of applied load and the contact mechanics-based Maugis model outlined in Eqs. (12–14) was applied to extract the capillary condensation and solid–solid contributions to the adhesive force. The SFA is particularly well suited for these experiments because the interferometric technique allows direct observation of the surface shape and size of the contact zone. Pulloff forces were also measured by pulling the surfaces apart. Fig. 7 shows adhesive forces obtained from both methods. From load-vs.-contact area measurements, it is clear that the adhesive force because of capillary condensation depends on humidity. It decreases from the highest values near saturation to zero in dry conditions. This is not unexpected and has been shown previously.<sup>[47]</sup> However, Eq. (5) predicts that the adhesive force because of capillary condensation is independent of humidity. There is agreement with Eq. (5) at high humidities. At low humidities before capillary condensation is detectable, pulloff forces agree well with predicted adhesive forces determined from force-vs.-contact area measurements and the Maugis model. At high humidity, force-vs.-contact area values are generally higher than the pulloff force measurements. It is

**Fig. 7** Normalized adhesive force for OTE on untreated mica as a function of RH. The open and closed circles denote the Laplace pressure contribution to the adhesive force and the total adhesive force predicted from the Maugis model. Experimental pulloff force measurements are denoted by x symbols, with error bars indicating the range of measured values. Horizontal lines denote the normalized adhesive force due to capillary condensation as calculated from Eq. (5) with  $\theta_1 = \theta_2 = 0^\circ$  (—),  $35^\circ$  (---), and  $75^\circ$  (- - -). Source: From Fig. 5 of Ref.<sup>[44]</sup>.

suggested that the difference is because of the history of the surfaces prior to pulloff. In force-vs.-area measurements, a load is applied to push the surfaces together before pulling them apart slowly, whereas in pulloff force measurements, the surfaces are separated more rapidly without applying an extra load. This work suggests that adhesion between OTE SAMs on mica is not dominated by capillary condensation below  $\sim 80\%$  RH. At higher RH, the effect of capillary condensation on the adhesive force is significant and depends on the amount of compression prior to detachment.

## CONCLUSION

Capillary condensation increases adhesion between contacting surfaces in humid environments. Hydrophobic SAMs reduce this effect by reducing surface wettability. SAMs must be resistant to water-induced degradation to effectively reduce adhesion in the long term. There are relatively few studies that address the effect of humidity on SAMs despite the importance of this effect in practical applications. Among these studies, there is substantial variability in the reported effectiveness of hydrophobic SAMs in reducing adhesion in humid environments. This depends on the particular SAM, the substrate, and the SAM deposition method. Even for initially hydrophobic

SAMs, exposure to humidity over long time periods is shown to reduce SAM stability and effectiveness in some cases. Further work in this area is needed to fully understand the effect of humidity on SAM stability and adhesion.

# Adsorption on Heterogeneous Surfaces

Vinay K. Gupta

Yu-Wen Huang

*Department of Chemical Engineering, University of Illinois at Urbana–Champaign, Urbana, Illinois, U.S.A.*

## INTRODUCTION

In this review, we focus on the role of surface heterogeneity in polymer adsorption and discuss novel experiments that clarify the impact of topographical and chemical heterogeneity on adsorption of flexible polymers and globular proteins. The comparison of the experimental results with existing theoretical predictions provides valuable insights into the adsorption process and guides future development of theory and experiments. Furthermore, these results provide a starting point for more sophisticated design and control of polymer adsorption at the nanoscale and in engineering of surfaces to achieve specific tasks.

The importance of polymer and protein adsorption stems from its critical role in a host of industrial applications such as adhesion, biocompatibility, colloidal stabilization, and chromatography. Scientifically, the interfacial behavior of globular proteins and long, flexible macromolecules and the accompanying balance of enthalpic and entropic effects from surface–segment interactions provide a system replete with interesting static and dynamic phenomena. Consequently, adsorption of polymers and biopolymers at a solid–liquid interface has been the subject of intense investigation over the last decade.

Despite the advances in characterization and theoretical understanding of near-equilibrium properties of adsorbed polymer layers, several aspects of the adsorption process remain elusive.<sup>[1–3]</sup> Among these elusive aspects is the effect of nanometer scale compositional and topographical heterogeneity of surfaces (Fig. 1A) on the process of adsorption and the structural properties of the adsorbed layer. Because adsorption frequently occurs on real surfaces such as minerals, pigments, colloidal particles, and biological membranes that are inherently heterogeneous, understanding the impact of surface heterogeneity is an essential prerequisite to controlling the adsorption process.

## BACKGROUND

### Modeling of Transport and Adsorption of Macromolecules

Adsorption at a surface occurs from a bulk polymer solution if the net change of free energy is negative. The surface–segment contacts of the polymer provide a gain of adsorption energy to balance the loss of translational and conformational entropy from the confinement at the interface. The properties of the adsorbed layer depend not only on the thermodynamic details of the system but also on the adsorption history.<sup>[4]</sup> Therefore control of adsorption requires a complete understanding of adsorption kinetics and the role of the surface.

Three main steps are typically involved in polymer adsorption: mass transport toward the surface, surface attachment, and spreading or conformational rearrangement toward equilibrium configurations.<sup>[1–3]</sup> The driving force for transport from bulk solution is the gradient between the bulk solution concentration ( $C_b$ ) and the subsurface concentration ( $C_s$ ). Because the gradient is established rapidly in most cases, the flux of the polymer can be

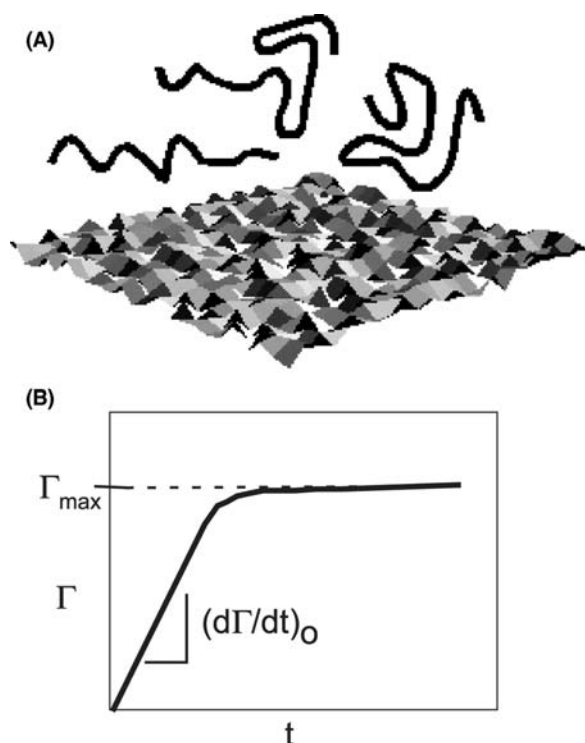

$$J(t) = \frac{C_b - C_s(\Gamma)}{R_m} \quad (1)$$

where the mass transfer resistance ( $R_m$ ) depends on the convection–diffusion in bulk solution.  $R_m$  can be expressed as  $1/k_m$ , where  $k_m$  is the mass transfer coefficient.  $C_s$  depends on the surface excess ( $\Gamma$ ) of the polymer and its temporal evolution

$$\frac{d\Gamma(t)}{dt} = \frac{C_s(\Gamma) - C_{eq}}{R_b(\Gamma)} \quad (2)$$

The processes of penetration of a chain through an already adsorbed layer of polymer, attachment to the

**Fig. 1** Schematic of (A) a heterogeneous surface and (B) evolution of the surface excess ( $\Gamma$ ).

surface, and spreading on the surface determine the barrier resistance  $R_b$ .<sup>[5]</sup>

At pseudo-steady state, the flux and the rate of adsorption are equal, which gives

$$\frac{d\Gamma(t)}{dt} = \frac{C_b - C_{eq}}{R_m + R_b(\Gamma)} \quad (3)$$

During the formative stages of an adsorbed layer,  $R_m$  should dominate and for high-affinity adsorption,  $C_{eq} \sim 0$ . Therefore the initial rate of adsorption becomes

$$\left(\frac{d\Gamma(t)}{dt}\right)_0 = \frac{C_b}{R_m} \quad (4)$$

and  $\Gamma(t)$  typically shows a linear rise (Fig. 1B). Over a longer period equilibrium is established and  $\Gamma(t)$  reaches a plateau, which is determined by parameters such as solvency,  $C_b$ , surface-segment interaction, and molecular weight.

### Adsorption on Heterogeneous Surfaces: Theoretical and Simulation Studies

In previous theoretical studies on the role of physical heterogeneity, rough surfaces were modeled as random, fractal, and periodically structured.<sup>[6–10]</sup>

Most of these studies came to the conclusion that adsorption is enhanced with surface roughness. Ji and Hone<sup>[11]</sup> predicted that the enhancement is most significant when amplitudes and spatial size of roughness are of the order of a polymer chain or Kuhn length, which is of nanometer dimensions. The enhancement occurs as larger adsorption energy is gained by increasing probability of polymer-surface intersections in comparison to a smooth planar interface. Consequently, a polymer chain undergoes smaller distortion and configurational entropy penalty is also predicted to be less relative to adsorption on flat surfaces. These studies predicted that a polymer can adsorb on a rough surface and not on a flat surface even if the chemical interface is identical.

More recent investigations<sup>[12]</sup> have explored the role of polymer architecture in adsorption on rough surfaces. Striolo and Prausnitz predicted that adsorption occurs readily for branched polymers compared to linear polymer chains because a smaller entropic penalty is involved for adsorption of globular polymers. However, when the interaction between polymer segments and surface becomes strong enough, it was predicted that a linear polymer chain can spread more than the globular polymer as the entropic loss is overcome by the gain in adsorption energy from spreading. Thus for highly attractive segment-surface interactions, linear polymers are believed to adsorb strongly compared to globular polymers.

In previous theoretical studies, the influence of chemical heterogeneity on adsorption varied with the systems. The chemical heterogeneity of the surfaces was manipulated by changing the distribution, size, and shape of the heterogeneity.<sup>[13–18]</sup> Meanwhile, several types of polymers such as a homopolymer, a block-copolymer, and an end-sticking polymer were employed in simulations. Heterogeneous interaction between polymer and surfaces was predicted to be a larger weighing factor than physical heterogeneity in polymer adsorption.<sup>[19]</sup> Several remarkable effects were found in these studies. First, the heterogeneity on the surfaces induced adsorption even when the average surface was neutral. It was predicted that adsorption was enhanced for homopolymers because of the presence of heterogeneity. Second, most studies pointed out that the distribution and size of adsorbing sites and nonadsorbing sites play a crucial role. Again, the domain size was required to be commensurate to that of polymer chains. When a threshold value of either the distribution or the size of domains was reached, polymers responded to the surface in dramatically different ways. This was reflected in the adsorption behavior, the amount, and the arrangement of polymers on the surfaces. In the case of homopolymers, van der Linden and coworkers showed that a mere change in the distribution of sites could cause a

nonadsorbing surface to become adsorbing. Sumithra and Sebastian observed a sudden change in the size of an adsorbed polymer. In the case of block copolymers and end-sticking polymers, change of domain sizes on the surface caused segregation of polymers in a uniform adsorbed layer.

In addition to the focus on homopolymers and copolymers, recent studies have used Monte Carlo simulation and replica field theory to explore the adsorption behavior of random heteropolymers (RHPs) on chemically heterogeneous surfaces.<sup>[20,21]</sup> Striking recognition between polymers and random surfaces has been predicted. A sharp transition from weak to strong adsorption was seen when the statistical sequence of chain segments and the randomness of sites on surfaces were related. Similar instances of pattern matching have also been predicted during adsorption of charged polyelectrolytes on surfaces with a pattern of charges.<sup>[22]</sup> Recently, Genzer developed a three-dimensional self-consistent field lattice model to study adsorption of copolymers and showed that architecture as well as composition is important in the pattern recognition.<sup>[23]</sup> By using different copolymers such as alternating, diblock, and triblock copolymers with various ratio of adsorbing segments, chemical heterogeneity on surfaces could either be masked or amplified and recognition could be extended into the third dimension normal to the surface.

Thus theory and simulation based on statistical physics has explored extensively the influence of both chemical and physical heterogeneity on the adsorption behavior of polymeric chains. However, corroboration by systematic and well-defined experiments to test and exploit these predictions has been nonexistent. The bottleneck for realizing actual systems lies in the difficulty of manipulating heterogeneity on a size scale that is commensurate with that of a polymer chain (typical radius of gyration of 10–100 nm). By modifying and characterizing surfaces at a molecular level, we have carried out the first studies to overcome the experimental challenges. The next few sections review these experimental results.

## IMPACT OF NANOMETER SCALE PHYSICAL HETEROGENEITY

In recent years, synthesis of surfaces and control of interfacial properties has been transformed by the use of self-assembled monolayers (SAMs).<sup>[24]</sup> Their excellent chemical stability, low defect density, and spontaneous formation permit the preparation of a well-defined interface on a molecular level, easily and reproducibly. We have addressed the challenge of preparing physically heterogeneous surfaces that are commensurate with the typical dimensions of a

polymer chain and are chemically homogeneous.<sup>[25]</sup> The approach exploits ultraflat, template-stripped gold films and rough, evaporated gold films supporting self-assembled monolayers. In addition, a surface plasmon resonance technique that permits in situ measurements at the solid–liquid interface with high time resolution is used to investigate the kinetics of adsorption. With these two tools, we have studied in detail the adsorption of a flexible, uncharged polymer such as poly(ethylene oxide) (PEO) and established the interplay between physical heterogeneity, the polymer flux to the surface, and the polymer chain length.<sup>[26]</sup>

Fig. 2 shows the typical surface plot and cross-section analysis of a rough and an ultraflat gold substrate. When compared to cases considered by past theoretical studies of adsorption on physically heterogeneous surfaces, the images show that the experimental system here represents a case of polymer adsorption onto a random surface rather than a periodically structured surface. Both substrates possess a grainy but distinct surface texture, which indicates that the spatial distribution of surface roughness differs for the two surfaces. The evaporated rough gold substrate shows a larger range of feature heights compared to ultraflat template-stripped substrate.

Because the surfaces are characterized by small vertical deviations in surface topography with high spatial complexity, the variation of root-mean-square roughness  $R_{\text{rms}}$  with the lateral length-scale was analyzed. The variational  $R_{\text{rms}}$  for the rough and ultraflat gold substrates increases as the lateral length scale increases above 10 nm and becomes independent beyond a spatial scale of 60 nm. This macroscopic value is  $R_{\text{rms}} \sim 8 \text{ \AA}$  for the rough gold substrate and  $R_{\text{rms}} \sim 3 \text{ \AA}$  for the ultraflat surface, which is perceived in the real-space images as a difference in vertical heights. Between 10 and 60 nm, the geometric complexity of the surfaces is fractal-like and the fractal dimension ( $D_F$ ) for rough gold substrate is approximately 2.25 and for ultraflat substrate is approximately 2.15. Because of this fractal-like nature, the relative area of peaks and valleys on the surfaces shown in Fig. 2 changes with the image size for lateral length scales below 60 nm. This length scale is commensurate with the typical dimensions of a polymer chain. Furthermore, the vertical deviations in height for both surfaces are comparable to the size of a few monomers along the polymer chain over a wide spatial extent. The topography of these surfaces is well suited to test the predictions of theoretical studies.

In order to ensure that the two gold substrates have identical chemical interface, a self-assembled monolayer of dodecanethiol ( $\text{CH}_3(\text{CH}_2)_{11}\text{SH}$ ) was formed on both substrates. The advancing contact angle ( $\theta_a$ ) of hexadecane on the resulting surfaces was 46–47°,

**Fig. 2** STM image and cross section of a rough gold substrate (top) and an ultra-flat gold substrate (bottom).

which is consistent with an interface of densely packed  $\text{CH}_3$  groups. The receding contact angles ( $\theta_r$ ) for the monolayers supported on the rough gold substrate showed a contact angle hysteresis of  $4^\circ$  and the monolayers on the ultraflat substrate gave a hysteresis of  $1^\circ$ . These different values of hysteresis reflect the differences in the topography of the substrates supporting the monolayers.

Fig. 3A shows the adsorption isotherm for PEO with a molecular weight ( $M_w$ ) of 53.5 kDa. PEO has similar maximum surface excess ( $\Gamma_{\max}$ ) at low and high bulk concentrations, which indicates high affinity adsorption behavior on both surfaces [Eq. (4)]. Fig. 3B shows the effect of molecular weight on the adsorption amount in the plateau regime for a bulk concentration of 1 ppm. Higher  $M_w$  gives slightly larger adsorption amounts. This is generally because longer polymer chains can form longer loops and tails than shorter chains, as predicted by the Scheutjens–Fleer model.<sup>[1]</sup> The dependency of adsorption amount on molecular weight is stronger for shorter chains and approaches a limit for longer chains. Rough gold surfaces and ultraflat surfaces possess the same degree of hydrophobicity but different extents of surface roughness. Interestingly, plateau adsorption amounts on ultraflat surfaces are 20–30% lower than that on rough surfaces for the various molecular weights investigated. These results indicate that the maximum surface excess of the polymer increases because of the presence of physical heterogeneity. This is the first experimental

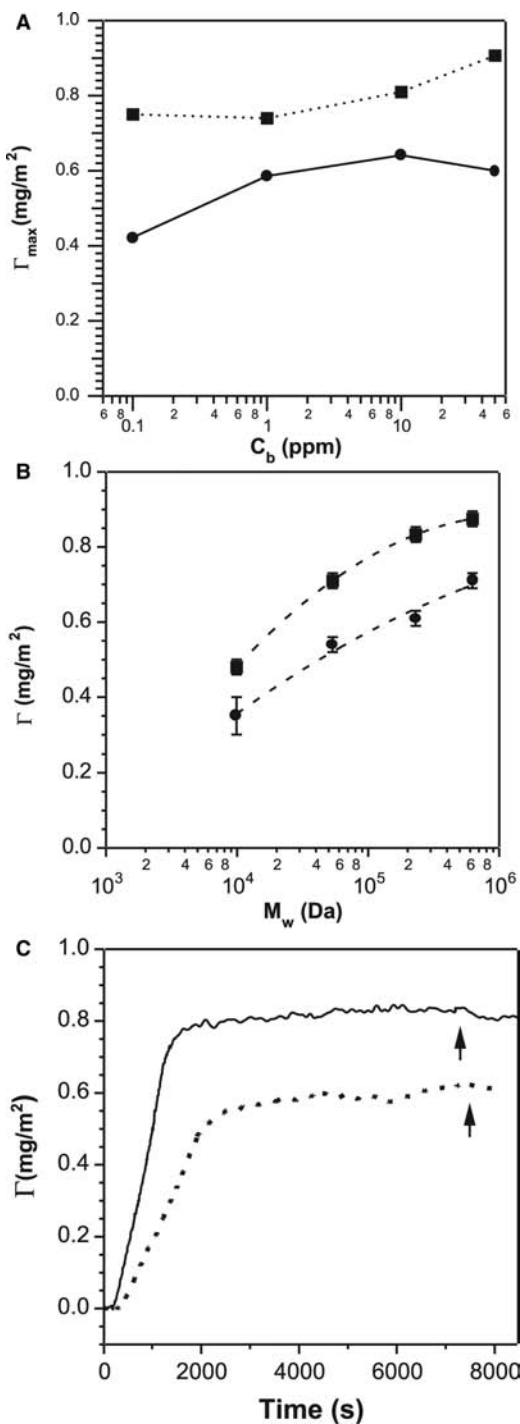

corroboration of the theoretical predictions that adsorbed amount of a polymer increases with surface roughness.

The surface area occupied by a PEO chain on the surface can be estimated from

$$A = \frac{M_w}{\Gamma_{\max} N_A} \quad (5)$$

The lower values of  $\Gamma_{\max}$  in Fig. 3B for the ultraflat surfaces lead to higher area per chain and indicate that the adsorbed polymer chains flatten slightly more on the smooth substrates relative to the rough surfaces. Because the spreading of chains on ultraflat surfaces will occur on time-scales that are characteristic of the polymeric system and the adsorption conditions, it is useful to analyze the evolution of  $\Gamma(t)$ . Fig. 3C shows the evolution of  $\Gamma(t)$  for a PEO chain ( $M_w = 230.7$  kDa) on rough and ultraflat surfaces. Both adsorption curves resemble the schematic  $\Gamma(t)$  shown in Fig. 1B. However, the effect of physical heterogeneity is clearly revealed in the initial adsorption rate, which is higher on rough surfaces. Except for a very short PEO ( $\sim 10$  kDa), the difference  $\Delta(d\Gamma/dt)_0$  is manifested in the adsorption of several different PEO ranging from 53.5 to 624 kDa.

Because the adsorption occurs under the same flow and concentration conditions (i.e.,  $R_m$  and  $C_b$ ), the simplified Eq. (4) cannot be used to interpret the

**Fig. 3** Adsorbed amount of PEO as a function of bulk concentration in solution (A) and molecular weight (B) on rough surfaces (squares) and ultra-flat surface (circles). (C) An illustration of  $\Gamma(t)$  for PEO adsorption on rough (solid line) and ultra-flat (dashed line) surfaces.

difference  $\Delta(d\Gamma/dt)_o$ . Instead, the experimental results suggest that

$$\left(\frac{d\Gamma(t)}{dt}\right)_o = \frac{C_b}{R_m + R_b(\Gamma)} \quad (6)$$

is more appropriate for the ultraflat surface and that a finite resistance  $R_b$  due to spreading, attachment, and penetration of polymer chains leads to a lower initial rate of adsorption. This conclusion is supported by a disappearance of the difference in initial rate of adsorption as the bulk concentration  $C_b$  and the bulk flow velocity is increased (Fig. 4). Physically, the polymer flux increases as  $J \propto C_b$  and  $k_m \propto v^{1/3}$ . As a consequence of the rapid transport of chains to the surface, the spreading of the chains on ultraflat gold during the initial stages of adsorption is suppressed and no difference in initial rate is observed. Fig. 4 shows that this interplay between transport effects and reorganization of polymer chains on the surface is a function of the length of the polymer chain. In contrast to PEO of  $M_w = 53.5$  kDa, it is significantly harder to suppress the difference in  $(d\Gamma/dt)_o$  by increasing the convective flux via  $C_b v^{1/3}$  for long chains. On the other hand, for low molecular weight materials, the difference in the rate of adsorption is not observed because of the progressive difficulty in accessing very low values of  $C_b v^{1/3}$  in the experimental window.

As chain length impacts the structure of the adsorbed layer, at this stage it is not possible to attribute the variation in kinetic effects with  $M_w$  to either the interaction potential between the polymer and the surface or the time scale of spreading. While the experiments on physically heterogeneous surfaces corroborate

**Fig. 4** Plot showing interplay between  $M_w$  and convective flux on the difference in initial rate of adsorption for rough and ultra-flat surfaces (see text for discussion). Experimental points are shown as symbols.

theoretical predictions, they also underscore the need for development of new kinetic models that will not only aid in interpreting results such as those presented here but also guide newer experiments for understanding polymer adsorption at an interface that is heterogeneous on the nanometer scale.

### IMPACT OF CHEMICAL HETEROGENEITY

Design of surfaces using SAMs provides a hitherto unexplored approach to experimentally understand the effects of chemical heterogeneity of surfaces on polymer adsorption.<sup>[27,28]</sup> It is well known that millimeter- or micrometer-sized patterns in self-assembled monolayers can be created using techniques such as UV photooxidation, microcontact printing, and micromachining.<sup>[29]</sup> However, these patterns are large compared to the typical dimensions of a polymer chain and not predicted to dramatically alter the adsorption behavior. Patterning on length scales smaller than 200 nm using nano-lithography is possible but impractical for areas as large as 1 cm<sup>2</sup> that are necessary for noninvasive optical measurements of adsorption.

In contrast, mixed SAMs formed by coadsorption from a mixture of long and short chains [e.g., CH<sub>3</sub>(CH<sub>2</sub>)<sub>9</sub>SH (DT) and HOOC(CH<sub>2</sub>)<sub>3</sub>SH (MPA)] can produce quenched heterogeneous surfaces with a statistical distribution of nanometer-sized domains when the relative proportion of the two species and the time of formation is carefully controlled.<sup>[30–32]</sup>

Fig. 5A shows a low-current STM image of the typical mixed monolayer used in the polymer adsorption. Bright domains correspond to areas dominated by a longer methyl-terminated alkanethiol (DT) while the rest of the gold surface corresponds to regions that are rich in the carboxylic acid terminated MPA. The STM image shows that the surface consists of isolated DT areas that are as small as a few nanometer in dimension and also regions where the DT domains cluster into larger patches. It is evident that the domains on the surface fall predominantly between 10 and 100 nm<sup>2</sup> in area and that the heterogeneous surface is well suited to study polymer adsorption. Because SAMs of MPA are known<sup>[33]</sup> to exhibit a pK<sub>a</sub> greater than 5, variation of the solution pH can also be used to control the state of ionization of the acid groups on the surface and create a patchy

**Fig. 5** A mixed SAM showing patchy domains of DT in the STM image before (A) and after image processing (B). The size of the image is 200 × 200 nm. Adsorption of (C) P2VP and (D) PEO on homogeneous surfaces of DT (diamonds) and MPA (squares) compared to adsorption on a patchy surface (circles). Open symbols correspond to pH = 4.5 and filled symbols to pH = 2.

distribution of charges on the surface. Using the heterogeneous SAMs we have studied the influence of chemical heterogeneity of the surface on adsorption of two broad classes of polymers: flexible, linear polymers and globular proteins.

### Adsorption of Flexible Polymers on Chemically Heterogeneous Surfaces

A number of polymer–surface combinations are realizable and therefore experiments have focused on a subset using nonionic or ionic polymers. The experiments have explored the adsorption of an uncharged polymer [e.g., nonionic PEO or neutral poly(2-vinylpyridine) (P2VP) or neutral poly(acrylic acid)(PAA)] or a charged polymer (e.g., positively charged P2VP) on a largely neutral heterogeneous surfaces and a neutral polymer (e.g., PEO) on a surface with heterogeneous distribution of charge.<sup>[27,28]</sup> Physically, these combinations represent simplified cases where no electrostatic contributions to the surface–segment interaction exist.

Fig. 5C and D shows the typical  $\Gamma(t)$  for P2VP and PEO on the chemically heterogeneous surface containing both DT and MPA sites. A comparison with  $\Gamma(t)$  on homogeneous surfaces of either MPA or DT is also shown. The kinetic curves show a characteristic shape of a constant initial rate of adsorption followed by a slow approach to a plateau. For P2VP adsorption on each type of homogeneous surface (MPA or DT) the value of  $\Gamma_{\max}$  is almost four times larger at pH 4.5 ( $\sim 0.6$ – $1.2$  mg/m<sup>2</sup>) when compared to the lower pH of 2.0 ( $\sim 0.15$ – $0.35$  mg/m<sup>2</sup>). P2VP becomes ionized at the low pH and electrostatic repulsion between neighboring segments of a charged polymer chain leads to lower  $\Gamma$  as accumulation of charge within the surface layer is not favorable. In contrast, no effect of pH is observed on the adsorption of PEO and the  $\Gamma(t)$  shown in Fig. 5D remains unchanged.

At low pH, the largely hydrophobic backbone of P2VP is shielded by the hydrophilic (protonated) pyridine group, which decreases the adsorption affinity to the hydrophobic methyl DT surface and results in a  $\Gamma_{\max}$  that is lower than the value observed on MPA. Thus at pH 2.0 the domains of DT in the heterogeneous surfaces correspond to sites that are less attractive to P2VP relative to the surrounding regions of MPA on the surface. In contrast, at pH 4.5 the DT sites are more attractive relative to the MPA sites.

The adsorption curves clearly show the effect of chemical heterogeneity. For both P2VP and PEO the initial rate of adsorption on the heterogeneous surface is the same as that observed on the homogeneous surfaces. Adsorption of either a charged polymer (P2VP at pH2) or an uncharged polymer (P2VP at pH4.5 and PEO) on a neutral surface shows that the adsorbed

amount  $\Gamma_{\max}$  lies in between the value observed on the two types of homogeneous surfaces. Thus although the initial kinetics are not altered dramatically by the presence of heterogeneity, the surface heterogeneity does impact later stages of adsorption. Physically, the intermediate value of  $\Gamma_{\max}$  indicates that the effective surface adsorption energy of the polymer chain represents some average of the interactions with the two different sites. The experiments also suggest that in these simplified physical situations it does not matter if the minority domains are more or less attractive than the surrounding areas. Other recent experiments by Chun and coworkers<sup>[28]</sup> have shown that beyond a threshold density of DT sites on the surface, the adsorbed amount of the polymer depends on the fraction of heterogeneous sites on the surface.

These first experimental results on compositionally heterogeneous surface verify theoretical predictions regarding polymer adsorption on chemically heterogeneous surfaces. Van der Linden and coworkers used a self-consistent lattice model to study the influence of the degree of clustering of attractive and repulsive sites. On a surface with a patchwise distribution of chemical sites, which is similar to the experiments reported here, the lattice model predicted that the homopolymer adsorption was proportional to the fraction of adsorbing sites. Fig. 5 demonstrates that the adsorption behavior in a real system closely matches the lattice model. Zajac and Chakrabarti used a Monte Carlo simulation to explore the adsorption of a homopolymer on chemically heterogeneous surfaces containing 30–50% of sites that were either repulsive to the polymer or were simply inactive. They predicted that during the early stages the presence of surface impurities did not alter the growth kinetics of the adsorbed layer. However, as chains spread on the surface and competed for sites, there was a net decrease in the number of chains that were adsorbed and that the decrease was proportional to the fraction of inactive or repulsive surface sites. The kinetic curves of  $\Gamma(t)$  measured in Fig. 5 corroborate the predictions from the simulations.

### Adsorption of Globular Proteins on Chemically Heterogeneous Surfaces

Protein adsorption at a surface is ubiquitous in biology and a critical component of synthetic implants and biocompatibility. Because of the intrinsic chemical heterogeneity of a globular protein and its nanometer size, the role of surface heterogeneity in protein adsorption is significant. Therefore we have focused on the adsorption behavior and morphology of a common protein–bovine serum albumin (BSA). To better understand the impact of surface heterogeneity, we also review the adsorption of BSA on homogeneous

surfaces and illustrate the changes in adsorption as chemical heterogeneity is introduced into the surface.

Fig. 6A shows adsorption kinetics on chemically homogeneous surfaces formed using single-component SAMs of DT, MPA, and MUA ( $\text{HOOC}(\text{CH}_2)_{10}\text{SH}$ ).  $\Gamma(t)$  shows that the protein is irreversibly adsorbed on those model surfaces and that the surface chemical properties clearly affect the adsorption amount. The hydrophobicity of each homogeneous surface in Fig. 6A was probed using contact angle measurement with water, which gave  $\theta_{\text{advancing}}$  as  $107^\circ$ ,  $35^\circ$ , and  $25^\circ$  for SAMs of DT, MPA, and MUA, respectively. The plateau values ( $\Gamma_{\text{max}}$ ) therefore follow a trend and increase with the hydrophobic nature of the surface, which is consistent with previous studies that have reported that the adsorption amount of BSA is dependent on the hydrophobicity of surfaces.<sup>[34,35]</sup>

The initial short span of time magnified in Fig. 6A shows that the chemical properties of the surface influence not only the adsorption amount but also the adsorption kinetics, which contrasts with the adsorption behavior of linear flexible polymers. Fig. 6A also shows that despite the identical carboxylic acid (COOH) terminal group of MUA and MPA, the rates of adsorption BSA are vastly different. These

differences in  $\Gamma(t)$  result from the combined influence of electrostatic forces and hydrophobic interactions that are an intimate part of protein adsorption. Bovine serum albumin has an isoelectric point of  $\text{pH} \sim 5$  and at the experimental  $\text{pH}$  of 7.5 the protein is negatively charged because of the presence of three domains that have a net charge of  $-10$ ,  $-8$ , and  $0$ , respectively.<sup>[36]</sup> The SAMs of MPA and MUA ionize at  $\text{pH} > 5$  and can be considered to be largely deprotonated at a  $\text{pH}$  of 7.5.<sup>[37]</sup> In contrast, DT remains neutral in charge. The slow adsorption rate on deprotonated MUA SAMs is therefore attributable to the electrostatic repulsion between the surface and the charged domains of BSA molecules. Because of the shorter chain length of MPA, the self-assembled monolayer is more disordered than the monolayer formed from the longer MUA, where intermolecular interactions between the alkanethiol chain lead to more conformational order. The disorder in the SAMs formed from MPA causes the exposure of methylene groups at the interface and this is manifested in the higher advancing contact angles. We believe that the gradual increase in the adsorption amount over time to  $\Gamma_{\text{max}}$  that is close to the hydrophobic DT surface results from the exposure of the methylene groups, which allows

**Fig. 6** (A) Comparison of the kinetics of BSA adsorption on homogeneous surfaces of DT, MPA, and MUA with the adsorption on heterogeneous surfaces A and B. Arrow indicates time when washing with pure buffer solution was begun. The time scale at the beginning of adsorption has been magnified in the plot. (B) Schematic illustration of heterogeneous surfaces with a well-mixed and a nanometer scale, patch-wise distribution of heterogeneity.

hydrophobic interaction between the hydrophobic residues on BSA and the SAMs even with the presence of electrostatic repulsion. The adsorption of BSA occurs when the molecule arrives in a preferred orientation, which overcomes the electrostatic repulsion from the surfaces and the adsorbed neighboring molecules but results in a slower rate of adsorption.

Aside from single-component SAMs as model homogeneous surfaces, several recent studies have used binary SAMs to investigate the specific and nonspecific binding of proteins and DNA.<sup>[38-40]</sup> In these studies, the surfaces were heterogeneous on a “molecular level” with each component being uniformly dispersed in the “well-mixed” binary SAMs. Fig. 6B illustrates schematically the differences between the well-mixed SAMs and the phase-separated SAMs that contain nanometer-sized heterogeneous sites distributed in a patchwise manner. The adsorption of BSA was studied on both types of heterogeneous surfaces to establish the role of the length-scale of surface heterogeneity. For comparison with the patchy heterogeneous surfaces (surface A), well-mixed SAMs (surface B)

were prepared from DT and MUA, which are similar in chain length and lead to uniformly dispersed monolayers.<sup>[41,42]</sup> The advancing contact angles are 87° and 85° for surfaces A and B, respectively, which lie in between the values measured on the corresponding single-component surfaces.

Fig. 6A shows the kinetics of BSA adsorption on surfaces A and B. Surprisingly, the plateau value ( $\Gamma_{\max}$ ) exceeds that on DT suggesting that adsorption can be enhanced by the presence of two well-mixed functional groups of CH<sub>3</sub> and COO<sup>-</sup> on the surface. The initial rate of adsorption on the well-mixed heterogeneous surfaces falls in between the rates on chemically homogeneous surfaces and once again illustrates the difference in adsorption behavior of a globular protein from that of a flexible polymer.

The morphology of the protein (Fig. 7) is one of many interesting aspects in the study of adsorption. Tapping mode AFM (TM-AFM) is a common scanning probe microscopy technique for visualization of biomaterials, cells, and proteins. Use of TM-AFM minimizes the force exerted on the surface during

**Fig. 7** Tapping mode AFM images of adsorbed BSA on SAMs of homogeneous surfaces of DT (A) and MPA (B) compared with the adsorbed BSA on well-mixed (C) and patch-wise (D) heterogeneous surfaces.

imaging, which avoids possible damage and distortion of the proteins. Fig. 7A shows that the adsorbed BSA on a DT surface has a dendrite-like structure of approximately 5 nm in height and 20 nm in width. A similar morphology was also observed by Ge and coworkers.<sup>[43]</sup> In past studies, it was found that a hydrophobic surface generally causes protein to unfold or denature upon adsorption and the unfolding can expose internal hydrophobic sites of the BSA. The preadsorbed BSA, in turn, provides preferential sites for adsorption of BSA from bulk solutions. Our experiments show that the dendrite-like structures form in an extremely short time (within seconds), which supports the hypothesis that proteins rapidly unfold upon adsorption. Kim and coworkers have proposed a different mechanism for a protein such as lysozyme, where clusters of proteins on the surface are believed to form by diffusion of adsorbed proteins on the surface.<sup>[44]</sup> Clearly, more experiments are needed to reach a definitive conclusion.

The adsorption morphology on surfaces formed by MPA and MUA (Fig. 7B) shows fluffy and relatively featureless morphology. Bovine serum albumin is a globular protein with approximate dimensions of  $4 \times 4 \times 14$  nm, which indicates that  $\Gamma_{\max}$  should be  $2.5 \text{ mg/m}^2$  for a closely packed protein monolayer in a side-on orientation and  $8.8 \text{ mg/m}^2$  in an end-on orientation. The adsorption amounts on MPA and MUA range from 0.3 to  $0.9 \text{ mg/m}^2$  (Fig. 6), which are much lower than these estimates of  $\Gamma_{\max}$ . The adsorbed BSA layers are therefore not continuous when one considers the rigidity of the BSA molecule resisting total unfolding on hydrophilic surfaces.<sup>[45,46]</sup> However, the individual BSA molecules or clusters of BSA cannot be clearly imaged due to the effects of tip-broadening and the chemical interplay between the SAMs and the BSA layers in tip-surface forces.<sup>[47]</sup> In these AFM images, nevertheless, the deep boundaries of gold grains/terraces can be roughly mapped out, which suggests that the BSA is likely adsorbed in a distributed manner on the hydrophilic surfaces.

The AFM images of adsorbed BSA on each type of heterogeneous surfaces are shown in Fig. 7C and D. While the adsorption amounts on the well-mixed and patchy heterogeneous surfaces do not differ significantly, the morphology of adsorbed BSA layer is strikingly different although the SAMs possess similar surface energy (reflected in the comparable values of  $\theta_{\text{advancing}}$ ). Comparison between Fig. 7A and Fig. 7C shows that when the surface changes from a hydrophobic ( $\theta_a \sim 107$ ), methyl-terminated interface to an interface where  $\text{CH}_3$  and  $\text{COO}^-$  are well mixed ( $\theta_a \sim 86$ ), the morphology of adsorbed BSA changes from a dendrite-like structure to a network-like structure. Surprisingly, the TM-AFM image of the adsorbed BSA on patchy surfaces indicates breakdown of both

dendrite and network structure. Instead, the layer of BSA shows few distinct features but appears as a continuous layer (Fig. 7D). When compared to the BSA layer on a MPA surface (Fig. 7B) where the morphology was featureless, the image in Fig. 7D shows the presence of a few holes/depression and occasional high spots. Results in Fig. 7 underscore the importance of the nanometer scale of the heterogeneity in surfaces. Recent studies<sup>[43,48,49]</sup> have reported adsorption of BSA on phase-separated Langmuir–Blodgett films where micrometer circular domains of a methyl  $\omega$ -functionalized organosilane were formed in a matrix of perfluoryl  $\omega$ -functionalized organosilanes. The morphology of the adsorbed BSA on each domain was found to be more or less similar to the corresponding single component LB film. Fig. 7C and D demonstrates that the adsorption characteristics of the BSA are strongly affected by the patchwise distribution of hydrophobic domains only when the surface heterogeneity is commensurate in size with the nanometer-sized, globular protein.

## CONCLUSION

The experiments reported here and the agreement with theoretical studies demonstrate that, in addition to fundamental insights into adsorption on heterogeneous surfaces, we can now pursue experimental systems that exploit the interactions between lateral nanoscale morphology of a surface and an adsorbing polymer chain. For example, recent simulations have shown that a pattern of distributed charges on a surface can be recognized during the adsorption of an oppositely charged polyelectrolyte chain. Similarly others have predicted that the nanoscale morphology of a surface and the heterogeneous chemical interactions with a polymer chain can be used to direct segregation or patterning within adsorbed layers. The present strategy of using molecularly designed self-assembled surfaces for polymer adsorption enables the exploration of physical phenomena such as biomimetic recognition and segregation in polymer adsorption on heterogeneous surfaces and promises both scientific and technological advances.

## ACKNOWLEDGMENT

The research reviewed here is based upon work performed with the support of the U.S. Department of Energy, Division of Materials Sciences under Award No. DEFG02-ER9145439, through the Frederick Seitz Materials Research Laboratory at the University of Illinois. Support from the University of Illinois and National Science Foundation is also acknowledged.

# Aerosol Nanoparticles: Coagulation Theory

Ken Won Lee

Soon-Bark Kwon

## INTRODUCTION

Many important physical properties of natural or man-made aerosol particles such as light scattering, electrostatic charges, and toxicity, as well as their behavior involving physical processes such as diffusion, condensation, and thermophoresis, depend strongly on their size distribution. An important aerosol behavior mechanism affecting the size distribution of aerosol particles is coagulation. Aerosol particles suspended in a fluid may come into contact because of their Brownian motion, or as a result of their relative motion produced by external forces (e.g., gravity, hydrodynamic forces, electrical forces, etc.). The result is a continuous decrease in number concentration and an increase in particle size. The theory of coagulation was originally devised for particles in liquids and was later extended to aerosols. In the case of solid particles, the process is sometimes called agglomeration, and the resulting particle clusters are known as agglomerates. Therefore in many basic and applied fields (e.g., synthesis of nanostructured material via gas-phase synthesis), the evolution of the particle size distribution because of coagulation is of fundamental importance and interest.

Aerosol coagulation is caused by relative motion among particles. When the relative motion is because of Brownian motion, the process is called Brownian coagulation. Brownian coagulation is a spontaneous and ever-present phenomenon for aerosols. When the relative motion arises from external forces such as gravity or electrical forces, or from aerodynamic effects, the process is called kinematic coagulation. Kinematic coagulation includes gravitational coagulation, turbulent coagulation, electrostatic coagulation, etc.

The objective of this entry is to review the theories of coagulation describing how particle number concentration and particle size change as a function of time. To do that, first, an overview of some important coagulation mechanisms is presented. Next, various solution techniques for the coagulation equation are comparatively reviewed.

## COAGULATION OF MONODISPERSE AEROSOLS

When an aerosol contains particles of the same size, it is called monodisperse, whereas if particles are present in a variety of sizes, the aerosol is polydisperse. Coagulation of a monodisperse aerosol was developed for Brownian coagulation by Smoluchowski.<sup>[1]</sup> Smoluchowski derived the monodisperse coagulation equation by solving the diffusion equation around a single particle, and by obtaining the flux of other particles toward it. He assumed that particles adhere at every collision and that particle size changes slowly. The change in particle number concentration is represented by the following equation:

$$\frac{dN}{dt} = -2K_{co}N^2 \quad (1)$$

where  $N$  is the number concentration of the particles,  $t$  is the time,  $K_{co}$  ( $=2\pi d_p D$ ) is the Brownian coagulation coefficient in the continuum regime,  $d_p$  is the diameter of the particles, and  $D$  is the diffusion coefficient of the particles. The diffusion coefficient  $D$  is given by the following Stokes–Einstein equation:

$$D = \frac{k_B T}{3\pi\mu d_p} \quad (2)$$

where  $k_B$  is the Boltzmann constant,  $T$  is the absolute temperature, and  $\mu$  is the gas viscosity. Using Eq. (2),  $K_{co}$  in Eq. (1) can be expressed as follows:

$$K_{co} = \frac{2k_B T}{3\mu} \quad (3)$$

By integrating Eq. (1), the number concentration is determined as a function of time as follows:

$$\frac{N}{N_0} = \frac{1}{1 + 2K_{co}N_0 t} \quad (4)$$

where  $N_0$  is the initial value for  $N$ .

**Fig. 1** Coagulation of monodisperse aerosol particles.

Because the rate of coagulation is proportional to  $N^2$ , it is rapid at high concentrations but decreases as coagulation reduces the concentration of particles. This relationship is shown in Fig. 1, which presents a plot of the number concentration of a monodisperse aerosol as a function of time. When the data are replotted as  $1/N$  vs.  $t$ , a straight line is obtained. The quantity  $1/N$  is in units of cubic centimeters and represents the average gas volume per particle. The slope of the line is the coagulation coefficient  $K_{co}$ .

volumes between  $v$  and  $(v + dv)$  from the combination of particles of volume  $v - \bar{v}$  and  $\bar{v}$ . The second term in the right-hand side of this equation represents the loss of particles with volumes between  $v$  and  $(v + dv)$  resulting from the coagulation of particles of volume  $v$  and  $\bar{v}$ . Thus this equation gives an expression for the net rate of change of particles whose volumes lie between  $v$  and  $(v + dv)$ . The collision kernel  $\beta(v, \bar{v})$  is dependent on the collision mechanism as well as on the particle size of two colliding particles.

## GENERAL COAGULATION EQUATION

In “Coagulation of Monodisperse Aerosols,” the equations describing coagulation were introduced for a monodisperse aerosol. We now consider the more complicated situation of polydisperse aerosols where a range of particle sizes is present. Because the rate of coagulation depends on the range of sizes present, the mathematics become much more complicated and no explicit solution exists.

The change in the particle size distribution of a polydisperse aerosol by coagulation is represented by the following population balance equation:<sup>[2]</sup>

$$\frac{\partial n(v, t)}{\partial t} = \frac{1}{2} \int_0^v \beta(v - \bar{v}, \bar{v}) n(v - \bar{v}, t) n(\bar{v}, t) \times d\bar{v} - n(v, t) \int_0^\infty \beta(v, \bar{v}) n(\bar{v}, t) d\bar{v} \quad (5)$$

where  $n(v, t)$  is the particle size distribution function at time  $t$ , and  $\beta(v, \bar{v})$  is the collision kernel for two particles of volume  $v$  and  $\bar{v}$ . The first term in the right-hand side of Eq. (5) represents the increase in particles with

## COLLISION KERNELS

### Brownian Coagulation

The Brownian collision kernel can be derived by either the kinetic theory of gases, or by the continuum diffusion theory according to particle size. Particles much smaller than the mean free path length of the gas molecules behave like molecules, and the kinetic theory of gases must be used to derive the collision kernel. In the meanwhile, for the particles much larger than the mean free path of the gas molecules, the continuum diffusion theory should be used. Generally, the Knudsen number  $Kn (= \lambda/r)$ , with  $\lambda$  as the mean free path length of the surrounding gas molecules and  $r$  as the particle radius, is used to define the particle size regime.

In the free molecule regime, where the Knudsen number is larger than about 50,  $\beta_{fm}(v, \bar{v})$  results from the kinetic theory of gases and is given as:<sup>[3]</sup>

$$\beta_{fm}(v, \bar{v}) = K_{fm}(v^{1/3} + \bar{v}^{1/3})^2 \sqrt{\frac{1}{v} + \frac{1}{\bar{v}}} \quad (6)$$

where  $K_{\text{fm}} = (3/4\pi)^{1/6}(6k_{\text{B}}T/\rho)^{1/2}$  is the Brownian coagulation coefficient for the free molecule regime and  $\rho$  is the particle density.

In the continuum regime, where the Knudsen number is smaller than about 1,  $\beta_{\text{co}}(v, \bar{v})$  is derived by the continuum diffusion theory as follows:

$$\beta_{\text{co}}(v, \bar{v}) = K_{\text{co}}(v^{1/3} + \bar{v}^{1/3}) \left( \frac{C(v)}{v^{1/3}} + \frac{C(\bar{v})}{\bar{v}^{1/3}} \right) \quad (7)$$

where  $C = 1 + Kn\{1.142 + 0.558 \exp(-0.999/Kn)\}$  is the gas slip correction factor.<sup>[4]</sup>

The entire transition regime is characterized by Knudsen numbers in the range of  $\sim 1 < Kn < \sim 50$ . In the transition regime, the coagulation rate is described neither by the continuum diffusion theory nor by the simple kinetic theory. Fuchs<sup>[5]</sup> found a semi-empirical solution of the collision kernel by assuming that outside of a certain distance, namely, an average mean free path of an aerosol particle, the transport of particles is described by the continuum diffusion theory including the slip correction, and that inside the distance, the particles behave like in a vacuum and the transport is described by the kinetic theory. The two theories were brought together by matching the fluxes at the absorbing sphere radius.

This so-called flux matching was the basis for most of the following theories because of its phenomenological approach and the guarantee that the collision kernel is valid over the entire size regime. All theories dealing with an absorbing sphere use a correction function first calculated by Fuchs. This function is mainly expressed as an enhancement of the collision kernel for the continuum regime including the slip correction:

$$\beta_{\text{B}}(v, \bar{v}) = K_{\text{co}}(v^{1/3} + \bar{v}^{1/3}) \times \left( \frac{C(v)}{v^{1/3}} + \frac{C(\bar{v})}{\bar{v}^{1/3}} \right) f(Kn_{\text{D}}) \quad (8)$$

where  $Kn_{\text{D}} = \frac{\beta_{\text{co}}(v, \bar{v})}{2\beta_{\text{fm}}(v, \bar{v})}$  and the subscripts ‘‘co’’ and ‘‘fm’’ designate the continuum regime including the slip correction and the free molecule regime, respectively. Dahneke<sup>[6]</sup> described the diffusion process as a mean free path phenomenon. To obtain the coagulation coefficient, Dahneke also matched the two fluxes but at a distance which is the mean free path of the particles. To compare the different theories, the following general enhancement function  $f(Kn_{\text{D}})$  is used:

$$f(Kn_{\text{D}}) = \frac{1 + B_1 Kn_{\text{D}}}{1 + B_2 Kn_{\text{D}} + B_3 Kn_{\text{D}}^2} \quad (9)$$

The coefficients  $B_1$ ,  $B_2$ , and  $B_3$  are given for some theories in Table 1. By comparing various theories on the collision kernel in the transition regime, Otto et al.<sup>[8]</sup>

**Table 1** Coefficients for enhancement function  $f(Kn_{\text{D}})$

	$B_1$	$B_2$	$B_3$
Fuchs <sup>[5]</sup>	$\frac{3}{2} \cdot \frac{\Delta_{12}}{\lambda_p}$	2	$3 \cdot \frac{\Delta_{12}}{\lambda_p}$
Fuchs and Sutugin <sup>[7]</sup>	$\frac{3}{2}$	2.566	3
Dahneke <sup>[6]</sup>	1	2	2
Harmonic mean	0	2	0

recommended Dahneke’s theory to be used partially for its simplicity and partially for its accuracy.

## Gravitational Coagulation

Kinematic coagulation is coagulation that occurs as a result of relative particle motion caused by mechanisms other than Brownian motion. From this section through ‘‘Electrostatic Coagulation,’’ various kinematic coagulations are introduced.

Particles of different sizes will settle at different rates under the influence of gravity and thereby create relative motion between them, which leads to collision and coagulation. This mechanism is called gravitational coagulation. The collision kernel by gravitational coagulation is expressed as the following equation when the slip correction factor is neglected:<sup>[9]</sup>

$$\beta_{\text{G}}(v, \bar{v}) = K_{\text{G}}\varepsilon(r, \bar{r})(r + \bar{r})^2|r^2 - \bar{r}^2| \quad (10)$$

where  $K_{\text{G}} (= \frac{2\pi g \rho}{9\mu})$  is the gravitational coagulation constant,  $g$  is the gravity constant,  $\rho$  is the particle density,  $\mu$  is the gas viscosity, and  $r [= (\frac{3v}{4\pi})^{1/3}]$  and  $\bar{r} [= (\frac{3\bar{v}}{4\pi})^{1/3}]$  are the radii of the colliding particles.  $\varepsilon(r, \bar{r})$  is the collision efficiency, which can be expressed as follows:

$$\varepsilon(r, \bar{r}) = \frac{3y_c^2}{2(r + \bar{r})^2} \quad \text{if } r \leq \bar{r}, y_c = r \text{ and if } r > \bar{r}, y_c = \bar{r} \quad (11)$$

When both the Brownian and gravitational coagulations are significant, the two collision kernels  $\beta_{\text{B}}$  and  $\beta_{\text{G}}$  are commonly added to predict the behavior of aerosols. This simple addition would appear to be based on a physical picture of each of the mechanisms acting independently with neither affecting the other, but it would seem that this is not the case. Thus the combined kernel was suggested by Simon, Williams, and Cassel<sup>[10]</sup> and their kernel is plotted in Fig. 2 with the sum kernel and each kernel of the Brownian and gravitational coagulations. Their kernel describing the combined effect of Brownian and gravitational coagulations increases the rate of coagulation compared with the sum kernel in the size range of 0.1–1  $\mu\text{m}$ . On the contrary, Qiao, Li, and Wen<sup>[12]</sup> reported that weak Brownian diffusion, the effect of which is

**Fig. 2** Comparison of Brownian and gravitational coagulation kernels. *Source:* From Ref.<sup>[11]</sup>.

non-linearly coupled with gravity, can act to decrease the coagulation rate.

### Turbulent Coagulation

In many physical situations, the flow field in a fluid is turbulent. There are two ways in which turbulence causes collisions between neighboring particles. First, there are spatial variations of the turbulent motion. Because of this process, collision mechanism is conventionally called “shear mechanism.” Second, each particle moves relative to the air surrounding it, owing to the fact that the inertia of a particle is different from that of an equal volume of air. Because the inertia of a particle depends on its size, neighboring particles of unequal size will have different velocities and this will also lead to collisions. This mechanism is called “accelerative mechanism.” Saffman and Turner<sup>[13]</sup> derived the following collision kernel by combining the shear mechanism and the accelerative mechanism:

$$\begin{aligned} \beta_T(v_1, v_2) &= \left(\frac{8\pi}{3}\right)^{1/2} (r_1 + r_2)^2 (w_a^2 + w_s^2)^{1/2} \\ &= \left(\frac{8\pi}{3}\right)^{1/2} (r_1 + r_2)^2 \left[ 3 \left(1 - \frac{\rho_f}{\rho_p}\right)^2 (\tau_1 - \tau_2)^2 \right. \\ &\quad \left. \times \left[ \left(\frac{Dv_f}{Dt}\right)^2 + \frac{1}{5}(r_1 + r_2)^2 \frac{\varepsilon}{\nu} \right]^{1/2} \right] \end{aligned} \quad (12a)$$

where  $r_i = [(3v_i/4\pi)^{1/3}]$  is the particle radius,  $\rho_f$  is the fluid density,  $\rho_p$  is the particle density,  $\varepsilon$  is the turbulent energy dissipation rate, and  $\nu$  is the kinematic viscosity of the fluid. The particle relaxation time  $\tau_i$  including the Cunningham slip correction factor  $C_{c,i}$  is defined as:

$$\tau_i = \frac{C_{c,i}(2\rho_p + \rho_f)r_i^2}{9\mu} \quad (12b)$$

where  $\mu$  is the dynamic viscosity of the fluid. The average acceleration of eddies in the dissipation range  $(Dv_f/Dt)^2$  is defined as:<sup>[14]</sup>

$$\left(\frac{Dv_f}{Dt}\right)^2 = 1.16\varepsilon^{3/2}\nu^{-1/2} \quad (12c)$$

The first and second terms in the square root term on the right-hand side of Eq. (12a) represent the accelerative mechanism and shear mechanism, respectively. However, under more vigorous turbulence or with larger particles, the approaching particles may no longer be entrained completely by the smallest eddies, so they will have less correlated velocities.

Recently, Kruis and Kusters<sup>[15]</sup> analyzed this problem using a turbulence spectrum, which describes both the viscous subrange and the inertial subrange. In their work, the relative particle velocity  $w$  is represented by

the following equations:

$$w_a^2 = 3(1-b)^2 v_f^2 \frac{\gamma}{\gamma-1} \times \frac{(\theta_1 + \theta_2)^2 - 4\theta_1\theta_2 \sqrt{\frac{1+\theta_1+\theta_2}{(1+\theta_1)(1+\theta_2)}}}{(\theta_1 + \theta_2)} \times \left\{ \frac{1}{(1+\theta_1)(1+\theta_2)} - \frac{1}{(1+\gamma\theta_1)(1+\gamma\theta_2)} \right\} \quad (13)$$

$$w_s^2 = 0.238bv_f^2 \left( \frac{v_1^2}{v_f^2} \frac{\theta_1}{C_{c,1}} + \frac{v_2^2}{v_f^2} \frac{\theta_2}{C_{c,2}} + 2 \frac{\overline{v_1 v_2}}{v_f^2} \sqrt{\frac{\theta_1 \theta_2}{C_{c,1} C_{c,2}}} \right) \quad (14)$$

The root mean square (rms) fluid velocity  $v_f$  is expressed as:

$$v_f^2 = \frac{\gamma(\varepsilon\nu)^{1/2}}{0.183} \quad (15)$$

where  $\gamma$  is the spectrum constant, which usually has a value between 10 and 100. The turbulent energy  $k$  ( $k = 3/2v_f^2$ ) and the dissipation rate  $\varepsilon$  are obtained mostly from fluid dynamic simulations. The added mass coefficient  $b$  is defined as:

$$b = \frac{3\rho_f}{2\rho_p + \rho_f} \quad (16)$$

The dimensionless particle relaxation time  $\theta_i$  is defined as:

$$\theta_i = \frac{\tau_i}{T_L} \quad (17)$$

where  $T_L$  is the Lagrangian time scale:

$$T_L = \frac{0.4v_f^2}{\varepsilon} \quad (18)$$

The rms particle velocity  $v_i$ , valid in both the viscous and the inertial subranges of turbulence, is represented as:

$$\frac{v_i^2}{v_f^2} = \frac{\gamma}{\gamma-1} \left\{ \frac{1+b^2\theta_i}{1+\theta_i} - \frac{1+b^2\gamma\theta_i}{\gamma(1+\gamma\theta_i)} \right\} \quad (19)$$

whereas the velocity correlation is:

$$\frac{\overline{v_1 v_2}}{v_f^2} = \frac{\gamma}{\gamma-1} \left\{ \frac{(\theta_1 + \theta_2 + 2\theta_1\theta_2) + b(\theta_1^2 + \theta_2^2 - 2\theta_1\theta_2) + b^2(\theta_1^2\theta_2 + \theta_1\theta_2^2 + 2\theta_1\theta_2)}{(\theta_1 + \theta_2)(1 + \theta_1)(1 + \theta_2)} - \frac{(\theta_1 + \theta_2 + 2\gamma\theta_1\theta_2) + b\gamma(\theta_1^2 + \theta_2^2 - 2\theta_1\theta_2) + b^2(\gamma^2\theta_1^2\theta_2 + \gamma^2\theta_1\theta_2^2 + 2\gamma\theta_1\theta_2)}{\gamma(\theta_1 + \theta_2)(1 + \gamma\theta_1)(1 + \gamma\theta_2)} \right\} \quad (20)$$

## Electrostatic Coagulation

Charged particles may experience either enhanced or retarded coagulation rates depending on their charges. For a unipolar aerosol, it is necessary to consider electrostatic dispersion (i.e., the tendency of charged particles of the same sign to move away from each other). This dispersion tends to reduce the concentration of an aerosol, for example, by causing particles to deposit on the walls of any containing vessel or nearby surface. In the presence of particle charging, the collision kernel of particles must be corrected by:

$$\beta_E(v_1, v_2) = \frac{\beta_n(v_1, v_2)}{W} \quad (21)$$

where the subscript “n” designates neutral particles. The Fuchs stability function  $W$  is given by:<sup>[16]</sup>

$$W = \frac{\exp(\kappa) - 1}{\kappa}, \quad \kappa = \frac{z_1 z_2 e^2}{(r_1 + r_2)k_B T} \quad (22)$$

where  $z_1$  and  $z_2$  are the numbers of unit charges contained in particles, and  $e$  is the electron charge. For  $\kappa > 0$  (like charge),  $W > 1$  and coagulation is retarded from that for neutral particles. Conversely, for  $\kappa < 0$  (unlike charge),  $W < 1$  and coagulation is enhanced.

## SOLUTIONS TO THE COAGULATION EQUATION

Methods of solving a coagulation equation were summarized by Williams and Loyalka.<sup>[17]</sup> These methods range from the discrete (computationally intensive) and sectional models in which Eq. (5) is transformed into a number of differential equations, to the less accurate monodisperse models. Approximate solutions can be found using the method of moments. Exact solutions for asymptotic limiting cases can be obtained with the self-preserving theory.

### Sectional Method

Because solving the coagulation equation with a direct numerical method is impractical owing to its time-consuming property, several approximate methods have been developed. The sectional method developed by Gelbard, Tambour, and Seinfeld<sup>[18]</sup> is known as a

very accurate but comparatively time-efficient tool. Their model solved a one-dimensional form of the aerosol general dynamic equation by dividing the particle size domain into a finite number of sections by particle volume, and by calculating the addition and subtraction of particle mass to each section. The model assumed that particles kept their spherical shape during growth; therefore the volume sections corresponded to sections of particle size. However, as irregular particles have become omnipresent in nanoparticle production (e.g., generation of titanic or silica particles by gas-phase reaction), substantial progress has been made in developing models that account for irregular particle shape through fractal dimensions. The volume and surface area of irregularly shaped particles were chosen as the two particle size dimensions because these are the most commonly employed powder properties in engineering applications. Then the two-dimensional aerosol dynamic equations were solved by extending a one-dimensional sectional technique to the two-dimensional space.<sup>[19]</sup> A two-dimensional particle size distribution function is defined as  $n_t(v, a)$ , where  $n_t(v, a) da dv$  is the number density of particles having a volume between  $v$  and  $v + dv$  and a surface area between  $a$  and  $a + da$  at time  $t$ . For an aerosol that is formed by gas-phase reaction at high temperatures, the rate of change in  $n_t(v, a)$  is given by the rate of simultaneous coagulation and coalescence (by sintering) among aerosol particles.<sup>[19,20]</sup>

$$\frac{\partial n_t(v, a)}{\partial t} = \left[ \frac{\partial n_t(v, a)}{\partial t} \right]_{\text{coag}} + \left[ \frac{\partial n_t(v, a)}{\partial t} \right]_{\text{sint}} \quad (23)$$

The coagulation term in Eq. (23) can be obtained by extending the classical collision theory to the two-dimensional space  $v, a$  as:

$$\begin{aligned} & \left[ \frac{\partial n_t(v, a)}{\partial t} \right]_{\text{coag}} \\ &= \frac{1}{2} \int_0^v \theta \left( a > \left( \frac{\bar{v}}{v_0} \right)^{2/3} a_0 + \left( \frac{v - \bar{v}}{v_0} \right)^{2/3} a_0 \right) \\ & \quad \times \int_{\left( \frac{\bar{v}}{v_0} \right)^{2/3} a_0}^{\frac{v}{v_0} a_0} \beta_{\bar{v}, v - \bar{v}}(\bar{a}, a - \bar{a}) n_t(\bar{v}, \bar{a}) \\ & \quad \times n_t(v - \bar{v}, a - \bar{a}) d\bar{a} d\bar{v} - n_t(v, a) \int_0^\infty \\ & \quad \times \int_{\left( \frac{\bar{v}}{v_0} \right)^{2/3} a_0}^{\frac{v}{v_0} a_0} \beta_{v, \bar{v}}(a, \bar{a}) n_t(\bar{v}, \bar{a}) d\bar{a} d\bar{v} \end{aligned} \quad (24)$$

where  $v_0$  and  $a_0$  are the volume and surface area, respectively, of the primary particle, which is the smallest possible particle (e.g., a molecule or a monomer).

The sintering contribution in Eq. (23) is related to the particle sintering rate through the continuity:<sup>[20]</sup>

$$\left[ \frac{\partial n_t(v, a)}{\partial t} \right]_{\text{sint}} = - \frac{\partial}{\partial a} \left[ \frac{da}{dt} n_t(v, a) \right] \quad (25)$$

The sintering of solid particles or highly viscous fluids can be the result of various sintering mechanisms such as solid-state surface or volume diffusion and viscous flow. For the mechanism of viscous flow coalescence beyond a small initial time scale, Hiram and Nir<sup>[21]</sup> found that the neck size approaches the radius of the resulting sphere exponentially. For longer times, this leads to a similar behavior for the particle surface:<sup>[20]</sup>

$$\frac{da}{dt} = - \frac{1}{\tau_f} (a - a_{\text{final}}) \quad (26)$$

where  $a_{\text{final}}$  is the surface area of the completely fused sphere of volume  $v$ , and  $\tau_f$  is the characteristic coalescence time. The characteristic time for coalescence or sintering  $\tau_f$  is the time needed to reduce by 63% the excess agglomerate surface area over that of a spherical particle with the same mass.

Therefore by combining Eqs. (23) and (24) and Eqs. (25) and (26), the overall aerosol population balance equation can be written as:

$$\begin{aligned} & \frac{\partial n_t(v, a)}{\partial t} - \frac{1}{\tau_f} \frac{\partial}{\partial a} \left( \left[ a - \left( \frac{v}{v_0} \right)^{2/3} a_0 \right] n_t(v, a) \right) \\ &= \frac{1}{2} \int_0^v \theta \left( a > \left( \frac{\bar{v}}{v_0} \right)^{2/3} a_0 + \left( \frac{v - \bar{v}}{v_0} \right)^{2/3} a_0 \right) \\ & \quad \times \int_{\left( \frac{\bar{v}}{v_0} \right)^{2/3} a_0}^{\frac{v}{v_0} a_0} \beta_{\bar{v}, v - \bar{v}}(\bar{a}, a - \bar{a}) n_t(\bar{v}, \bar{a}) n_t(v - \bar{v}, a - \bar{a}) \\ & \quad \times d\bar{a} d\bar{v} - n_t(v, a) \int_0^\infty \int_{\left( \frac{\bar{v}}{v_0} \right)^{2/3} a_0}^{\frac{v}{v_0} a_0} \beta_{v, \bar{v}}(a, \bar{a}) n_t(\bar{v}, \bar{a}) d\bar{a} d\bar{v} \end{aligned} \quad (27)$$

Equation (27) is a two-dimensional partial integro-differential equation that needs to be solved numerically. In solving the conventional one-dimensional coagulation equation, a sectional model has been developed. The sectional method proves to be both computationally efficient and numerically robust, especially in dealing with aerosols having an extremely large size spectrum. Xiong and Pratsinis<sup>[19]</sup> presented a set of  $M$  ordinary differential equations (ODEs) using an efficient ODEs solver.

### Self-Preserving Solution

One of the interesting features of coagulation known to date is that the shape of the size distribution of suspended particles undergoing coagulation often does not change after a long time and the distribution becomes *self-preserving*.<sup>[22-24]</sup>

Conventionally, in the self-preserving formulation, the dimensionless particle volume is defined as:

$$\eta = \frac{N(t)v}{\phi(t)} \tag{28}$$

and the dimensionless size distribution density function is defined as:

$$\Psi(\eta) = \frac{n(v, t)\phi(t)}{N^2(t)} \tag{29}$$

Friedlander and Wang<sup>[24]</sup> obtained the following equation for the Brownian coagulation in the continuum regime:

$$\begin{aligned} (1 + ab)\eta \frac{\partial \Psi(\eta)}{\partial \eta} + (2ab - b\eta^{1/3} - a\eta^{-1/3})\Psi(\eta) \\ + \int_0^\eta \Psi(\eta - \bar{\eta})\Psi(\bar{\eta}) \left\{ 1 + \left( \frac{\eta - \bar{\eta}}{\bar{\eta}} \right)^{1/3} \right\} d\bar{\eta} = 0 \end{aligned} \tag{30}$$

where  $a = \int_0^\infty \eta^{1/3}\Psi(\eta)d\eta$  and  $b = \int_0^\infty \eta^{-1/3}\Psi(\eta)d\eta$ . Friedlander and Wang derived analytical solutions of Eq. (30), shown in Eqs. (31) and (32), for small  $\eta$  regime and for large  $\eta$  regime, respectively:

$$\Psi(\eta) = \frac{0.5086}{\eta^{1.06}} \exp(1.758\eta^{1/3} - 1.275\eta^{-1/3}) \tag{31}$$

$$\Psi(\eta) = 0.915 \exp(-0.95\eta) \tag{32}$$

Equation (30) can be solved numerically for the entire  $\eta$  range. The results obtained by Friedlander and Wang are shown in Fig. 3 together with the results of numerical simulations by Vemury, Kusters, and Pratsinis,<sup>[25]</sup> who solved the coagulation equation [Eq. (5)] using the sectional method of Landgrebe and Pratsinis.<sup>[26]</sup> Lai et al.<sup>[27]</sup> used the above technique to derive the self-preserving size distribution for the free molecule regime.

Wang and Friedlander<sup>[28]</sup> applied the same method to the Brownian coagulation either with slip correction or with simultaneous shear flow. However, in their work, they had to introduce an unrealistic assumption that some parameters are special functions of time. Pich, Friedlander, and Lai<sup>[29]</sup> obtained the self-preserving particle size distribution for the problem of simultaneous coagulation and condensation, but the similar constraint confined the application of the solution obtained.

### Moment Method

Although the self-preserving size distribution theory played a very important role for researchers in understanding the coagulation mechanism, one shortcoming of the theory is its inability to resolve the size distribution for the time period before an aerosol attains the self-preserving size distribution. Therefore it was still necessary to resort to numerical calculations. However, during coagulation, the size distribution of particles changes by the interaction of particles in so many size classes at each time step that the computing time becomes excessive for the calculation of the change of size distribution of particles. To overcome this problem and to accelerate the computations, much effort has been made. Cohen and Vaughan<sup>[30]</sup> succeeded in reducing the coagulation equation to a set

Fig. 3 Self-preserving size distribution for Brownian coagulation.

of ODEs for the moments of size distribution. By choosing a specific functional form for the distribution of the particle size, they were able to calculate the parameters of the size distribution as a function of the three leading moments. This method, known as the moment method, has the advantage of simplicity while providing important information on the change of the size distribution of aerosol.<sup>[31]</sup> Therefore the moment method has been widely applied in the simulation of aerosol coagulation.<sup>[32,33]</sup> Here, the application of the moment method to Brownian coagulation of fractal agglomerates,<sup>[34]</sup> which are often involved in the synthesis of nanoparticles, is addressed as an example for the continuum regime where the slip correction factor is equal to 1.

In the moment method, to represent a polydisperse aerosol size distribution, the log-normal function (one of the most commonly used mathematical forms for the study of the dynamics of particles) is used. The size distribution density function for particles whose radius is  $r$  for the log-normal distribution is written as:

$$n(r, t) = \frac{1}{r} \frac{N(t)}{\sqrt{2\pi \ln \sigma(t)}} \exp \left[ \frac{-\ln^2 \{r/r_g(t)\}}{2 \ln^2 \sigma(t)} \right] \quad (33)$$

where  $N(t)$  is the total number concentration of particles,  $\sigma(t)$  is the geometric standard deviation based on particle radius, and  $r_g(t)$  is the geometric number mean particle radius. For studying the coagulation problem in which two particles collide to become a particle whose volume is the sum of the two volumes, it is convenient to rewrite Eq. (33) in terms of particle volume:

$$n(v, t) = \frac{1}{3v} \frac{N(t)}{\sqrt{2\pi \ln \sigma(t)}} \exp \left[ \frac{-\ln^2 \{v/v_g(t)\}}{18 \ln^2 \sigma(t)} \right] \quad (34)$$

where  $v_g$  is the geometric number mean particle volume. If one obtains the time evolution of the three parameters  $N(t)$ ,  $\sigma(t)$ , and  $v_g(t)$ , the particle size distribution of the coagulating aerosol of interest for any time  $t$  can be constructed using Eq. (34).

The  $k$ th moment of the particle size distribution is written as:

$$M_k = \int_0^\infty v^k n(v, t) dv \quad (35)$$

where  $k$  is an arbitrary real number. According to the properties of a log-normal function, any moment can be written in terms of  $M_0$ ,  $v_g$ , and  $\sigma$  as follows:

$$M_k = M_0 v_g^k \exp \left( \frac{9}{2} k^2 \ln^2 \sigma \right) \quad (36)$$

If Eq. (36) is written for  $k = 0, 1$ , and  $2$ , and subsequently solved for  $v_g$  and  $\sigma$  in terms of  $M_0$ ,  $M_1$ , and

$M_2$ , we have:

$$\ln^2 \sigma = \frac{1}{9} \ln \left( \frac{M_0 M_2}{M_1^2} \right) \quad (37)$$

$$v_g = \frac{M_1^2}{M_0^{3/2} M_2^{1/2}} \quad (38)$$

The collision kernel of fractal agglomerates  $\beta_F(v, \bar{v})$  covering the continuum regimes is represented by the following expression:<sup>[35]</sup>

$$\beta_F(v, \bar{v}) = K_{co} (v^{1/D_f} + \bar{v}^{1/D_f}) \left( \frac{1}{v^{1/D_f}} + \frac{1}{\bar{v}^{1/D_f}} \right) \quad (39)$$

where  $K_{co}$  is defined by Eq. (3), and  $D_f$  is the mass fractal dimension, which varies between 1 and 3.<sup>[36]</sup> Substituting Eq. (39) into Eq. (5) and integrating from 0 to  $\infty$ , one can obtain the following equations using Eq. (35):

$$\frac{dM_0}{dt} = -K_{co} (M_0^2 + M_{-1/D_f} M_{1/D_f}) \quad (40)$$

$$\frac{dM_1}{dt} = 0 \quad (41)$$

$$\frac{dM_2}{dt} = 2K_{co} \{ M_1^2 + M_{(D_f-1)/D_f} M_{(D_f+1)/D_f} \} \quad (42)$$

Equation (41) merely indicates that  $M_1 = \text{const}$ . Substituting Eq. (36) for the moments appearing in the right-hand side of Eqs. (40) and (42), and substituting Eqs. (37) and (38) thereafter, we have the following two equations for  $k = 0$  and  $2$ , respectively:

$$\frac{dM_0}{dt} = -K_{co} \left( M_0^2 + M_0^{(2+(1/D_f^2))} M_1^{-2/D_f^2} M_2^{1/D_f^2} \right) \quad (43)$$

$$\frac{dM_2}{dt} = 2K_{co} \left\{ M_1^2 + M_0^{1/D_f^2} M_1^{(2-(2/D_f^2))} M_2^{1/D_f^2} \right\} \quad (44)$$

The governing equation has just been converted into a set of three first-order ODEs. Eqs. (41), (43), and (44) can be solved using any standard numerical package for solving first-order ODEs. After  $M_0$ ,  $M_1$ , and  $M_2$  are solved from Eqs. (43), (41), and (44), respectively,  $\sigma$  and  $v_g$  can be computed using Eqs. (37) and (38). Subsequently, the size distribution of the fractal agglomerates for any time can be constructed using Eq. (34).

## Coagulation in Nanoparticle Synthesis

Among the most recent developments in the theoretical description of gas-to-particle conversion process is the simultaneous modeling of precursor decomposition, coagulation, and sintering processes in the aerosol, originally reported by Koch and Friedlander<sup>[20]</sup> and

Kobata, Kusakabe, and Morooka<sup>[37]</sup> and refined further by Xiong and Pratsinis,<sup>[19]</sup> Xiong, Pratsinis, and Mastrangelo<sup>[38]</sup> and Tsantilis and Pratsinis<sup>[39]</sup> using elaborate two-dimensional sectional models of the population balance equation. In chemical vapor synthesis (CVS), particles pass through the complete temperature profile of a hot wall reactor together with the gas stream. The CVS technique is based on the process of chemical vapor deposition (CVD), which is widely employed to prepare coatings at a high level of control of the growth parameter and, consequently, of the microstructure. As the process is very important for basic research and industrial production, the conditions for CVD growth have been determined for many material systems. The formation process of nanoparticles in the gas phase has been studied intensively both experimentally and theoretically. Many kinetic models exist to describe the dependence of the particle size on various synthesis parameters such as partial and total pressure, temperature, etc. It is of particular interest to study the particle formation on an atomic scale to understand the diffusional processes that lead to coagulation and particle rearrangement on the short time scale of their formation. Molecular dynamics (MD) simulation is used to study the particle formation and the coagulation/sintering processes.

## CONCLUSION

Therefore the coagulation of particles suspended in a gas or a liquid strongly influences the particle size distribution and is of fundamental interest in a wide range of applications in science and engineering. In this entry, some theories of coagulation are reviewed.

The coagulation of a monodisperse aerosol was studied for Brownian coagulation by Smoluchowski<sup>[1]</sup> and the change of particle number concentration with respect to time was provided. The general coagulation equation of polydisperse aerosol particles was introduced and the collision kernels for Brownian, gravitational, laminar shear, turbulent, and electrostatic coagulations were presented. In case of Brownian coagulation, the kinetic theory and the continuum diffusion theory were used to derive the collision kernel for the free molecule regime and the continuum regime, respectively, and the two theories were brought together by flux matching to produce the kernel for transition regime. At the end of this entry, various solution techniques were introduced including the sectional method, the self-preserving solution, and the moment method. The sectional method provides the most accurate prediction on the size distribution changes. The self-preserving size distribution theory presents the asymptotic size distribution. The moment method has the advantage of simplicity while

providing important information on the change of the size distribution of aerosol.

## ACKNOWLEDGMENTS

We are grateful to Dr. Sung-Hoon Park (University of British Columbia) and Mr. Xiang Rongbiao for their valuable comments on the manuscript.

# AFM: Biopolymers

Nehal I. Abu-Lail

Terri A. Camesano

Department of Chemical Engineering, Worcester Polytechnic Institute,  
Worcester, Massachusetts, U.S.A.

## INTRODUCTION

Biopolymers are macromolecules of biological origin, which include nucleic acids (DNA and RNA), proteins, peptides, and polysaccharides. Although these macromolecules influence biological processes in different ways, most biological processes are associated to some extent with the physical properties of biopolymers (chain structure, flexibility, and excluded volume interactions). For example, the conformation of bacterial surface biopolymers affects their adhesion to host tissue in the establishment of infection. In other biological processes such as protein synthesis, the specific structural units of the biopolymers (nucleic acids and proteins) control the biological function.<sup>[1]</sup>

Interest in analyzing the physical properties and structural features of biopolymers stems from the wide variety of functions they can perform in living systems of humans,<sup>[2]</sup> animals,<sup>[2,3]</sup> plants,<sup>[4]</sup> bacteria,<sup>[5]</sup> and fungi<sup>[6,7]</sup> or the important roles they play in industrial operations. The ultimate aim behind the characterization of biopolymer properties is to provide a better understanding and control of their behavior in biological, medical, and/or industrial processes. Examples of applications affected by biopolymer properties are environmental bioremediation,<sup>[8–10]</sup> biomedical applications such as wound healing,<sup>[11–13]</sup> gene therapy,<sup>[14]</sup> growth mechanisms of macromolecular crystals,<sup>[15]</sup> food technology,<sup>[16,17]</sup> and bacterial adhesion.<sup>[18]</sup>

## OVERVIEW

A wide range of techniques and instruments have been used to characterize biopolymer properties. Examples include the use of vibrational circular dichroism (VCD) to investigate DNA condensation,<sup>[19]</sup> fluorescence correlation spectroscopy (FCS) to study the diffusion properties, size, and conformation of native and denatured *schizophyllan* in dilute solutions,<sup>[20]</sup> size exclusion chromatography (SEC) to characterize *Pseudomonas putida* KT2442 surface biopolymers,<sup>[21]</sup>

X-ray diffraction (XRD) to study the ordered conformation of gel-forming polysaccharides,<sup>[22]</sup> transmission electron microscopy (TEM) to image well-characterized algal cellulose microfibrils,<sup>[23]</sup> scanning electron microscopy (SEM) to study the extracellular matrix of nutrient-limited adherent bacterial populations,<sup>[24]</sup> Fourier transform infrared (FTIR) spectroscopy to study the effect of protein immobilization on birnessite,<sup>[25]</sup> and laser light scattering (LLS) to investigate the effect of pH on gelatin self-association in dilute solutions.<sup>[26]</sup> Other techniques such as optical tweezers<sup>[27]</sup> and the surface-force apparatus<sup>[28]</sup> have also been used to measure the interactions between biopolymers and surfaces.

Because of the accelerating developments made in atomic force microscopy (AFM) as a surface characterization technique, AFM is now a preferred instrument in the study of biological macromolecules. Atomic force microscopy is characterized by high lateral (6 Å) and vertical (1 Å) resolutions<sup>[29,30]</sup> and a high signal-to-noise ratio.<sup>[31]</sup> These features give rise to the AFM's ability to image detailed structures of individual or groups of delicate biopolymers.<sup>[31]</sup> In contrast to conventional biological imaging methods such as SEM and TEM, AFM can be used to image biopolymers in their native state without the need for staining,<sup>[3]</sup> labeling,<sup>[31]</sup> or coating with a conducting gold layer.<sup>[8]</sup> In addition, AFM can be used to probe biopolymers in ambient air or liquid without the need to operate under vacuum.<sup>[3]</sup> In particular, the ability to image biopolymers in liquid with AFM allows for investigation of macromolecules under native conditions for several hours or even days without damage.<sup>[31,32]</sup> Although AFM can be used to image biopolymers in air, precautionary measures have to be taken to ensure that the sample is not damaged and that artifacts are not created. When samples are allowed to air-dry, there is the possibility of coagulation or rearrangement of the molecules on the substrate during the drying process.<sup>[33]</sup>

Interaction forces between biopolymers and surfaces should be measured in a liquid environment to

minimize the presence of large capillary forces that are present in air ( $\sim 30$  nN).<sup>[34]</sup> The high adhesive forces caused by capillary forces are destructive to many biological samples and mask other interaction forces of lesser magnitudes, such as van der Waals forces and electrostatic interactions.

Atomic force microscopy has evolved from an imaging technique to a versatile tool that also allows for investigation of molecular forces at interfaces with great detail. Atomic force microscopy can also be used to probe the chemical nature,<sup>[35]</sup> elasticity,<sup>[36]</sup> roughness,<sup>[13]</sup> and surface charge<sup>[37]</sup> of biopolymers. We review the use of AFM as a state-of-the-art tool to characterize biopolymers. Examples will be provided on the use of AFM to characterize DNA, proteins, and polysaccharides.

## PROBING DNA WITH ATOMIC FORCE MICROSCOPY

### Earlier Efforts to Establish High-Resolution DNA Imaging

Since the invention of AFM, continuous improvements have been made in the ability to image and characterize deoxyribonucleic acid (DNA), which carries the genetic code of all living organisms. Most early attempts to image DNA were performed in air<sup>[38]</sup> because early attempts to image DNA in liquid (especially water) showed that if the molecules were not fixed properly, they could move during the imaging process. Their movement limited the ability to obtain reproducible results.<sup>[39]</sup> This challenge was overcome by stable binding of double-stranded DNA molecules to flat mica using chemical modification of the mica with 3-aminopropyltriethoxysilane. DNA molecules were bound to mica by this technique and molecules with contour lengths of 20–80 nm were stably imaged under repetitive scanning.<sup>[40]</sup> With techniques available at that time, the highest resolution achievable in DNA imaging was 2–3 nm. Because this was an order of magnitude less than the resolution required for DNA sequencing,<sup>[41]</sup> better substrate and sample preparation methods were required. Continuous and accelerated efforts were focused on reaching high-resolution AFM imaging of DNA. For example, Bensimon et al.<sup>[42]</sup> invented a technique for alignment of DNA on a silanated mica substrate, known as “molecular combing.” With this preparation technique, DNA could be elongated and even minute quantities ( $10^3$  molecules) could be imaged, which opened the way for faster physical mapping of the genome and increased detection abilities. Many variations of DNA immobilization based on coating of a surface with an

aminosilane compound or a self-assembled monolayer can be found in the literature.<sup>[43–45]</sup>

### Imaging of DNA Structure

Although there are numerous successful examples of high-resolution DNA imaging, we will focus on selected examples. Atomic force microscopy imaging has been widely used to discern the structure of DNA. Single- and double-stranded DNA were each imaged in propanol, butanol, and air. Measured molecular lengths were  $\sim 1$   $\mu\text{m}$ .<sup>[46]</sup> From imaging DNA on mica, single- and double-stranded DNA could be differentiated.<sup>[47]</sup> The images of the double-stranded DNA showed an open circular shape without drastic contortions and a contour length within 7% of the calculated length. Single-stranded DNA was present as compact open circles with nodes or lumps almost uniformly distributed or as highly elongated circles with a few nodes, the latter being more common.<sup>[47]</sup>

Because of much effort, rapid characterization of the structure of DNA by tapping mode AFM imaging in ambient conditions has become a relatively routine technique.<sup>[48]</sup> Examples on the use of tapping mode AFM imaging to discern differences between linear double-stranded  $\lambda$ -DNA, circular double-stranded plasmid DNA, and supercoiled double-stranded DNA plasmids with twists and writhes are shown in Fig. 1. DNA supercoiling has also been observed. The intramolecular triplex H-DNA formed by mirror-repeated purine–pyrimidine repeats and stabilized by negative DNA supercoiling was imaged. These images showed that the H-DNA is a protrusion with a different thickness than the DNA duplex (Fig. 2).<sup>[49]</sup> The conformation of DNA can be also studied with AFM imaging. For example, pH was shown to affect DNA conformation because  $\lambda$ -DNA could be denatured by HCl addition and renatured upon NaOH addition.<sup>[50]</sup>

### Characterization of DNA Molecular Properties

Analyzing AFM images provides a wealth of information on the size and conformation of DNA. For example, DNA imaged under ambient conditions using near-contact mode showed width values up to four times smaller than values measured in non-contact mode, even with the same tip.<sup>[51]</sup> The discrepancy was attributed to the greater resolution achievable through near contact compared with non-contact mode imaging. Estimation of the length of double-stranded DNA molecules as short as 100–200 base pairs from AFM images in air was considered an advance in DNA characterization. The measurements gave lengths consistent with the known dimensions of A-DNA.<sup>[52]</sup> It was not possible to image shorter

**Fig. 1** Top-view AFM images of different double-stranded (ds) DNA topologies on amino-terminated mica (vertical color scale = 3 nm) taken in AFM tapping mode under ambient conditions. (A) Linear  $\lambda$ -DNA (with 48.5 kbp), (B) non-twisted circular DNA plasmids (vector with 3.2 kbp) and (C) circular supercoiled DNA with twists and writhes due to internal supercoiling (supercoiled DNA ladder 2–16 kbp). The measured width of dsDNA of all geometrical topologies was  $\sim 3$ –7 nm and affected by the tip geometry. The molecular height was  $\sim 1$  nm. Source: From Ref.<sup>[48]</sup> with permission from Wiley & Sons Inc.

DNA molecules (25–50 base pairs) because intermolecular cross-bridging and base pairing in the molecules caused only globular forms to be viewed.<sup>[52]</sup>

In a revolutionary development, carbon nanotube AFM tips are starting to provide a new dimension in AFM imaging. These tips are ideal for AFM work because of their small diameter, high aspect ratio, large Young's modulus, mechanical robustness, well-defined structure, and unique chemical properties.<sup>[53]</sup> With the use of carbon nanotube tips, high-resolution images of RecA-double stranded DNA complexes were obtained (Fig. 3). The images revealed the 10-nm pitch of RecA-double stranded DNA complexes and RecA filaments as three-dimensional surface topographical features, without reconstruction analysis. The depth of the notch between two pitches was  $< 1$  nm.<sup>[54]</sup>

New imaging modes also helped improve DNA characterization. In a recent study, magnetic-mode AFM was used to characterize the process of DNA

**Fig. 2** Atomic force microscopy images of DNA deposited at pH = 5.0. These images represent high-resolution images of H-DNA. The two images are schematics of the height and width. Source: From Ref.<sup>[49]</sup>. © 2001, with permission from Elsevier.

adsorption on a highly oriented pyrolytic graphite (HOPG) electrode surface. The images of single- and double-stranded DNA molecules showed that both types have the tendency to self-assemble from solution onto the HOPG surface (Figs. 4 and 5). The adsorbed film heights were dependent on the DNA concentration and were held to the surface with non-covalent interactions such as hydrogen bonding, base stacking, and electrostatic, van der Waals, and hydrophobic interactions.<sup>[55]</sup>

### Stretching DNA to Study Biomechanical Properties

The biomechanical properties of DNA can be obtained through stretching these molecules in a technique known as single molecule force spectroscopy (SMFS). DNA molecules are tethered to a surface at one end and stretched through application of an external force, which may be magnetic,<sup>[56]</sup> caused by hydrodynamic flow,<sup>[56]</sup> or result from the AFM cantilever stiffness<sup>[57]</sup> or an electrical field.<sup>[58]</sup> Typically, one DNA molecule is picked up from an adsorbed layer of DNA molecules by the AFM tip because of an applied contact force of several nanoNewtons. Upon retraction of the tip from the layer, the DNA strand is stretched. The resulting force from this stretching is measured as cantilever deflection, which can be converted to force by accounting for the spring constant of the cantilever. Several methods exist for determining these spring constants, as reviewed in Ref.<sup>[59]</sup>. Stretching experiments provide important information about the mechanical properties of DNA. We will discuss three examples: probing DNA elasticity, quantifying interactions between complementary strands of DNA, and DNA sequencing.

**Fig. 3** Topographic AFM images of RecA-dsDNA filaments observed with (A) a CNT tip and (B) with a standard tip (TESP-type tip). *Source:* From Ref.<sup>[54]</sup>. © 2001, with permission from Elsevier.

### Elasticity of DNA

The elasticity of single molecules can be estimated directly from force-extension measurements by applying random-walk statistical mechanical-based models. The most frequently used models are the freely jointed chain (FJC), extensible freely jointed chain (FJC+), and wormlike chain (WLC) models.<sup>[36]</sup> The elasticity of DNA molecules was first estimated by applying the FJC model to force-extension data between single DNA molecules (chemically attached by one end to a glass surface and by the other end to a magnetic bead) and an AFM tip under three different salt concentrations.<sup>[56]</sup> The FJC model failed to explain the force-extension data because of the fact that it does not account for the extensibility of the molecules. It appeared that the DNA molecules could deform when exposed to stress. The authors discounted the WLC model because they speculated that the latter model

would also fail due to the inability to account for the extensibility of DNA.

However, in some cases, the WLC model was appropriate for explaining DNA's mechanical properties. For example, the elasticity of  $\lambda$ -phage DNA was explained well with the WLC model, although the FJC model showed a large deviation from the experimental data.<sup>[58]</sup> The WLC model provided a contour length of  $32.8 \pm 0.1 \mu\text{m}$  and a persistence length of  $53.4 \pm 2.3 \text{ nm}$ .<sup>[58]</sup> An additional difference between the FJC and WLC models is that the FJC model accounts for entropic effects only, while the WLC model also accounts for enthalpic interactions.

In another example, the elasticity of a single supercoiled DNA molecule was probed via SMFS. Sharp

**Fig. 4** Magnetic alternating contact (MAC) mode AFM topographical images in air of the DNA biosensor surface prepared by 3 min of free adsorption onto HOPG from (A)  $10 \mu\text{g/ml}$  and (B)  $5 \mu\text{g/ml}$  dsDNA in phosphate buffer (pH 7.0, 0.1 M). *Source:* From Ref.<sup>[55]</sup>. © 2001 American Chemical Society.

**Fig. 5** Magnetic alternating contact mode AFM topographical images in air of the DNA biosensor surface prepared by 3 min of free adsorption onto HOPG from a  $5 \mu\text{g/ml}$  single-stranded DNA in phosphate buffer (pH 7.0, 0.1 M). *Source:* From Ref.<sup>[55]</sup>. © 2001 American Chemical Society.)

transitions were observed in the elasticity of the molecules at  $\sim 0.45$  and  $\sim 3$  pN for underwound and overwound molecules, respectively. These transitions were attributed to the possibility of the formation of alternative DNA superstructures or because of DNA transcription and replication.<sup>[60]</sup>

### Interaction Forces between Complementary Strands of DNA

Understanding the intermolecular forces within the DNA double helix is important to control the behavior of DNA in various applications, such as DNA sequencing. In the first effort to measure the forces between single DNA strands, DNA oligonucleotides were covalently attached to a spherical probe and to a silica surface.<sup>[57]</sup> Force measurements between these strands showed three distinct force regimes, centered at 1.52, 1.11, and 0.83 nN. The forces were directly associated with the rupture of the interaction between a single pair of molecules involving 20, 16, and 12 base pairs, respectively. This study demonstrated the importance of AFM in detecting the presence of, and relative positions of, specific base sequences with angstrom resolution.<sup>[57]</sup>

In a study on double-stranded  $\lambda$ -phage DNA, the split of the molecule into single strands was observed via force microscopy.<sup>[61]</sup> Stretching experiments revealed a transition in the force-extension measurement at 65 pN attributed to the conversion of B-DNA to a new overstretched conformation called S-DNA. This transition was followed by a nonequilibrium melting transition at 150 pN (Fig. 6). The melting transition is the part of the curve at which the double-stranded DNA split into single strands that fully recombined upon relaxation.<sup>[61]</sup>

### DNA Sequencing

Because of the continuous increase in the resolution of AFM to the angstrom level, sequencing of DNA became possible. The principle behind this application is that the force-extension curve that arises when DNA is stretched is sequence-dependent. In one of the first studies to address DNA sequencing, a comparison was made between the force measurements on poly(dG-dC) and poly(dA-dT), where “d” represents the deoxynucleotide.<sup>[61]</sup> With knowledge of the melting transition for  $\lambda$ -phage DNA,<sup>[62]</sup> single strands of poly(dG-dC) and poly(dA-dT) were prepared. Upon relaxation, these strands reannealed into hairpin structures as a result of their self-complementary sequences.<sup>[61]</sup> Studying the unzipping of these hairpins with AFM directly revealed the base pair unbinding forces for G-C and for A-T, which were  $20 \pm 3$  and  $9 \pm 3$  pN, respectively. In another study of DNA unzipping, the force needed to open the double strands upon tip retraction was measured as a function of extension of the DNA molecule (Fig. 7). The required force was between 10 and 20 pN on a length scale of 10 bases. The force profiles were characteristic for each specific DNA sequence.<sup>[63]</sup>

### PROBING PROTEINS WITH ATOMIC FORCE MICROSCOPY

#### High-Resolution Imaging of Proteins

High-resolution protein imaging with AFM is a well-established technique. Proteins are often bound to mica for imaging because their tight binding facilitates imaging.<sup>[64]</sup> Alternately, proteins are covalently bound

**Fig. 6** The mechanical compliance of DNA strongly depends on the specific base pairing in the double helix. (A) For double-stranded poly(dG-dC) DNA, there was a transition from B-DNA to a new overstretched form (S-DNA) that occurred at 65 pN (see arrows), similar to the transition observed in  $\lambda$ -DNA. The melting transition occurred at 300 pN for this DNA, compared to 150 pN in  $\lambda$ -DNA. (B) In duplex poly(dA-dT) DNA, the force of the B to S transition is reduced to 35 pN and the strands melt during this transition, so that no separate melting transition can be observed. *Source:* From Ref.<sup>[61]</sup>. © 1999 Nature Publishing Group (<http://www.nature.com/>).

**Fig. 7** Complementary DNA oligonucleotides are chemically attached to an AFM tip and a glass surface. As the tip is brought in contact with the surface, a double strand forms, which can subsequently be unfolded upon retraction of the tip. *Source:* From Ref.<sup>[63]</sup>. © 2003 American Chemical Society.

to chemically modified surfaces.<sup>[65]</sup> Examples of AFM imaging studies on proteins are too numerous and diverse to be contained in this entry. We focus on two illustrative examples: 1) imaging of ligand–receptor interactions between cholera toxin B-oligomers bound to bilayers of biologically relevant lipids<sup>[66]</sup> and 2) imaging microtubules, protein structures of eukaryotic cells.<sup>[67]</sup>

In the first example, the interactions between cholera toxin B-oligomers (CTX-B) and a dipalmitoylphosphatidylcholine (DPPC) bilayer containing 10 mol% GM1 (the membrane receptor for CTX-B) were characterized. Images taken before and after the CTX-B oligomers were added to the lipid bilayer confirmed the high binding affinity of CTX-B to the receptor GM1 (Fig. 8). The high quality of the images revealed the ability of AFM to image membrane proteins without the need for cross-linking.

As a second example, a comparison was made between AFM, scanning tunneling microscopy (STM), and transmission electron microscopy (TEM) for their abilities to image microtubules isolated from pig brains. Atomic force microscopy was the easiest to use and most reproducible imaging technique.<sup>[67]</sup> The AFM images revealed the linear structure of the microtubules (Fig. 9) and the possibility of crossing of various tubules.

The capabilities of AFM imaging of proteins were extended to many other interesting applications such as capturing the conformational changes of proteins under physiological conditions<sup>[68]</sup> and visualization of DNA–protein complexes.<sup>[69]</sup>

**Fig. 8** (A) A typical AFM image of a DPPC bilayer with 10 mol% GM1 before CTX-B was added. (B) The CTX-B bound to the ganglioside in the bilayer is clearly seen. The coverage is complete indicating that the distribution of the ganglioside is uniform. *Source:* From Ref.<sup>[66]</sup>. © 1995, with permission from Elsevier.

### Folding and Unfolding of Proteins

Proteins are molecules that are composed of a sequence of amino acids. This sequence of amino acids determines the complex helical shape that the protein will assume. The protein helix can be denatured under special conditions (chemical or thermal) and refold to its native state upon the removal of the denaturing source.<sup>[70]</sup> Each protein has a unique structure and a specific folding pattern for its polypeptide chain that

**Fig. 9** Atomic force microscopy top-view image of chemically immobilized microtubules (MTs) on silicon imaged under buffer solution (MES buffer with 0.7 M glycerol). Protein concentration was 2.0 mg/ml at the start of polymerization. Microtubules fixed with 5% glutaraldehyde before immobilization and imaged without damage under liquid, demonstrating an improved resistance to tip pressure. *Source:* From Ref.<sup>[67]</sup>. © 1995, with permission from Elsevier.

is required for proper biological function.<sup>[71,72]</sup> Understanding the process of folding and unfolding of proteins can help in controlling protein function for many applications.

The force-extension curves measured with AFM can characterize protein folding and unfolding.<sup>[73,74]</sup> For example, the mechanical properties of titin immunoglobulin (a giant sarcomeric protein of striated muscle) were studied by repetitive stretching of an individual titin molecule with AFM.<sup>[71]</sup> The stretching force was recorded as a function of molecule elongation. At large extensions, the force extensions exhibited a sawtooth-like pattern, with a periodicity that varied between 25 and 28 nm. These peaks were attributed to unfolding of individual domains of the protein. The forces required to unfold these domains were 150–300 pN and were dependent on the pulling speed. Refolding of protein was observed upon relaxation.

In a similar study, the folding and unfolding of fibronectin (a modular extracellular matrix protein) was investigated via AFM.<sup>[75]</sup> Statistical analysis of the force-extension curves clearly revealed the unfolding of three different types of fibronectin. The unfolding of fibronectin was irreversible within the timescale of one extension-relaxation cycle. The folding and unfolding of other proteins such as human tenascin-C<sup>[72]</sup> (Fig. 10), titin Ig,<sup>[76]</sup> and barnase<sup>[77]</sup> were also studied with AFM.

### Probing Ligand–Receptor Interactions

Ligand–receptor interactions can occur during the formation of double-stranded DNA, in enzymatic reactions, and in antigen–antibody recognition.<sup>[78]</sup> To measure these interactions, the AFM tip is functionalized with either the ligand or the receptor and the surface is functionalized with the other component.<sup>[79]</sup> In the first AFM study to measure the interactions between ligands and receptors, the interactions between a model receptor, streptavidin, and its ligand, biotin, were probed under physiological conditions.<sup>[80]</sup> The adhesion forces between the two functionalized surfaces were 3–8 times higher than the non-specific interactions measured between blocked streptavidin and biotinylated surfaces. Statistical analysis of the adhesive forces revealed the maximum number of streptavidin–biotin interactions and the force required to rupture the ligand–receptor bond. In another study of the interactions between avidin and biotin, the unbinding forces of discrete complexes were proportional to the enthalpy change of the complex formation, but independent of the free energy.<sup>[81]</sup> As another example, the interactions between P-selectin and P-selectin glycoprotein ligand-1 were probed with SMFS.<sup>[82]</sup> By modeling the resulting intermolecular

forces, knowledge of the rupture forces, elasticity, and kinetics of the interactions of the P-selectin/P-selectin glycoprotein ligand-1 interactions were obtained.

### PROBING POLYSACCHARIDES WITH ATOMIC FORCE MICROSCOPY

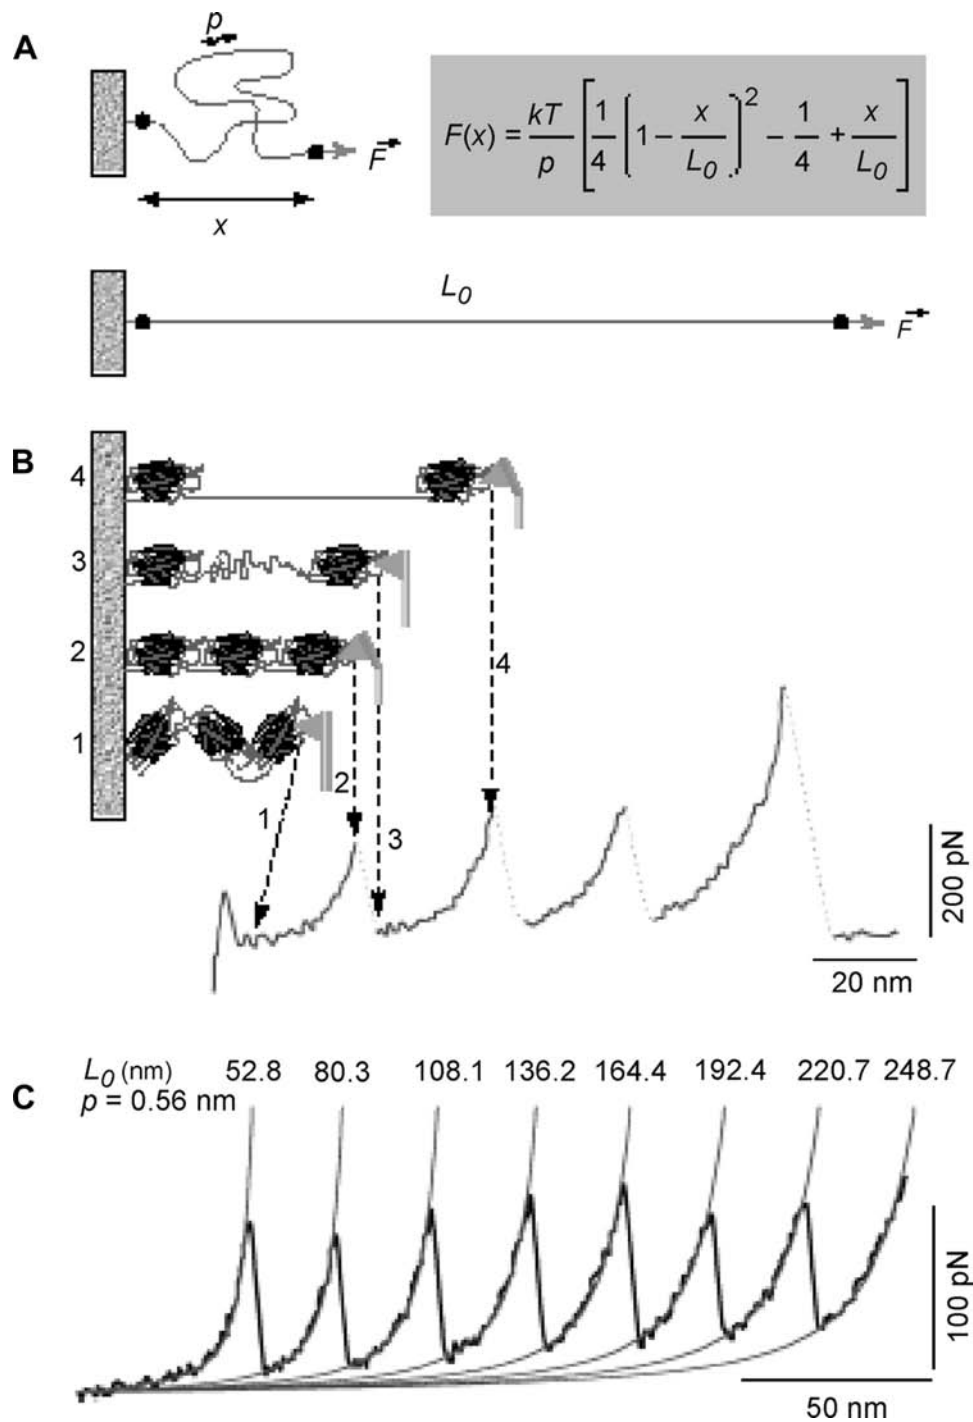

Polysaccharides are a large group of molecules that exist as components of plant, animal, algal, bacterial, and yeast cells. They provide structural support and act as an energy reservoirs in plants and animals.<sup>[23]</sup> Polysaccharides also play an important role in microbial activity, including evasion of host defense systems and attachment to host tissue in infections. Polysaccharides are important in biofilm formation, which affects such diverse microbial processes as the uptake of trace metals in soil,<sup>[83]</sup> failure of medical implants such as artificial heart valves,<sup>[84]</sup> the success of bioremediation,<sup>[85]</sup> and the virulence of pathogenic infections.<sup>[86]</sup> Polysaccharides are also linked with cancer pathology.<sup>[87]</sup> In many of these fields, the mechanisms by which polysaccharides control the biological processes are not well known. A better understanding of the properties of polysaccharides and their subsequent biological functions can be obtained by high-resolution studies using AFM imaging and force measurements.

### Quantitative Characterization of Polysaccharide Morphology by Atomic Force Microscopy Imaging

Atomic force microscopy imaging of polysaccharides can be used to obtain quantitative information on the molecule's height,<sup>[88]</sup> thickness,<sup>[88]</sup> width,<sup>[89]</sup> contour length,<sup>[33]</sup> persistence length,<sup>[34]</sup> end-to-end distance,<sup>[88]</sup> and the polydispersity and distribution of polysaccharides on the surfaces of living microbial cells.<sup>[90]</sup>

Conformational transitions of polysaccharides can be investigated with AFM imaging. For example, the denaturation/renaturation process for the xanthan triple helix was observed with tapping mode AFM imaging under ambient conditions. The triple helix denatured upon heating and renatured when cooled only if sufficient salt was present in solution.<sup>[88]</sup> The effect of different solvent chemistries (pH and ionic strength) on polysaccharide conformation was also investigated with tapping mode AFM. For example, the conformation of succinoglycan deposited on mica was observed in the presence and absence of salt. When there was no salt in the aqueous solution, a combination of rigid and flexible chains was observed, while

**Fig. 10** The entropic elasticity of proteins and domain unfolding. (A) The entropic elasticity of proteins can be described by the WLC model, which expresses the relationship between force ( $F$ ) and extension ( $x$ ) of proteins using its persistence length ( $p$ ) and its contour length ( $L_0$ );  $k$  is Boltzmann constant and  $T$  is temperature. (B) The sawtooth pattern of peaks observed when force was applied to extend the protein corresponds to sequential unraveling of individual domains of modular proteins. As the distance between the substrate and the cantilever increases (from state 1 to state 2), the protein elongates, generating a restoring force that bends the cantilever. When a domain unfolds (state 3), the free length of the protein increases, returning the force of the cantilever to near zero. Further extension results in force on the cantilever (state 4). The last peak represents the final extension of the unfolded protein prior to detachment from the AFM tip. (C) Consecutive unfolding peaks of recombinant human tenascin-C were fit using WLC model. The contour length ( $L_0$ ) for each fit is shown; the persistence length ( $p$ ) was fixed at 0.56 nm. *Source:* From Ref.<sup>[72]</sup>. © 1999, with permission from Elsevier.

Fig. 11 Conceptual representation of the conformation of bacterial surface biopolymers at low and high salt concentrations.

only flexible single chains were observed in the presence of 0.01 M KCl.<sup>[89]</sup>

Another exciting application of AFM with respect to polysaccharide research is the imaging of dynamic biological processes. Gunning et al.<sup>[91]</sup> imaged molecular motion of a water-soluble wheat pentosan polysaccharide extracted from wheat flour. Parts of the molecules desorbed and reabsorbed onto the mica surface during tapping mode imaging in 10-mM HEPES buffer. Loops, trains, and tails were directly observed, confirming that polymer chains were desorbing and reabsorbing. The use of AFM to study other dynamic biological processes, including enzymatic breakdown of polysaccharides, is therefore not far from being realizable.

### Force Microscopy for Mechanical Characterization of Polysaccharides

Studying the force spectra recorded on polysaccharides (pure polysaccharides or polysaccharides on a microbial surface) provides useful information on the elastic, mechanical, and sometimes chemical nature of the macromolecules. Examples of the types of information that can be deduced from SMFS are the following: quantitative information about polysaccharide elasticity, estimated by applying polymer statistical models;<sup>[92]</sup> identifying the components of a mixture of pure polysaccharides;<sup>[93]</sup> probing the elasticity of polysaccharides on microbial cells;<sup>[7,36,94]</sup> and qualitative prediction of the conformation of microbial biopolymers.<sup>[95]</sup> We will discuss some of these examples in detail.

In the first study to quantify the elasticity of macromolecules on a microbial surface, surface macromolecules of dormant spores of *Aspergillus oryzae* were probed via SMFS.<sup>[94]</sup> The elongation forces were well described by the FJC + model, with estimated values of the Kuhn length and the segment elasticity in agreement with reported values for the structural properties of the polysaccharides dextran and amylose.

Single molecule force spectroscopy was also used to qualitatively predict the conformation of biopolymers,

predominately polysaccharides, on the surface of the bacterium *P. putida* KT2442. Forces were measured on individual bacterial cells in solutions with varying added salt concentrations (water–1 M KCl). The biopolymers on the microbial surface adopted a more flexible conformation with increasing solution salt concentration.<sup>[95]</sup> The flexibility of the molecules was quantified using the FJC model for polymer elasticity. Because of the increased flexibility of the biopolymers in high salt solutions, the biopolymers collapsed onto the surface of the bacterium, leading to a more rigid surface when in high salt (Fig. 11). The transition in polysaccharide conformation was related to the slope of the compliance region of the approach curves measured between the bacterial cells and the AFM silicon nitride tip (Fig. 12). Changes in biopolymer conformation and the biomechanical properties of the bacterium were related to bioadhesion.<sup>[95]</sup>

Atomic force microscopy can also be used as a spectroscopic technique for chemical fingerprinting of polysaccharides. Transitions in the flexibility of

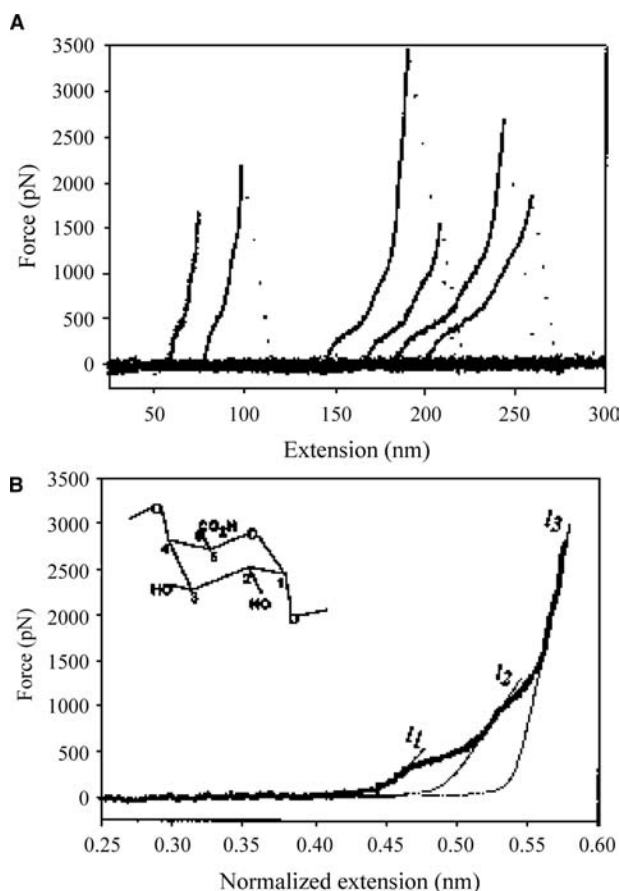

Fig. 12 A comparison between average approach curves (each curve is an average of 25 individual force measurements) for *P. putida* KT2442 in various solutions. Slopes of the compliance region of these curves are  $-0.014$ ,  $-0.010$ ,  $-0.054$ ,  $-0.035$ ,  $-0.109$ , and  $-0.114$  nN/nm, from water to 1 M KCl, respectively.

xanthan, amylose, and dextran upon the cleavage of the pyranose ring were observed by AFM and linked with the chemical structure of the molecules.<sup>[96]</sup> Specifically, the pyranose ring was identified as the structural unit controlling the molecules' elasticities. Cleavage of the pyranose ring with 5 mM sodium metaperiodate eliminated the extra enthalpic component of the elasticity and made the force transition disappear. The transitions were attributed to force-induced elongations of the ring structure and, for some molecules, to transitions in the pyranose ring from a chair to boat structure. These transitions produced fingerprints in the extension-force spectrum that were characteristic of the ground-energy conformations of the pyranose ring and the type of glycosidic linkage present in each polysaccharide<sup>[93,97]</sup> (Fig. 13).

**Fig. 13** Force-extension curves for single-pectin molecules reveal a two-step transition. (A) The shape of the curves for molecules with varying lengths reveals two enthalpic extensions at  $\sim 300$  and  $\sim 800$ – $900$  pN. (B) High-resolution normalized plot of the force-extension relationship for a single-pectin molecule. The thin lines are fits of the FJC model modified to include the extensibility of the monomers. *Source:* From Ref.<sup>[97]</sup> (PNAS, vol. 96) © 1999 by the National Academy of Sciences, Courtesy of the National Academics Press, Washington, D.C.

## CONCLUSION

The use of AFM and SMFS to characterize the physicochemical properties of biopolymers was reviewed. Atomic force microscopy is preferred over other surface characterization techniques because of several unique advantages, including 1) high lateral and vertical resolutions, 2) high signal-to-noise ratio, 3) ability to probe biopolymers in their native environment with minimal sample preparation, 4) ability to measure interaction forces at interfaces, and 5) ability to obtain quantitative information about the chemical structure of macromolecules.

High-resolution imaging of single molecules of DNA, proteins, and polysaccharides, including polysaccharides on microbial surfaces, can now be routinely performed with AFM. Images can provide quantitative information on molecular properties and can be used to elucidate biopolymer conformation. Among the more interesting examples of probing biopolymers with SMFS are DNA sequencing, quantifying ligand-receptor interactions between proteins and lipids, protein folding and unfolding, identifying polysaccharide components from mixtures, and probing the distribution of macromolecules on living cells.

New advancements continue to be made in the formulation of more sensitive AFM probes, improved instrumentation, less-invasive sample preparation techniques, and facilitated data analysis. Undoubtedly, AFM will continue to be a key tool for probing the properties of delicate biopolymers at the nanoscale. Knowledge of the relationships between molecular structure and function of biopolymers will benefit such diverse fields as biotechnology, food safety, environmental science, pharmaceuticals, and medicine.

## INTRODUCTION

Bottom-up strategies in molecular nanotechnology, including the self-assembly of small molecular building blocks into supramolecular aggregates based on non-covalent interactions, are regarded as a viable route to realize molecular devices, as well as to fabricate and template well-defined nanometer-scale structures and objects.<sup>[1]</sup> Recent progress in nanostructuring has enabled several groups to control the arrangement of molecules and supramolecular aggregates on surfaces by exploiting designed intermolecular interactions and/or scanning probe microscopy (SPM) approaches at variable temperatures.<sup>[2–5]</sup> This work, which is based on the profound knowledge in the fields of supramolecular chemistry<sup>[6–9]</sup> and intermolecular (surface) forces,<sup>[10,11]</sup> will ultimately lead to a general strategy to develop hierarchical functional nanostructures with molecular precision.

We have designed and investigated rosette nanostructures, which are based on multiple hydrogen bonding<sup>[12]</sup> between the basic building blocks—melamine-substituted calix[4]arenes and 5,5-diethylbarbiturate (DEB). These thermodynamically stable nanostructures can be ordered on solid substrates in highly regular, chiral 2-D assemblies, or immobilized as individual entities in self-assembled monolayers (SAM). In this entry, we review our recent progress in the formation, and in particular in the real-space structural analysis, of nanometer-sized supramolecular rosette nanostructures and their aggregates in 2-D via atomic force microscopy (AFM).

## SELF-ASSEMBLY OF HYDROGEN-BONDED NANOSTRUCTURES

The non-covalent synthesis of well-defined structures with nanoscale dimensions has recently been receiving increasing attention.<sup>[12,13]</sup> The components in these structures, termed *supramolecular aggregates*,<sup>[6]</sup> are connected to each other via reversible and weak non-covalent interactions, comprising, for instance, forces based on the hydrophobic effect, as well as electrostatic,  $\pi - \pi$  stacking, hydrogen bonding, or metal–ligand coordination interactions.<sup>[14–17]</sup> These interactions are distinctly different from the non-reversible and more stable interactions in covalently linked molecules and offer a number of important advantages. For instance, in our synthesis of nanoscale self-assembled aggregates,<sup>[18]</sup> hydrogen bonds are utilized that form spontaneously under thermodynamically controlled conditions. The thermodynamic control together with the reversibility of the individual interactions provide the assemblies with their ability to “proof-read” and correct mistakes. Hence carefully designed molecules assemble into well-defined, error-free motifs because they are encoded with the correct H-bonding information and geometry.

One well-known H-bonded system is based on isocyanuric acid (CA) and melamine. The three orthogonal acceptor–donor–acceptor (ADA) hydrogen bonding arrays of isocyanuric acid (CA) are complementary to the three DAD hydrogen bonding arrays of melamine (M). Mixing both components in a 1:1 ratio leads to an infinite 2-D lattice held together by hydrogen bonds (Fig. 1).

**Fig. 1** 2-D melamine–isocyanuric acid lattice.

Lehn et al.<sup>[19]</sup> and Whitesides et al.<sup>[20,21]</sup> identified this complementary hydrogen bonding motif in the melamine–isocyanuric lattice and showed that, depending on the preorganization of the melamines and the steric interactions between the building blocks, cyclic *rosettes* instead of *tapes* could be formed *selectively* (Fig. 1). Recently, our group showed, based on model calculations, that it is indeed possible to promote the rosette formation over tape formation by steric repulsion in the linear tapes, but the effect is not as large as was earlier believed.<sup>[22]</sup>

As an extension of the rosette motif, our group has shown that calix[4]arenes diametrically substituted with two melamine units at the upper rim form *double rosette* assemblies  $\mathbf{1a}_3 \cdot (\text{DEB})_6$  or  $\mathbf{1b}_3 \cdot (\text{DEB})_6$  in the presence of two equivalents of 5,5-diethylbarbiturate (DEB) (or isocyanuric acid) (Fig. 2).<sup>[23,24]</sup> These assemblies comprise 9 different components held together by 36 hydrogen bonds. The synthetic strategy involves the sideways connection via the calix[4]arene units of two rosette layers, which gives additionally improved stability to the non-covalent assemblies. The assemblies are stable even at  $10^{-4}$  M concentration in apolar solvents, such as chloroform, benzene, and toluene.

X-ray diffraction studies of similar double rosettes showed that the two rosette layers are tightly stacked on top of each other with an interatomic separation of 3.5 Å at the edges and 3.2 Å at the center of the rosette.<sup>a</sup> The assemblies  $\mathbf{1a}_3 \cdot (\text{DEB})_6$  have a height of 1.2 nm and a width of  $\sim 3.0$  nm.

These double rosettes can easily be extended to *tetrorosettes* by using *tetramelamine* as a building block. In this unit, two calix[4]arene dimelamines are

connected by a flexible linker unit X (Fig. 3).<sup>[25]</sup> A tetrorosette consists of 15 components (three tetramelamines and twelve 5,5-diethylbarbiturates) held together by 72 hydrogen bonds forming a nanostructure  $\mathbf{2}_3 \cdot (\text{DEB})_{12}$  with four parallel rosette “floors.” The thermodynamic equilibrium for this type of assembly is reached within seconds after mixing the corresponding building blocks, but the rate of exchange of the components decreases in comparison with the double rosette.<sup>b</sup> In addition, we have reported on the extension of this series of double and tetrorosettes to higher-order complex structures, such as hexa- and octarosettes.<sup>[26]</sup>

The isolation, manipulation, and characterization of non-covalent nanostructures require special consideration, because these assemblies are less robust than the corresponding covalent structures in solution. Nevertheless, conventional proton nuclear magnetic resonance ( $^1\text{H}$  nmR) can be used for the structural identification of the above-described hydrogen-bonded assemblies, because they are very well defined structures and the exchange between the assembly and components is relatively slow.<sup>c</sup> Furthermore, matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry using the  $\text{Ag}^+$ -labeling technique<sup>[29,30]</sup> gives additional evidence for the formation of the hydrogen-bonded nanostructures. Positively charged assemblies are generated in a nondestructive way by, for example, coordination of  $\text{Ag}^+$  to a cyano group or by complexation of  $\text{Ag}^+$  between two phenyl rings.

<sup>b</sup>Formation of the first double rosette disfavors the formation of the second double rosette.

<sup>c</sup>More detailed information about the characterization of double rosette assemblies can be found in Refs.<sup>[27,28]</sup>

<sup>a</sup>Interatomic separations of 3.5 Å at the edges and 3.2 Å at the center of the rosette were determined, see Ref.<sup>[24]</sup>.

**Fig. 2** Formation of the double rosette assemblies **1a<sub>3</sub>·(DEB)<sub>6</sub>** and **1b<sub>3</sub>·(DEB)<sub>6</sub>**.

The multicomponent nature of hydrogen-bonded nanostructures based on rosette motifs, as well as the multiple sites available for further chemical derivatization,<sup>[31]</sup> make these structures a very interesting alternative for the precise spatial arrangement of functional diversity on solid supports, for instance, using metal nanoparticles and peptide chains. In this context, the immobilization of rosette nanostructures on solid supports and the control over the spatial arrangement in 2-D are key issues for the development of supramolecular platforms. Given

the nanometer-scale dimensions of individual rosettes, atomic force microscopy (AFM)<sup>[32]</sup> proved to be a particularly well-suited tool to study the higher-order assemblies obtained by various approaches, as will be discussed below.

### ATOMIC FORCE MICROSCOPY

Soon after its invention,<sup>[32]</sup> AFM was developed as a characterization technique for real-space structure

**Fig. 3** Formation of tetra-rosette assemblies **2<sub>3</sub>·(DEB)<sub>12</sub>** (left) and gas phase minimized structure (right). *Source:* From Ref.<sup>[55]</sup>. © 2002 National Academy of Sciences, U.S.A.

determination at surfaces of non-conductors on micrometer- as well as subnanometer-length scales.<sup>[33–36]</sup> The general scanning probe microscopy approach as enabling technology is regarded as one of the workhorses of emerging (molecular) nanotechnology.

In contrast to scanning tunneling microscopy (STM), which is inherently limited to conductive substrates or conductive substrates covered with an insulating layer of, e.g., molecules less than  $\sim 1.0$ – $1.5$  nm thick,<sup>[37]</sup> AFM is generally applicable to the study of virtually any surface.<sup>[32–36]</sup> Different modes, including contact mode, force modulation mode,<sup>[38]</sup> and intermittent contact (or tapping) mode,<sup>[39]</sup> have been developed to elucidate surface structure, but also spatial composition in a variety of systems.<sup>[40–43]</sup> The potential of the technique to follow dynamic processes in real-time, especially under temperature control, has been attracting increasing attention in recent years.<sup>[44–46]</sup>

In particular, thin organized films of organic matter have been the focus of many AFM investigations. High-resolution images of ultraviolet (UV)-photopolymerized films of Langmuir films comprising diacetylene units were among the first molecularly resolved *contact mode* AFM images of soft matter.<sup>[47]</sup> While contact mode AFM performed in ambient conditions or in liquid typically yields lattice resolution, such as for self-assembled monolayers on solid substrates<sup>[48–51]</sup> or thin organic films,<sup>[52]</sup> in several cases true molecular resolution has been obtained.<sup>[53]</sup> For the study of delicate assemblies, such as the 2-D arrays of rosette nanostructures discussed in this review, tapping mode atomic force microscopy (TM-AFM) proved to be superior to contact mode AFM, because lateral (shear) forces are absent<sup>[34]</sup> and the normal forces can be controlled by careful selection of suitable imaging parameters (*vide infra*). The resolution in these experiments is limited by the shape and sharpness of the probe tip.

## 2-D ARRANGEMENTS OF ROSETTE NANOSTRUCTURES ON HOPG

Highly ordered, highly regular 2-D arrays of rosette nanostructures can be obtained by deposition of the rosettes from a suitable solvent, such as chloroform or toluene, on freshly cleaved highly oriented pyrolytic graphite (HOPG) surfaces, as unveiled by AFM approaches (*vide infra*).<sup>[54,55]</sup> The concentration of the solution, the temperature, the rate of solvent evaporation, the presence of defects, such as step edges, on the graphite substrates and possible reorganization of the adsorbate molecules are among the factors that influence the formation of the 2-D assemblies. In particular, the slow evaporation of the solvent in a near-saturated atmosphere of the solvent helps to suppress 3-D (bulk) crystallization of the rosettes.<sup>[55]</sup>

### Double Rosettes $1a_3$ ·(DEB)<sub>6</sub> on HOPG

Deposition of double rosettes  $1a_3$ ·(DEB)<sub>6</sub> onto HOPG leads to the formation of typical 2-D arrays, so-called nanorod domains. These domains and their internal structure can be conveniently analyzed via TM-AFM, as shown in Fig. 4. To avoid possible damage of the soft organic layer, the AFM is operated slightly off resonance, the amplitude is minimized, and very soft tapping conditions are employed.<sup>[56–61]</sup>

Tightly packed rows with an interrow distance of  $3.8 \pm 0.2$  nm can be observed in two adjacent domains in all three basic TM-AFM image channels, i.e., height (constant amplitude), amplitude (error signal), as well as phase angle shift. The clear observation of the domain boundary shows that the true resolution of the experiment is  $\leq 1$  nm. The apparent height of the domains varied between  $\sim 0.5$  and  $\sim 1.5$  nm. However, the absolute determination of feature heights in heterogeneous systems with spatially different

**Fig. 4** (A) TM-AFM image of  $1a_3$ ·(DEB)<sub>6</sub> on HOPG. *Source:* From Ref.<sup>[54]</sup>. © 1999 Am. Chem. Soc. (B) Gas phase minimized structures of *n*-dodecyl-substituted double rosettes  $1b_3$ ·(DEB)<sub>6</sub> (top) and *n*-propyl-substituted double rosettes  $1a_3$ ·(DEB)<sub>6</sub>.

**Fig. 5** Dual height (A) and amplitude (B) TM-AFM images of the multiphase film structure in films of  $2_3:(DEB)_{12}$  on HOPG [nanorod (a), crystal (b), granular (c), and gas/liquid phase (d)].

tip-sample interactions must be regarded with some reservation.<sup>[62,63]</sup>

The angle between the directions of the rows observed in Fig. 4 is  $\sim 73^\circ$ . This angle deviates significantly from the  $60^\circ$  angle anticipated for a simple epitaxial layer structure on graphite ( $C_3$  symmetry), in which the nanorods or domains are oriented along the underlying graphite lattice. If we take more recent data on related tetra-rosettes  $2_3:(DEB)_{12}$  into account, the origin of this mismatch may be attributed to the presence of a chiral layer structure (vide infra).<sup>[55]</sup>

The observed interrow distances ( $3.8 \pm 0.2$  nm) can be attributed to a face-to-face stacking of the double rosettes based on the interrow spacings observed for double rosettes with different substituents on the calix[4]arene unit. As mentioned, for *n*-propyloxy substituents, an interrow distance of  $3.8 \pm 0.2$  nm was measured based on the cross-sectional analysis of many AFM images, while *n*-dodecyloxy-substituted rosettes show a spacing of  $5.3 \pm 0.2$  nm.<sup>[54]</sup> This observation, together with the gas phase minimized structures (Fig. 4B), implies that the rows are composed of rows of rosettes, in which the nanostructures are arranged such that the calix[4]arene units point outward to the neighboring row, and that the rosettes are stacked approximately face-to-face. In addition, a detailed study showed that, for both *n*-propyloxy-substituted and *n*-dodecyloxy-substituted double rosettes, little to no interdigitation of the protruding *n*-alkane chains exists in the 2-D arrays on HOPG.<sup>[54]</sup>

### Tetra-rosettes $2_3:(DEB)_{12}$ on HOPG

The morphology of  $2_3:(DEB)_{12}$  on HOPG resembles the morphology of  $1a_3:(DEB)_6$  on HOPG and typical

domains with parallel rows are observed by TM-AFM (Fig. 5). The appearance of the domains, as well as the other phases (vide infra), is similar to the mentioned double rosettes. The interrow spacing of  $4.6 \pm 0.1$  nm is comparable to the double rosettes discussed above, which implies a similar arrangement as the one shown in Fig. 4B. Before the internal structure is elucidated in more detail, the different phases present on the samples will be discussed.

The different phases present on the HOPG surface can be identified based on their appearance in the TM-AFM micrographs, as well as the temporal development of the layer morphology at elevated temperatures (Figs. [5–7]). In addition to the nanorod domains (denoted “a” in Fig. 5), a 3-D crystal phase

**Fig. 6** TM-AFM amplitude images (scan size,  $5 \times 5 \mu\text{m}^2$ ) recorded during the restructuring of multiphase film of  $2_3:(DEB)_{12}$  on HOPG at  $34^\circ\text{C}$  (every 5th frame). The arrows point to diffusing and shrinking domains of the granular phase.

**Fig. 7** TM-AFM amplitude images acquired after storage of the film shown in Fig. 6 (right) for 60 hr at 34°C: (A) multiphase film structure including four nanorod domains labeled a–c (left, inset:  $5 \times 5 \mu\text{m}^2$  scan of the same region before storage) and (B) higher-resolution image of two nanorod domains labeled a in (A). Note that the nanorod domains have been formed in an area that was initially covered by the featureless gas or liquid-like phase.

(b), a granular phase (c), and a gas/liquid phase (d) can be distinguished. The 3-D crystal phase appeared elevated ( $>5 \text{ nm}$ ) and did not change in time, even at elevated temperatures (40°C) or after annealing at  $>60^\circ\text{C}$ . The granular phase also appeared elevated in TM-AFM height images, but became mobile upon increasing the temperature to  $>30^\circ\text{C}$ , while the gas/liquid phase was identified based on the fuzzy image contrast on flat HOPG terraces.

All phases are reminiscent of those reported by Loi et al.<sup>[64–66]</sup> of polyphenylene dendrimers on HOPG. In contrast to this dendrimer system, the tetra-rosette  $2_3\cdot(\text{DEB})_{12}$  nanostructures were found to be (meta)-stable in a limited temperature range. At temperatures  $>40^\circ\text{C}$ , the ordered arrays of tetra-rosettes disappeared and did not reform upon lowering the temperature to  $<20^\circ\text{C}$ .

The morphology of the layers deposited onto HOPG following a brief vacuum treatment (to remove residual solvent) was observed to change during the AFM measurements. As shown in Fig. 6, the granular phase was mobile at 34°C and several islands decreased in size or changed position relative to the immobile crystalline phase. This mobility can be attributed to a rearrangement of the layer structure during the AFM experiment at controlled temperature.<sup>[44–46,67,68]</sup>

At this stage, nanorod domains were *not* observed on this particular sample. However, after prolonged storage at 34°C, nanorod domains formed in areas that appeared featureless in the TM-AFM amplitude images shown in Fig. 6. In Fig. 7, TM-AFM images of the same area of the specimen are shown. Four nanorod domains can be observed.

The observed changes in the size of isolated islands of the granular phase (Fig. 6) and the formation of nanorod domains in previously apparently uncovered areas of HOPG after storage of the sample film for 60 hr at 34°C (Fig. 7) support the presence of a gas/liquid phase, as well as the surface diffusion of *intact* rosette nanostructure  $2_3\cdot(\text{DEB})_{12}$ .

The ordered arrays of supramolecular nanostructures are formed *spontaneously* by a self-assembly process at the HOPG surface. The formation of nanorod domains in areas where the gas/liquid phase had been previously observed indicates that the assembly is truly a supramolecular assembly of supramolecular nanostructures, i.e., an ordered 2-D array of individual rosette entities. Further, it indicates that surface diffusion of intact rosettes and subsequent nucleation and growth are one pathway to the formation of the nanorod domain of rosettes on HOPG surfaces. This pathway is well-known for, e.g., self-assembled monolayers of alkanethiols on gold.<sup>[69–71]</sup>

In addition to the intermolecular interactions between individual rosette assemblies, the adsorption energy of these supramolecules to HOPG plays an important role in this process. This can be concluded from the correlation of the nanorod structures with the  $C_3$  symmetry directions of the underlying substrate (vide infra). For methylene groups (in *n*-alkanes) and phenyl groups on HOPG, adsorption energies of  $E_{\text{ad}}(\text{CH}_2) \sim 7 \text{ kJ/mol}$ <sup>[72]</sup> and  $E_{\text{ad}}(\text{phenyl}) \sim 15 \text{ kJ/mol}$ , respectively,<sup>[73]</sup> have been reported. The tetra-rosette adsorbates  $2_3\cdot(\text{DEB})_{12}$  do not possess long alkyl-substituents; thus the adsorption energies will be modest. This feature is responsible for the observed dynamic behavior of the multiphase films even at temperatures between room temperature and  $\leq 40^\circ\text{C}$ , as revealed by real-time AFM experiments at controlled temperature (Fig. 6), which clearly indicates that the individual tetra-rosette assemblies can diffuse on HOPG at these temperatures.

### Chirality of Tetra-rosette Assemblies in 2-D

For the tetra-rosette  $2_3\cdot(\text{DEB})_{12}$ , domain boundaries can be clearly imaged and isolated defects are well-resolved (Fig. 8). The orientation of the rods appeared to be related by the underlying HOPG substrate. As

**Fig. 8** (A) TM-AFM phase images of nanorod domains of tetra-rosettes  $2_3\bullet(\text{DEB})_{12}$  on HOPG: The orientation of several nanorod domains is related to the threefold symmetry of the HOPG substrate as shown by the three arrows; within the distinct defect in the largest domain (inside circle), a different orientation can be recognized. *Source:* From Ref.<sup>[55]</sup>. © 2002 National Academy of Sciences, U.S.A. (B) The angle between different domains on the same sample can be estimated as  $46^\circ$ , as shown by the arrows.

shown by the arrows in Fig. 8A, three distinct orientations are observed in this micrograph.

Because the domains possess a mutual orientation of  $60^\circ$ , an orientation along the lattice of graphite seems plausible. However, upon close inspection of Fig. 8A, a deviating subdomain orientation can be observed for the “defect” in the center of the AFM nanograph. The rods in this subdomain are oriented at an angle of  $\sim 45^\circ$  with respect to the orientation of the surrounding domain. The interpretation of this peculiar orientation is complicated by the fact that the orientation of the underlying graphite remains unknown; in contrast with contact mode AFM,<sup>[74]</sup> it is impossible to resolve the corresponding lattice structure with TM-AFM. A similar angle of  $46^\circ$  between different domains is shown in Fig. 8B, which indicates that there are two sets of orientation of the nanorods.

The origin of the different orientations was unraveled by elucidating the nanometer-scale arrangement of the rosettes in high-resolution TM-AFM images (Fig. 9). Here a *chiral* superstructure with smaller periodicity is clearly present. The raw data shown in Fig. 9A suggests the presence of inclined elongated features along the rows.

The quantitative analysis of the 2-D fast Fourier transforms (inset in Fig. 9A) reveals an oblique lattice structure with  $a = 2.5 \pm 0.3$  nm,  $b = 5.0 \pm 0.1$  nm,  $\gamma = 122 \pm 3^\circ$ . This unit cell, which has an area of  $10.6 \text{ nm}^2$  and contains probably one tetra-rosette nanostructure, is indicated in the Fourier filtered section shown in Fig. 9B. In different domains, the same structure is found; however, the inclination of the elongated features is directed to the complementary direction, i.e., the angle is  $-122 \pm 3^\circ$ .

In the absence of elements of chirality, the rosette assemblies form as a racemic mixture of P and M enantiomers in solution.<sup>[75,76]</sup> However, the lattice structures formed on HOPG are clearly chiral with two types of domains that display opposite inclination angles with respect to the nanorod direction. The

observation of these two sets of domains that differ in orientation by  $46^\circ$ , while each set exists in domains with mutual angles of  $60^\circ$ , is consistent with a spontaneous chiral resolution of the P and M rosettes into enantiopure (homochiral) domains on HOPG. Consequently, the orientation of the nanorod domains appears to be  $\pm 23^\circ$  with respect to the orientation of the underlying HOPG. The same orientation is probably present for the double rosettes discussed above. Such behavior has been observed before for *molecular* adsorbates.<sup>d</sup> Hence the observation of chiral resolution indicates that the rosette nanostructures behave as individual entities and can form higher-order hierarchical structures in two dimensions.

The observed nanorods in the chiral structure consist of rows of tetra-rosette assemblies, as concluded from a comparison of the AFM data and the known crystal structure of the corresponding double rosette assemblies<sup>[24]</sup> and the gas phase minimized structure of the tetra-rosettes (Fig. 3).<sup>[80]</sup> The area requirement for such an arrangement is ca.  $8.6\text{--}9.9 \text{ nm}^2$ , depending on the orientation. This value compares well with the experimentally observed  $10.6 \text{ nm}^2$  (vide supra). In this simplified analysis, the possible spreading of the alkyl side chains of the rosettes due to the strong interaction of the methylene units with the graphite and the concomitant flattening of the nanostructures was not taken into consideration; hence the estimated area requirement can be regarded as a lower limit. The precise orientation of the  $2_3\bullet(\text{DEB})_6$  nanostructure within the rows remains unknown at this point because the height and width of the tetra-rosettes are essentially the same (Fig. 3); thus no definite assignment of the orientation of this assembly in the nanorod domains on HOPG can be made based on the presently available AFM data.

<sup>d</sup>For a discussion of chirality in 2-D, see e.g., Refs.<sup>[77–79]</sup>.

**Fig. 9** (A) High-resolution tapping mode AFM image of tetra-rosette nanorod domain structure resolved for  $2_3\bullet(\text{DEB})_{12}$  on HOPG (left, inset: 2-D FFT); (B) Fourier filtered AFM image and unit cell of the lattice structure (right). This chiral structure can be described by an oblique lattice with  $a = 2.5 \pm 0.3$  nm,  $b = 5.0 \pm 0.1$  nm, and  $\gamma = 122 \pm 3^\circ$ . ### GROWTH OF INDIVIDUAL ROSETTE NANOSTRUCTURES AT SURFACES

One of the ultimate challenges in nanotechnology is the controlled growth and positioning of *individual* nanostructures onto solid supports. As a first step, the growth of single double rosette nanostructures on gold monolayers has been studied.<sup>[81]</sup> For this purpose, calix[4]arene dimelamine **3**, bearing a thioether functionality, is embedded into a hexanethiol self-assembled monolayer (SAM) on gold,<sup>[82–84]</sup> followed by the growth of single assemblies on the monolayer. The insertion process is based on the general approach for dendrimer insertion into SAMs and interfacial reaction at SAMs developed in our groups.<sup>[85–88]</sup> Similarly to the exchange reaction in solution, the growth of rosettes occurs via an exchange reaction between dimelamines **3** and the dimelamines constituting a preformed double rosette assembly  $1a_3\cdot(\text{DEB})_6$  in

solution. The exchange, and consequently the growth process, are the result of the high thermodynamic stability of the H-bonded assemblies combined with a relatively low kinetic stability (Fig. 10).<sup>[89]</sup>

The SAMs formed by insertion of calix[4]arene dimelamine **3** and subsequently by growth of the assembly  $1a_2\cdot 3\cdot(\text{DEB})_6$  were studied via TM-AFM. In the first case, TM-AFM images show single isolated features with an average height of  $1.1 \pm 0.2$  nm, in good agreement with the height obtained from the Corey–Pauling–Koltun (CPK) model of the adsorbate **3** (0.9 nm). By contrast, the TM-AFM images acquired subsequent to the growth of the rosette assemblies show two differently sized features (Fig. 11).

The height of the larger features (3.5 nm, Fig. 11C) agrees well with the expected size for the assembly  $1a_2\cdot 3\cdot(\text{DEB})_6$ , considering the crystal structure of a similar double rosette assembly. Therefore these features are attributed to mixed assemblies  $1a_2\cdot 3\cdot(\text{DEB})_6$

**Fig. 10** Schematic representation of the methodology followed for the growth of assemblies  $1a_2\cdot 3\cdot(\text{DEB})_6$  in SAMs on gold.

**Fig. 11** (A) TM-AFM image ( $500 \times 500 \text{ nm}^2$ ) of hexanethiol monolayers on Au(111) containing calix[4]arene dimelamine **3** acquired in air. (B) TM-AFM image ( $500 \times 500 \text{ nm}^2$ ) after treatment with a solution of assembly  $\mathbf{1a}_3 \bullet (\text{DEB})_6$ . (C) Comparison of heights. The height profile corresponds to the line drawn in the AFM image (B). Color scale from dark to bright:  $z = 10 \text{ nm}$ . Source: From Ref.<sup>[81]</sup>. obtained through reversible exchange of components **1a** and **3**. The height of the smaller features (0.9 nm, Fig. 11C) corresponds to single isolated molecules of **3**, which were not involved in exchange reactions with assemblies  $\mathbf{1a}_3 \bullet (\text{DEB})_6$ .

## CONCLUSION

We have shown that well-defined nanometer-sized structures can be formed from individual low molecular mass components in a bottom-up strategy. Highly regular 2-D arrays of these rosette nanostructures are formed at the HOPG–air interface, thus establishing a second hierarchical level. Based on the successful elucidation of the orientation of individual rosettes within the nanorods, novel approaches that allow one to control the chirality of 2-D structures formed by assembly of rosettes on HOPG, as well as the syntheses and assembly of novel *functionalized* rosettes, we develop a strategy that will enable us to position supramolecular nanostructures comprising functions with molecular precision in space. The obtained assemblies are hierarchical in nature and thus open pathways to increased complexity. The anticipated functionalized 2-D arrays of rosettes will be useful as, e.g., templates for the deposition of metals and other materials, sensor arrays, etc. In addition, individual rosette nanostructures can be successfully “synthesized” in suitably functionalized self-assembled monolayers on gold. The incorporation of functions will open the way toward surface-immobilized molecular nanotechnology. To realize the ultimate challenge of the controlled

growth and positioning of *individual* nanostructures on solid supports, different positioning strategies, including scanning probe approaches, are currently being pursued in our laboratories.

# AFM: Imaging Artifacts

Stephanie Butler Velegol

Department of Civil and Environmental Engineering, Pennsylvania State University,  
State College, Pennsylvania, U.S.A.

## INTRODUCTION

The invention of the atomic force microscope (AFM; also known as scanning probe microscope, SPM) in 1986<sup>[1]</sup> has revolutionized the way researchers study surfaces.<sup>[2]</sup> Material surfaces such as metallic or polymeric thin films can be imaged under ambient conditions (air, liquids) with nanometer resolution. Furthermore, it is now possible to image biological species such as DNA, proteins, and bacteria in their natural environment. However, researchers using the AFM for imaging must do so with great care to avoid the many artifacts that can be present during imaging. It is the purpose of this entry to identify these artifacts and to present ways to avoid these artifacts while using the AFM. Interestingly, the discovery of many of these artifacts has opened doors to new uses of the AFM. This will be discussed as well.

## OVERVIEW

Before discussing the artifacts present in the AFM, a brief discussion of the AFM mechanism is warranted. Fig. 1 shows the mechanism of a typical AFM. The primary components are: 1) helium–neon laser; 2) AFM probe; 3) piezoelectric scanner; and 4) photodiode detector. Laser light is reflected off the top of a probe and is detected by a photodiode detector. The probe consists of a sharp tip attached to a flexible cantilever beam. The piezoelectric scanner controls either the vertical position of the surface (Fig. 1), or the vertical position of the probe. The piezoelectric scanner is able to move in three dimensions with angstrom-level precision. When the surface and the tip are brought closer together, the interaction between them causes the tip to be deflected either toward the surface (because of attractive forces), or away from the surface (because of repulsive forces). This deflection of the tip is recorded as the change in the position of the laser on the detector. The piezo responds to this change by increasing or decreasing the height of the sample to maintain a constant distance between the tip and the surface. Images can be recorded as either the deflection on the detector (deflection image), or the vertical

distance of the piezo (height image). The vertical resolution of AFM images is dictated by the interaction between the tip and the surface. The lateral resolution is determined by the size of the tip, as will be discussed below.

Fig. 2 shows a diagram of a typical pyramidal AFM tip on a cantilever. In most systems, the cantilever is tilted approximately  $12^\circ$  toward the surface. At a  $0^\circ$  scan angle, the tip moves across the surface in the direction of the arrow in Fig. 2. The AFM tips have traditionally been pyramidal in shape, but can also be of other shapes, such as a nanowire or a colloidal sphere.

Because the functionality of the AFM depends on the interaction between the tip and the surface, most of the artifacts that exist with the AFM are because of the size, shape, and cleanliness of the tip. Artifacts are also introduced when the tip interacts with the surface in a way that changes the surface itself. Finally, there are artifacts that exist because of the electronics of the control system. Table 1 shows a summary of each artifact along with the solution to the problem. Details of each artifact are discussed below.

## ARTIFACTS BECAUSE OF FINITE SIZE AND PYRAMIDAL SHAPE OF TIP

The image produced by the AFM is a convolution of both the shape of the surface being imaged and the tip geometry. The rule of thumb is that the image will accurately reflect the surface structure if the difference in the image of the radius of curvature of the tip is one-tenth the radius of the imaged structure.<sup>[3]</sup> The exception to this rule occurs if the height of the imaged structure is comparable to the height of the tip.

### Broadening of Surface Features

For any object on the surface with a finite height, the side of the tip will interact with the side of the surface feature. For the surface structures shown in Fig. 3, the side of the tip interacts with the surface structure when it is a distance of  $b$  away from the edge of the object. This will produce a broadening of the object in the

Fig. 1 Schematic of AFM.

image by a distance of  $b$  on both sides of the surface structure. If the lateral dimension  $a$  of the object is large and the height of the object is small (Fig. 3A), this effect is small. However, if the lateral dimension of the surface structure is small, or the height of the surface structure is large (Fig. 3B and C, respectively), the interaction of the side of the tip with the surface structure will result in significant broadening of the object in the image. For these reasons, this artifact will be predominant in images of nanoparticles (including proteins or DNA) as well as images of large particles such as bacteria.

An experimental example of the broadening of a small object because of the tip size (similar to Fig. 3B) has been observed when imaging DNA. Images obtained with a tip, with a radius of 30–50 nm, indicate that the diameter of the DNA strand is 14 nm whereas the true diameter is 2 nm.<sup>[4,5]</sup> In this case, the height of the image (as determined by the line plot) will be correct and only the width will be distorted.

Fig. 2 Typical shape of AFM tip and cantilever relative to the surface. The tip is square pyramidal and the cantilever is tilted toward the surface at an angle of 12°. The arrow indicates the direction of scan (at 0° scan angle).

An effect similar to Fig. 3C can be observed while imaging large bacteria in aqueous media (Fig. 4). Although the radius of the bacteria (500 nm) is much larger than the radius of curvature of the AFM tip (5–40 nm), the object is also very tall compared to the tip. The diagonal lines represent the interaction of the diagonal edges of the tip with the side of the bacterium or sphere. Note that the lines appear mostly on one side because of the 12° tilt of the cantilever.<sup>[6]</sup> Similar effects have been observed in tapping-mode images of *P. chrysosporium* spores<sup>[7]</sup> and images of a fixed liver endothelial cell (LEC).<sup>[8]</sup>

There have been many attempts to correct this image artifact. One way is to use a standard tip and then reconstruct the image to determine the true size of the surface structure.<sup>[9–15]</sup> In most cases, these reconstruction techniques require knowledge of the shape and size of the AFM tip. Information such as the radius of curvature of the AFM tip can be obtained from the manufacturer but is best determined experimentally by the technique of reverse imaging. In this technique, the surface structure is smaller than the tip itself, so that the image reflects mostly the shape of the tip. The surface structure can be a grading of spikes,<sup>[15]</sup> circular depressions,<sup>[13]</sup> or close-packed spheres.<sup>[10]</sup> Digital Instruments® also has a Tip Estimation software program that can be used to determine the shape of the tip. Blind restoration, or blind reconstruction, can also be used to deconvolute the images without information about the tip shape.<sup>[4,16]</sup> This is performed via mathematical morphology operations (e.g., dilation and erosion) that can estimate the shape of the tip from the image.<sup>[4]</sup>

Another solution to the broadening effect is to use a tip with a high aspect ratio such as a nanowire (Fig. 5).

**Table 1** How to identify and avoid common AFM imaging artifacts

Artifact	Cause	Solution
Broadening of features	Interaction of surface with side of tip (structure above surface is too small laterally, or too high vertically)	Use deconvolution techniques
	Contamination on tip	Use sharpened tip (higher aspect ratio) Clean tip with UV/ozone or piranha solution Test for cleanliness by taking a force curve before and after imaging Image tip with SEM before and after imaging
	Bluntness of tip	Use new tip image tip Image tip with SEM to ascertain shape Use deconvolution techniques to determine actual surface structure
Smaller features	Interaction of surface with side of tip (surface structure below surface is too small laterally, or too deep)	Use deconvolution techniques
Surface structures that disappear while imaging	Lateral forces between tip and surface are too large and objects are pushed away via AFM tip	Use sharpened tip (higher aspect ratio) Use tapping mode
		Minimize force during imaging Bond surface structures to surface
Destruction of soft surfaces	Vertical forces between tip and surface are too high	Use tapping mode
		Use smaller force during imaging Use cantilever with smaller spring constant Stiffen surface
Appearance of “shadows” on opposite side of tip movement	Overshoot of control system	Slow down imaging speed
Distortion after image zoom	Drift in piezoelectric scanner	Change scan direction Rescan area of interest
Periodic “noise” in image	Mechanical or electrical noise	Remove vibrations from room Decrease gains on control system

The high aspect ratio reduces the interaction of the side of the tip with the surface structure, but one must be cautious when using a sharpened tip because it can create large pressures on the surface that are more likely to damage soft samples. For large objects on the surface, adjusting the angle between the cantilever and the surface so that they are parallel can minimize artifacts because of high vertical dimensions.

### Features Appear Too Small

If the probe needs to go into a feature that is below the surface, the surface structure in the image may appear too small because of the interaction between the tip and the inside of the structure. This artifact

has been observed in images of germanium surfaces bombarded by ions.<sup>[9]</sup> Atomic force microscope images showed the presence of columnar structures present because of the shape of the tip and did not appear in electron microscopy images. In this case, the tip may not be able to image the corner of the feature (Fig. 6A), or may not be able to reach the bottom of the structure (Fig. 6B). This will be particularly noticeable if the hole is small laterally (Fig. 6A) and/or deep (Fig. 6B).

Again, this artifact may be removed by using a tip with a higher aspect ratio (such as a sharpened tip, or a nanowire). Reconstruction of the image can also be performed, although the deconvolution algorithm cannot reconstruct parts of the tip that did not make contact with the sample.<sup>[12]</sup>

**Fig. 3** Schematic of image artifacts because of the size and shape of the tip. In all cases, the side of the tip interacts with the surface object with a lateral dimension of  $L$  and a height of  $h$  at a distance of  $d$  away from the object. This causes a distortion in the image, indicated by the dotted line. In (A), the radius of the tip is much smaller than the radius of the object being imaged, and the artifact is minimized. In (B)  $L$  is small and the distortion is more noticeable. In (C), the height of the object  $h$  causes a greater distortion of the image.

### Artifacts Because of Contamination of Tip or Misshapen Tips

Because the lateral resolution of the image depends on the radius of the tip, any change to the tip that causes the tip to become broader will sacrifice this resolution. These changes to the tip may be because of contaminants on the tip, or because of tip damage.

Scanning electron microscopy has shown that many tips have defects and have been contaminated before they are even used (Fig. 7).<sup>[17]</sup> These contaminants may include silicone oils from packaging,<sup>[18]</sup> or irregular apices. More commonly, the tip can pick up contamination during imaging.<sup>[17]</sup> The presence of these contaminants, or defects, can change the shape of the image and result in an irregularly shaped image, or a broadening of the image. The presence of contaminants is particularly problematic for AFM applications where the tip is chemically modified because these techniques rely on a clean tip surface.

There are multiple suggestions for cleaning tips before using them. The most common cleaning procedure is to use UV/ozone cleaning.<sup>[18]</sup> This destroys organics on the tip and can be performed easily using an UV/ozone cleaner. Another more rigorous

**Fig. 4** Atomic force microscope line artifacts because of the interaction of the side of the tip with a tall surface structure (Fig. 3C). (A) and (B) are tapping-mode amplitude and phase images of 1-mm-high *E. coli*. The white bar represents 1 mm. The vertical scale for the height images is 1 mm. The scan direction is from right to left, with a  $0^\circ$  scan angle. The lines highlighted in black show the artifact, which appears as lines  $\pm 27^\circ$  to the scan direction. The line artifacts appear on the right side of the image because of the tilt of the cantilever relative to the surface. *Source:* ©American Chemical Society.

approach is to soak the tips for 30 min in piranha solution (70:30  $\text{H}_2\text{SO}_4/\text{H}_2\text{O}_2$ ).<sup>[17]</sup> These cleaning procedures ensure only that the tip is clean before it is used, but does not prevent the tip from becoming contaminated during imaging.

One suggestion to test for the cleanliness of the tip during imaging is to measure the force between the tip and a clean surface (such as clean glass or mica) before and after imaging your surface of interest. A change in force indicates a chemical change in the tip.<sup>[17]</sup> Another suggestion is to image the tip via SEM before and after use. Although this is a

Veeco Metrology

**Fig. 6** Schematic of image artifacts because of imaging a surface structure with a lateral dimension of  $L$  and a depth of  $h$  below the surface. In (A), the tip is not able to image the corner of the structure, whereas in (B), the tip is not able to image the bottom of the structure. The dotted line represents the image produced by the AFM.

time-consuming step, it will identify any contaminant that adheres while imaging.

A tip may become misshapen either during manufacturing of the tip, or during imaging. This effect is

similar to the presence of a contaminant and will result in a strangely shaped image. The new shape of the tip can be identified by using a deconvolution program (discussed above), or by imaging with an SEM.

## CHANGING SURFACE STRUCTURES DURING IMAGING

Unlike optical microscopy or electron microscopy, atomic force microscopy uses physical force to image the surface “by feel” and not by electromagnetic radiation or electrons. This mechanical force can often be destructive to the surface itself. Lateral forces because of the rastering of the tip over the surface can cause surface objects to be displaced during imaging, whereas vertical forces can cause indentation of soft surfaces.

### Displacement during Imaging

As the tip is rastered across the surface, there is a lateral force applied to the object being imaged. This lateral force can remove the object from the surface if the object is not adhered strongly to the surface. If the object is removed during imaging, the structure will suddenly disappear from the image. The image may show just part of the surface structure (imaged before it disappears). It is possible to observe this more clearly by first imaging a small area at a high force for some time and then imaging a larger area with a smaller force. The middle of Fig. 8 shows an area that has been imaged for some time. All the particles in this area have been removed because of imaging.<sup>[19]</sup>

The lateral interaction between the tip and the surface can be minimized by imaging with tapping-mode atomic force microscopy instead of contact-mode atomic force microscopy, or by decreasing the amount of force used while imaging. In tapping-mode atomic force microscopy, the tip is not in constant contact with the sample surface. Instead, the tip is vibrated close to the resonance frequency of the AFM probe. When the vibrating tip strikes the surface, some of the energy is absorbed by the surface. This causes a decrease in the vibrational amplitude of the probe. The piezo adjusts the distance between the surface and the tip to maintain constant vibrational amplitude.

Although tapping-mode atomic force microscopy will reduce lateral forces on the surface objects, it is often necessary to take more steps to ensure that the objects are not displaced. One approach is to ensure that the objects are strongly anchored to the surface. This is particularly important for imaging negatively charged objects on a negatively charged surface, which is the case for most biological species on silica or mica. For example, Shibata-Seki et al.<sup>[19]</sup> showed that liposomes can be pushed out of the way at a force  $>4.2$  nN. Similarly, SK-N-SH (human neuroblastoma cells) and AV12 (Syrian hamster cells) can be moved during imaging, especially if they are alone.<sup>[20]</sup>

**Fig. 8** Demonstration of AFM artifacts because of high forces. In situ AFM images of liposomes on substrates taken at different load forces over the same region. Images were taken with a standard  $\text{Si}_3\text{N}_4$  cantilever tip (spring constant of  $0.12$  N/m). (A) Load force was approximately  $0.72$  nN. (B) Load force was approximately  $4.2$  nN. (C) Load force was approximately  $2.2$  nN. Source: From Ref.<sup>[19]</sup>; ©Elsevier.

One solution is to modify the surface so that it can covalently bond with the object. This can be accomplished by using amino-silanization<sup>[21,22]</sup> on silica. In this method, silane trimethoxysilyl-propyl-diethylenetriamine functionalizes the glass. The object can then bond to the functionalized surface via an amide bond linkage.

Another solution is to render the surface cationic using a cationic polymer. These polymers include spermine,<sup>[23]</sup> polylysine,<sup>[24]</sup> polyethyleneimine (PEI),<sup>[25,26]</sup> chitosan,<sup>[25]</sup> and diethyl-aminoethyl dextran (DEAE—dextran).<sup>[25]</sup> A complete study of the adhesion of *Escherichia coli* as well as polystyrene spheres via the above surface modification showed that PEI is the most effective adhesion mechanism.<sup>[25]</sup> When using cationic polymers, care should be taken to remove all the non-adhered polymers, as non-adhered polymers may stick to and contaminate the tip during imaging.

**Fig. 9** Creation of a deflated bacterium because of high vertical forces. (A), (C), (E), and (G) are height images, whereas (B), (D), (F), and (H) are deflection images. The bacterium is deflated in (C) and (D) at the dotted line. A similar deflated bacterium is shown in (G) and (H). *Source:* ©American Chemical Society.

Another option for imaging bacteria is to trap them in holes in a filter to prevent them from moving around.<sup>[27]</sup> You et al.<sup>[20]</sup> showed that bacteria adhered to the surface via cell–EPS interactions or cell–cell

interactions may be strong enough to prevent displacement. Finally, studies on DNA have shown that imaging in air<sup>[23]</sup> or propanol<sup>[28]</sup> prevents water–tip interactions and makes imaging easier.

### Indenting During Imaging

Tips can cause not only lateral forces but also vertical forces that can deform the surface. This is particularly seen on soft surfaces such as polymers, and biomaterials such as bacteria. Fig. 9 shows a bacterium in an aqueous solution being irreversibly “deflated” because of tapping-mode atomic force microscopy imaging. The arrows indicate the direction of scanning.<sup>[6]</sup> At first, the image of the bacterium shows a height of 1 μm (Fig. 9A and B). As scanning continues, the height of the image suddenly decreases, as shown on the top of Fig. 9C and D. Finally, in Fig. 9E and F, the bacterium has been completely deflated. Another deflated bacterium shown in Fig. 9G and H shows a rectangular indent in the top left corner of the image. Other biological species such as tobacco mosaic virus (TMV)<sup>[23]</sup> and human neuroblastoma cells (SK-N-SH)<sup>[20]</sup> have been irreversibly damaged during imaging.

This indentation will occur if the effective spring constant of the object is similar to the spring constant of the cantilever. If the surface is a Hookian elastic material, the deformation, or indentation, of the surface  $i$  and the deflection of the cantilever  $d$  can be expressed by Eq. (1):

$$i = \frac{k_c d}{k_s} \quad (1)$$

where  $k_c$  is the spring constant of the cantilever and  $k_s$  is the spring constant of the surface.

The first step to avoid this indentation is to use tapping-mode atomic force microscopy. However, as shown in Fig. 10, this does not completely eliminate the indentation. Another solution is to use a cantilever

**Fig. 10** Linearity and  $x$ – $y$  calibration of the AFM piezo. (A) Test pattern. (B) Image produced when the piezoelectric scanner is not linear. *Source:* From *Microscopy Today*.

with a smaller spring constant. This will decrease  $k_c$  and decrease  $i$  in Eq. (1) but may also sacrifice some resolution. In both contact-mode atomic force microscopy and tapping-mode atomic force microscopy, it is possible to image with a lower force, which can decrease the indentation.

Finally, in some cases, it may be possible to “stiffen” the surface structure. In the case of biological cells, this can be performed by exposing the cells to glutaraldehyde.<sup>[26,29,30]</sup> This makes imaging easier because the spring constant of the bacteria increases; however, the procedure may render the cells more hydrophobic.<sup>[31]</sup> Another option is to image the soft surface in a media other than water, such as air<sup>[28]</sup> or propanol.<sup>[29,32]</sup> These techniques will provide better images but may not accurately represent the image topography in an aqueous solution.

## SCANNER ARTIFACTS

The scanner head on the AFM can introduce artifacts while imaging. These artifacts result from non-linearity in the horizontal and vertical movements of the scanner, vertical overshoot because of the control system, and scanner drift.

The piezoelectric scanner moves the tip across the surface in both horizontal ( $x$ - $y$ ) and vertical ( $z$ ) planes. It is critical that the scanner is moving linearly with time and that it is calibrated. If the scanner is not moving linearly, features on one side of the image will

appear smaller than the other side (Fig. 10).<sup>[33]</sup> If the scanner is moving linearly but not calibrated, the dimensions in the horizontal dimension will not be accurate. Most AFM packages come with a standard grid that can be used to check the linearity and accuracy of the scanner. Similar compensation software tools can be used to calibrate the scanner in the vertical plane.

Another common artifact because of the scanner is the presence of “shadows” on the opposite side of the direction of scanning (Fig. 11). These shadows are because of hysteresis in the vertical control of the piezoscanner. The scanner overshoots the edge and shows a decrease in height, even in the line profile. Decreasing the scan speed can reduce this effect, whereas reversing the scan direction can reveal the true edge of the object.

The scanner is sensitive to temperature changes. These temperature changes can cause drifts in the scanner and distortions of the image. This most commonly appears at the beginning of a scan of a zoomed-in region of an image (Fig. 12).<sup>[33]</sup> For this reason, an area should be scanned multiple times to make sure there are no changes.

## ELECTRONIC ARTIFACTS

While imaging with the AFM, it is important that the equipment is isolated from external vibrations. These can include acoustic vibrations from sound or

**Fig. 11** Tapping-mode atomic force microscopy images of *E. coli* bacteria with a scan angle of 0° (A), 180° (B), and 90° (C). In (D), the scan angle is 180° and the tip direction is from left to right. The dark spots of the image are always on the back side of the scanning probe direction. This is because of an overshoot in the feedback control system. *Source:* ©American Chemical Society.

**Fig. 12** Artifact caused by scanner drift. (B) A zoomed-in area of (A). The pattern is distorted because of scanner drift. Source: From *Microscopy Today*.

mechanical vibrations of the floor. These artifacts typically appear as periodic patterns in the image. The equipment can be isolated from the room by using an isolation table, or by suspending the apparatus from a tripod.

Electronic noise can also cause periodic patterns in the image. If the gains of the control system are set too high, the system control system will become unstable. Reducing the gains can eliminate this problem. Similar effects can be observed with faulty electronics.

## USING ARTIFACTS TO YOUR ADVANTAGE

Although the artifacts discussed should be avoided to obtain the most accurate image possible, the identification of many of these artifacts has led to breakthroughs in new ways of using the AFM. These breakthroughs include nanomanipulation and nanoindentation.

Although it is often not desired to move the object to be imaged, researchers have recently taken advantage of the interaction between the tip and the objects on the surface to manipulate surface objects. The ability of the AFM tip to move with angstrom-level precision makes it ideal for nanomanipulation. The surface can be imaged using weak attractive forces. The tip can then be brought into stronger contact with individual objects to manipulate them.<sup>[34]</sup> This technique has been used to build two-dimensional and three-dimensional structures of nanoparticles,<sup>[34,35]</sup> as well as to manipulate biomolecules such as DNA and proteins.<sup>[36–38]</sup>

Researchers have also taken advantage of vertical forces applied during imaging using the AFM for nanoindentation. Nanoindentation allows measurements of mechanical properties of various surfaces including polymers surfaces<sup>[39–42]</sup> and biological surfaces.<sup>[8,21,26,43–46]</sup> For polymeric surfaces, the indentations

made with a high spring constant cantilever (100–300 N/m) made at various forces are imaged via tapping mode. The depth of the indentations is used to determine the spring constant of the surface according to Eq. (1). For more elastic surfaces, such as biological surfaces, the mechanical properties of the surface can be determined by analyzing the AFM force curves.<sup>[8,21,26,43–46]</sup>

## CONCLUSION

The AFM is a powerful tool for imaging surfaces. With proper care, accurate images can be obtained and can provide important quantitative information about surfaces on the nanometer scale. However, it is imperative that researchers using this tool are aware of the many artifacts that can be present in the created images. These artifacts may be because of the shape and size of the AFM tip, the lateral or vertical interaction between the tip and the surface, or the electronics of the AFM system. Once aware of these artifacts, corrections can be made to create more accurate images of the surface structures of interest.

# AFM: Imaging and Force Spectroscopy on Cell Surfaces

Yves F. Dufrêne

*Unite de Chimie des Interface, Université catholique de Louvain, Louvain-la-Neuve, Belgium*

## INTRODUCTION

Characterization of the structural and physical properties of microbial cell surfaces is a continuously expanding field of microbiology.<sup>[1–10]</sup> Studying cell surfaces is important not only in basic research to elucidate their functions (cell shape, protection, molecular sieve, molecular recognition, cell adhesion, and cell aggregation), but also in medicine (fouling of implants, microbial infections) and biotechnology (cellular interactions in fermentation technology, removal of heavy metals). Electron microscopy has long been the technique of choice for probing cell surface structure down to the molecular level.<sup>[1,2,4,6,7]</sup> Yet the requirement of vacuum conditions may raise the question of whether the information obtained is always relevant to the real, hydrated state. In parallel, a variety of approaches have been developed to probe the cell surface physical properties, including chemical analysis of wall constituents, specific binding studies, selective degradation by enzymes, cell wall mutants, modifications by antibiotics, and surface analysis using various physical techniques.<sup>[1,4,5,10]</sup> Many of these techniques provide averaged information obtained on a large ensemble of cells; that is, they are not suited for mapping the nanoscale distribution of physical properties on individual cells.

Since the late 1980s, atomic force microscopy (AFM)<sup>[11]</sup> has been increasingly used in biology and it is now established as a versatile tool to address the structure, properties, and functions of biological structures, going from single molecules to lipid membranes and living cells.<sup>[12–17]</sup> Basically, AFM offers two main advantages over conventional microscopy techniques. First, it provides images of the specimen with nanometer (subnanometer) resolution, in real-time and under physiological conditions. Second, because the instrument works by sensing the force between a very sharp tip and the sample surface, this principle can be exploited to measure molecular interactions and physical properties on a local scale. These capabilities provide a range of novel opportunities in microbiology.<sup>[18]</sup> For example, the following questions can

now be addressed with AFM. Does the surface nanostructure of untreated living cells correlate with that observed by electron microscopy? How does surface structure change with time during dynamic processes such as cell growth and cell division? How do external agents such as enzymes and antibiotics affect the cell surface architecture? Do surface properties such as hydrophobicity, charge, and elasticity vary across the surface of a single cell? What are the intermolecular forces involved in molecular recognition and cellular interactions? What is the elasticity of single-cell surface macromolecules? The intent of this article is to survey recent achievements brought by AFM in microbiology, particularly emphasizing studies on whole cells. Rather than providing an exhaustive review of the literature in the area, the paper discusses imaging and force spectroscopy applications using a selection of recent data.

## IMAGING

### Image Recording and Sample Preparation

Atomic force microscopy images are created by raster-scanning a sharp tip across the sample, while sensing the force experienced by the tip. To this end, the sample is mounted on a piezoelectric scanner that ensures three-dimensional positioning with high resolution. The force is monitored by attaching the tip to a soft cantilever and by measuring the bending or “deflection” of the cantilever. The larger the cantilever deflection, the higher the force that will be experienced by the tip. Nowadays, most instruments use an optical method to measure the cantilever deflection with high resolution. A laser beam is focused on the free end of the cantilever and the position of the reflected beam is detected by a position-sensitive photodiode.

In contact mode, the most common imaging mode, images can be acquired in two ways, i.e., either in the constant-height mode in which the cantilever deflection is recorded while the sample is horizontally scanned, or in the constant-deflection mode in which the sample height is adjusted to keep the deflection of the

cantilever constant using a feedback loop. In the latter case, the feedback output can be used to display a true height image, which gives calibrated height information about the sample morphology. Alternatively, the error signal can also be employed to generate a so-called deflection image that does not provide quantitative height information but is more sensitive to fine surface details. Besides contact mode, several other imaging modes have been developed. Among these, tapping mode atomic force microscopy in which the tip is oscillated at a given frequency is very useful for imaging soft samples.

After the first AFM images of biological structures were published, it was soon realized that a crucial factor for successful imaging is specimen preparation. This led to the development of a number of immobilization methods. For single molecules, two-dimensional protein crystals, lipid membranes, and animal cells, immobilization protocols are generally based on physical adsorption onto flat substrates such as mica, glass, and silicon oxide (for a detailed description of these procedures, see Ref. [19]). However, for microbial cells, sample preparation is often challenging because of the cell geometry. Indeed, a microbial cell must be viewed as a fairly rigid spherical or rod-like particle of 1–5  $\mu\text{m}$  size. This geometry usually leads to a very small cell–substrate contact area and therefore to cell detachment by the scanning tip. Presumably, this is the main reason why the potential of AFM in cellular microbiology had been neglected in the early age. However, the past few years have seen tremendous progress in the application of AFM to microbiological specimens owing to improvements in imaging conditions and sample immobilization procedures.

The selection of an appropriate imaging environment is critical for high-resolution imaging because it directly influences the force acting between tip and sample. In air, high-resolution imaging is often difficult as a result of strong adhesion forces resulting from the presence of a water layer on both tip and sample. This problem is eliminated when imaging in aqueous solution, which is actually the most relevant environment for microbiological specimens. By selecting appropriate buffer conditions (nature of electrolytes, ionic strength, pH), it is generally possible to maintain a very low applied force, typically in the range of 0.1–0.5 nN.<sup>[20]</sup> Hence it is certainly very useful to investigate the effect of salt composition, pH, and ionic strength on the image quality when high resolution is desired.

### Imaging of Living Cells

By combining high spatial resolution with the possibility to work in liquids, AFM enables researchers to

visualize the surface morphology of untreated living cells, thus providing information that is complementary to data obtained with classical microscopy techniques. As mentioned above, an important requirement is that the cells must be firmly attached to a solid substrate. This can be achieved by mechanically trapping the cells into a porous polymer membrane. Fig. 1 presents a three-dimensional height image showing a single *Saccharomyces cerevisiae* cell protruding from a pore of a polymer membrane. In these conditions, images could be repeatedly obtained in aqueous solution without detaching the cell or altering the surface morphology. Generally, the entire cell surface was very smooth, an observation that was consistent with previous chemical and electron microscopy studies. However, some cells showed circular protrusions, about 1  $\mu\text{m}$  in diameter, which reflected the bud scars left on the surface after cell division.<sup>[21]</sup>

Provided that the cell is well attached, it is possible to acquire high-resolution images at different locations. For *S. cerevisiae*, topographic images were recorded to a lateral resolution of 2 nm, without significant modification of the surface morphology. The surface roughness (on  $250 \times 250 \text{ nm}$  areas) was found to be smaller than 1 nm.<sup>[21]</sup> Interestingly, a very different surface architecture was observed for fungal spores. Fig. 2A shows that the surface of *Aspergillus oryzae* spores was covered by a layer of regularly arranged nanostructures, referred to as rodlets, that were several hundred nanometers in length and had a periodicity of 10 nm.<sup>[22]</sup> Presumably, these crystalline-like nanostructures play an important role in determining the biological functions of the spore (i.e., dispersion, protection).

Accordingly, AFM is a valuable technique for probing the surface architecture of native microbial cells. However, researchers must realize that high-resolution

**Fig. 1** Atomic force microscopy height image ( $6 \times 6 \mu\text{m}$ ;  $z$  range: 1  $\mu\text{m}$ ) of a living *S. cerevisiae* cell immobilized in a porous polymer membrane.

**Fig. 2** High-resolution deflection images acquired under water for the surface of *A. oryzae* spores: (A) dormant spore ( $500 \times 500$  nm); (B) spore after  $\sim 10$  h of germination ( $1 \times 1 \mu\text{m}$ ). *Source:* From Ref.<sup>[22]</sup>. © 2001 American Chemical Society.

imaging often remains difficult, especially for bacterial surfaces. A first source of problems is related to sample softness. The above images were obtained on cells that possess thick, mechanically strong cell walls. In comparison, bacterial walls are thinner and more fragile, meaning that imaging may be destructive, especially in contact mode. For instance, the image contrast obtained for the surface of *Lactococcus lactis* was dominated by tip-sample interactions; that is, grooves oriented along the scanning direction were created by the scanning tip.<sup>[23]</sup> For some bacteria, the presence of flexible, loosely bound macromolecules or appendages at the surface may further limit the image resolution. The immobilization procedure may also be an issue. The porous membrane approach described here is only suited for spherical cells, indicating that alternative strategies must be used for other geometries. Consequently, further developments are necessary (non-destructive dynamic imaging modes, novel immobilization procedures) before researchers can achieve molecular resolution and perhaps monitor molecular conformational changes as is already the case with isolated cell surface layers made of two-dimensional protein crystals.<sup>[14]</sup>

### Following Dynamic Processes

Of particular interest is the possibility to study the changes of cell surface structure associated with dynamic processes such as cell growth and germination. An example of this is the germination of fungal spores. For *A. oryzae* spores,<sup>[22]</sup> high-resolution images revealed that dramatic changes of the surface morphology occurred upon germination, the rodlet layer (Fig. 2A) changing into a layer of soft material (Fig. 2B). On close examination, this material showed streaks oriented in the scanning direction, suggesting

that soft, loosely bound material was interacting with the scanning tip. These direct observations were in good agreement with previous structural and chemical studies showing that germination results in the disruption of the proteinaceous rodlet layer and reveals inner spore walls that are rich in polysaccharides. As we shall see below, morphological changes were directly correlated with profound modifications of molecular interactions as measured by force spectroscopy.

Real-time imaging also enables to follow the progressive effect of external agents such as solvents, ions, chemicals, enzymes, and antibiotics on the cell surface. In this context, the surface morphology of yeast cells was investigated at fixed time intervals following addition of protease and amyloglucosidase solutions.<sup>[21]</sup> Progressive changes of the cell surface topography were clearly observed after protease addition (Fig. 3). With time, the surface became eroded and showed large depressions, about 500 nm in diameter, surrounded by protruding edges, about 50 nm in height (estimated from height images). By contrast, no modification of the cell surface was noted upon addition of amyloglucosidase, which was consistent with the cell wall biochemical composition. These real-time experiments have a strong potential in cell wall enzyme digestion studies as well as in medicine, where they may be used to investigate the effect of antibiotics on microbial cell walls.

**Fig. 3** Series of deflection images ( $4.2 \times 4.2 \mu\text{m}$ ; insets:  $2.5 \times 2.5 \mu\text{m}$ ) recorded in real time for a single *S. cerevisiae* cell prior to and after contact with a protease solution for 6, 9, 15, 19, 30, 40, 50, and 60 min. *Source:* From Ref.<sup>[21]</sup>. © 2003 John Wiley & Sons, Inc.

## FORCE SPECTROSCOPY

### Principle of Force Spectroscopy

The basic idea behind force spectroscopy is that rather than scanning the tip in the  $x$  and  $y$  directions, the cantilever deflection is recorded as a function of the vertical displacement of the sample, i.e., as the sample is pushed toward the tip and retracted from it. Using appropriate corrections, the raw voltage vs. displacement curve is converted into a force vs. distance curve, which then enables the measurement of molecular interactions and physical properties.<sup>[24,25]</sup> Interestingly, spatially resolved information can be obtained by recording a so-called “force–volume image” consisting of arrays of force–distance curves.<sup>[25]</sup>

A typical force–distance curve obtained for a non-deformable surface in liquid is shown in Fig. 4. When the tip is far away from the sample surface, there is no force acting on the tip and the cantilever is not deflected (label 1). As the tip approaches the surface, the cantilever may bend upward as a result of repulsive forces (label 2) until the tip jumps into contact when the gradient of attractive forces exceeds the spring constant plus the gradient of repulsive forces (label 3). When the force is increased in the contact region, different behaviors may be observed depending on the sample stiffness. On a hard, nondeformable surface, the plot is a vertical line (label 3), while on a soft surface, elastic indentation will occur, leading to a different shape. In the latter case, analyzing the in-contact part of the curve with appropriate theoretical models enables quantitative determination of the sample elasticity. Upon retracting the tip from the surface, the curve often shows a hysteresis referred to as the adhesion “pull-off” force (label 4), which can be used to estimate the surface energy of solids or the binding forces between complementary biomolecules. In the presence of long, flexible macromolecules, elongation

**Fig. 4** Example of force–distance curve (see text for details).

forces usually develop nonlinearly as a result of the deformation of the molecules. In this case, it is common to present the force curve as the positive pulling force vs. extension. Theoretical models from statistical mechanics enable the elasticity of the molecules to be deduced from the force–extension profile. In the next sections, the various applications offered by force spectroscopy in microbial cell surface research are surveyed.

### Spatially Resolved Force Spectroscopy

The microbial surface is rarely of homogeneous composition, but is rather made of a complex mixture of macromolecules. As a result, a single cell can show important lateral variations of physical properties. Until recently, such local variations of properties were very difficult to measure, especially on hydrated, living cells. With spatially resolved force spectroscopy, it is possible to map the distribution of parameters such as adhesion and elasticity at the subcellular level.<sup>[25]</sup> The power of this approach is illustrated in Fig. 5. During cell growth, disruption of cell wall layers may

**Fig. 5** Mapping adhesion forces and cell wall elasticity using spatially resolved force spectroscopy. (A) Deflection image ( $2 \times 2 \mu\text{m}$ ) and (B) adhesion map ( $z$  range = 10 nN) acquired on the same area of a germinating spore of *P. chrysosporium*; the adhesion map was obtained by recording  $64 \times 64$  force–distance curves, calculating the adhesion force for each force curve, and displaying adhesion force values as grey levels (brighter contrast means larger adhesion forces). (C) Deflection image ( $1.5 \times 1.5 \mu\text{m}$ ) and (D) force map obtained for a *S. cerevisiae* cell after cell division; the force map, qualitatively reflecting the sample mechanical properties, was generated by recording  $32 \times 32$  force–distance curves and taking a slice of the force volume at a given sample height in the contact region of the curves (brighter contrast means softer properties).

occur and newly formed material may accumulate in localized regions, leading to heterogeneous surface properties. For germinating spores of *Phanerochaete chrysosporium*,<sup>[26]</sup> the heterogeneous surface morphology (Fig. 5A) was directly correlated with differences in adhesion forces (Fig. 5B). The strong adhesion forces measured on localized zones were suggested to be responsible for cell aggregation observed during germination.

Another example of surface physical heterogeneity is found in yeast during budding. While chitin is usually not found in the cell walls of *S. cerevisiae*, it accumulates in the very localized region of the wall involved in budding where it may act as a stiffening agent. In this context, force–volume images were recently recorded in parallel with topographic images on the surface of budding yeast cells.<sup>[27]</sup> In Fig. 5C,D, it can be seen that the force map was highly contrasted, the bud scar region being clearly darker compared to the surrounding cell surface. These data indicated that the bud scar was qualitatively stiffer than the surrounding cell wall, a finding that was further supported by theoretical treatment of the force curves (see next section).

### Elasticity of Cell Walls

The mechanical properties of microbial layers can be addressed on a local scale using AFM force measurements. A first approach consists in pressing isolated cell wall material into a groove in a solid surface with the AFM tip and then deducing the elastic modulus from the applied force vs. depression distance curve. In a pioneering study, this “depression technique” was used to measure the elastic modulus of the sheath of the archeon *Methanospirillum hungatei* GP1.<sup>[28]</sup> The large modulus values (20–40 GPa) indicated that this single-layered structure of unusual strength could withstand an internal pressure of 400 atm. For murein sacculi of Gram-negative bacteria in the hydrated state, elastic moduli of 25 MPa were measured, which are in excellent agreement with theoretical calculation of the elasticity of the peptidoglycan network.<sup>[29]</sup>

For whole cells, quantitative information on sample elasticity is obtained by converting force curves into force vs. indentation curves and analyzing them with theoretical models.<sup>[30]</sup> Using this “nanoindentation method,” the wall compressibility of whole *Magneto-spirillum gryphiswaldense* cells was determined to be about 42 mN/m.<sup>[31]</sup> Interestingly, local nanoindentation measurements on *S. cerevisiae* revealed significant variation of elasticity across the cell surface: Young’s modulus was 6 MPa on the bud scar and 0.6 MPa on the surrounding cell surface.<sup>[27]</sup> These measurements provided the first direct evidence that the chitinous

bud scar in yeast is about 10 times stiffer than the surrounding nonchitinous cell wall.

### Chemically Functionalized Tips

Because commercial AFM tips usually have a poorly defined surface chemistry, they are not suited for quantitative surface force measurements. Tips of well-defined chemical composition can be created by functionalizing the surface with organic monolayers (alkanethiols or silanes) terminated by specific functional groups.<sup>[32]</sup> In doing so, researchers can measure local surface forces and physicochemical properties such as surface charge and surface hydrophobicity. Ahimou et al.<sup>[33]</sup> used AFM tips functionalized with ionizable carboxyl groups (COO<sup>-</sup>/COOH) to probe the surface charges of *S. cerevisiae* at the nanometer level (Fig. 6). Force–distance curves were strongly influenced by pH: While no adhesion was measured at neutral/alkaline pH, multiple adhesion forces were recorded at acidic pH. Adhesion maps always showed fairly homogeneous contrast, indicating that the cell surface properties were homogeneous. The change of adhesion forces as a function of pH was interpreted as resulting from a change of cell surface electrostatic properties, a claim that was supported by the correlation obtained between the AFM titration curve constructed by plotting the adhesion force vs. pH

**Fig. 6** Use of chemically functionalized tips for mapping cell surface charges. The left panel presents force–distance curves recorded in solutions of varying pH between the surface of *S. cerevisiae* and an AFM tip functionalized with carboxyl groups. The right panel shows adhesion force maps recorded at pH 7 and pH 4. The differences in adhesion forces observed with pH were related to a change of ionization state of the cell surface. Source: From Ref.<sup>[33]</sup>. © 2002 American Chemical Society.

and the electrophoretic mobility vs. pH curve obtained by classical microelectrophoresis. Using a similar approach, it has been shown that hydrophilic (OH) and hydrophobic (CH<sub>3</sub>) tips can be used to map cell surface hydrophobicity.<sup>[34]</sup> These studies demonstrate that chemically functionalized tips enable quantitative measurement of surface properties at the subcellular level.

### Biologically Functionalized Tips

Atomic force microscopy tips can also be functionalized with biomolecules to measure receptor–ligand interactions. A typical experiment consists in attaching ligands to the AFM tip and receptors to a solid substrate, or vice versa, bringing the modified surfaces in contact, and then measuring the unbinding force by pulling the tip away from the substrate. Successful measurements require that the binding of the biomolecules to the tip and substrate is much stronger than the intermolecular force. This is typically achieved by

using the chemisorption of alkanethiols on gold or the covalent binding of silanes on silicon oxide. Using this technique, a variety of intermolecular forces have been measured in recent years, among which the forces between biotin–avidin, antibody–antigen, complementary strands of DNA, carbohydrate–carbohydrate, and lectin–carbohydrate.<sup>[16,35,36]</sup>

Although they are not yet widely used in microbiology, AFM tips modified with biomolecules have a promising potential to measure receptor–ligand interaction forces associated with cell surfaces. This approach was recently applied to measure the specific interactions involved in yeast flocculation, an aggregation event of crucial importance in fermentation technology.<sup>[37]</sup> The yeast *Saccharomyces carlsbergensis* is known to flocculate according to a lectin-mediated mechanism in which active lectin receptors appear at the cell surface in the stationary phase and bind mannose residues of adjacent cells (Fig. 7). Atomic force microscopy tips functionalized with oligoglucose carbohydrates were used to record force–distance curves on yeast cells. While nonflocculating

**Fig. 7** Use of biologically functionalized tips for probing cell surface receptors. Optical micrographs of *S. carlsbergensis* cells in the exponential phase (left) and in the stationary phase (right). Force curves recorded between exponential (left) or stationary (right) cells and AFM tips functionalized with oligoglucose carbohydrates. The adhesion force measured on stationary cells was attributed to the specific interaction between cell surface lectins and glucose residues on the AFM tip.

exponential cells showed no or poor adhesion, stationary cells showed adhesion forces of 121 pN (Fig. 7). Control experiments (blocking with mannose, use of a nonfloculating strain) lead to the conclusion that the measured adhesion forces reflected individual lectin-carbohydrate interactions involved in yeast flocculation. This type of experiments should have an important impact on medicine because they may be used to measure the interaction forces between pathogens and host cells.

“Cell probes” represent another type of biologically modified tips that are useful for measuring interaction forces between cells and solid substrata. Here a crucial issue is to ensure that both the metabolic activity and natural surface architecture are preserved during immobilization procedures. In this context, Bowen and coworkers developed an approach in which a single living cell is glued on the apex of a tipless cantilever using a micromanipulator. In doing so, the adhesion between fungal spores,<sup>[38]</sup> yeast cells,<sup>[39]</sup> and various solid surfaces was directly quantified. Another non-destructive strategy consists in coating an amino-functionalized bead with living bacterial cells and then attaching it to an AFM cantilever. This approach enabled the forces between *Shewanella oneidensis* bacteria and mineral surfaces to be quantitatively measured;<sup>[40]</sup> an important finding was that stronger adhesion energies were measured under anaerobic conditions. Accordingly, AFM-based force spectroscopy measurements provide a means to study a variety of cellular interactions at the molecular level.

### Mechanical Properties of Single Molecules

Remarkably, AFM can also be used to probe intramolecular forces associated with individual molecules, thereby providing quantitative information on the elasticity of the molecules, on conformational transitions along the chains, on the mechanical stability of chemical bonds, and on secondary structures. In recent years, these single-molecule force spectroscopy experiments have been applied to a variety of biomolecules, including DNA, proteins, and polysaccharides.<sup>[16,35,36,41–43]</sup> Outstanding work has also been carried out on isolated microbial cell surface layers. In the first such study, Müller, Baumeister, and Engel<sup>[44]</sup> combined AFM imaging and force spectroscopy to unzip proteins from the hexagonally packed intermediate (HPI) layer of *Deinococcus radiodurans*. Force-extension curves recorded for the inner surface of the HPI layer showed saw-tooth patterns with six force peaks of about 300 pN. This behavior was attributed to the sequential pulling out of the protomers of the hexameric HPI protein complex. After recording the force curve, a molecular defect the size of a hexameric complex was clearly visualized by

means of high-resolution imaging. In another study, Oesterhelt et al.<sup>[45]</sup> unraveled the unfolding pathways of individual bacteriorhodopsins. Molecules were individually extracted from the membrane, anchoring forces of 100–200 pN being found for the different helices. Upon retraction, the helices were found to unfold and the force spectra revealed the individuality of the unfolding pathways. Scheuring et al.<sup>[46]</sup> combined AFM imaging and single-molecule force spectroscopy to gain insight into the mechanical properties of the *Corynebacterium glutamicum* S-layer. The results provided a basis for understanding the extraordinary stability of these protein networks that protect microorganisms from hostile environment. The above studies demonstrate that AFM imaging and force spectroscopy is a powerful approach to address the structure-function relationships of microbial cell surface layers at the single molecule level.

Single-molecule elasticity experiments on living cells are very challenging in view of the complex and dynamic nature of their surface architecture. Recent studies indicate that progress is being made in this area. Atomic force microscopy was used to pull on macromolecules exposed at the surface of living *A. oryzae* spores with the aim to gain insight into their elasticity.<sup>[22]</sup> As mentioned earlier, topographic imaging revealed that, upon germination, the crystalline-like surface of dormant spores changed into a layer of soft granular material attributed to cell surface polysaccharides. This structural modification was correlated with a change of molecular interactions: While dormant spores showed poor adhesion, germinating spores showed attractive forces of 400 pN magnitude along with elongation forces that were attributed to the stretching of the cell surface polysaccharides (Fig. 8). This interpretation was supported by the finding that fitting the curves with a theoretical model from statistical mechanics yielded parameters similar to those reported for individual amylose and dextran molecules. It was concluded that the stickiness and flexibility of cell surface polysaccharide chains may promote spore aggregation via macromolecular bridging interactions between opposing cells.

Single-molecule force spectroscopy has also been applied to bacterial cells. The elasticity and adhesion of surface polymers from *Pseudomonas putida* was measured in solvents spanning a range of polarity and ionic strengths.<sup>[47]</sup> Adhesion forces in water and formamide were about the same and smaller than forces observed in methanol. Different models from statistical mechanics were used to analyze the force-extension profiles. Although biopolymer contour lengths varied over a wide range in all solvents, shorter lengths were observed when salt was present, indicating that the polymer chains were less extended in the presence of salt. In a related study, the heterogeneity

**Fig. 8** Pulling on cell surface macromolecules. Force–distance curve recorded under water between a silicon nitride tip and the surface of a germinating *A. oryzae* spore (thin line). The elongation force was well described by an extended freely jointed chain model (thick line) with parameters consistent with the stretching of a single polysaccharide chain.

in bacterial surface macromolecules was probed on the surface of *P. putida*.<sup>[48]</sup> Force measurements on different bacterial cells showed a range of adhesion affinities and polymer lengths, but substantial heterogeneity was also observed in the curves on a single bacterium. These experiments indicated that heterogeneity in biopolymer properties on an individual bacterium and within a population of bacterial cells may be much greater than previously believed and should be incorporated into models of bacterial adhesion. Summarizing, the above studies indicate that single-molecule force measurements should be very useful in future microbiological research for elucidating the properties of cell surface macromolecules.

## CONCLUSION

Atomic force microscopy imaging and force spectroscopy have recently opened a wide spectrum of novel applications for microbiologists and biophysicists. Using imaging in aqueous solution, microscopists can visualize cell surface nanostructures (surface layers, appendages), follow physiological changes (germination, growth), and monitor the effect of external agents (antibiotics, metals) in real time. By recording force–distance curves on cell surfaces, researchers can learn about local biomolecular interactions and physical properties. Spatially resolved force mapping offers a means to determine physical/chemical heterogeneities at the subcellular level, thereby providing complementary information to classical characterization methods. Force spectroscopy can be used to quantitatively probe the elasticity of cell wall components and whole cells. Functionalizing the AFM tip with chemical groups, biomolecules, and living cells enables quantitative measurements of surface charge, surface hydrophobicity, receptor–ligand interactions, and cell–material interactions. Finally, single-molecule force

spectroscopy can be applied to cell surface molecules to gain insight into their mechanical properties. Clearly, these AFM-based experiments contribute to improve our understanding of the structure–function relationships of microbial cell surfaces and will have considerable impact on biotechnology and medicine.

## INTRODUCTION

Sorption plays an important role both in natural waters and in water treatment processes, and is one of the techniques used to remove metal ions from aqueous solutions. However, the uptake of metal ions from aqueous solutions is limited by interactions between ions and surfaces in contact with the solution. Moreover, the fate and transport of metal ions are controlled by their reactions with surfaces at the solid–liquid interface. For example, inorganic colloids such as clays, metal oxides, and carbonates have been reported as effective sorbents of metal ions through ion exchange and surface complexation reactions.<sup>[1–4]</sup> It has also been noted that surface properties of sorbents, such as surface charge and electrical double layer, change continuously during sorption of metal ions.<sup>[5,6]</sup> As a result, physical transport, chemical reactivity, and/or bioavailability of the pollutants is altered during the sorption process.

Earlier studies have shown that sorption of ions from aqueous solutions by colloidal particles affects colloidal stability, mobility, and reactivity.<sup>[2,7–11]</sup> This sorption process also has significant influences on interparticle forces and the zeta potential of the colloidal sorbent. In most cases, reactions of metal ions with functional groups on the surface of particles are time-dependent.<sup>[12]</sup> A quantitative understanding of the changes in surface properties caused by chemical interactions between the particles and the ions present in the surrounding environment is critical to the prediction and control of the behavior of the colloidal system. This knowledge can be obtained by using atomic force microscopy (AFM), which provides direct and real-time measurements of colloidal forces during sorption of ions. However, the extent of metal ion sorption by colloidal particles is strongly influenced by several factors such as solution pH, ionic strength,

size and type of the substrate, concentration of metal ions and particles, reaction time, and temperature.<sup>[6]</sup> Atomic force microscopy is employed here to elucidate the influence of solution ionic strength and concentration of metal ions on sorption and colloidal behavior. The AFM cantilever with an attached colloidal particle can be regarded as a sensor in water/wastewater systems.

## ATOMIC FORCE MICROSCOPY

Atomic force microscopy was developed from scanning tunneling microscopy by Binnig, Quate, and Gerber<sup>[13]</sup> in 1986. In addition to rendering images of surfaces with nanoscale resolution, AFM has been used extensively in direct measurements of interaction forces between approaching similar surfaces and dissimilar surfaces such as particle–particle,<sup>[14–27]</sup> particle–plate,<sup>[19,25,28]</sup> and particle–bubble<sup>[29–37]</sup> surfaces.

The influences of solution conditions such as pH and ionic strength were investigated.<sup>[5,14–19,25]</sup> The measured force was discovered to decay exponentially with distance when the ionic strength increases and the pH decreases. The comparison between experimental data and the prediction of the Poisson–Boltzman equation<sup>[14,18]</sup> as well as the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory was performed in some cases (e.g., Refs.<sup>[5,15–17,19,25]</sup>). Such studies clearly showed good agreement. The type of solution also plays a role in interfacial forces. For example, with increasing weight fraction, alcohol was found to suppress the long-range electrostatic repulsive force and to enhance the attractive force.<sup>[20]</sup>

Atomic force microscopy has been used to explore non-DLVO as well as DLVO forces.<sup>[21–24,28,38]</sup> For instance, the interaction between bacteria and the silicon nitride surface of the AFM tip was dominated

by steric force.<sup>[38]</sup> The steric force and the thickness of polymer layers on the surface of bacteria were affected by the solution pH. In solutions of high ionic strength, a repulsive hydration force was found to exist between similarly charged hydrophilic particles, whereas attractive forces were found to exist between oppositely charged hydrophilic particles.<sup>[21]</sup> Both short-range and long-range hydrophobic attractive forces were analyzed by Rabinovich and Yoon<sup>[23]</sup> and Nalaskowski et al.<sup>[24]</sup> for different types of systems.

Atomic force microscopy can be used to evaluate surface charge density. Based on force measurements between silica and  $\alpha$ -alumina surfaces for different values of solution pH, the zeta potential was found to be in agreement with the values obtained from direct electrokinetic measurements.<sup>[17]</sup> A similar study was conducted by Butt,<sup>[39]</sup> who used AFM to determine local surface charge densities of the plasma membranes of *Halobacterium halobium* in electrolyte solutions. Butt's previous work<sup>[40]</sup> revealed that the electrostatic force increases with increasing surface charge density and decreases roughly exponentially with distance. It can be reduced by imaging in high salt concentrations. Electrical double layers were also examined.<sup>[26,41]</sup> A repulsive force resulting from the overlapping of electrical double layers of similar approaching surfaces in intermediate-pH aqueous electrolyte solutions was observed.<sup>[18]</sup>

Information obtained from AFM measurements, including surface charge densities,<sup>[27,39]</sup> steric interactions,<sup>[28,38]</sup> and functional groups on surfaces,<sup>[41,42]</sup> is helpful in determining the structure of biological macromolecules and in understanding their functions through interparticle forces. In addition, AFM has been successfully employed to determine the Hamaker constant in various systems<sup>[15,16,27]</sup> and to evaluate the roughness of interfaces.<sup>[24,43]</sup>

The study of surface forces between colloidal probes and air–bubble interfaces has received increased attention in the past decade. A repulsive force was observed between a hydrophilic particle and a bubble, whereas a force between a hydrophobic particle and a bubble exhibited strong attraction.<sup>[29,30]</sup> The dependence of particle–bubble interactions on surfactant molecules was studied.<sup>[31,32]</sup> The force between a hydrophobic particle and an air–bubble interface was found to become repulsive when surfactants were added to the aqueous solution. Contact angle and adhesion also decreased simultaneously. For hydrophilic particles, different behaviors were observed depending on the adsorption of surfactants on the particle surface.

Besides particle–bubble interactions, surface interaction forces of oil–particle,<sup>[34]</sup> oil–water,<sup>[35]</sup> and protein inclusion bodies–bubble<sup>[36]</sup> systems were determined as well. Atomic force microscopy was also applied to measure the contact angle.<sup>[32,37]</sup>

The use of AFM to study changes in topography and surface forces as a result of sorption was recently reported. The type and concentration of both electrolyte solutions and surfactants were shown to have an effect on the structure of surfactants adsorbed onto the surface and also on the sorption behavior.<sup>[15,23,24,44–52]</sup> The structural transformation of the mixture between two surfactants that have different surface aggregate structures was investigated by Ducker and Wanless.<sup>[53]</sup> The shape of the aggregate at interfaces can be controlled by the mole fraction of surfactants in bulk solution. The establishment of changes in electrokinetic properties of surfaces because of the adsorption of surfactants was performed quantitatively.<sup>[54]</sup>

Temperature is also an important parameter in determining the adsorbed surfactant structure.<sup>[55,56]</sup> The binding site competition between cations in the electrolyte solution and cationic surfactant was observed.<sup>[57]</sup> Protons were found to produce more defects in the aggregates of surfactants than potassium ions do. Although surfactants slow the adsorption of hydrogen ions, it has no effect on that of potassium ions.

Atomic force microscopy provides not only information on force measurements because of sorption of surfactants, but also images of the structure of surfactants such as copolymer<sup>[56]</sup> and blend components.<sup>[58]</sup>

## SORPTION OF METAL IONS

The sorption of metal ions has been widely studied by flame atomic absorption spectrometry (FAAS), voltammetric techniques, potentiometric titrations, time-resolved laser fluorescence spectroscopy (TRLFS), X-ray absorption fine structure (XAFS) spectroscopy, X-ray absorption spectroscopy, extended X-ray absorption fine structure (EXAFS) spectroscopy, biosorption, etc.<sup>[6,59–66]</sup> Most of the experimental studies of metal sorption by particles have been described by distribution ratios or isotherm equations such as the Langmuir and Freundlich models.

In recent studies, AFM has been used to investigate the sorption of metal ions. For example, the adsorption of copper ions onto a silicon nitride probe was qualitatively studied by Larson and Pugh.<sup>[67]</sup> Chin, Yiacoymi, and Tsouris<sup>[5]</sup> used AFM to measure colloidal surface forces between a silica particle and a smooth glass plate in an aqueous solution, both with and without the presence of copper ions. The adsorption of metal ions on oxide surfaces was found to include specific interactions between ions and surface hydroxyl groups.<sup>[5,6]</sup> Under acidic conditions, copper ions have a low sorption affinity for oxide surfaces. Furthermore, the surface charge of silica is positive at low pH (lower than pH 2) and copper also has a

positive charge. Therefore silica and copper repel. During the experiment, the surface charge density of the silica particle remained the same because no sorption occurred. The experiment also showed that the interaction force between the silica particle and the glass plate was similar to that measured in solutions without copper ions.<sup>[5]</sup>

The sorption of metal ions by oxide surfaces was found to increase as the pH of the solution increases.<sup>[2,12,68–70]</sup> Tenorite (CuO) and metastable copper hydroxide are the dominant copper species at high pH. The removal of copper ions is attributed to the precipitation of tenorite.<sup>[6]</sup> If copper precipitates accumulate on silica particles, the forces are expected to change because the zeta potential of copper precipitates is different from that of silica.

Typically, each metal ion species has a critical pH range in which sorption competence increases from close to zero to 100%. Silica particles have OH<sup>−</sup> groups on the surface. The isoelectric point of silica occurs at approximately pH 2.<sup>[6]</sup> Above this pH, silica exhibits a negative zeta potential. However, silica shows a positive zeta potential at lower pH values. Therefore at the experimental pH of 5.5, silica has a negative charge. The force between the silica and the glass plate is repulsive because the plate also has a negative charge. For negatively charged colloids, charge reversal from negative to positive is usually observed with the presence of hydrolyzable metal ions above the pH of zero charge of colloids.<sup>[5]</sup>

At neutral pH, the sorption of copper ions causes the charge reversal of silica particles, thus changing the force between the silica particle and the glass plate from repulsive to attractive. Experimental data agreed well with calculations based on the DLVO theory for the case of constant surface charge. Electrostatic repulsion was found to decrease with increasing ionic strength and decreasing pH.

In addition to other sorption mechanisms, the formation of surface precipitates may also be a factor in changes in force profiles with time because the dissolution of silica can lead to the formation of metal ion surface precipitates.

By conducting the same experiment but using non-sorptive polystyrene particles instead of silica, Chin, Yiacomí, and Tsouris<sup>[5]</sup> also proved that no sorption of copper ions onto the glass surface occurs at experimental pH. The force between the tip and the glass was found to be repulsive; therefore Chin et al. concluded that no sorption of copper ions onto the glass plate had occurred.

Changes in the surface charge and the adjacent electrical double layer caused by the sorption of ions have been previously demonstrated.<sup>[5,6]</sup> If sorption occurs on the external surface of colloidal particles suspended in an aqueous solution, the resulting modification of

the electrical double layer is reflected in the interaction force between two particles. Therefore by measuring this interaction force as a function of time during sorption, it is possible to extract information on the sorption kinetics of ions by particles. The concept is employed in this work to investigate the effect of copper ion sorption by a silica particle on the interaction force between the particle and the glass plate. Note that in this study, the term *sorption* generally refers to various mechanisms of metal ion accumulation on silica particles.

## PRINCIPLE OF ATOMIC FORCE MICROSCOPY AND DATA ANALYSIS

Atomic force microscopy controls the movement of samples by applying a voltage to the piezoelectric tube, whereas the deflection of the cantilever is monitored using a laser beam. This beam was focused on the end of the cantilever and reflected to a photodiode. Deflection-vs.-displacement data were converted to ASCII format by the NanoScope software (Digital Instruments, Santa Barbara, CA) and imported into a spreadsheet program. To achieve a force-vs.-separation curve, zero values for force and distance were defined. The zero value for force was set at the point at which the deflection was constant. Zero distance was determined to be the position at which the deflection of the tip was the same as the displacement of the sample. The force was then calculated by means of Hooke's law:

$$F = kx \quad (1)$$

where  $F$  is the force,  $k$  is the spring constant, and  $x$  is the tip deflection. The separation distance is the sum of the tip deflection and the sample displacement.

## DERJAGUIN–LANDAU–VERWEY–OVERBEEK THEORY

According to the theory of colloidal stability (DLVO), the interaction force can be separated into two contributions: a repulsive electrostatic interaction, and an attractive van der Waals force.<sup>[71]</sup> The total interaction force  $F_{DLVO}$  is taken as a sum of these two terms:

$$F_{DLVO} = F_{\text{electrostatic}} + F_{\text{vdW}} \quad (2)$$

where  $F_{\text{electrostatic}}$  and  $F_{\text{vdW}}$  refer to the electrostatic and van der Waals components, respectively.

Although the system geometry is for sphere–flat plate interactions, the radius of the AFM tip was small relative to the flat plate and can be simplified. To

describe the electrostatic interaction force, a linearized form of the Poisson–Boltzmann equation and the Derjaguin approximation was used. The electrostatic interaction force is calculated from:

$$F_{\text{electrostatic}} = \frac{4\pi\sigma_{\text{silica}}\sigma_{\text{glass}}R}{\epsilon\kappa} e^{-\kappa D} \quad (3)$$

where  $\sigma_{\text{silica}}$  and  $\sigma_{\text{glass}}$  are the charge densities of a silica particle and a glass plate, respectively;  $R$  is the radius of the particle tip;  $\epsilon$  is the permittivity of water;  $\kappa$  is the inverse of double-layer thickness; and  $D$  is the separation distance. The inverse of the double-layer thickness is described as:

$$\kappa \equiv 5.552 \times 10^{-6} \sqrt{I/\epsilon kT} \quad (4)$$

where  $k$  is the Boltzmann constant,  $T$  is the absolute temperature, and  $I$  is the ionic strength.

Within the Derjaguin approximation, a simple expression for the non-retarded van der Waals forces is given by:

$$F_{\text{vdW}} = -\frac{AR}{6D^2} \quad (5)$$

where  $A$  is the Hamaker constant. Based on Lifshitz theory, the Hamaker constant ( $A$ ) for silica and glass in water was found to be  $5.4 \times 10^{-21}$  J.

The total force is:

$$F_{\text{DLVO}} = \frac{4\pi\sigma_{\text{silica}}\sigma_{\text{glass}}R}{\epsilon\kappa} e^{-\kappa D} - \frac{AR}{6D^2} \quad (6)$$

The measured zeta potentials of the sphere and the substrate were converted to surface charge densities by using the Grahame equation<sup>[72]</sup> and by assuming that the zeta potential is the same as the surface potential:

$$\sigma = 0.117[I]^{1/2} \sinh(\psi_0/51.4) \quad (7)$$

where  $\psi_0$  is the surface potential [mV] and  $\sigma$  is the surface charge density [C/m<sup>2</sup>]. This model is based on the assumption that the surface charge remains constant as the two surfaces approach each other. Previous studies<sup>[11,16,19]</sup> showed that the assumption of constant surface charge is more accurate than the assumption of constant surface potential because of large changes in surface potential as the two double layers interpenetrate.

## MATERIALS AND METHODS

### Colloidal Probe Preparation

In this study, 3- $\mu\text{m}$  silica particles from Bangs Laboratories, Inc. (Fishers, IN) were used as colloidal probes. The particles were non-porous and had hydroxyl (–OH) surface groups. A silica particle was glued to the end of a tipless contact-mode cantilever (Digital Instruments) with epoxy (ITWDevcon, Danvers, MA) by means of a micromanipulator and a camera/monitor system. Two sharp-tip needles were attached to the micromanipulator. The first was used to transfer epoxy glue to the end of the cantilever, and the second was used to pick up a silica particle and place it on top of the epoxy. Consequently, the free surface of the colloidal probe is glue-free.

The spring constant is a critical factor in the conversion of deflection data to force and can be estimated from the geometry, mass, and Young's modulus of a cantilever.<sup>[17,21,23]</sup> To have more accurate force data, the spring constants of cantilevers were verified by using the “cantilever tune” function in AFM. Because the resonant frequency of a cantilever changes after an additional mass is loaded, frequencies were measured before and after a particle was glued on the cantilever. The mass of the added particle  $M$  was calculated from its density, as reported by the manufacturer. Particle size was determined by scanning electron microscopy (SEM). The spring constant of the cantilever  $k$  was then calculated by the method of Cleveland and Manne:<sup>[73]</sup>

$$k = (2\pi)^2 \frac{M}{(1/\nu^2) - (1/\nu_0^2)} \quad (8)$$

where  $\nu_0$  and  $\nu$  are the resonant frequencies of a cantilever before and after the loading of particle, respectively. The cantilever with a 3- $\mu\text{m}$  silica particle tip is shown in Fig. 1.

### Sample Preparation

The substrate was a non-sorptive borosilicate glass coverslip. The coverslips (Ted Pella, Inc., Redding, CA) were cleaned by soaking them overnight in a 1 N HCl solution (Fisher Scientific, Fair Lawn, NJ). They were then immersed in acetone (Aldrich, Milwaukee, WI) for 30 min, boiled in a mixture of 5H<sub>2</sub>O:1H<sub>2</sub>O<sub>2</sub>:1NH<sub>4</sub>OH at 85°C for 25 min, washed with chromic acid (LabChem, Inc., Pittsburgh, PA) for 25 min, and then reimmersed in water. Glass substrates underwent plasma cleaning (model PDC-32G; Harrick Scientific Corp., Ossining, NY) before being used to remove any residual organic contaminants. The smoothness of the surface was determined by

**Fig. 1** A SEM photomicrograph of a 3- $\mu\text{m}$  silica particle tip.

AFM images obtained using a silicon nitride tip (Digital Instruments). Water of 18 M $\Omega$ /cm resistivity at 25°C was prepared by an E-pure system (model D4631; Barnstead Thermolyne Co., Dubuque, IA).

Measurements of zeta potential were carried out using a ZetaPlus zeta potential analyzer (Brookhaven Instrument Corp., Holtsville, NY). These values were then used for theoretical calculations of interparticle forces.

### Force Measurements

Interaction forces between the small probe and the substrate were measured using AFM (model MMAFM-2; Digital Instruments). Fresh solutions at different values of ionic strength (as NaCl) and copper concentration [as Cu(NO<sub>3</sub>)<sub>2</sub>] were prepared by using triply distilled 18 M $\Omega$  deionized water. Because the sorption of copper ions onto silica particles occurs at intermediate pH values,<sup>[5,6]</sup> all solutions were prepared at pH 5.5. An O-ring was used to seal the fluid cell of the AFM to prevent flooding and to isolate the cell from possible contamination from the ambient environment. Initially, the colloidal probe was immersed in NaCl solution. Then, at the beginning of the sorption experiment, the metal ion solution was manually injected into the cell.

## RESULTS AND DISCUSSION

Both the equilibrium and the dynamics of copper ion uptake by silica particles under various solution conditions were studied. A repulsive force was initially observed in all experiments. This force is attributed

**Fig. 2** Dynamic force-profile measurements during the adsorption of copper ions by a silica tip for a copper concentration of  $7.6 \times 10^{-6}$  M. Ionic strength = 0.005 M NaCl, pH = 5.5,  $A = 5.43 \times 10^{-21}$  J. Data points represent direct force measurements by AFM. Lines represent predictions of the DLVO theory for the corresponding values of the zeta potential.

to an electrostatic repulsion between the negatively charged silica particle tip and the negatively charged glass surface. After copper ions were introduced into the system, they began to be adsorbed onto the surface of the silica particle. Consequently, the surface charge of silica was converted from negative to positive, and the repulsive force was gradually changed to an attractive force. The zeta potential of silica particles was a variable parameter that was used in calculations based on the DLVO theory to fit the experimental data. In Figs. 2 through 9, symbols represent force measurements at different times during sorption, and calculated results are represented by lines.

**Fig. 3** Dynamic force-profile measurements during the adsorption of copper ions by a silica tip for a copper concentration of  $1.5 \times 10^{-6}$  M. Ionic strength = 0.005 M NaCl, pH = 5.5,  $A = 5.43 \times 10^{-21}$  J.

**Fig. 4** Dynamic force-profile measurements during the adsorption of copper ions by a silica tip for a copper concentration of  $7.6 \times 10^{-7}$  M. Ionic strength = 0.005 M NaCl, pH = 5.5,  $A = 5.43 \times 10^{-21}$  J.

**Fig. 7** Dynamic force-profile measurements during the adsorption of copper ions by a silica tip for an ionic strength of 0.05 M NaCl. pH = 5.5, copper concentration =  $7.6 \times 10^{-5}$  M,  $A = 5.43 \times 10^{-21}$  J.

**Fig. 5** Equilibrium state of adsorption of copper ions by a silica tip. Ionic strength = 0.005 M NaCl, pH = 5.5,  $A = 5.43 \times 10^{-21}$  J.

**Fig. 6** Effect of ionic strength on force-profile measurements at equilibrium.

### Effect of Metal Ion Concentration

The effect of copper concentration on the interaction force between a colloidal silica probe and a glass substrate was investigated. The forces were measured for solutions of various copper ion concentrations at a background electrolyte concentration of 0.005 M and at a pH of 5.5. In the previous study, Chin, Yiacoumi, and Tsouris<sup>[5]</sup> observed an immediate change in the measured force because of sorption of copper ions, with the surface charge of the silica particle being reversed from negative ( $-48$  mV) to positive (2 mV) in 10 min.

Fig. 2 presents the total measured force for  $7.6 \times 10^{-6}$  M copper concentration, which is 10 times lower than the concentration used by Chin, Yiacoumi,

**Fig. 8** Dynamic force-profile measurements during the adsorption of copper ions by a silica tip for an ionic strength of 0.0005 M NaCl. pH = 5.5, copper concentration =  $7.6 \times 10^{-5}$  M,  $A = 5.43 \times 10^{-21}$  J.

**Fig. 9** Equilibrium state of adsorption of copper ions by a silica tip. pH = 5.5, copper concentration =  $7.6 \times 10^{-5}$  M,  $A = 5.43 \times 10^{-21}$  J.

and Tsouris<sup>[5]</sup> As shown in this figure, sorption progressed more slowly than in the previous study, with the charge reversal occurring in 60 min. Because the concentration gradient was lower, a longer period of time was required for the surface of the silica particle to be fully covered by copper ions. The interaction force reached equilibrium after approximately 164 min. Similar experiments were repeated at the same pH and ionic strength with  $1.5 \times 10^{-6}$  and  $7.6 \times 10^{-7}$  M copper concentrations, as shown in Figs. 3 and 4, respectively. The sorption of copper ions onto a silica tip took place at a slower rate because of the lower concentration gradient. Approximately 180 min was required for the interaction force to reach equilibrium when the concentration of copper was  $1.5 \times 10^{-6}$  M, whereas 240 min was required when the concentration of copper was  $7.6 \times 10^{-7}$  M. These results indicate that as the metal ion concentration is decreased, more time is required for the interaction force to reach equilibrium.

Metal ion sorption equilibrium using various metal ion concentrations is shown in Fig. 5. At equilibrium, a strong attractive force was found in all solution conditions, indicating that the surface of the silica particle was fully covered by copper ions. The surface charge was positive in all cases. Therefore at equilibrium, the surface charges of a silica sphere and a glass plate have opposite signs, which lead to an attractive force. The measured forces for all solution conditions demonstrated the same behavior. The zeta potential of the silica particle at equilibrium was estimated to be +65 mV, which matched the calculated result according to the DLVO theory based on Eq. (6). This behavior shows that for the concentration range used in these experiments, the metal ion concentration had no effect on sorption at equilibrium, which can be explained by the full coverage of sorption sites.

## Effect of Ionic Strength

All sorption experiments were conducted at  $7.6 \times 10^{-5}$  M copper concentration and at a pH of 5.5, using different ionic strengths. The force–distance profiles between a silica sphere and a glass plate in a variety of NaCl solutions without copper ions (Fig. 6) indicate that the magnitude of electrostatic repulsion decreases with increasing ionic strength. This behavior can be explained by Eq. (4), in which decay length is reduced as ionic strength is increased because of the compression of the electrical double layer. As the ionic strength is increased, as shown in Eq. (7), this value overcomes the repulsion caused by an increase in the surface charge density.

Figs. 7 and 8 present the curves for force-vs.-separation distance for the silica–glass system at a copper concentration of  $7.6 \times 10^{-5}$  M in 0.05 and 0.0005 M NaCl solutions, respectively. These figures show that sorption is a relatively fast process. In the case of high ionic strength, surface charge reversal occurred 2 min after the copper ion solution was introduced into the system. However, at a much lower ionic strength, a repulsive force was still observed after the same period of time. Although the latter system required a longer period of elapsed time before reversal of the surface charge occurred, both systems reached equilibrium within approximately the same time (1 hr).

Equilibrium measurements of the same copper concentration but performed with solutions of different ionic strength are illustrated in Fig. 9. All force curves exhibited a strong attractive force at equilibrium, confirming the findings of Subramaniam, Yiacoumi, and Tsouris<sup>[6]</sup> that ionic strength has no significant effect on sorption equilibria.

## CONCLUSION

Atomic force microscopy was used to investigate the effect of metal concentration and ionic strength on metal ion sorption. Changes in interaction forces as a function of time demonstrated surface charge reversal and the occurrence of sorption. This study also showed that metal concentration has an effect on sorption dynamics (e.g., charge reversal occurs more slowly and the system requires a longer period of time to reach equilibrium at a lower concentration). However, ionic strength has no significant effect on sorption kinetics. Moreover, neither metal concentration nor ionic strength exhibits any effect on sorption equilibria, indicating that surface sites of the silica particle are fully covered by copper ions under the experimental conditions in this study.

## ACKNOWLEDGMENTS

Support for this research was provided by the National Science Foundation through a Career Award (BES-9702356 to S.Y.) and by the Division of Chemical Sciences, Office of Basic Energy Sciences, U.S. Department of Energy, under contract DE-AC05-00OR22725 with UT-Battelle, LLC. The authors are also thankful to Dr. Marsha K. Savage for editing the manuscript.

# AFM: Nanolithography on Organized Films

Seunghyun Lee

Haiwon Lee

*Department of Chemistry, Hanyang University, Seoul, South Korea*

## INTRODUCTION

The ongoing miniaturization in size and integrity of electronic and mechanic devices has led to an interest in fabrication of nanometer-sized uniform structures on surfaces. With the device downscaling dimensions to the nanometer range, current interest is focused on the state-of-the-art lithographic development such as electron beam lithography, extreme UV lithography, imprint lithography, and scanning probe microscope (SPM) lithography. Binnig et al.<sup>[1]</sup> first developed the scanning probe microscope in 1982, and since then, SPM have been primarily used to obtain topographic and electronic surface maps. Nowadays, SPM is also being used to fabricate patterns and structures in nanometer scale, as well as to directly modify chemical or physical structure of surfaces.

Among several nanolithographic methods, scanning probe lithography (SPL) is one of the best lithographic techniques for forming nanostructures. Scanning probe lithography using a sharpened tip of an atomic force microscope (AFM) or a scanning tunneling microscope (STM) with the highest spatial resolution has demonstrated outstanding capabilities for atomic-level manipulation, and also wide varieties of potential applications such as electronic devices,<sup>[2,3]</sup> biochips, and biosensors<sup>[4,5]</sup> using different approaches—a direct method of writing patterns consisting of relatively small molecules on solid state surface, an exposure of organic thin films such as self-assembled monolayers (SAMs) and a selective anodic oxidation of various substrates. In particular, AFM lithography is the most promising method for fabricating organic thin films or the substrate itself in nanometer scale. Whereas STM-based lithography is mainly carried out in ultrahigh vacuum (UHV), fabrication using AFM lithography can be performed in liquid state as well as in ambient environment. Also, several novel methods using AFM as a lithographic tool have been developed in the past 10 years. This is a very active research area because of the flexibility and simplicity of the technique. In this technique, an AFM tip may be used to carry catalysts to selectively induce surface reactions, to attach molecules on surfaces as a pen,

and to direct local oxidation on surfaces as an electrode.

Subsequently, several principal AFM nanolithography techniques on organized molecular films such as self-assembled monolayers, Langmuir–Blodgett (LB) monolayer, and spin-coated polymer films will be illustrated.

## AFM-BASED NANOLITHOGRAPHY

### Dip-Pen Nanolithography

Mirkin et al.<sup>[6,7]</sup> introduced a dip-pen nanolithography (DPN) to construct patterns of molecules on a substrate in a positive printing by using an AFM tip as a “pen,” Au substrate as a “paper,” and alkanethiols with chemical affinity for Au substrate as “molecular inks.” In DPN, molecules are moved from the AFM tip to the solid substrate via capillary action to perform nanoscale patterns directly. The schematic diagram of patterning process in a DPN is shown in Fig. 1, and Fig. 2 represents the nanopatterns of alkanethiol on gold substrate via DPN.

Although DPN resolution relies on some parameters such as grain size of Au substrate, the contact time of tip–substrate, and relative humidity, this technique is a simple method for transporting molecules from AFM tip to substrate to control the architecture of a surface on the sub-100 nm.

Recently, DPN has been improved to generate nanoarray with dot-and-line pattern of biomolecules such as proteins, oligonucleotides, and magnetic nanoparticles. In case of fabricating magnetic nanostructures, 16-mercaptohexadecanoic acid (MHA) is used to make nanopatterns on Au substrate via DPN at the first stage, and then this patterned Au substrate is dipped into 1-octadecanethiol solutions to form passivated layer. Then, this sample is immersed into the iron oxide nanoparticles suspension solution once more. After going through these procedures, nanoarray with almost identical magnetic dots and lines composed of nanoparticles is prepared.<sup>[8]</sup>

To investigate a various surface-mediated biological recognition phenomenon, the construction of biomaterial

**Fig. 1** Schematic representation of DPN. A water meniscus forms between the AFM tip coated with alkanethiol and the Au substrate. *Source:* Prof. Chad A. Mirkin.

nanoarray is needed. DPN is useful not only to fabricate nanopatterns for differentiating active area from non-specific binding site of the substrate, but also to recognize specific binding properties. DPN forms nanopatterns on Au substrate using alkanethiols coated on AFM tips, and initially, the system of organothiol-gold substrate was used to fabricate nanopatterns because it was simple to use. However, the electrical conductivity of the gold substrate interferes with the observation of charge transport and near-field optical properties in building up nanostructures on surfaces like this, and also quenches the emission from any surface-bound materials with fluorescence.<sup>[9,10]</sup> Thus oxidized silicon substrate, as well as gold substrate, are used to generate nanoarray of proteins, oligonucleotides. In the case of oxidized

**Fig. 2** Nanoscale molecular letters written on an Au(111) surface with 16-mercaptohexadecanoic acid (MHA) molecules by DPN. *Source:* Prof. Chad A. Mirkin.

silicon wafers as substrate, there are two ways to modify the substrate to form nanoarray through DPN. One is to charge the silicon oxide surfaces negatively by treatment of base, and the other is to modify the surface with aldehyde functional group. AFM tip is modified by organosilane that forms a biocompatible and hydrophilic surface layer. Next, proteins are attached to the modified silicon oxide surface via DPN with AFM tip coated by immersing the tip in protein solution because of electrostatic interaction between the positively charged sites of the proteins and the negatively charged surface or covalent bonding between the surface with aldehyde functional head group and amine group on the proteins.<sup>[11]</sup> In a similar manner, DPN can be extended to useful direct-write methods to fabricate nanoarray of proteins using silicon oxide substrate and gold substrate.

### Nanografting Lithography

Liu et al.<sup>[12-14]</sup> have reported the nanografting technique for fabricating a patterned self-assembled monolayer (SAM) by combining mechanical displacement of selected molecular resist by an AFM tip and backfilling of new adsorbates.

In this case, SAM alkanethiol molecules at selected areas of the gold surface are removed by an AFM tip with a force greater than the threshold displacement force to fabricate desired patterns within the SAM. Next, new alkanethiol molecules having different alkyl chains from the contacting solution are immediately adsorbed onto the exposed regions by an AFM tip. **Fig. 3** shows the procedure for the nanografting lithography.

Using nanografting, the fabricated patterns can be quickly obtained in situ without changing the mask or repeating the entire fabrication procedure.

A nanopen reader and writer (NPRW), an improved nanografting technique, was introduced to produce nanopatterns on gold surface.<sup>[15]</sup> This technique combines the advantage of both nanografting and DPN. Compared to the existing nanografting technique, the NPRW technique has several advantages. In contrast to DPN, the resolution of NPRW is not influenced by the texture of the paper and the humidity of the experimental surroundings. Also, nanopatterns are easily fabricated and characterized in both solution and ambient environments, as well as solution phase in NPRW experiments. This technique is useful for producing nanopatterned arrays of biomolecules such as DNA and proteins.<sup>[16-18]</sup>

### Constructive Nanolithography

More recently, nanopatterning techniques using applied bias between the scanning probe microscope tip and the sample were reported. Sagiv et al. suggested a constructive nanolithography<sup>[19-21]</sup> that can be adapted

Fig. 3 Schematic diagram of the nanografting process. Source: Prof. Gang-Yu Liu.

to construct hybrid metal–organic nanostructures on silicon surface. In the constructive nanolithography, an electrically conducting AFM tip composes non-destructive chemical information on the exposed outer surface of self-assembled monolayers, and converts modified surface into a nanopatterned template for spatial control of the surface self-assembly of various selected organic and inorganic nanostructures.

Metallic silver nanoparticles are generated at selected surface regions by AFM tip-induced electrochemical reduction of the surface-bound metal ions on a thiol-top-functionalized silane monolayer (TFSM).<sup>[19]</sup> They also take the shape of the organic bilayer template on spatially modified,<sup>[20]</sup> non-destructive *n*-octadecyltrichlorosilane (OTS) SAMs via an electrically biased AFM tip, and then build various inorganic particle or layer. The scheme of constructive nanolithography is summarized in Fig. 4.

### Nanolithography Using Current Sensing AFM

Zhao and Uosaki<sup>[22,23]</sup> prepared well-defined nanopatterns of alkanethiol SAMs on gold substrate by using

current sensing atomic force microscopy (CS-AFM). When the conducting tip with a sufficient bias was scanned over a SAM in inert solvent containing alkanethiols with different chain length, the original SAM underneath the tip was removed and a new nanometer-sized spatial SAM of the alkanethiol was formed. In this method, toluene was chosen as the medium because of its non-polarity and low dielectric constant. A leak of current can be avoided, and the amount of water contained in toluene also has a crucial effect on lithographic performance. The mechanism of CSAFM-based lithography is as follows:

For positive bias condition,

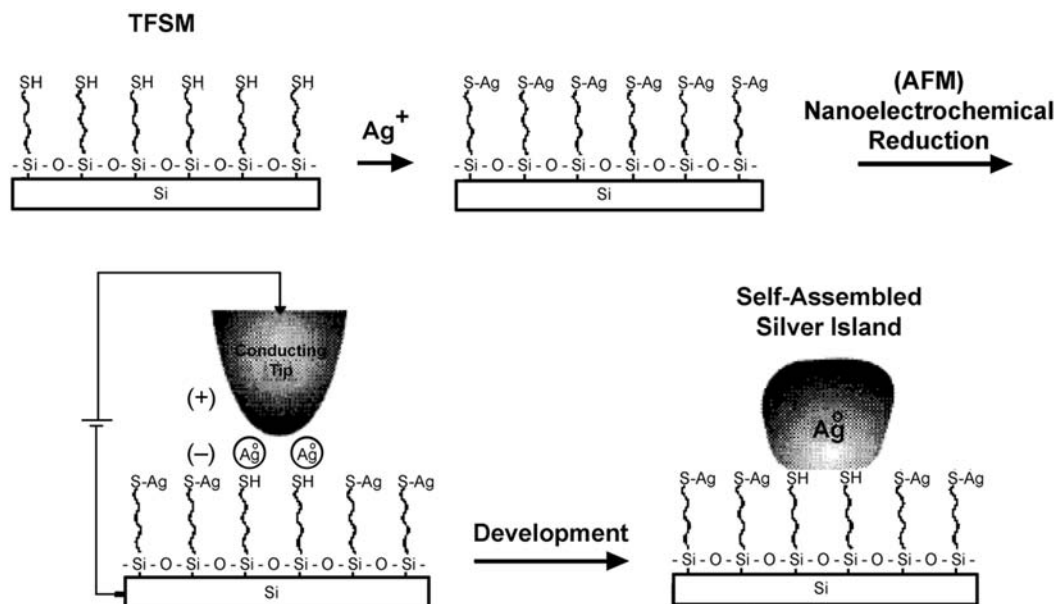

Fig. 4 Scheme of the constructive nanolithography: the site-defined self-assembly of silver metal on a thiol-top-functionalized silane monolayer preassembled on silicon. Source: Prof. Jacob Sagiv.

For negative bias condition,

### Anodization AFM Nanolithography

Some AFM-based nanolithographic methods are not practical because their lithographic speed is only in the order of nanometer/second, and both nanografting and current sensing AFM lithography are usually accomplished under liquid–solid interface.

However, the anodization lithographic technique, one of the most promising methods to prepare nanopattern with AFM, is accomplished by the reaction on the substrate surface.

AFM anodization lithography has also been reported elsewhere for producing protruded oxide patterns on a substrate by faradaic current from the cathode tip to the anode substrate.<sup>[24–37]</sup> Anodic patterning can be mainly accomplished on silicon<sup>[33,34]</sup> or titanium substrate<sup>[38,39]</sup> by electrochemical reactions mediated by the scanning probe tip. Electrochemical anodization occurs by emitted electrons from the tip at the locally scanned area on a silicon substrate in the presence of an atmospheric water column between the tip and the scanned area of the sample. This direct modification of silicon or metal surfaces by the anodization process using the electric field from an AFM tip is one promising method of accomplishing direct-writing lithography for the electronic device fabrication.

The first report of tip-induced oxidation of silicon was the STM study by Dagata et al.<sup>[40]</sup> They used an H-passivated silicon surface with a positively biased tip for generating oxide features on the surface. They suggested that the electrochemical oxidation reaction, which is locally induced beneath the tip in an adsorbed water column on the sample surface, is responsible for metal and semiconductor surfaces.

As shown in Fig. 5, the emitted electrons flow from the tip to the substrate through an organic resist, and they cause the anodization process with water on

**Fig. 5** Schematic description of AFM anodization nanolithography on silicon substrate.

the silicon substrate. Accordingly, a protruded oxide pattern is newly formed at the local area of the substrate as a result of the anodization process.

Sugimura and Nakagiri<sup>[25]</sup> have suggested an electrochemical reaction between the tip and the sample for the anodization lithography as follows:

Anode reactions at sample surface:

Cathode reaction at AFM tip:

As the AFM anodization nanolithography is closely related to the magnitude of current, the size of the protruded pattern strongly depends on the amount of accepted electrons on the substrate. Also, it has been reported that the geometric factors of the nanopattern, such as the protruding height and the line-width, are affected by scan speed or duration time of the cathode AFM tip,<sup>[26,33,37,38]</sup> surface group, environmental relative humidity,<sup>[30,34,35,37]</sup> and the applied voltage between the tip and the sample.<sup>[33,34]</sup> Even the operational mode of AFM, both contact mode and noncontact mode, also influences on anodization patterning.<sup>[41]</sup>

The key to reach high resolution and precision is to selectively modify the surface either by breaking chemical bonds or through direct chemical reactions using local tip–surface interactions. The selection of high-performance resist materials is one of the important factors in the successful application of AFM lithography.

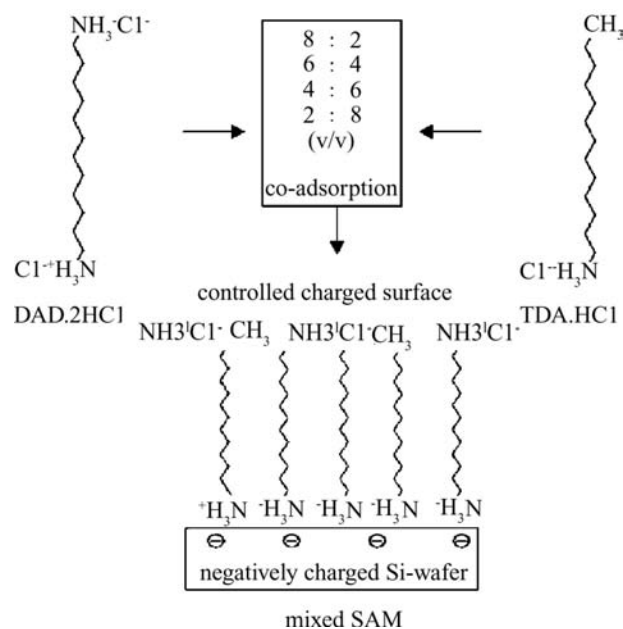

In the case of resist, the resist film should be prepared in a thin and uniform layer to attain high resolution in nanometer scale. Langmuir–Blodgett (LB) films<sup>[28,29,42]</sup> and self-assembled monolayers<sup>[27,30,43–46]</sup> have been used as resists and patterned with nanometer precision. These films are well-organized molecular assemblies formed by layer-by-layer deposition via either van der Waals force or covalent bonding.<sup>[47]</sup> The size of the molecule determines the layer thickness and can be carefully controlled to produce layers of uniform coverage. SAM films, consisting of organosilane, bipolar amphiphiles, and alkanethiol molecules, show a great potential as ultrathin resist films. Such SAM films, formed through the chemisorption onto oxide and metal surfaces, have excellent uniformity in molecular order and resistivity to various types of chemical reagents. As most of the lithographic works

with organic resists have been exclusively carried out on silicon surface for practical application, several organic resists with different functional groups have been studied in order to investigate the surface group effect on the anodic anodization using AFM.

### Anodization AFM nanolithography on self-assembled monolayers (SAMs)

Achieving fast lithographic scan speed is an important task to apply AFM to electronic devices. Because organic resist on silicon substrate can affect to the lithographic speed, it raises considerable interest in AFM anodization lithography.

In the case of AFM anodization, the electronic feature of terminal group of a resist on the surface is very important, because electrons are transferred from a tip to a substrate via the resist molecules and affects the line-width and the height of protruded oxide nanopatterns. An effective AFM lithographic process can be affected by the functional groups of self-assembled molecules. Lee and coworkers prepared the mixed SAMs of the 1,12-diaminododecane · dihydrochloride (DAD · 2HCl) and *n*-tridecylamine · hydrochloride (TDA · HCl) with the same alkyl chain on charged silicon substrate to observe effects of the surface of groups of the organic resists on lithographic AFM anodization.<sup>[27,30]</sup> Both DAD · 2HCl and TDA · HCl have an ammonium chloride on their headgroups to bind electrostatically onto charged silicon surface. In contrast to the head-group, they have different terminal groups at their air–molecule interfaces.

**Fig. 6** Preparation of the mixed SAM of DAD and TDA on a negatively charged Si wafer.

The schematic diagram of preparing mixed SAMs of DAD · 2HCl with a cationic surface group and TDA · HCl with a methyl surface group is shown in Fig. 6.

The difference of the mixing ratio of the two molecules has a great influence on the wetting property of SAM surface. The ammonium chloride ionic pair, the terminal functional group of DAD · 2HCl increases the hydrophilicity of the SAM resist, and so enlarges the size of water column between the AFM tip and the substrate interfaces related to contact angle. This characteristic causes the line-width and the height of the grown up oxide nanopattern to be expanded and the threshold voltage for protruding an oxide pattern decreases.

The results of contact angle measurement and AFM anodization lithography according to mixing ratio of DAD · 2HCl and TDA · HCl are shown in Fig. 7.

### Anodization AFM nanolithography on Langmuir–Blodgett (LB) films

Several research groups reported that the resist films could be adapted to the AFM anodization lithography to fabricate the high-resolution patterns. Pattern with tens of nanometer line-width were easily obtained when an appropriate resist was selected. Although there are many reports about the kinetics and the mechanism of silicon oxide growth in anodization process, the detailed anodization processes on the well-oriented organic resist system has yet to be clearly presented.

Lee and coworkers<sup>[28,29]</sup> used the easily obtainable Langmuir–Blodgett film of palmitic acid and hexadecylamine to elucidate the mechanism of AFM anodization process. A series of AFM images containing the lithographic stages at various bias voltage ranging from 4.00 to 8.00 V are shown in Fig. 8.

In the case of 4.00 V bias voltage in Fig. 8(A), no visible change of surface topography is observed. However, as the applied voltage increases, the growing protruded oxide patterns are sufficiently observed. To confirm the nature of the degraded surface, measured frictional force compared with the morphology changes are shown in Fig. 9.

Fig. 10A shows the AFM images patterned at 5.50 V and tip speed of 1.0 μm/sec. The degradation pattern with 202 ± 5 nm of line-width and 0.7 ± 0.3 nm of degradation depth is specified by difference between B and C points. The stripped substrate does not have the pattern of degradation but the protruded pattern with 212 ± 4 nm of line-width and 0.8 ± 0.3 nm of line-height as revealed in Fig. 10(B). The complete stripping of the resist was confirmed by the topographical change of the landmark from 1.2 ± 0.1 nm of vertical difference between B and D in Fig. 10A to 3.3 ± 0.1 nm in Fig. 10B.

**Fig. 7** (A) Water contact angle changes of the mixed SAMs at the various compositions of DAD · 2HCl and TDA · HCl. (B) Line-width changes of mixed SAMs at the various compositions of DAD · 2HCl and TDA · HCl. (C) Required applied voltages for protruding an oxide pattern with  $10 \pm 1 \text{ \AA}$  line-height using mixed SAMs at the various compositions.

This experimental result shows the direct evidence that degradation and anodization are simultaneously preceded in the AFM anodization nanolithography by a two-step mechanism: 1) a partial degradation of the resist was first achieved and 2) silicon oxide started

**Fig. 8** Lithographic pattern at constant lithographic speed at the specified voltage: (A) 4.00 V, (B) 5.00 V, (C) 5.50 V, (D) 5.85 V, (E) 6.00 V, and (F) 8.00 V.

to be grown at the presence of a resist, as shown in Figs. 8 and 9.

Among the number of factors influenced on AFM anodization lithography, the effect on polarity change of the bias potential applied between the cantilever and a

**Fig. 9** Oscilloscope mode of topographies and friction at the specified bias voltage: (A) 5.50 V, (A) 5.85 V, and (C) 6.00 V.

**Fig. 10** Topological views and cross sectional views of the patterned surface at 5.50 V bias voltage: (A) before stripping a resist film, (B) after stripping a resist film.

sample affects to generate patterned shape. Langmuir–Blodgett (LB) film composed of palmitic acid is used to investigate the polarity effect of AFM anodization lithography.<sup>[29]</sup> Lithographic result obtained at  $-10$  V of tip bias (tip negative; the normal polarity for AFM anodization lithography) shows the protruded pattern with  $1.5 \pm 0.1$  nm height and  $80 \pm 10$  nm width in Fig. 11(A). And then, as shown in Fig. 11(B), the result acquired at 10 V of tip bias (tip positive) has a grooved pattern with  $2 \pm 0.2$  nm height and  $80 \pm 10$  nm width.

This methodology, using polarity change of bias potential, will expand the application of AFM anodization lithography.

**Fig. 11** Lithographic pattern obtained at (A)  $-10$  V and (B) 10 V with section analysis.

### Anodization AFM nanolithography on the spin-coated polymer films

The preparation of ultrathin resist film is one of the key factors in the successful application of AFM lithography. From this viewpoint, spin-coated polymer film is usually easy to prepare, thermally stable, and more resistant to etching solution than organic self-assembled layer.

**Fig. 12** Topographic AFM images of the protruded lines.

**Fig. 13** Topographic AFM image of grooved line pattern after etching process.

As shown in Fig. 12, the protruded lines by AFM anodization lithography on spin-coated methacrylate-based polymer film are about 60–80 nm.<sup>[48]</sup>

Methacrylate-based polymer has a unique molecular structure of acid labile silicon whose side groups enhance the thermal stability and the etching resistance of terpolymer. Also, an organic solvent easily strips this polymer.

Fig. 13 shows the AFM image of line pattern on silicon substrate after etching of the protruded pattern of methacrylate-based polymer with appropriate hydrofluoric acid (HF) solution. The obtained line pattern is about 90 nm of line-width and 15 Å of the etched depth. After the etching process, the polymer resist

**Fig. 14** Topographic AFM image of line pattern after stripping process.

was completely removed by using a stripping process with tetrahydrofuran (THF) solvent. The AFM image of stripped line patterns having line-width of 100 nm and line-height of 28 Å is shown in Fig. 14.

Because of these characteristics, polymers can be used as practical resists in AFM anodization lithography.

## CONCLUSION

Various AFM-based nanolithography techniques are highlighted in this entry. These approaches using molecular assemblies are clearly the combination of the “bottom-up” methodology and “top-down” process to fabricate nanostructures of materials.

AFM nanolithography exhibits the highest spatial precision and resolution to reach fundamental scientific issues such as molecular fabrication, and quantum properties of specific system. These advantages make AFM a promising lithographic tool for future molecular electronics such as terabit nanostorage, and biotechnology, especially in biochips and sensors.

## INTRODUCTION

Non-specific protein adsorption onto solid surfaces occurs in many important applications. These include drug storage, where adsorption of a therapeutic protein onto the container walls may denature and render the drug inactive, as well as change its solution concentration, posing a major problem when exact dosing is required.<sup>[1]</sup> Protein adsorption can contribute to blood clotting and heart disease;<sup>[2]</sup> the biocompatibility of materials used in medical implants, food processing, and chromatographic media depends on the interaction of proteins with the surface.<sup>[3–8]</sup> Newly developed biosensors and immunoassay methods depend on the immobilization of proteins.<sup>[9]</sup> Fouling of contact lenses is due, in part, to the non-specific adsorption of protein on the lens surface.<sup>[10]</sup> In all of these applications, a fundamental understanding of protein adsorption is required to control the interaction between the protein and the solid.

This entry discusses the role of atomic force microscopy (AFM) in elucidating protein adsorption mechanisms onto solid surfaces. After a brief review of other experimental techniques, we outline the advantages and disadvantages of AFM for in situ study of protein adsorption and summarize findings for AFM available to date. We conclude with a brief discussion of the protein adsorption process.

## OVERVIEW

### Measurement Techniques

A wide range of techniques provides information on protein adsorption onto solid surfaces. Vibrational sum frequency spectroscopy (VSFS)<sup>a</sup> is a surface-specific

non-linear optical technique in which a sum frequency signal is obtained from an ordering of dipoles at surfaces. Moieties that are well aligned at the surface can be observed by VSFS. Using this technique, information on protein organization in addition to water structure and organization can be obtained. In particular, Kim et al.<sup>[11]</sup> used this technique to study the organization of lysozyme at the water/quartz interface at various pH values.

The interaction force between two solid surfaces can be measured as a function of distance by the surface force apparatus (SFA). Claesson et al.<sup>[12]</sup> employed SFA to study a wide range of proteins (globular, unordered, fibrous) and determined protein conformation, orientation, and the operative forces. Small compact globular and soft globular proteins could be distinguished by measuring their compressibility. Blomberg et al.<sup>[13]</sup> used SFA to study the adsorption of lysozyme on mica as a function of protein concentration, determining the protein's adsorption orientation, ability to form multilayers, and adsorption irreversibility.

Conformation information on adsorbed protein is also available from several spectroscopic methods. Circular dichroism spectroscopy (CD), Fourier transform infrared spectroscopy (FTIR), and Raman spectroscopy all probe protein secondary structure. These techniques have been useful in demonstrating how proteins alter their structure upon adsorption. Proteins have been shown to have greater structural perturbation on hydrophobic surfaces, compared to hydrophilic surfaces using CD,<sup>[14,15]</sup> FTIR,<sup>[7]</sup> and Raman spectroscopy.<sup>[8,16]</sup>

A significant amount of literature on protein adsorption is concerned with the kinetics and total mass of protein adsorbed onto a solid surface. The quartz crystal microbalance (QCM) measures the changes in resonance frequency and dissipation factor of an oscillating quartz crystal and can provide information on the adsorbed mass and temporal variations in surface viscoelastic properties. Otzen, Oliveberg, and Hook<sup>[17]</sup> employed QCM to study the adsorption of

<sup>a</sup>A glossary of abbreviations appears at the end of this entry.

protein S6 onto a methyl-terminated quartz surface and found that the adsorption kinetics of protein S6 depends on the equilibrium fraction of denatured protein in the bulk, rather than on the kinetics of bulk denaturation. Upon comparison with optical techniques, such as ellipsometry and optical waveguide light-mode spectroscopy (OWLS), Hook et al.<sup>[18]</sup> showed that QCM reports higher adsorbed mass, this being attributed to water bound to the adsorbed protein.

Total internal reflection fluorescence (TIRF) measures the fluorescence emission of fluorescent-tagged protein triggered by an evanescent wave arising from a totally internally reflected light beam inside an adjacent optically clear adsorption substrate. This method permits adsorption isotherms and adsorption kinetics to be measured. It has also been used to show that proteins reorient and/or undergo conformational change at the surface, depending on the surface concentration,<sup>[19]</sup> the rate of adsorption to the surface,<sup>[19]</sup> and the hydrophobicity of the surface.<sup>[20,21]</sup> These factors all affect the final surface loading.<sup>[22]</sup>

Other optical methods exist to determine adsorption kinetics and isotherms. Ellipsometry gauges the change in polarization of light that is reflected from the surface of a sample. This technique requires a reflecting surface. In OWLS, light is totally internally reflected within an optical waveguide, setting up an evanescent wave in the nearby solution. The electric and transverse magnetic modes of the evanescent wave are then measured. In surface plasmon resonance (SPR), a laser beam undergoes total internal reflection at the adsorption glass/metal interface. Coupling between the photon and a surface plasmon causes excitation of surface plasmon at the interface and a reduction in intensity of the internally reflected light. Scanning angle reflectometry (SAR) is another optical method that is used to determine protein adsorption isotherms and kinetics. All these techniques measure the adsorption thickness and the refractive index of the layer above the adsorption interface, which can then be used to calculate adsorbed mass. Surface plasmon resonance<sup>[23]</sup> and ellipsometry<sup>[24]</sup> show how adsorption packing and kinetics vary for proteins of various dimensions and conformations. Ellipsometry has shown that more protein adsorbs onto hydrophobic surfaces compared to hydrophilic surface.<sup>[25]</sup> Ellipsometry also has been used to show that more protein is irreversibly adsorbed on hydrophobic surfaces<sup>[26]</sup> and that the degree of irreversibility is time dependent.<sup>[25,26]</sup> Time-dependent spreading of protein at the interface has been studied using OWLS<sup>[27]</sup> and ellipsometry.<sup>[25]</sup> Multilayer formation for lysozyme has been observed using ellipsometry.<sup>[24,28]</sup> Optical techniques have been used to study how ionic strength affects protein adsorption area,<sup>[29]</sup> adsorption isotherms,<sup>[28,30]</sup> kinetics,<sup>[28]</sup> and irreversibility.<sup>[28]</sup>

## Atomic Force Microscopy Techniques

All of the above experimental techniques provide information on length scales much larger than the dimensions of a single protein molecule. Hence they cannot provide data on the spatial distribution of proteins on a surface. Conversely, atomic force microscopy (AFM) enables direct observation of real-space topographic surfaces on a nanometer scale and can, in principle, detect the spatial distribution of adsorbed protein. Atomic force microscopy can image surfaces in solution, so that proteins remain in an aqueous environment. By imaging in situ, adsorption dynamics are observable. By combining the real-time and real-space resolution of AFM, one obtains information on the spatial and temporal distribution of adsorbed protein. The literature on AFM studies of proteins is vast. However, most studies are primarily concerned with imaging large, isolated single-protein molecules<sup>[31–33]</sup> and not on adsorption patterns and mechanisms. We review studies on the fundamentals of the protein adsorption process. Table 1 contains a listing of AFM research that we mention in this entry, along with the particular properties studied.

Access to lateral spatial information on protein adsorption enables supramolecular organization on the surface to be observed in real time. This includes the ability to directly observe clustering and multilayer formation. Height differences across the surface provide information on the adsorbed protein conformation and orientation and their changes in time. Non-uniform surfaces can be imaged, allowing comparison between protein adsorption on differing surface chemistry and on patterned interfaces. Atomic force microscopy provides information on the interaction forces between the protein-covered surface and the scanning probe and mechanical properties using the force-distance-curve feature.

## ATOMIC FORCE MICROSCOPY

### Features

Originally designed to measure the topography of surfaces, AFM has the potential to obtain atomic-scale spatial resolution. Although specific designs differ, AFM generally operates by raster scanning a fine, cantilevered tip over a solid surface while measuring tip deflection with a laser. As the tip encounters features on the surface, the tip deflects; the feedback mechanism moves the sample closer or farther from the cantilever-tip assembly in response. This height movement, in addition to the raster scanning movement, is controlled to angstrom precision by a piezoelectric crystal. It is the height of the sample surface (rather

See [Abbreviation Glossary](#).

than the tip deflection) that is reported as the height of features on the surface.

Two main methods for imaging topographical features exist. In “contact mode,” the tip is kept in constant contact with the surface while maintaining a constant force (or deflection). The instrument feedback loop operates by raising or lowering the sample surface to maintain a constant tip force. This is the original method of operation for the AFM; it has the advantage of high resolution. Continuous improvements in preparation techniques and imaging conditions make it possible to image proteins with lateral resolution of  $\sim 0.5$  nm and vertical resolution of  $\sim 0.1$  nm in this mode.<sup>[34,35]</sup> “Tapping-mode” imaging was developed to reduce possible damage to the sample that results from the tip “dragging” along the surface. This is especially relevant for “soft” biomolecules such as proteins. Tips can damage protein structure and sweep away loosely adsorbed biomolecules. In tapping-mode imaging, the cantilevered tip oscillates at resonance frequency and only intermittently “taps” the surface at the bottom of its oscillation. In this imaging mode, the feedback loop maintains a constant oscillation amplitude, rather than the tip force. Using tapping mode, proteins that are loosely adsorbed can be imaged without being swept away by the scanning tip.<sup>[31]</sup> The lateral resolution suffers somewhat in this mode, but is still sufficient to monitor protein adsorption.

A major advantage of AFM is that imaging can be performed in liquid solution. Thus protein can be imaged in aqueous solution. With a fluid flow cell, the liquid environment can be changed while the sample remains on the surface. Thus protein solution, surfactant solution, or different buffer solutions can be introduced. Imaging adsorbed proteins after drying the surface is a common application. Although sample preparation and imaging in open air tends to be easier and faster, we caution that the drying process may distort protein structure and pattern formation. In most, but all of the images presented in “Atomic Force Microscopy and Protein Adsorption,” the tapping mode in aqueous environment is employed.

Other imaging variations for the AFM exist. One mode, known as lateral- (or friction-) force mode can “image” a force map by detecting differences in chemistry and mechanical properties at the surface. This is possible by operating the AFM in contact mode and measuring the “twisting” of the cantilever as the tip moves over different regions of the sample. Twisting of the cantilever is a result of the tip adhering to the surface as it is scanned; the amount of twisting is a function of the adhesion between the tip and surface. A resulting friction map distinguishes parts of the surface with different chemistry and/or mechanical properties.

In addition to imaging, AFM is able to measure the interaction normal force between the tip and the surface. This occurs by measuring the tip deflection as the surface approaches the probe tip, comes into contact, slightly pushes the tip, then retracts and separates from the tip. Information is garnered on the physical and mechanical properties of surfaces and the interaction forces between the tip and surface. When the interaction between the surface and tip material is not of direct interest, tips can be coated with proteins or monolayers that expose a specific chemical functionality to probe-specific interactions. This is sometimes referred to as chemical force microscopy.<sup>[36]</sup> If force curves are taken at regular distances over a surface, a so-called force-volume (actually force-area) map can be created. In a force-volume map, the tip deflection from a force curve at a defined tip-sample distance is mapped into a two-dimensional array. This discloses the tip interactions with the surface over various regions of the surface. The force-volume map can be compared to the topographical surface images and physical features on the surface can be correlated to the force interactions.

### Imaging Artifacts

Care should be taken when interrogating AFM images. Interpreting images without cognizance of possible artifacts can lead to misinterpretation. Because AFM is an intrusive process, the probe tip may mechanically induce protein adsorption patterns on the surface, possibly contributing to the overall adsorption process. Many researchers have reported the “sweeping” action of the tip. Ta, Sykes, and McDermott<sup>[37]</sup> and McMaster et al.<sup>[38]</sup> both reported streaky images attributable to tip mechanical influence. Denis et al.<sup>[39]</sup> found that elongated structures were bent toward the left or right depending on the scanning direction of the tip. Johnson, Yuan, and Lenhoff<sup>[40]</sup> attributed bare patches devoid of adsorbed molecules to the tip sweeping away protein molecules. Immunoglobulin G (IgG)<sup>[41]</sup> and immunoglobulin M (IgM)<sup>[42]</sup> are known to aggregate on mica as a result of tip mechanical influence.

Contamination of the AFM tip by unwanted particles in solution or particles garnered from the surface is a common problem and is difficult to avoid. Depending on the scanning size, the effects on imaging may be significant. Tip contamination alters the tip-surface interaction force and may have a significant effect on the height information obtained.<sup>[43]</sup> In Ta and McDermott's<sup>[44]</sup> studies with friction-force microscopy, the authors observed that tip contamination probably occurred and affected the magnitude of the tip friction. Fortunately, their studies were directed at friction contrast, rather than absolute values. In our

work with in situ lysozyme adsorption onto mica, tip contamination distorted the apparent size of the protein adsorbed onto the surface, compounding the problem of tip broadening.<sup>[45]</sup>

With tip broadening, the AFM image is enlarged as a result of a convolution of the imaged particle and the imaging tip.<sup>[46,47]</sup> Tip broadening is significant when the size of the imaged particle is of the same length scale of the tip point, which is the case for proteins. Enlargement of the image causes overestimation of the amount of protein adsorbed onto the surface, making quantitative assessment of adsorption amounts problematic. Sheller, Petrash, and Foster<sup>[48]</sup> have shown that a grain size analysis of the unmodified image of albumin adsorption yielded a value of 10–15% coverage. However, after taking into account tip broadening, the coverage was reduced to 3–4%. In Ta, Sykes, and McDermott<sup>[37]</sup> studies with fibrinogen adsorption, it is difficult to identify early adsorption features as single molecules or clusters. Thus these researchers considered the adsorbed particles to be clusters of protein. In the work of Kim et al.<sup>[45]</sup> with lysozyme and mica, tip contamination contributed to the tip-broadening problem. This can be seen in Fig. 1. We initially interpreted the observed enlargement of the protein features on the surface as a result

of cluster growth over time. However, this was disproved when after 19 hr (Fig. 1D), smaller clusters were again observed, presumably after the tip was inadvertently “cleaned” of debris. There exist methods to characterize the shape of the tip so that the amount of broadening can be estimated.<sup>[49,50]</sup> However, the amount of contamination can change at any time during imaging or exposure to protein solution, as documented in Kim et al.<sup>[45]</sup>

Finally, we remark that AFM is limited to surfaces that are smooth on the length scale of the protein molecules or aggregates. Accordingly, solid surfaces studied to date include mica, graphite, silicon (i.e., actually a SiO<sub>2</sub> overgrowth), selected polymers, and coated monolayers on these surfaces.

### ATOMIC FORCE MICROSCOPY AND PROTEIN ADSORPTION

One of the main advantages of AFM over other techniques is its ability to gather information on the supramolecular organization of adsorbed protein. Atomic force microscopy, unlike optical techniques such as OWLS, SPR, TIRFS, or ellipsometry, has superb lateral spatial resolution. Further, unlike electron

**Fig. 1** Effect of tip contamination on AFM imaging. Atomic force microscopy images of adsorption of HEWL on mica in 10 mM acetate buffer, pH 4.0, under stopped-flow conditions. Initial bulk concentration of HEWL is 2  $\mu\text{g}/\text{mL}$ . Each image was taken at the exact same location. A large prominent white feature (i.e., debris) marks the same location on the mica surface. (A) Bare mica before exposure to protein solution. (B) Lysozyme adsorption after 15 min, (C) 3 hr 34 min, and (D) 19 hr. Note that in this last scan, the particles below the large feature are much smaller than those above the feature and those scanned at earlier times. All images are 250 nm  $\times$  500 nm. *Source:* Reprinted From Ref.<sup>[45]</sup> with permission from The American Institute of Physics.

microscopy, sample preparation is relatively easy. Protein adsorption events can be observed in situ in aqueous environments and in real time.

## Supramolecular Organization

### Real-time imaging

Takahara et al.<sup>[51–53]</sup> observed a real-time increase of bovine serum albumin (BSA) coverage on surfaces covered with *n*-octadecyltrichlorosilane (OTS) islands surrounded by 2-perfluorooctyltrichlorosilane (FOETS) at both pH 4.7 and 7.5. Complete monolayer coverage can be obtained with sufficient protein in solution. Mueller, Butt, and Bamberg<sup>[54]</sup> imaged myelin basic protein (MBP) adsorption onto negatively charged, acidic lipid bilayers supported on mica and observed that protein elevations on the surface grew laterally and eventually fused with neighboring protein elevations to form a complete monolayer. As reported in Fig. 2, hen egg white lysozyme (HEWL) formed clusters on mica that increased in number until a complete monolayer was formed.<sup>[45]</sup> Coen et al.<sup>[55]</sup> saw similar adsorption patterns for protein A adsorbing onto silicon.

Because of its excellent lateral resolution, AFM can distinguish between different adsorption patterns. Cullen and Lowe<sup>[56]</sup> examined how protein and surface structures dictate adsorption patterns by adsorbing IgG and glucose oxidase (GOx) onto highly oriented pyrolytic graphite (HOPG), as shown in Figs. 3 and 4. Within minutes, patches of IgG containing 300–500 molecules were observed across the HOPG plane (Fig. 3B). Over time, more patches at random locations appeared on the surface until a complete monolayer formed (Fig. 3D). Conversely, in Fig. 4, GOx nucleated initially at HOPG defects. Subsequent adsorption occurred at locations adjacent to protein already adsorbed, forming “sheets” of protein and leaving regions of bare HOPG. In both cases, the protein appeared to aggregate on the surface, which is likely a result of hydrophobic residues exposed during adsorption conformation change leading to favorable intraprotein interaction at the surface. The differences in adsorption patterns arise from physicochemical differences between the two proteins, which we will discuss later.

Conversely, Ta et al.<sup>[37,44]</sup> demonstrated how differences in the hydrophobicity of the solid surface affect protein adsorption patterns. Fig. 5 displays consecutive

**Fig. 2** Lysozyme adsorption onto mica. Atomic force microscopy images of adsorption of HEWL on mica in 10 mM acetate buffer, pH 4.0, under stopped-flow conditions. The initial bulk concentration of HEWL is 5  $\mu\text{g}/\text{mL}$ . Each image is 500 nm  $\times$  100 nm. The light areas are clusters of protein molecules and the dark areas represent the bare mica surface. (A) Bare mica surface before contact with the protein solution. (B) Lysozyme adsorption after 4 min, (C) 32 min, (D) 52 min, (E) 1 hr 26 min, (F) 1 hr 59 min, and (G) 23 hr. **Fig. 3** Immunoglobulin G adsorption onto HOPG. Time-resolved AFM images of the adsorption of IgG from a phosphate-buffered saline (PBS) solution with a bulk concentration of  $50 \mu\text{g/mL}$  of protein to a freshly cleaved HOPG surface. Image size: (A–C)  $5.3 \mu\text{m} \times 5.3 \mu\text{m}$ , (D)  $5 \mu\text{m} \times 5 \mu\text{m}$ . All images were obtained with an applied repulsive force of  $\sim 1 \text{ nN}$  and presented as left-shaded topographic images. *Source:* Reprinted from Ref.<sup>[56]</sup> with permission from Elsevier.

AFM images of bovine fibrinogen (BFG) film growth on HOPG. At 75 sec (Fig. 5C), a network of branched strands can be observed extending across the HOPG plane with no apparent preference for step defects. After 125 sec (Fig. 5E), more networks of branched strands are apparent. A complete monolayer is formed after 225 sec (Fig. 5G). Fig. 5H shows a friction image of the complete monolayer, indicating that the frictional forces between the tip and protein film are low and constant, meaning that the protein structure is robust and crystalline-like.

On mica, as depicted in Fig. 6, BFG homogeneously adsorbed across the surface until a full monolayer was formed. This adsorption process is very similar to that of lysozyme on mica shown in Fig. 2. The authors also compared BFG adsorption onto octadecanethiol (ODT;  $\text{CH}_3$ -terminated) and mercaptohexadecanoic acid (MHA;  $\text{COOH}$ -terminated) self-assembled monolayers (SAMs) supported on gold-covered glass.<sup>[44]</sup> The hydrophobic,  $\text{CH}_3$ -terminated surface showed similar adsorption behavior to that of the HOPG surface, with strand-like surface features gradually filling in the surface to form a smooth, well-packed, uniform monolayer. Friction-force images showed that the friction properties across the surface did not significantly

**Fig. 4** Glucose oxidase adsorption onto HOPG. Time-resolved AFM images of the adsorption of GOx from a phosphate-buffered saline (PBS) solution with a concentration of  $50 \mu\text{g/mL}$  of protein to a freshly cleaved HOPG surface. All images are  $5 \mu\text{m} \times 5 \mu\text{m}$  in area, imaged with an applied repulsive force of  $\sim 1 \text{ nN}$  and presented as left-shaded topographic images. *Source:* Reprinted from Ref.<sup>[56]</sup> with permission from Elsevier.

change during the adsorption process. However, the hydrophilic,  $\text{COOH}$ -terminated surface showed different adsorption behavior to that of the mica surface. Instead of homogeneously filling the surface as in Fig. 6, on the  $-\text{COOH}$  surface, circular, island-like domains 4-nm in height appeared on the surface and grew laterally, ultimately forming a complete, well-packed layer. Friction-force images in this case showed friction contrast between the adsorbed protein and bare surface. The discrepancy between the adsorption patterns on the hydrophilic mica and the  $\text{COOH}$ -terminated surface may be because of the specific chemical differences at the interface such as polarity and charge density and distribution.

#### Multilayer formation

With AFM, one can visually determine the existence of multilayers and when and how they occur. Kim et al.<sup>[45]</sup> showed that lysozyme formed a second layer of adsorption (Fig. 2G), only after the first monolayer was complete (Fig. 2F). In addition, formation of the second layer was significantly slower than the first. Coen et al.<sup>[55]</sup> showed that protein A, when adsorbed on silicon, also formed multilayers as pictured in Figs. 7 and 8. Fig. 7A shows an incomplete monolayer

**Fig. 5** Bovine fibrinogen adsorption onto HOPG.  $6.6\ \mu\text{m} \times 6.6\ \mu\text{m}$  consecutive AFM images of BFG film growth on HOPG monitored in real time with continuous flow. Parts A and B are topographic images ( $z$ -scale = 10 nm). Parts C, E, and G are sequential topographic images ( $z$ -scale = 10 nm) while parts D, F, and H are the corresponding lateral force images ( $z$ -scale = 0.2 V). For timing purposes, the center of the scan in part B is defined as  $t = 0$ , as this is the point initial adsorption is observed. C and D were captured 75 sec after initial adsorption. E and F correspond to 125 sec, and G and H correspond to 225 sec. Arrow a highlights a BFG strand that elongates to a branching point shown in arrow b. Arrow c demarks the growth of a single aggregate later fully formed and highlighted by arrow e. Arrow d indicates a defect site on the HOPG plane. Source: Reprinted from Ref.<sup>[37]</sup> with permission from the American Chemical Society.

of protein A, with the dark spots indicating locations of bare silicon. The existence of a single incomplete monolayer in Fig. 7 was confirmed using X-ray photoelectron spectroscopy (XPS). As with lysozyme

adsorption on mica, subsequent protein layers seen in Fig. 8A did not form until the previous monolayer was complete. The cases of lysozyme on mica and protein A on silicon differ in their electrostatic conditions. At pH 4.0, mica is negatively charged while the lysozyme is positively charged. For the protein A/silicon system, at pH values between 5 and 6, the protein is slightly negatively charged and the surface is also negatively charged. Despite differences in charge conditions, both systems displayed multilayer formation. The role of electrostatics in protein adsorption is covered later.

### Adsorbed Protein Structure and Orientation

Using AFM, it is possible to ascertain adsorbed protein structure and orientation. Although height information (i.e., adsorbate layer thickness) is available from other experimental techniques, AFM has the advantage of directly imaging differences in terrain height with nanometer lateral resolution. Optical techniques average over hundreds of nanometers.

Several researchers have shown with AFM that proteins exhibit structural changes and lateral spreading at the surface. Bovine fibrinogen adsorbed onto ODT ( $\text{CH}_3$ -terminated) SAMs displays an adsorbed AFM height of 1–1.5 nm that is in contrast to the adsorbed height of 4 nm on MHA ( $\text{COOH}$ -terminated) SAMs.<sup>[44]</sup> The smallest dimension of the BFG molecule obtained from X-ray crystallography is 4–6 nm. The lower height on the  $\text{CH}_3$ -terminated SAMs is indicative of more extensive conformational spreading on that surface, which is a result of its more hydrophobic nature. Glucose oxidase was also shown to have a lower adsorbed height of 5–8 Å on HOPG<sup>[56]</sup> compared to the dimensions of the native protein ( $7.0 \times 5.5 \times 8.0\ \text{nm}$ ).<sup>[57]</sup> However, not all proteins show extensive lateral spreading on hydrophobic surfaces. The thickness of IgG films on HOPG was shown to be 3 nm, compared to the dimensions of the protein given by X-ray crystallography ( $14.2 \times 8.5 \times 3.8\ \text{nm}$ ).<sup>[58]</sup> In fact, using AFM, Raghavachari et al.<sup>[59]</sup> have shown an apparently opposite behavior. Fig. 9 illustrates the hydrophilic mica surface after 1 hr of exposure to von Willebrand factor (VWF) followed by protein-free phosphate buffer saline (PBS) wash-out. The VWF on this surface adopted a spread-out conformation. On the hydrophobic OTS surface, shown in Fig. 10, VWF maintained a “ball of yarn” configuration.

Different amounts of spreading were observed for subsequent layers in the multilayer adsorption of protein A on silicon.<sup>[55]</sup> The first monolayer exhibited a height of approximately 1 nm. This is shown in Fig. 7B by the section line of the silicon surface after

**Fig. 6** Bovine fibrinogen adsorption onto mica. Atomic force microscopy images,  $5\ \mu\text{m} \times 5\ \mu\text{m}$ , of BFG film growth on mica monitored in real time with continuous flow. All images are topographic with a  $z$  scale = 10 nm except for part A, where the  $z$  scale = 5 nm. (A) Upward scan  $t = 0$  sec is defined at halfway through the scan. (B) Successive downward scan, with an elapsed time of 75 sec. (C) Successive upward scan with an elapsed time of 125 sec. (D) Successive downward scan with an elapsed time of 175 sec. (E) Successive upward scan with an elapsed time of 225 sec. (F) Upward scan with an elapsed time of 325 sec. *Source:* Reprinted from Ref.<sup>[37]</sup> with permission from The American Chemical Society.

15 sec of adsorption. The size of native protein A is roughly 3 nm.<sup>[55]</sup> Thus a significant amount of lateral spreading (and likely unfolding) occurred in the first layer of adsorbed protein, assignable to direct contact with the silicon surface. The height of the second monolayer was considerably larger at 2–3 nm (Fig. 8B), indicating less structural perturbation. The height on the third monolayer was approximately 3 nm (not shown.) Thus Coen et al.<sup>[55]</sup> concluded that the protein in the third layer was not conformationally altered. Each new monolayer adsorbs onto a different surface. Therefore it is not surprising that the adsorbed protein structure differs in each layer. However, given very long time exposure to the surface, protein in the multilayers may continue to rearrange, slowly unfolding and aggregating into the sublayer.

In many cases, protein molecules were observed to adsorb in a side-on orientation on solid surfaces. Kim et al.<sup>[45]</sup> showed that the height of adsorbed lysozyme on mica was approximately 2.5 nm while the native protein dimensions from X-ray crystallography are  $3 \times 3 \times 4.5$  nm.<sup>[60]</sup> The height of adsorbed C hordein on mica is 2–3 nm<sup>[38]</sup> while the dimensions of

the protein are 1.9 nm in width by 28.2 nm in length.<sup>[61]</sup> By adsorbing in a side-on fashion, the protein maximizes contact with the surface.

There are cases where protein does not adsorb in a side-on fashion. Sheller, Petrash, and Foster<sup>[48]</sup> examined human serum albumin (HSA) adsorption onto hexadecyltrichlorosilane (HTS;  $\text{CH}_3$ -terminated) SAMs and found that the adsorbed orientation depends on surface concentration. For low submonolayer coverage, as shown in Fig. 11C,D, the height profile of protein adsorbed onto the surface measured by AFM was 3.6–3.7 nm. Protein films of a full monolayer, as shown in Fig. 11A,B, had a thickness of 16–17 Å as measured by X-ray reflectivity. Sheller et al. suggested that for higher surface coverage of protein, there is a significant net removal of weakly adsorbed protein from the surface by adjacent, strongly adsorbed protein spreading on the surface. This implies that the stronger adsorbed protein undergoes structural changes to a greater extent giving more contacts with the surface. When the surface coverage is low, the exchange process is not significant, and proteins adsorb in any configuration. Thus both strongly and weakly bound protein

**Fig. 7** Protein A adsorption onto silicon. (A) Atomic force microscopy picture of the silicon surface after a 15-sec adsorption of protein A from a 0.1 mg/mL solution. The first monolayer of protein A is almost complete. Bare mica is evidenced by the black spots in the image. The vertical scale is 5 nm. adhere to the surface with varying degrees of conformation change. Sheller et al. do not provide experimental evidence that weakly bound protein remains on the surface for long exposure times.

### Non-uniform Surfaces

The exceptional lateral resolution of AFM allows study of non-uniform and patterned surfaces and of the differences in protein adsorption as a direct result of surface non-uniformities. Patterned surfaces presenting both hydrophobic and hydrophilic regions highlight the differences in the degree of hydrophobicity on protein adsorption.<sup>[44]</sup> Fig. 12 shows a topographical (A) and friction image (B) of a protein-free surface, patterned with ODT and MHA SAMs. These images illustrate that the two SAMs are topographically

**Fig. 8** Protein A multilayer adsorption onto silicon. (A) Atomic force microscopy picture of the silicon surface after an 8-min adsorption of protein A from a 0.1 mg/mL solution. A second layer of adsorbed protein is evident as the brightest spots. The vertical scale is 5 nm. rather similar, but the friction-force image establishes that the tip experiences different adhesive forces on the two SAMs. Fig. 13 presents friction images of the patterned surface before (Fig. 13A) and during exposure to bovine fibrinogen (BFG) solution (Fig. 13B–D). Image D was collected after 22 min of exposure to the protein solution and again shows that the tip experiences different adhesive forces now on the fibrinogen layers of each type of SAM. This result indicates that the protein adsorbs on both surface regions, but in a different conformation or orientation on the hydrophobic (CH<sub>3</sub>-terminated) and hydrophilic (COOH-terminated) surfaces.

Patterned surfaces also highlight differences in adsorption behaviors on different surfaces with varying electrostatic conditions.<sup>[51–53]</sup> Fig. 14A shows a mixed monolayer consisting of OTS surrounded by FOETS supported on a silicon substrate. When

**Fig. 9** von Willebrand factor adsorption onto mica. A is an AFM image ( $2\mu\text{m} \times 2\mu\text{m}$  scan) of VWF multimers adsorbed on hydrophilic mica and imaged under PBS. Most of the VWF molecules are extended and are not ball of yarn structures. Extended VWF multimer chains overlap with themselves and with neighboring chains (arrows). Intramolecular structural features in the VWF multimer chain are discernible. Individual chains of multimers are not clearly distinguishable because of the high surface density of VWF. Mean lateral dimensions of the VWF multimers are  $640 \pm 161\text{ nm} \times 303 \pm 113\text{ nm}$ . B and C are expanded AFM images of VWF on mica, showing intramolecular structural features of individual chain VWF multimers. VWF chains are composed of globular domains (B, large arrow) joined by thin rod-like interconnecting sections (B, small arrow). C contains an example of a crossover (see arrow) of the VWF multimer chain within the same VWF chain. *Source:* Reprinted from Ref.<sup>[59]</sup> with permission from Elsevier.

exposed to a BSA solution at pH 7.5, only the FOETS regions demonstrated significant adsorption, as illustrated in Fig. 14B. However, at pH 4.7, the isoelectric point of BSA, the protein adsorbed to both phases, as demonstrated in Fig. 14C. Although BSA adsorbed onto both OTS and FOETS surfaces when uncharged, it has an apparently higher affinity for FOETS, which is, apparently, more hydrophobic than OTS. At pH 7.5, the protein carries a net negative charge and readily adsorbed on FOETS. Adsorption onto the

**Fig. 10** von Willebrand factor adsorption onto OTS. Atomic force microscopy image ( $2\mu\text{m} \times 2\mu\text{m}$  scan) of VWF multimers adsorbed on hydrophobic OTS and imaged under PBS. Most VWF multimers display the characteristic compact ball of yarn structures observed by electron microscopy. Each VWF multimer is closely packed with intramolecular overlap and crossover of chains. Intramolecular structural features of the VWF multimer chain are resolved. However, the compact arrangement of the chain makes it difficult to discern the structural features belonging to neighboring repeat units. In some multimer chains, short sections are not as compact and appear extended (arrows). Completely extended chains are rare. None are seen in this image area. The average lateral dimensions of the VWF multimers are  $256 \pm 74\text{ nm} \times 152 \pm 62\text{ nm}$ . *Source:* Reprinted from Ref.<sup>[59]</sup> with permission from Elsevier.

OTS phase was possibly prevented by electrostatic repulsion from already adsorbed negatively charged protein on the FOETS phase.<sup>[51–53]</sup>

The effects of the physical differences in terrain on protein adsorption can also be elucidated by AFM. Galli et al.<sup>[62]</sup> examined the effect of nanostructures created by local anodic oxidation on protein adsorption. They created elevated lines 30–40 nm in width and 1–3 nm in height on silicon (Si) and titanium (Ti) surfaces (actually  $\text{SiO}_2$  and  $\text{TiO}_2$  overgrowths, respectively). Fig. 15 shows an AFM image of the 1-nm high lines on Si. Fig. 16 shows that the lined nanostructures (highlighted with arrows) made no difference to protein A (a globular protein with a size of 3 nm) adsorption in terms of adsorbed amount. In contrast, F-actin, a filamentous protein with a diameter between 6.5 and 8.2 nm, had a tendency to adsorb along the 1-nm-high nanostructured lines, whereas no preferential orientation occurred on the flat surfaces. Fig. 17 shows F-actin adsorbed on the Si surface containing

**Fig. 11** Human serum albumin adsorption onto HTS. nanostructures 1 nm in height. Fig. 18 shows F-actin adsorption on Ti with 1- and 3-nm nanostructures and with no nanostructures. Thus on Si and Ti, F-actin had a tendency to adsorb along 1-nm-high nanostructured lines, whereas no preferential orientation occurred on the planar surfaces. Galli et al. speculated that the reason for preferential orientation is that the contact area between the surface and protein is

increased along the lines. However, on Ti, 3–4-nm-high lined nanostructures garnered very low F-actin adsorption. This height corresponds to half the diameter of F-actin. These authors cite similar height dependencies for a variety of cells.<sup>[63–65]</sup> It is possible that F-actin is not sufficiently labile to adsorb across these higher nanostructures and maintain enough contacts with the surface to adsorb.

### Force Interactions

A major strength of AFM is the probing of interactions between the protein-coated surface and the tip. Force interactions can be mapped across different regions of the surface. Radmacher et al.<sup>[66]</sup> illustrated the utility of force–distance curves for protein adsorption. Fig. 19A and B present force curves on bare mica and on aggregates of lysozyme on mica in 10 mM KH<sub>2</sub>PO<sub>4</sub> (pH 6.4), respectively. Force curves report the cantilever deflection (which can readily be translated into force) as a function of the sample height as the tip approaches, and then retracts from the surface. The

**Fig. 14** Bovine serum albumin adsorption on OTS/FOETS supported monolayers. Atomic force microscopy image of the mixed (OTS/FOETS) monolayer (A) before exposure to BSA, (B) after exposure to a 0.1 g/L BSA solution in PBS (0.01M) at pH 7.5 and (C) pH 4.7 for 10 min. Line sections are shown below each AFM image. *Source:* Reprinted from Ref.<sup>[53]</sup> with permission from Elsevier.

large ( $\sim 25$  nm) negative deflection of the retract curve on bare mica indicates that the tip is highly attracted to the surface, whereas the smaller ( $\sim 8$  nm) negative deflection over lysozyme indicates a smaller attraction. An identical result was found by Kim et al.<sup>[45]</sup> The deviation in linearity on the contact region of the force–distance curve for lysozyme is a result of the elastic deformation of the protein. By fitting to a Hertzian model, Radmacher et al.<sup>[66]</sup> estimated the Young’s modulus for adsorbed lysozyme on mica to be  $0.5 \pm 0.2$  MPa. In addition, the time for liftoff, the region of the retract force curve when the tip loses contact with the surface, is longer for lysozyme compared to that of the bare mica surface. This is related to the viscosity of lysozyme on the surface, estimated to be  $800 \pm 400$  Pa sec.<sup>[66]</sup>

Clearly, AFM can detect mechanical properties of protein films. Given a high-enough applied force, the tip can break through protein films. Thus by examining the force curves, one can uncover protein assembly at the surface. On myelin basic protein (MBP) clusters adsorbed at both acidic (30 wt.% cholesterol, 56% egg phosphatidylcholine, 14% dioleoylphosphatidylserine) and basic (30 wt.% cholesterol, 56% egg phosphatidylcholine, 14% dioleoyl trimethyl-ammonium salt) lipid bilayers supported on mica, Mueller et al.<sup>[54]</sup> observed a “jump-in” on the initial approach curve that disappeared for subsequent force curves at the same location. The adhesion force between the tip and the cluster was approximately 0.5 nN as measured by tip deflection upon retraction. Fig. 20B shows a typical set of consecutive force curves on an acidic lipid

**Fig. 15** Nanostructured Si. Atomic force microscopy image of Si surface with 1-nm high lines. The vertical scale is 5 nm. *Source:* Reprinted from Ref.<sup>[62]</sup> with permission from Elsevier.

Source: Reprinted from Ref.<sup>[62]</sup> with permission from Elsevier.

bilayer. Force–distance curves consistently displayed a characteristic “jump-in” upon approach at 5 nN and a negligible adhesion force. The “jump-in” indicates the moment when the tip breaks through the lipid bilayer and protein layer (if present) to the solid surface.

**Fig. 18** F-actin adsorption on Ti nanostructures. (A) Nanostructures created on Ti. Main lines are 3–4 nm high. Secondary lines are 1 nm high. (B) F-actin adsorbed on nanostructured Ti. The vertical scales are 8 nm. Source: Reprinted from Ref.<sup>[62]</sup> with permission from Elsevier.

Fig. 20C also gives four consecutive force–distance curves but now for a MBP cluster adsorbed on the acidic lipid bilayer. The disappearance of the jump after the first force curve in Fig. 20C indicates that the tip locally destroyed the protein structure and that the original structure did not recover. The tip may irreversibly compress and break apart the protein aggregate structure, leaving behind a permanently damaged protein–lipid bilayer complex and expose the bare surface. On the bare lipid layer, as shown in

**Fig. 19** Force-distance curves on mica and lysozyme. (A) Force curve on the substrate mica. (B) Force curve on an aggregated cluster of lysozyme adsorbed onto mica. Note that the hysteresis during retract is larger on mica, indicating a higher adhesion force. However, liftoff over the lysozyme cluster is gradual in comparison to mica. This effect is probably due to damping of the cantilever by the lysozyme. As a result of elastic indentation, the contact region of the force curve is not just a straight line, but shows some deviation in the case of lysozyme (see fitted dashed contact lines in parts A and B). *Source:* Reprinted from Ref.<sup>[66]</sup> with permission from The American Chemical Society.

Fig. 20B, the jump-in consistently occurred and the recovery after tip breakthrough occurred fast, probably because of the high mobility of the lipid molecules. On zwitterionic bilayers (not shown), protein clusters showed inconsistent behavior. This is not surprising because the protein aggregates on zwitterionic bilayers were irregular in height and two-dimensional morphology.<sup>[54]</sup>

Chen et al.<sup>[67]</sup> found long-term structural changes in BSA films adsorbed on polystyrene (PS) surfaces. Albumin-coated probes exhibited high adhesion forces on bare PS, but only small adhesion forces on protein-exposed surfaces. When high probe forces were exerted on the BSA films, high adhesion forces were observed, indicating that the albumin-coated probe was able to penetrate the protein layer to the bare PS surface. These authors found that the contact-force limit increases with protein adsorption time. Hence after adsorption, protein continues to undergo structural changes that increase the mechanical strength (or integrity) of the film.

Force interactions between the tip and the surface at a fixed distance away from the surface can allow presentation of a two-dimensional array or a force-volume image. Fig. 21A shows a force-volume map and the corresponding topograph (Fig. 21B) of a BSA film adsorbed onto PS.<sup>[67]</sup> The brighter shades on the force-volume map indicate higher adhesion energy. These correspond to the low area of the topograph corresponding to bare PS. Kim et al.<sup>[45]</sup> employed force-volume imaging for a lysozyme submonolayer on mica

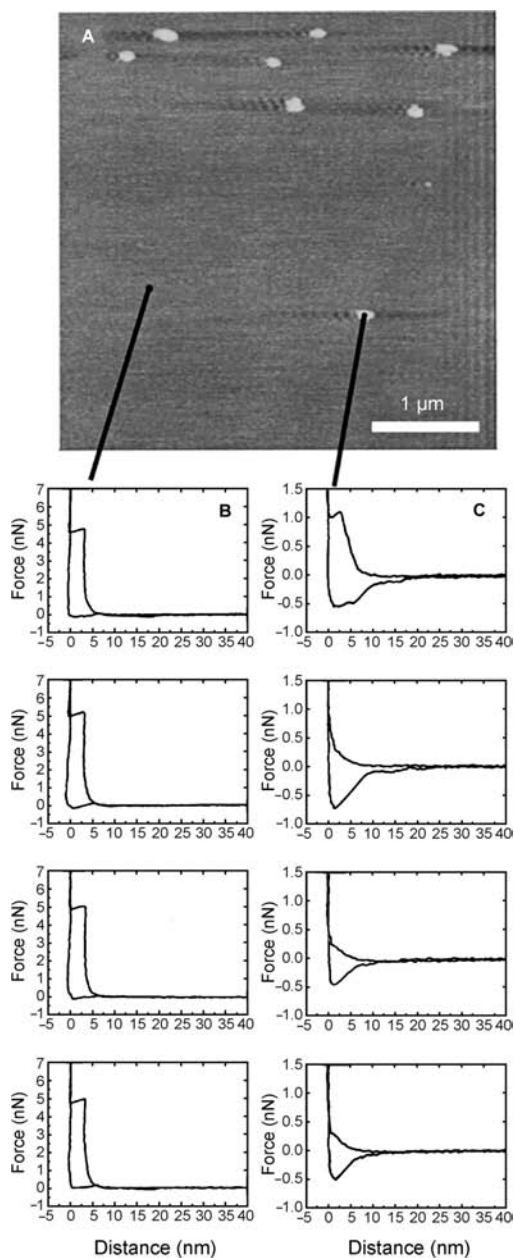

to distinguish between areas that corresponded to bare mica and to lysozyme.

Force-distance curves can be used to detect differences in adsorbed protein structure. Denis et al.<sup>[39]</sup> studied collagen adsorption on CH<sub>3</sub>- and OH-terminated SAMs using force-distance curves. Approach interaction curves for protein adsorbed onto CH<sub>3</sub>-terminated SAMs exhibited significant curvature, whereas the approach curves for protein adsorbed onto-OH-terminated SAMs demonstrated no curvature. This result indicates that collagen adsorbed on the hydrophobic CH<sub>3</sub>-terminated SAMs was “softer” than that adsorbed on the hydrophilic OH-terminated SAMs. Differences in protein adsorption behavior on hydrophobic and hydrophilic surfaces are addressed below.

## PROTEIN ADSORPTION MECHANISMS

### Electrostatic Effects

Electrostatic interactions between the protein and surface in addition to those between proteins can play an important role in the adsorption onto solid surfaces. Many adsorption processes are driven in part by electrostatic attraction between the surface and protein. For example, lysozyme at pH 4.0 is positively charged, whereas mica is negatively charged; protein adsorption occurs quite readily as shown in Fig. 2.<sup>[31,45,66]</sup>

**Fig. 20** Sequential, spatially resolved force spectroscopy on an acidic bilayer with adsorbed MBP aggregates. (A) Height image of an acidic lipid bilayer 15 min after injection of 2  $\mu\text{g}/\text{mL}$  MBP solution. (B) Column of four consecutive force curves take at the indicated position in the flat area of the image. (C) Column of four consecutive force curves taken on the indicated MBP aggregate. The penetration force was smaller than in b, the jump vanished during the force scans, and an adhesion of approximately 0.5 nN was observed. *Source:* Reprinted from Ref.<sup>[54]</sup> with permission from The American Chemical Society.

Cytochrome *c* at pH 7.4 is positively charged and significantly adsorbs on negatively charged bilayers, minimally on neutral bilayers, and not at all on positively charged bilayers.<sup>[54]</sup> In addition, cytochrome

**Fig. 21** Force-volume map of BSA adsorbed onto polystyrene. (A) Two-dimensional distribution of the adhesion energy between a BSA-coated probe and a polystyrene surface preadsorbed with BSA, with (B) a simultaneous recorded surface topography ( $2\ \mu\text{m} \times 2\ \mu\text{m}$ ). Only the left portion of the surface was exposed to the protein solution. The measurements were performed in pH 7 phosphate buffer at the boundary region between the BSA-free and BSA-covered polystyrene surfaces. The adhesion energies are extracted from force–distance curves measured at each sampling point, with brighter shades indicating higher adhesion energy. The topographic image is artificially shadowed for a better presentation. *Source:* Reprinted from Ref.<sup>[67]</sup> with permission from The American Chemical Society.

*c* adsorption was reversible under high salt conditions (5 M NaCl) whereas the protein appeared to be irreversibly adsorbed at lower salt conditions (150 mM NaCl). In some cases, protein can still adsorb onto

surfaces even when they are similarly charged. MBP at pH 7.4 is positively charged and adsorbs onto a positively charged bilayer.<sup>[54]</sup> Patel et al.<sup>[68]</sup> have shown that negatively charged catalase at pH 8.0 adsorbs onto negatively charged SAMs. Likewise, HSA can adsorb to both positively and negatively charged polymer surfaces.<sup>[30]</sup> There are several reasons why this can occur. First, a protein of a particular net charge still presents oppositely charged residues on its structure and those residues can favorably interact with the charged solid surface. Second, as discussed later, the driving force for adsorption usually involves hydrophobic forces. These can overcome a net electrostatic repulsion with the surface.

High-ionic-strength solutions shield electrostatic repulsions between charged proteins resulting in increased protein adsorption. Johnson, Yuan, and Lenhoff<sup>[40]</sup> illustrated this with ferritin adsorption onto trimethoxysilylpropyldiethylenetriamine (DETA) coated glass. However, adsorption amount does not monotonically increase with ionic strength because of the competition between surface-protein interactions and surface protein-protein interactions.<sup>[40]</sup> Protein-protein repulsion can also be minimized by adjusting the solution pH to the isoelectric point ( $pI$ ) of the protein, where the protein has a zero net charge, but may have a large dipole moment. Several researchers have reported that adsorption is increased or maximized at the  $pI$ .<sup>[40,51-53,69,70]</sup> Kajiyama et al. observed that BSA adsorbed on both OTS and FOETS phases only at the  $pI$  (Fig. 14C). But when BSA carried a net charge, it only adsorbed only onto the FOETS phase (Fig. 14B) as a result of the electrostatic repulsion between adsorbed protein and protein in solution.<sup>[51-53]</sup> Johnson, Yuan, and Lenhoff<sup>[40]</sup> reported that at the  $pI$ , ferritin adsorption approached the random sequential adsorption (RSA) jamming limit. This increased adsorption could be attributed to the fact that at the  $pI$ , intramolecular charge repulsions are minimized and the protein adopts its most compact shape.<sup>[69]</sup> Thus the protein requires less space on the surface to adsorb as compared to a more elongated structure that exists when the protein carries a net charge. However, this reasoning must be tempered by the observation that denatured and random-coil-like proteins adsorb more quickly<sup>[17]</sup> most likely because the surface unfolding kinetic step is hastened.

### Kinetics of Adsorption

General trends have been observed in the kinetics of protein adsorption. Almeida, Salvadori, and Petri<sup>[70]</sup> divided the process into four stages, assuming a continuous supply of protein. The first stage is a mass-transfer-limited stage where proteins rapidly adsorb

onto the surface. Feng et al.<sup>[2]</sup> described this initial step as a “fast process.” In our work with lysozyme, protein on the surface could be imaged within minutes of exposure to an unstirred protein solution.<sup>[45]</sup> The second stage is a non-linear reduction of the adsorption rate until a monolayer plateau is established. During the second stage, the slowing down of adsorption may be explained by lower availability of free adsorption sites on the surface while the protein diffuses, structurally rearranges, and aggregates on the surface. The third stage represents completion of monolayer coverage followed by the fourth stage, where slow multilayer growth begins. The slow growth of a second layer of lysozyme on mica has been reported (Fig. 2).<sup>[45]</sup> It is thought that the slower kinetics of multilayer adsorption is possibly because the proteins in the bulk solution are largely in their native conformation and do not readily interact with protein that is minimally unfolded at the surface. As the monolayer remains longer on the surface and unfolds more, interactions with bulk native protein is likely enhanced.

Currently, the kinetics of protein adsorption at solid surfaces cannot be reliably predicted. This is because of the complicated collection of possible behaviors including irreversibility of protein adsorption, slow conformational changes, and aggregation both within a given layer and between multilayers. The onset of irreversibility can occur in the first and second stages of adsorption. For example, the surface concentration of cytochrome *c* leveled off at a non-zero value when washout began at this second stage.<sup>[27]</sup> The initial lysozyme clusters observed after 4 min of exposure to mica in Fig. 2 are already irreversibly adsorbed.<sup>[45]</sup> Subsequent lateral migration and surface aggregation strongly affects the kinetics of adsorption.<sup>[27]</sup>

### Growth Mechanisms: Surface Diffusion/Lateral Migration

Many proteins have been found to diffuse laterally on the surface. Tilton, Gast, and Robertson<sup>[71,72]</sup> have shown using fluorescence recovery after photobleaching (FRAP) that even proteins that are irreversibly adsorbed undergo lateral motion. These workers report surface diffusion coefficient values for bovine serum albumin (BSA) irreversibly adsorbed on poly(methyl methacrylate) (PMMA) and poly(dimethylsiloxane) (PDMS) of  $1.2 \pm 0.3 \times 10^{-9}$  and  $2.6 \pm 0.1 \times 10^{-9}$  cm<sup>2</sup>/sec, respectively. We explained the clustering of lysozyme molecules on mica as arising from surface diffusion and aggregation of irreversibly adsorbed protein molecules.<sup>[45]</sup> The irreversible adsorption of lysozyme onto mica probably disturbs the protein conformation sufficiently to expose hydrophobic residues giving rise to surface cluster formation through

interprotein aggregation at the surface. Mueller, Butt, and Bamberg<sup>[54]</sup> reported a similar mechanism of adsorption, diffusion, and aggregation resulting in clusters of MBP adsorbed onto lipid bilayers. The adsorption patterns shown in Figs. 3 and 4 of IgG and GOx on HOPG also imply surface mobility and aggregation of proteins. Denis et al.<sup>[39]</sup> attributed the elongated structures of collagen on solids to surface mobility. Collagen formed elongated structures on smooth surfaces exposing  $-CH_3$  moieties, but not on rough surfaces or surfaces exposing  $-OH$  moieties. This was ascribed to the diminished mobility on the rough surfaces. In Hook et al.'s<sup>[18]</sup> ellipsometry and OWLS studies with serum proteins, it was found that the adsorption saturation mass frequently exceeds the mass predicted by the RSA model. The explanation lies in the ability of protein on the surface to move laterally, clearing space for additional protein to adsorb. Calonder, Tie and Van Tassei<sup>[27]</sup> reported that the kinetics of additional protein adsorption depends on the amount of time protein has to rearrange and move to form clusters.

### Multilayer Formation

Some proteins have the ability to form multilayers. We ascertained that lysozyme forms a second layer, but only after establishing a first monolayer on mica (Fig. 2).<sup>[45]</sup> The growth of the second layer occurred on a slower time scale than that for the first monolayer, indicating that the adsorption mechanism must be different. This is not surprising considering that once the first monolayer is established, subsequent proteins must adsorb onto a completely different interface. We speculate that the driving force for adsorption on a second layer is exposed, hydrophobic residues resulting from protein conformational changes, occurring in the first layer, that interact with protein in the bulk solution. Hydrophobic interactions may also explain the irreversibility of the second layer of adsorbed lysozyme. Wahlgren, Arnebrant and Lundstrom<sup>[28]</sup> and Malmsten<sup>[73]</sup> likewise reported multilayer adsorption of lysozyme using ellipsometry. Coen et al.<sup>[55]</sup> also documented multilayer adsorption for protein A onto silicon. As was observed with lysozyme, formation of subsequent layers of protein A did not occur until the previous layer was saturated with protein (Figs. 7 and 8). It was observed that protein in the first monolayer was significantly unfolded (Fig. 7), whereas protein in the second layer was less structurally altered (Fig. 8). Protein in the third layer had no significant structural perturbations.<sup>[55]</sup> Hook et al.,<sup>[18]</sup> using OWLS and ellipsometry, found that hemoglobin formed multilayers on titanium oxide surfaces, and Ladam et al.,<sup>[30]</sup> using SAR, showed that HSA forms

multilayers on a positively charged polyallylamine surface.

Nevertheless, not all proteins have the ability to form multilayers. Green et al.<sup>[23]</sup> found that albumin does not form multilayers on negatively charged polystyrene and neither did HSA.<sup>[30]</sup> However, multilayer formation can occur over long time scales and most studies do not investigate adsorption beyond a few minutes. Thus it is important to extend the time scale of investigation over several hours or days before eliminating possible irreversible and multilayer adsorption behavior. Also, these phenomena are clearly protein and surface specific.

### Protein Structure and Adsorption Behavior

Several studies directly compare different adsorption patterns on different solid surfaces. Immunoglobulin G has been observed to adsorb randomly on HOPG surfaces, forming clusters, whereas GOx prefers to adsorb at HOPG step defects forming “sheets” that eventually grow from these initial nucleation sites (Figs. 3 and 4).<sup>[56]</sup> Bovine fibrinogen adsorbs onto HOPG in a strand network (Fig. 5), whereas on mica, it adsorbs homogeneously (Fig. 6).<sup>[37]</sup> This variety of adsorption behavior is most likely related to specific protein structure. The location and the number of hydrophobic and hydrophilic residues can play a large part in the final adsorption pattern. Glucose oxidase is heavily glycosylated and, at pH 7.2, is more negatively charged than is IgG.<sup>[74]</sup> Thus it is not surprising that GOx nucleates preferentially at higher energy step defects on HOPG rather than on the basal planes. In contrast, IgG is more hydrophobic and can interact more strongly with the hydrophobic surface. Ta, Sykes, and McDermott<sup>[37]</sup> explained the discrepancy in the adsorption patterns for BFG on mica and on HOPG based on the native protein structure. The BFG molecule is known to have two distal D domains connected to a central E domain.<sup>[75]</sup> The D domains are hydrophobic with low structural stability. From each D domain extends an  $\alpha C$  domain with both hydrophobic and hydrophilic regions.  $\alpha C$  domains are known to have a tendency to interact intra- and intermolecularly with other  $\alpha C$  domains. Ta, Sykes, and McDermott<sup>[37]</sup> proposed that on HOPG, the D domains hydrophobically bind to the surface while the  $\alpha C$  domains interact with other  $\alpha C$  domains. In contrast, on negatively charged mica surfaces, the positively charged  $\alpha C$  domains likely interact strongly with the surface and unavailable for intermolecular binding.

The particular protein structure clearly affects the final adsorbed conformation. The von Willebrand factor has a native structure where the termini are

extensively disulfide bonded and, therefore, structurally very stable.<sup>[76]</sup> The termini are also very hydrophilic. The remainder of the molecule is balanced in its hydrophobic and hydrophilic character. On mica, VWF is thought to be more loosely bound; thus, the extended structure of the protein and the high coverages, as shown in Fig. 9, may be a result of a combination of repulsive hydration, electrostatic, and attractive van der Waals interactions.<sup>[59]</sup> On HOPG, evidence of spreading is shown by its smaller height compared to the native structure (Fig. 10). However, both the amount of lateral spreading and the surface coverage under similar conditions are much smaller than for VWF on mica (compare Figs. 9 and 10). The origin of this difference is not transparent. The authors suggest that on HOPG, “the spreading stresses [of VWF] may be transmitted via the structurally rigid termini causing the VWF to adopt compact structures.” Structural stability of the protein is a key factor in determining the extent of conformational change upon adsorption. This was illustrated by Billsten et al.,<sup>[77]</sup> who measured the extent of change in secondary structure by CD of T4 lysozyme mutants adsorbed onto silica nanoparticles (average diameter ~15 nm). Not unexpectedly, it was found that the less structurally sound, native structures lost more secondary conformation upon adsorption.

### Protein Structural Changes

Protein molecules adsorbed on a non-specific surface tend to undergo conformational change. Structural alteration results from the interaction forces between the hydrated surface and the hydrated protein, which disturb the delicate balance of energy and entropy that maintains the protein in a particular conformation in solution. Conformation rearrangement is seen widely in many experiments. Height measurements and antibody-binding experiments by Coen et al.<sup>[55]</sup> demonstrated that the first layer of protein A adsorbed at the silicon surface is denatured (Fig. 7). Height profiles of both GOx (Fig. 4)<sup>[56]</sup> and IgG (Fig. 3)<sup>[37]</sup> on HOPG suggest that the proteins are structurally reconfigured at the surface. Circular dichroism spectroscopy has been used to show that  $\alpha$ -chymotrypsin and cutinase change their  $\alpha$ -helix content when adsorbed on either Teflon or silica.<sup>[14,15]</sup> Interleukin-2, upon exposure to silicone rubber tubing for 24 hr, lost 99.5% of its bulk activity. Experimentation with FTIR revealed that the protein adopts a non-native conformation in which the  $\alpha$ -helix,  $\beta$ -sheet, and turn content changes.<sup>[7]</sup> Sane, Cramer, and Przybycien<sup>[8]</sup> also found that lysozyme's secondary structure is disturbed after adsorption onto reversed-phase chromatographic supports.

The extent of conformational change is related to many factors including the relative hydrophobicity of the surface, the exposure time of adsorption, and the adsorption density or surface packing of protein. The hydrophobic residues of a protein are usually more concentrated in the core. Upon contact with a hydrophobic surface, the free energy of the system decreases as water molecules that were adjacent to the hydrophobic areas on the protein and on the solid surface are driven out to allow the hydrophobic residues to reside next to the surface. One can imagine that the more hydrophobic a surface is, the greater is the structural rearrangement that will occur. Ta, and McDermott<sup>[44]</sup> confirmed this assertion in AFM studies of BFG adsorption onto CH<sub>3</sub>- and COOH-terminated SAMs. On the hydrophobic -CH<sub>3</sub> surface, the height profile indicates that the protein flattened out, whereas on the more hydrophilic -COOH surface, BFG did not change shape to the same degree. Norde et al.<sup>[14,15]</sup> established that  $\alpha$ -chymotrypsin and cutinase retain some enzymatic activity on hydrophilic silica while losing all activity on hydrophobic Teflon. In a study of BSA adsorption, Norde and Giacconelli<sup>[78]</sup> showed that irreversible structural changes occurred on polystyrene, but not on silica. Wahlgren and Arnebrant<sup>[25]</sup> reported that  $\beta$ -lactoglobulin underwent more significant structural changes on methylated silica and polysulfone than on silica. Fibrinogen and albumin were shown to leave larger “footprints” on hydrophobic surfaces as compared to a hydrophilic surface.<sup>[21,79]</sup> However, proteins do not unfold and denature solely on hydrophobic surfaces. Coen et al.<sup>[55]</sup> reported a highly denatured monolayer of protein A on hydrophilic silicon.

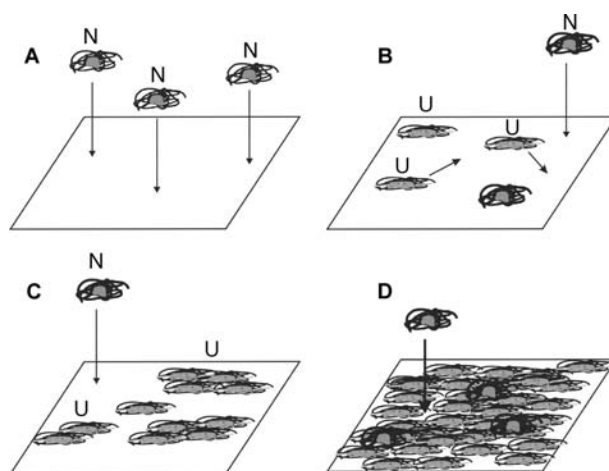

The structural rearrangement of the protein at a surface is thought to be a “slow” process. Over time, the number of residue contacts with the surface increases, making the surface-protein interaction stronger. The amount of high-density lipoprotein (HDL) that can be desorbed from polyethylene surfaces by surfactant exposure is significantly decreased after 24 hr of storage.<sup>[2]</sup> In addition to making more and stronger bonds with the surface, the unfolding protein is thought to change its packing structure, possibly aggregating to form intertwining networks. In force-distance curve experiments, Chen et al.<sup>[67]</sup> discovered that the force required to penetrate through a layer of albumin adsorbed on polystyrene increased over time. Friction-force microscopy of BFG on patterned CH<sub>3</sub>- and COOH-terminated SAMs revealed that the friction behavior of the adsorbed protein on this surface changes over time, as in Fig. 13.<sup>[44]</sup> Almeida, Salvadori, and Petri<sup>[70]</sup> have shown that the contact angles for monolayers of enolase adsorbed onto both hydrophilic silicon wafers and (aminopropyl)-trimethoxysilane (APS) and hydrophobic PS change

with time, indicating structural rearrangements are occurring well after the protein is initially adsorbed to the surface.

The amount of crowding on the surface affects the amount of structural rearrangement that can occur. If the average nearest neighbor distance is relatively large, then the protein has a greater opportunity to spread. However, if the surface is more crowded, there is only limited space for the protein to spread. Using CD, Norde et al.<sup>[14,15]</sup> showed that a higher fraction of  $\alpha$ -chymotrypsin and cutinase adsorbed on silica remain in their native state if the surface coverage was higher. Of course, with time, structural reconfiguration is still likely to occur, but at a slow rate. For BSA on silica and PS, Norde and Giacconelli<sup>[78]</sup> reported similar findings. However, Sane, Cramer and Przybycien<sup>[8]</sup> showed that the secondary structure of lysozyme is more disturbed on more crowded surfaces. They attributed this finding to lateral interactions between the adsorbed lysozyme.

Irreversible adsorption of protein on a surface is most likely to result from significant structural changes occurring on the surface. As unfolding proceeds, more contacts are created with the surface. In analogy to polymer adsorption, it becomes difficult for the partially denatured protein to be removed. Wahlgren, Arnebrant, and Lundstrom<sup>[28]</sup> showed that the longer lysozyme was adsorbed on silicon oxide, the larger was the fraction of protein irreversibly adsorbed. This is true for  $\beta$ -lactoglobulin on silicon oxide as well.<sup>[26]</sup> Given more time to unfold, both the number of contacts with the surface and their strength increases. Foster showed that the irreversibility of albumin adsorption was higher for hydrophobic CH<sub>3</sub>-terminated SAMs than for bare silica. Both Wahlgren and Arnebrant<sup>[25]</sup> and Marsh, Jones, and Sferrazza<sup>[26]</sup> confirmed this with  $\beta$ -lactoglobulin adsorption onto hydrophilic and hydrophobic surfaces. This was attributed to hydrophobic surfaces being more likely to denature protein to a greater extent than hydrophilic surfaces. However, given the tendency of proteins to reconfigure at long times, the distinction in the amount of protein irreversibly adsorbed on hydrophilic and hydrophobic surfaces is likely to decrease. Wertz and Santore<sup>[79]</sup> showed that adsorbed protein layers were more susceptible to washout at higher coverage because the increased crowding on the surface limited the amount of solid surface area available per protein molecule.

Fig. 22 shows a general kinetic picture of protein adsorption onto a non-specific solid surface (i.e., a solid surface without designed specific binding sites for the protein). Particular proteins on particular surfaces may not visit all the listed steps. Initially, in Fig. 22A, protein is in its native conformation (labeled as “N” with a shaded hydrophobic core and a more

**Fig. 22** Generalized illustration of protein adsorption. (A) At early times, protein in its native “N” state rapidly adsorbs onto bare surface. (B) Once adsorbed, protein begins slow unfolding and spreading on the surface (labeled as “U”), rendering them irreversibly adsorbed, but yet mobile on the surface. Additional protein adsorbs onto the surface on available bare surface. (C) Protein aggregates on the surface to form clusters. The rate of protein adsorption onto the surface decreases as less bare surface is available. (D) A complete monolayer is eventually established. Multilayer adsorption and reconfiguration occurs on a slow time scale.

diffuse hydrophilic corona) in the bulk aqueous environment. Mass transfer processes bring the native protein particle to the surface where it quickly adsorbs onto the mostly empty surface via a combination of van der Waals, electrostatic, and hydrophobic forces. At this stage, interaction forces between the surface and the protein can be weak, and reversible desorption is possible. Once adsorbed at the surface, the protein undergoes structural rearrangement as it is no longer completely surrounded by bulk water. Replacement of surface water by protein segments can be favorable leading to partial unfolding (labeled as “U” in Fig. 22B). The time for and extent of unfolding depends both on surface chemistry (e.g., hydrophobic vs. hydrophilic) and quite importantly on the stability of the native protein. Typically, surface conformation change gives rise to unburying of hydrophobic residues and to lateral “spreading” of the protein adsorbate as more residues can now contact the surface. The amount of spreading depends on the surrounding coverage. Irreversible adsorption and partial denaturation develops at this point. Simple model calculations indicate the conformation change can be extensive creating loops and trains, quite analogous to polymer adsorption from solution.<sup>[80,81]</sup> Although irreversibly attached to the surface, the individual protein monomers participate in lateral diffusion, as shown in Fig. 22B. Collisions between adsorbate protein molecules permit surface aggregation via interprotein

exposed hydrophobic residues. Clusters result, as shown in Fig. 22C, similar to bulk aggregation of partially denatured protein. Upon clustering, the surface aggregates are likely to be immobile because of the increased number of contacts with the surface. As slow reconfiguration and clustering continues, more protein arrives at the surface, but the rate of adsorption slows because of the decreasing availability of bare surface area. It may be possible for protein to adsorb onto already adsorbed protein but this apparently occurs on a longer time scale compared to that onto the unoccupied surface. Typically, the surface fills into a monolayer before multilayers begin forming in Fig. 22D. If the rate of protein arrival to the surface is fast compared to the time scale for lateral diffusion, formation of clusters is bypassed and monolayer coverage is directly reached. Additional protein may adsorb onto the first layer by interaction with hydrophobic residues exposed as a result of the conformation changes induced in the underlying layer. Initially, the multilayer protein might be reversibly adsorbed. However, irreversible incorporation and aggregation is later anticipated. Slow cooperative reconfiguration of the multilayer protein film may continue for very extended times.

## CONCLUSION

Atomic force microscopy is a powerful technique to study protein adsorption. With nanometer lateral resolution of height and force interactions, AFM provides information that optical and spectroscopic techniques cannot. This includes elucidation of the supramolecular assembly of adsorbed protein and of multilayer formation. It can also provide information on of the structure and orientation of the protein as it adsorbs onto the surface. Because of its excellent lateral resolution, non-uniform surfaces can be studied to compare the adsorption behavior of proteins when presented with various surfaces at the same time. Through its ability to measure forces on a piconewton scale, AFM can measure force interactions between the protein-coated surface and the tip. This gives insight into the forces arising between the protein-coated surface and tip material and the mechanical properties of protein films.

In conjunction with optical and spectroscopic instruments, AFM provides insight into the mechanisms of aqueous protein adsorption onto a solid surface. Electrostatics play a significant role in the amount of protein adsorbed, protein structure, and packing structure. The kinetics of adsorption can be broken down into several stages to reveal kinetic details such as conformation change, surface crowding, monolayer establishment, and multilayer growth.

Multilayer growth does not appear to be a universal phenomenon and probably depends on the particular chemical composition and adsorption configuration of a protein. However, we caution that there are only a few long-term (several hours to days) experiments on multilayer formation with a sufficiently wide range of proteins. Once adsorbed on the surface, some proteins exhibit lateral movement, and can form clusters, affecting the total mass adsorbed and the final adsorption patterns. Typically, the particular adsorption patterns observed at the surface can be explained on the basis of the specific protein structure and chemistry. In general, an adsorbed protein undergoes structural perturbation. Structural rearrangement can be minimal or dramatic depending on the system. The extent of unfolding is thought to be related to the hydrophobicity of the surface, although instances of irreversible adsorption on hydrophilic surfaces are legion. Highly unfolded and, therefore, denatured proteins may have many points of contact with the surface and are, thus, more likely to be irreversibly adsorbed. Atomic force microscopy has contributed considerably to the understanding of protein adsorption on non-specific solid surfaces and will undoubtedly continue to play an important role.

## GLOSSARY OF ABBREVIATIONS

AFM	atomic force microscopy
APS	(aminopropyl)-trimethoxysilane
BFG	bovine fibrinogen
BSA	bovine serum albumin
CD	circular dichroism spectroscopy
DETA	trimethoxysilylpropyldiethenetriamine
FOETS	[2-(perfluorooctyl)ethyl]trichlorosilane
FRAP	fluorescence recovery after photobleaching
FTIR	Fourier-transform infrared spectroscopy
GOx	glucose oxidase
HDL	high-density lipoprotein
HEWL	hen egg white lysozyme
HOPG	highly oriented pyrolytic graphite
HAS	human serum albumin
HTS	hexadecyltrichlorosilane
IgG	immunoglobulin G
IgM	immunoglobulin M
MBP	myelin basic protein
MHA	mercaptophexadecanoic acid
ODT	octadecanethiol
OTS	<i>n</i> -octadecyltrichlorosilane
OWLS	optical waveguide lightmode spectroscopy
PBS	phosphate-buffered saline
pI	isoelectric point
PDMS	poly(dimethylsiloxane)
PMMA	poly(methyl methacrylate)
PS	polystyrene

QCM	quartz crystal microbalance
RSA	random sequential adsorption
SAM	self-assembled monolayer
SAR	scanning angle reflectometry
SFA	surface force apparatus
SPR	surface plasmon resonance
TIRF	total internal reflection fluorescence
VSFS	vibrational sum frequency spectroscopy
VWF	von Willebrand factor
XPS	X-ray photoelectron spectroscopy

## INTRODUCTION

Chemical mechanical polishing (CMP), otherwise known as chemical mechanical planarization, has been an enabling catalyst for rapid technological advancements in microelectronic fabrication and design over the last decade. Although now a multibillion-dollar business in the microelectronics industry, besides patents, there is a dearth of scientific publications on the subject. After initially touching on the significance of CMP, this entry reviews the literature on the versatility of atomic force microscopy (AFM) as a means to probe and simulate the CMP process at the single-particle level.

## IMPORTANCE OF CHEMICAL MECHANICAL POLISHING

Chemical mechanical polishing has become the preferred technology for achieving wafer-level global planarization in ultra-large-scale integration circuits.<sup>[1–5]</sup> In this process, the creation and subsequent controlled abrasion of angstrom- to nanometer-thick chemically modified surface layers is used to remove topographic variations from the surface of microelectronic wafers enabling layer-by-layer device construction. The success and versatility of CMP technologies have been realized largely through the formulation of submicron to nanoscale particulate slurries, which provide both the mechanical and chemical action required for effective and efficient “flattening” of wafer surfaces for subsequent multilayer metallization.<sup>[3–11]</sup> Chemical mechanical polishing is now a multibillion-dollar industry and the fastest-growing unit operation in the microelectronic

manufacturing.<sup>[4]</sup> Yet the fundamental science behind CMP is not well understood. The numerous process variables (>20) as well as the lack of publications outside patent literature have led to a jumbled picture of the essential processes that dictate CMP performance.

Conventional approaches to academic and industrial CMP research have focused on studies in which ensemble endpoints, such as material removal rate, surface roughness, and maximum defect size, are measured subsequent to the use of benchtop or industrial-scale polishing devices to access slurry performance. These studies typically provide comparative results and evidence toward the utility of a particular slurry formulation but generally lack information about the fundamental molecular and nanoscale interactions that control polishing performance. This article discusses the versatility of AFM as a means to probe and simulate the CMP process. The characterization and integration of self-assembled surfactant systems into effective CMP slurries are used to exemplify the utility of the AFM for the elucidation of elementary parameters critical for optimal slurry design. As devices become smaller, more intricate, and incorporate new materials for enhanced electronic properties, the technology-driven slurries of the past may not provide the performance necessary for the continued large-scale production of latest-generation microelectronic devices. To advance manufacturing techniques, a sound scientific understanding of the fundamental nanoscale to microscale interfacial interactions and mechanisms present in the CMP process must be developed.<sup>[3]</sup> The integration of AFM-based single particle measurements in fundamental CMP studies may provide an added level of insight necessary for

the design of “smart” and “tunable” slurries that support the manufacture of future electronic devices.

## DISCUSSION

### Fundamental Issues in Slurry Design

Chemical mechanical polishing utilizes both chemical and mechanical interactions to essentially flatten, or planarize, dielectric and metal surfaces using a slurry composed of chemicals and submicron particles.<sup>[1–11]</sup> As illustrated in Fig. 1, the CMP process has three main components: 1) the wafer surface (onto which the device is built), 2) the polymeric polishing pad (which entraps and holds the abrasive particles), 3) the polishing slurry composed of submicron particles and reactive chemical agents. Slurry is dosed onto a rotating polymeric pad onto which the wafer is pressed while rotating, causing attrition of unwanted asperities. The overall aim of the process is to remove topographic features from the surface such that multilayer metallization, or layer-by-layer construction of devices, can occur. The general strategy for this is to engineer slurries that provide a pressure-sensitive material removal response. This is desired such that the higher asperities are preferentially removed and the end product is a planarized surface.

Chemical mechanical polishing slurry solutions often contain multiple chemical reagents at high ionic strength and high pH values at the time of polishing to provide the necessary reactivity with the wafer surface. Although these conditions favor the formation of a chemically modified layer, they complicate strategies for maintaining slurry stability. The presence of less than 1 ppm of aggregates in a slurry can cause deleterious deformation of the wafer surface;<sup>[6–8]</sup> therefore an optimally polishing

CMP slurry must be aggregate-free. Stable suspensions provide more repeatability, lower surface defectivity, and better consistency in polishing.<sup>[4]</sup>

Because of the difficulties in adequately dispersing CMP slurries in the presence of the necessary chemical reagents, some manufacturers have resorted to the mixing of particulate slurries with the salts and reactive chemicals at the point of use.<sup>[4]</sup> This technique effectively reduces the time for particulate coagulation and may aid in slurry handling. However, problematic aggregation and slurry particle deposition onto the wafer surface still occur. The next generation of particulate slurries should possess more advanced approaches such as the incorporation of robust steric dispersants.<sup>[5]</sup>

To assess whether or not the stability requirements for a slurry have been met, one typically performs a number of particle sizing or turbidity tests. These measurements provide evidence of whether or not a system will coagulate under the given chemical environment; however, the extent or magnitude of the barrier to coagulation is not directly revealed. Because of this shortcoming, AFM normal force measurements to simulate particle–particle interactions have gained considerable attention in the fields of colloid and interfacial science over the last decade.<sup>[12]</sup> An AFM with an attached liquid cell or suitable liquid reservoir provides a readily accessible means of directly measuring nano-scale surface force interactions in numerous solution environments. These force–distance curves can be further evaluated to derive parameters such as the surface charge,<sup>[13–15]</sup> the mechanical properties of surface layers,<sup>[16]</sup> and the mode and potential mechanism behind the observed surface forces.<sup>[17]</sup> The advent of colloidal probes has further advanced this approach by extending the measurement beyond the typical silicon or silicon nitride tip materials toward real particle systems.

Fig. 1 Schematic representation of chemical mechanical polishing process.

In CMP, chemical reagents not only facilitate the formation and passivation of chemically modified surface layers, but also modulate dispersion within the particle system.<sup>[3–11]</sup> Therefore care must be taken to ensure that the system to be measured by AFM adequately represents the real system at hand. Slight changes, for instance, in surface chemistry, crystalline structure, and morphology, can alter the adsorption behavior of species from solution as well as the bare interaction forces between surfaces, thereby obscuring the appropriate interpretation. Because CMP slurries are formulated with submicron or nanosized particles that are nearly impossible to singly attach at the tip apex, bare AFM tips or larger-sized particles are used for simulating the CMP process. Recently, AFM tips with attached nanotubes have been procured that may be further functionalized with the appropriate nanoparticle at the free end.<sup>[18]</sup> Unfortunately, a large degree of uncertainty remains with respect to the appropriate treatment of mechanical response of these “nanoprobes” under compression and lateral motion.<sup>[19]</sup>

### Interpreting Slurry Stability

When focused on particle–particle interactions, a flat substrate may be chosen to simulate a particle surface, and either a bare tip or an attached larger particle may be used to probe the system. The former is applicable when no appreciable interference from the AFM tip material, apart from the real particle system, is expected. The utilization of AFM normal force–distance curves to interpret slurry stability has been well documented.<sup>[13–15]</sup> Intuitively, if solely attractive or repulsive forces are measured between a representative probe–substrate system, then the corresponding particulate system will be unstable or stable, respectively. If both types of forces are present, there will exist critical forces or distances in the system that define stability. As a general rule of thumb, slurry stability typically ensues if repulsive force barriers greater than 10 kT are present.<sup>[20]</sup>

At solution ionic strengths on the order of 0.1 M, purely electrostatic mechanisms for particulate stability are ineffective because of extensive double-layer compression. Hence other measures such as the addition of dispersants are needed to prevent coagulation. Recently, self-assembled alkyl trimethyl ammonium surfactants have been shown to provide robust stability in silica suspension slurries under saturated salt solutions, extremes in pH,<sup>[21,22]</sup> and under high shear<sup>[23]</sup>—conditions where traditional polymeric or inorganic dispersants are often ineffective. These findings prompted fundamental investigations into the properties of these self-assembled surfactant structures at the solid–liquid interface for the formulation

**Fig. 2** Turbidity in nephelometric turbidity units (NTU) of silica particles after 60 min in a solution of 0.1 M NaCl at pH 4 as a function of C<sub>12</sub>TAB concentration, and the measured interaction forces between an AFM tip and silica substrate under identical solution conditions. *Source:* From Ref.<sup>[21]</sup>.

of silica dielectric CMP slurries.<sup>[5,8]</sup> Atomic force microscopy has uncovered fundamental mechanisms and key relationships for CMP slurry and dispersant system design in this system.

>The onset of silica slurry stability at high ionic strengths as discussed above has been linked to the onset of repulsive force barrier.<sup>[21]</sup> Fig. 2 illustrates the excellent agreement between ensemble turbidity measurements and the AFM normal force measurements for the silica wafer–silicon nitride tip system at pH 4.0 and 0.1 M NaCl as a function of dodecyl trimethyl ammonium bromide surfactant (C<sub>12</sub>TAB) concentration. The mechanism behind C<sub>12</sub>TAB-induced stabilization was subsequently investigated through zeta potential, contact angle, adsorption isotherms, and Fourier transform infrared spectroscopy–attenuated total internal reflection (FTIR–ATR) analysis.<sup>[21,22]</sup> These experiments illustrated that the repulsive barrier was induced via hydrophilic adsorbed surfactant assemblies that were micelle-like in origin. Ref.<sup>[25]</sup> reviews the adsorption of cationic surfactants from solution to oxide surfaces.

The general mechanisms by which micellar interfacial surfactant structures physically intervene in the engagement process of approaching surfaces have been documented.<sup>[16,26]</sup> Fig. 3 illustrates a typical force–distance curve between two approaching surfactant-coated oxide surfaces, under low electrolyte conditions. The depicted force profile was measured between a 7.5- $\mu$ m silica colloidal probe and a planar silica substrate at twice the bulk critical micelle concentration (CMC) concentration (32 mM) of C<sub>12</sub>TAB. Under

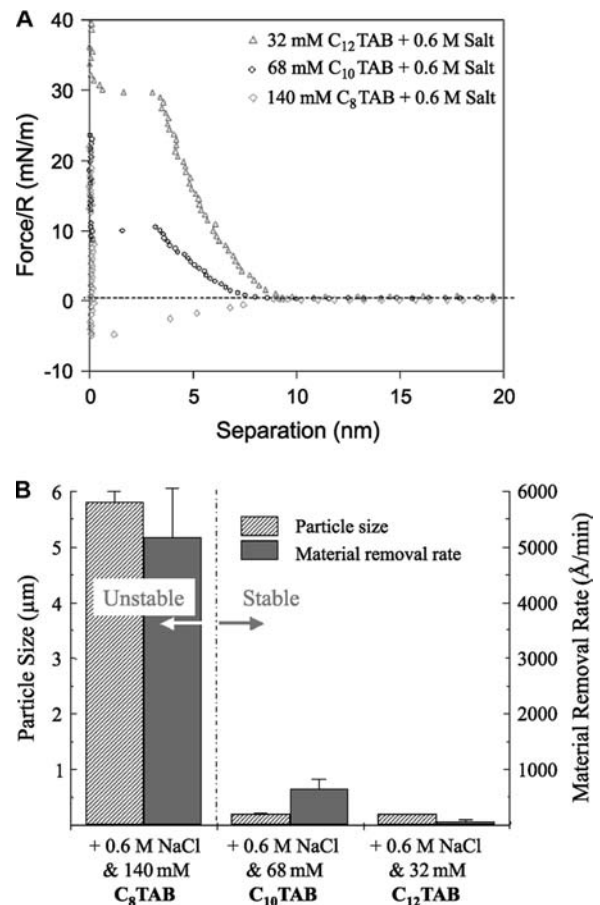

**Fig. 3** A typical force-separation curve for the interaction of a 7.5- $\mu\text{m}$  silica sphere and a flat silica substrate in a solution of 32 mM  $\text{C}_{12}\text{TAB}$ . Data from several runs are presented. *Source:* From Ref.<sup>[24]</sup>.

these solution conditions, a saturated layer of micelles is adsorbed to both the colloidal probe and the flat interface. As the surfaces are brought together, the positively charged micelles begin to interact through long-range electrostatic forces. At shorter distances, just before and during the initial contact, a combination of electrostatics and short-range hydration forces between surfactant headgroups contributes to the interaction profile. As the intervening micelles are further pressed together, a sharp pseudo-linear increase in repulsion occurs from steric contributions resulting from the elastic deformation of the surface aggregates. Then at a critical applied load, these aggregates break apart and the surfaces jump into contact. After this point, the measured interaction is in constant compliance, and no further deformation of the adsorbed surfactant structures is measured. A thin layer of surfactant monomers still resides between the approaching surfaces as indicated in Fig. 3; however, this layer is not mechanically detectable by AFM normal force measurements because of the sensitivity limits of the experimental configuration. Moreover, the apparent modulus of molecular-scale organic layers is largely impacted by the underlying surface, and the existence of a rigid underlayer is known to lead to effective mechanical properties orders-of-magnitude larger than those of the film alone.<sup>[26,27]</sup>

Because of the potential for these surfactant systems to provide stability in CMP slurry formulations in the

presence of harsh additives, alkyl trimethyl ammonium surfactants were added to silica slurries and tested for polishing performance. Two-hundred-nanometer monodisperse Stober silica particles were used as the abrasive particles at a loading of 12 wt.% to closely resemble conventional CMP slurries while still maintaining a certain degree of idealness for fundamental interaction studies. The pH in the slurries was maintained at 10.5 such that the “gel-like” chemically modified layer formation could occur at the wafer surface, and 0.6 M NaCl was added to simulate the ionic strength induced by industrial CMP additives. Experiments performed on a benchtop polishing device illustrated that the robust dispersion provided by the surfactant systems exhibiting an appreciable repulsive force barrier at post-CMC concentrations (Fig. 4A) led to excellent surface finish and low surface defectivity (Fig. 4B). However, at the same time, negligible polishing rates occurred. For optimally polishing CMP slurry, both high removal rates ( $>600$  nm/min) and

**Fig. 4**  $\text{C}_{12}\text{TAB}$ ,  $\text{C}_{10}\text{TAB}$ , and  $\text{C}_8\text{TAB}$  surfactants at 32, 68, and 140 mM concentrations in the presence of 0.6 M NaCl at pH 10.5 (a) Maximum repulsive force responses obtained with AFM; (b) slurry particle size (stability) and material removal rate responses. *Source:* From Ref.<sup>[30]</sup>.

low surface defectivity [ $>2$  nm root-mean-square (RMS) and maximum defect sizes  $<20$  nm] must be achieved simultaneously.<sup>[3,5,8]</sup> An important conclusion from the above finding is that that dispersion is a necessary but not a sufficient component for CMP slurry design; this emphasizes the importance of particle–wafer interactions in CMP processes.

### Particle–Substrate Interactions

Although particle–particle interaction can be simulated by AFM to ensure adequate slurry stability—which translates into lower surface defectivity and fewer wafers lost to large-scale surface deformations (scratches)—particle–surface interactions drive the material removal and planarization processes. Hence the overall effectiveness of the CMP process largely depends on these interactions. Not surprisingly, the majority of AFM studies involving CMP focus on these interactions almost in entirety.

At the nanoscale, one can envision the CMP process as a single particle phenomenon. This is depicted in Fig. 5 where an abrasive particle is entrapped by a polymeric pad asperity as it transverses across the wafer surface. The particle–surface interactions incurred by the applied normal and lateral loads ( $F_N$  and  $F_L$ , respectively) result in the removal of the thin chemically modified layer. As the bare wafer surface is exposed to the solution environment, chemical reagents form a new chemically modified surface layer. This process repeats itself as subsequent particles are brought into contact with the wafer surface.

From this perspective, the CMP process can be effectively simulated by rastering an AFM probe against a wafer surface. Recently, several authors have performed this experiment to simulate the CMP of metal materials by scratching metal substrates with an unmodified AFM tip.<sup>[28–30]</sup> In metal CMP, a brittle oxide layer is formed on the more ductile metal surface, which is thought to be removed, almost in

**Fig. 5** Schematic illustrating a single particle material removal event during CMP.

entirety, via the mechanical normal and shear stresses imposed by the abrasive particles.<sup>[3]</sup> Contrary to silica polishing, in these systems, an AFM tip may provide an adequate surrogate for an abrasive particle. However, it should be stressed that this assumption is speculation because no definitive studies have been conducted yet to verify the brittle fracture/film delamination mechanisms for metal CMP.<sup>[3]</sup> Nonetheless, bare AFM tips have been reported to adequately simulate an abrasive particle in metal CMP.

Deveecchio, Schametz, and Frankel<sup>[28]</sup> used a silicon AFM tip and a pure alumina substrate to simulate the polishing of a metallized wafer. By rastering the tip over a known area on the metal surface for a given time and applied load, they were able to derive nominal material removal rates from AFM experiments. The material volume losses from “scratched” areas were determined by subsequent imaging at low applied loads. This value was normalized by the rastering time to obtain a nominal removal rate. Using this approach, the nominal material removal rates were studied under a range of conditions including varying tip/sample forces, solution pH, and electrode potentials (used to imitate an oxidizing agent). Baseline experiments performed in air had a negligible removal rate, illustrating that the observed phenomenon results from both the mechanical abrasion and the solution chemistry. As with ensemble CMP experiments, the removal rate was found to be strongly dependent on the solution pH, the relative amount of oxidation, and the applied load.

A standard silicon nitride AFM tip was used by Lim et al.<sup>[29]</sup> to measure frictional and topographic changes at the copper surface in the presence of nitric acid and neutral solution with benzotriazole (BTA), a corrosion inhibitor. No significant changes were found to occur in neutral solutions with BTA. However, under acidic conditions where isotropic dissolution of the copper surface is known to occur, BTA acted as a passivation agent. Moreover, the BTA-passivated chemically modified layers could be removed via abrasion with the AFM tip, resulting in preferential material removal at the contacting asperities. The presence of higher interfacial friction with BTA-passivated copper surfaces as well as tip-mediated, localized dissolution of copper interface was observed. Similarly, Berdyeva, Emery, and Sokolov<sup>[30]</sup> also used a silicon nitrate tip to simulate the CMP of copper surfaces oxidized in aqueous solutions of peroxide and glycine at varying pH values. The material removal rate and observed indentation depth as a function of pH was consistent with the previous CMP results. The friction force between the tip and the surface was measured, and, in general, it was shown that the lower friction coefficients correspond to the slower removal rates.

Maw et al.<sup>[31]</sup> recently proposed an alternative approach for studying CMP processes. Single surface

10 x 10 μm Image (z = ± 1 μm)

**Fig. 6** IC-1000 polishing pad surface as imaged by AFM (top image) and SEM (bottom image) showing the macro-porosity and microporosity. *Source:* From Ref.<sup>[30]</sup>.

asperity wear was simulated by measuring the dulling or material removal from a silicon nitride AFM tip rastered against a variety of substrates in aqueous solution. The chemical nature of the substrate was shown to play a critical role in the wear of dielectric oxide materials—significant material removal was observed only when the surface was populated with the appropriate metal-hydroxide bonds. These results suggest that pressure-induced bridging between oxide bonds on the substrate may assist in CMP processes.

The investigation described above further illustrates the importance of the selection of an appropriate probe material when attempting to simulate a CMP process via AFM. A bare AFM tip should be used only to simulate another material on which the probe is not expected to significantly react with the solution environment, wafer surface, or otherwise facilitate the adsorption of solution species that would interfere with the measurement process. These criteria may not be applicable in silica CMP especially if the abrasive particle material is also silica. Although a significant fraction of the silicon nitride surface may contain silica

because of hydrolysis in water, the surfaces are nevertheless different in charge, hydroxyl site density, and modulus.<sup>[31]</sup> Under such situations, an attached larger-sized particle (colloidal probe) with nearly identical surface chemistry with respect to the primary slurry particles may provide the best simulation. For reasons of sensitivity, reproducibility, and scalability with radius, smooth particles are generally preferred unless an adequate surface morphology match can be made or specific morphological features are investigated.

The range of normal loading forces required for simulation must also be known. This requires an approximation of the pressure per particle experienced in the CMP process. The applied tool pressures in CMP operations can range from less than 1 to over 7 psi. Because of the corrugation (Fig. 6) of the polishing pad, only a fraction of the pad surface transfers this loading force. Hence the localized forces transferred by pad asperities can be appreciably higher, and the pressure per particle will depend on the pad characteristics such as its effective surface morphology and elastic modulus.

Recently, FTIR-ATR was used to measure the effective pad contact area as a function of applied pressure.<sup>[9]</sup> The IR spectra of the IC 1000 pad sample were collected with applied download forces ranging from 23 to 79 kPa. As the applied load was increased, the signal intensity also increased, indicating that more pad contact was achieved with the ATR crystal. To obtain the percent pad coverage, the same analyses were also conducted on a piece of polyurethane without corrugation, identical in composition to the pad. The results represented in Fig. 7A and B evidence that only a fraction of the pad surface was in contact with the wafer surface or with the ATR crystal. Indeed, the percent pad contact values varied between 0.25% and

**Fig. 7** Percent IC-1000 pad contact as a function of applied load. *Source:* From Ref.<sup>[30]</sup>.

0.5% in the selected pressure range. These results agree with the literature findings, which have reported the pad contacts between 0.05% (hard pad with elastic modulus value  $E = 100$  MPa) and 0.54% (soft pad with  $E = 10$  MPa) at 7 psi.<sup>[32]</sup> Through scanning electron microscope (SEM) and subsequent image analysis of the particle-laden pad after polishing, the number of 200-nm particles in contact with the pad at 12 wt.% solids loading was estimated to be  $42 \times 10^6$  per in.<sup>2</sup>, and the interpreted applied load was then found to be 750 nN per particle. Through these approximations, it became evident that the steric force barriers imposed by micellar aggregates on the silica surface in Fig. 3 were exceeded during the polishing process. Therefore micelles were not present on the wafer surface during CMP and could not be responsible for the lack of material removal. Hence the presence of surfactant monomer was found to impede the polishing process.

To investigate this anomalous polishing behavior, rectangular tipless cantilevers (MikroMasch) were selected with a normal spring constant in the range of  $K_N = 2.8 \pm 0.3$  N/m to ensure that normal forces comparable to those experienced in CMP could be accessed. Sol-gel silica particles (7.5  $\mu\text{m}$ ) were attached to the end of the cantilevers using a small amount of high-temperature melting epoxy (Shell Epikote 1009) to ideally simulate the slurry particles. As with the previous normal force measurements, the frequency method<sup>[33]</sup> was used to determine the exact values of the normal spring constants, and forces normal to the flat surface were measured according to the method introduced by Ducker, Senden, and Pashley<sup>[13,14]</sup> As will become evident, the utility of colloidal probes and AFM, in general, for CMP simulations offers multiple routes to probe the fundamental interactions that define the CMP process.

### Lateral Forces and Surfactant Adsorption

Atomic force microscopy lateral force measurements have been used to investigate the loss of material attrition in the surfactant-based slurry system. The lateral interaction force between a silica colloidal particle and an atomically smooth flat silica surface was measured to simulate particle-wafer system interactions. Fig. 8 illustrates representative lateral force vs. loading force curves for the case of silica surfaces interacting across pure water and a 32-mM solution of  $\text{C}_{12}\text{TAB}$ . Data from several experiments are presented to illustrate the reproducibility of the measurements. Each experimental series was taken at a fixed position on the sample. Subsequent to each increase in the normal force, 10 friction force cycles were allowed to transpire to allow the lateral force magnitude to stabilize prior to taking a reading. Consecutive runs taken over

**Fig. 8** Lateral force as a function of the applied load for a 7.5- $\mu\text{m}$  silica sphere interacting with a smooth silica surface in pure water and in solution 32mM  $\text{C}_{12}\text{TAB}$ . Data from several runs are presented. *Source:* From Ref.<sup>[24]</sup>.

different areas show good reproducibility with a maximum deviation of about  $\pm 5\%$ . This suggests that there was no significant wearing of the probe during measurement. It is important to mention that the experimental results from different probes have similar features with regards to lateral and adhesive force interactions under the given solution conditions; however, slight differences in magnitude might appear because of variations in the local roughness of the probe surface.<sup>[34]</sup> For consistency, the data presented have been obtained using the same colloidal probe, unless otherwise noted. The lateral force measurements presented were also taken at a constant lateral scan velocity of 2  $\mu\text{m}/\text{sec}$ . However, it should be noted that contrary to studies on chemisorbed self-assembled monolayers<sup>[35–37]</sup> and adsorbed polyelectrolytes,<sup>[38]</sup> no significant dependence of the frictional force was found when the scan rate was varied between 1 and 20  $\mu\text{m}/\text{sec}$ . The measurements in surfactant solutions were systematically performed 30 min after the solution injection to prevent variations in the extent of consolidation or the packing and morphological state of the adsorbed layers.<sup>[39,40]</sup>

The lateral force measurements were performed using the “friction-force” mode of the AFM, in which the colloidal probe is pressed against the substrate at a constant applied load while the substrate slides horizontally underneath the cantilever. Further details of the measurement procedure are given elsewhere.<sup>[41–47]</sup>

In lateral force microscopy (LFM), a micron-sized colloidal probe significantly improves the reproducibility of lateral force measurements by reducing the relative impact of probe wear on the experimental results; surprisingly, however, attached particles have

only been incorporated in a few AFM/LFM studies.<sup>[38,40,41]</sup> The friction force, as measured between bare silica surfaces in deionized water, was found to increase linearly with the applied load in agreement with the Amontons' law. Accordingly, the data for these conditions can be fitted to a linear function of the type  $F_L = a + \mu F_N$ , where  $F_N$  is the applied load,  $\mu$  is the frictional coefficient, and  $a$  is the adhesive force contribution. The average friction coefficient obtained for pure water was found to be  $\mu = 0.22$  and is in the range of the literature values (0.1–1.0) measured between quartz surfaces.<sup>[48]</sup>

It has been established that  $\text{CH}_3\text{-CH}_3$  group interactions result in a significant reduction in friction when compared with the interactions of higher-energy functional groups<sup>[49,50]</sup> from previous studies of monomolecular films adsorbed at interfaces. The presence of surfactant at the solid–liquid interface is thought to prevent material removal by inhibiting bare surface contact or by acting as boundary layer lubricants. The interactions between intervening surfactant hydrocarbon tails and the silica surface replace the pure  $\text{SiOH}$  and  $\text{SiO}^-$  interactions found in the pure water. From this perspective, the extent of lubrication should therefore depend on the number of surfactant residing between the interface, which was found to be the case, as illustrated in Fig. 9. As free surfactant concentration increased, the lubrication between the interfaces also increases. The maximum amount of lubrication is a plateau value that occurs at and above the bulk CMC (16 mM), representing an order-of-magnitude decrease in the frictional interactions. These measurements confirm that surfactant monomer actively participates in mitigating the particle–wafer surface

**Fig. 9** Lateral force as a function of the applied load for a 7.5-mm silica sphere interacting with a smooth silica surface in pure water and  $\text{C}_{12}\text{TAB}$  solutions of various concentration. Source: From Ref.<sup>[24]</sup>.

**Fig. 10** Repulsive force barrier and pull-off force as measured between a 7.5-mm silica sphere and a flat silica surface as function of the  $\text{C}_{12}\text{TAB}$  concentration. Source: From Ref.<sup>[24]</sup>.

engagement. As noted earlier, the experiments were performed at high loading forces at which the micellar structures have already been broken.

The enhanced lubrication at and above the CMC may be caused by the relative number of surfactant in the local vicinity of the interface. This is indicated in Fig. 10, where the extents of the repulsive force barrier at the surfactant concentrations of 16 and 32 mM are shown to be nearly identical, indicating that saturation adsorption has been reached as previously demonstrated through experimental adsorption isotherms.<sup>[21,25]</sup> Hence under these conditions, the probable number of entrapped surfactant monomers should be the highest and identical, resulting in equivalent frictional interactions. Similarly, at lower free surfactant concentrations, the extent of lubrication should be lower, resulting from fewer surfactant residing between the interfaces. These trends have been verified in Fig. 9, which illustrates that the lubrication efficacy of surfactant solution increases with free surfactant concentration until the bulk CMC is reached. Both electrostatically bound and hydrophobically associated surfactant monomers are thought to participate in the surfactant-mediated lubrication phenomena. The lowest concentration of amine shown in Fig. 9, 1 mM  $\text{C}_{12}\text{TAB}$ , corresponds to the point of zeta-potential reversal (PZR) at which the surfactant molecules are primarily electrostatically bound to the interface. The surfactant adsorption is still as low as 20–25% of that of the saturation value at the PZR.<sup>[51,52]</sup> At higher concentrations, adsorption primarily takes place through hydrophobic association. These additional hydrophobically bound surfactant monomers participate in a further decrease of the frictional force until saturation adsorption.

### Pull-Off Force Measurements—Deciphering Dispersant Molecule Adhesion Mechanisms

To design surfactant-dispersed slurries with appreciable polishing rates, the dominant mechanism leading to the presence of residual monomer at the solid–liquid interface needed to be determined. Pull-off force measurements—the force required to detach the colloidal probe from the planar substrate—were performed in an attempt to gain additional information on the origins and strength of adhesion of the residual surfactant layer. As with the lateral force microscopy measurements, the magnitude of the pull-off force is also strongly influenced by the existence of the intervening molecular films. In the presence of surfactant, the value of typical pull-off forces between the probe used in this investigation and the planar silica substrate increased by an order of magnitude in comparison to the pure state as indicated in Fig. 10. This additional adhesive component between the surfaces is attributed to the hydrophobic interactions between strongly bound surfactant molecules adsorbed to the opposing silica surfaces. However, whether these interaction forces represent the detachment of the adsorbed headgroups from the interface or the disengagement of the interacting hydrophobic surfactant groups themselves remains unknown. These two proposed scenarios are illustrated in Fig. 11. By monitoring the maximum pull-off force as a function of concentration, some clues are given. As indicated in Fig. 10, the adhesive force reaches a plateau value in the vicinity of the PZR and not at the maximum monolayer coverage, which occurs just

**Fig. 11** Schematic representation of the two proposed scenarios for surfactant-mediated detachment of the silica surfaces in this study. (A) The surfactants remain in hydrophobic association and detach at the head–surface interface. (B) The surfactants remain adsorbed at the opposing interfaces and detach through breaking of hydrophobic chain–chain interactions. *Source:* From Ref.<sup>[24]</sup>.

prior to 8 mM  $C_{12}TAB$ .<sup>[21]</sup> This suggests that force required to separate the engaged surfaces is largely electrostatic and not caused by the detachment of hydrophobic bonds. To verify this, the relative magnitude of the interfacial energies expected for the two scenarios depicted in Fig. 11 was investigated and compared with the values calculated from experimental results.

To estimate the energy required for electrostatic detachment, the contribution of the coulombic interaction to the interfacial separation energy  $\gamma_{el}$  was estimated by:<sup>[53,54]</sup>

$$\gamma_{el} = \frac{1}{2} \Gamma_{el} z e \psi_i \quad (1)$$

where  $\Gamma_{el}$  represents the adsorption density of the electrostatically adsorbed surfactant monomers to the substrate,  $z$  is the valency of the headgroups,  $e$  is the electronic charge, and  $\psi_i$  is the potential of the inner Helmholtz plane of the surface prior to surfactant adsorption. For simplicity, it was assumed that  $\psi_i \approx \zeta$ , the zeta potential of the silica surface in pure water, and that  $\Gamma_{el} = \Gamma_{PZR}$ , the amount of surfactant adsorbed at the PZR. Taking typical values<sup>[25,51,52]</sup> of  $\zeta = -60$  mV and  $\Gamma_{PZR} = 1 \mu\text{M}/\text{m}^2$ , the magnitude of  $\gamma_{el}$  was found to be approximately  $3.8 \text{ mJ}/\text{m}^2$ .

To estimate the amount of energy required to separate the surfaces through purely hydrophobic interactions between the hydrocarbon tails (Fig. 11B), the interfacial separation energy,  $\gamma_h$ , was estimated as:

$$\gamma_h = \Gamma_h n \theta_h \quad (2)$$

where  $\Gamma_h$  is the density of strongly bound surfactant molecules that mediate the separation event,  $n$  is the number of  $\text{CH}_2$  groups that effectively interact between the individual surfactant molecules, and  $\theta_h$  is the energy per  $\text{CH}_2$ – $\text{CH}_2$  group interaction. For this estimate, it was assumed that  $\Gamma_h = \Gamma_{el}$  (or the lower limiting case in which only the electrostatically adsorbed molecules are detached), and that full interpenetration of the hydrocarbon chains ( $n = 12$ ) occurs. By employing a typical value<sup>[17]</sup> for  $\theta_h$  as  $6.3 \times 10^{-21}$  J,  $\gamma_h$  was calculated to be approximately  $45 \text{ mJ}/\text{m}^2$ .<sup>[55]</sup> Alternatively, the magnitude of the interfacial separation energy for hydrophobic detachment can be estimated to be close to the experimental values of the adhesion force between chemisorbed  $\text{CH}_3$  group-terminated surfactant monolayers interacting across an aqueous medium. From both force and contact angle measurements, the range of this interfacial energy  $\gamma_{ch}$  is found to be between 40 and  $100 \text{ mJ}/\text{m}^2$ ,<sup>[55]</sup> which compares to the above result and 1 order-of-magnitude greater than  $\gamma_{el}$ .

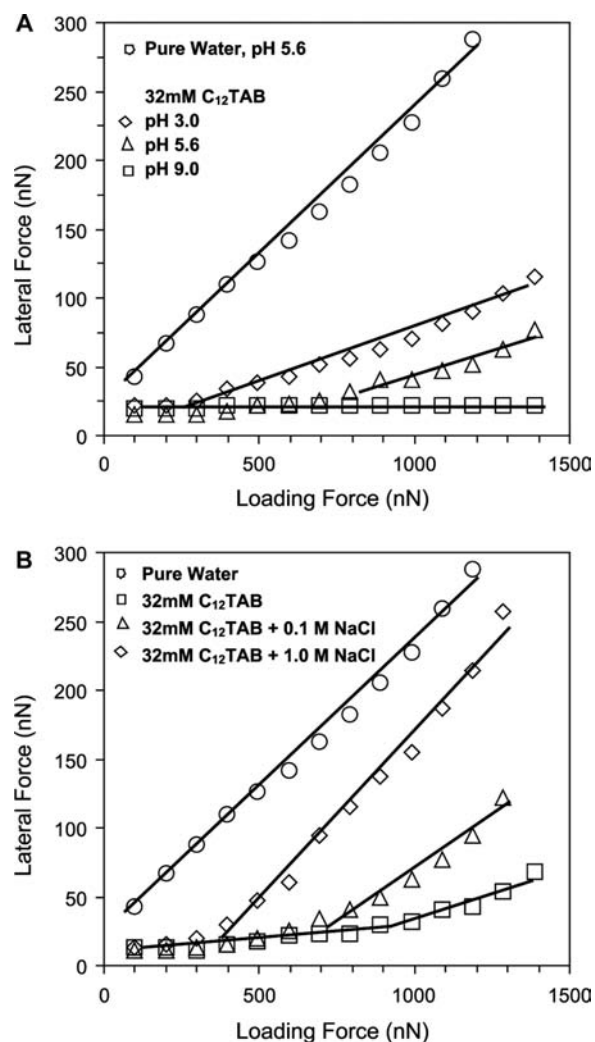

To further compare these values with the experimental pull-off force measurements in this study, the Johnson–Kendall–Roberts (JKR)<sup>[56]</sup> (upper limiting value) or Derjaguin–Muller–Toporov (DMT)<sup>[57]</sup> (lower limiting value) theories were employed. Accordingly, the effective experimental interfacial separation energies were given by:

$$\gamma(\text{JKR}) = \frac{F_{\text{pull-off}}}{3\pi R}, \text{ or } \gamma(\text{DMT}) = \frac{F_{\text{pull-off}}}{4\pi R} \quad (3)$$

By incorporating values of  $F_{\text{pull-off}}$  from Fig. 10, it was found that  $\gamma \approx 3\text{--}4\text{ mJ/m}^2$ , which is in the range of  $\gamma_{\text{el}}$ . This is an order-of-magnitude less than that speculated for purely hydrophobic-mediated detachment. Hence although the adsorption of surfactant at the solid–liquid interface mediates by both chain–chain and head–surface interactions, contributions from the adsorption affinity of the surfactant headgroup to the surface appear to dominate the overall resilience of the remaining films at the interface. For the surfactant system in this investigation, the chain–chain interactions appear much greater than the head–surface affinity (assumed purely electrostatic), causing the latter to dictate the extent of adhesion (pull-off force) and possibly the extent of lubrication. Accordingly, the scenario depicted in Fig. 11a was determined to be more plausible when the two surfaces are pulled apart. Hence to modulate the material removal rate in these surfactant-based slurries, the electrostatic attraction of the surfactant to the wafer and particle surfaces needs to be manipulated.

Although evidence in the preceding section suggested that the resilience of residual surfactant moieties depends largely on the extent of head–surface engagement, the utility of this for the control of the extent of particle–surface engagement mediated by physisorbed surfactant systems has not been illustrated. It is well established that quaternary amine surfactants adsorb to silica interfaces through a combination of electrostatic, hydrogen-bonding, and hydrophobic interactions.<sup>[58]</sup> However, the relative importance of these interactions in maintaining surface attachment and lubrication is not well understood.

If one assumes that the extent of lubrication is mediated by intervening molecular films attached to the solid–liquid interface primarily by electrostatic interactions, then there should be a large dependence on the lateral force with solution pH. It is well documented that the number of deprotonated (negatively charged) silanol groups at silica interfaces increases with pH causing an increase in the net surface charge. The isoelectric point of silica is near pH 2.5; the zeta potential is about  $-50.0\text{ mV}$  at pH 5.6 and  $-70\text{ mV}$  at pH 9.0.<sup>[59]</sup> Hence the extent of lubrication caused by electrostatically adsorbed surfactant structures

**Fig. 12** Lateral force as a function of the applied load for a 7.5-mm silica sphere interacting with a smooth silica surface in solutions of 32 mM  $\text{C}_{12}\text{TAB}$  at (A) various pH values and (B) at various concentrations of NaCl given in logarithmic scale. *Source:* From Ref.<sup>[24]</sup>.

should increase with pH. This is indeed the case, as Fig. 12 indicates. For all solution pH values, the lateral forces at low loading forces (100–300 nN) were found to be identical; however, a deviation in lubrication performance occurred at higher normal forces indicated by the variant of Amontons’ law and potentially a non-Prestonian polishing response.<sup>[3]</sup> This experimental evidence suggests that at a critical load, the adsorbed surfactant structures begin to detach from the surface as marked by the increase in the apparent friction coefficient. This “activation energy” for surfactant detachment shifts to higher energies (loads) with pH. At a pH of 9.0, the transition was not observed for loads up to 1400 nN and was attributed to the strong electrostatic interactions between the surfactant and the silica surface at high pH.

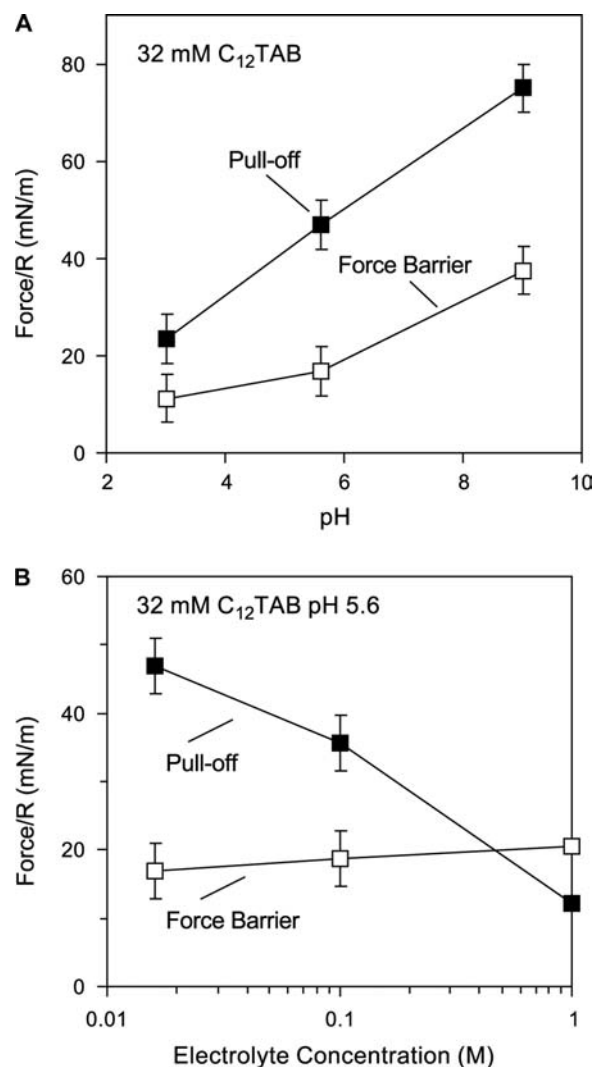

The above illustrates that electrostatic interactions could be used to modulate friction, which physically can be interpreted as the extent of silica-silica engagement; however, for silica CMP, a high pH is generally fixed to ensure the formation of a gel-like layer. This prompted investigations into an alternative approach for modulating the extent of particle engagement and material removal in CMP systems. The influence of co-ion competition with respect to the surfactant molecule for negatively charged surface sites was investigated to suit this purpose. The frictional force between silica surfaces in the presence of post-CMC surfactant solutions at a pH of 5.6 and various ionic strength NaCl solutions were measured and are depicted in Fig. 12B. A significant increase in frictional engagement occurs at high  $\text{Na}^+$  concentrations, further indicating that the electrostatic binding efficacy to the silica interface largely controls the extent of bare surface engagement in these surfactant systems. These findings also suggested for the first time that competitive adsorption strategies may be used to tailor the frictional properties and possibly the material removal rates in slurries dispersed by physisorbed surfactants. Fig. 12B further shows that as the number of competing ions increases, the transition load at which higher friction coefficients appear becomes lower and the magnitude of the friction coefficient becomes higher.

### Optimizing Slurry Formulation Through Systematic Atomic Force Microscopy Measurements

The strategies suggested above focused on diminishing the extent of surfactant surface affinity to allow for greater engagement of the bare particle with the substrate surfaces. It has not been clearly demonstrated, however, whether or not this loss in surfactant surface affinity will result in aggregation of the silica particulate system, which would be deleterious to CMP operations. Pull-off force and repulsive force barrier measurements were conducted as a function of pH and electrolyte concentration to further develop the correlations between stability, surfactant surface affinity, and lubrication. The pull-off force indicates the relative strength of attachment of surfactants to the solid-liquid interface, whereas the presence of a repulsive force barrier indicates that particle stability still exists.<sup>[21]</sup>

Fig. 13A presents the pull-off and repulsive force barrier measurements as a function of pH for the same experimental conditions as in Fig. 12a. At twice the CMC surfactant concentrations, both the repulsive barrier and the pull-off force increase with increasing pH. These trends are attributed to both the greater

**Fig. 13** Force barrier and pull-off force between a 7.5-mm silica sphere and flat silica surface in solutions of 32 mM C<sub>12</sub>TAB as function of (a) solution pH and (b) solution electrolyte concentration. *Source:* From Ref.<sup>[24]</sup>.

electrostatic affinity and perhaps the greater localized concentration of surfactant at the silica-solution interface at higher pH values. Both the enhancement of the barrier and the pull-off forces correlate well with the increased lubrication observed with pH as demonstrated in Fig. 12A.

However, as indicated in Fig. 13b, the extent of the repulsive barrier does not primarily depend on the magnitude of surfactant surface affinity. Although both the lubrication and the pull-off force decrease by nearly an order of magnitude with a 1-M increase in ionic strength, the repulsive force barrier remains nearly constant. This counterintuitive resilience of the surfactant-mediated repulsion under high electrolyte concentrations was first demonstrated in a previous study,<sup>[21]</sup> in which the primary factor for establishing

an effective force barrier was the extent of surfactant–surfactant cohesion in the three-dimensional surface structures. The relationship between the surfactant force barrier and the surfactant surface affinity has been inferred recently.<sup>[24]</sup> Fig. 13B demonstrates that the relative number of strongly bound surfactant monomers at the solid–liquid interface has little bearing on the mechanical properties, or the extent of the repulsive force barrier, imparted by adsorbed micelles or bilayer-like structures. Hence to some extent, it is possible to control the degree of lubrication imbibed by adsorbed surfactants without significantly altering the suspension stability. The above discussion indicates that multifunctional and tailored pressure-sensitive surfactant-based lubricants are plausible through the use of competitive adsorption and surface affinity concepts.

In another study<sup>[8]</sup> utilizing an alternative colloidal probe, it was found that modifying the cohesion between surfactant chain length does not significantly induce a modification in the lubrication, or surface engagement, behavior in the absence of salt as depicted in Fig. 14A. However, with the addition of 0.6 M NaCl, the induced ion competition resolves the difference in surface affinity between C<sub>8</sub>TAB, C<sub>10</sub>TAB, and C<sub>12</sub>TAB surfactants as illustrated in Fig. 14B. A similar result has been previously shown in studies concerning lateral force measurements of monomolecular chemisorbed or deposited films.<sup>[60,61]</sup> These investigations depict a reduction in lubrication with a reduction of the hydrocarbon chain length for intervening films.

As the extent of chain–chain cohesion increases with amphiphile chain length, a reduction in friction occurs because these molecules can more effectively mask the underlying surface because of their higher mutual affinity. Although it is possible to modify surfactant chain length to decrease surfactant surface affinity and thereby induce surface engagement and material removal, maintaining slurry stability at the same time presents an issue. The normal force–distance interaction curves between a silica sphere and a silica wafer in the presence at post-CMC concentrations in the presence of 0.6 M NaCl were previously given in Fig. 4. Under pseudo-CMP conditions, the lower chain surfactant (C<sub>8</sub>TAB) is unable to provide a steric barrier; however, it is able to incur significant surface engagement. The benchmark polishing studies collaborate with these results illustrating a material removal rate of over 5000 Å/min for C<sub>8</sub>TAB compared with removal rates of over 500 and approximately 50 Å/min, respectively, for the C<sub>10</sub>TAB and C<sub>12</sub>TAB slurries in the presence of 0.6 M electrolyte. However, as predicted by the normal force measurements, the C<sub>8</sub>TAB slurries result in an unacceptable surface finish with a root-mean-squared surface roughness near 1 nm and defect diameters on the order of 50 nm.

**Fig. 14** Atomic force microscopy friction force measurements between a silica wafer and a 7.5- $\mu\text{m}$  silica particle for solutions containing C<sub>12</sub>TAB, C<sub>10</sub>TAB, and C<sub>8</sub>TAB surfactants at post-CMC concentrations in the absence (A) and the presence (B) of 0.6 M NaCl. *Source:* From Ref.<sup>[30]</sup>.

Because of the inadequacy of the above results to provide for both good surface quality and adequate material removal, an alternative approach was attempted. It was hypothesized that by modifying the strength of the competing ion from solution, the affinity of the surfactant to the surface could be modulated resulting in a potentially tunable material removal. Moreover, as shown with the lateral force measurements with alternative salt concentrations, the kink or the sudden increase in surface engagement after a certain load in the loading curves tends to shift toward lower loads with increasing salt and indicates that non-Prestonian polishing responses<sup>[3]</sup> may be achieved through ion competition strategies with the appropriate formulation.

To test whether modifying the surfactant surface affinity via alternative competing species could be a

**Fig. 15** Atomic force microscopy friction force measurements between a silica wafer and a 7.5- $\mu\text{m}$  silica particle in DI water at pH 10.5 (baseline), with 32 mM  $\text{C}_{12}\text{TAB}$  with 0.6 M NaCl and 0.1 or 0.2 M  $\text{CaCl}_2$ .

valid approach for achieving both high material removal rates and good surface quality after polishing,  $\text{CaCl}_2$  was added to the silica slurries in the presence of 32 mM  $\text{C}_{12}\text{TAB}$ . Equivalent ionic strengths were maintained in the solutions containing surfactant. The lateral force measurements are displayed in Fig. 15, which illustrates that the surface engagement between the silica surface and the silica particle significantly increased in comparison to the NaCl surfactant solutions and the baseline (pH 10.5, no salt) conditions. Approaching normal force measurements in all three cases (not shown) as well as direct particle sizing indicated that all three slurries were stable. The corresponding polishing results (200-nm sol-gel silica at 12 wt.%) confirmed the LFM experiments and showed that the  $\text{CaCl}_2$ -based surfactant slurries could achieve higher removal rates ( $\sim 1000 \text{ \AA}/\text{min}$  greater) and improved surface quality (nearly identical to the non-polishing surfactant slurries) when compared with the baseline slurry. Hence by changing the magnitude of interaction of competing ions in solution, the polishing behavior of surfactant-based slurries can be modulated, resulting in improved material removal, enhanced surface finish, and potentially tunable polishing responses with the competing ion concentration in solution.

## CONCLUSION

The AFM is a powerful tool for simulating nanoscale CMP processes. Through a systematic study of both normal force (approaching and pull-off) and lateral

force interactions, fundamental mechanisms resulting in modified polishing behavior can be investigated. In CMP operations, the behavior of the slurry is often the defining parameter for overall polishing performance. The integration and effectiveness of dispersants in CMP processes can provide an improved nanoscale surface finish as well as an alternative means to control the extent of material removal.

In this entry, the use of AFM to probe quaternary ammonium surfactant systems for the purpose of the integration and the optimization in silica dielectric polishing slurries was reviewed. Approaching AFM normal force measurements were shown to effectively predict slurry stability and subsequent surface defectivity from benchtop polishing tests. Pull-off force measurements in conjunction with systematic lateral force measurements were found to be effective for deciphering key mechanisms behind modulated polishing performance. The influence of intervening surfactant moieties on the frictional interactions between oxide surfaces was also examined in detail.

As new, softer, and more fragile materials are introduced into microelectronic device fabrication, more intricate slurry formulations will be needed to provide for efficient material removal while maintaining adequate levels of surface defectivity and selectivity in polishing. The AFM is expected to grow more important in future CMP slurry development investigations as well as in fundamental investigations into nanoscale CMP processes. The ion competition strategies and dispersant strategies discussed within may also play a significant role in the development of novel “smart” slurries for future CMP processes.

## INTRODUCTION

Amphiphilic diblock copolymers,<sup>[1,2]</sup> which have hydrophilic and hydrophobic chains, self-assemble to form a monolayer at the air/water interface and a micelle in selective solvents. The diblock copolymer monolayer system is of great importance and interest from the scientific and technological points of view. The relationship between the fundamental molecule structure and properties, such as length and stiffness of each chain, hydrophilicity–hydrophobicity balance, and the nanostructure of monolayer formed, is an important aspect in establishing a tailor-made polymer assembly at the surface and interface. Furthermore, the hydrophilic chain in the polymer monolayer is an excellent model system of the “polymer brush,”<sup>[3]</sup> which is useful in surface modification, colloid stabilization, etc.

## OVERVIEW

We have been studying amphiphilic diblock copolymer monolayers at the air/water interface by in situ X-ray<sup>[4–9]</sup> and neutron reflectometry.<sup>[10]</sup> In recent years, our interest has been focused on ionic amphiphilic diblock copolymer monolayer systems that form an ionic polymer brush in water subphase.<sup>[6,8,9]</sup> The long-range electrostatic interaction and osmotic pressure inside the ionic polymer brush are important for the monolayer nanostructure, in addition to short-range steric forces and conformational effects that are usually seen in the neutral brush. This situation causes a large variety of brush structures. Elucidation of the polymer brush nanostructure will enable on-demand control of surface structure and a wide-range application of the polymer brush system.

The diblock copolymer chosen for the investigation is composed of a fluid-like, very flexible hydrophobic chain and a weak polyacid chain, poly(1,1-diethylsilacyclobutane)<sub>m</sub>-*block*-poly(methacrylic acid)<sub>n</sub> [poly(Et<sub>2</sub>SB-*b*-MAA)].<sup>[11]</sup> The fluid-like nature of Et<sub>2</sub>SB makes it

possible to form a polymer monolayer with smooth interface between air and hydrophobic layer with 3–5 Å roughness.<sup>[6]</sup> Furthermore, the electron density contrast between Et<sub>2</sub>SB and MAA is larger than that in the general diblock copolymer system. Merited by these two, a suitable system for X-ray reflectivity measurement could be achieved by this diblock copolymer.

The nanostructure of the polymer monolayer has been systematically investigated as a function of hydrophilic chain length, surface pressure, and pH.<sup>[6,8,9]</sup> Interesting features are as follows: 1) The hydrophobic layer thickness takes a minimum as a function of hydrophilic chain length at any surface pressure studied.<sup>[6]</sup> 2) The hydrophilic layer under the water is not a simple layer but is divided into two layers, i.e., a “carpet”-like dense MAA layer near the water surface and a polyelectrolyte brush layer.<sup>[9]</sup> 3) The thickness of this dense layer is about 10–20 Å independent of surface pressure and polymerization degree of PMAA in the range studied.<sup>[9]</sup> Phenomenon 1) can be explained by reasonable speculation based on 2) and 3).

The above-mentioned phenomena (1–3) have not been predicted or reported before except for one case.<sup>[31,32]</sup> By combining precision synthesis of diblock copolymers, in situ and high-resolution X-ray reflectivity (XR) measurement, and highly quantitative analysis, we have clarified the nanostructure of polymer self-assembly at the interfaces.

## IN SITU X-RAY REFLECTIVITY EXPERIMENT

The X-ray reflectivity (XR) technique has been attracting attention as a useful tool for the in situ investigation of the surface nanostructure in laboratory-scale experiments.<sup>[12–14]</sup> The usefulness and powerfulness of the neutron reflectivity (NR) technique have also been widely recognized, and novel NR instruments have been constructed<sup>[10]</sup> although NR is still regarded as a special technique because of the limitation of experimental facilities.

X-ray reflectivity measurements were performed with an RINT-TTR-MA (Rigaku Corp., Tokyo, Japan) apparatus in which the X-ray generator and detector vertically rotate around the sample stage. The Langmuir–Blodgett (LB) trough (length 130 mm  $\times$  width 60 mm), made of aluminum coated with Teflon<sup>®</sup> (USI System, Fukuoka, Japan), was mounted on the sample stage to study the water surface system. Details of the XR apparatus and data treatment have been fully described elsewhere.<sup>[15–17]</sup> Data analysis is based on the theory of Parrat<sup>[18]</sup> and Sinha et al.<sup>[19]</sup> The measurements were performed under specular conditions; that is, the incident and reflection angles were kept equal. The specular reflectivity of X-ray provides information on an electron-density variation normal to the surface in the order of angstroms. The scattering vector  $q$  in specular reflectivity is defined by  $q = 4\pi\sin\theta/\lambda$ , where  $\theta$  is the incident or reflection angle from the sample surface, and  $\lambda$  is the wavelength of the incident X-rays, which was 1.5406 Å (Cu K<sub>α1</sub>).

## AMPHIPHILIC DIBLOCK COPOLYMER AND POLYMER BRUSH

Amphiphilic diblock copolymers have both hydrophilic and hydrophobic chains in one molecule. It is possible to design diblock copolymer amphiphiles with large hydrophilic and hydrophobic parts in contrast with amphiphilic small molecules whose hydrophilic and hydrophobic parts are both short. Because of the large hydrophobicity due to the long hydrophobic chain, the diblock copolymer forms a polymer monolayer on water with dangling hydrophilic chain. The long hydrophilic chain in the monolayer forms a “polymer brush” in the water subphase.

The brush structure is mainly characterized by brush thickness, brush density, and density profile in the brush. Theoretical predictions, especially for charged brush, have been made since the early 1990s.<sup>[20–22]</sup> In the past two decades, experimental studies on the polymer brush have been greatly promoted by advances in reflectometry<sup>[12–14]</sup> and methods of surface graft polymerization.<sup>[23]</sup>

The polymer brush in water has been mainly studied on either the hydrophilic chain in diblock copolymer monolayer at air/water interface or grafted polymer chain from a solid substrate immersed in water. The advantages of the monolayer at the air/water interface are as follows: 1) The graft length and polydispersity can be precisely controlled and characterized in the polymerization procedure of a diblock copolymer. 2) The graft density can be easily and freely controlled by changing the surface pressure after spreading a diblock copolymer on a water surface if the sample is insoluble to the subphase. On the other hand, if the sample is not perfectly insoluble, it might be anticipated that the  $\pi$ -A

isotherm gives only apparent graft density. An estimation of the solubility and its effect on the monolayer is needed. The solubility problem in our case can be solved by a simple calculation from density and thickness of the hydrophobic layer.<sup>[6]</sup> For a grafted polymer chain from a solid substrate, once a well-characterized sample is prepared, the same graft density is always maintained regardless of subphase condition, i.e., pH and salt concentration. However, simultaneous control of graft density and chain length is still difficult, and special instruments and efforts are needed for their characterization.

In the course of polymer brush studies, a neutral diblock copolymer system has been studied by reflectometry from the preliminary stage.<sup>[24–29]</sup> The polyethyleneoxide (PEO) brush in the water subphase is a well-studied representative system.<sup>[26–29]</sup> Many investigations on the polyelectrolyte brush have been performed since the late 1990s.<sup>[6,30–37]</sup> In the polyelectrolyte brush systems, the grafted polymer system is often introduced instead of the monolayer system at the air/water interface.<sup>[33–36]</sup> This trend owes much to the progress of living radical polymerization.<sup>[23]</sup> However, as described above, the diblock copolymer system has many advantages. Furthermore, the diblock copolymer system is suitable for investigating the relationships between the monolayer structure and the hydrophilic–hydrophobic balance that has not yet been systematically studied either experimentally or theoretically. We believe that detailed discussions on the monolayer structure at the air/water interface and the interesting features related to the hydrophilic–hydrophobic balance are possible only when the diblock copolymer system is utilized.

## MONOLAYER STRUCTURE INVESTIGATED BY X-RAY REFLECTOMETRY

### Monolayer Preparation

Three polymer samples with different MAA (hydrophilic) chain lengths and a constant Et<sub>2</sub>SB (hydrophobic)

chain length were synthesized by anionic polymerization.<sup>[6,11]</sup> The characteristics of the samples are summarized in Table 1. A polymer monolayer was prepared by spreading the sample solution [1 mg/mL tetrahydrofuran (THF) solution] on the water surface in a Langmuir trough. After solvent evaporation, the surface was compressed to reach the desired surface pressure at which XR measurements were carried out.

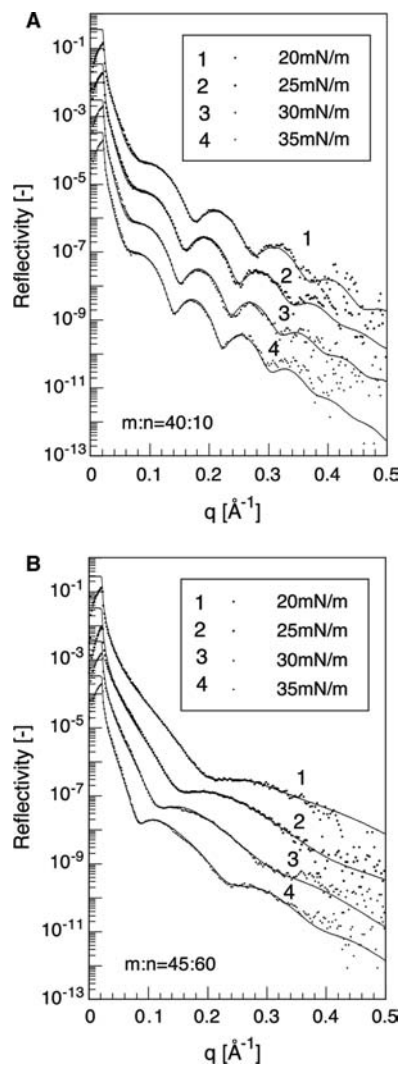

### Nanostructure of Polymer Monolayer—Carpet/Polymer Brush Double-Layer Formation in Hydrophilic Layer

The XR profiles of poly(Et<sub>2</sub>SB-*b*-MAA) monolayer on water surface are shown in Fig. 1. The profiles had clear, high-order Kiessig fringes that were rarely observed in profiles on water surface systems mainly because of surface roughness and low contrast. Such clear profiles enabled highly quantitative data analysis and detailed discussion on the monolayer structure in the Å scale.<sup>[6,9]</sup>

In principle, if the monolayer is composed of two discrete layers with a thickness of  $d_1$  and  $d_2$ , the reflectivity profile should be represented as a superimposition of three cosine curves with a frequency of  $d_1$ ,  $d_2$ , and  $(d_1 + d_2)$ , on the decay of  $-4$  power governed by Fresnel's law. The cosine curve is amplified by each electron density contrast between layers. The sufficient density contrast between each layer enables us to detect three kinds of frequencies. However, in a poly(Et<sub>2</sub>SB-*b*-MAA) system, the Et<sub>2</sub>SB hydrophobic layer is more enhanced in the reflectivity curves because this layer has larger electron density contrast than the MAA hydrophilic layer. As a result, the frequency of fringes in the observed curves reflects the thickness of the Et<sub>2</sub>SB layer, but the profile contains a contribution from the MAA layer. In fact, the small fringes that originated from the whole layer including the MAA layer were found in a  $m:n = 43:81$  sample around  $q = 0.05 \text{ \AA}^{-1}$ .

The monolayer structure was determined by model fitting of the XR profiles. The amphiphilic diblock copolymer monolayer on water is supposed to be composed of hydrophobic and hydrophilic layers. Therefore a two-box model, which has two discrete layers with interface roughness between layers, is applied first to reproduce experimental data. A three-box model was applied if there was not sufficient agreement by the two-box model.<sup>[8,9]</sup>

As is indicated in Fig. 1 by lines, a three-box model was needed to reproduce the XR profiles for the  $m:n = 43:81$  monolayer above 20 mN/m. The small fringe at a lower  $q$  pointed above could not be reproduced by the two-box model. Profiles for the other two samples were well reproduced by a two-box model at any surface pressure studied.

**Fig. 1** X-ray reflectivity profiles for poly(Et<sub>2</sub>SB)<sub>*m*</sub>-*b*-poly(MAA)<sub>*n*</sub> monolayer on water. (A)  $m:n = 40:10$ , (B)  $m:n = 45:60$ , (C)  $m:n = 43:81$ . Each profile was shifted downward by one decade for clarity. The solid lines are the best-fit curves by the two-box model ( $m:n = 40:10$ ,  $45:60$ ) and the three-box model ( $m:n = 43:81$ ). Source: A,B—From Ref.<sup>[6]</sup>. © 2002 by the American Chemical Society. C—From Ref.<sup>[9]</sup>. © 2003 by John Wiley & Sons, Inc.

The density profiles obtained by the three-box model fitting are shown in Fig. 2. The  $m:n = 43:81$  monolayer (Fig. 2C) above 20 mN/m was found to be composed of an Et<sub>2</sub>SB layer and two MAA layers: The MAA layer was divided into two MAA layers, an upper MAA layer and a lower MAA layer. The upper MAA layer just beneath the Et<sub>2</sub>SB layer has a higher density than the lower MAA layer. The lower layer has a lower density and has a large roughness at the interface with a water subphase. This means that this MAA layer has a diffuse structure like a polymer brush. So we call the former a *dense MAA layer* and the latter a *diffuse MAA layer*. The diffuse layer is, in principle, the

Fig. 1 (Continued).

“brush layer.” A schematic figure of the monolayer structure is also shown in Fig. 3. The thickness of the dense MAA layer is about 15 Å and its density is almost the same as the bulk density of MAA. The surface pressure and chain length dependence of the monolayer structure will be discussed in the following section.

### Effect of Surface Pressure—Transition from Carpet Layer to Carpet/Polymer Brush Double Layer

X-ray reflectivity measurements were carried out at different surface pressures, i.e., at different grafting densities (number of polymer chains per unit area), by compressing the monolayer. Brush density was from 0.1 to 0.8 nm<sup>-2</sup> in the surface pressure range studied.<sup>[6,9]</sup>

The distinguishing feature shown in Fig. 2 is that the existence of the MAA dense layer with 10–20 Å thickness is independent of surface pressure. The maximum density of the dense MAA layer in contact with water surface, i.e., contact with a hydrophobic Et<sub>2</sub>SB layer, is almost the same as the bulk MAA density. The dense layer seems to have an important role in determining the monolayer structure as discussed in the following section.

In Fig. 2C, the transition from a carpet-like dense layer to a dense/diffuse double layer as the surface pressure increases is clearly visualized. At a low surface pressure (20 mN/m), the brush layer cannot be seen by XR; that is, almost no brush layer exists. By an increase of the surface pressure, the MAA brush layer was formed in addition to the dense layer, and the thickness of the diffused brush layer increased with a further increase of surface pressure.

The density difference between the dense MAA layer and the diffuse MAA layer was largest at 25 mN/m, at which the density of the dense MAA layer was also at maximum. The MAA fraction that contributed to the dense MAA layer was calculated to be 40% at 25 mN/m with an assumption that the MAA bulk density was 1.22 g/cm<sup>3</sup>. The density difference became smaller as surface pressure increased beyond this point. At the same time, the brush layer formed and its thickness increased as the surface pressure increased.

From these observations, a possible interpretation of the structural change is that a part of the MAA chains is no longer necessary in dense layer above 20 mN/m and they are pushed out to the water sub-phase and then joined to make a polyelectrolyte brush. In this sense, the dense layer plays a role similar to a

**Fig. 2** Density ( $\delta$ ) profiles for poly(Et<sub>2</sub>SB)<sub>*m*</sub>-*b*-poly(MAA)<sub>*n*</sub> on water. (A) *m*:*n* = 40:10, (B) *m*:*n* = 45:60, (C) *m*:*n* = 43:81.  $\delta$  is proportional to electron density, and defined by  $\text{r.i.} = 1 - \delta - i\beta$ , where r.i. is the refractive index. Each profile was shifted upward by one decade for clarity. The order of the profiles is consistent from (A) to (C). *Source*: A,B—From Ref. [6]. © 2002 by the American Chemical Society. C—From Ref. [9]. © 2003 by John Wiley & Sons, Inc.

“carpet” or “cushion” for the Et<sub>2</sub>SB hydrophobic layer on water.

### Effect of Hydrophilic Chain Length—Minimum Hydrophobic Layer Thickness and Discrete Layers in the Hydrophilic Layer

The XR profiles for all three samples at 30 mN/m are compared in Fig. 4. As mentioned above, the period of the fringe corresponds to the hydrophobic Et<sub>2</sub>SB layer

**Fig. 3** Schematic representation of the “carpet” layer and the brush layer in poly(Et<sub>2</sub>SB)<sub>43</sub>-*b*-poly(MAA)<sub>81</sub> monolayer.

thickness. It is obvious that the period of the profile for *m*:*n* = 45:60 (middle MAA length) is the longest, which means that the Et<sub>2</sub>SB layer for the sample is the thinnest. The same tendency was observed at any other surface pressure studied.<sup>[6,9]</sup>

In Fig. 5, the MAA chain length dependence of each layer thickness is shown. The Et<sub>2</sub>SB layer showed an interesting phenomenon: The Et<sub>2</sub>SB thickness at the same surface pressure takes a minimum at a medium MAA length at every surface pressure studied (Fig. 5A). The variation of MAA layer thickness with

**Fig. 4** X-ray reflectivity profiles for poly(Et<sub>2</sub>SB)<sub>*m*</sub>-*b*-poly(MAA)<sub>*n*</sub> on water at 30 mN/m. (1) *m*:*n* = 40:10, (2) *m*:*n* = 45:60, (3) *m*:*n* = 43:81. Each profile was shifted downward by one decade for clarity. The solid lines are the best-fit curves obtained by the two-box model (*m*:*n* = 40:10, 45:60) and the three-box model (*m*:*n* = 43:81).

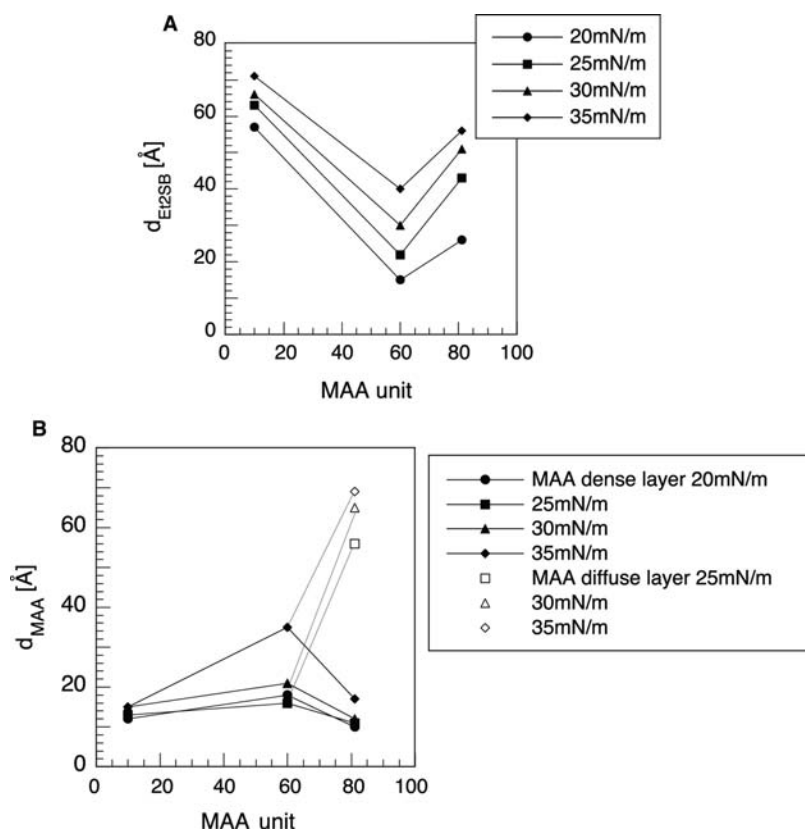

MAA unit length is also interesting. The thickness variation of the three samples with different hydrophilic chain length ( $m:n = 40:10, 45:60, 43:81$ ) in Fig. 5 showed that the thickness of this dense layer is 10–20 Å independent of surface pressure and polymerization degree of PMAA in the range studied. It is also confirmed in the density profiles in Fig. 2. For  $m:n = 45:60$  sample, slightly larger thickness, i.e., 18–35 Å, was observed. It is fair to say that we could not distinguish the dense and the short diffuse MAA layers from the XR profiles in this case.

The independence of the thickness in MAA layer just beneath the Et<sub>2</sub>SB layer, i.e., dense layer, is interesting because the number of MAA units largely varies from 10 to 80 units. Although the data are not shown here, our newly synthesized samples with different chain lengths ( $m:n = 30:20$  to  $30:90$ ) also have a dense layer with a thickness of 10–20 Å.<sup>[32]</sup> A thickness of about 15 Å might be the “critical thickness” for a dense layer, or for a dense layer–brush layer transition.

On the other hand, a well-established polyelectrolyte brush is formed only for the  $m:n = 43:81$  polymer monolayer. For  $m:n = 40:10$  and  $m:n = 45:60$  polymer monolayer, only dense MAA layer is formed.

The minimum hydrophobic layer thickness can be related to the double-layer formation in the hydrophilic

layer. To explain the Et<sub>2</sub>SB layer thickness variation, it is reasonable to consider that the MAA layer has two opposite effects, positive and negative, on surface pressure, and that the formation of a dense MAA layer and diffuse MAA layer in  $m:n = 43:81$  monolayer is the key point. For a small  $n$  sample,  $m:n = 40:10$ , because the MAA contribution to surface pressure is small, much surface compression is needed to achieve the surface pressure desired. This results in the largest thickness of Et<sub>2</sub>SB layer. For the medium  $n$  sample,  $m:n = 45:60$ , a *positive* contribution of MAA chain due to its layer size to the surface pressure appears. Hence at the same surface pressure, the Et<sub>2</sub>SB layer becomes thinner. For the large  $n$  sample,  $m:n = 43:81$ , a *negative* contribution due to brush formation appears in addition to the *positive* contribution mentioned above. An increase in Et<sub>2</sub>SB layer thickness should be observed to compensate for the negative contribution. At this stage, it is not clear whether the dense and the diffuse MAA layers directly correspond to the positive and the negative contributions to surface pressure, respectively. However, it is reasonable to think that the layer near the surface should contribute to a larger increase in surface pressure (a decrease in surface energy) than the brush layer in the subphase.

**Fig. 5** Thickness variation of the hydrophobic and hydrophilic layers with MAA length. (A) Et<sub>2</sub>SB layer and (B) MAA layer. The MAA layer in the  $m:n = 43:81$  sample was well reproduced by two discrete layers, a dense MAA layer and a diffuse MAA layer. Source: From Ref.<sup>[9]</sup>. © 2003 by John Wiley & Sons, Inc.

### Effect of pH on the Monolayer Structure—Anomalous $pK_a$ at the Surface

The hydrophilic chain of the diblock copolymer is a weak polyacid, which enabled us to control the monolayer structure by pH. Hence the pH dependence of the monolayer nanostructure was investigated by changing the pH of the subphase.<sup>[6,8]</sup>

A marked structural change by pH was observed especially for the  $m:n = 43:81$  monolayer. Fig. 6 shows the XR profiles for  $m:n = 43:81$  monolayer at different pHs. The fringe with a short period, which was notable for pH 2 and 7 (pure water), was not observed for the profile on the subphase of pH 10. Density profiles (Fig. 7) obtained by model fitting of the XR profiles indicate that the brush layer was not detected for the  $m:n = 43:81$  sample on pH 10 subphase (dotted line) at 25 mN/m, at which the carpet/brush layer formation was detected for acid (solid line) and neutral (dashed line) conditions. Taking the block ratio into consideration, a highly diffused brush should be formed by alkaline condition. Because of the low contrast between the brush layer and water subphase coming from the low volume fraction of the polymer chain in the brush layer, the brush layer could not be detected by XR measurements.

**Fig. 6** X-ray reflectivity profiles for poly(Et<sub>2</sub>SB)<sub>43</sub>-*b*-poly(MAA)<sub>81</sub> monolayer on various pH subphases at 25 mN/m. (1) pH 2, (2) pH 7 (pure water), (3) pH 10. Each profile was shifted downward by one decade for clarity. The solid lines are the best-fit curves obtained by the two-box model (pH 10) and the three-box model (pH 2, pH 7). *Source:* From Ref.<sup>[8]</sup>. © 2003 by IUCr.

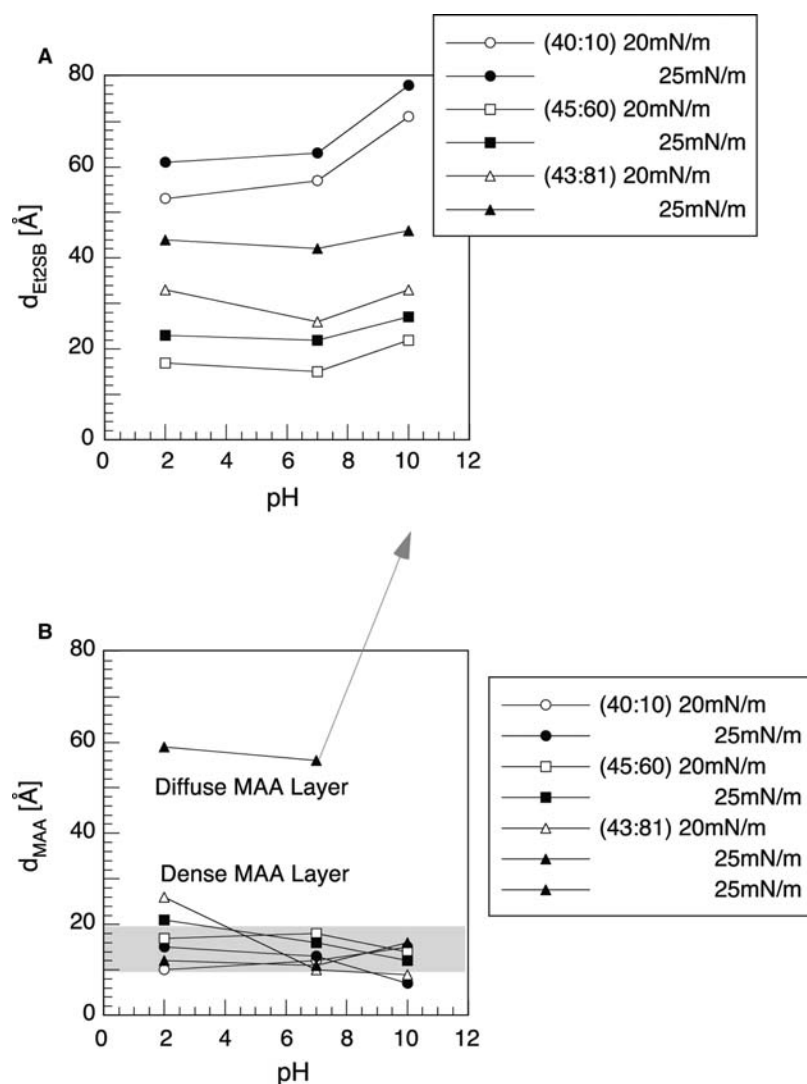

**Fig. 7** Density ( $\delta$ ) profiles for poly(Et<sub>2</sub>SB)<sub>43</sub>-*b*-poly(MAA)<sub>81</sub> monolayer on various pH subphases at 25 mN/m. (1) pH 2 (solid line), (2) pH 7 (dashed line), (3) pH 10 (dotted line). *Source:* From Ref.<sup>[8]</sup>. © 2003 by IUCr.

The variation in hydrophobic and hydrophilic layer thickness with pH for all three samples is summarized in Fig. 8. Almost the same monolayer structure was obtained at acidic (pH 2) and neutral (pure water) conditions, but significant differences were found on the monolayer on subphase of pH 10. For the shortest MAA chain samples, the thickness of the Et<sub>2</sub>SB layer in monolayer at pH 10 is explicitly larger than those in acidic and neutral conditions at the same surface pressure. For the long MAA polymer, the carpet/brush structure in the monolayer was not observed and only a dense carpet layer was detectable. Obviously, the observed change of nanostructure with pH is a result of the change of the degree of ionization of carboxylic acid on the hydrophilic chain.

In general, a drastic change is expected at the pH around  $pK_a$ , which is  $pH = 4-5$  in bulk solution for carboxylic acids. However, in this system, at the air/water interface, the change occurs between neutral pH and  $pH = 10$ . This means that the  $pK_a$  value of the carboxylic groups on the polymer chain in the monolayer is higher than that for bulk state, and it should be located between 7 and 10. This is one of the special characteristics of the surface. The possible origin of this anomalous  $pK_a$  at the surface might be an anomalous structure of water, which shows two-dimensional packing of molecules such that the density of polymer chain in the brush is high. This should be clarified in future works.

### Comparison with Proposed Theory

Theoretical studies on the structure of the polyelectrolyte brush with variable charges (e.g., weak polyacid) have been carried out as a function of grafting density

**Fig. 8** Thickness variation of the hydrophobic and hydrophilic layers with pH at 20 and 25 mN/m. (A) Et<sub>2</sub>SB layer and (B) MAA layer. The  $m:n = 43:81$  monolayer was well described by a three-box model at pH 2 and pH 7 but well reproduced by a two-box model at pH 10. Considering the  $m:n$  block ratio, the diffuse MAA layer should exist at pH 10 in a very diffused form as indicated by the arrow.

and ionic strength.<sup>[20–22]</sup> The variation of brush thickness with grafting density and ionic strength is not monotonic and is categorized into several regimes. The regimes are characterized by the ratio  $\alpha/\alpha_b$ , where  $\alpha$  is the degree of dissociation in brush and  $\alpha_b$  is the degree of dissociation in bulk. For a brush of weak polyacid in a salt-free solution as in our system,  $\alpha$  is considered to be very small compared to  $\alpha_b$ , and categorized into neutral brush regime. In this regime, the brush is expected to behave like a neutral brush.<sup>[21,22]</sup> However, our observation of the two discrete MAA layers seems to be characteristic of the polyelectrolyte brush. In addition, the two discrete layers have not been observed in a neutral brush system. These discrepancies are simply because of the oversimplification of the theoretical model: To theoretically describe the polymer brush, the interaction between the brush and the substrate surface (grafted surface) should be taken into account.

### The “Real” Nanostructure of Polymer Monolayer and Polymer Brush

The surface pressure and chain length dependencies of the monolayer structure are schematically summarized in Fig. 9.<sup>[6,9]</sup> The density profiles are described besides drawings. As also indicated in Fig. 9, the value of the area per molecule is largest for middle  $n$  sample. Similarly, the hydrophobic layer thickness is thinnest for the middle  $n$  sample. The polymer monolayer formed by the samples with a shorter MAA length is composed of a hydrophilic layer and a dense MAA layer, i.e., without a well-established brush layer at any surface pressure. For the monolayer of a longer MAA sample, a similar situation is observed at a lower surface pressure. With increasing surface pressure, long MAA chains extend to the sub-phase to form a brush layer that has a lower density than the dense layer.

**Fig. 9** Schematic representation of the dense layer and the brush layer in  $\text{poly}(\text{Et}_2\text{SB})_m\text{-}b\text{-poly}(\text{MAA})_n$  monolayer on water surface as functions of the surface pressure and the hydrophilic PMAA length. Density profiles are also shown beside the drawings. Source: From Ref.<sup>[9]</sup>. © 2003 by John Wiley & Sons, Inc.

## CONCLUSION

The nanostructure of a monolayer of the ionic amphiphilic diblock copolymer, poly(1,1-diethylsilacyclobutane)-*block*-poly(methacrylic acid) [ $\text{poly}(\text{Et}_2\text{SB-}b\text{-MAA})$ ], at the air/water interface was investigated by in situ XR as a function of surface pressure, MAA chain length, and pH. The MAA brush under the water surface was found to be composed of two parts: a dense layer with a higher density and a diffuse layer with a lower density. The dense layer is always formed independent of MAA chain length, surface pressure, and pH. By contrast, the diffuse layer is formed in addition to the carpet layer only when the hydrophilic chain length is long enough and the surface pressure, i.e., the brush density, is also high enough at lower pHs. At pH 10, the diffuse layer was not observed in the studied range. The dense layer thickness was found to be almost constant at 10–20 Å, independent of surface pressure and MAA chain length. Furthermore, the discrete MAA structure could be an explanation for the interesting observation that the MAA chain length dependence of the thickness of  $\text{Et}_2\text{SB}$  layer showed a minimum at a critical MAA chain length. Either dense or diffuse layer structure and minimum thickness has never been expected in a theoretical study, which indicate the great importance of the in situ experimental study.

We found several new aspects of the diblock copolymer monolayer structure in this study. In situ studies

are essential for identifying the carpet/brush double-layer structure and anomalous  $\text{p}K_a$ . Systematical in situ investigation should clarify the nature of polyelectrolyte brush and make it possible to design and control its structure totally by chain length, chain length ratio, pH, and salt concentration. These findings are expected to contribute to the development of fundamental polymer surface chemistry and of polymer surface nanomaterials.

# Anion-Templated Self-Assembly: Inorganic Compounds

Louise S. Evans

Philip A. Gale

School of Chemistry, University of Southampton, Southampton, U.K.

## INTRODUCTION

The use of anions to template the formation of new supramolecular entities is a relatively new approach to self-assembly, but one that is expanding the available number of non-covalent and coordinate bonding motifs for the construction of new interlocked materials and new supramolecular nanoarchitectures.<sup>[1–5]</sup> Transition metal directed approaches (e.g., using a transition metal to template catenane formation) rely on the directionality of the coordination sphere of the metal to define the geometry of the new self-assembled entity. Hydrogen bonds to anions are also directional in nature,<sup>[6]</sup> and this, combined with the range of geometries that anions possess, allows them to be used to template a variety of new organic supramolecular species. The range of anion geometries has also allowed anionic species to be employed in templating roles in the formation of inorganic clusters and new materials.

This entry focuses on “inorganic” systems, subdivided by the type of metal cation used. Readers interested in organic systems are directed to the entry on “Anion-Templated Self Assembly: Organic Compounds,” keeping in mind that there are many overlaps between these categories and this division is intended only as an aid to the reader.

## INORGANIC ANION-TEMPLATED SYSTEMS

### Vanadium

Müller et al. have extensively investigated the roles anions can play in templating the formation of structures from linked  $V^{n+}O_x$  polyhedra.<sup>[7]</sup> Specifically, Müller et al. have shown that anionic templates such as nitrate and acetate can control the linking of these species.<sup>[8,9]</sup> For example, different shell-like clusters were shown to form by reduction of vanadate (V) or oxidation of vanadate (IV)/vanadate (V) species in water in the presence of anions such as  $NO_3^-$  (1),  $SCN^-$  (2), and  $CH_3COO^-$  (3) (Fig. 1).

Oxo-vanadium species can be templated by ion-pairs.<sup>[10]</sup> In the central cavity of the system  $[V_{14}O_{22}(OH)_4(H_2O)_2-$

$(C_6H_5PO_3)_8]^{6-}$  (4), Müller and coworkers have shown that two chloride ions and two ammonium ions reside, the templation of this cluster being reliant upon the presence of the ion-pair (Fig. 2).

Salta et al. have also shown the templating ability of chloride ions to assist the formation of oxovanadium–organophosphate cluster structures. They have synthesized a number of cage structures containing differing numbers of templating chlorides. For example, cluster 5 shown in Fig. 3 contains a single chloride template (Fig. 3).<sup>[11]</sup>

### Iron

Hasenknopf et al. have used iron bipyridyl complexes to form a pentameric circular helicate around a chloride anion. The formation of this circular species was found to be dependent on the nature of the iron salt present. Complexation of iron chloride by the tris(bipyridine) ligand (6) produced the pentameric structure  $[Fe_5L_5Cl]^{9+}$  (7), templated around a chloride ion locked at the center of the structure (Scheme 1). Attempts to use bromide as the templating anion produced a mixture of the penta- and hexameric structures, while the use of non-halide iron salts, such as iron sulfate or tetrafluoroborate, produced only the untemplated hexameric structure 8.<sup>[12,13]</sup> Further work revealed that the above reaction of  $FeCl_2$  (and also the analogous one using nickel) progressed first through a linear helicate, which then progressively transformed into the circular structures.<sup>[14]</sup> Use of the longer ligand produced a tetrameric double helicate, irrespective of the type of iron salt used.

### Cobalt

Cobalt-based tetrahedral supramolecular arrays have been reported by Fleming et al.<sup>[15]</sup> Cage complexes have been synthesized from a pyrazoyl–pyridine ligand by reaction of the ligand with the appropriate metal acetate hydrate in methanol followed by addition of aqueous sodium tetrafluoroborate (resulting in the complex precipitating from solution). As shown in Fig. 4, a  $BF_4^-$  anion is located at the center of the

**Fig. 1** Anion-templated polyhedral V–O structures **1** (top left), **2** (top right) and **3** (below). *Source:* From Ref.<sup>[8]</sup>.

tetrahedral cage<sup>[9]</sup> formed by the four cobalt(II) metal ions at the vertices and six bridging ligands, thus each cobalt is octahedrally complexed. Each of the fluorines of the encapsulated anion is directed toward the triangular faces of the cluster rather than the metal

ions, implying electrostatic interactions are the driving force for this templation process, the anion partially balancing the  $8^+$  charge of the ring. Presumably, the anion has adopted an orientation dictated by

**Fig. 2** Structure of the oxo-vanadium cluster **4** showing templating ammonium and chloride ion-pairs in the center of the cavity. *Source:* From Ref.<sup>[10]</sup>.

**Fig. 3** A view of the structure of **5** showing chloride template. *Source:* From Ref.<sup>[11]</sup>.

**Scheme 1** Chloride-templated assembly of a pentameric circular helicate.

the geometry of the internal cavity. Multiple  $\pi$ -stacking interactions between the ligands also assist the assembly of the structure. Such a configuration can also be templated by  $\text{ClO}_4^-$ , but in the absence of any template anion the cage does not form. Interestingly

**Fig. 4** Part view of the tetrahedral cage structure **9**, with the central templating  $\text{BF}_4^-$  anion. *Source:* From Ref.<sup>[15]</sup>.

when nickel is used a different structure is formed (a dinuclear structure species with no templating anion). If an analogous ligand containing a biphenyl spacer is used, then a larger tetrahedral complex forms; however, the central cavity is empty, i.e., the system is not templated by an anion.<sup>[16]</sup> In solution it has been shown that the  $\text{BF}_4^-$  ions diffuse in and out of this cavity. This example illustrates how delicately balanced these systems are, and how changing only one aspect of the system in a small way can have a dramatic impact on the assembled structure.

The same research group have used cobalt in combination with a bis{3-(2-pyridyl)pyrazol-1-yl}dihydroborate ligand to form a cyclic structure encapsulating a perchlorate anion.<sup>[17]</sup> Reaction of [bis{3-(2-pyridyl)pyrazol-1-yl}dihydroborate] with cobalt(II) produced the cycle **10** shown in Fig. 5. Each ligand acts as a bridge between two adjacent metal ions, with an alternating pattern of one and then two ligands. The isostructural octanuclear ring is also formed if Ni(II) is used.

## Nickel

Mingosnet al. have synthesized metallamacrocycles and metallacages, by reacting  $\text{NiCl}_2$  with atu (Hatu = amidinothiourea) to produce the monomer  $[\text{Ni}(\text{atu})_2]$ ,

**Fig. 5** Crystal structure of the cobalt cage **10** with the central  $\text{ClO}_4^-$  ion. Source: From Ref.<sup>[17]</sup>.

with further reaction yielding the metallacage  $[\text{Ni}_6(\text{atu})_8\text{Cl}]\text{Cl}_3$  (**11**).<sup>[18]</sup> The eight amidinothiourea units coordinate to the six nickel ions through the nitrogen and sulfur atoms via hydrogen bond interactions (Fig. 6). A single chloride ion was identified as being bound at the center of the cage, through eight  $\text{N-H}\cdots\text{Cl}$  hydrogen bonds and Lewis acid/base interactions utilizing the two  $\text{NiS}_4$  units. The analogous bromide species  $[\text{Ni}_6(\text{atu})_8\text{Br}]\text{Br}_3$  has been synthesized. Confirmation of the templating role of the halide anion was provided by the failure of nitrate, acetate, or perchlorate to produce the desired cage, and instead monomer salts  $[\text{Ni}(\text{Hatu})_2]^{2+}$  were formed. However, subsequent addition of halide ions to the salt was found to generate the cage complex.

Campos-Fernandez, Clerac, and Koomen have also used nickel in anion-templated complex formation.<sup>[19]</sup> When solutions of  $[\text{Ni}(\text{CH}_3\text{CN})_6][\text{BF}_4]_2$  and bptz (3,6-bis(2-pyridyl)-1,2,4,5-tetrazine) were mixed in a 1:1 molar ratio the molecular square  $[\text{Ni}_4(\text{bptz})_4(\text{CH}_3\text{CN})_8][\text{BF}_4]_8$  (**12**) was produced (Fig. 7). One  $\text{BF}_4^-$  anion is held in the internal cavity of the square. A similar assembly is also produced when zinc is used instead of nickel, and in both these cases the templating ion can be either the tetrafluoroborate or perchlorate. However, if the larger anion  $\text{SbF}_6^-$  is used (by starting from

$[\text{Ni}(\text{CH}_3\text{CN})_6][\text{SbF}_6]$ ), a pentameric compound is obtained as the major product  $[\text{Ni}_5(\text{bptz})_5(\text{CH}_3\text{CN})_{10}][\text{SbF}_6]_{10}$ .<sup>[20]</sup>

## Molybdenum

A number of supramolecular structures using second-row transition metals have been reported. Chen et al. have employed metal-metal bonded molybdenum species to form the cyclic hexanuclear structure  $\{[\text{trans-Mo}_2(\text{O}_2\text{CCF}_3)_2(\mu\text{-dppa})]_3(\mu\text{-CO}_3)(\mu\text{-X})_3\text{F}\}$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) (**13**). This complex is the product of the reaction between  $[\text{trans-Mo}_2(\text{O}_2\text{CCF}_3)_2(\text{MeCN})_6][\text{BF}_4]_2$ ,  $\text{K}_2\text{CO}_3$  and dppa (*N,N'*-bis(diphenylphosphine)amine).<sup>[21]</sup> The quadruply bonded  $\text{Mo}_2$  units are held in position by the central carbonate ion. It is assumed that the chloride ions present in the complex originate from the solvent as the analogous Br and I complexes are formed during the reaction in acetonitrile and the subsequent addition of  $\text{ZnX}_2$  ( $\text{X} = \text{Br}$  or  $\text{I}$ ) (Fig. 8).

## Palladium and Platinum

Fujita and coworkers have recently reported the synthesis of palladium(II) cage complexes around

**Fig. 6** Structure of the nickel cage **11** showing the central chloride. *Source:* From Ref.<sup>[18]</sup>.

hydrophobic anions.<sup>[22]</sup>  $[\text{enPd}(\text{NO}_3)_2]$  was added to the tridentate ligand 1,3,5-tris(4-pyridylmethylbenzene) in the presence of sodium 4-methoxyphenylacetate producing the cage structure **14** shown in Fig. 9. A variety of carboxylate salts containing phenyl, naphthyl, or adamantyl groups were used as templates. NMR studies of the complexes suggest that the hydrophobic part of the

anion is located within the cavity of the cage while the polar group protrudes from the structure. Neutral linear ligands such as *p*-xylene were also able to template these systems, but in the absence of a templating anion no cage was produced.

More recently, the formation of anion-templated nanotubes has been reported.<sup>[23]</sup> Reaction of  $[\text{Pd}(\text{en})_2(\text{NO}_3)_2]$  with pentakis(3,5-pyridine) **15** in the presence of a rod-like anionic template, e.g., 4,4'-biphenylenedicar-

**Fig. 7** Dunbar's tetrafluoroborate templated nickel square **12**. *Source:* From Ref.<sup>[19]</sup>.

**Fig. 8** The hexa-molybdenum-based complex **13**. *Source:* From Ref.<sup>[21]</sup>.

Fig. 9 Anion templated palladium cage 14.

boxylate, quantitatively yielded the coordination channels **16–18** (Scheme 2). The reaction is reversible, with the extraction of the template possible at high temperatures. This results in the destruction of the nanotubes, which reassemble upon the re-introduction of the template molecule. Elucidation of the crystal structures of both the cages and nanotubes revealed the linear templates to be bound via combinations of  $\pi$ - $\pi$  stacking, CH- $\pi$  interactions, and hydrophobic effects.

Schnebeck, freisinger, and Lippert have reported a synthetic solid-state ion channel which incorporates both palladium and platinum.<sup>[24]</sup> The reaction of  $[\text{Pt}(\text{en})(\text{H}_2\text{O}_2)]^{2+}$  and 2,2'-bipyrazine (bpz), and subsequent reaction with  $[\text{Pd}(\text{en})]^{2+}$  afforded the hexametallic molecular triangle **19** with one of the palladium corner sites displaying a 50% occupancy:  $[\{(\text{en})\text{Pd}\}_{2.5}(\text{2,2}'\text{-bpz})_3\{\text{NH}_3\}_2\text{Pt}_3][\text{ClO}_4]_6(\text{NO}_3)_5 \cdot 5\text{H}_2\text{O}$  (en = ethylenediamine, bpz = 2,2'-bipyrazine) (Fig. 10A). The molecular triangle hosts within its center one  $\text{ClO}_4^-$  ion (Fig. 10B), and in the solid state uses

i)  $\text{K}_2\text{CO}_3$ ,  $\text{Cu}^0$ , dimethylacetamide, heat; ii)  $\text{L} = \text{PPh}_3$ :  $[\text{PdCl}_2(\text{PPh}_3)_2]$ ,  $\text{AgOTf}$ ,  $\text{CH}_2\text{Cl}_2$ ,  $\text{L} = \text{Py}$ :  $[\text{PdI}_2(\text{Py})_2]$ ,  $\text{AgOTf}$ , acetone,  $\text{NH}_4\text{PF}_6$ ; iii)  $\text{MeCN}/\text{Et}_2\text{O}$ ; iv) 0.5 equiv  $[\text{PdI}_2(\text{Py})_2]$ ,  $\text{AgOTf}$ ,  $\text{MeCN}$ ,  $\text{NH}_4\text{PF}_6$ ,  $\text{OTf} = \text{Trifluoromethanesulfonate (triflate)}$ .

**Scheme 3** Route of formation of the palladium cage, and a schematic showing the association of two of the fluorines with the metal centers.

$\text{NO}_3^-$  ions and  $\text{H}_2\text{O}$  molecules sandwiched between adjacent triangles to “glue” the structure together (Fig. 10C and D), the glue in part being a balancing of the cationic charge on each triangle. Thus this structure is templated by the  $\text{ClO}_4^-$  anion at an individual unit level and at the macromolecular level is held together by  $\text{NO}_3^-$  ions and the water molecules. The similar structure  $[\{(\text{en})\text{Pt}(\text{bpz})\text{Pd}(\text{en})\}_3](\text{NO}_3)_4(\text{PF}_6)_8$  was formed by the addition of chelating metal entities such as  $(\text{en})\text{Pd}^{\text{II}}$  to  $[\{(\text{en})\text{Pt}(\text{bpz})\}_3](\text{NO}_3)_6$ . It has been demonstrated that this molecule simultaneously encapsulates a  $\text{NO}_3^-$  ion and a  $\text{PF}_6^-$  ion at its center.<sup>[25]</sup>

In solution the host demonstrates an affinity for anions such as  $\text{PF}_6^-$ ,  $\text{ClO}_4^-$ ,  $\text{BF}_4^-$ , and  $\text{SO}_4^{2-}$ .

Mingos and coworkers have used palladium in conjunction with nickel to generate mixed metal systems similar to compound **11** above. Adding a solution of  $[\text{Pd}(\text{PhCN})_2\text{Cl}_2]$  to the nickel monomer  $\text{Ni}(\text{atu})_2$  produced the mixed metal cage  $[\text{Ni}_4\text{Pd}_2(\text{atu})_8\text{X}]\text{X}_3$  (Fig. 11A).<sup>[26]</sup> Once again a halide ion is encapsulated at the center of the cage. Either chloride or bromide may be used as the template. The metallamacrocycle  $[\text{Pd}_2\text{Ni}_2(\text{atu})_4(\text{PPh}_3)_4\text{Cl}][\text{ClO}_4]_2$  was formed via a very similar route: reaction of one equivalent of *trans*

**Scheme 4** Route to the hexanuclear silver array.

**Fig. 12** Two perspective views of the  $\text{Ag}_6(22)_2\text{F}$ . Source: From Ref.<sup>[30]</sup>.

**Fig. 14** X-ray crystal structure of the chloride complex of  $25\text{-Cl}^-$ . Source: From Ref.<sup>[36]</sup>.

$\text{Pd}(\text{Ph}_3)_2\text{Cl}_2$  with one equivalent of  $\text{Ni}(\text{atu})_2$ .<sup>[27]</sup> Two of the  $\text{Ni}(\text{atu})_2$  groups have been replaced by the four inward pointing  $\text{PPh}_3$  ligands in the solid-state structure. Once again a chloride ion was found to have templated the formation of the cage by being at the center of the metallacycle (Fig. 11B). The bromide analogue displays the same characteristics; however, in the absence of a halide, monomeric units are produced.

McMorran and Steel have investigated the treatment of the ligand 1,4-bis(3-pyridyloxy)benzene with  $[\text{PdCl}_2(\text{PPh}_3)_2]$  and  $[\text{PdI}(\text{py})_2]$  in the presence of silver triflate producing dimeric complexes.<sup>[28]</sup> Crystallization of the dimeric species in the presence of ammonium hexafluorophosphate resulted in a reorganization of components to give a  $\text{M}_2\text{L}_4$  helical cage **21** as shown in Scheme 3, at the center of which was a  $\text{PF}_6^-$  anion. The anion

**Scheme 5** A schematic representation of the arrangement of the platinum, copper, and  $\text{BF}_4^-$  components.

Scheme 6 Synthesis of [12]mercuracarborand-4 **25**.

forms weak  $F \cdots Pd$  interactions, bridging between the two metals in the helical structure.

## Silver

Steel and Sumbly have recently reported the formation of cages and polymers with silver as the metallic component.<sup>[29,30]</sup> Using hexa(2-pyridyl)[3]radialene (**22**), prepared from reaction of diarylmethyl anions with tetrachlorocyclopropene<sup>[31,32]</sup> and reaction of this with silver tetrafluoroborate produces  $[Ag(\mathbf{22})F(BF_4)_5 \cdot 11H_2O]$ , a hexametallc cage, with each **22** acting in a hexapodal-hexadentate mode (Scheme 4). Within the cavity is a fluoride ion bound in a trigonal arrangement to three silver atoms with the other three arranged symmetrically away from this (Fig. 12). Reaction of this same ligand with silver nitrate yields a coordination polymer with each ligand coordinated to four silver atoms, in a twisted helical arrangement.

Further examples of the use of silver are provided by Rais et al. These researchers have reported the synthesis of  $[Ag_{14}(C \equiv C^tBu)_{12}Cl]OH$ , from a solution of  $AgBF_4$  being mixed with  $tBuC \equiv CH$  and  $NEt_3$  to form the initially insoluble polymeric  $[Ag(C \equiv C^tBu)]_n$ , which upon the addition of chloride is transformed into the metallacage **23** (Fig. 13).<sup>[33]</sup> More recently, the more direct route from  $AgBF_4$ ,  $tBuC \equiv CH$ ,  $NEt_3$ , and  $NMe_4Cl$  has been developed.<sup>[34]</sup> Via this same route  $[Ag_{14}(C \equiv C^t-$

Fig. 15 The europium-based cubane structure. Source: From Ref.<sup>[39]</sup>.

Fig. 16 The X-ray crystal structure of complex **30**. Source: From Ref.<sup>[41]</sup>.

$Bu)_{12}X][BF_4]$  ( $X = F, Cl, Br$ ) has also been prepared. Each cage has a single halide at its center and is formed through halide templation and metallophilic interactions (Fig. 14). The use of the alternative silver salts  $AgTos$  and  $AgNO_3$  produced only polymeric compounds ( $Tos = p$ -toluenesulfonate).

The first example of an inorganic “tennis ball” motif encapsulating an anion has been reported by Kim et al.<sup>[35]</sup> Dissolution of the complex  $\{(dach)Pt(BETMP)\}_2 - Cu(BF_4)_2$  ( $dach = trans(\pm)$ -1,2-diaminocyclohexane,  $BETMP = Bis(ethylthio)methylenepropanedioate$ ) resulted in the formation of complex **24** shown in Scheme 5. The starting material contains hydrogen bond acceptors (carboxylate) and donor (amine)

**Scheme 7** Preparation of both the tetra and pentameric forms of  $\{[P(\mu\text{-N}^t\text{Bu})_2](\mu\text{-NH})\}_{2n}$ . Source: From Ref.<sup>[41]</sup>.

groups, allowing the complex to dimerize around a central  $\text{BF}_4$  anion giving the tennis ball motif.

One of the first examples of work in this area is the mercuracarborand macrocycles reported by Hawthorne et al.<sup>[36–38]</sup> Preparation of tetraphenyl [12]mercuracarborand-4 (**25**) was achieved via the reaction of mercuric chloride with 1,2-dilithiocarborane (Scheme 6). Addition of mercury chloride templated the lithiated carboranes into a tetrameric cycle around a chloride template (Fig. 14). Synthesis of the iodide analogue was successfully performed, but instead of the anion being incorporated into the plane of the cycle, it was perched 1.25 Å above the plane. Use of nonspherical anions resulted in the formation of acyclic compounds instead of the desired macrocycles.

Very few examples of lanthanide clusters templated by anions have been reported. The exception is the series of lanthanide (III)-tyrosine metallamacrocycles synthesized by Wang et al.<sup>[39,40]</sup> The clusters were prepared by L-tyrosine-controlled hydrolysis of the appropriate lanthanide perchlorate, where  $\text{Ln} = \text{La}, \text{Pr}, \text{Nd}, \text{Sm}, \text{Eu}, \text{Gd}, \text{and Dy}$ . In all cases an isostructural pentanuclear structure resulted. Below, as an example, is the europium (III)-tyrosine metallamacrocycle **26** (Fig. 15), with core formula  $[\text{Eu}_{15}(\mu_3\text{-OH})_{20}(\mu_5\text{-X})]^{24+}$ .

Its pentameric structure is clearly demonstrated with the Eu ions forming three layers, each containing five ions. At the center is a chloride ion, which simultaneously coordinates the five inner-layer  $\text{Eu}^{\text{III}}$  atoms. The formation of this complex can best be described as a chloride-induced self-assembly, i.e., the chloride is acting as a template. When a lanthanide perbromate was used the equivalent pentameric complex with a bromate at the center was produced. Yet when iodide was used as the templating agent an alternative

dodecanuclear lanthanide complex was formed, with a core formula of  $[\text{Ln}_{12}(\mu_3\text{-OH})_{16}(\text{I})_2]^{18+}$  ( $\text{Ln} = \text{Dy}, \text{Er}$ ). Such complexes have a square cyclic arrangement with an iodide on either side of the square plane. Syntheses that do not use halides as the templating agent do not produce these penta and dodecanuclear species.

### Main Group

Wright et al. have investigated the formation of a series of macrocycles, from the reaction of  $[\text{CIP}(\mu\text{-N}^t\text{Bu})]_2$  (**27**) with  $[\text{NH}_2\text{P}(\mu\text{-N}^t\text{Bu})]_2$  (**28**) in the presence of a base to produce a  $\{[P(\mu\text{-N}^t\text{Bu})_2](\mu\text{-NH})\}_{2n}$  framework.<sup>[41]</sup> In the absence of a templating anion, the tetrameric species **29** is formed (i.e.,  $n = 4$ ), but when the same reaction is performed in the presence of an excess of  $\text{LiCl}_2$  then the major product is the pentameric form  $\{[P(\mu\text{-N}^t\text{Bu})_2](\mu\text{-NH})\}_5(\text{HCl})$  **30** (Fig. 16; Scheme 7). The templating chloride ion is found at the center of the macrocycle, held in position by five hydrogen bond interactions between it and the NH groups.

### CONCLUSION

We believe that the recent advances in the use of anions in self-assembly processes will lead to their employment in the templating of both inorganic and organic supramolecular nanoarchitectures in the future. This area of chemistry is yet to be fully explored and in particular the exploitation of the geometry of the anionic guest to guide the assembly process has untapped potential for the construction of new supramolecular species. We look forward to advances in this area of chemistry in years to come.

## INTRODUCTION

The field of self-assembly is an increasingly attractive area of supramolecular chemistry. With many principles derived from biological systems, it often enables the synthesis of large, complex structures that would be far too demanding using conventional covalent techniques.<sup>[1–3]</sup> Utilizing weak, reversible, non-covalent interactions, self-assembly can, through rational design of simple ligands, help minimize the amount of information inherent in the building blocks for the system and allow for error checking and self-correction.<sup>[4–6]</sup> To date, the range of non-covalent interactions used in self-assembly processes includes hydrogen bonding, metal coordination, hydrophobic, and  $\pi$ – $\pi$  donor–acceptor interactions.<sup>[7–18]</sup> The range of structures prepared via templated self-assembly continues to become increasingly diverse and intricate.<sup>[7–18]</sup>

Interest in the binding and recognition of anionic guest species has increasingly grown in the last decade or so, such that the field is now considered an important area of supramolecular chemistry. Anions often play key roles in biological processes; many enzyme substrates and cofactors are anionic and DNA itself is a polyanion. The fields of medicine and catalysis also help illustrate the diverse areas in which anions play key roles. Some anions are of environmental concern (e.g., there is a need to sense and remove nitrate and phosphate pollutants from natural waterways). In the past two decades, progress in the binding and recognition of anions has advanced considerably, and there are now many reviews dedicated entirely to this specific area of supramolecular chemistry.<sup>[19–22]</sup>

In light of this, it is surprising that investigations into the use of anions as templates in the self-assembly of supramolecular architectures has, until recently, been limited. Reasons for this may stem from the anion's small charge-to-radius ratio (more diffuse nature), pH sensitivity, and high solvation energy. The large geometrical diversity found in anions indicates the possibilities for predefining a wide range of supramolecular structures.

At the time of writing, we are unaware of any reviews dedicated solely to anion-templated self-assembly and are thus led to believe that this encyclopedia offers the first reviews of this topic.<sup>a</sup> Readers interested in anion-templated self-assembly of inorganic based frameworks are directed to the entry “Anion-Templated Self-Assembly: Inorganic Compounds.” This entry focuses solely on the anion-templated self-assembly of organic compounds.

## ANION-TEMPLATED SELF-ASSEMBLY OF ORGANIC FRAMEWORKS

The range of organic supramolecules prepared via anion-templated self-assembly is highly varied. Examples given in this review include solid-state polymers, helicates, pseudorotaxanes, and rotaxanes. Although nuclear magnetic resonance (NMR) and mass spectrometry data provide solution evidence of assembly in many examples, X-ray crystallography remains an invaluable tool for confirmation of the role of anions in many of the early reports.

The first example of anion templation in organic systems is in the rational design of organic solid-state structures reported by Geib et al.<sup>[24]</sup> in 1991. In contrast to traditional *endo* hydrogen bonding sites that form discrete 1:1 complexes with complementary receptors, they illustrate that by utilizing an *exo* configuration, the same components can be made to assemble into an alternating polymeric structure.

By simple protonation of the pyridine ring in 2,6-dibutyramidopyridine, repulsive interactions force rotation about the pyridine–amide bond, leading to the formation of two intramolecular hydrogen bonds to the carbonyl oxygen. Therefore the amide–NH groups are outwardly (or *exo*) directed and thus available for intermolecular hydrogen bonding. Addition of bis(4-nitrophenyl)hydrogenphosphate not only results

<sup>a</sup>Since the submission of this review article, Ref.<sup>[23]</sup> has appeared in the literature.

**Fig. 1** Ribbon arrangement of Hamilton's self-assembled solid-state hydrogen-bonded structure.

**Fig. 2** Mendoza's tetraguanidinium strand self-assembles into a double helicate structure.

in protonation but leads to the self-assembly of a polymeric alternating ribbon structure. The diaryl hydrogen phosphate plays two key roles in this assembly: protonation of the pyridine ring and provision of an anionic hydrogen bond acceptor of suitable geometry. The ribbon arrangement has hydrogen bonds in its core, with the anionic and cationic components segregated onto opposite sides of the structure in parallel alignment to each other (Fig. 1). A further structure was assembled using diphenyl hydrogen phosphate, indicating the generality of this assembling strategy.

The first example of an anion-templated helicate was reported by Sánchez-Quesada et al.<sup>[25]</sup> in 1996. A tetraguanidinium strand **1** was prepared, in which the spacer unit is too short for it to be able to wrap around one sulphate anion (Fig. 2). Consequently, two strands are forced to self-assemble into a double helicate structure, the handedness of which is imposed by the chiral receptor. Evidence for the helical nature of the anion-templated structure is provided by ROESY

(Rotational nuclear Overhauser Effect Spectroscopy) NMR techniques. In addition and in contrast to many helicates assembled by coordination chemistry, these organic helicates are overall neutral.

In 1996, Sessler et al.<sup>[26]</sup> reported on the self-assembly of polypyrrolic macrocycles. Based on the anion binding properties of sapphyrins and calix[4]pyrroles, zwitterionic carboxylate-appended structures **2** and **3** (Fig. 3) were synthesized. The ability to bind intramolecularly is absent because of the choice of spacer; with the sapphyrin compound methylene, carboxylate groups are positioned at either R<sup>2</sup> or R<sup>4</sup>, with the other R groups being hydrogen or methyl groups, and on the calixpyrrole, R is a propylene carboxylate.

It was found that these structures assemble into dimers; the carboxylate group of one molecule is chelated by the pyrrole core of another (Fig. 4). The tail of this second molecule is subsequently bound by the first molecule.

Protonated sapphyrins are known to have a high affinity for fluoride anions. Addition of fluoride ions is shown to inhibit the dimer assembly, thus providing further evidence for the assembly process. This example demonstrates how known anion binding sites can be exploited in the self-assembly of discrete supramolecular species.

Sessler et al.<sup>[27]</sup> have also reported on the possible templating effect of anionic nitrates in the synthesis of an oligopyrrolic macrocycle. An unusual example of large polynuclear anions as templates in organic synthesis is provided by Kim, Calabrese, and McEwen<sup>[28]</sup> who utilized the [CaCl<sub>3</sub>(DMAc)<sub>3</sub>]<sup>-</sup> (DMAc = dimethyl acetamide) pseudo-octahedral anion in a directing role in the preparation of cyclic aromatic amides.

The use of anions in the synthesis of [L<sub>4</sub>]imidazoliophanes was reported by Alcalde et al.<sup>[29,30]</sup> in 1999. Based on a [3 + 1] convergent cyclization (Scheme 1), yields are significantly enhanced by the presence of certain anions (e.g., 42% yield in the absence of anions, to 83% for chloride and 88% for bromide). Templating is postulated to be because of the formation of

**Fig. 3** Carboxylate-appended sapphyrins and calix[4]pyrroles.

**Fig. 4** Side view of the non-covalent calix[4]pyrrole dimer where  $R = (\text{CH}_2)_3\text{CO}_2\text{H}$ . Source: From Ref.<sup>[26]</sup>. *Angewandte Chemie International Edition English*.

an intermediate in which  $\text{C-H}\dots\text{Cl}^-$  hydrogen bonds force a conformation that favors subsequent cyclization.

In recent years, interest in the preparation of mechanically interlocked supramolecules, such as catenanes and rotaxanes, has grown immensely. Rotaxanes are systems where a threadlike molecule is encircled by a macrocycle. Large stopper groups prevent the macrocycle from slipping off the ends of the thread. These molecules present a great challenge to the synthetic chemist because of their unusual nature and the possibilities for unusual molecular properties.<sup>[31–37]</sup> An extension of rotaxane work is the ever-expanding field of molecular shuttles and machines.<sup>[31–37]</sup> To date, the majority of rotaxane preparations have involved the use of hydrogen bonds, metal cation coordination chemistry, and  $\pi$ - $\pi$  donor-acceptor interactions to mediate the assembly.<sup>[38–42]</sup> More recently, some research groups have started to look into the possibility of using anions to template the formation of these interlocked, complex structures.

**Scheme 1** Alcalde's convergent synthesis of [4]imidazoliophanes.

**Fig. 5** Stoddart's [4]pseudorotaxane.

In 1997, Fyfe et al.<sup>[43]</sup> reported what they describe as “anion-assisted self-assembly” of polypseudorotaxanes. Pseudorotaxanes are supramolecular complexes in which one molecule is threaded through another, but the absence of stopper groups means they can subsequently dissociate. These equilibrium complexes are important as they not only provide a great deal of information on the assembling motif but are precursors to both rotaxanes and catenanes. Earlier work by Montalti and Prodi<sup>[44]</sup> and Ashton et al.<sup>[45,46]</sup> established a strategy for pseudorotaxane formation constructed from macrocyclic polyethers and dibenzylammonium ions. Favorable  $[\text{N}^+\text{-H}\dots\text{O}]$  and  $[\text{C-H}\dots\text{O}]$  hydrogen bonds and  $\pi$ - $\pi$  stacking interactions help thread the ammonium ions through the macrocycles. Extension of this work to higher-order pseudorotaxanes hinted at the organizational role of an encapsulated  $\text{PF}_6^-$  ion within the interior of the supramolecule.

With tri-*p*-phenylene[51]crown-15, there lies the possibility of incorporating three ammonium ions into the cavity, thus forming a [4]pseudorotaxane (Fig. 5). Each ammonium ion interacts independently with a single polyether loop by the expected  $[\text{N}^+\text{-H}\dots\text{O}]$  and  $[\text{C-H}\dots\text{O}]$  interactions. Crystal structure evidence reveals that a single  $\text{PF}_6^-$  anion is located centrally and partially encapsulated within a cleft generated by the saddlelike conformation of the complex. A series of  $[\text{C-H}\dots\text{F}]$  hydrogen bonds to the hydroquinone rings on the polyether macrocycle

Fig. 6 Stoddart's [5]pseudorotaxane.

and to the ammonium benzylic methylene groups stabilizes and imposes order on the  $\text{PF}_6^-$  ion.

The larger [5]pseudorotaxane formed between four ammonium threads and tetrakis-*p*-phenylene[68]-crown-20 also features an ordered  $\text{PF}_6^-$  ion (Fig. 6). In this case, the anion is completely encapsulated by the four tetrahedrally arranged ammonium ions and by the four hydroquinone rings of the macrocycle. Order is imposed on the octahedral anion by a series of [C–H...F] hydrogen bonds involving the methylene hydrogen atoms of the threads and the hydroquinone protons of the polyether ring.

Stoddart et al. conclude that the  $\text{PF}_6^-$  anion “programs” the geometry of both complexes. However, although the anion undoubtedly plays a role in the assembly of these complexes and the final geometry

Fig. 7 Schematic of Smith's ion pair binding rotaxane indicating the predominant co-conformation of axle and wheel orientation in  $\text{CDCl}_3$ . Tr = Trityl.

of the system, it is worth noting that secondary ammonium threads have been shown to assemble with polyether chains, especially dibenzo[24]crown[8], where the counter-anion is found to play no role in the assembly.

The first example of anion-templated synthesis of rotaxanes was reported by Hübner et al.<sup>[47]</sup> in 1999. Relying on the anion recognition properties of macrocyclic lactams, the synthesis proceeds via a “supramolecular nucleophile” or “wheeled phenoxide.” The hydrogen bond-donating ability of the lactam wheel is used to complex an organic anion, which can then serve as a nucleophile in an  $\text{S}_{\text{N}}2$  reaction. The reaction of *p*-tritylphenolate bound inside the lactam wheel with the suitable axle component gives the [2]rotaxane (Scheme 2) in a remarkably high yield of 95%. It is worth noting that the rotaxane product is neutral; the anion template is “used up” in the synthesis.<sup>[48]</sup>

Further reports have demonstrated the versatility of this so-called “trapping” methodology using a wide

Scheme 2 Vogtle's anion-templated rotaxane synthesis.

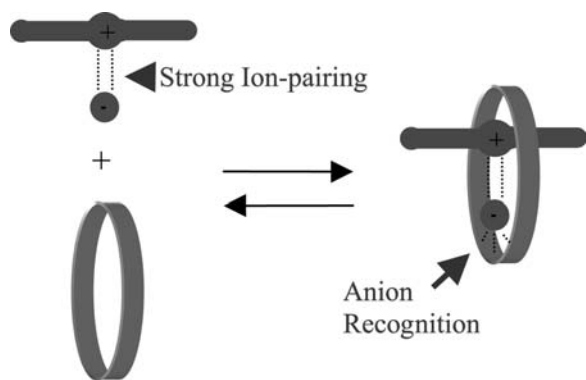

**Scheme 3** Schalley's "stopping" rotaxane synthesis using an anion template.

variety of axle building blocks. Rotaxanes with carbonate, acetal, and ester centerpieces have been prepared in varying yields.<sup>[49]</sup> Attempts to extend the synthesis to proceed via carboxylate anions have proven problematic and demonstrate that phenolate formation is essential in the preparation of these rotaxanes.

Smith et al. have tried to exploit the trapping technique developed by Vögtle in the preparation of ion pair binding [2]rotaxanes. Earlier ion pair binding macrocycles developed by Smith et al. incorporate an anion binding isophthalamide cleft that bridges a cation binding crown region and a close structural analogue has now been used to form the wheel of new rotaxanes.<sup>[50,51]</sup> In these macrocyclic systems, it was found that not only could an alkali

metal cation and an anion be bound simultaneously, but that the anion affinity is enhanced by the presence of suitable cations. It has been shown that the new host is capable of binding the potassium salt of 4-tritylphenolate and that subsequent reaction of the "wheeled phenolate" with isophthaloyl dichloride yields a thermodynamically stable [2]rotaxane in 20% yield (Fig. 7).

Evidence for rotaxane formation is provided by fast atom bombardment (FAB) mass spectrometry and  $^1\text{H}$  NMR assignments carried out by a combination of homonuclear correlation spectroscopy (COSY) and ROESY methods. ROESY evidence also suggests that the presence of  $\text{K}^+$  cations freezes out a single co-conformation. In the absence of  $\text{K}^+$  cations, broad signals that sharpen on heating, indicating a number of

**Fig. 8** Wisner et al.<sup>[59]</sup> have developed a powerful and versatile anion-templated assembling motif for interlocked molecules.

axle–wheel orientations, are observed at room temperature. This cation-dependent behavior hints at future work whereby molecular motion could be controlled. The binding of chloride has been found to have an effect on the dynamic behavior of the rotaxane, although the combined effect of  $K^+/Cl^-$  binding produces the most rigid structure.<sup>[52,53]</sup>

Since this initial report, Deetz et al.<sup>[53]</sup> have embarked on a systematic study of their ion pair binding rotaxanes including rotaxanes with larger anion binding cavities and longer acetal-based threads, which could potentially be used in molecular shuttle devices.

Schalley et al.<sup>[54]</sup> have ascertained that low yields are often obtained with these rotaxane “snapping” syntheses because the nucleophilic anion required for rotaxane formation is often buried within the wheel and thus protected against attack of the semiaxle. To circumvent this problem, Ghosh, Mermagen, and Schalley<sup>[55]</sup> have designed a centerpiece, which contains a phenolate group and two sites for stopper attachment. Complete deprotonation of the phenolate using Schweisinger’s  $P_1$  base forms a supramolecular complex with the axle bound within the wheel. The final step is the attachment of the stopper units via amide bond formation to yield [2]rotaxanes in 20–30% yield

**Fig. 9** The chloride anion templates the self-assembly of the threadlike and macrocyclic components giving an interlocked structure.

**Fig. 10** Stick representation of the pseudorotaxane crystal structure. Left: View through the annulus of the macrocyclic ring. Right: View in the plane of the macrocyclic ring. (Scheme 3). Rotaxane formation is confirmed by both  $^1H$  NMR and matrix-assisted laser desorption ionization (MALDI) mass spectrometry.

However, computer modelling results suggest that a phenolate–wheel complex can form in which the components are not threaded, with both arms of the axle on the same side. This is primarily because of the flexibility of the centerpiece; therefore the addition of stoppers can result in a non-interlocked axle–wheel complex. Increased rigidity in the axle may lead to higher rotaxane yields. The functionalized centerpiece raises the possibility of inducing molecular motion within related systems, especially if phenol-to-phenolate interconversion can easily be achieved.<sup>[55]</sup>

Recent reports from Li et al.<sup>[56]</sup> have been concerned with the anion-templated synthesis of related rotaxanes using modified tetralactam wheels that have *exo*-oriented bipyridine functionalities capable of complexing metal ions.

**Fig. 11** Imidazolium (left) and nicotinamide (right) threads used by Beer et al. in the assembly of pseudorotaxanes.

Beer et al. have since begun exploiting anions in the templated synthesis of pseudorotaxanes and rotaxanes. Inspired by the demonstration of anion recognition by simple isophthalamide molecules by Kavallieratos et al.<sup>[57,58]</sup> they have designed a novel assembling motif consisting of two amide clefts orthogonally disposed about a central chloride anion core. Neutral isophthalamide receptors bind chloride in 1:1 stoichiometry and so are unsuitable for assembly purposes. However, the

use of a cationic molecule as one of the ligands enables two receptors to bind to the halide anion.<sup>[59]</sup> As a consequence of increased amide acidity because of the cationic nature of the pyridinium ring, the chloride counter-anion is bound much more tightly compared with an analogous isophthalamide neutral compound. The tight ion pair leaves the chloride anion coordinatively unsaturated in non-competitive solvents, with an empty meridian exposed, which is capable of coordinating with another suitable hydrogen bonding ligand. Incorporation of a neutral isophthalamide fragment into a macrocyclic structure provides the

**Scheme 4** Beer et al.'s anion-templated rotaxane synthesis.

wheel component of the pseudorotaxane through which the cationic component can be threaded in non-competitive solvents. The general strategy adopted by Beer et al. is illustrated in Fig. 8.

For the pyridinium pseudorotaxanes first reported, additional stability is provided by  $\pi$ - $\pi$  interactions and hydrogen bonding (Fig. 9).<sup>[59]</sup> A high degree of selectivity was exhibited in these systems, with the pyridinium threads binding in the order  $\text{Cl}^- > \text{Br}^- > \text{I}^- > \text{PF}_6^-$ . Therefore the system not only self-assembles but also displays a high degree of anion-specific recognition.

The crystal structure of the pyridinium-based pseudorotaxane reveals the threaded nature of the components (Fig. 10) and provides evidence of  $\pi$ - $\pi$  acceptor-donor interactions and hydrogen bonding between the pyridinium methyl group and the polyether chain.

Further work has demonstrated the versatility of this assembling motif by the formation of pseudorotaxanes based on nicotinamide and imidazolium cationic threads (Fig. 11).<sup>[60]</sup> Neither of the threads have hydrogen bond donors capable of binding to the polyether ring and although the former has one

**Fig. 14** Guanidinium-appended porphyrins (R = H,  $\text{SiPh}_2\text{Bu}'$ ).

**Fig. 15** Hydrogen bonding between 2,5-diamidopyrrole anions (R = Ph).

amide group capable of anion binding, the latter has none and threads simply by virtue of being an ion pair.<sup>[60]</sup> The chloride anion can be seen to “drag” the cationic thread into the macrocycle, and further stabilization is provided by second-sphere acceptor-donor interactions. With nicotinamide and imidazolium, selective macrocycle binding for chloride threads over hexafluorophosphate threads was demonstrated.

Wisner et al.<sup>[61]</sup> have also reported on the extension of this work to the anion-templated formation of [2]rotaxane. An acyclic chloride anion template based on simple pyridinium pseudorotaxane threads has been designed, which acts as the “axle” of the rotaxane. The second component is a neutral acyclic molecule incorporating an isophthaloyl anion binding cleft and has two long side chains terminating in allyl groups capable of ring closing metathesis (RCM). The side chains each possess a hydroquinone group, as with the original pseudorotaxane macrocycle (to facilitate donor-acceptor interaction), and polyether chains capable of hydrogen bonding. The two components associate strongly in non-competitive solvents, and rotaxane formation facilitates ring closing metathesis of the neutral component about the ion pair using Grubbs' catalyst with yields up to 47% obtained (Scheme 4).<sup>[61]</sup> No rotaxane formation occurs with pyridinium bromide or hexafluorophosphate salts, indicating the templating nature of the chloride anion.

An impressive feature of this method of rotaxane assembly is that the resultant product retains a degree

**Fig. 16** Gale's diamidopyrrole ligand.

**Fig. 17** X-ray crystal structure of Gale's "anion-anion" assembled solid-state polymer. *Source:* From Ref.<sup>[65]</sup>. American Chemical Society.

of functionality based on the anion template itself. Exchange of the templating chloride anion for the non-competitive hexafluorophosphate anion leaves a highly selective binding site within the rotaxane. Binding studies have shown that although the pyridinium  $\text{PF}_6^-$  thread alone binds anions with a selectivity trend  $\text{AcO}^- \gg \text{H}_2\text{PO}_4^- > \text{Cl}^-$ , the pyridinium  $\text{PF}_6^-$  rotaxane exhibits a complete selectivity reversal and a high selectivity for chloride (i.e., the templating anion). Beer et al. assign this binding selectivity to the creation of a unique hydrogen bond donating pocket within the [2]rotaxane superstructure, which possesses a complementary topology to chloride (Fig. 12). Larger anions cannot penetrate this diamide cleft and bind at the periphery of the rotaxane, or via a large displacement of the pyridinium thread from the macrocyclic cavity. Therefore this example demonstrates not only anion templation for the synthesis of mechanically interlocked components but also shows how a rigorous design procedure has led, via self-assembly, to a functional supramolecule whose properties are dependent on the templation process.<sup>[57,58]</sup>

Keegan et al.<sup>[62]</sup> have reported the first structurally characterized anion-directed assembly of a dinuclear double helicate. The di-ammonium-bis-pyridinium salt  $[(\text{H}_4\text{LCl})_2] \cdot 6\text{HCl} \cdot \text{H}_2\text{O}$ , where L is a diamino-bis-pyridine ligand, assembles into a double helical structure, featuring a major and a minor groove, with two ligands wrapping around two chloride anions (Fig. 13). The chloride anions are coordinated by two pyridinium moieties and interact weakly with methylene and aromatic CH groups.

Camiolo et al.<sup>[63]</sup> have demonstrated the anion-controlled assembly of porphyrin-bicyclic guanidinium conjugates in aqueous solution. Exploiting the cooperative interaction of porphyrin and guanidinium moieties with anions, they have reported the assembly of structures in which chirality is controlled by the anion template used (Fig. 14).

Detailed investigations using, primarily, circular dichroism indicate that the assembly process is achieved by the presence of small achiral anions. The authors propose that the anions serve as linkers that diminish repulsive forces between the porphyrin units.

Gale et al. have been investigating the use of pyrroles in anion-templated self-assembly. In 2002,

they reported on the deprotonation and subsequent dimerization of a series of simple 2,5-diamidopyrrole compounds. It was shown that the anionic diamidopyrrolate ion can recognize another diamidopyrrolate ion through hydrogen bonding.<sup>[64]</sup>

The components arrange themselves orthogonally to each other (Fig. 15). Not only is  $\text{NH} \dots \text{N}^-$  (pyrrole) hydrogen bonding observed in this case, but  $\pi$ -H interactions are also present.<sup>[64]</sup>

The first extension of this work was the so-called "anion-anion" assembly of a supramolecular polymer.<sup>[65]</sup> These polymers are based on two pyrrole units linked together and are the first example of interlocked materials based on hydrogen bonding where both components are anionic. One of the ligands developed is shown in Fig. 16.

Crystallization of this ligand from acetonitrile in the presence of excess TBA fluoride gave the doubly

**Fig. 18** Crystal structure of Gale's fluoride templated helix. Top: Side view. Bottom: Top view showing  $\pi$ -stacking interactions. TBA salts and some hydrogens omitted. *Source:* From Ref.<sup>[66]</sup>. The Royal Society of Chemistry.

Fig. 19 Wright's tetrameric macrocycle (left) and chloride anion-templated macrocycle (right).

deprotonated anions forming interlocked chains of anions via  $\text{NH} \dots \text{N}^-$  hydrogen bonding (Fig. 17).<sup>[65]</sup>

Coles et al.<sup>[66]</sup> have also extended their self-assembly interests to the use of isophthalamide clefts in the formation of a double helix. This is the first reported use of neutral ligands forming anion-templated helicates. A ligand is designed featuring an anion binding amide cleft and electron-withdrawing groups to enhance ligand–anion interactions. A crystal structure of the ligand in the presence of fluoride anions was obtained and shows the double helix structure formed around two fluoride anions, again via  $\text{N-H} \dots \text{F}$  hydrogen bonds (Fig. 18). Further stabilization is provided by  $\pi$ – $\pi$  interactions between terminal nitroaromatic groups.

Bashall et al.<sup>[67]</sup> have recently reported the synthesis of a series of macrocycles containing  $\{[\text{P}(\mu\text{-N}^t\text{Bu})_2](\mu\text{-NH})\}_n$  frameworks. A tetrameric macrocycle is formed on the reaction of  $[\text{ClP}(\mu\text{-N}^t\text{Bu})_2]$  with  $[\text{NH}_2\text{P}(\mu\text{-N}^t\text{Bu})_2]$  in the presence of a base (THF/Net<sub>3</sub>). However, addition of an excess of LiCl results in the formation of a pentameric macrocycle  $\{[\text{P}(\mu\text{-N}^t\text{Bu})_2](\mu\text{-NH})\}_5(\text{HCl})$ , with the ratio of tetrameric to pentameric being influenced strongly by excess chloride (Fig. 19).

Structural characterization of the pentamer indicates that the chloride anion is positioned at the center of the macrocycle and is hydrogen-bonded to the five NH groups of the ring.

## CONCLUSION

This review is intended to provide a general discussion of the emerging field of anion-templated self-assembly in organic systems. It can be seen that the range of organic compounds self-assembled by anion templates is highly diverse. Rational design has been employed from the start, and the field has rapidly developed to the stage at which topologically complex structures, such rotaxanes, are being prepared.

As with self-assembly as a whole, the range of complex molecules prepared by self-assembly techniques,

which would otherwise be practically impossible using covalent synthesis, is becoming increasingly diverse. A bright future for anion-templated self-assembly seems highly likely, with the above results illustrating the rapid progress made in such a short time span. There is no doubt that even on a short-term basis, many more impressive results will be seen within the literature and it remains the authors' view that anions will have a key role to play in the future of self-assembly.

## INTRODUCTION

Novel nanofabrication techniques are being explored as alternatives to conventional lithographic techniques to mass produce structures with feature sizes smaller than 100 nm and to minimize costs.<sup>[1]</sup> Porous anodic aluminum oxide (AAO) is a self-ordered, hexagonal array of straight cylindrical pores with high densities ( $10^8$ – $10^{11}$  pores/cm<sup>2</sup>), tunable diameters (5–250 nm), and depths (a few nanometers to hundreds of micrometers).<sup>[2–5]</sup> It can be fabricated through electrochemical anodization of aluminum at moderate and constant temperatures of 0–10°C in aqueous acidic electrolytes.<sup>[6–8]</sup> Anodic aluminum oxide is optically transparent in the fingerprint UV/vis and IR regions<sup>[9]</sup> and thermally stable up to 1000°C.<sup>[10]</sup> Moreover, it has recently been demonstrated to have unique advantages in several technological applications, including nanotemplating,<sup>[3,4]</sup> membrane transport,<sup>[11]</sup> and photonic crystals.<sup>[12]</sup> Through-hole AAO membranes have been used as evaporation masks to fabricate nanodot arrays<sup>[13,14]</sup> and as etching masks to transfer patterns into several substrates including diamond,<sup>[15]</sup> silicon,<sup>[16,17]</sup> and other semiconductors.<sup>[18]</sup>

The high fragility of through-hole AAO membranes<sup>[19]</sup> limits their integration into established microfabrication processes where robust membranes are needed. Although an elastic polypropylene support ring that runs around the circumference of AAO membrane permits one to pick up the membrane with membrane tweezers without shattering the membrane,<sup>[20]</sup> this approach fails when the membrane undergoes a high-temperature and/or an ultrahigh vacuum. To provide additional supports to fragile AAO, one could pattern aluminum surfaces with an anodization barrier prior to anodization. During anodization of the patterned surfaces, the anodization barrier prevents

anodization in the patterned areas while the oxide grows in the unpatterned areas. Recently, Huang et al.<sup>[21]</sup> have reported the first anodization barrier of polymethylmethacrylate deposited on aluminum films. Because of the penetration of the electrolyte through this polymeric layer, the underlying surface was partially anodized to form AAO up to 10-nm deep. In addition, the procedure required optical lithography, polymer nanoprinting, ion-beam exposure, and milling. Because of its excellent adhesion to aluminum surfaces and electrical insulation as well as its inertness to acidic electrolytes,<sup>[22]</sup> a SiO<sub>2</sub> layer prepatterned on aluminum surfaces could provide a good anodization barrier. The patterning of aluminum surfaces with a SiO<sub>2</sub> layer can be achieved through a sol–gel coating or a dielectric evaporation.

This entry describes a patterned anodization of bulk aluminum sheets and evaporated aluminum films prepatterned with an anodization barrier of SiO<sub>2</sub> through a sol–gel process or a dielectric evaporation. Using a two-step anodization process,<sup>[6–8]</sup> we formed highly ordered, uniform, and straight nanopores of AAO in the unpatterned areas, and did not observe any pores in the patterned areas before and after SiO<sub>2</sub> was removed. This approach provides intermittent aluminum supports to fragile AAO membranes, allowing facile incorporation of AAO in a robust form into microdevices for microelectronics, microfluidics, and integrated optics.

## ANODIZATION CELL

In most of the reported anodization processes, the whole aluminum sheet has been exposed to the anodizing electrolyte to fabricate ordered AAO. This results in a complete conversion of an aluminum surface into

fragile AAO, and thus limits the integration of AAO into microfabrication technologies that require robust AAO at specifically defined sample areas. To address this issue, Li and Metzger<sup>[23]</sup> coated one side of aluminum sheet with an insulating layer. To further address this, we prepared a custom-built novel anodization cell and used it in our experiments (Fig. 1). This jacketed cell is specifically designed for general temperature-controlled electrochemical experiments where film and/or membrane electrodes are used, and is compatible with a commercially available cell stand (BAS Inc., Indiana). The samples to be anodized, aluminum sheets or vacuum-evaporated aluminum films on glass slides, serve as the anode. The anode is clamped down against a Teflon-coated rubber O-ring in the anodization cell. Another piece of aluminum sheet serves as the cathode. Alligator clips are used to connect the power supply to the electrodes.

**Fig. 1** Custom-built anodization cell: (1) aluminum cathode; (2) thermocouple thermometer; (3) aluminum anode; (4) Teflon-coated O-ring; (5) water inlet; and (6) water outlet.

## PATTERNED ANODIZATION ON BULK ALUMINUM SHEETS

**Scheme 1** shows our procedure to fabricate freestanding and through-hole AAO membranes with intermittent aluminum supports on bulk aluminum sheets. Sol-gel coating<sup>a</sup> or dielectric evaporation forms the SiO<sub>2</sub>-patterned surfaces. The patterned surfaces were anodized using a two-step anodization process as previously described.<sup>[6–8]</sup> Briefly, the patterned surface was degreased in a 5 wt.% sodium hydroxide solution at 60°C for 30 sec, neutralized in a 50% (wt/wt) nitric acid solution for 5 sec, and then rinsed with deionized water. The pretreated surface was first anodized at a voltage of 40 V in a 0.3 M oxalic acid solution at 0°C for 20 min to eliminate large ridges and to texture the surface. The oxide was removed in a mixed solution of 0.2 M chromic acid and 0.4 M phosphoric acid at 60°C for 5 min. The surface was then anodized for 2 hr to create long-range ordering, with the newly formed oxide being removed again under the same conditions as used in the first anodization. Finally, the thus-treated surface was anodized again under the same conditions for 30 min to grow highly ordered pores. The postetching treatment of the resulting AAO consists of three steps: 1) removal of the remaining aluminum in a saturated mercury(II) chloride solution;

2) removal of the barrier layer at the bottom in a 5 wt.% phosphoric acid solution at 30°C; and 3) removal of the patterned SiO<sub>2</sub> on the top in a 5 wt.% sodium hydroxide solution at room temperature.

Aluminum sheets (99.999%, 0.25-mm thick) were purchased from Aldrich. Before use, they were cut into small pieces (20 × 20 mm). The SiO<sub>2</sub> sol used for patterning was prepared by adopting a two-step, acid-catalyzed sol-gel process. In a typical preparation, tetraethylorthosilicate (TEOS), ethanol, deionized water (18.2 MΩ cm) and dilute hydrochloric acid solution (HCl) were mixed in a molar ratio of 1:3.8:1:0.0005. The resulting solution was refluxed at 60°C for 90 min to provide the stock sol. Before use, 1 mL of stock sol was diluted with ethanol, followed by addition of water and dilute HCl solution, to provide a final overall molar ratio of TEOS/ethanol/water/HCl to be 1:22:5:0.0053. The SiO<sub>2</sub> sol was introduced into Marsmatic technical pens (0.13-mm tip, Staedtler) and was used to pattern the aluminum sheets.

**Fig. 2A** shows an illustrative scanning electron microscope (SEM) cross-sectional micrograph of AAO on a bulk aluminum sheet prepatterned with SiO<sub>2</sub> circular dots (ca. 1-mm diameter). Highly ordered, uniform, and straight pores are evident in the unpatterned areas. The average pore diameter, depth, and density are determined by SEM images to be 43 ± 7 nm, ~10 μm, and 1.7 × 10<sup>10</sup> pores/cm<sup>2</sup>, respectively. No pores appear in the areas beyond the O-ring, indicating no electrolyte leak from the inside to the outside of the O-ring. No pores are

<sup>a</sup>Although sol-gel processes have been widely used as one of the major template synthetic strategies to fabricate nanostructures (tubules, fibrils, and wires) of semiconductors and other inorganic materials in porous membranes including AAO,<sup>[24,25]</sup> there is no report on the application of sol-gel to obtain an anodization barrier on aluminum surfaces for patterned anodization. Advantages of sol-gel processes include simplicity of the procedure, stability of sol-gel films in acidic environments, and plausibility of composite coatings.

**Scheme 1** Schematic diagram for the micropatterning process of aluminum foils through a sol-gel resist. (A) Micropatterning of anodization barriers using various techniques including microwriting, screen printing, and chemical vapor deposition; (B) patterned anodization; (C) removal of the remaining aluminum in a saturated mercury(II) chloride solution; (D) removal of the barrier layer at the bottom in a 5 wt.% phosphoric acid solution and removal of the patterned SiO<sub>2</sub> on the top in a 5 wt.% sodium hydroxide solution.

observed in the patterned areas. Appearing visible as a thin overhang around the periphery of the AAO membrane, the patterned SiO<sub>2</sub> layer shows no cracking and/or peeling against the applied voltage and anodizing electrolytes. Shown in Fig. 2B, no pores are observed beneath the SiO<sub>2</sub> layer if it is removed using a 5 wt.% sodium hydroxide solution at room temperature for 5 min. The pores were also widened to be about 60 nm as a result of base etching. This demonstrates an excellent inhibition of the SiO<sub>2</sub> layer in preventing the electrolyte from penetrating into the SiO<sub>2</sub>/aluminum interface. The inhibition ability of the SiO<sub>2</sub> layer, together with the good adhesion to aluminum and the capability of undergoing long-time anodization, makes SiO<sub>2</sub> an ideal resist for patterned anodization of aluminum.

**Fig. 2** Scanning electron micrographs of ordered AAO on an aluminum sheet prepatterned with SiO<sub>2</sub> circular spots (ca. 1-mm diameter) through a sol-gel process: (A) cross-sectional view of the AAO/Al interface; (B) surface view of the AAO/Al interface. B was obtained by dissolving SiO<sub>2</sub> in a 5 wt.% sodium hydroxide solution.

After carefully removing the remaining aluminum, the bottom-barrier layer, and the patterned SiO<sub>2</sub> layer, a freestanding, highly ordered, through-pore AAO membrane with intermittent aluminum supports is obtained. In our control experiments, we anodized patterned aluminum sheets under the same conditions, except for the different anodization times in the final step (from 30 min up to 11 h). We then measured the membrane thickness by SEM for the resulting freestanding and through-hole AAO membranes. We found that the membrane thickness increased almost linearly with the anodization time in the final step up to 9 h, after which it increased slightly with the anodization time in the final step. For example, the membrane thicknesses are  $13.2 \pm 1.3$ ,  $23.6 \pm 0.4$ , and  $24.3 \pm 0.4 \mu\text{m}$  for a 5, 9, and 10 hr anodization in the final step, respectively, with the aspect ratio of the nanopores in the membranes being  $307 \pm 58$ ,  $549 \pm 90$ , and  $565 \pm 92$ , respectively. Because the

**Fig. 3** Transmission electron micrographs of surface (A) and cross section (B) of freestanding and through-hole AAO membranes.

pH value of the electrolyte mainly defines the nanopore diameter,<sup>[26]</sup> during the two-step anodization process in a given polyprotic acid, the nanopore diameter is held almost constant. One can control the anodization time in the final step to control the depth of the nanopores. This offers a unique advantage to tailor the aspect ratio of the nanopores. Huang et al.<sup>[21]</sup> found that sub-100-nm AAO pores with aspect ratios 1000:1 can easily be formed without elaborate processing.

Fig. 3 shows the transmission electron microscopic (TEM) surface (A) and cross section (B) of a cutout of the freestanding and through-hole AAO membranes. Highly ordered, uniform, and hexagonal pores are evident in Fig. 3A. The average pore diameter became larger than that shown in Fig. 2A. This is because of the pore widening from the phosphoric acid solution used to remove the bottom-barrier layer. Through-hole nanopores oriented normal to the aluminum surface are also clearly shown in Fig. 3B.

### ANODIZATION ON EVAPORATED ALUMINUM FILMS ON GLASS

Although irregular pore arrays of AAO were obtained through a single-step anodization process of bulk aluminum foils at the beginning of 1950s,<sup>[27]</sup> regular

pore arrays were not fabricated until 1995 when Masuda and Fukuda<sup>[6]</sup> demonstrated that a two-step anodization process can dramatically improve the periodicity of the pores. During the past several years, almost all reported works have been using bulk aluminum instead of thin aluminum films. This greatly limits the integration of AAO into potential technologies because of the inherent fragility of AAO membranes<sup>[19]</sup> and the practical need of many technologies to have materials in thin-film forms. Very few reports are available on anodization of vacuum-evaporated aluminum films,<sup>[13,17,21,28,29]</sup> in which single-step anodization processes with short anodization times (5–13 min) were used, resulting in a low ordering of pore arrangement. To improve the ordering of the pore arrangement, one should use the two-step anodization process with longer anodization times, as for bulk aluminum foils.<sup>[30]b</sup> To the best of our knowledge, there has been no report on the application of two-step anodization process to the evaporated aluminum films.

Thin aluminum films ( $\sim 2.2 \mu\text{m}$ ) were obtained by electron beam evaporation of 99.99% aluminum at a rate of 2.0 nm/sec in a vacuum of  $2 \times 10^{-7}$  Torr on microscopic glass slides (Baxter Scientific, M6145). The glass slides were cleaned in freshly prepared “piranha solution” (7:3 concentrated  $\text{H}_2\text{SO}_4$  and 30%  $\text{H}_2\text{O}_2$ ), thoroughly washed with water, and blown dry with nitrogen. The films were stored under vacuum in a drying chamber or were immediately used.

Prior to use, the aluminum film was degreased by sonicating in ethanol for 10 min, and blown dry under a stream of nitrogen. The two-step anodization process that was established for bulk aluminum<sup>[6–8]</sup> was used to anodize aluminum films. Typically, the film was first anodized at a voltage of 40 V in a 0.3 M oxalic acid solution at  $0^\circ\text{C}$  for 15 min to texture the surface. After removing the oxide in a mixed solution of 0.2 M chromic acid and 0.4 M phosphoric acid at  $60^\circ\text{C}$  for 5 min, the surface was anodized again for 15 min to create long-range ordering. The newly formed oxide was removed again under the same conditions as used in the first anodization. Finally, the thus-treated surface was anodized under the same conditions to grow highly ordered pores. The final anodization was stopped at a point when the anodizing current significantly dropped. At this point, all the aluminum is consumed. For a  $\sim 2\text{-}\mu\text{m}$ -thick film, the anodizing time in the final step is usually about 12 min.

Using the two-step anodization process, we repeatedly observed a circular disk of oxide (ca. 8-mm diameter) locating in the center of the area defined by the

<sup>b</sup>For bulk aluminum sheets, it is reported that longer anodization times lead to greater pore regularity through self-organization processes that occur during anodization.

**Fig. 4** Scanning electron micrographs of surface (A) and cross section (B) obtained on vacuum-evaporated aluminum films on glass.

O-ring (12-mm diameter). No oxide was present beyond this disk. Huang et al.<sup>[21]</sup> observed similar delamination behavior. They attributed it to the stress generated as a result of volume expansion when aluminum is anodized to porous alumina. Depositing an adhesion layer between aluminum and glass substrates may eliminate delamination. Fig. 4A shows a scanning electron microscope (SEM) surface micrograph of AAO obtained on the central disk. Highly ordered, uniform, and straight pores can be seen. The average pore diameter, depth, and density are determined by SEM images to be  $60 \pm 8$  nm,  $\sim 3 \mu\text{m}$ , and  $1.3 \times 10^{10}$  pores/cm<sup>2</sup>, respectively. This membrane thickness results in a volume expansion of alumina to aluminum of about 1.3, which is in good agreement with the mechanical stress model<sup>[31,32]</sup> and the 10% porosity rule.<sup>[26]</sup> Fig. 4B shows the SEM cross-sectional micrograph. There is a thin oxide barrier layer on which parallel, straight-through pores are evident. There are voids of alumina below the barrier layer. Similar voids were previously observed for anodization of aluminum thin films on silicon,<sup>[13,17]</sup> with the formation being attributed to a localized temperature increase or electric-field-enhanced dissolution near

**Fig. 5** Scanning electron micrographs of the surface of ordered AAO on an evaporated aluminum film prepatterned with SiO<sub>2</sub> microgrids ( $75 \times 75 \mu\text{m}$ ): (A) low-magnification image; (B and C) high-magnification images.

the interface. Because of this unique structure, the bottom part of the oxide layer can be easily removed by postetching treatment with phosphoric acid solution. This allows for the alumina to be directly used as an etch mask for pattern transfer into other substrates.<sup>[17]</sup>

#### PATTERNED ANODIZATION ON EVAPORATED ALUMINUM FILMS

The SiO<sub>2</sub> pattern ( $\sim 4.0\text{-}\mu\text{m}$  thick)<sup>c</sup> was dielectrically deposited on the freshly evaporated aluminum films on glass at a rate of  $2 \text{ \AA}/\text{sec}$  by electron beam

<sup>c</sup>Control experiments demonstrated that a relatively thick layer of SiO<sub>2</sub> is required for complete inhibition of electrolyte from penetrating into the SiO<sub>2</sub>/aluminum interface. For example, when anodizing bulk aluminum sheets and evaporated aluminum films with a thickness of  $\sim 2 \mu\text{m}$  for the patterned SiO<sub>2</sub> layer, we have observed pore formation in the patterned areas although no cracking and/or peeling of SiO<sub>2</sub> is observed.

evaporation at a base pressure of  $1.5 \times 10^{-5}$  Torr, using a TEM copper grid ( $75 \times 75 \mu\text{m}$ ) as an evaporation mask. The thus-patterned surfaces were anodized using the two-step anodization process as for the evaporated aluminum films on glass.

Fig. 5 shows SEM surface micrographs of the patterned surface after anodization. Parts A and B correspond to low-magnification and high-magnification images, respectively. No pores appear in the patterned areas while highly ordered and uniform pores appear in the unpatterned areas, i.e., the borders of the  $\text{SiO}_2$  microgrids (Fig. 5C).

## CONCLUSION

In summary, we have developed an efficient, inexpensive procedure to fabricate highly ordered, through-hole nanoporous AAO with intermittent aluminum supports from patterns of controlled size and shape. The use of patterned  $\text{SiO}_2$  layer as anodization barriers in the patterned anodization provides the required structural robustness, electrical insulation, and excellent adhesion to aluminum surfaces, and constitutes the basis of a method for the direct assembly of novel nanodevices, especially for nanoelectronic manufacturing. Our ongoing investigation is centered on scaling down the patterned features to the micron and submicron dimensions, development of methods for use of micropatterned AAO in fluidic and electronic nanovias, and construction of heterostructural nanowires using patterned AAO as a template through chemical vapor deposition and/or pulsed electrodeposition.

## ACKNOWLEDGMENTS

We are grateful to the Army Research Office and the Ceramic and Composite Materials Center for financial support. We thank Mr. Marcos Barela and Dr. Huifang Xu for their assistance with the SEM and TEM measurements, and Dr. Michael J. O'Brien for his assistance with aluminum evaporation.

# Antidot Lattices: Chaotic Transport

Tsuneya Ando

Department of Physics, Tokyo Institute of Technology, Tokyo, Japan

## INTRODUCTION

Advances in microfabrication and crystal growth technology have enabled the preparation of lateral superlattices with submicron structures on top of a two-dimensional (2-D) electron system with mean free path as large as 100  $\mu\text{m}$ . The 2-D system modulated by a periodic strong repulsive potential is called antidot lattice. The transport in this system is ballistic (i.e., electrons are scattered from the antidot potential itself rather than from impurities). The purpose of this entry is to give a brief review on chaotic transport in antidot lattices in the presence of magnetic fields mainly from a theoretical point of view.

Various interesting phenomena have been observed in antidot lattices in magnetic fields: quenching of the Hall effect,<sup>[1,2]</sup> Altshuler–Aronov–Spivak oscillation near vanishing fields,<sup>[3–6]</sup> the so-called commensurability peaks in magnetoresistance,<sup>[1,7–16]</sup> and fine oscillations around them.<sup>[17,18]</sup>

Antidot lattices are introduced in “Antidot Lattices.” In “Commensurability Peaks,” the origin of commensurability peaks is discussed with emphasis on the roles of classical chaotic motion. In “Aharonov–Bohm-Type Oscillation,” the Aharonov–Bohm-type oscillation superimposed on the commensurability peak is analyzed based on semiclassical quantization of periodic orbits existing in the chaotic sea. Triangular lattices are discussed in “Triangular Antidot Lattices” with emphasis on differences from square lattices. In “Altshuler–Aronov–Spivak Oscillation,” a kind of the Altshuler–Aronov–Spivak oscillation appearing in weak magnetic fields is discussed in relation to the roles of inherent disorder in the antidot potential arising during the fabrication process. A new method based on a scattering matrix to calculate electronic states and transport properties is introduced in “Scattering Matrix Formalism,” together with some examples of the results obtained. A summary and conclusions are given in “Conclusion.”

## ANTIDOT LATTICES

Fig. 1 shows an illustration of the potential of a square antidot lattice. It is characterized by the period  $a$  and

the diameter  $d$  of the antidot. We have typically  $d \gtrsim 1000 \text{ \AA}$ , larger than the Fermi wavelength of the 2-D electron system ( $\lambda_F \sim 500 \text{ \AA}$ ) for a typical electron concentration less than  $5 \times 10^{11} \text{ cm}^{-2}$  in a GaAs/AlGaAs heterostructure. Correspondingly, the period of the antidot is usually  $a \geq 2000 \text{ \AA}$ . This means that the system is in the boundary between the quantum regime and the classical regime. In classical mechanics, electron motion is fully chaotic and, in fact, the antidot lattice is a kind of a Sinai billiard, which is a typical system where chaotic motion has been intensively studied.

The model antidot potential used often for a square antidot is given by:

$$U(\mathbf{r}) = U_0 \left| \cos\left(\frac{\pi x}{a}\right) \cos\left(\frac{\pi y}{a}\right) \right|^{2\beta} \quad (1)$$

where  $U_0$  is the potential maximum and the parameter  $\beta$  characterizes its steepness. The antidot diameter can be defined as  $d/2 = |\mathbf{r}|$ , with  $U(\mathbf{r}) = E_F$ , where  $E_F$  is the Fermi energy and  $\mathbf{r}$  is chosen in the direction of a nearest neighbor. In a triangular lattice, the corresponding potential is given by:

$$U(\mathbf{r}) = U_0 \left| \cos\left(\frac{\pi \mathbf{a}_1 \cdot \mathbf{r}}{a^2}\right) \cos\left(\frac{\pi \mathbf{a}_2 \cdot \mathbf{r}}{a^2}\right) \times \cos\left(\frac{\pi(\mathbf{a}_1 - \mathbf{a}_2) \cdot \mathbf{r}}{a^2}\right) \right|^{4\beta/3} \quad (2)$$

with  $\mathbf{a}_1 = (\sqrt{3}a/2, a/2)$  and  $\mathbf{a}_2 = (0, a)$ .

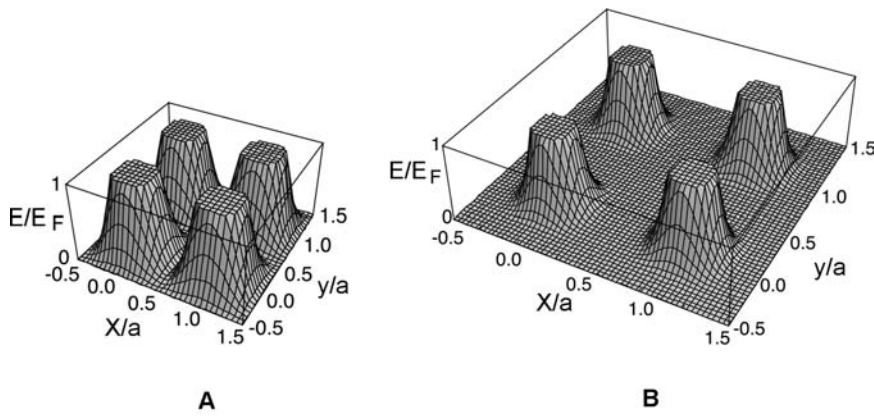

Sometimes, we use the following model potential:

$$U(\mathbf{r}) = E_F \left( \frac{d/2 + \Delta - r}{\Delta} \right)^2 \theta(d/2 + \Delta - r) \quad (3)$$

where  $r$  is the distance from the center of an antidot,  $\Delta$  is the parameter characterizing the steepness of the potential, and  $\theta(t)$  is the step function defined by  $\theta(t) = 1$  for  $t > 0$  and 0 for  $t < 0$ .

A self-consistent calculation in quantum wires at GaAs/AlGaAs heterostructures<sup>[19,20]</sup> suggests that the potential is nearly parabolic for a wire with small width, and consists of a flat central region and a parabolic increase near the edge for a wider wire. The width

**Fig. 1** A model antidot potential in a square lattice. (A)  $d/a = 0.5$  and  $\beta = 1$ . (B)  $d/a = 0.3$  and  $\beta = 4$ . The potential is cut off at the Fermi energy.

$\Delta$  of the region where the potential increases from the bottom to the Fermi energy is of the same order as the Fermi wavelength  $\lambda_F$  for typical electron concentrations. This leads to roughly  $\beta \sim 1$  for  $d/a \sim 0.5$ ,  $\beta \sim 2$  for  $d/a \sim 0.4$ , and  $\beta \sim 4$  for  $d/a \sim 0.3$  in the case  $d \sim 1000 \text{ \AA}$ .

**COMMENSURABILITY PEAKS**

Fig. 2 shows an example of observed diagonal and Hall resistivity in a square antidot lattice.<sup>[1]</sup> Two prominent peaks appear in the diagonal resistivity  $\rho_{xx}$  in weak magnetic fields and, correspondingly, some steplike structures are present for the off-diagonal Hall resistivity  $\rho_{xy}$ . Cyclotron orbits can be classified into those affected and not affected by antidots.<sup>[1]</sup> At certain magnetic fields, electrons can move on the commensurate classical orbit encircling a specific number of antidots, as shown in Fig. 3 (pinned orbits). Magnetoresistance was expected to increase at this magnetic field.

However, a numerical simulation based on classical electron motion showed that the change in the volume of the pinned orbits in the phase space is not enough to cause commensurability oscillation, and suggested that chaotic orbits that have a character close to the periodic orbits give larger contribution.<sup>[21]</sup> The importance of the “runaway” orbit, which skips regularly from an antidot to its neighboring antidot in the same direction, was also proposed.<sup>[22]</sup> Experiments on rectangular and/or disordered antidots<sup>[23–27]</sup> and numerical simulations<sup>[27–29]</sup> provided pieces of evidences showing the importance of such orbits.

A better way of understanding the origin of commensurability peaks is through diffusive orbits and magnetic focusing. Consider first the limit of a small aspect ratio  $d/a \ll 1$ . In this case, the electron loses its previous memory of the direction of the velocity when it collides with an antidot; therefore successive

scattering with antidots can be approximately regarded as independent of each other.<sup>[30]</sup> This means that antidots are nothing but independent scatterers.

In magnetic fields, transport is possible through the migration of the center of the cyclotron motion; therefore conductivity vanishes in the absence of scattering. When  $2R_c < a$ , where  $R_c$  is the classical cyclotron radius, the scattering of an electron from an antidot cannot give rise to diffusion or conduction because the electron is trapped by the antidot.

**Fig. 2** An example of  $\rho_{xx}$  and  $\rho_{xy}$  observed in patterned (solid lines) and unpatterned (dotted lines) 2-D systems. Source: From Ref.<sup>[1]</sup>. Two prominent peaks and step structures appear in the diagonal and Hall resistivity, respectively, at  $\sim 0.2$  and  $\sim 0.6$  T in antidot lattices.

Amphiphilic  
– Axle

**Fig. 3** Some examples of pinned orbits. It was suggested that the resistivity exhibits a peak at the magnetic fields where the classical cyclotron orbit encircles 1, 2, 4, 9, 21, etc., antidots.

Scattering from antidots starts to contribute to conductivity when  $2R_c > a - d$ . The migration of the center of the cyclotron orbit occurs most frequently because of successive scattering from nearest-neighbor antidots at the magnetic field corresponding to  $2R_c = a$ . At this magnetic field, the measure of such orbits becomes maximum in the phase space because of a kind of magnetic focusing effect. In fact, a slight change  $\theta$  in the direction from the direction normal to the line connecting neighboring antidot leads to a change only on the order of  $2R_c\theta^2$  in position when the electron collides with a neighboring antidot, as shown in Fig. 4. This leads to an increase of the phase space volume of the orbits contributing to the increase of the diffusion coefficient at  $2R_c \approx a$ . This magnetic

**Fig. 4** Schematic illustration of magnetic focusing leading to the fundamental commensurability peak.

focusing is different from mechanisms suggested in other works.<sup>[25,27,31]</sup>

As shown in Fig. 5, the orbit corresponding to  $2R_c = a$  can be denoted as  $(n_x, n_y) = (\pm 1, 0)$  or  $(0, \pm 1)$ , where the line segment connecting the point  $(n_x, n_y)$  and the origin constitutes the diameter of the circle. With a further decrease in the magnetic field, successive scattering with next nearest-neighbor antidots becomes possible and the conductivity has a peak around  $2R_c = \sqrt{2}a$  corresponding to  $(\pm 1, \pm 1)$ . However, this contribution becomes less prominent because the orbit passes through the position of a nearest-neighbor antidot. The next peak arises from  $(\pm 2, 0)$  or  $(0, \pm 2)$ , and  $(\pm 2, \pm 1)$  or  $(\pm 1, \pm 2)$ , which lie close to each other. The latter contribution should be larger because its measure is twice as large as that of the former; therefore the peak occurs roughly around  $2R_c \sim \sqrt{5}a$ . However, this peak should be weaker as these orbits also pass through the position of other antidots. The next prominent peak is expected to be given by  $(\pm 2, \pm 2)$ ,  $(\pm 3, 0)$ ,  $(0, \pm 3)$ ,  $(\pm 3, \pm 1)$ , and  $(\pm 1, \pm 3)$ . The peak is expected to be at  $2R_c \approx 3a$  because the orbits  $(\pm 3, 0)$  and  $(0, \pm 3)$  are not disturbed by other antidots. Most of the commensurability peaks observed experimentally can be explained qualitatively in this way.

When the diameter  $d$  is no longer negligible in comparison with the period  $a$ , the commensurability peak in the diagonal conductivity  $\sigma_{xx}$  deviates from the condition  $2R_c = (n_x^2 + n_y^2)^{1/2}a$ . In the following, we confine ourselves to the fundamental peak given by  $(\pm 1, 0)$  and  $(0, \pm 1)$ . A cyclotron orbit starting at an

**Fig. 5** Some examples of diffusive cyclotron orbits contributing to the migration of the guiding center. The dashed circles correspond to pinned orbits (the number denotes antidots in the orbit).

**Fig. 6** The region (shaded) of the center of cyclotron orbits passing through two nearest-neighbor antidots.

antidot and colliding with a neighboring antidot has a center in the region schematically illustrated in Fig. 6, to which the phase space volume of such orbits is proportional. Fig. 7 shows the area as a function of the magnetic field. The area has a maximum at  $2R_c = a + fd$ , where  $f \sim 0.3$  is a constant weakly dependent on  $d/a$ . This means that the commensurability peak is shifted to the weak-field side roughly in proportion to  $d/a$ .

For a non-negligible  $d/a$ , the correlation among successive scattering from antidots becomes important. In fact, it manifests itself most directly in the Hall conductivity. As illustrated in Fig. 8, it tends to enhance the left circular motion of electrons in the weak-field region  $2R_c \gtrsim a$  and reduce it in the high-field region  $2R_c \lesssim a$ . This leads to an enhancement of  $|\sigma_{xy}|$  for  $2R_c \gtrsim a$  and a reduction for  $2R_c \lesssim a$ , giving rise to a steplike structure around  $2R_c \approx a$ .

With the increase of  $d/a$ , the measure of the diffusive orbits increases, as shown in Fig. 7, and the diagonal conductivity becomes larger and comparable to  $\sigma_{xy}$  (numerical calculations show that  $\sigma_{xx} \sim |\sigma_{xy}|$

around  $d/a \sim 0.5$ <sup>[30]</sup>). Therefore the commensurability peaks in the resistivity become different from those in the diagonal conductivity. Let  $\Delta\sigma_{xx}$  and  $\Delta\sigma_{xy}$  be small changes around the field corresponding to the commensurability peak and let  $\bar{\sigma}_{xx}$  and  $\bar{\sigma}_{xy}$  be the average ( $\Delta\sigma_{xx} \ll \bar{\sigma}_{xx}$ ,  $|\Delta\sigma_{xy}| \ll |\bar{\sigma}_{xy}|$ ). Then, we have:

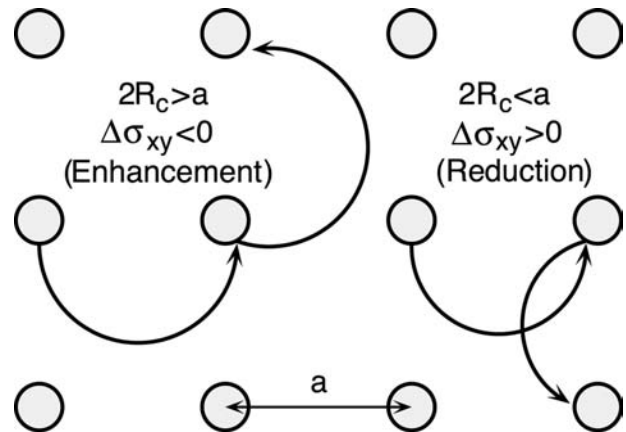

$$\Delta\rho_{xx} = \frac{(\bar{\sigma}_{xy}^2 - \bar{\sigma}_{xx}^2)\Delta\sigma_{xx} - 2\bar{\sigma}_{xx}\bar{\sigma}_{xy}\Delta\sigma_{xy}}{(\bar{\sigma}_{xx}^2 + \bar{\sigma}_{xy}^2)^2} \quad (4)$$

This means that  $\Delta\sigma_{xy}$  determines the structure of  $\rho_{xx}$  when  $\bar{\sigma}_{xx} \sim |\bar{\sigma}_{xy}|$  (i.e., the reduction of  $|\sigma_{xy}|$  in the high-field side gives the peak in  $\rho_{xx}$  for a large  $d/a$ ).

Fig. 9 shows an example of the results of numerical simulations in classical mechanics<sup>[30]</sup> It shows that the peak in  $\sigma_{xx}$  is broadened considerably with the increase of  $d/a$  and, at the same time, shifted to the lower magnetic field side. A step structure corresponding to the first derivative of  $\sigma_{xx}$  with the magnetic field appears in  $\sigma_{xy}$ . However, it is interesting that the

**Fig. 7** The area of the region where cyclotron orbits pass through two nearest-neighbor antidots. The diagonal conductivity is roughly proportional to the area at  $2R_c \sim a$ .

**Fig. 8** A schematic illustration of scattering from two adjacent antidots. This leads to an enhancement of  $|\sigma_{xy}|$  for  $2R_c \lesssim a$  and a reduction for  $2R_c \gtrsim a$ .

**Fig. 9** Some examples of (A)  $\rho_{xx}$ , (B)  $\sigma_{xx}$ , and (C)  $\sigma_{xy}$  calculated in classical mechanics. Each curve of  $\rho_{xx}$  is normalized by its maximum value and shifted successively. The results for  $\sigma_{xx}$  are shifted successively by  $e^2/h$ . The peak positions of  $\sigma_{xx}$  are indicated by triangles and vertical dotted lines. The mean free path is  $\Lambda = 3.3a$ . Source: From Ref.<sup>[30]</sup>.

commensurability peak in the resistivity  $\rho_{xx}$  remains around  $2R_c = a$ , independent of  $d/a$ . This results from the fact that the resistivity is rather a complicated function of  $\sigma_{xx}$  and  $\sigma_{xy}$ . For  $d/a \geq 0.5$ , the structures in  $\sigma_{xx}$  and  $\sigma_{xy}$  disappear almost completely and  $\rho_{xx}$  does not show a clear commensurability peak.

A large aspect ratio usually corresponds to a small antidot period  $a$  and to a narrow spacing between the nearest-neighbor antidot comparable to the Fermi wavelength  $\lambda_F$ . Therefore quantum effects can be important for antidot lattices with large  $d/a$  for a fixed value of  $a$ . In fact, a quantum mechanical calculation<sup>[32]</sup> in a self-consistent Born approximation<sup>[33,34]</sup> shown in Fig. 10 gave the result for  $d/a = 0.5$  that the diagonal conductivity  $\sigma_{xx}$  exhibits essentially no structure and the off-diagonal Hall conductivity has a small dip at  $2R_c \sim a$ , leading to the fundamental commensurability peak at  $2R_c \sim a$ . Some experiments have shown that  $\sigma_{xx}$  has a dip at  $2R_c \sim a$  for antidot lattices with larger  $d/a$ .<sup>[27,35]</sup> The structure appearing in the off-diagonal Hall resistivity at the fundamental

**Fig. 10** (A)  $\rho_{xx}$ , (B)  $\sigma_{xx}$ , and (C)  $\sigma_{xy}$  calculated in a self-consistent Born approximation as a function of the magnetic field for  $\beta = 2$ . Source: The experimental data From Ref.<sup>[17]</sup>, are also shown for comparison. From Ref.<sup>[32]</sup>.

commensurability peak was analyzed experimentally and theoretically.<sup>[36]</sup>

In high magnetic fields, the structure of the energy bands is relatively simple and can be understood as combinations of Landau bands, which have non-zero dispersion in the presence of antidot lattices and quantized edge states localized along an antidot boundary. With the decrease of the magnetic field, these magnetic minibands start getting mixed with each other. This mixing gives rise to many bands having a large quantized value of the Hall conductivity, both negative and positive.<sup>[37]</sup> Extremely large values are usually canceled out if they are summed over adjacent minibands. Actual calculations seem to show that this cancellation is not complete and the Hall conductivity tends to have a dip around a certain magnetic field, giving rise to a peak in the resistivity. The Hall conductivity is sensitive to parameters such as the Fermi energy and sometimes exhibits even a signature change. Therefore the origin of commensurability peaks becomes unclear when quantum effects become important.

**Fig. 11** Observed quantum oscillation superimposed on the fundamental commensurability peak. The oscillation becomes clear in the difference of the resistivity at  $T = 4.2$  K and that at  $T = 1.5$  K (shifted vertically by 1 kΩ). *Source:* From Ref.<sup>[17]</sup>.

### AHARONOV–BOHM-TYPE OSCILLATION

A fine oscillation was observed to be superimposed on commensurability peaks of the magnetoresistance.<sup>[5,17,18]</sup> Figs. 11 and 12 give examples of such Aharonov–Bohm-type oscillation reported in Refs.<sup>[17]</sup> and<sup>[18]</sup>. The period is roughly given by  $\Delta B \sim \Phi_0/a^2$ , where  $\Phi_0 = ch/e$  is the magnetic flux quantum. Numerical calculations have been performed on this Aharonov–Bohm-type oscillation.<sup>[32,38,39]</sup> In the following, some of the results<sup>[32,40]</sup> obtained in a self-consistent Born approximation are reviewed briefly.

The calculated diagonal and Hall conductivity at  $T = 4$  K, shown in Fig. 10, oscillate with period  $\Phi_0$  over the range of magnetic fields considered. This oscillation originates from the butterfly band structure of Hofstadter,<sup>[41]</sup> as suggested theoretically.<sup>[42–44]</sup> In fact, the band structure exhibits a quasi-periodic oscillation as a function of the magnetic flux passing through a unit cell with period given by the magnetic flux quantum. At a lower temperature ( $T = 1$  K), another kind of oscillation appears in addition to this butterfly

**Fig. 12** An example of observed quantum oscillations superimposed on the fundamental commensurability peak. *Source:* From Ref.<sup>[18]</sup>.

oscillation. Actually, these oscillations are sensitive to the antidot potential and the difference between this new oscillation and the butterfly oscillation becomes much clearer for the more realistic parameter  $\beta = 1$ , although not shown here.

The density of states in classically chaotic systems can be calculated semiclassically using the so-called periodic orbit theory.<sup>[45–47]</sup> According to the trace formula, the density of states is given by the sum of a classical contribution and a quantum correction. The latter is given by semiclassically quantized energy levels associated with periodic orbits and the former is proportional to the classical phase space volume at the energy. The contribution of a particular periodic orbit can be written as the summation of  $\delta$  functions for a stable orbit:

$$D_{\text{osc}}^{\text{po}}(E) = \frac{T}{\hbar} \sum_{m=0}^{\infty} \left[ \sum_{n=-\infty}^{\infty} \delta \left( \frac{S_c}{\hbar} - \left( m + \frac{1}{2} \right) v - 2n\pi \right) - \frac{1}{2\pi} \right] \quad (5)$$

and the summation of Lorentzian functions for an unstable orbit:

$$D_{\text{osc}}^{\text{po}}(E) = \frac{T}{\hbar} \sum_{m=0}^{\infty} (\pm 1)^m \left[ \sum_{n=-\infty}^{\infty} \frac{1}{\pi} \times \frac{(2m+1)u/2}{[S_c/\hbar - 2\pi(\mu/4 + n)]^2 + [(2m+1)u/2]^2} - \frac{1}{2\pi} \right] \quad (6)$$

where  $S_c$  is the classical action,  $T$  is the period, and  $v$  is the stability angle. For unstable orbits,  $u$  is the Lyapunov exponent,  $\mu$  is the Maslov index, and the sign becomes  $\pm$  accordingly as the neighborhood of a periodic orbit is hyperbolic or inverse hyperbolic. The integer  $m$  is considered as a quantum number for a motion transverse to the periodic orbit.<sup>[48]</sup> The quantization conditions are:

$$S_c = \begin{cases} 2\pi\hbar \left[ n + \frac{1}{2\pi} \left( m + \frac{1}{2} \right) v \right] & \text{for stable orbit} \\ 2\pi\hbar \left( n + \frac{\mu}{4} \right) & \text{for unstable orbit} \end{cases} \quad (7)$$

with integer  $n$  and non-negative integer  $m$ .

Fig. 13 shows some examples of periodic orbits having a short trajectory.<sup>[49,50]</sup> The orbit (a) is localized in the potential well region surrounded by four neighboring antidots. It turns continuously into a normal cyclotron orbit in sufficiently high magnetic fields. The orbit (b) circling around an antidot is considered to be most important in giving rise to the quantum oscillation.

Fig. 14 shows an example of the calculated density of states together with quantized energy levels associated with the orbits (a) and (b) for  $m = 0$ .<sup>[32,40]</sup> The density of states is correlated well with semiclassical energy levels, although many features remain to be explained.

**Fig. 13** Some examples of periodic orbits having a short trajectory in a square antidot in a magnetic field  $Ba^2/\Phi_0 = 8.5$  roughly corresponding to the main commensurability peak. The parameters are  $a/\lambda_F = 4.31$ ,  $U_0/E_F = 8.4$ ,  $d/a = 0.6$ , and  $\beta = 2$ . *Source:* From Ref.<sup>[49]</sup>.

**Fig. 14** The density of states calculated in a self-consistent Born approximation for  $\hbar/\tau = 0.18$  meV and  $\beta = 1$ . It is large in the light region and small in the dark region. The energy levels for the orbits (a) and (b) are given by lines (solid lines for stable orbits and dotted lines for unstable orbits). *Source:* From Ref.<sup>[40]</sup>.

A semiclassical expression can be obtained for the conductivity tensor,<sup>[32,51,52]</sup> but has proved to be unsuccessful for the parameter range corresponding to the experiments mentioned above.<sup>[32]</sup> As discussed in “Commensurability Peaks,” diffusive orbits have a dominant contribution to transport in the magnetic field region near the commensurability peak. These orbits are perturbed by the presence of quantized periodic orbits, which is likely to lead to a quantum oscillation. The semiclassical expression for the conductivity does not take into account such effects.

## TRIANGULAR ANTIDOT LATTICES

Commensurability peaks have been observed also in triangular antidot lattices. Their origin is the same as in square lattices and is understood in terms of diffusive orbits and magnetic focusing. Fig. 15 shows some examples of diffusive orbits contributing to the migration of guiding centers of cyclotron orbits. They are specified by two integers  $(n_1, n_2)$  such that  $n_1 a_1 + n_2 a_2$  corresponds to a vector whose length is equal to the cyclotron diameter (i.e.,  $2R_c/a = \sqrt{n_1^2 + n_2^2 + n_1 n_2}$ ).

There are some important differences from the square lattice. First, diffusive orbits are strongly disturbed by the presence of other antidots with increasing antidot diameter. As schematically illustrated in Fig. 16, diffusive orbits start to be severely influenced for  $d/a > (\sqrt{3} - 1)/2 \approx 0.37$  in the triangular case, in contrast to  $d/a > 2/3 \approx 0.67$  in the square case. Therefore commensurability peaks are much more sensitive to the aspect ratio.

**Fig. 15** Some examples of diffusive cyclotron orbits contributing to the migration of the guiding center in a triangular lattice. The dashed circles correspond to pinned orbits (the number denotes antidots in the orbit). The measure of the diffusive orbits has a dip around the field corresponding to  $(n_1, n_2) = (2/3, 2/3)$ .

Second, there is a wide gap in the magnetic field between the fundamental peak given by  $a/R_c = 2$  [ $(n_1, n_2) = (\pm 1, 0)$  or  $(0, \pm 1)$ ] and the next peak given by  $a/R_c = 2/\sqrt{3}$  [ $(n_1, n_2) = (\pm 1, \pm 1)$ ]. As shown in Fig. 17, the area of the region corresponding to a guiding center of a cyclotron orbit passing through a pair of nearest-neighbor antidots starts to overlap with that of another pair at a magnetic field given by the condition  $R_c + d/2 = a/\sqrt{3}$ . This leads to a reduction in the measure of the diffusive orbits around  $a/R_c \sim \sqrt{3}$ , giving rise to a small dip in the diffusion coefficient at this magnetic field (see below).

Fig. 18 shows some examples of results of quantum and classical calculations.<sup>[37,53]</sup> The commensurability peaks are rapidly shifted to the lower magnetic field side with increasing  $d/a$ , which is more appreciable in quantum results. In fact, the peak is shifted down to the vanishing magnetic field; therefore only a large

**Fig. 16** Schematic illustration of diffusive orbits giving rise to a fundamental commensurability peak in (A) square and (B) triangular lattices. The orbit starts to be disturbed by other antidots for smaller  $d/a$  in the triangular case.

**Fig. 17** The region (shaded) of the guiding center of cyclotron orbits passing through two nearest-neighbor antidots in a triangular lattice when  $R_c + d/2 \approx a/\sqrt{3}$ .

**Fig. 18** Calculated resistivity and conductivities in triangular antidot lattices. Quantum and classical results are shown by solid and dotted lines, respectively. The peak positions of  $\sigma_{xx}$  (closed and open circles for quantum and classical, respectively) are shown in the inset. The upward arrow indicates a small dip at  $a/R_c = \sqrt{3}$ . Source: From Ref.<sup>[37]</sup>.

negative magnetoresistance can be seen for  $d/a \geq 0.5$ . These results can be well understood in terms of the differences between the square and triangular lattices mentioned above (a weak dip may be identified in the diagonal conductivity at the magnetic field given by  $a/R_c = \sqrt{3}$  for  $d/a = 0.2$ ).

The strong disturbance of diffusive orbits in triangular lattices with a large aspect ratio suggests that the number of events that an electron is scattered by the same antidot is larger than that in square lattices. This means that the electron trajectory is much more complicated in triangular lattices than in square lattices, explaining the reason that the conductivity itself is considerably smaller in triangular lattices and that the amplitude of the Altshuler–Aronov–Spivak oscillation is much larger, as will be discussed in “Altshuler–Aronov–Spivak Oscillation.”<sup>[54,55]</sup> This also explains the similar behavior of the Altshuler–Aronov–Spivak oscillation of the localization length, which was observed experimentally<sup>[56]</sup> and also demonstrated theoretically.<sup>[57,58]</sup>

### ALTSHULER–ARONOV–SPIVAK OSCILLATION

The conductance of a conductor in the form of a hollow cylinder oscillates as a function of the magnetic flux passing through its cross section with a period given by half of the flux quantum  $\Phi_0 = ch/e$ . This oscillation is a result of interference effects and is called the Altshuler–Aronov–Spivak oscillation.<sup>[59]</sup> This oscillation was experimentally observed in cylindrical metal films<sup>[60]</sup> and networks of thin metallic wires<sup>[61]</sup> in the diffusive regime, where the mean free path is much smaller than the sample size or the wire width.

Similar oscillations have been observed also in antidot lattices.<sup>[3–6]</sup> Fig. 19 shows an example.<sup>[6]</sup> The essential features of the experiments can be summarized as follows: 1) the oscillations are observed clearly in triangular lattices but are almost invisible in square lattices;<sup>[5,6]</sup> and 2) the negative magnetoresistance is observed together with the oscillation. In the following, a numerical study<sup>[54,55]</sup> is reviewed briefly.

Real antidot lattices have inherent randomness arising from fabrication processes, in addition to impurities whose strength is characterized by the mean free path  $\Lambda$ . This disorder is introduced through fluctuations in antidot diameters around the mean value  $d$ . The amount of fluctuations is characterized by the root mean square deviation  $d_f$ . The conductance is calculated by Green’s function technique<sup>[62]</sup> for systems with length  $L_x$  and width  $L_y$  containing a finite number of antidots ( $\sim 25$ ).

**Fig. 19** Comparison of the resistivity in a triangular (solid line) and a square (dotted line) antidot lattice observed experimentally. A prominent oscillation with a period determined by  $\Phi_0/2$  appears in the triangular lattice.

Fig. 20 gives calculated conductance of a triangular antidot lattice with  $a/\lambda_F = 4$  in the absence of disorder in the antidot potential. In the ballistic regime  $\Lambda/\lambda_F = 16$ , where  $\Lambda$  is larger than the antidot period, the conductance exhibits an irregular oscillation. This is a consequence of the fact that an irregular oscillation with period  $\Phi_0$  caused by interference

**Fig. 20** Conductance of a triangular antidot lattice with size  $L_x \times L_y$  as a function of magnetic flux passing through a unit cell. Source: From Refs.<sup>[54]</sup> and<sup>[55]</sup>.

effects has a dominant contribution. In fact, both phase and form of the oscillation vary sensitively depending on parameters such as  $d/a$ ,  $a/\lambda_F$ , and  $\beta$ . With the decrease in the mean free path, the amplitude of the irregular oscillation becomes smaller and that of the Altshuer–Aronov–Spivak oscillation characterized by period  $\Phi_0/2$  becomes more and more dominant. In particular, a beautiful oscillation manifests itself in the diffusive regime where  $\Lambda/\lambda_F = 2$  or  $\Lambda/a = 1/2$ .

Similarly, the contribution of the irregular oscillation diminishes with the increase of disorder in the antidot potential, as shown in Fig. 21. The oscillation with period  $\Phi_0/2$  becomes dominant for a disorder as large as  $d_f/a = 0.07$ . Fig. 21 shows that the oscillation is accompanied by a weak negative magnetoresistance, or a slight increase in the conductance as a function of a magnetic field. This is in agreement with one of the features of the experiments discussed above. The amplitude of the oscillations saturates for  $d_f/a > 0.07$ .

In the square lattice, the oscillation has a smaller amplitude than that in the triangular lattice, again in excellent agreement with experiments not shown here explicitly. Note that the conductance of the triangular lattice is much smaller than that of the square

**Fig. 21** Conductance of a triangular antidot lattice in the presence of fluctuations in antidot diameter. Source: From Refs.<sup>[54]</sup> and<sup>[55]</sup>.

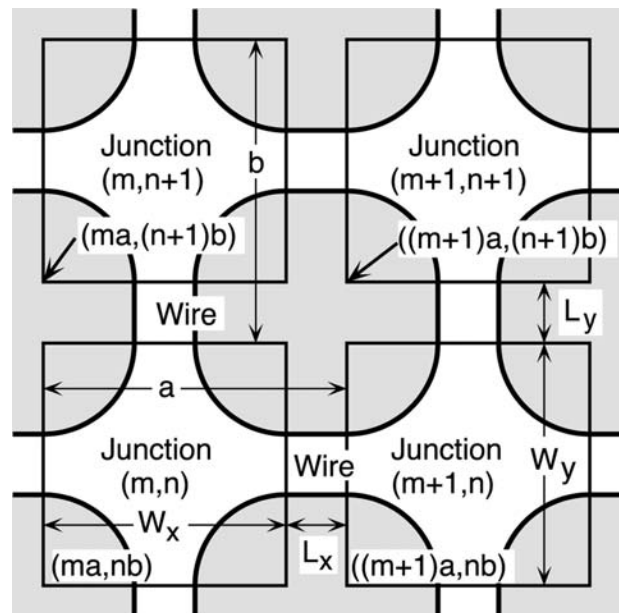

lattice. Electrons perform more complicated motion and stay longer in the triangular lattice than in the square lattice.<sup>[5,6]</sup> This is presumably the main origin of the enhancement of oscillation in the triangular lattice, as has been discussed in “Triangular Antidot Lattices.”

## SCATTERING MATRIX FORMALISM

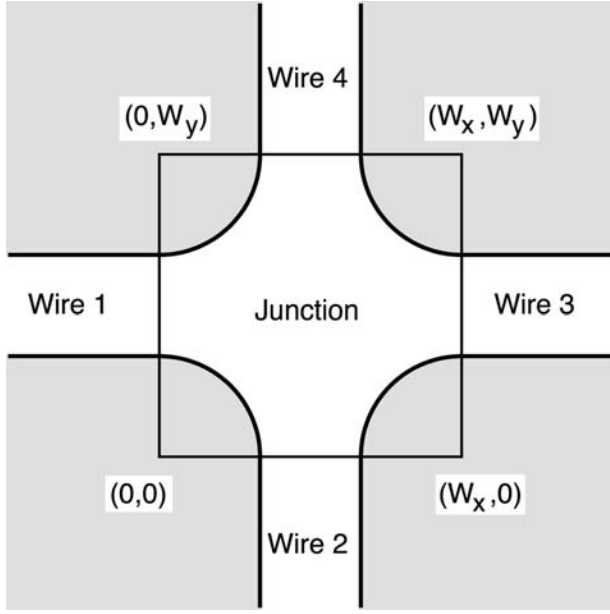

### Quantum Wire Junction

Difficulties of quantum mechanical calculations of energy levels and transport coefficients in antidot lattices lie in the fact that we have to consider a magnetic unit cell that can become very large, depending on the magnetic flux passing through a unit cell. In this section, a new method of full quantum calculations of energy bands and transport quantities<sup>[63,64]</sup> is reviewed.

We shall replace an antidot lattice by a 2-D array of quantum wire junctions with width  $W_x$  in the  $x$  direction and  $W_y$  in the  $y$  direction, as illustrated in Fig. 22. Each junction is connected to neighboring junctions through a quantum wire with length  $L_x$  and  $L_y$  in the  $x$  and  $y$  directions, respectively. The lattice period in the  $x$  direction is  $a$  and that in the  $y$  direction is  $b$ . For the calculation of an  $S$  matrix, we consider the model shown in Fig. 23. We divide this system into five regions (i.e., four wires and a junction).

**Fig. 22** Two-dimensional array of quantum wire junctions.

**Fig. 23** A quantum wire junction for calculation of an  $S$  matrix.

The vector potential is chosen as  $\mathbf{A} = (-By, 0)$ . The modes in wires 1–4 are given by:

$$\begin{aligned}
 \psi_{1\nu}^{\pm}(x, y) &= (v_{\nu}^x)^{-1/2} \eta_{\nu\pm}(y) \exp[i(\pm\kappa_{\nu}^x + W_y/2l^2) \\
 &\quad \times (x + L_x/2)] \\
 \psi_{2\nu}^{\pm}(x, y) &= (v_{\nu}^y)^{-1/2} \xi_{\nu\pm}(x) \exp(-ixy/l^2) \\
 &\quad \times \exp[i(\pm\kappa_{\nu}^y - W_x/2l^2)(y + L_y/2)] \\
 \psi_{3\nu}^{\pm}(x, y) &= (v_{\nu}^x)^{-1/2} \eta_{\nu\pm}(y) \exp[i(\pm\kappa_{\nu}^x + W_y/2l^2) \\
 &\quad \times (x - W_x - L_x/2)] \\
 \psi_{4\nu}^{\pm}(x, y) &= (v_{\nu}^y)^{-1/2} \xi_{\nu\pm}(x) \exp(-ixy/l^2) \\
 &\quad \times \exp[i(\pm\kappa_{\nu}^y - W_x/2l^2) \\
 &\quad \times (y - W_y - L_y/2)] \quad (8)
 \end{aligned}$$

where  $l = \sqrt{eB/\hbar c}$  is the magnetic length,  $\nu$  denotes modes,  $v_{\nu}$  corresponds to velocities,  $\eta(y)$  is an eigenfunction for a wire in the  $x$  direction, and  $\xi(x)$  is that for a wire in the  $y$  direction for the vector potential  $\mathbf{A} = (0, Bx)$ .

There are two kinds of modes. One of them is a traveling mode whose wave number  $\kappa$  is real and the other is an evanescent mode whose wave number has an imaginary part. The sign  $+(-)$  denotes a mode traveling or decaying in the positive (negative) direction. The wave function in a wire region is represented using expansion coefficients  $C$  with respect to modes in the wires:

$$\Psi_i(x, y) = \sum_{\nu} [C_{i\nu}^+ \psi_{i\nu}^+(x, y) + C_{i\nu}^- \psi_{i\nu}^-(x, y)] \quad (9)$$

The  $S$  matrix gives the following relation between incoming and outgoing waves:

$$\begin{pmatrix} C_1^- \\ C_2^- \\ C_3^+ \\ C_4^+ \end{pmatrix} = \mathbf{S}(E) \begin{pmatrix} C_1^+ \\ C_2^+ \\ C_3^- \\ C_4^- \end{pmatrix} \quad (10)$$

where  $\mathbf{C}$  consists of expansion coefficients  $C$ ; therefore its dimension is the number of modes.

### Energy Bands and Density of States

We can calculate the energy bands of an infinitely large array of junctions using Bloch's theorem. In the following, we confine ourselves to the case in the absence of the magnetic field for simplicity. The extension to the case in magnetic fields is discussed in Ref.<sup>[64]</sup>. The Bloch condition for  $\Psi_i(x, y)$  gives the conditions for expansion coefficients  $C_{1\nu} = \exp(-ik_x a) C_{3\nu}$  and  $C_{2\nu} = \exp(-ik_y b) C_{4\nu}$ . These are rewritten as the following relation between incoming and outgoing waves:

$$\begin{pmatrix} C_1^- \\ C_2^- \\ C_3^+ \\ C_4^+ \end{pmatrix} = P(k_x, k_y) \begin{pmatrix} C_1^+ \\ C_2^+ \\ C_3^- \\ C_4^- \end{pmatrix} \quad (11)$$

where:

$$P(k_x, k_y) = \begin{pmatrix} 0 & 0 & P_x^{-1} & 0 \\ 0 & 0 & 0 & P_y^{-1} \\ P_x & 0 & 0 & 0 \\ 0 & P_y & 0 & 0 \end{pmatrix} \quad (12)$$

with  $P_x = \exp(ik_x a)$  and  $P_y = \exp(ik_y b)$ . Energy bands are given with the condition that Eqs. (10) and (11) have non-trivial solutions for  $\mathbf{C}$ :

$$\det[P(k_x, k_y) - \mathbf{S}(E)] = 0 \quad (13)$$

This equation gives energy bands as equi-energy lines in the  $\mathbf{k}$  space at the energy  $E$ .

**Fig. 24** shows some examples of calculated energy bands for a square lattice ( $b = a$ ). The parameters are  $a/\lambda_F = 4.31$ ,  $U_0/E_F = 8.4$ ,  $d/a = 0.6$ , and  $\beta = 2$  (this choice of  $\beta$  is likely to be too large for realistic antidots). The corresponding equipotential lines are given in **Fig. 13**. The magnetic field  $Ba^2/\Phi_0 = 4$  corresponds to about 0.4 T for a typical antidot lattice with  $a \sim 2000 \text{ \AA}$ . The bands are calculated by including all traveling modes and a single evanescent mode having the smallest imaginary wave vector. The horizontal dotted lines denote the bottom of one-dimensional subbands in the wire region.

**Fig. 24** Calculated energy bands in a magnetic field  $Ba^2/\Phi_0 = 4$ . In the  $S$  matrix method, all traveling modes and only a single evanescent mode are taken into account. *Source:* From Ref.<sup>[64]</sup>.

The results using the  $S$  matrix formalism with only a single evanescent mode agree quite well with the exact results in which all the evanescent modes are included. This shows that the inclusion of a few evanescent modes is sufficient for an accurate description of energy bands of antidot lattices. The bands for  $Ba^2/\Phi_0 = 4$  corresponding to  $2R_c/a \sim 2$  may be regarded as a mixture of a band with a large dispersion (run-away orbit) and those having a small dispersion for  $0.4 \lesssim E/E_F \lesssim 1.0$ .<sup>[32]</sup> The energy bands become more complicated for higher energies.

Fig. 25 shows the corresponding energy dependence of the density of states and the conductivity calculated using the Boltzmann transport equation. The density of states is measured in units of the 2-D value  $m^*/\pi\hbar^2$  and the conductivity in units of  $ne^2\tau/m^*$ , where  $n$  is the electron concentration in the absence of the antidot potential and  $m^*$  is the effective mass. They are averaged over the Gaussian distribution with broadening  $\Gamma/E_F = 0.02$ . Some structures of the conductivity

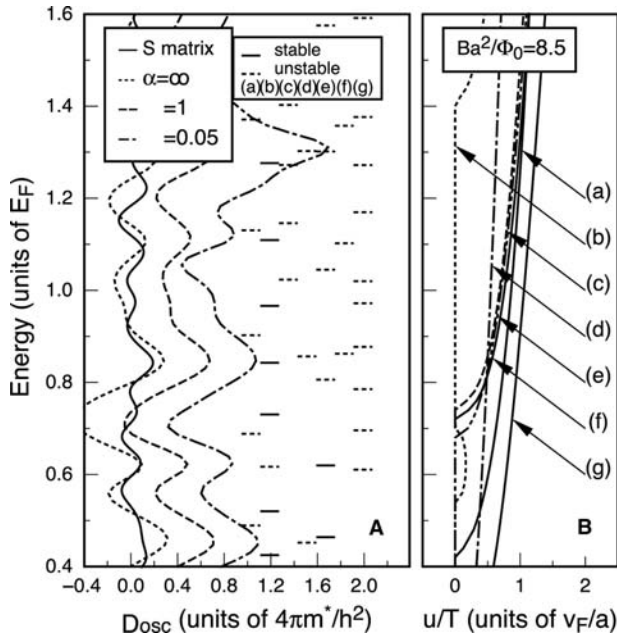

**Fig. 25** The energy dependence of the density of states (solid line) and conductivity (dotted line) in the magnetic field  $Ba^2/\Phi_0 = 4$ . *Source:* From Ref.<sup>[64]</sup>.

correspond to those of the density of states, but most of them do not.

A semiclassical analysis has been made for the density of states by considering six periodic orbits (a)–(f) given in Fig. 13.<sup>[49,64,65]</sup> As a cutoff of a quantum number  $m$  in Eq. (5), the factor  $\exp(-\alpha m)$  has been introduced, where  $m$  is the quantum number for a motion transverse to each periodic orbit. Fig. 26 shows some examples in the magnetic field corresponding to  $Ba^2/\Phi_0 = 8.5$ , where the condition of the fundamental commensurability peak is nearly satisfied (i.e.,  $2R_c \sim a$  at the Fermi level).

The orbit (a) is stable in the energy region  $E/E_F \leq 0.43$ , the orbit (b) in  $0.72 \leq E/E_F \leq 1.41$  and  $E/E_F \leq 0.52$ , the orbit (c) in  $0.7 \leq E/E_F \leq 0.74$ , and the orbit (e)  $E/E_F \leq 0.68$ . Orbit (c) merges into orbit (b) and disappears at  $E/E_F = 0.7$ . The quantized levels associated with such stable orbits give clear peaks in the semiclassical density of states, many of which are in agreement with those of the

**Fig. 26** (A) The oscillatory part of the density of states at  $Ba^2/\Phi_0 = 8.5$  corresponding to  $2R_c/a \approx 2$ . The dashed line is shifted to the right by 0.4 and the dot-dashed line is shifted by 0.8. (B) The corresponding Lyapunov exponents. *Source:* From Ref.<sup>[49]</sup>.

**Fig. 27** Schematic illustration of a finite antidot lattice for which the numerical calculation is performed. It has eight sites in the direction of the wire width and 16 sites in the direction of the wire length.

quantum-mechanical density of states. Particularly, near the Fermi energy, the orbit (b) circling around an antidot gives a major contribution in agreement with the analysis mentioned in “Aharonov–Bohm-Type Oscillation.” Inclusion of higher transverse modes does not considerably affect the structures of the semiclassical density of states. However, peaks at  $E/E_F = 0.97$  and 1.1, which roughly correspond to peaks of quantum-mechanical density of states, are shifted to the higher-energy side including higher transverse modes and the agreement becomes worse. A more elaborate work in which many periodic orbits are taken into account is necessary for a full understanding of the correspondence between the quantum-mechanical and semiclassical results for the density of states.

**Aharonov–Bohm Oscillation**

To calculate transport quantities, we take a quantum wire junction array as a model of an antidot lattice, as shown in Fig. 27.<sup>[39]</sup> This is a kind of four-terminal system where constrictions at edges are connected, respectively, to four reservoirs through ideal leads. Transport coefficients are calculated based on the Büttiker–Landauer formula<sup>[66–68]</sup> from an *S* matrix for a junction array obtained by connecting *S* matrices for a single junction.

**Fig. 28** Diagonal resistance as a function of the magnetic field for  $d/a = 0.6$  and the mean free path  $\Lambda/\pi a = 2$ . *Source:* From Ref.<sup>[65]</sup>.

Amphiphilic  
– Axle

In the following, square antidot lattices are considered and parameters are chosen as  $d/a = 0.5$ . The parameter  $\Delta$  for the model potential given by Eq. (3) characterizing the steepness of the potential is chosen as  $\Delta/a = 0.24$ . This model potential becomes close to that given by Eq. (1) for  $\beta = 1$  and  $d/a \sim 0.5$ . Effects of impurities are introduced through random short-range scatterers, and fluctuations in the diameter of antidots are also introduced.

First, we consider the commensurability peak and the superimposed Aharonov–Bohm oscillation. Fig. 28 shows the dependence of the calculated magnetoresistance on the Fermi wavelength  $\lambda_F$  for the mean free path  $\Lambda/\pi a = 2$  in the absence of the antidot disorder.<sup>[65]</sup> The Aharonov–Bohm-type oscillation is clearly seen to be superimposed on the commensurability peak. The vertical solid and dashed lines indicate semiclassical quantized levels of the stable and unstable periodic orbits, respectively, encircling a dot, which are calculated based on Eq. (7). The Aharonov–Bohm-type oscillation varies with the Fermi

energy in a somewhat irregular manner, but is correlated quite well with semiclassical levels.

For the model potential (Eq. (3)), the periodic orbit encircling an antidot is quite sensitive to the aspect ratio  $d/a$  and disappears when  $d/a$  exceeds a critical value depending on the magnetic field. Fig. 29 shows the boundary of the existence of the periodic orbit encircling an antidot for a model potential given by Eq. (3).<sup>[69]</sup> The insets in the right-hand side of the figure show the periodic orbit (solid line) for  $d/a = 0.6$  and  $0.677$ . With the increase of  $d/a$ , it merges into another orbit (dotted line), which is unstable and has a longer trajectory, and disappears. It contains the boundary in the case of  $\Delta/a = 0.18$  and  $0.36$  as well. The critical aspect ratio becomes smaller with the increase of  $\Delta/a$  (i.e., as the antidot potential becomes broader).

Fig. 30 shows the calculated results of magnetoresistance for various values of the aspect ratio in the case of dominant impurity scattering.<sup>[69]</sup> The Aharonov–Bohm-type oscillation changes as a function of the magnetic field in an irregular manner, but the

**Fig. 29** Critical values of the aspect ratio at which the periodic orbit encircling an antidot disappears.  $\Delta/a = 0.18$  (solid line),  $0.24$  (dotted line, realistic), and  $0.36$  (dashed line). The right upper and lower insets show the periodic orbit (solid line) giving the Aharonov–Bohm-type oscillation and the other (dotted line) that is unstable. These orbits merge and disappear when the aspect ratio approaches a critical value. *Source:* From Ref.<sup>[69]</sup>.

**Fig. 30** Calculated resistance as a function of the total flux  $\Phi$  passing through a unit cell divided by the flux quantum  $\Phi_0$  for varying Fermi wavelengths. Short vertical lines represent semiclassically quantized energy levels associated with the periodic orbit encircling an antidot (solid and dotted lines for stable and unstable orbits, respectively). *Source:* From Ref.<sup>[69]</sup>.

dependence on the field is, on the whole, in good agreement with that of the position of quantized levels of the periodic orbit. The oscillation disappears or becomes unrecognizable near the field corresponding to  $2R_c = a$  for a large aspect ratio  $d/a = 0.7$ . This field corresponds to the disappearance of the periodic orbit. In fact, the periodic orbit is absent in the hatched region, where no clear Aharonov–Bohm-type oscillation is visible. This provides a clear evidence that the Aharonov–Bohm-type oscillation is caused by the specific periodic orbit (b) in Fig. 13 encircling an antidot.

Fig. 31 shows the resistivity for the mean free path  $\Lambda/\pi a = 2$  in the absence of the antidot disorder at several values of  $d/a$  and  $a/\lambda_F$ .<sup>[70]</sup> Both commensurability peak and Aharonov–Bohm-type oscillation vary in an irregular manner with the change in the Fermi energy and the aspect ratio. This can be understood in terms of the anomalous behavior of the Hall conductivity because of the complicated band mixing, as mentioned in “Commensurability Peaks.”

Fig. 32 shows the resistivity in the presence of disorder  $d_f/a = 0.07$  in the antidot diameter without

impurities.<sup>[70]</sup> The irregular dependence of the commensurability peak and the Aharonov–Bohm-type oscillation on the Fermi energy and the aspect ratio has disappeared completely. In particular, the resistivity shows a smooth Aharonov–Bohm-type oscillation much closer to experiments. This suggests that such a band structure is destroyed almost completely by the presence of the antidot disorder.

Many periodic orbits can contribute to the Aharonov–Bohm-type oscillation in ideal antidot lattices. In the presence of disorder in the antidot potential, the shortest orbit encircling a single antidot is expected to be less influenced and its quantized energy levels can survive, whereas those of other orbits are strongly disturbed and smeared out. In other words, the antidot disorder tends to enhance the contribution of the energy levels of this orbit relative to those of other orbits. This explains the fact that the Aharonov–Bohm-type oscillation is sensitive to the Fermi energy for impurity scattering but not for scattering from antidot disorder.

The present formalism is quite effective in the study of insulator–quantum Hall transition and the localization oscillation observed experimentally.<sup>[56]</sup> In fact, a numerical study demonstrated the presence of quantum oscillations of the localization length with periods of  $\Phi_0/2$  and  $\Phi_0$ , and also an insulator–quantum Hall

**Fig. 31** Calculated magnetoresistance in the case of dominant impurity scattering. The arrows indicate the field corresponding to  $2R_c/a = 1$ . transition point where the Fermi level crosses extended states.<sup>[71]</sup> It showed also that extended states float in energy and disappear at a critical magnetic field. This problem is outside the scope of this entry; therefore this will not be discussed further.

## CONCLUSION

A review of magnetotransport in antidot lattices has been given mainly from a theoretical point of view. The commensurability peaks appearing in magnetoresistivity can be understood in terms of an enhancement in the measure of diffusive orbits contributing to the diffusion coefficients caused by a magnetic focusing effect. Differences existing between square and triangular lattices and roles of quantum effects have been understood by the same mechanism. It has also been shown that realistic antidot lattices have a large amount of disorder in the potential, which accounts for the appearance of the Altshuler–Aronov–Spivak oscillation and manifests itself in the commensurability peak and the superimposed Aharonov–Bohm-type oscillation. The disorder in the antidot potential also gives rise to localization of electron wave functions oscillating as a function of a magnetic field and the insulator–quantum Hall transition in high magnetic fields.

# Atmospheric Nanoparticles: Formation and Physicochemical Properties

James N. Smith

Atmospheric Chemistry Division, National Center for Atmospheric Research,  
Boulder, Colorado, U.S.A.

## INTRODUCTION

Atmospheric nanoparticles, defined as particles with spherical equivalent diameters smaller than 50 nm, are either directly emitted from combustion sources, or are formed in the atmosphere by a process called nucleation. They then quickly grow by the condensation of gas monomers or clusters, or by coagulation with other particles, to become a critical participant in a number of important atmospheric processes such as heterogeneous chemistry, cloud formation, precipitation, and the scatter and absorption of solar radiation. An understanding of nanoparticles has increased dramatically in recent years because of significant advances in instrumentation to detect, size, and determined their chemical composition. Recent observations now show us that atmospheric nanoparticles are ubiquitous: Measurements carried out in city centers, isolated islands and forests, and the remote troposphere have never failed to encounter periods characterized by concentrations of up to  $10^6$  nanoparticles/cm<sup>3</sup>. Theoretical advances in nucleation and growth, at present, have not made the same sort of progress as observation, but this is an area of rapid progress.

The goal of this entry is to provide an overview of the role that nanoparticles play in the atmosphere, the observational and theoretical tools currently being employed in their study, and recent observations that continue to direct progress in understanding their formation and fate. Although much is known about these transient particles, researchers appear to be at the cusp of huge scientific advances that will make it possible to predict their formation and behavior in the atmosphere.

## BACKGROUND

Excellent texts are available on the subject of atmospheric particulate matter,<sup>[1,2]</sup> which is commonly referred to as atmospheric aerosol. These texts are also adequate references on atmospheric nanoparticles; however, recently, a review chapter<sup>[3]</sup> and a special

journal issue<sup>[4]</sup> have focused specifically on this area. The goal of this section is to provide a broad overview of the distribution, sources, and lifetimes of atmospheric aerosol. This is followed by a review of relevant atmospheric process involving nanoparticles.

## Atmospheric Particle Size Distributions

Close to the Earth's surface, continental air typically contains from  $10^3$  to  $10^5$  particles/cm<sup>3</sup>. These particles have spherical equivalent diameters  $d_p$  ranging from 1 nm to 100  $\mu$ m. A plot of particle number concentration, surface area, or volume *vs.*  $d_p$ , such as those shown in Fig. 1 for typical rural settings, usually shows that these particles are distributed over three or more modes. Most particles are smaller than 100 nm in diameter (Fig. 1A), in a mode referred to as the Aitken mode. The term *ultrafine aerosol* is often used for those with diameters smaller than 100 nm. The other two predominant modes are the accumulation mode ( $0.1 < d_p < 2.5 \mu$ m) and the coarse mode ( $d_p > 2.5 \mu$ m). Within the Aitken mode, for  $d_p < 50$  nm, many properties of the condensed phase, most notably vapor pressure, become quite different from those of the bulk phase: Thus particles smaller than 50 nm have come to be known as nanoparticles. The implications of the distributions in Fig. 1 on atmospheric processes can be generalized as follows: For phenomena that depend on the particle number concentration, it is the Aitken mode that contributes the most; for those processes that are surface area dependent, the accumulation mode is most influential; for those that depend on total aerosol volume or mass, the coarse mode dominates.

## Atmospheric Particle Sources and Sinks

The different modes in aerosol size distribution reflect differences in the atmospheric sources, transformations, and sinks Fig. 2. Particles in the coarse mode are generated by mechanical processes such as wind and friction. The accumulation mode contains particles that have grown in the atmosphere by condensation

**Fig. 1** Particle (A) number, (B) surface area, and (C) volume distributions for typical rural conditions, generated using the parameterization of Jaenicke.<sup>[6]</sup>

of gases, or coagulation with other particles. The Aitken mode contains particles that are generated chemically, either directly emitted from a source (primary aerosol) or are created or grown from gas phase reactions in the atmosphere (secondary aerosol). The dominant loss mechanisms for Aitken mode particles are coagulation and condensation growth. Particles in the accumulation mode leave the atmosphere by adhering onto wetted surfaces, most commonly rain and cloud drops, through a process called wet deposition. Coarse mode particles eventually settle to the ground in a process called dry deposition. Fig. 3 shows the typical timescales for these removal processes. Dry deposition, coagulation, and condensational growth are relatively rapid processes, whereas wet deposition is the least efficient means of particle removal. The result is that particles in the accumulation mode are the longest-lived particles, having lifetimes that may span several days. Therefore these particles are commonly spatially homogeneous, and number distributions in this size range do not change rapidly with time. In contrast, Aitken mode particles have lifetimes of a few minutes to an hour. Therefore these particles commonly exist close to their source (e.g., near busy freeways) and their number distributions usually change rapidly with time.

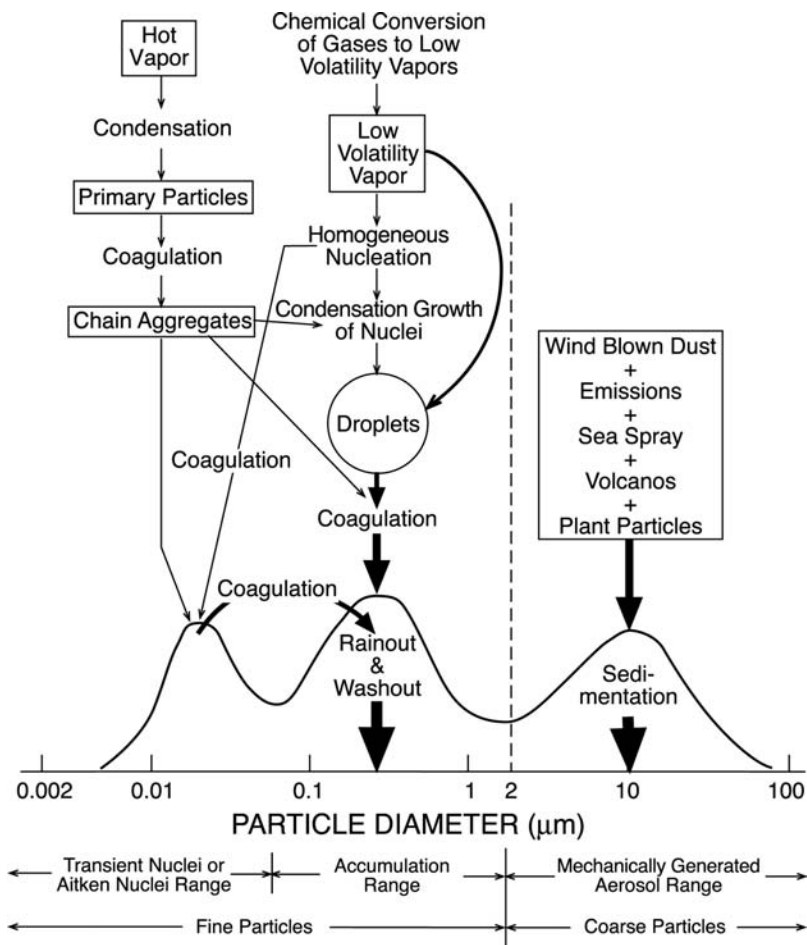

## Nanoparticles in the Atmosphere

Nanoparticles, as a subset of the Aitken mode, are generated chemically either as primary emissions or through gas phase reactions in the atmosphere. The latter process is, in fact, nucleation and will be the focus of much of the discussion that follows. It is also true that nanoparticles are some of the most transient in the atmosphere, with a corresponding heterogeneous spatial distribution that depends on source distribution and meteorological conditions. Additionally nanoparticles may frequently dominate an aerosol number distribution, but usually not distributions of surface area and almost never of volume (Fig. 1). In view of these observations, it is reasonable to ask if nanoparticles play an important role in atmospheric processes, outside of their crucial role as the primary source of new particles. A question of equal importance, although outside the scope of this article, is whether atmospheric nanoparticles play a deleterious role in human health through respiration. The answer to this question is a qualitative “yes,” although the mechanism and magnitude of this effect are far from clear.<sup>[3,8,9]</sup>

The contribution of nanoparticles to scattering and absorption of solar radiation, which controls processes such as visibility reduction and climate, is understood to be negligible.<sup>[2]</sup> This is because of the low efficiency with which nanoparticles interact with solar radiation.<sup>[10]</sup> Perhaps the most important contribution of nanoparticles on climate is to influence the optical properties, abundance, and persistence of clouds.<sup>[11]</sup> An abundance of new particles could increase the number of cloud condensation nuclei (CCN), which are water-soluble aerosols on which water vapor condenses to form cloud droplets. The overall result of this so-called “indirect effect of aerosols on climate” is an issue of active research and debate, but is generally thought to be a reduction in incoming solar radiation.<sup>[11]</sup>

At the time of this writing, very little is known about whether nanoparticles may play a unique role in the chemistry of the atmosphere. It is certainly true that chemical reactions occur on atmospheric nanoparticles, just as they occur on all aerosol;<sup>[1]</sup> however, in most circumstances, the minimal contribution of nanoparticles to overall aerosol surface area (e.g., Fig. 1B) decreases the likelihood that these particles may influence the chemistry of the gas phase. The exception to this may be during “nucleation bursts,” which are periods of intense new particle production that can dominate the surface area distribution.<sup>[12]</sup> Although it may be true that the concentrations of certain reactive compounds may be enhanced in nanoparticles through the processes of nucleation and condensational growth, a simple analysis has

**Fig. 2** Schematic of the distribution of particle surface area in the atmosphere. Modes, sources, and sinks are indicated. *Source:* From Ref.<sup>[7]</sup>. ©IEEE, 2003.

shown that, even during nucleation burst periods, this enhancement would need to be a factor of  $10^6$  greater than reactant concentrations in typical cloud droplets to have a similar effect.<sup>[3]</sup>

**Fig. 3** Residence time of particles in the lower 1.5 km of the atmosphere as a function of particle radius, generated using data from Jaenicke.<sup>[19]</sup> Also shown are approximate size ranges for predominant removal mechanisms.

### OBSERVATIONS OF ATMOSPHERIC NANOPARTICLE PHYSICOCHEMICAL PROPERTIES

Most of the important advances in our understanding of atmospheric nanoparticles have resulted from dramatic improvements in instrumentation for characterizing their size, number, and composition. As we will see later, these observations have challenged our theoretical understanding of both aerosol nucleation and growth. This section will provide an overview of these instruments, and some representative measurements.

#### Physical Characterization

Advances in the physical characterization of atmospheric nanoparticles now allow us to size and detect them when they are less than an hour old, corresponding to diameters of about 3 nm. It is now possible to characterize nanoparticle growth rates; thus we can start to make links between the presence of these nanoparticles and the variety of phenomena that they

**Fig. 4** (A) Particle size distribution vs. local time for a nucleation event in St. Louis, MO. (B) Number mean diameter vs. local time for distributions in (A), showing a linear nanoparticle growth rate. *Source:* From Ref.<sup>[60]</sup> Courtesy of Q. Shi, University of Minnesota.

control. The current section briefly summarizes these physical characterization techniques.

The condensation nucleus counter (CNC)<sup>[13]</sup> can detect particles as small as 3 nm in diameter.<sup>[14]</sup> It accomplishes this by flowing the sample air first through a region that is saturated with a condensing vapor, usually *n*-butanol, and then through a cooled region. The gas then becomes supersaturated with the vapor, which causes the particles to grow to a size that can be detected by light scattering. The minimum detectable particle size is a function of vapor supersaturation; thus two CNCs with different supersaturations (or different transmission characteristics) can be operated in parallel and, by subtracting their readings, can be used to determine the concentration of particles within a certain size range. This subtraction technique is the most frequently used way of observing atmospheric nanoparticles.<sup>[15]</sup> Recent advances have been reported in the development of particle size magnifiers,<sup>[16]</sup> which are similar to CNCs but are being developed with the goal of detecting particles at diameters of 1 nm and below.

Size classification of nanoparticles is now possible using a number of techniques. The differential mobility analyzer (DMA)<sup>[17]</sup> is an “electrical mobility classifier” device that can size-classify particles down to 3 nm in diameter.<sup>[18]</sup> It does this by charging particles and passing them through a region where a sheath gas and an electric field are combined in such a way that only particles of a certain surface area-to-charge ratio can pass through the exit aperture. These instruments are commonly combined with CNCs to obtain nanoparticle size distributions. Fig. 4A shows an example of a continuous record of particle size distributions

from an urban site (St. Louis, MO), which features a new particle formation event that reached detectable levels at 8:00 A.M. Subsequent growth of the mean diameter of the spectrum is quite linear (Fig. 4B). This can be equated with aerosol growth if one assumes that the aerosol was homogeneous in a large-scale air mass.

Two additional methods for obtaining nanoparticle size distributions are the pulse height analysis (PHA) and the ion mobility spectrometer (IMS) techniques. PHA<sup>[20]</sup> operates on the principle that particles smaller than 10 nm grow by condensation in the CNC to reach a unique final diameter, which can be sized by optical techniques. The IMS can measure the size spectra of charged nanoparticles down to diameters below 1 nm, by measuring their drift velocity in a constant electric field.<sup>[21]</sup> IMS measurements have shown that, under certain conditions, nanoparticle formation is correlated with bursts of atmospheric ion clusters.<sup>[21]</sup>

### Chemical Composition

Until recently, the chemical characterization of atmospheric nanoparticles has not seen the same sort of progress as physical characterization. However, currently, several techniques have been developed for obtaining chemical composition information by: 1) indirectly inferring it by measuring some other behavior; 2) using off-line collection and analysis techniques; 3) using on-line real-time mass spectrometry-based techniques. In this section, these various methods will be briefly described.

Some of the earliest measurements of the chemical properties of nanoparticles were performed by using

a DMA to size-select particles, then exposing these particles to a controlled environment and acquiring a particle size distribution on the result to observe any changes in aerosol size.<sup>[22]</sup> Most of these instruments, called tandem differential mobility analyzers (TDMAs), expose size-selected particles to high humidity to investigate their hygroscopic properties, but others characterize volatility by applying high temperatures<sup>[23]</sup> or organic composition by using a gas saturated with various organic vapors.<sup>[24]</sup> In a related application, the growth characteristics of aerosol in a CNC have been investigated using the PHA technique, which was used to infer that nanoparticles in a boreal forest region were composed primarily of organic acids.<sup>[25]</sup>

Off-line sampling techniques involve collecting particles on a substrate, often in a size-segregated manner, for later chemical analysis. Such analysis might involve extraction of the constituents from the substrate and analysis of the integrated composition by techniques such as ion chromatography and inductively coupled plasma mass spectrometry (ICP-MS), illuminating the substrate with a light source to investigate optical absorption, or the study of isolated particles on the substrate by microanalytical techniques such as secondary ion mass spectrometry (SIMS) and Fourier transform infrared spectroscopy (FTIR).<sup>[26]</sup> The application of off-line techniques to nanoparticle composition is challenged by an inability to collect sufficient mass of these particles; nonetheless, most of what is known about the composition of the smallest particles in the atmosphere is derived from off-line techniques. Low-pressure impactors are often employed for collecting size-segregated ultrafine particles,<sup>[27–30]</sup> but these devices do not usually extend into the sub-50 nm diameter range. Observations of ultrafine urban aerosol from low-pressure impactors show particles to be composed of 50–70% (by weight) organic compounds and 6–14% (by weight) of each of the following: elemental carbon, sulfate, nitrate, and trace metals.<sup>[27,28]</sup> Recently, a particle concentrator that allows the collection of particles as small as 10 nm in diameter, requiring integration times of 3 hr or more, has been described.<sup>[31]</sup> That study found a distinct mode in the 36–50-nm diameter range, affected primarily by combustion processes; however, correlations between elemental and organic carbon compositions also suggested that these particles contained secondary organic compounds.<sup>[31]</sup> Dimethylamine has been identified by the chemical analysis of newly formed particles collected in a low-pressure impactor in a boreal forest.<sup>[30]</sup> One recent example of the use of off-line microanalytical techniques has been reported in the study of recently formed particles in a coastal setting. That study observed both iodine and sulfur in particles with diameters below 10 nm,<sup>[32]</sup> suggesting

that biogenic iodine species emitted from seaweeds may be responsible for new particle formation or growth.

On-line chemical analysis techniques directly analyze particles in real time, usually by vaporizing particles through lasers or heated surfaces, ionizing the resulting gas, and injecting the ions into a mass spectrometer for analysis.<sup>[33]</sup> These techniques are highly desirable for the study of nanoparticle composition, as they have capabilities of both high sensitivity and short sampling times. Most current on-line techniques rely on improving the nanoparticle sampling efficiency of existing instruments (e.g., Phares, Rhoads, and Wexler.)<sup>[34]</sup> This has been accomplished primarily by the use of aerodynamic focusing lens systems<sup>[35]</sup> whose transmission efficiency degrades significantly for particle diameters smaller than 20 nm. Most of these instruments are very new—field measurements have only just started; therefore very little published data are available. One example of published results comes from the 1999 Atlanta Southern Oxidant Study, which found that particles as small as 14 nm are almost completely organic.<sup>[36]</sup> The authors point out the ability to analyze nanoparticles is based, to some degree, on particle composition. For example, sulfate was not identified in any particles with their instrument, whereas other measurements during the same field campaign identified sulfate as a major constituent.<sup>[37]</sup>

New instruments that have been designed specifically for the on-line characterization of nanoparticles

**Fig. 5** Measurements of the chemical composition of sub-20 nm diameter aerosol performed outside of the author's laboratory in Boulder, CO, on June 6, 2002. (A) Ammonium ion concentration, normalized by collected aerosol volume (left axis) and as the ratio to the ion signal from an equivalent volume of ammonium sulfate aerosol. (B) Integrated volume-normalized concentration of ions with molecular weight greater than 65 amu.

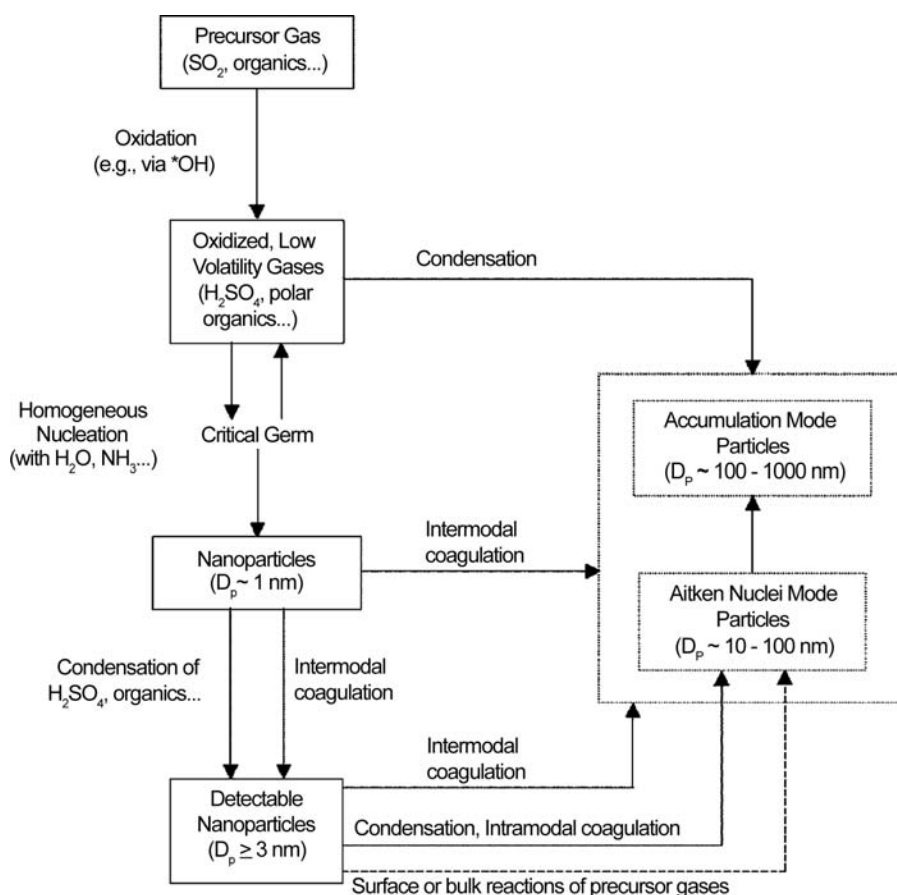

have also been introduced. Most of these new devices are limited to obtaining atomic, rather than molecular, composition of the aerosol, and usually employ high-power lasers<sup>[38]</sup> and plasmas<sup>[39]</sup> to desorb and ionize aerosols smaller than 20 nm in diameter. The author has recently reported the development of the thermal desorption chemical ionization mass spectrometer (TDCIMS), an instrument capable of on-line measurements of the molecular composition of nanoparticles as small as 5 nm in diameter at time resolutions of ca. 20 min.<sup>[40,41]</sup> The TDCIMS operates by charging and then collecting nanoparticles on a metal filament, then resistively heating the filament and analyzing the desorbed gas by chemical ionization mass spectrometry (CIMS). Fig. 5 shows an example of continuous TDCIMS measurements of sub-20-nm-diameter aerosols performed outside our laboratories in Boulder, CO, in the spring of 2002. The major ion observed is ammonium (Fig. 5A); however, the integrated concentration of ions larger than 65 amu varies greatly during the day (Fig. 5B). The TDCIMS has also performed measurements of the composition of freshly nucleated particles at the 2002 Aerosol Nucleation and Real-time Characterization Experiment (ANARChE) in Atlanta, GA. Preliminary results from that experiment suggest that freshly nucleated

aerosols in Atlanta are composed almost entirely of sulfate with variable degrees of neutralization by ammonium.<sup>[42]</sup>

## ATMOSPHERIC NANOPARTICLE FORMATION AND GROWTH: MODELS AND OBSERVATIONS

Given the current understanding of the atmospheric impact of nanoparticles, it is clear that the ability to predict the physicochemical properties of nanoparticles requires equal effort placed on understanding the growth of nanoparticles and their formation. Because instruments are, thus far, unable to directly observe newly formed aerosol in the atmosphere, the interpretation of observations of nucleation also requires an understanding of the mechanism and dynamics of condensational growth. The goal of the present section is to review the current theoretical basis for nucleation and growth.

Fig. 6 shows a schematic of the formation and growth of atmospheric nanoparticles. The primary formation process is homogeneous nucleation, which is defined as the formation of thermodynamically stable particles from the condensation of gaseous precursors. Primary sources, such as diesel

**Fig. 6** Schematic of nucleation and growth processes. *Source:* From Ref.<sup>[3]</sup>. Mineralogical Society of America.

engines,<sup>[43,44]</sup> can be significant sources of nanoparticles in urban settings but will not be discussed in this entry. Heterogeneous nucleation, defined as condensation of gases on foreign media such as gas phase ions, might also lead to the formation of atmospheric nanoparticles. It is important to note that, in the atmosphere, homogeneous nucleation is in competition with scavenging of the low-volatility gas by preexisting aerosol. Because of this, new particle formation in the atmosphere tends to occur in bursts (Fig. 4), either when the total aerosol surface area is suddenly dropped, or when a sudden meteorological or chemical change modifies the concentration of condensable vapor.

### Condensational Growth

One of the most unique properties of nanoparticles involves their evaporation and condensation behavior. As the curvature of a particle surface decreases, the separation between adjacent surface molecules increases leading to an overall decrease in the attractive forces between them. The result of this is that, at equilibrium, the partial pressure surrounding the curved surface will exceed the saturation vapor pressure for the flat surface. The equation that describes this effect is known as the Kelvin, or Thomson–Gibbs, equation:

$$S = \frac{p_d}{p_s} = \exp\left(\frac{4\sigma M_w}{\rho R T d^*}\right) \quad (1)$$

Here the vapor saturation ratio  $S$  is defined as the ratio of the vapor pressure surrounding the particle  $p_d$  to the saturation vapor pressure of the flat surface  $p_s$ . The surface tension, molecular weight, and density of the liquid are given by  $\sigma$ ,  $M_w$ , and  $\rho$ , respectively.  $R$  is the universal gas constant,  $T$  is temperature, and  $d^*$  is the diameter of a particle that will neither grow nor evaporate at  $S$ . Fig. 7A shows the relationship between  $S$  and  $d^*$ . The line given by Eq. (1) can be thought of as the boundary between condensational growth (region A in Fig. 7A) and evaporation (region B). If a particle's diameter and saturation ratio place it on the line and  $S$  were suddenly lowered, then the particle will completely evaporate; if, conversely,  $S$  were raised, then the droplet will grow indefinitely. The Kelvin equation predicts that a pure 10-nm-diameter water particle would require a minimum relative humidity of 125% to prevent evaporation.

In reality, there are no pure particles in the atmosphere. If the particle contains a soluble material, then during evaporation it will experience two competing effects: the Kelvin effect, which would require an increase in vapor pressure to stop evaporation, and the solute effect, in which the increase in solute

**Fig. 7** Saturation ratio vs. particle size for (A) pure water, using Eq. (1), and (B) water with NaCl added, assuming a dry particle diameter of 4 nm. Shaded line in (B) indicates line of stable equilibrium. Capital letters indicate regions of condensational growth and evaporation (see text).

concentration in the particle reduces the saturation ratio required for droplet stability. As the particle shrinks, the solute effect dominates over the Kelvin effect. The Köhler equation describes this competition:

$$\frac{p_d}{p_s} = \left(1 + \frac{6imM_w}{M_s\rho\pi d_p^3}\right)^{-1} \exp\left(\frac{4\sigma M_w}{\rho R T d^*}\right) \quad (2)$$

In Eq. (2),  $i$  is the solute van't Hoff factor and  $m$  is the mass of the dissolved solute with molecular weight  $M_s$ , and  $\rho$  is the density of the solvent. As Fig. 7B shows, the effect of this is dramatic. A nanoparticle in a gas at a saturation ratio that places it in region A will grow indefinitely. A particle in region B will grow until it reaches the shaded part of the curve, where it equilibrates with its surroundings. A particle in region C will evaporate until it reaches the shaded part of the curve, where it again forms a stable particle. The shaded part of the curve in Fig. 7B defines a true equilibrium, unlike the remaining part of the curve and the entire Kelvin equation curve shown in Fig. 7A, both of which define points of unstable equilibrium. This equilibrium particle size will change only if the saturation ratio changes, which will move it up or down the shaded line. If a particle were to grow until it reaches the curve maximum, then it will enter region A and proceed to grow into a cloud particle. However, if the saturation ratio were continuously lowered, the particle dries to form a solid residue. For a particle containing insoluble materials, the effect is to increase the solute

effect. Effectively, the insoluble material displaces the equivalent volume of solvent. Thus for the same diameter particle, the solute concentration is larger and the solute effect is greater. It is important to note the assumptions that are used to derive Eqs. (1) and (2). These are the capillarity assumption, in which bulk thermodynamic properties (e.g., surface tension  $\sigma$ ) are assigned to particles of all sizes, and the incompressibility approximation, which states that the overall particle volume can be calculated by summing the volumes of the individual species.

Once a stable nanoparticle is formed, the rate at which it grows by condensation is determined by the number of random collisions of vapor molecules with the particle. The kinetic theory of gases can be applied for particle diameters smaller than the mean free path of the vapor, resulting in:

$$\frac{dd_p}{dt} = \frac{2M_w(p - p_d)}{\rho N_a \sqrt{2\pi m k T}} \quad (3)$$

In Eq. (3),  $m$  is the mass of the vapor molecule;  $p$  is the partial pressure of the surrounding vapor;  $N_a$  is Avogadro's number;  $k$  is the Boltzmann constant; and  $p_d$  is the partial pressure of the vapor given by the Kelvin equation [Eq. (1)]. [Eq. (3)] states that nanoparticle growth is independent of particle size—precisely the observation provided by the particle growth measurements shown in Fig. 4.

### Homogeneous Nucleation

If homogeneous nucleation were to start on an individual water molecule ( $d^* = 0.4$  nm), then, according to the Kelvin equation, a saturation ratio of 220 would be required. Yet experiments with pure water at 20°C have shown that the process occurs at saturation ratios greater than 3.5.<sup>[45]</sup> Clearly, homogeneous nucleation in the atmosphere does not occur by condensation of vapor on individual molecules. In reality, intermolecular forces such as van der Waals forces lead to the formation of molecular clusters. As these clusters form and fall apart, some portions of these will reach the critical cluster size, which, for pure materials, is given by the Kelvin equation [Eq. (1)], and become stable nanoparticles. This is the microscopic view of homogeneous nucleation. Theoretical treatments of homogeneous nucleation fall into three categories: purely molecular theories, which apply only to simple molecules (e.g., Senger et al.);<sup>[46]</sup> phenomenological theories, which predict nucleation rates using measurable fluid properties as input; and intermediate theories, which share characteristics of each (e.g., Zeng and Oxtoby).<sup>[47]</sup> The focus of the current section will be on the phenomenological treatment classical

nucleation theory (CNT) since most of our current understanding is rooted in this theory. A good reference for recent progress in models and observations of nucleation can be found in the published proceedings of a recent conference devoted to this.<sup>[48]</sup>

As in the discussion of condensation, we start with the case of homogeneous nucleation by a single species. In CNT, the energy change associated with the spontaneous formation of a critical embryo  $\Delta G_{\text{embr}}$  is the sum of the energy change associated with molecules leaving the vapor phase and entering the embryo and the energy associated with the curved embryo surface:

$$\Delta G_{\text{embr}} = n^* \Delta \mu + \pi d^{*2} \sigma \quad (4)$$

where  $n^*$  is the number of molecules in the embryo,  $\Delta \mu$  is the difference in chemical potential for the molecule between solution and vapor, and  $\sigma$  is the surface tension, which is again approximated by the bulk surface tension (capillarity assumption). The nucleation rate, defined as the number of embryos nucleated per unit volume per unit time, is collision rate between molecules and embryos of the critical cluster size, multiplied by the number of critically sized embryos as given by the Boltzmann distribution. The result is:

$$J = \frac{p_v}{\sqrt{2\pi m k T}} \pi d^{*2} n_1 \exp\left(-\frac{\Delta G_{\text{embr}}}{kT}\right) \quad (5)$$

where  $n_1$  is the monomer concentration in the gas phase and  $m$  is the mass of the vapor molecule.

The chemical composition of the critical embryo can be determined by applying the nucleation theorem,<sup>[49]</sup> which relates the saturation ratio dependence on  $\Delta G_{\text{embr}}$  and  $n^*$ :

$$\frac{d\Delta G_{\text{embr}}}{d(kT \ln S)_T} = -n^* \quad (6)$$

The nucleation theorem is generally applicable to either molecular, phenomenological, or intermediate theory of nucleation. Combining Eqs. (5) and (6), one finds:

$$\frac{dJ}{d(\ln S)_T} = n^* + \frac{d(\ln K)}{d(\ln S)_T} \quad (7)$$

where  $K$  is the preexponential factor in Eq. 5. The  $d(\ln K)/d(\ln S)_T$  term can be generally neglected,<sup>[50]</sup> leaving a simple way of determining the critical cluster size  $n$  from observations of  $J$  and  $S$ .

The extension of CNT to multicomponent nucleation is straightforward<sup>[51]</sup> and involves solving

the simultaneous equations:

$$\frac{\ln S_{1,\text{sol}}}{v_1} = \frac{\ln S_{2,\text{sol}}}{v_2} = \dots = \frac{\ln S_{i,\text{sol}}}{v_i} \quad (8)$$

where  $S_{i,\text{sol}}$  is the saturation ratio of species  $i$  with respect to the liquid solution and  $v_i$  is the partial molecular volume of species  $i$ . Once the mole fraction of each compound  $x_i$  in the critical cluster is found from  $v_i$ , the embryo diameter is calculated from:

$$d^* = \frac{4\sigma \sum x_i v_i}{\sum x_i \Delta\mu_i} \quad (9)$$

$\Delta G_{\text{embr}}$  can then be found by substituting  $d^*$  into the multicomponent form of Eq. (4), in which  $n\Delta\mu$  is replaced by the sum of all  $n_i\Delta\mu_i$ . This can then be used to calculate  $J$  by using a multicomponent form of Eq. (5).<sup>[52]</sup>

The principal limitation of CNT is its reliance on the capillarity assumption. For binary nucleation, it has been found that the predictions of CNT are reasonable when the nucleating species form ideal solutions,<sup>[50]</sup> however, when one of the components tends to concentrate on the surface, the theory can yield unphysical results.<sup>[53]</sup> Most intermediate nucleation theories address this issue by retaining most of CNT while introducing correction factors for the nonideal behavior of molecular clusters. Another modification to CNT is required when the nucleating species readily hydrates (i.e., binds with one or more water vapor molecules). The most important example of this in the atmosphere is sulfuric acid/water binary nucleation, which will be discussed later.

## Coagulation

A brief discussion shall be devoted to coagulation, as it is one of the primary loss mechanisms for nanoparticles (Fig. 6). Coagulation is the process by which particles collide with one another and adhere to form larger particles. Nanoparticles are particularly susceptible to loss by Brownian coagulation, in which collisions are caused by relative Brownian motion. A simplified theory of coagulation<sup>[45]</sup> states that the rate of change of the number concentration,  $N$ , for particles of a given size is expressed as

$$\frac{dN}{dt} = -K_0 N^2 \quad (10)$$

$K_0$  is the coagulation coefficient, and is a function of diffusion coefficients and diameters of each particle in the mixture. Two interesting observations emerge from coagulation theory: First, the  $N^2$  dependence in

Eq. (10) means that coagulation is rapid when particle number concentrations are large. The second observation, which comes from the analysis of  $K_0$ , is that coagulation rate is at its minimum when particles are all of the same size, and rises rapidly when larger particles are added to the mixture.

## Observations of Atmospheric Nanoparticle Nucleation and Growth

In a recent review of more than 100 investigations of particle nucleation and growth rates, it was found that the formation rates of 3 nm diameter particles (The minimum detectable size) are in the range of  $0.01 - 10 \text{ cm}^{-3} \text{ sec}^{-1}$  in the clean remote troposphere, but can be up to  $100 \text{ cm}^{-3} \text{ sec}^{-1}$  in urban areas and as high as  $10^5 \text{ cm}^{-3} \text{ sec}^{-1}$  in certain coastal areas and in industrial plumes.<sup>[15]</sup> Sulfuric acid is the species most commonly associated with nucleation in the atmosphere, although there is still no direct proof of this because the chemical composition of nucleating clusters has, thus far, not been measured. Observations at a remote site in Colorado Fig. 8, show clear correlations between increases in sulfuric acid vapor and nucleation. This frequently observed phenomenon and sulfuric acid's extremely low volatility have made it the most likely candidate for study. Sulfuric acid forms hydrates that tend to decrease its effectiveness as a nucleating agent by a factor of  $10^5 - 10^6$ , compared with the absence of hydrates.<sup>[1]</sup> Models that account for hydrate formation do so by treating hydrates as small liquid droplets.<sup>[55]</sup> When these models are applied to observations of nucleation, results such as those shown in Fig. 9 are commonly observed. In Fig. 9, conditions that initiated nucleation are plotted for a variety of sites in the troposphere. These observations are compared with two different CNTs that included corrections for hydrate formation. The plot shows basic agreement with binary nucleation theory for events observed in and around clouds, and discrepancies of two to three orders of magnitude for terrestrial locations. In this locations, not only does binary CNT inadequately predict the concentrations needed for nucleation, it also cannot model the functional dependence of nucleation rate on sulfuric acid and water concentration. Weber et al.<sup>[56]</sup> found that the formation rate is proportional to the first to second power of  $\text{H}_2\text{SO}_4$  concentration, which, according to Eq. (7), indicates that the critical embryo contains only one or two sulfuric acids.

The current understanding of atmospheric nucleation, which has evolved from measurements such as those shown in Figs. 8 and 9, is that, with the exception of a small set of observations from very clean locales, binary nucleation theory does not

**Fig. 8** Measured (A)  $\text{H}_2\text{SO}_4$ , (B) nanoparticle concentration, and (C) aerosol surface area concentrations at Idaho Hill, CO, a remote forest site. *Source:* From Ref.<sup>[54]</sup>. American Geophysical Union.

adequately model the observed sulfuric acid concentrations that initiated nucleation. Because the observations where the discrepancy occurs were at or near ground level, this suggests that one or more of the following may be occurring: 1) nucleation is occurring as a ternary process, perhaps including ammonia or an organic compound; 2) some other compound in addition to, or instead of, sulfuric acid is participating in binary nucleation; and 3) a heterogeneous process, perhaps involving nucleation of vapor onto ion centers, is occurring. Although none of the above three possibilities can be categorically eliminated, the ternary theory of sulfuric acid/ammonia/water is increasingly viewed as the most likely mechanism.<sup>[57]</sup> This view is aided by the observation that the presence of ammonia in sulfuric acid/water solutions considerably decreases the vapor pressure of sulfuric acid.<sup>[58]</sup> In addition,

**Fig. 9** Comparison of conditions that resulted in nucleation events at various sites in the remote troposphere to predictions of the onset of sulfuric acid/water binary nucleation using two CNT models that include hydrate effects (solid and dashed lines). *Source:* From Ref.<sup>[53]</sup>. American Geophysical Union.

laboratory studies have shown that very low levels of tens of parts per trillion of ammonia can boost nucleation substantially.<sup>[59]</sup> A heterogeneous process of nucleation on ion centers might also explain current observations of nucleation.<sup>[54]</sup> Laboratory investigations have shown that the presence of gaseous ions can enhance nucleation rates.<sup>[61]</sup> Yet, to date, there have been no measurements of the composition of atmospheric ions during nucleation events to validate this hypothesis.

In the review of observations mentioned above, observed particle diameter growth rates are typically in the range of 1–26 nm/hr in midlatitudes, and depend heavily on the presence of condensable vapors and temperature. Attempts to interpret these observations by using Eq. (3) for the condensation of sulfuric acid and water generally underpredict growth by a factor of 5–10.<sup>[5]</sup> Either other species are contributing to particle growth, or growth is occurring by other processes in addition to monomer addition. The former option is quite likely to occur, as many oxidized organic compounds have sufficiently low vapor pressure to contribute to aerosol growth. Unfortunately, the property that makes such compounds candidates for condensational growth also makes them extremely difficult to study. For the latter option, preliminary results from the ANARChE study suggest that growth can be accounted for by including cluster condensation in Eq. (3).

## CONCLUSION

Atmospheric nanoparticles, which are defined here as particles with a spherical equivalent diameter smaller

than 50 nm, are now understood to be important atmospheric constituents that can dominate a particle number distribution spectrum. They can be directly emitted from combustion sources, but on a global scale, the most important formation process is by homogeneous nucleation. Nanoparticle growth, which in some locales can be as rapid as 26 nm/hr, can occur as a result of coagulation and physical uptake of compounds into the aerosol. Such growth links the presence of nanoparticles to a variety of phenomena such as climate, health, visibility degradation, and chemical transformations in the atmosphere. Measurement techniques are already able to detect and size nanoparticles at sizes as small as 3 nm. Future advances may include the ability to detect postnucleation clusters, which would require detection sensitivity to about 1 nm particles. Chemical composition techniques are undergoing rapid progress, with on-line instruments now capable of characterizing the composition of particles in the 5–20 nm diameter range. Modeling of the formation and growth of nanoparticles has traditionally relied on CNT and approximations to key nanoparticle physical properties such as the capillarity assumption. These have found some success at predicting formation rates in some parts of the atmosphere, but for the majority of locales, theories based on binary CNT are overpredicting the chemical environment required for nucleation by several orders of magnitude. Ternary nucleation of sulfuric acid, ammonia, and water may be the solution to this discrepancy, and is expected to be an important component of future theoretical advances.

# Automotive Parts: Impact of Nanotechnology

Ganesh Skandan

Amit Singhal

Damian Sobrevilla

NEI Corporation, Piscataway, New Jersey, U.S.A.

## INTRODUCTION

This article explores the present impact of nanotechnology (mostly nanomaterials so far) on the consumer automotive market. Our attempt throughout the paper has been to situate technical aspects of nanotechnology as they pertain to the automotive market in a business context. The initial part of the paper describes some early successes of nanomaterials embraced by the industry, bearing in mind that the market entrants are few and far apart. This includes a description of technology developments in the area of *coatings*, particularly the outer body *clearcoat*, and a summary of *bulk* nanostructured materials, specifically polymer-clay nanocomposites for non-critical automotive body parts. Even though the aftermarket is a smaller component of the overall market, several new products for the aftermarket have begun to appear, ostensibly incorporating nanotechnology. The section, Potential Applications, briefly describes a number of research and development activities that are in various stages of testing and qualification. Fig. 1 depicts the present and future possible applications of nanotechnology in an automobile. Concluding thoughts and the road ahead for nanotechnology as it relates to the automotive market are presented in the final section.

## BACKGROUND

A discussion of nanotechnology in the context of automotive applications is timely because the acceptance of a new enabling technology into the mainstream market can be gauged by its acceptance in the automotive industry, and nanotechnology is by and large an enabling technology. In fact, approval by the automotive industry is a test of the robustness of any technology, particularly in the area of advanced materials.

The automotive sector has been the backbone of the US economy for most of the past 100 years. The health of the overall economy is often measured by the “health” of the automakers. Until a few years ago,

the three US automakers, General Motors (GM), Ford Motor Company, and Chrysler dominated the world market. With the purchase of Chrysler by Daimler-Benz and the decision by Japanese and European car-makers to assemble cars in the U.S.A., the dominance by US-based automakers has quite noticeably diminished. Despite the disparate performance in the recent times of GM and Ford on one hand and foreign-based automakers on the other, and owing to company-specific issues coupled with changes in the landscape of the consumer economy, new car sales continue to be an important lagging indicator that US economists watch for. Considering the hype surrounding nanotechnology and the huge amount of research sponsored by governments worldwide, it is worth taking a reality check of the payoffs to date.

Nanotechnology either adds value to an existing application, or enables the creation of new applications. The acceptance criteria (technical as well as economic) set by the automotive industry for any technology is more stringent than anywhere else. Therefore, one measure of commercial success and societal impact of nanotechnology can be measured in terms of the level of penetration in the automotive market. A report by the firm Frost & Sullivan, entitled “Global Analysis of Nanotechnology in the Automotive Market,” estimates that revenues arising out of nanotechnology will be ~\$6.46 billion by 2015, with the maximum impact being made in the areas of paints and coatings, catalytic converters, and fuel additives.<sup>[1]</sup>

Although nanotechnology is a burgeoning field, there are already a number of components that use nanomaterials. In some cases, such as carbon black used in tires and catalyst particles used in catalytic converters, they have been in use prior to being recognized and termed as nanostructured materials. All the same, the total dollar value of newly developed nanomaterials in use today in a vehicle as a fraction of the cost of an automobile is too small to even measure. Nonetheless, as outlined in this entry, the potential for nanomaterials to be ubiquitous in automobiles is huge. Because the authors themselves are actively involved

**Fig. 1** Potential nanotechnology applications to modern automobile.

in various aspects of nanotechnology as they relate to the automotive market, some bias toward a positive outlook is unavoidable (mention of the authors' activities is made in various sections of the article). This article will concentrate on the payoffs as revealed on the modern automobile.

## NANOSTRUCTURED COATING TECHNOLOGIES

One of the concerns that faze researchers is the long time it takes for a product to be introduced in the primary automotive market. For example, it took several years of concerted effort to develop nanoparticle-enhanced *clearcoats* by Pittsburgh Plate Glass Company for Mercedes-Benz.<sup>[2,3]</sup> Successful launch of this product has been one of the most recent success stories involving nanotechnology in automotive applications. The clear lacquer contains nanoscale particles, which beneficially alter the three-dimensional cross-linked polymer network. The scratch resistance of the nanoparticle containing coating is reported to be increased threefold, with the gloss being extended for substantially longer periods of use. The chemical resistance of the coating has been preserved because of the nanoparticle addition.

The paintwork in automobiles is complex, and is composed of multiple steps and many layers of coatings, each one having a specific feature. The multilayered coating used by Mercedes-Benz, as described by Kimberley,<sup>[4]</sup> consists of five layers with a combined thickness of  $\sim 100\ \mu\text{m}$ . The first layer is a zinc phosphate coating, which protects the metal from corrosion. A subsequent dip coating in a primer paint coats the edges and grooves, thereby providing additional protection against corrosion. The anticorrosion layers together are about  $\sim 25\ \mu\text{m}$  thick. A coat ( $\sim 25\ \mu\text{m}$ ) of the base paint, which contains the desired color is then applied. The addition of aluminum flakes in this layer leads to paints with a metallic finish. The top *clearcoat* is

the final coating layer, and is about  $40\ \mu\text{m}$  thick. The top coat provides the gloss and protection against the elements. The demands on the performance of the clearcoat are significant as it should protect against such things as bird droppings, acid precipitation, dust, chipping, sunlight, fluctuations in temperature, and automatic car wash swipes. The complex nature of these coatings perhaps explains the long lead times from conception to implementation of a new product, and nanotechnology is no exception.

Based upon the extensive amount of ongoing work on ultraviolet (UV) light cured polymers, it is likely that the next innovation employing nanotechnology will be in *clearcoat* polymers cured by UV light. The current industrial practice for curing the clearcoat during production is by heating the automotive body to  $\sim 60^\circ\text{C}$ . It has been argued that UV-curable clearcoats possess many potential advantages such as excellent scratch and mar resistance, and improved initial appearance.<sup>[5]</sup> Further, the volatile organic compound content could also be substantially reduced. The authors are quick to point out that the UV curing process should make use of current automotive paint application infrastructure, and should allay common concerns that automotive manufacturers have, such as ozone production, power consumption, shadow zones, and worker safety. Accordingly, the authors demonstrated that the UV curable clearcoats can be cross-linked not only by using conventional high intensity lamps, but also by using diffuse fluorescent radiation and xenon flash lamps.

Antireflection coatings, which are multilayered coatings with the thickness of each layer being well below  $100\ \text{nm}$ , have been in commercial production for quite sometime.<sup>[6]</sup> An example is an antireflection coating on glass with a trade name Schott Conturan.<sup>[7,8]</sup> Saint Gobain produces a grade of glass that has nanoscale layers of sun protecting and infrared reflecting material embedded within.<sup>[8,9]</sup>

In contrast to exterior coatings, much less commercial implementation has occurred in the area of

nanostructured coatings for interior components in an automobile, and in particular, aluminum engine blocks. This is not to say that there is lack of potential, but perhaps because the issues involved are fairly complex and the coating has to simultaneously satisfy a multitude of functional performance requirements. As Dahotre and Nayak<sup>[10]</sup> have outlined in a recent review article, the coating must possess a low coefficient of friction, good corrosion resistance, good scuffing resistance, amenability to honing to create a surface topography with many small recesses that can store oil, good thermal insulation to prevent heat from being lost through the engine block, and affinity for oil coating. The scientific basis by which nanostructured coatings could improve the engine efficiency is shown in Fig. 2. It turns out that the mechanical properties of interest (e.g., hardness, modulus, and plasticity) reach a maximum value when the microstructure of the material transitions from being a coarse-grained structure to an amorphous structure. Candidate materials that are being investigated for possible replacement of cast iron liners in the cylinder bores of aluminum alloy engine blocks include nickel-based coatings deposited using atmospheric plasma deposition techniques, diamond-like carbon coatings, and laser-annealed iron oxide coatings.

## NANOMATERIALS FOR STRUCTURAL APPLICATIONS

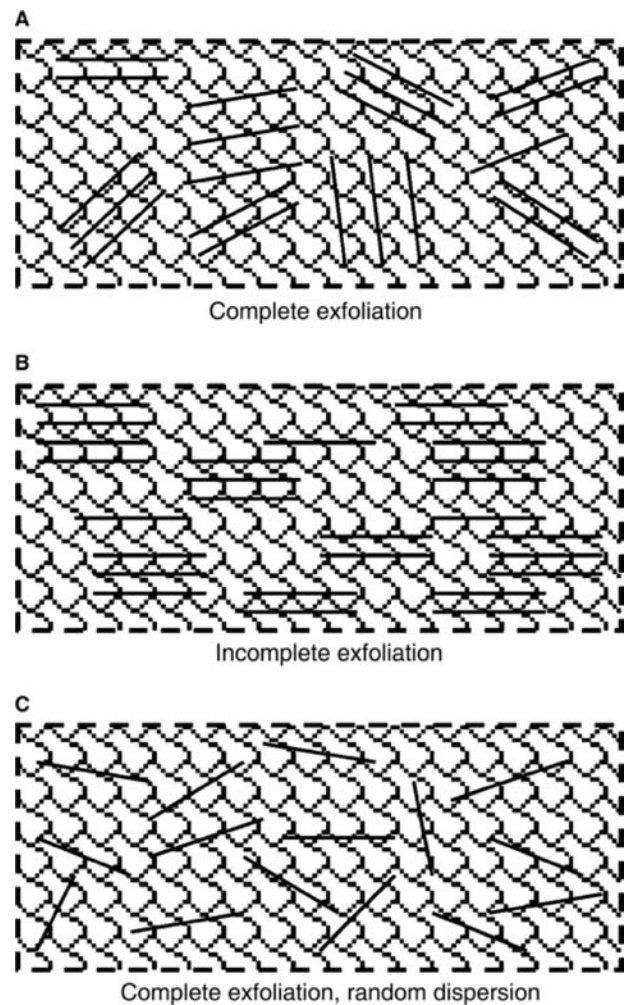

Bulk polymer nanocomposites, particularly for automotive applications, have been synonymous with dispersed clay-polymer nanocomposites. After about 10 years of intense R&D, both in academia and industry, GM and Toyota Motor Company were among the first

**Fig. 2** Schematic depiction of mechanical properties as a function of grain size.

to introduce nanocomposite products.<sup>[11]</sup> The exterior step-assist in GM's 2002 Safari and Astro vans are made of nanoclay/thermoplastic polyolefin nanocomposites,<sup>[12]</sup> manufactured by Bassell, utilizing clay particles from Southern Clay Products. The dispersion of the nanoparticles increases the flexural modulus by ~75%, compared to the neat resin. A more recent polymer nanocomposite product is the side molding on the 2004 Chevrolet Impala.<sup>[13]</sup> It is estimated that GM can use ~500,000 lbs/yr of nanocomposites. From a nanoparticle supplier's standpoint, this represents a potential sale of 25,000 lbs/yr because clay-based nanocomposites are typically composed of ~5 wt.% dispersion of either exfoliated or intercalated platelet-shaped clay particles in a thermoplastic resin (Fig. 3).<sup>[14]</sup>

Ever since the beginning, the driving force for developing polymer nanocomposites has been to replace metals with lighter weight materials that are low-cost and provide adequate performance. This in turn would

**Fig. 3** Different exfoliation and dispersion schemes for montmorillonite organoclay reinforced polymer nanocomposites. *Source:* Adapted from Ref.<sup>[14]</sup>.

lead to enormous savings in energy consumption through reduced use of fuel during the automobile's life cycle. Garces et al.<sup>[15]</sup> of Dow Chemical Company estimated that using polymer nanocomposites for just the non-critical structural parts in an automobile, such as front and rear fascia, cowl vent grills, valve/timing covers, and truck beds, would lead to billions of kilograms in weight saved per year. This is because polymer nanocomposites offer an estimated 25% weight savings over glass and carbon fiber filled plastics, and as much as 80% over steel. Expanding their use to other parts such as body panels, could lead to further savings in weight.

In a broad sense, materials advances in automotive applications have centered on using structural plastics, lightweight metals instead of steel and cast iron, and reinforcing polymers with fillers such as glass fibers, talc, mica, and calcium carbonate. Unfortunately, none of these approaches is a panacea. Conventional fillers add too much weight and compromise on the toughness and surface finish. Lightweight metals are expensive and suffer from the same processing limitations of steel and iron. Similarly, structural plastics cost more and require postforming modifications of the surface and long cycle times.<sup>[14]</sup>

As with any other technology, there have already been a few marketplace casualties despite stunning technical results. Toyota Motor Company had been a pioneer in the area of polymer nanocomposites, and was the first to develop an alternative production process to the conventional method of dispersing and exfoliating into polymers by melt compounding. They developed Nylon 6-clay hybrid (NCH) nanocomposites by the in situ intercalation polymerization method, where the monomer was first intercalated in the clay, and subsequently polymerized in situ.<sup>[16]</sup> The tensile modulus of NCH containing only 1.6 wt.% clay was twice that of Nylon 6, and the coefficient of linear thermal expansion was reduced by half. The initial target for the nanocomposite material was a timing-belt cover. Cost and other considerations prevented successful commercial introduction.<sup>[17]</sup>

Over the past several decades, the automobile industry has found itself at the crosshairs of environmental groups, who demand more fuel-efficient vehicles. Reducing the weight automatically leads to improved fuel efficiency. However, reducing the weight through the use of advanced materials invariably ends up increasing the cost, which is often not commensurate with the improved performance offered by the new material. Because bulk polymer nanocomposites undoubtedly possess certain mechanical properties that are better than in heavier traditional materials, cost is the major stumbling block for widespread acceptance. In a seminal study, Lloyd and Lave<sup>[14]</sup> lay out an economic case for using polymer nanocomposites

in automotive applications. On the basis of detailed financial and statistical assessment, the authors present a compelling case for using polymer nanocomposites in automobiles. Because of the uncertainty involved with a relatively new technology, they have estimated the value of this material as a function of its efficiency and the amount of steel it can replace. At the upper bound 67% efficiency, the nanocomposite substitution will be worth a little more than \$8/lb in materials and processing cost. At a lower bound 38% efficiency, the substitution will be worth slightly below \$4/lb. Given that the market price for filled polymer nanocomposites is between \$1 and \$2, these materials present a persuasive value proposition. It should be noted that although vehicles with greater fuel economy lead to potentially large economic and environmental benefits, US consumers have been traditionally indifferent to fuel economy. With crude oil prices in the range of \$50–60 per barrel as of the writing of this entry, and speculation that it might touch \$100 per barrel in the foreseeable future, change in the US consumers' attitude toward fuel economy could come sooner rather than later. One could hazard a guess that polymer nanocomposite manufacturers are eagerly awaiting higher gas prices. A combination of mounting social–environmental concerns and rising oil prices might lessen the current cost obstacle for more pervasive introduction of nanotechnology into the behemoth automotive industry.

## NANOTECHNOLOGY-ENABLED PRODUCTS FOR THE AFTERMARKET

Recognizing that it is easier to get a product into the automotive aftermarket as opposed to the primary market, Nanofilm Ltd., a 20-year old thin film developer, started selling an auto glass treatment product into the retail market.<sup>[18]</sup> The Clarity Defender, as it is called, repels rain, snow, mud, bugs, bird dropping, spray paint, and most liquids that come in contact with the windshield. The windshield coating from Nanofilm is expected to last a lot longer than competing products. It is not clear as to what component of the treatment solution is made of a nanomaterial, but then in almost all cases the consumer is concerned more with a new and improved end-product rather than a nano-enabled product.

Along the same vein, the NanoBreeze™ Car Air Purifier, produced and marketed by NanoTwin Technologies, is said to clean and purify the air inside the passenger compartment of any motor vehicle.<sup>[19]</sup> When placed over a dashboard vent, the air circulating inside the car is cleaned by reduction and oxidation through a photocatalytic reaction. The heart of the NanoBreeze

is a nano-TiO<sub>2</sub>-coated fiberglass wrapping on a fluorescent tube. The inside of the tube is coated with a phosphor that generates UV-A radiation.

## POTENTIAL APPLICATIONS

Presting and Konig,<sup>[7]</sup> researchers at Daimler Chrysler in Germany have written an aptly titled article “Future nanotechnology developments for automotive applications,” because the list of current applications is rather small. This goes to show that the automotive industry, despite being a \$2000 billion worldwide industry at retail [including both original equipment manufacturer (OEM) and aftermarket], is conservative and extremely cost conscious. As with many new and exciting fields of science and technology, the list of potential applications is invariably a lot larger than that of current applications. Nanotechnology in the context of automobiles is not immune to this trend.

An emerging theme is that nanotechnology, particularly nanomaterials, is likely to be an enabler in a number of different components and subsystems in the automobile. This can pan out as envisioned, provided the materials manufacturers come to grips with cost and reproducibility issues. If nanotechnology lives up to its promise, many parts of a car could contain a variety of nanostructured materials. Some of these potential applications are described below.

### Catalysts

Noble metal catalysts, including those based on platinum, are used to decompose the combustion products in a catalytic converter into relatively less harmful emissions. Catalysts have always been particles at the nanoscale—they just were not called nanoparticles. The enormously high surface area is used for efficient gas–solid reactions. A company called Nanostellar Inc.<sup>[20]</sup> has started developing nanocomposite catalysts, which it says will substantially reduce the amount of platinum that is presently used. Platinum-based catalysts are also used in the electrodes of a fuel cell. Because the catalyst is expensive and accounts for a large part of the cost in a fuel cell, there is an interest in developing alternative non-noble metal catalysts. If QuantumSphere<sup>[21]</sup> has its way, its nanonickel could replace platinum-based catalysts. It is not clear though how the surfaces of non-noble metals can be passivated and prevented from complete oxidation. A third company, Catalytic Solutions, is an active player in this market as well.<sup>[22]</sup> The use of oxide-based compositions has also been investigated as potential replacements for noble metal catalysts.<sup>[23]</sup>

## Nanotechnology-Based Magnetic Sensors

A modern automobile uses a multitude of sensors, many of them magnetic sensors that are based on the Hall Effect (or inductive effect), and more recently anisotropic magnetoresistance. A magnetic sensor allows contactless, and hence, wear-free determination of mechanical parameters such as angle of rotation and angular speed.<sup>[24]</sup> A new phenomenon called Giant Magnetoresistance (GMR), discovered in 1988,<sup>[25,26]</sup> offers the possibility of increasing the output signal, the opportunity to miniaturize, and the ability to sense in 360°. The sensor element essentially consists of multilayers of metals, each layer only a nanometer or two thick. The GMR effect is unique to the multilayered magnetically inhomogeneous nanostructured material (Fig. 4). Giebeler et al.<sup>[24]</sup> have shown that the GMR effect, which has been in commercial use in hard disc drives for about 10 years, can be used in automotive applications to determine many functions such as valve position, and chassis height and position. Extensive research at Robert Bosch GmbH and Mitsubishi<sup>[27]</sup> has led to the development of commercial magnetic sensors based on the GMR effect.

### Nanomaterial-Based Engine Coolants

Researchers at the Argonne National Laboratory created a sudden burst of excitement in the engine coolant (i.e., antifreeze) business in the mid-1990s by demonstrating that the thermal conductivity (and hence the heat transfer coefficient with a constant or greater heat capacity) of nanoparticle containing fluids is greater than that of the neat fluid.<sup>[28,29]</sup> The experiments were conducted with nanoparticles dispersed in ethylene glycol, which is the major component of an engine coolant. A few companies, such as Valvoline, picked up on this and research was carried out where nanotubes were dispersed in heat transfer fluids.<sup>[30]</sup>

**Fig. 4** GMR sensor sample layer configuration: hard magnetic layer of artificial antiferromagnet with soft magnetic detection layers (top and bottom, Fe/Co).

NEI Corporation, the employer of the authors, has advanced the state-of-the-art to a commercially viable fluid, both from a technical and a commercial standpoint. Working in concurrence with an OEM customer, tests are underway by an engine coolant manufacturer to qualify the fluid for use in aftermarket and OEM applications.

### Nanomaterials-Enabled Lithium-Ion Batteries

Cathode and anode materials determine the fundamental performance of a battery, and the role of a battery in an automobile is changing as we see more and more hybrid electric vehicles on the road. The hybrid can range from a micro-hybrid, where the engine shuts off when the vehicle stops at say a traffic light and the integrated starter/alternator assists the gasoline engine in accelerating the vehicle, to a full-hybrid where an electric motor powered by a large battery drives the vehicle by itself.<sup>[31]</sup> The gasoline engine in a full-hybrid is relatively small as its primary function is to recharge the battery. The hybrid has taken the emphasis away from the all-electric vehicle, which for the time being is restricted to golf carts and off-road vehicles of the like. The unavailability of a cost-effective and low-weight battery technology has prevented the all-electric vehicle from becoming a reality. Nevertheless, the Nickel Metal Hydride (NiMH) battery of a hybrid electric vehicle is an important component and weighs substantially (e.g., Cobasys NiMHax HEV 288-60, weighs 75 kg).<sup>[32]</sup> Lead-acid batteries, which have been the 12 V power supply in modern automobiles, simply do not have sufficient energy density and cycle life for use in a hybrid electric vehicle. In contrast, NiMH has good power capability. In terms of energy density and cycle life, the lithium-ion (Li-ion) battery reigns supreme, however, obtaining batteries of the size required for use in an automobile has been an elusive target. Apart from cost, which is a huge limiting factor, the large size poses safety concerns that have not been fully resolved to date. Cost considerations are staggering—the target price by the US Department of Energy for cathode materials for hybrid electric vehicles is \$8/kg.<sup>[33]</sup> Few materials synthesis technologies are currently available that can meet this target. Pasquier et al.<sup>[34]</sup> have proposed a cell chemistry that utilizes nanostructured lithium titanate (LTO). The charge-discharge capabilities of the proposed chemistry are better than conventional Li-ion chemistries, which utilize carbon anode and lithium cobalt oxide (LCO) cathode, and the energy density is much higher than that of a carbon-carbon double-layer supercapacitor (Fig. 5). The cycle life of Pasquier et al.'s proposed device is far better than that of any competing Li-ion battery. Work done at NEI Corporation has

Fig. 5 Energy-Power Ragone plot comparison of LTO/C and LTO/LCO batteries. Source: Adapted from Ref.<sup>[34]</sup>.

unequivocally demonstrated that nanostructured anode and cathode materials have higher capacity and/or better rate capability than their coarse-grained counterparts.<sup>[35]</sup> In one particular case, for a given rate of charge, the capacity is higher by 100%.<sup>[36]</sup> As with any other technology, the economics and life cycle cost will determine if a hybrid electric vehicle will utilize advanced Li-ion devices with nanostructured electrodes.

### Improved Fuel Cells through Use of Nanomaterials

A discussion on automobiles is always incomplete without reference to the “coming” hydrogen economy. It is envisioned that fuel cells will someday deliver the power for driving the motor in all vehicles, and therefore we will need an infrastructure for producing, storing, and delivering hydrogen safely at ambient temperature and pressure, as well as at low cost. On recognition of its large surface or interfacial area, as the case may be, the nanostructured material became a subject of intense investigation in the mid-1990s for use as a medium of hydrogen storage. In particular, early reports indicated that single-walled carbon nanotubes (SWNTs) could store up to 10 wt.%<sup>[37]</sup> of H<sub>2</sub>, which exceeded the target of 6.5% set by the US Department of Energy<sup>[38]</sup> for a commercially viable technology. However, careful experiments in trying to reproduce these initial reports revealed that the absorption mechanism is by and large physisorption. As yet, it has not been successful to reproduce the early reports and consequently meet the Department of Energy target using SWNTs. On the other hand, a well-known class of materials called “alanates” (e.g., NaAlH<sub>4</sub> and LiAlH<sub>4</sub>) adsorb hydrogen reversibly and some reports have shown that a nanocomposite

material has an increased efficacy for hydrogen adsorption.<sup>[39,40]</sup>

Oddly enough, the heart of a fuel cell has generated relatively less number of opportunities for utilizing nanotechnology. Perhaps the biggest area of research in enabling a better performing fuel cell has been the Nafion<sup>®</sup> separator membrane in a polymer electrolyte membrane fuel cell. The ideal membrane should satisfy the following requirements: 1) low cost and ready availability; 2) a high proton conductivity of over  $10^{-2}$  S/cm at room temperature; 3) chemical and thermal stability at an operating temperature of 150°C; 4) enough water uptake above 100°C; 5) good mechanical properties (strength, flexibility, and processability); 6) low gas permeability; 7) low water drag; 8) minimal fuel crossover in case of direct methanol fuel cell; and 9) fast kinetics for electrode reactions.<sup>[41]</sup> Some studies<sup>[42]</sup> have shown that dispersing exfoliated clay nanoparticles with appropriately engineered end-groups can improve the performance of neat Nafion.

## Solar Power and Nanotechnology

Harnessing energy by the use of either solar cells or thermoelectric modules that convert heat released by the engine to electricity has taken the fancy of some automakers. For example, Mercedes-Benz and Audi offer a line of cars with solar cells on the roof to provide power to a ventilation system that keeps the interior of the car cool when the engine is off.<sup>[8]</sup> This is akin to sail boats equipped with a few large solar panels that generate electricity and store in a battery. Ge nanostructures embedded in a Si matrix is a variation of the conventional crystalline Si solar cell, and can provide improved conversion efficiencies.<sup>[43]</sup> One needs to only stretch one's imagination (as Presting and Koning<sup>[7]</sup> have done) to somehow integrate a dye-sensitized solar cell, which uses nanoparticles of TiO<sub>2</sub> as an active constituent of the photovoltaic cell, on to the surface of a car body. In all fairness, given the conservative nature of the automotive industry, only a very small fraction of vehicles on the road will see solar cells in the foreseeable future.

## CONCLUSIONS

The lure of a huge market in the automotive sector is clearly a driving force for researchers and developers to come up with new materials and technologies that can be of value to a consumer who is willing and able to pay additional money for the added benefit. Even though the modern automobile still has four tires and a steering wheel, much like the cars from more than a 100 years ago, each and every component goes

through a steady metamorphosis. This offers opportunities for new technologies that offer new functionalities to be incorporated into the design. All the same, introducing nanomaterials and nanotechnology-based products into either the aftermarket or the OEMs is replete with challenges. As with anything else, this includes identifying the value chain and being able to deliver on the promised value proposition. Additionally, issues pertaining to manufacturability and robustness need to be addressed early in the development phase of the product. Last, but not the least, cost considerations take center stage when it comes to the automotive market.

## ACKNOWLEDGMENTS

The authors are grateful to Mr. John Blair of Executive Strategies for stimulating discussions, helpful comments, and suggestions.

# Axle Molecules Threaded through Macrocycles

Daryle H. Busch

Thomas Clifford

Department of Chemistry, University of Kansas, Lawrence, Kansas, U.S.A.

## INTRODUCTION

Interlocked structures exploit a mode of interaction that is old beyond history with everyday objects, but is relatively new in the molecular sciences.<sup>[1–3]</sup> Just as interlocking iron rings make chains for pulling or suspending heavy loads and as two-dimensional arrays of interlocked iron rings were used to make chain mail for the armor of knights of yore, one-dimensional and two-dimensional interlocking molecular rings may provide exciting, new materials for the future. If chains can be made, then why not molecular braiding, knitting, or weaving? A molecular cloth composed of linear polymer molecules, woven at the molecular level, would certainly have unanticipated properties. For example, the behavior might appear at first to resemble a live object. At room temperature, each molecular strand in the cloth would likely have some of its vibrational modes activated, so that the cloth would constantly be subject to motions that would tend to unravel it. This unraveling could be prevented, probably by having large groups on the ends of each strand, so that they could not pass through the openings in the weave, a subject of this entry.

One reason interlocked molecular structures are not yet available in multitudes of shapes and sizes, including the familiar forms just described, is that they are difficult to make. Unlike ordinary thread, string, or rope, it is difficult to get a hold on a molecular strand, so it is more difficult to put them through the motions that would create a needle work product—and that is precisely what this brief missive is about. It is about one of the simplest of tasks that has to be overcome if one wants to make chains, or knit, or weave on the molecular level. The subject is the threading of a, more or less, linear molecule through a molecular ring. One of the two simplest interlocked molecules is the *rotaxane* and it is composed of an axle molecule, inserted through a ring molecule and held there by its own end groups that are simply too big to permit the axle to be propelled easily out of the ring (Fig. 1).

## OVERVIEW

Actually, to a very small extent, linear molecules will spontaneously insert themselves into ring molecules in condensed phases.<sup>[4,5]</sup> However, if the axle and the ring contain atomic groupings that can bind to each other, then a so-called templating interaction may occur and the threading of the axle through the ring may occur extensively.<sup>[6,7]</sup> Such templates have been used extensively by chemists to make chains with several interlocked rings<sup>[3]</sup> and to tie knots, including the overhand knot, the square knot, and the granny.<sup>[8]</sup> Two structural designs have been suggested, and partially demonstrated, for the formation of polymers by rotaxane formation. They are shown in Fig. 2. The first, the *daisy-chain polyrotaxane*, uses molecules that contain both a ring and an axle so that they are able to self-assemble into polymer forms. The second, the *riveted polyrotaxane*, is formed by riveting together molecules that have two rings, similar in construction to one side of a bicycle drive chain.

If the molecular axle and the ring of a rotaxane are not locked in place by big blocking end groups on the axles, they are called pseudo-rotaxanes, to acknowledge their temporary nature. In fact, it is the pseudo-rotaxanes that are of interest here because, whatever the ultimate goal may be, the threading process does indeed initially produce a pseudo-rotaxane. Fig. 1 shows the progression from independent axle and ring molecules to pseudo-rotaxane, and then to rotaxane for a simple example. Focusing on the real issue that is at hand, chemists would like to be able to make molecular cloth, but they are, metaphorically, just learning how to thread the needle—and that is the current subject.

## THE BEGINNINGS OF MOLECULAR THREADING

About half a century ago, Wasserman<sup>[9]</sup> proposed the formation of rotaxanes and calculated the extent to

**Fig. 1** Progression from axle and macrocycle to pseudo-rotaxane and then to rotaxane.

which a pseudo-rotaxane should form if there were no particular intervening force to stabilize the interlocked molecule. Under Wasserman's defined conditions, about 0.01% pseudo-rotaxane formation might be expected. Some years later, Harrison and Harrison<sup>[5]</sup> performed elaborate experiments to determine the extent of spontaneous threading. Their results strongly supported the earlier conclusion that only a small fraction of the axle and ring molecules undergoes threading in the absence of some intervening force.

In their strikingly original templating studies, Chambron, Dietrich-Buchecker, and Sauvage<sup>[8]</sup> created a number of interlocked molecules along pathways that required threading. In these studies, the copper(I) ion served as the anchor for the template, locking axle molecules into rings both in final product rotaxanes and in intermediates in the synthesis of more complicated structures. Even with templates based on robust metal-ligand interactions, yields were low in the early studies of rotaxane or pseudo-rotaxane formation.

This offered a major challenge to the more ambitious goals of researchers because high levels of threading would be necessary to make materials that require many sequential steps as, for example, in polymer formation. Furthermore, it is essential that the interlocked materials not contain equivalents of hazardous materials. For that reason and because they have opened the way to a quantitative study of intermolecular threading, attention has more recently focused on weaker templating forces arising from hydrogen bonding and  $\pi$ - $\pi$  stacking interactions. From the standpoint of eventual development of useful products, templates using these supramolecular modes of interaction are most promising. Earlier studies judged success in threading based on the yields of rotaxanes that were formed. For example, in 1992, Wenz and Keller<sup>[10]</sup> showed that high threading yields occurred with polyamines going through cyclodextrins. This suggested that multiple hydrogen bonds could generally produce high levels of threading. Yields of 30–40% were

Fig. 2 Polymers based on rotaxane formation.

heralded as substantial achievements.<sup>[11,12]</sup> Furthermore, the synthesis of a [3]-rotaxane in 84% yield by coupling two molecules of a pseudo-[2]-rotaxane was considered as strong evidence of threading at least at the 90% level (Fig. 3).<sup>[13]</sup> Equilibrium constants for pseudo-rotaxane formation are at the center of developing and understanding how threading occurs on the molecular level.

### EQUILIBRIUM CONSTANTS FOR PSEUDO-[2]-ROTAXANE FORMATION

Traditional nuclear magnetic resonance (NMR) techniques (Fig. 4) have dominated the determination of equilibrium constants for the molecular threading process, with much less literature on values obtained from diffusion methods (NMR) and from direct

Fig. 3 Coupling of pseudo-[2]-rotaxanes to produce a [3]-rotaxane.

**Fig. 4** Nuclear magnetic resonance measurements for the determination of equilibrium constants.

thermodynamic measurements. Detailed measurements yield relatively reliable values, but estimates are often made from single measurements.<sup>[14]</sup> Analysis of these equilibrium measurements reveals the present state of knowledge with regard to the threading of axle molecules through macrocyclic molecules. Significant amounts of data exist only for templated formation of pseudo-rotaxanes, and the templating can, as indicated above, involve a variety of interactions. The most powerful templates involve covalent bonds such as those formed in ordinary organic compounds, but the metal–ligand equivalent, the coordinate bond, is more often used. Of greatest importance are the weaker linkages collectively called *supramolecular interactions* because the individual molecular partners retain their individualities while working together, like a fireman on a ladder, rather than being fused into a single entity, like a branch from a pear tree grafted onto a quince tree stalk. Outstanding among these are hydrogen bonding, which is the subject that has been most studied;  $\pi$ – $\pi$  stacking, which is second in importance; and hydrophobic force, which is notable among the oligocyclic sugars called cyclodextrins.

### FACTORS AFFECTING EQUILIBRIUM CONSTANTS FOR MOLECULAR THREADING

Equilibrium constant is defined in its traditional form by Eq. (1). The subscript in  $K_a$  indicates that the corresponding chemical equation has been written in the associative direction, rather than in the dissociative direction (Eq. (2)):

$$K_a = [\text{pseudo-rotaxane}]/[\text{axle}][\text{macrocycle}] \quad (1)$$

For supramolecular interactions of this kind (generally called complex formation), a simple relationship exists between the equilibrium constant  $K_a$ , and the rate constants for the associative (threading) reaction  $k_a$  and the dissociative (unthreading) reaction  $k_d$  (Eq. (3)):

$$K_a = k_a/k_d \quad (3)$$

Equilibrium constant data are presented in Tables 1 and 2 and the molecular partners, the ring and the axle, are identified by abbreviations. The abbreviations are identified with the correct molecular structures in Figs. 5 and 6. For the most part, the names from which the abbreviations have been constructed appear in the related text.

### Effect of Solvent

Both the diversity of molecular partners that can be united in the threading process and the effect of solvents on the threading equilibria are well illustrated by the first 10 entries in Table 1. The macrocycle used in the first five entries, symmetrical dibenzo-24-crown-8 (s-DB24Cr8), and the axle, dibenzylammonium ion, are prototypical for studies of this class, and Ashton et al.<sup>[15]</sup> used them to show the great impact of solvents that compete for hydrogen binding interactions that template the threading process. A relatively large equilibrium constant is found for the equilibrium in deuterio-chloroform ( $27,000 \text{ M}^{-1}$ ), but the value decreases markedly when the solvent is changed to acetonitrile ( $460 \text{ M}^{-1}$ ) or acetone ( $360 \text{ M}^{-1}$ ), and no threading occurs when dimethyl sulfoxide is used as the solvent. The monotonic effect of mixing the solvents is shown by the datum for the mixed solvent chloroform/acetonitrile ( $1700 \text{ M}^{-1}$ ).<sup>[16]</sup>

A dramatic solvent effect has been observed with the system consisting of the axle, bis(cyclohexylmethyl)-ammonium hexafluorophosphate (DCHXMA), and

ICE = intermediate chemical exchange; X = no threading detected.

the ring, DB24Cr8. After reflux (40°C) in  $CH_2Cl_2$  for 32 days with a 6:1 excess of macrocycle, ~98% of the axle molecule exists as pseudo-rotaxane. Subsequently, the material showed no evidence of dissociation in 3:1  $CDCl_3/CD_3CN$  on standing at room temperature for weeks. However, the crystalline rotaxane dissociated completely when dissolved in perdeuterated DMSO in 18 hr or less at 25°C.<sup>[17]</sup> These observations dramatize both the great variation in threading equilibrium constants in different solvents and the fact that the kinetics of equilibrations can be very slow. Reflecting on the collision event that must occur between the axle molecule and the macrocyclic molecule, it is a little like throwing a stiff thread at the hole in a needle during a wind storm. It may not be quite that bad, but the specific conformational, orientational, and trajectory requirements for threading and unthreading are quite limited, compared with the complete portfolios of orientations and motions available to the axle

and the macrocycle. Clearly, the events of interest here may be expected to be of low probability.

The influence of markedly different templating forces is evident from studies with more exotic systems. The distinctly polar environment within *cucubit[7]juril* (CR7) binds the dimethylviologen cation,  $MV^{2+}$ , very strongly in water (Table 1, line 6).<sup>[18]</sup> The contrasting relatively nonpolar environment within the hydrophobic cavity of a cyclodextrin (lines 7–10) provides a distinctly parallel behavior for reasons that might be considered opposite to those of the CR7. Kano et al.<sup>[19]</sup> report that the equilibrium constant in water for binding to tetramethyl- $\beta$ -cyclodextrin (TMe- $\beta$ -CD) of the long, negatively charged, sulfonate-terminated arm of the tetrasubstituted porphyrin, TPPOC3PS, is too large to measure by their methods. However, values of 8700 and 290  $M^{-1}$  were determined in ethylene glycol and methanol, respectively. No binding was observed in DMSO. For related axle molecules and the same

Fig. 5 Axle molecules cited in the text.

cyclodextrin, the equilibrium constant increased as water was mixed with the ethylene glycol solvent.

### Substituent Effects

The prototypic combination of s-DB24Cr8 and dibenzylammonium ion was used to evaluate the effects of axle substituents on the equilibrium constants for threading (Table 1, entries 11–16).<sup>[16]</sup> The affinity of the axle for the macrocycle ( $K_a$ ) increases smoothly as the electron-withdrawing capability of the substituents increases. This is consistent with the stabilization of hydrogen bonding to ether oxygen atoms of the macrocycle DB24Cr8 as the acidity of the protons of the substituted dibenzyl ammonium ion increases. Replacing the protons at the *para* positions on the phenyl groups with methyl groups has the opposite effect, as expected. Moving the substituent (Br) to a *para* methyl group (DBDXA) leaves a small effect.<sup>[20]</sup>

The position of the benzo groups on DB24Cr8 has little impact (lines 2 and 18),<sup>[21]</sup> but replacing ether oxygens with pyridine nitrogens more than doubles the binding constant (lines 17 and 19).<sup>[22]</sup> The more basic nitrogen donors on the macrocycle form stronger hydrogen bonds to the protons of the axle ammonium function.

### Steric Effects

The beginnings of an understanding of steric effects came with the investigation of the equilibria and rates of reaction of the common macrocycle DB24CR8 with various axle molecules related to dibenzylammonium ion by replacing the phenyl groups with cyclopentyl, cyclohexyl, and cycloheptyl rings. Both rate and equilibrium data are reported.<sup>[23]</sup> The bis-*para*-*i*-propyl-phenyl ammonium ion, used for reference purposes, gives association and dissociation rate constants of

Fig. 6 Macrocycles cited in the text.

$3.2 \times 10^{-3} \text{ M}^{-1} \text{ sec}^{-1}$  and  $1.3 \times 10^{-6} \text{ sec}^{-1}$ , respectively, and a  $K_a$  value of  $2470 \text{ M}^{-1}$  at  $40^\circ\text{C}$ . Remarkably, the rates of association and dissociation for the two saturated ring derivatives, cyclopentyl and cyclohexyl, bracket those for the reference axle (*D-i*-PrDBA), but exhibit identical equilibrium constants at  $40^\circ\text{C}$ ; that value is  $K_a = 110 \text{ M}^{-1}$ . As described above in “Effect of Solvent,” the cyclohexyl derivative reacts at an astoundingly low rate (weeks), whereas the smaller cyclopentyl derivative threads on the second-to-minute time scale. The cycloheptyl derivative gave no evidence for binding at all.

### Effects of Chain Length and Branching

Using an interesting family of axle molecules that are blocked on one end and have a carboxylic acid on the other end, Zehnder and Smithrud<sup>[24]</sup> found a small increase in affinity with longer chains. Clifford et al.

explored chain length and a number of other factors affecting the threading process with monobenzo-24-crown-8, B24Cr8, and 29 axle molecules (R-AM) having an anthracen-9-ylmethyl group in common.<sup>[14]</sup> Their results are summarized in Table 2. The normal linear alkyl groups methyl through *n*-nonyl, plus octadecyl, made up a thorough exploration of the influence of chain length on threading. The equilibrium constants ranged from  $120$  to  $180 \text{ M}^{-1}$ , with a mean of  $160 \pm 20 \text{ M}^{-1}$ . No systematic variation was found for the seven  $K_a$  values available for *n*-alkyl threading groups. Within the range of uncertainty, the  $K_a$  values changes vary randomly as chain length. There is no hint of an even-odd hydrocarbon variation.

In contrast to the insensitivity of the equilibrium constant to chain length, the axles are readily separated into two groups based on the rates at which they undergo threading. Axles shorter than pentyl equilibrate rapidly on the NMR time scale, whereas those longer than pentyl equilibrate slowly. The pentyl group

exchanges on an intermediate time scale that prevented the determination of  $K_a$  with the tools available to these researchers. The general conclusion is that the equilibrium constant for threading is essentially insensitive to the length of the chain, but the rates at which threading and unthreading occur depend strongly on chain length. It is interesting that long chains give the same effect on rate as increased bulk, as represented by

increased ring sizes for the saturated rings cyclopentyl and cyclohexyl substituents on axle molecules (vide supra).

Branched alkyl axle components show a distinctive behavior. For the axle groups *i*-propyl, *i*-butyl, and *i*-pentyl (Table 2, lines 10–12), branching moves regularly to greater distance from the ammonium binding site. Correspondingly,  $K_a$  increases from a very low value of  $17 M^{-1}$  at *i*-propyl to  $164 M^{-1}$  for *i*-pentyl, essentially the average value noted above for linear ligands. This suggests that the steric effect because of alkyl branching greatly weakens threading, but that it is only effective when the branching occurs near the ammonium binding site. Similarly, comparing the isomers of the butyl group,  $K_a$  decreases markedly from *n*-butyl through *i*-butyl and *s*-butyl, finally disappearing at *t*-butyl. Furthermore, all of the branched structures described up to this point equilibrate on the rapid NMR time scale, a performance completely consistent with their linear isomers. The 2-methylhexyl-substituted R-AM axle molecule gives an equilibrium constant between those for the *i*-propyl and *i*-butyl derivatives, but reacts on the slow NMR time scale.

The cyclohexyl derivative (Table 2, line 14) binds with a  $K_a$  identical to that of an *i*-propyl group, but the binding rate is slow, a feature already discussed for saturated ring derivatives. Based on the work of others, the failure of these studies to produce a  $K_a$  value for the cyclohexylmethyl derivative may be attributed to either insufficient reaction time, or to the specific properties of the solvent acetone.<sup>[17]</sup>

### Influence of Terminal Groups

Hydroxyl, carboxylic acid, and phenyl groups were studied as terminal groups on the threading components of the anthracen-9-ylmethyl blocked axle molecules (R-AM) of Clifford, Abushamleh, and Busch<sup>[14]</sup> B24Cr8 was used as the macrocycle. For hydroxyalkyl derivatives (Table 2, lines 22–25), the  $K_a$  values all fall in the range around and just below  $100 M^{-1}$ , suggesting that the OH group substantially weakens the binding compared with a simple alkyl thread. In contrast, a carboxylic acid group at the terminal site (lines 26–28) definitely enhances  $K_a$ , giving values in the range between 200 and  $300 M^{-1}$ . Interestingly, the alcohol functional group does not affect the rates (i.e., hydroxypentyl falls in the intermediate rate region, just like pentyl itself). In contrast, pentanoic acid equilibrates on the slow NMR time scale, acting as if both the carboxyl carbon and oxygens contribute to the “effective” chain length.

Phenyl terminal groups on the threading arm of the axle molecule (Table 2, lines 19–21) show a behavior that parallels that of both the carboxylic acid derivatives

and the branched alkyl groups. Like branched alkyls,  $K_a$  increases substantially for each methyl group placed between it and the ammonium group, proceeding to a value of  $282 \text{ M}^{-1}$  for 3-phenylpropyl. However, unlike the branched alkyls, the highest value for  $K_a$  found for the phenyl derivatives is almost double that for *n*-alkyls. In this enhancement of threading affinity, the phenyl group resembles the carboxylic acid group. It is reasonable to suggest that the enhanced affinities associated with terminal carboxylic acids and phenyl substituents arise from additional intermolecular attractions, and that these interactions are facilitated by the increasing flexibility that comes with a small increase in chain length. It is also conceivable that the weakened binding of alcohol functions may be because of competitive binding with the solvent, externally, as well as within the macrocycle. Competition between threading and binding outside the macrocycle has been observed.<sup>[25]</sup>

## CONCLUSION

The threading of axle molecules through macrocyclic molecules is but one of several elementary steps that must be controlled if scientists are eventually to learn to manipulate the interlocking of molecules to produce new materials, such as fabrics, only one molecule thick. Threading produces pseudo-rotaxanes and, in the absence of templating forces, the random threading of axle molecules through rings occurs to only a very small extent (hundredths of a percent). However, through the use of intermolecular forces, the axle may be selectively templated inside the ring in high yields. Examples of binding sources for templating include metal ion complexation, hydrogen bonding, and  $\pi$ - $\pi$  stacking of aromatic rings. Like polymers in general, new materials based on molecular interlocking will require large numbers of sequential steps. If such steps involve threading, that process must be accomplished with high efficiency.

Much has been learned about threading using hydrogen bonding templates, based mainly on macrocyclic polyethers with (as axles) secondary ammonium groups having one or two, more or less, linear arms that actually perform the threading. Therefore the equilibrium constant and the fraction of the axle and ring that are in the pseudo-rotaxane form increase with increased macrocycle basicity and with increased acidity of the ammonium ion axle (for the types of interactions described here, the opposite is possible). Hydrogen bonding sites outside the ring compete with threading, and terminal hydroxyl groups on axle molecules weaken threading. For linear alkyl groups, affinity is insensitive to chain length. However, branched alkyls show variable steric effects; branching inside the  $\gamma$ -position of the axle lowers the threading affinity. However, threading is favored by carboxylic acid groups and by phenyl groups

at the ends of alkyls (also at the  $\gamma$ -position or greater).  $K_a$  is strongly favored by nonpolar solvents having poor hydrogen bonding abilities. In contrast, strongly hydrogen-bonding solvents greatly weaken the interactions. The solvent effects are dramatically different in systems based on cyclodextrins—large cyclic molecules that bind their axle molecules through hydrophobic interactions. They bind most strongly in water and  $K_a$  is decreased by the addition of organic solvents. Remarkably, cucubituril selectively binds cationic axles, and the binding is extremely strong in water.

Returning to the hydrogen-bonded templates, steric effects and chain length effects all dramatically affect the rate of the equilibration process, in some cases, with no change in equilibrium constant. Saturated rings appended to ammonium ions through methylene groups exhibit extreme behavior. The cyclopentyl derivative equilibrates in  $\sim 10$  min under conditions where the cyclohexyl derivative requires over a month. For simple *n*-alkyl groups, chains shorter than pentyl react on the fast NMR time scale, whereas those longer than pentyl react on the slow NMR time scale, despite the fact that there is no assignable change in affinity with chain length. Seemingly, neither branching nor the presence of functional groups has a substantial effect on the rate pattern of linear alkyl groups.

The increased understanding of the elemental process of threading an axle molecule through a large molecular ring should fuel research on interlocked molecular species of high molecular weights. Polymerization in one, two, or three dimensions by rotaxane formation or by interlocked rings (*catenane* formation) will lead to new and exciting materials. Expectations include materials of great strength and unusual flexibility. How the abilities of the individual interlocked molecular units to move independently will affect the various properties of molecularly interlocked materials remains unclear. Expectations continue to grow that such structures will have information-related applications, in the limit, as integral parts of a *molecular computer*. If history is our guide, it is the unexpected applications that will eventually be the most important and will change people's lives.

# Barcoded Nanowires

Rebecca L. Stoermer

Christine D. Keating

*Department of Chemistry, Pennsylvania State University,  
University Park, Pennsylvania, U.S.A.*

## INTRODUCTION

Metal nanowires have been prepared with segments of different materials along their lengths. These particles can be synthesized in a large number of optically distinguishable striping patterns, and thus have been referred to as barcoded nanowires. These barcoded wires can be used for encoding information such as the type of biological assay being performed on the surface of the particle. Thus they have application in multiplexed bioanalysis.

A variety of methods exist for metal and semiconductor nanowire synthesis. Of these, few are capable of producing wires with segments of different materials along the length of the wire. Templated electrodeposition has been used for production of striped metal nanowires tens to hundreds of nanometers in diameter and several microns in length. The length of each segment can be as small as tens of nanometers or as long as the entire wire. The resulting nanowires have potential application as components in self-assembled functional electronic devices. Segments of differing electronic properties (e.g., conductors, semiconductors, and even monolayers) can be incorporated to prepare building blocks for the bottom-up assembly of electronic devices.

Optically encoded (barcoded) particles also have potential applications analogous to barcodes in the retail industry, where the products are tracked by the barcode pattern. Typically, the barcode labels used on retail products are readily identifiable to the human eye. In addition to these overt tags, there is also interest in microscopic barcodes invisible to the naked eye. Striped nanowires can serve as such microscopic identifiers, and have enormous potential for use in biological sensing applications where many different bioassays must be simultaneously followed. In this last application, the barcoded nanowires perform a function analogous to the individual spots of a DNA microarray, encoding the identity of biomolecules attached to their surface.

## SYNTHESIS OF NANOWIRES

A variety of synthetic methods have been reported for the preparation of nanowires of carefully regulated composition, size, and aspect ratio. They include electrochemical<sup>[1–3]</sup> and photochemical<sup>[4]</sup> reduction methods in various media including aqueous surfactant,<sup>[5]</sup> porous alumina templates,<sup>[6,7]</sup> polycarbonate membranes,<sup>[8]</sup> and carbon nanotube templates.<sup>[9,10]</sup> Nanowires have also been prepared by catalytic synthesis,<sup>[11,12]</sup> electroless deposition,<sup>[13–15]</sup> seeding growth methods,<sup>[16–19]</sup> vapor–liquid–solid growth,<sup>[20,21]</sup> and photochemical synthesis.<sup>[22]</sup> Magnetic wires have also been made via metal electrodeposition.<sup>[23]</sup>

Other types of fabricated nanowires include nanocables having coaxial structures generated with silver centers coated with silica,<sup>[24]</sup> electrochemically prepared gold-core, silver-shell nanowires,<sup>[25]</sup> metal oxide wires made using either a mild, solution-based colloidal approach,<sup>[26]</sup> solvothermal methods,<sup>[27]</sup> sonochemistry,<sup>[28]</sup> thermal evaporation,<sup>[29]</sup> or gas-phase catalytic growth methods,<sup>[12]</sup> and nanowire diodes created by coating polymer films on metal nanowires.<sup>[30]</sup>

## SYNTHESIS OF STRIPED NANOWIRES

Although a number of synthetic methods are available for creating nanowires, only a few methods exist that allow for the creation of nanowires with stripes of different materials along their lengths. One such method is the vapor–solid–liquid (VSL) growth technique, which has primarily been used to create semiconductor nanowires and superlattices.<sup>[21,31,32]</sup> Another involves electrochemical synthesis whereby metal ions are reduced into membrane templates.<sup>[6,33–36]</sup>

In VSL nanowire synthesis, a catalyst nanoparticle, which defines the diameter of the wire, is used to initiate wire growth from a reactant vapor. As more vapor is introduced, wire growth continues. An equilibrium phase diagram is used to select a catalyst that

can form a liquid alloy with the nanowire material. For example, gold nanoparticles have been used as catalysts for the VSL growth of silicon wires.<sup>[12]</sup> To obtain striped heterostructured nanowires, different vapor sources are consecutively fed into the system.<sup>[21,31,32]</sup> For example, semiconductor superlattices have been prepared in which photoluminescence from the wires is patterned based on the position of GaP and GaAs segments.<sup>[32]</sup>

Striped metal nanowires are typically prepared by electrochemically reducing metal ions into the pores of a template. Porous aluminum oxide or track-etch membranes are commonly used.<sup>[3,37–41]</sup> Alumina membranes are prepared by anodizing Al at constant potential to give a nanoporous membrane.<sup>[39,41]</sup> Pore diameters can be varied (from tens to several hundred nanometers) by controlling the anodization potential.<sup>[40]</sup> Track-etch membranes are prepared by using nuclear fission fragments to attack a non-porous sheet of desired material (e.g., polycarbonate or polyester), to yield indentations in the material that are further chemically etched into pores.<sup>[41]</sup>

To electrochemically produce barcoded nanowires, one side of a template membrane (e.g., Al<sub>2</sub>O<sub>3</sub>) is coated with a silver film to serve as a cathode for reducing metal ions from solution into the pores of the membrane template. This can be accomplished by vapor deposition or sputtering. The opposite side of the template is then immersed in a plating solution of a desired metal for electrochemical deposition. The length of the metal stripe created is dictated by the amount of current passed and the amount of time the plating is allowed to deposit. Once a stripe of a desired length has been created, the plating solution is simply changed such that the next metal segment can be added. The thickness of each individual stripe can in principle be controlled with great accuracy during the electrodeposition process.<sup>[42,43]</sup> Indeed, repeating Cu and Co segments only 8-nm-thick have been prepared from a solution containing both metal ions.<sup>[31]</sup> Selective electrodeposition of each metal from this solution is accomplished by careful control over plating solution composition (i.e., relative concentrations of the two metal ions) and the electrode potential, which is switched between values favoring Cu deposition to those favoring Co deposition during synthesis.<sup>[44–46]</sup>

The aspect ratio ( $l/d$ , where  $l$  is the length and  $d$  is the diameter of the nanowires) of the wires is controlled by the membrane pore diameter (which dictates wire width), and the deposition time (which determines the length). The maximum wire length is limited by the thickness of the template (which is roughly 50–60  $\mu\text{m}$  for commercial alumina membranes) and to breakage for wires with high aspect ratios (over 25:1 aspect ratio). Once the electrochemical deposition is complete, the silver backing and membrane are

dissolved away, leaving behind a suspension of striped metal nanowires.

To date, barcoded nanowires have been prepared with Au, Ag, Pt, Pd, Ni, Co, and Cu metal segments.<sup>[33]</sup> Fig. 1A shows a reflectance image of a 320-nm AuAgPd striped nanowire imaged at 430 nm. At this wavelength, Au has the lowest reflectivity, followed by Pd and then Ag. Fig. 1 shows that these metals can be optically distinguished based on reflectivity difference. The number of possible distinctive patterns or permutations available to the barcoded metal wires is  $m^s$ , where  $m$  is the number of metal types and  $s$  is the number of stripes in each wire. For example, wires consisting of four metals (i.e., Au, Pt, Co, and Ag) with six stripes leads to 4096 possible striping patterns ( $4^6 = 4096$ ). Ag/Au striped wires having 13 distinguishable stripes have been reported,<sup>[47]</sup>  $2^{13} = 8192$  possible patterns. Addition of a third metal leads to over 1.5 million possible patterns. To account for patterns that repeat in the forward and reverse direction, the following equation should be used: possibilities =  $m^s + m^{\text{ceil}(s/2)}/2$ , where  $m$  is the number of metals in the rod,  $s$  is the number of stripes, and  $\text{ceil}$

**Fig. 1** (A) Reflectance image of an AuAgPd nanowire taken at 430-nm wavelength. (B) Line scan profile of intensity vs. distance across the nanowire length.

stands for ceiling function, which rounds the exponent of  $n$  to the next highest integer (i.e.,  $3/2$  rounds up to 2). Using this equation, the actual number of different patterns that could be obtained from a 4-metal, 6-stripe wire is 2080, and for a 3-metal, 13-segment particle is  $7.98 \times 10^5$ .

## CHARACTERIZATION

Once nanowires are fabricated, they are characterized via many methods to determine their actual compositions, sizes, shapes, optical, and electrical properties. Transmission electron microscopy (TEM) is used to determine the size and shape of nanowires. Scanning electron microscopy (SEM) is used to examine the stripes and the metal-metal interfaces between segments. With SEM, striping patterns of heterostructured nanowires and surface defects can be identified, which cannot be detected using TEM. Fig. 2 is an example of a field emission (FE) SEM image of a 5- $\mu\text{m}$ -long, 320-nm-diameter AuAuAgAu striped nanowire. Energy dispersive X-ray spectroscopy is used to determine the average chemical composition of nanowires, including the microstructure of single metal and multilayered wires.<sup>[12,48,49]</sup>

In identifying the striping pattern in barcoded nanowires, optical reflectance microscopy is used. The striping pattern is deciphered based on reflectance differences of adjacent metal stripes. For optical resolution using reflectance detection, the different metal segments have to be separated by a distance greater than  $\lambda/2\text{NA}$ , where NA is the numerical aperture of the objective lens (a typical oil immersion lens has  $\text{NA} = 1.4$ ). The optical properties of 320-nm-diameter

**Fig. 2** Field emission SEM image of a AuAuAgAu nanowire, acquired with backscattered electron detection. The Ag segment appears darker as compared to the Au.

**Fig. 3** Reflectance values for various bulk metals. Source: From Ref.<sup>[81]</sup> ©American Chemical Society.

nanowire segments resemble those of their bulk counterparts.<sup>[40,50–54]</sup> Reflectance values for various bulk metals, plotted over a range of wavelengths, are shown in Fig. 3.<sup>[55]</sup> The differences in reflectivity of the various metal types allows for the detection of multiple metal stripes in a single barcoded nanowire. Fig. 1B shows a line scan of the AuAgPd striped nanowire pictured in Fig. 3A. This scan illustrates the changes in reflectance intensity across the length of the wire. Freeman et al.<sup>[56]</sup> have demonstrated a 100-particle library of barcoded nanowires in which more than 70 of the patterns could be identified with greater than 90% accuracy. These authors developed software for rapid readout of barcode striping pattern.

## POTENTIAL USES FOR BARCODED NANOWIRES

### Nanoelectronics

Striped metal nanowires have potential application as primary components for nanoscale electronic devices.<sup>[57–59]</sup> Current-voltage responses of nanowires can be altered by incorporating either semiconductor, particulate, or molecular segments into the wires during fabrication.<sup>[30,60]</sup> Thus far, nanowire conductors, rectifiers, switches, and photoconductors have been created and characterized.<sup>[61–63]</sup> These electrically functional nanowires are promising as building blocks in the bottom-up assembly of electronic devices. Nanowire assembly into parallel, raft-like structures has been investigated for developing bottom-up nanoscale patterning.<sup>[64,65]</sup> Biomolecular recognition processes such as DNA hybridization have also been used for directing such assembly.<sup>[66]</sup> Further application, for

which techniques are still being developed, includes assembling nanowires into cross-point arrays for memory and logic devices.

### Biological Multiplexing

Performing many simultaneous experiments (i.e., multiplexing) has become an important theme in bioanalysis. For example, functional genomics experiments often follow mRNA expression levels for many—or even all—genes in an organism's genome simultaneously. These experiments employ fluorescence on planar microarrays in which spots of DNA corresponding to the different genes of an organism's genome are positioned on a planar glass slide.<sup>[67,68]</sup> The  $x,y$  coordinates of each spot correlate to its identity. Microarrays permit the detection of thousands to tens of thousands of species at once, saving both time and reagents. However, there are some drawbacks of using microarrays, which include limitations in the dynamic range of analyte detection, long diffusion times for analyte binding, and variations in fluorescence signals between arrays.<sup>[69]</sup> Encoded particles have been introduced to address issues of diffusion and increase flexibility in microarray design.<sup>[70,71]</sup> Polystyrene microbeads incorporating red and infrared fluorescent dyes in different intensity ratios are one type of encoded particle introduced for use in multiplexing applications.<sup>[72–74]</sup> Although microbeads offer improved diffusion as compared to two-dimensional arrays, the use of fluorescence limits the number of species that can be simultaneously detected, as the spectral bandwidths of the fluorescent peaks are large and oftentimes overlap. Semiconductor quantum dots, which have reduced spectral bandwidths as compared to molecular dyes, have been used in place of organic fluorophores in encoded beads as well as other applications.<sup>[75–80]</sup> These particles are very promising for multiplexing, and are resistant to photobleaching; however, the detection still relies on fluorescence, which ultimately limits the number of species that are

possible to detect simultaneously (i.e., only one color of fluorophore can typically be used in detection, as other channels are occupied with encoding the particle identity).

Barcoded nanowires are a promising alternative to fluorescent tags in some applications. The barcode striping pattern will not photobleach, reflective read-out is simple and does not require expensive excitation sources or detectors, and many patterns can be synthesized and are optically detectable. These particles can be employed as encoded substrates for biosensing, analogous to DNA chips, or as tags for simultaneous detection and identification, analogous to fluorescent molecules or nanocrystals. Scheme 1 illustrates the second approach, where barcoded nanowires may potentially be used as tags to detect and identify specific DNA hybridization events. In this example, a glass slide is spotted with several different capture sequences of DNA selective to the 5' (or 3') region of the target sequence. Target sequences, labeled double prime (") in the figure, bind to the surface via hybridization to these capture strands. They are then detected by hybridization-driven assembly of barcoded nanowires that carry a third strand of DNA, complementary to the 3' (or 5') region of the target sequence. Optical reflectance microscopy can then be used to count and identify the wires bound to each spot on the surface, giving the amount and identity of target molecules present in the initial solution. This approach is conceptually simple, and does not require fluorescence for detection. Improvements in the selectivity of nanoparticle attachment will be important for the ultimate use of this approach in multiplexed analysis.<sup>[66]</sup>

Barcoded nanowires not only serve as identifying markers, but can also serve as easily detectable substrates on which binding events take place.<sup>[34]</sup> Scheme 2 illustrates how barcoded nanowires can serve as encoded substrates for antigen and DNA detection.<sup>[81]</sup> Scheme 2 (left) illustrates a standard sandwich immunoassay performed on the nanowire surface. The striped particles are first derivatized with a capture antibody (a) that is specific for an analyte, which in

**Scheme 1** Overview of nonfluorescent bioassay using barcoded rods. DNA strands labeled A–C are not complementary to their primed counterparts (A'–C'); however, the strands labeled as double prime (") link the respective sequences to their primed counterparts via complementary DNA hybridization. (Not drawn to scale.)

**Scheme 2** Schematic of assays using barcoded nanowires as substrates. (Left) For immunoassays, the striped particles are first derivatized with a capture antibody (A) that is specific for the analyte (B), which is also an antibody. Following incubation of the capture antibody with the analyte, the fluorescently labeled detection antibody (C) is added. (Right) For DNA hybridization assays, particles are derivatized with NeutrAvidin (NA) followed by reaction with a biotinylated capture sequence (A) that is specific for a solution phase analyte (B). Fluorescently labeled oligonucleotides (C) were then added for detection. *Source:* From Ref.<sup>[81]</sup>. ©American Chemical Society.

this case is also an antibody. Following incubation of the capture antibody with the analyte (b), a fluorescently labeled detection antibody (c) is added. Scheme 2 (right) shows the analogous experiment for DNA detection. Here the barcoded nanowire serves as the substrate on which a DNA probe sequence (a) is attached. Probe sequences are designed to be complementary to one half of the target sequence, as in the previous example (Scheme 1). The target DNA sequence (b) binds to the probe from solution via hybridization, and is subsequently detected by hybridization to a fluorescently tagged third DNA strand (c). In either of these two types of bioassay, target detection and quantification is made possible by the fluorescence intensity of the labeled probe molecules, while target identification (i.e., DNA sequence) is determined by the nanowire barcode pattern as observed in reflectivity optical microscopy.<sup>[34,81]</sup>

Both immunoassays and DNA hybridization assays have been performed on barcoded nanowires.<sup>[34,81]</sup> Nicewarner-Pena et al.<sup>[34]</sup> demonstrated two simultaneous immunoassays in which two different fluorescent dyes were employed. Keating et al.<sup>[81]</sup> have also reported three simultaneous DNA assays using a single fluorescent probe for all three assays. Under some conditions, it proved possible to observe the barcode-stripping pattern in the fluorescence image,<sup>[81]</sup> such that acquisition of a single image enabled both identification and detection. Barcoded nanowire libraries of 100 particles have already been reported,<sup>[56]</sup> and could be combined with these types of biological assays for increased multiplexing. Ultimately, it should be possible to perform thousands or tens of thousands of different DNA hybridizations simultaneously on different particles in

the same suspension, similar to the level of multiplexing now possible only with planar DNA microarrays.

## Nonbiological Tagging

Finally, barcoded nanowires have potential application as covert tags in non-biological materials. Macroscopic barcodes are currently largely used in manufacturing to track materials. These tags are visible to the naked eye. There is also a desire to create hidden, or covert, tags for use in some applications such as in paper currency, stock certificates, and passports. The hidden tags currently incorporated into such documents include near-IR fluorescent dyes or particles, chemical isotopes, and sometimes even biological molecules. A problem with some of these internal tags lies in their durability.<sup>[33]</sup> Striped metal nanowires are too small to see with the naked eye, and can serve as robust and easily identifiable covert tags. They have been incorporated into inks, paper, explosives, glass, metals, bulk polymers, and textiles, where they could still be identified via optical microscopy.<sup>[33]</sup>

## CONCLUSION

Striped metal nanowires can be readily prepared via templated electrodeposition, and have promise not only in future electronic devices built from the bottom-up, but also as optically encoded, microscopic barcodes. Optical encoding is accomplished by incorporating segments of different wavelength-dependent reflectivities, which are then read out in an optical microscope. Very large numbers of distinguishable barcode patterns can in principle be synthesized and optically detected. Such particles are attractive in both nonbiological and biological tagging applications. When coated with proteins or DNA oligonucleotides, these barcoded nanowires can serve as encoded supports for biomolecule detection. Many simultaneous bioassays can in principle be performed using suspensions of barcoded nanowires, each particle pattern corresponding to a different bioassay.

## INTRODUCTION

During the last decade, the development of a novel type of composite material led to a significant improvement of mechanical, thermal, and vapor transport properties of films and coatings. Such materials are based on finely dispersed or interspersed organic–inorganic components down to their nanodimensions and are characterized by an intimate contact of their components and their nanodimensionality, whereas their specific architecture (crystal structure, morphology, etc.) is often preserved in the material. This results in a particularly strong interaction between components and an optimal summation of their properties. Especially interesting are nanocomposites in which one or more components have been oriented because orientation often results in additional strengthening and enhancement of properties. Coatings and films from such materials are endowed with exceptional mechanical and thermal stability, allowing for small thicknesses and making them very interesting for various applications. In this entry, we describe the resistance to the vapor penetration of multilayer nanocomposites with a focus on the resistance to gas/vapor diffusion, rather than on their separation ability (permselectivity). Such properties acquire a special importance in the packaging of materials such as food, beverages, chemical and medical packaging, etc.

### Permeability of Polymers

The permeation of a gas/vapor (permeant) through a polymeric membrane/film is driven by the

concentration gradient of the permeant dissolved in the membrane.<sup>[1–3]</sup> If the concentration gradient is kept constant throughout the membrane and if Henry’s law is applied, the amount of gas/vapor diffusing through the film/unit area and per unit time  $Q$  can be expressed quantitatively:

$$Q = \frac{P(P_2 - P_1)}{\ell} \quad (1)$$

in which  $\ell$  is the thickness of the membrane/film  $P_2 - P_1$  is the differential gas/vapor pressure across the membrane and  $P$  is the permeability coefficient of the material of the film with

$$P = D \times S \quad (2)$$

where  $D$  is the translational diffusion coefficient of the gas and  $S$  is the solubility coefficient of Henry’s law. It is given by the amount of permeant (expressed in cubic centimeters or cubic meters of gas at standard temperature and pressure) divided by the amount of polymer (often given as volume) and by the pressure gradient across the film. Thus  $Q$  expresses the transmission rate of a permeant and is often used in assessing the quality of a packaging material as a barrier to vapor/gas permeation. Units are expressed and converted in Table 1.<sup>[2]</sup>

Permselectivity is another important characteristic of a membrane giving the relative barrier properties vis-à-vis different permeants. Such selectivity is expressed as a ratio of permeabilities. For two

**Table 1** Units for diffusivity, solubility, and permeability

	Units	
Diffusivity ( $D$ )	$\text{cm}^2/\text{sec}$	$\text{m}^2/\text{sec}$
Solubility ( $S$ )	$[\text{cm}^3 \text{ (STP)}]/[(\text{cm}^3) \text{ (atm)}]$	$[\text{m}^3 \text{ (STP)}]/[(\text{m}^3) \text{ (Pa)}]$
Permeability ( $P$ )	$[(\text{cm}^3) \text{ (cm)}]/[(\text{m}^2) \text{ (day) (atm)}]$	$[(\text{cm}^3) \text{ (mil)}]/[(\text{cm}^2) \text{ (day) (cm Hg)}]$

permeants A and B, the permselectivity  $\alpha_{A/B}$  is:

$$\alpha_{A/B} = \frac{P_A}{P_B} = \frac{S_A D_A}{S_B D_B} \quad (3)$$

For a binary system where one component is nonporous (filler), the solubility of the filled polymer  $S$  in a given vapor can be determined<sup>[4]</sup> and barrier properties (permeabilities) for different permeants can be calculated.<sup>[2]</sup>

### Factors Influencing Permeability

As can be seen from Eq. (2), the permeability of polymers with respect to a given permeant depends on both the translational diffusion ( $D$ ) and solubility constants ( $S$ ).<sup>[2,3]</sup> As is well known,  $D$  increases with temperature and with the strength of attractive interactions between the polymer and the permeant. Permeability decreases with an increase in the size of the permeant and with the decrease in the free volume of the polymer. Thus glasses are less permeable than rubbers. Consequently, the increase in the degree of crystallinity of a polymer, the increase in chain order, the increase in the degree of cross-linking, and the increase in the packing density and compact morphology of the polymer are all structural factors decreasing permeability and enhancing the barrier properties of a polymer. The solubility coefficient of Henry's law of the permeant  $S$  in a given polymer can be estimated from the solubility parameter, which in turn can be obtained from the tables.<sup>[2]</sup> Polymers that interact strongly with permeants will favor permeability and, conversely, polymers interacting poorly with a given permeant will decrease permeation and thus enhance the barrier properties of the composite vis-à-vis a given permeant. Thus inorganic fillers reducing the free volume of the composite system and/or interacting poorly with a given permeant (such as talc, titanium dioxide, calcium carbonate, etc.) will enhance barrier properties vis-à-vis a number of compounds. Organic fillers may act in the same direction if they repel the particular gas/vapor (e.g., hydrophobic fillers vis-à-vis water vapor). If the composite is obtained by macroscopical or even microscopical blending of components, many desirable properties of the polymer may deteriorate. This is especially true of mechanical properties.

Such deterioration may compromise the mechanical integrity of a separation membrane. The advantage of nanocomposites resides in their intimate nanoscale mixing and a very high interface between the polymer and the added ingredients. The improvement of particular properties of the polymer component is obtained with a far smaller amount of additives. In contrast to ordinary composite materials, nanocomposites, although heterophase on a molecular scale, can be considered homogeneous on a macroscale. Therefore the nanocomposite combines the advantageous properties of its components without the decrease in the properties of the polymer because of the existence of a large heterophase and large amounts of additives. In what follows, we will focus our attention on barrier properties of various layered nanocomposite systems with a special emphasis on the preparation and the properties of polymer-layered aluminosilicate nanocomposites.

## POLYMER-LAYERED ALUMINOSILICATE NANOCOMPOSITES

### General Considerations

Polymer-layered aluminosilicate nanocomposites have recently attracted much attention in many applications.<sup>[5-9]</sup> Such nanocomposites can provide significant improvements in various properties of polymers such as mechanical,<sup>[10]</sup> thermal,<sup>[11,12]</sup> barrier,<sup>[9,13]</sup> and flame retardancy.<sup>[14]</sup> The applications of such materials extend to the automotive, electrical, biomedical, and packaging industries.<sup>[5]</sup> The remarkable properties of aluminosilicate nanocomposites are due not only to their chemical structure but to the particular properties of the lattice expanding layered clays allowing for relatively easy formation of nanocomposite materials and films. Layered aluminosilicates are semicrystalline materials consisting of 1-nm-thick lamellae and are structurally composed of sheets of octahedrally coordinated aluminum atoms sandwiched between two layers of tetrahedrally coordinated silicon atoms, such as those shown in Fig. 1.<sup>[6]</sup>

The lamellae are associated along their edges and are also stacked disorderly in the vertical direction, forming aggregates which, for the in situ clay, can have an average dimension of several micrometers.

**Fig. 1** Structure of 2:1 phyllosilicates. *Source:* From Ref.<sup>[6]</sup>; © Springer-Verlag, 1999.

The lamellae are negatively charged because of occasional internal substitutions of higher-valence atoms within the layers such as Al by lower-valence atoms such as Mg or others. This results in a diffusive negative surface charge on the lamella. The negative charge is compensated by exchangeable cations, most commonly  $\text{Na}^+$  or  $\text{Ca}^{2+}$ , that hold the structure together. The weakening of these cohesive coulombic forces by solvation leads to the expansion of the lattice. Therefore the interlamellar spaces (often called galleries) can be filled with polar molecules of different nature and sizes, including polymers. The electrostatic cohesive forces can be experimentally weakened to a point of complete dissociation of the aggregate (or particle), leaving a totally dispersed lamellae 1 nm thick and 20–50 nm in transversal length (exfoliation and delamination). Conversely, the in situ sample is often characterized by a wide distribution of aggregate sizes that can reach macroscopical dimensions. The most commonly used layered, expanding clay minerals are, among others, montmorillonites (MMTs), saponites, and hectorites, all of dioctahedral structure, often called 2:1 phyllosilicates. Their general structural formula, upper exchange capacity, and the typical average transversal dimension of the lamellar aggregate are given in Table 2.<sup>[15,33]</sup> Several methods for the preparation of polymer-layered aluminosilicate

**Fig. 2** Scheme of different types of composite arising from the interaction of layered silicates and polymers: (A) phase-separated microcomposite; (B) intercalated nanocomposite; and (C) exfoliated nanocomposite. *Source:* From Ref.<sup>[7]</sup>; © Elsevier Science, 2001.

composites are described in the literature.<sup>[5–9]</sup> Generally, there are two basic ways of proceeding (Fig. 2).<sup>[7]</sup>

One involves the use of an in situ hydrophilic aluminosilicate; the other involves the use of a structurally modified clay rendered organophilic (“organic clay”) by the insertion of alkyl chain derivatives into the expandable galleries of the pristine, hydrophilic clay. This is often accomplished by exchanging  $\text{Na}^+$  or  $\text{Ca}^{2+}$  ions against organic cations containing long alkyl chains. To form polymer–aluminosilicate composites, one or the other form of clay can be mixed with the polymer in a solution or with a polymer melt. It can also be obtained by polymerizing the monomer previously intercalated into the expanding lattice. Both ways of proceeding can lead, under proper circumstances, to exfoliation of the aluminosilicate. However, the use of the “organic” clay to obtain exfoliated systems is more frequent. As pointed out above, polymer-layered silicate nanocomposites (PLSNs) are characterized by properties vastly superior to those of ordinary microcomposites (non-lamellar non-porous systems) including barrier properties. The enhanced barrier properties of PLSNs can be explained by the so-called “tortuous path model”<sup>[16]</sup> given schematically in Fig. 3.

In this, model the “tortuosity” of the molecular trajectory of the permeant is determined by several

**Table 2** Commonly used 2:1 phyllosilicates<sup>a</sup>

2:1 Phyllosilicate	General formula	CEC <sup>[33]</sup> (mEq/100 g)	Average length <sup>b</sup> (nm)
Montmorillonite	$\text{M}_x(\text{Al}_{4-x}\text{Mg}_x)\text{Si}_8\text{O}_{20}(\text{OH})_4$	119	218
Saponite	$\text{M}_x\text{Mg}_6(\text{Si}_{8-x}\text{Al}_x)\text{O}_{20}(\text{OH})_4$	100	165
Hectorite	$\text{M}_x(\text{Mg}_{6-x}\text{Li}_x)\text{Si}_8\text{O}_{20}(\text{OH})_4$	55	46

<sup>a</sup>M = monovalent cation;  $x$  = degree of isomorphous substitution ( $0.5 \leq x \leq 1.3$ ).

<sup>b</sup>Average length of a delaminated clay particle.

Fig. 3 The tortuous path model.

parameters such as the length  $L$  of the lamellae and its state of aggregation expressed by the transversal dimension of the particle  $W$ , concentration of the delaminated clay  $\phi$ , and the mutual orientation of the lamellar planes expressed by the order parameter  $S$  defined below:<sup>[17]</sup>

$$\frac{P_s}{P_p} = \frac{1 - \phi_s}{1 + \frac{L}{2W}\phi_s\left(\frac{2}{3}\right)\left(S + \frac{1}{2}\right)} \quad (4)$$

$$S = \frac{1}{2}\langle 3 \cos^2 \theta - 1 \rangle \quad (5)$$

where  $P_s$  and  $P_p$  represent the permeabilities of the polymer-silicate nanocomposite and pure polymer, respectively;  $L$  and  $W$  are the average length and width of a delaminated clay particle, respectively; and  $\theta$  is the average angle between the normal direction  $n$  to the barrier membrane and the normal direction to the surface of the lamellar plane  $p$ , as shown in Fig. 4.

It follows from this model that for a given concentration  $\phi$  of the aluminosilicate, barrier properties are maximized for a composite with highly delaminated aggregates (high  $L/W$  ratio) and a high degree of lamellar orientation ( $S \rightarrow 1$ ).

### Preparation of Polymer-Layered Silicate Nanocomposites

As pointed out earlier, several preparation methods of PLSNs exist. One method frequently used is based on an in situ intercalative polymerization of an inserted monomer.

#### In situ intercalative polymerization

A monomer in the form of a vapor, liquid, or solution in a poorly adsorbing solvent is brought into contact with the layered silicate.<sup>[18-27]</sup> The monomer interacting strongly with the exchangeable cations can then

Fig. 4 Effect of sheet orientation on the relative permeability in exfoliated nanocomposites  $\phi_s = 0.05$  and  $W = 1$  nm. Source: From Ref.<sup>[17]</sup>; © American Chemical Society, 2001.

be polymerized by means of initiators, which may be deposited on the clay or dissolved in the liquid phase. The polymerization can also be brought about by gamma radiation. This method does not lead to completely exfoliated nanocomposites. It produces aggregated particles with a high silicate content and an intergallery polymer in which the stereostructure may keep a “memory” of its polymerization matrix.<sup>[19,20]</sup>

#### Intercalation by a molten polymer

In this method, the polymer is heated to a melt and blended with the clay mineral.<sup>[28–32]</sup> The mineral may be of a pristine hydrophilic nature or a modified “organic” hydrophobic clay. The blending may be assisted by hydrodynamic shear forces (shear produced by mixing, extrusion, etc.). Under such circumstances, the polymer is likely to diffuse into the interstices and galleries of the aluminosilicate particles. In the case of strong interactive forces between segments of the polymer chain and the lamellae of the aluminosilicate, exfoliation of clay particles may take place, leading to polymer–clay hybrid nanocomposites. The effectiveness of blending will depend on parameters such as the melt viscosity, molecular mass, segmental structure of the polymer, and its softening temperature. The advantages of this approach are its simplicity, effectiveness, and the possibility of using a variety of large-scale formulations.<sup>[13]</sup> The disadvantage resides in the possibility of thermal degradation of the polymer in the blend.

#### Exfoliation–adsorption from solvent

The clay mineral (often in its “organic” form) is treated by a (relatively volatile) solvent with a high affinity for both the polymer and the clay mineral.<sup>[33–35]</sup> The solvent intercalates into the galleries of the aluminosilicate under conditions leading to exfoliation. It is then blended with a solution of the polymer. The polymer chain, through strong segmental interactions with the surface of the individual lamellae, replaces the solvent through cooperative segmental diffusion. The elimination of the solvent through evaporation leads then to formation of an ordered multilayer nanocomposite. This approach to the formation of multilayered nanocomposites is not favored in industries because of the high cost of solvents and of their disposal.

#### Electrostatic layer-by-layer self-assembly

In this technique, a clay mineral (“organic” or pristine) is deposited from a solution (or suspension) on a smooth substrate (glass, mica, polymer, etc.) by dipping the substrate into a solution of a positively

charged polyelectrolyte.<sup>[36–40]</sup> Thus a positively charged surface is developed on the substrate on which negatively charged, ordered lamellae of aluminosilicate can be easily deposited by dipping the now positively charged substrate into a suspension of a finely dispersed aluminosilicate preferentially in a highly exfoliated state. An ordered, negatively charged lamellar layer is formed on top of the positively charged polymer. If necessary, the underlying substrate can be disposed off, generating free-standing nanocomposite films.<sup>[41,42]</sup> The process of dipping can be repeated and varied to build ordered multilayered systems with several components, leading to a variety of film-forming and membrane-forming nanocomposite materials, which can be used for the separation of gases and vapors and other barrier applications. This approach to forming organic/inorganic nanocomposites has many advantages—it is simple, economical, and flexible. A variety of high-performance materials can be produced because of the synergistic effects of individual organic and inorganic components. It can be used directly in industries for coating various substrates such as cellulose acetate,<sup>[42]</sup> PET,<sup>[43,44]</sup> Nafion™,<sup>[45]</sup> etc.

### Barrier Properties of Polymer-Layered Silicate Nanocomposites

Messersmith and Giannelis<sup>[25,26]</sup> have reported on the permeability to water vapor of nanocomposite films based on poly( $\epsilon$ -caprolactone) (PCL) and delaminated organic aluminosilicates prepared by in situ intercalative polymerization. An 80% reduction in water vapor permeability compared to the unfilled PCL was observed for only a 4.8% volume of the aluminosilicate in the composite films due probably to the increased tortuosity path length (Fig. 5).<sup>[25]</sup>

Nanocomposites prepared by melt extrusion have attracted much industrial attention because of the simplicity of the preparation process and the possibility of using a variety of large-scale formulations. Recently, barrier properties of melt extruded clay nanocomposites for ethylene-co-vinyl alcohol (EVOH),<sup>[28]</sup> polyethylene,<sup>[29]</sup> and polyamide<sup>[30]</sup> have been reported. Furthermore, property improvements for such nanocomposites were observed in tensile strength and Young’s modulus. In melt extrusion, it should be noted that the formation of strong barrier membranes requires not only a good organoclay–polymer compatibility but also optimum processing conditions.<sup>[31]</sup>

Yano et al.<sup>[33,34]</sup> have reported the effects of the average length of the exfoliated clay particles on gas (O<sub>2</sub>, H<sub>2</sub>O, and He) permeabilities for polyimide nanocomposites prepared by the exfoliation–adsorption

**Fig. 5** Relative permeability ( $P_c/P_o$ ) vs. volume fraction silicate for nanocomposite films. Source: From Ref.<sup>[25]</sup>; © Wiley Interscience, 1995.

method. According to Eq. (4), the permeability depends on the length  $L$  of the exfoliated clay particle (see Table 2 and Fig. 6).<sup>[33]</sup>

It should be also noted that a 2 wt.% concentration of MMT in polyimide membranes reduced the permeability coefficients of various gases by 50%.<sup>[34]</sup> Although the barrier properties of polymer films containing conventional fillers decrease linearly with the filler content, the polyimide nanocomposites showed a much more pronounced decrease of permeability as a function of the filler content and of the aspect ratio of the particle, as shown in Fig. 7.<sup>[35]</sup>

The technique of ELBL formation of barrier materials was only very recently described. As pointed out earlier, this method has a significant potential to form highly ordered nanocomposites. The ordering of

**Fig. 6** Relative permeability with respect to water vapor as a function of the average length of the exfoliated clay particle (aspect ratio) in polyimide–clay nanocomposites. Source: From Ref.<sup>[33]</sup>; © Wiley Interscience, 1997.

aluminosilicates is an important factor in enhancing the barrier properties of nanocomposite membranes. The first ELBL nanocomposite film was reported by Kleinfeld and Ferguson<sup>[40]</sup> An example of materials and a schematic of the procedure for an alternate layer-by-layer adsorption process are shown in Fig. 8.<sup>[46]</sup>

In this process, exfoliated aluminosilicate nanoparticles are prepared by means of extensive shaking, sonication, and centrifugation of their water suspensions.<sup>[47]</sup> The exfoliated particles of the aluminosilicates are then deposited on a substrate and a nanolayer of a cationic polyelectrolyte is deposited on top of the exfoliated clay. The thickness control of the nanofilm is maintained by a repetition of steps described above. Kotov et al.<sup>[43]</sup> studied the barrier properties of nanocomposite films of MMT and cationic polyelectrolytes such as poly(vinylpyridinium) (Fig. 9) and others using an untreated PET substrate.

The permeation rate of  $O_2$  decreased linearly with the number of deposition cycles, as shown in Fig. 10.<sup>[43]</sup>

However, the permeation rate for water vapor did not change regardless of the number of deposited layers because of the intrinsic hydrophilic nature of the polyelectrolytes and of the clay. Kim et al.<sup>[45]</sup> achieved a substantial reduction in water vapor permeation rate using cationic polyacetylenes substituted with a long alkyl chain such as poly(*N*-octadecyl-2-ethynylpyridinium bromide) and saponite nanoplatelets on Nafion<sup>TM</sup> substrate (Fig. 11).

Such systems displayed an increase of barrier properties with the number of deposited layers and a very substantial decrease of permeability with respect to the substrate. For example, the water vapor permeability of this nanocomposite decreased by 95% when compared to the pristine Nafion<sup>®</sup> film.<sup>[45]</sup> This rather dramatic effect may be explained by the

**Fig. 7** Relative permeability of  $CO_2$  as a function of clay concentration in the polyimide–clay nanocomposites. The inset illustrates a possible self-similar aggregation mechanism for the clay platelets. Source: From Ref.<sup>[35]</sup>; © American Chemical Society, 2001.

**Fig. 8** Procedure for alternate layer-by-layer adsorption. *Source:* From Ref.<sup>[46]</sup>; © Elsevier Science, 2001.

formation of an ordered micellar structure of polyacetylene furthered by the long hydrocarbon substituent when adsorbed on the surface of the clay platelet. In this respect, one can think that the partial crystallinity of the polymer film, because of chain order on surfaces (epitaxial or otherwise), can contribute to enhancing the barrier properties of polymer-clay nanocomposites. Electrostatic layer-by-layer nanocomposite films can be deposited on various substrates such as PET, cellulose acetate, EVOH, etc. The technique of

**Fig. 9** Structure of polyelectrolytes used for the preparation of MMT-polyelectrolyte LBL assemblies. *Source:* From Ref.<sup>[43]</sup>; © American Chemical Society, 2001.

**Fig. 10** Dependence of the permeation rate of oxygen through PET substrate coated with  $(P_1/M)_n$  (●) and  $(P_2/M)_n$  (□) film on the number of deposition cycles  $n$ . *Source:* From Ref.<sup>[43]</sup>; © American Chemical Society, 2001.

cross-linking of polyelectrolyte films has also been reported to contribute to the increase in vapor and gas barrier properties of nanocomposite films while simultaneously improving their pH stability, heat resistance, and mechanical properties.<sup>[44,48]</sup> This effect was illustrated in the case of heat-induced amide formation. Ku et al.<sup>[44]</sup> have prepared electrostatically layered aluminosilicate nanocomposites by sequential deposition of poly(allylamine hydrochloride) (PAH)/poly(acrylic acid)/poly(allylamine hydrochloride)/saponite on PET film. The oxygen permeability of cross-linked nanocomposites decreased with the heating temperature (i.e., the degree of cross-linking). Composite films prepared by 10 deposition cycles followed by heating at 190°C for 2 hr produced films with one third of the permeability of the uncoated PET film. Therefore cross-linking of the multilayer components may enhance water vapor and gas barrier properties. As mentioned above, such properties depend also on the crystallinity of the polymer layer and, in some cases, both factors may contribute simultaneously to the increase of barrier properties. Cross-linking also improves the mechanical properties of the film. In some applications, it is needed to avoid food contact with inorganic materials in nanocomposite packaging containers. Multilayered nanocomposites produced by using existing dies may be an

**Fig. 11** Structure of poly(*N*-octadecyl-2-ethynylpyridinium bromide).

alternative for these applications. In this process, nanocomposite materials form an internal layer and are sandwiched between two other unfilled polymer layers. Nylon is a suitable material for a barrier layer because it is an effective gas barrier and has good adhesion to PET. The clay content of the central Nylon layer was reported to range between 1% and 3 wt%.<sup>[49]</sup> This approach can improve recyclability and optical transparency.<sup>[13]</sup> In spite of several advantages, it should be noted that barrier properties of such nanocomposite films will be adversely affected by the unfilled polymer layers.

### MULTILAYERED POLYMER-POLYMER NANOCOMPOSITES

Multilayered polymer-polymer nanocomposites (MPPNs) are formed through nanolayers of different pristine polymers deposited successively on top of each other. The most direct method leading to the formation of MPPNs is the electrostatic layer-by-layer (ELBL) self-assembly described above. Multilayered polymer-polymer nanocomposites are used in the formation of protective barriers in which the advantageous properties of its nanolayer components are combined to give effective protection from various gases and vapors. Here as in previously described nanocomposite films, because of the nanodimensional thickness of such coatings and films, a number of deleterious properties such as opacity, thermal resistance, and lack of flexibility leading to mechanical failure can be avoided. It was reported that the ordered nanolayered or microlayered coextrusion could provide

higher barrier properties when compared to the conventional melt blends.<sup>[50]</sup> After coextrusion, the permeability was measured and related to the number of layers and morphology. Multilayered polymer nanocomposite films prepared by layer-by-layer self-assembly without additives have been also investigated<sup>[51]</sup> for gas, alcohol/water, ion, and proteins separation. Zhou et al.<sup>[52,53]</sup> prepared poly(*N*-octadecyl-2-ethynylpyridinium bromide) and PSS nanocomposite films on a Nafion<sup>TM</sup> substrate using ELBL assembly and Langmuir-Blodgett (LB) techniques. The membranes displayed a high permselectivity for oxygen ( $\alpha = 3.5-4.7$ ) because of the strong affinity of conjugated double bonds to oxygen.<sup>[54]</sup> Sullivan and Bruening<sup>[55]</sup> recently reported polyimide membranes on porous alumina supports obtained through electrostatic deposition of poly(amic acid) salts and PAH followed by heating at 250°C for 2 hr. These are shown in Fig. 12. Such polyimide membranes displayed high-flux permselectivities ( $O_2/N_2$  up to 6.9 and  $CO_2/CH_4$  up to 68).

### MISCELLANEOUS SYSTEMS

Thin film metal oxide on polymer substrates can be used as barrier coatings and films in various applications such as, for example, in protecting pharmaceuticals and food products from oxygen.<sup>[56-60]</sup> In this process, many attempts to optimize oxygen barrier properties have been carried out with respect to adhesion, internal stress, and nanoscopy and microscopical defects. The polymer/metal oxide nanocomposites were also used as gas separation membranes. Poly(amide-imide)/TiO<sub>2</sub> nanocomposite membranes

**Fig. 13** The variety of micellar mesostructures obtained with monomers and polymers of diacetylene substituted with ethylene oxide (EO) side groups of different lengths ( $n$ ). Source: From Ref.<sup>[60]</sup>, © American Chemical Society, 2001.

were also described.<sup>[58]</sup> The permselectivities of such membranes attained 50.8 in the case of  $H_2/CH_4$  by using only 7.3% of the incorporated  $TiO_2$ . In contrast to the conventional concept, Merkel et al.<sup>[59]</sup> recently reported on the preparation of ultrapermeable nanocomposite membranes using glassy amorphous poly(4-methyl-2-pentyne) (PMP) and fumed silica particles. Although conventional, size-selective, polymer membranes allow small molecules to preferentially permeate, the reverse-selective membranes allow larger species to diffuse preferentially. The reverse selectivity of such membranes results from inefficient chain packing, producing an increase in the free volume of the polymer. The nanosized filler particles such as fumed silica play an important function as nanospacers, preventing rigid PMP chains from orderly packing and thus increasing the reverse selectivity. The nanocomposite structure of polydiacetylene (PDA) and silicic acid can be tuned by different hydrophilic head groups  $(EO)_n$ , as shown in Fig. 13. The hexagonally ordered PDA ( $n = 5$ )/silica nanocomposites showed significantly lower permeabilities when compared to pure polymers.<sup>[60]</sup>

## CONCLUSION

During the last decade, nanocomposite membranes were extensively used in the formation of coatings, films, and separation membranes. This field is characterized by vigorous research in the area of barriers and permselectivity. Exfoliation and ordering of aluminosilicate nanoparticles are key factors for enhancing the barrier properties of polymer–mineral nanocomposites. Among various methods of membrane formation, ELBL self-assembly was shown to be a promising technique. In addition to synthetic and structural improvement of such barrier materials, cost and production effectiveness still have to be enhanced in the future.

## ACKNOWLEDGMENTS

We gratefully acknowledge the financial support of the U.S. Army. We thank D. Steeves, P. W. Gibson, D. Froio, J. Lucciarini, and J. A. Ratto of the U.S. Army for the measurements of barrier properties and helpful comments. We also appreciate the PET film gift of Bobby Reekers of Dupont Co.

# Basic Nanostructured Catalysts

Robert J. Davis

Department of Chemical Engineering, University of Virginia, Charlottesville, Virginia, U.S.A.

## INTRODUCTION

Solid bases catalyze a wide variety of chemical transformations (e.g., condensations, alkylations, cyclizations, and isomerizations). However, compared with their solid acid analogues, they have received relatively little attention from the industrial and academic communities. The search for novel solid bases that catalyze reactions with high product selectivity, high reaction rate, and low deactivation rate is an ongoing process. The following text describes current research trends in the design and utilization of nanostructured solid bases composed mainly of supported metals and metal oxides.

## HISTORICAL PERSPECTIVE

The earliest use of alkalis was probably about 4000 B.C. during the New Stone Age period in the production of quicklime (CaO) by roasting limestone (CaCO<sub>3</sub>).<sup>[1]</sup> The early uses of quicklime were for the removal of fat and hair from leather and in the production of cement. Around 3000 B.C., a dilute solution of potash (K<sub>2</sub>CO<sub>3</sub>) produced by leaching ashes from wood fires was found to have cleaning powers.<sup>[1]</sup> Adding fat to the solution likely formed the first soap. At about the same time, evidence shows that glass containing sodium carbonate was also being produced. These early uses of bases preceded the common uses of acids by several thousand years. The first commonly used acid was probably acetic acid because it was used to prepare white lead pigment around 300–400 B.C.<sup>[1]</sup>

Despite the tremendous lead time in technology with bases, applications in catalysis by solid bases lag far behind that by solid acids. Tanabe and Holderich<sup>[2]</sup> recently performed a statistical survey of industrial processes using solid acids, solid bases, and acid–base bifunctional catalysts and have counted 103, 10, and 14 industrial processes for these types of catalysts, respectively. The number of acid-catalyzed processes outnumbers those catalyzed by solid bases by an order of magnitude. However, as novel base materials are discovered and new base-catalyzed reactions are found to be commercially relevant, new processes are sure to appear.

## DEFINITION AND EVALUATION OF BASICITY

Basicity, in the context of the following discussion, can be defined in the Lewis sense as the donation of electrons from a solid surface to an acceptor species. Thus for a typical solid base such as a metal oxide, the exposed metal cation is regarded as a Lewis acid site and the exposed oxygen atom is regarded as a Lewis base site, as illustrated in Fig. 1. Because basicity is related to the electronic charge on the oxygen atom, it is important to understand how this charge depends on composition. One very simple method that is often used to compare structurally similar compounds is based on the intermediate electronegativity principle of Sanderson. The Sanderson intermediate electronegativity ( $S_{E,int}$ ) of a solid is calculated from the mean of the individual electronegativities of the elements present according to Eq. (1), where  $S_{E,Z}$  is the individual electronegativity of element  $Z$  and  $x$  is the atomic ratio of element  $Z$  present. The general idea is that an equalization of the electronegativities in a compound results from electron transfer that occurs in the formation of the compound.<sup>[3]</sup> The calculation of the intermediate electronegativity takes into account only the composition of the compound, ignoring the effect of structure and surface composition. From the Sanderson intermediate electronegativity, the partial negative charge on oxygen ( $\delta_q)_O$  can be calculated from Eqs. (2) and (3). A high partial negative charge on oxygen indicates strong basicity of the oxide surface:

$$S_{E,int} = \left( \prod S_{E,Z}^x \right) (\sum x)^{-1} \quad (1)$$

$$\Delta S_{E,O} = 2.08(S_{E,O})^{1/2} \quad (2)$$

$$(\delta_q)_O = \frac{(S_{E,int} - S_{E,O})}{\Delta S_{E,O}} \quad (3)$$

Typical measurements of basicity are obtained by titration with indicators having a wide range of  $pK_a$  values. For a reaction of an acid indicator BH with a solid base B\* (Eq. (4)), the Hammett basicity function  $H_-$  is defined by Eq. (5), where [BH] is the concentration of the indicator and [B<sup>-</sup>] is the concentration of its conjugate form. One problem with using adsorbed indicators to evaluate basicity is the interference of

**Fig. 1** Schematic illustration of Lewis acid and Lewis base sites on a metal oxide surface. M represents a surface metal cation and O represents a surface oxygen anion.

indicator reactions that are not because of acid–base chemistry. In addition, evidence of reaction is often provided by a color change, which requires the use of colorless catalysts. Clearly, there is a need for other methods to probe surface base sites:

$$\text{H}_- = \text{p}K_a + \log \frac{[\text{B}^-]}{[\text{BH}]} \quad (5)$$

One commonly used method to study solid base sites involves adsorption of a probe molecule followed by examination with infrared (IR) spectroscopy. Infrared spectrometric studies of various probe molecules adsorbed on solid bases have been reviewed by Lavalley.<sup>[4]</sup> One of the major problems with this technique is that many of the commonly used probe molecules decompose or react on interaction with the basic site, and thus do not effectively interrogate the catalyst surface. For example, pyrrole has been found to dissociatively chemisorb on highly basic metal oxides such as  $\text{ThO}_2$  and  $\text{CeO}_2$ , forming the  $\text{C}_4\text{H}_4\text{N}^-$  pyrrolate anion.<sup>[4]</sup> A probe molecule should undergo specific chemical interactions with the base sites without dramatically altering the catalyst surface. Therefore the search for a unique, widely applicable adsorbate molecule to probe the surface base sites of heterogeneous catalysts is a daunting process. No single probe is universally adept at characterizing the active sites on all basic solids. Carbon dioxide is probably the most widely used probe for surface basicity because of its stability and ease of handling. Because carbon dioxide is a weakly acidic molecule, it selectively adsorbs on base sites. However, carbon dioxide adsorption on metal oxides results in many different types of surface species, which can complicate interpretation.

Temperature-programmed desorption (TPD) of adsorbed probe molecules can also be used to measure the number and strength of sites found on solid base catalysts. Because strongly bound probe molecules have high adsorption energies, increased temperatures are necessary to desorb these species. Experiments are typically performed under identical experimental conditions (carrier gas flow, heating rate, and sample size)

so that a qualitative comparison can be made between samples. During a TPD experiment, the amount of desorbed molecules is often monitored by mass spectrometry and the surface interactions are explored with IR spectroscopy.

## NANOSTRUCTURED MATERIALS AS SUPPORTS FOR BASES

Alkali metals and metal oxides are among the strongest bases known. However, these materials typically have a very low surface area that limits their ability to be effective catalysts. New material processing technology can be used to create bulk materials with very high surface-to-volume ratios (i.e., very small crystallite sizes), but the resulting fine powders become very difficult to use as heterogeneous catalysts. Therefore basic metals and metal oxides are often supported on high surface area carriers to achieve high dispersion of the base sites without sacrificing ease of handling.

To illustrate the concept of supporting alkali metal oxides on supports, Dorskocil, Bordawekar, and Davis<sup>[5]</sup> loaded rubidium onto magnesia, titania, alumina, carbon, and silica by decomposition of an impregnated acetate precursor at 773 K. Results from x-ray absorption spectroscopy indicated that the local structure around Rb was highly dependent on the support composition. For example, the Rb–O distance was significantly shorter on carbon and silica compared with more basic carriers. Results from  $\text{CO}_2$  stepwise TPD showed that Rb/MgO possessed strongly basic sites that were not present on pure MgO. However, the basic sites formed by Rb addition to the other supports were weaker than those on Rb/MgO. The TPD experiments were complemented by adsorption microcalorimetry of both ammonia (titrates acid sites) and carbon dioxide (titrates base sites) on the same samples.<sup>[6]</sup> Microcalorimetry revealed that incorporation of rubidium onto the supports neutralized acid sites and created new base sites. Decomposition of 2-propanol at 593 K was used as a probe reaction to relate catalytic activity to surface basicity.<sup>[5]</sup> As anticipated, Rb/MgO and MgO were highly active and selective for dehydrogenation of alcohol. The addition of Rb to alumina and titania significantly decreased the activity of the support oxides for the acid-catalyzed dehydration of 2-propanol. Both reactivity and characterization results on Rb/SiO<sub>2</sub> were consistent with the formation of a highly disordered, weakly basic, surface silicate phase that exhibited little activity for alcohol decomposition. Evidently, highly basic rubidium oxide reacted with the silica surface, probably through surface hydroxyl groups, to form rubidium silicate. Because the overall rate of acetone formation from 2-propanol correlated with the ranking of support

basicity, as evaluated from the Sanderson intermediate electronegativity principle, strongly basic alkali-containing catalysts should utilize basic carriers to minimize alkali-support interactions that lower base strength.

It has become clear that to have strongly basic catalysts on conventional supports, the carrier should be preconditioned with a base to create a surface phase that can accommodate a strong base. Another strategy used to support bases involves incorporation into the nanopores of a crystalline material such as a zeolite. The following discussion focuses on the most commonly studied nanostructured materials that have been explored as supports for base catalysts.

## Zeolites

Zeolites are highly porous aluminosilicates that are constructed from  $\text{TO}_4$  tetrahedra (T = tetrahedral atom, e.g., Si, Al), with each apical oxygen atom shared with an adjacent tetrahedron. When tetrahedra containing  $\text{Si}^{4+}$  and  $\text{Al}^{3+}$  are connected to form a three-dimensional zeolite framework, a negative charge is associated with each  $\text{Al}^{3+}$  atom. The negative framework charge is balanced by an exchangeable cation to achieve electrical neutrality. Some of the counterions in the zeolite pores can be readily exchanged with other cations, altering the acid-base character of the zeolite framework. Exchanging zeolites with a less electronegative charge-balancing cation such as cesium creates a more basic zeolite. An excellent review of basic zeolites was written by Barthomeuf.<sup>[7]</sup>

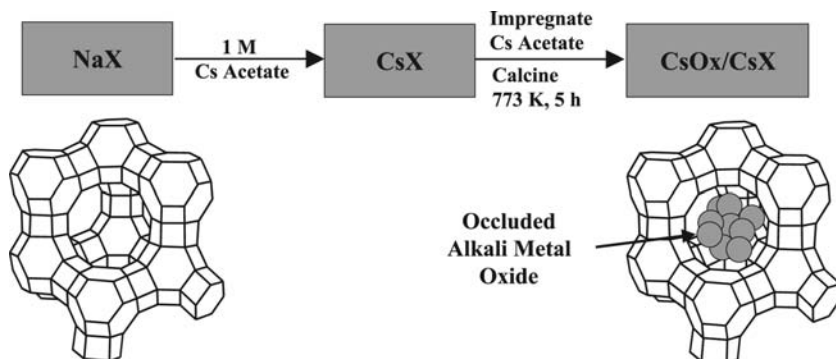

The main feature that makes zeolites very interesting nanostructured supports is that their pores are uniform in size and are in the same size range as small molecules. Zeolites are molecular sieves because they discriminate molecules based on size. Molecules smaller than the pore size are adsorbed in the crystal interior, whereas those that are larger are excluded. This feature of zeolites creates a unique reaction environment for supported base catalysts, if the base sites are located in the micropores.

## Alkali Metal Oxides in Zeolite Pores

Fig. 2 illustrates a typical procedure for incorporating alkali metal oxide clusters into the pores of zeolite X. Zeolite X is of the faujasite type with a Si/Al ratio ranging from 1 to 1.5. The rather high content of aluminum in the structure indicates that the framework has a substantial negative charge that is balanced by exchangeable cations. The exchangeable cations are usually replaced with heavy alkali metal cations prior to impregnating an alkali metal compound. In Fig. 2, an aqueous solution of cesium acetate is impregnated into the micropores of Cs-exchanged X zeolite. Thermal treatment in air is sufficient to decompose the acetate precursor and leave behind alkali metal oxide in the pores of the zeolite.

The basic properties of cesium oxide occluded in the pores of zeolite X have been characterized by a wide variety of methods, including  $\text{CO}_2$  adsorption microcalorimetry,<sup>[8,9]</sup>  $\text{CO}_2$  TPD,<sup>[9-14]</sup> IR spectroscopy of adsorbed  $\text{CO}_2$ ,<sup>[10,15]</sup> nuclear magnetic resonance (NMR) spectroscopy,<sup>[10,16,17]</sup> and x-ray absorption spectroscopy.<sup>[15]</sup> For basic zeolites containing occluded Cs oxide that have been thermally activated at about 773 K, most of the  $\text{CO}_2$  desorbed with a peak temperature less than 573 K. This result suggests a rather moderate base strength for the occluded Cs species. In fact, results from  $\text{CO}_2$  adsorption microcalorimetry indicated that most of the adsorption sites at 373 K are characterized by an adsorption enthalpy of about  $-100 \text{ kJ mol}^{-1}$ , which is hundreds of kilojoules lower in magnitude than that anticipated for adsorption of  $\text{CO}_2$  on a stoichiometric alkali metal oxide.

The stoichiometry of the occluded alkali metal oxide cluster is still an open question. Lasperas et al.<sup>[13,14]</sup> used TPD of  $\text{CO}_2$  from cesium oxide loaded onto CsX zeolite to measure an adsorption stoichiometry of one  $\text{CO}_2$  desorbed per occluded pair of Cs atoms. Because that ratio matches the ideal reaction stoichiometry of  $\text{Cs}_2\text{O}$  plus  $\text{CO}_2$  to form  $\text{Cs}_2\text{CO}_3$ , they concluded that the oxide in the zeolite pores was likely  $\text{Cs}_2\text{O}$ . In contrast, Bordawekar and Davis<sup>[8]</sup> reported results from  $\text{CO}_2$  adsorption microcalorimetry that

**Fig. 2** Synthesis procedure for preparing cesium oxide species in the supercages of Cs-exchanged zeolite X.

indicated an adsorption stoichiometry of one  $\text{CO}_2$  adsorbed per four occluded Cs atoms. An explanation for the difference is not readily apparent. What appears to be consistent from the various works is that cesium is fairly well distributed throughout the zeolite pores at loadings below about two cesium atoms per supercage. At higher loadings, cesium deposits on the external surface of the zeolite.

The rather moderate base strength evaluated by  $\text{CO}_2$  adsorption microcalorimetry suggests that the occluded Cs is not in a form that is typical of a stoichiometric alkali oxide. Krawietz, Murray, and Haw<sup>[18]</sup> recently reported that they could not successfully prepare bulk-phase  $\text{Cs}_2\text{O}$  by conventional chemical methods, whereas stoichiometric lighter alkali metal oxides could be prepared. The heavy alkali preferred instead to form higher oxides. Their intriguing result points to the possibility that higher oxides such as cesium peroxide and cesium superoxide might be present in zeolite-supported cesium oxide samples. Indeed, higher oxides of Cs should exhibit less base strength than the stoichiometric oxide  $\text{Cs}_2\text{O}$ . Yagi and Hattori<sup>[19]</sup> have shown that dioxygen retains its molecular identity when adsorbed on thermally activated cesium oxide clusters occluded in zeolite X. In other words, exposure of the material to  $^{18}\text{O}_2$  yields both  $^{18}\text{O}_2$  and  $^{16}\text{O}_2$  in the gas phase, with only traces of  $^{18}\text{O}^{16}\text{O}$  being observed. A mechanism involving the formation of peroxides was invoked to explain the isotopic distribution. Although the authors of that study speculate that the zeolite initially contained  $\text{Cs}_2\text{O}$  clusters, the presence of peroxides should not be ruled out.

Intrazeolitic clusters of cesium oxide species are active in a variety of base-catalyzed reactions. For example, the decomposition of 2-propanol to acetone was catalyzed by cesium oxide species in Y zeolite at a rate (based on surface area) comparable to  $\text{MgO}$ .<sup>[20]</sup> In general, solid bases catalyze the dehydrogenation of 2-propanol to acetone, whereas solid acids typically catalyze dehydration to propene. Another reaction catalyzed by basic materials is the cycloaddition of  $\text{CO}_2$  to an oxirane such as ethylene oxide. The rather moderate adsorption strength of  $\text{CO}_2$  on zeolites containing occluded alkali metal oxides indicates that  $\text{CO}_2$  might be useful as a reagent in catalytic reactions on these solids.

Reactions of  $\text{CO}_2$  with ethylene oxide and epoxypropylbenzene were studied over a series of base catalysts, including alkali-loaded X zeolites, Cs-loaded alumina, magnesia, and a homogeneous catalyst, tetraethylammonium bromide.<sup>[21]</sup> Interestingly, the site time yield (defined here as the total number of product molecules formed divided by the number of  $\text{CO}_2$  adsorption sites divided by the total reaction time) of the homogeneous catalyst was only three to four times greater than that of the basic zeolite catalysts containing occluded alkali metal oxide for the cycloaddition of  $\text{CO}_2$  to ethylene oxide. Perhaps the most important part of that study was the demonstration that the porosity of the catalyst influenced the conversion of epoxides. A schematic illustration of the concept is presented in Fig. 3. Ideally, the nonmicroporous base  $\text{MgO}$  should catalyze  $\text{CO}_2$  addition to ethylene oxide regardless of the presence of larger molecules because  $\text{MgO}$  exposes very accessible catalytic surface sites. However, steric restrictions in the pores of a zeolite should affect ethylene oxide conversion in the presence of large molecules. Table 1 summarizes the site time yields measured during the various runs with pure and mixed feeds. Pure ethylene oxide reacted at about the same rate over the zeolite and  $\text{MgO}$  catalysts. For mixed epoxide experiments, both epoxypropylbenzene and its cyclic carbonate retarded the diffusion of ethylene oxide into the zeolite pores and severely reduced (by almost an order of magnitude) the rate of ethylene carbonate production. However, the bulky reactant and product negligibly affected (less than a factor of 2) the rate of ethylene carbonate production over non-microporous  $\text{MgO}$ . These results indicate that most of the basic sites of the zeolite catalysts containing occluded alkali metal oxide species were located within the micropore network and suggest their use as shape-selective base catalysts. Future work with these materials should exploit the molecular sieving property of the zeolite support. Of course, care must be utilized with highly polar solvents and products because the alkali metal oxides would be expected to leach with time in those liquid systems.

Zeolites containing occluded cesium oxide species are also active catalysts in the double-bond isomerization of 1-butene,<sup>[8–12]</sup> even at temperatures as low as 273 K.<sup>[11,12]</sup> The *cis/trans* ratio of the product

<sup>b</sup>EO = ethylene oxide; EPBz = 2,3-epoxypropylbenzene.

<sup>c</sup>EC = ethylene carbonate; BzD = 4-benzyl-1,3-dioxolan-2-one.

<sup>d</sup>Defined as (molecules of product) × (number of CO<sub>2</sub> adsorption sites)<sup>-1</sup> × (total reaction time)<sup>-1</sup>.

Source: From Ref.<sup>[21]</sup>.

2-butenes typically ranges from about 10 to 20, indicating a base-catalyzed reaction path. Given the rather moderate base strength of the catalysts as determined by CO<sub>2</sub> microcalorimetry, the high activity of the occluded cesium is quite impressive. Because the active sites for butene isomerization are readily poisoned by CO<sub>2</sub>, the active site density can be measured by selective regeneration of the poisoned catalyst at various temperatures. Using this method, Li and Davis<sup>[9]</sup> discovered that about 5% of the base sites titrated by CO<sub>2</sub> adsorption at 373 K is responsible for butene isomerization on CsOx/CsX. Evidently, most of the basic sites counted by CO<sub>2</sub> adsorption do not play any role in the butene isomerization reaction. Similar conclusions were reported by Yagi et al.<sup>[12]</sup> Only very few strong basic sites account for the high activity of the catalysts.

### Alkali metal clusters in zeolite pores

Zeolites containing alkali metals in the pores are strong base catalysts. Martens et al.<sup>[22–25]</sup> have reported a unique method for synthesizing zeolite-supported alkali metals via azide precursors. Unlike their alkali metal counterparts, the azides themselves are stable at ambient conditions. Decomposition of the alkali azide in the pores of the zeolite forms either ionic or neutral alkali metal clusters, depending primarily on the heating rate used to decompose the supported azide. As determined by electron spin resonance (ESR) spectroscopy, a fast heating rate of 25 K min<sup>-1</sup> formed ionic clusters, whereas a slow heating rate of 1 K min<sup>-1</sup> formed primarily neutral metal clusters.<sup>[23]</sup>

In separate studies, ESR spectroscopy of the alkali metal-loaded KX zeolites indicated the formation of potassium clusters, despite using other alkali azides

as precursors.<sup>[15,26]</sup> Apparently, the zeolite cations exchanged with the impregnated alkali either during azide impregnation or thermal treatment. The reduction of potassium ions by cesium metal makes sense thermodynamically, but the reduction of potassium ions by sodium metal is harder to rationalize. Perhaps the large amount of potassium in the zeolite facilitates the transformation. Quantitative work clearly needs to be done in this area. Interestingly, some of the zeolites also exhibited broad ESR lines at high *g*-values, indicating the presence of additional extra lattice alkali metal clusters. The relative importance of extra framework metal clusters in catalytic reactions must be determined.

The microcalorimetry of O<sub>2</sub> adsorption on thermally activated zeolite samples containing occluded alkali metals revealed very high initial enthalpies of –300 to –400 kJ mol<sup>-1</sup>, possibly indicating the formation of alkali metal oxides and peroxides.<sup>[8]</sup> However, the uptake of O<sub>2</sub> was always orders of magnitude lower than the content of alkali metal azide that was loaded into the zeolites. Therefore the active site density in these materials was probably very low. Because adsorption of small molecules such as O<sub>2</sub> and CO<sub>2</sub> is irreversible, poisoning of these catalysts can be problematic if impure feeds are used.

The side-chain alkylation of aromatics with olefins is catalyzed by strong solid bases such as alkali metals. Thus Martens et al.<sup>[25]</sup> studied the side-chain alkylation of alkylaromatics with ethylene over zeolites containing occluded alkali metals. They observed that the alkylation activity of Na metal in NaX zeolite was higher than that of Na metal in NaY zeolite. In addition, the alkylation activity for isopropylbenzene was lower than that of ethylbenzene, possibly because of steric effects.

The liquid-phase alkenylation reaction of *o*-xylene with butadiene to form 5-*o*-tolyl-2-pentene (OTP) is also catalyzed by zeolite-supported alkali metals.<sup>[15]</sup> Like toluene alkylation with ethylene, the alkenylation reaction requires a stronger base site than that associated with supported alkali metal oxides. The selectivity to OTP, based on the total amount of monoalkenylated, dialkenylated, and trialkenylated products, was greater than 85% for *o*-xylene conversions ranging from 1% to 14%. However, extra lattice metal clusters were evident on each of the alkali-metal-loaded zeolites that were effective catalysts for the alkenylation reaction, suggesting that these clusters might be the active species. For each reaction in which OTP was produced, the solution color indicated that alkali metal formed from the decomposition of the supported azide may have leached into solution to form an organoalkali complex. Thus catalytic activity was likely because of metal species in the solution as well as those associated with the zeolite (possibly through reaction with the

zeolite). Shape-selective reactions on these catalysts might be problematic in the liquid phase.

Zeolites containing alkali metals also catalyze reactions such as butene isomerization<sup>[8,22]</sup> and aldol condensation of acetone.<sup>[25]</sup> However, these reactions do not require the alkali to be in metallic form to be catalytic. It is very likely that the alkali metal clusters are converted into supported oxides or hydroxides during aldol condensation because the ESR signal of the alkali metal disappeared on exposure to acetone.<sup>[25]</sup> Nevertheless, the selectivity of the aldol condensation reaction over various zeolite catalysts indicates that the shape-selective environment in the micropore can be important.

#### Amide and imide clusters supported in zeolites

Baba et al.<sup>[27,28]</sup> reported on the synthesis and catalytic activity of low-valent ytterbium (Yb) and europium (Eu) in the cages of Y zeolite. In their method, Yb or Eu metal ingots were placed together with dehydrated zeolite Y under a nitrogen atmosphere. Then, liquid ammonia was introduced to the reactor that was cooled with dry ice and ethanol. The metal dissolved in the ammonia and subsequently impregnated into the zeolite pores. Ammonia was removed from the sample by heating under vacuum. The resulting materials catalyzed the selective conversion of 1-butene at 273 K to *cis*-2-butene, which is consistent with base catalysis. The *cis/trans* ratio of the product 2-butene was ~10 for the Eu-loaded sample and ~4.5 for the Yb-loaded sample.<sup>[27]</sup> The counteraction of the zeolite affected the activity of the catalysts according to  $K > Rb > Cs > Na > Li$ . Potassium was the best cation, presumably because only low levels of cation exchange were achieved with the heavier alkalis.<sup>[27]</sup> The activity of the catalysts also increased linearly with loading of Eu on Y zeolite until ~8 wt.% Eu was achieved.<sup>[27]</sup> At lower levels, the Eu was apparently well dispersed in the zeolite pores. The new materials were also effective in the Michael reaction of 2-cyclopent-2-enon with dimethyl malonate, another base-catalyzed reaction.<sup>[28]</sup> A very important feature of these catalysts is that maximum activity was achieved in base-catalyzed reactions after evacuation pretreatment at 490 K.<sup>[28]</sup> Higher temperatures caused a rapid decline in catalytic activity.

Characterization of the lanthanide-loaded zeolites revealed some insights into the possible base sites involved in the catalysis. Infrared spectroscopy of the initial Yb-loaded zeolite Y before thermal treatment showed the presence of amide species.<sup>[28]</sup> The amide peaks in the IR spectrum decreased with evacuation temperature and nearly disappeared by 473 K, which is consistent with decomposition of the amide species. The x-ray absorption spectrum associated with the Yb  $L_2$  edge was also recorded for Yb-loaded zeolite

as a function of evacuation temperature.<sup>[28]</sup> The shape of the absorption edge was used to derive the relative amounts of  $Yb^{2+}$  and  $Yb^{3+}$  in the sample. Interestingly, the temperature at which the maximum in activity occurred for base catalysis (~490 K) almost coincided with the highest level of  $Yb^{2+}$  in the sample. Heating to higher temperatures increased the relative amount of  $Yb^{3+}$  compared with  $Yb^{2+}$ <sup>[28]</sup> and lowered the dispersion of Yb throughout the zeolite.<sup>[29]</sup> A reasonable model for the thermal evolution of these materials involves occluded amides  $(NH_2)_2$  and  $(NH_2)_3$  at low temperature, occluded imide NH at moderate temperature, and occluded nitrides at the highest temperature. The imide is the likely species responsible for base catalysis on these materials.

#### Mesoporous (Alumino)Silicates

The aluminosilicate form of MCM-41 is a mixed oxide that is templated with large surfactant molecules during synthesis to yield a solid with highly oriented, unidimensional mesopores in a nanometer size range that depends on the surfactant size.<sup>[30]</sup> Although the pores are packed in a regular hexagonal array, the local structure of the aluminosilicate wall is amorphous. A pure silica form of MCM-41 can also be synthesized. As discussed earlier, the charge imbalance because of the presence of  $Al^{3+}$  in a silicate framework requires extra framework cations for electrical neutrality. Alkali metal cations can be used to form a basic mesoporous solid, similar to a zeolite. Although the ion-exchanged MCM-41 materials are weakly basic, base strength can be improved by incorporation of occluded cesium in the mesopores by an impregnation method similar to that depicted in Fig. 2.

Kloetstra and van Bekkum<sup>[31]</sup> reported that Na-exchanged and Cs-exchanged MCM-41 are selective, water-stable, recyclable catalysts for the base-catalyzed Knoevenagel condensation of benzaldehyde and ethyl cyanoacetate. The same group also reported on the base catalysis of occluded Cs species in the pores of MCM-41 for the Michael addition of diethyl malonate to chalcone<sup>[31]</sup> and to neopentyl glycol diacrylate.<sup>[32]</sup> Results from TPD of adsorbed  $CO_2$  and catalytic activity for the Michael addition showed that basicity increased with occluded Cs loading. The researchers also noted an unfortunate problem with the stability of the support to repeated thermal cycles, presumably because of the formation of cesium silicate. However, the framework stability of the MCM-41 was observed to increase with increasing aluminum content. More recently, Kloetstra, Van Laren, and Van Bekkum<sup>[33]</sup> have added La to Cs-loaded MCM-41 materials and demonstrated their activity in both Knoevenagel condensation and Michael addition

Fig. 4 Synthesis procedure for anchoring organic strong base in the pores of MCM-41 mesoporous silica.

reactions. The combined results from these studies revealed that the base sites formed by occlusion of basic compounds in the pores of MCM-41 are not significantly different than those formed on other amorphous (alumino)silicates. The major advantage of these catalysts appears to be the high surface area of the support oxide that is exposed in the mesopores. The large pores of MCM-41, compared with those of zeolite molecular sieves, permit the adsorption and reaction of relatively large molecules that are relevant to fine chemicals synthesis.

A unique approach to synthesizing stronger base sites in MCM-41 involves the immobilization of a strong organic base on the pore wall. For example, Rao, De Vos, and Jacobs<sup>[34]</sup> reported recently the synthesis and reactivity of a strong base catalyst in which a guanidine base is covalently coupled to the silicate wall of pure silica MCM-41. Their synthetic strategy is schematically illustrated in Fig. 4. The pore walls of MCM-41 were first treated with 3-(trimethoxysilyl)propyl oxirane to provide a reactive tether to the silica. Next, 1,5,7-triazabicyclo[4.4.0]dec-5-ene (TBD) was put in contact with the oxirane-derivatized MCM-41 to react with the NH group and to couple the strong base to the solid. The materials appeared to be much more effective solid base catalysts in Michael addition reactions than Cs-containing MCM-41 because milder reaction temperatures and shorter reaction times were used to achieve high product yield.

### Carbogenic Molecular Sieves

Carbogenic molecular sieves (CMS) formed by pyrolysis of a poly(furfural alcohol)–poly(ethylene glycol) mixture are chemically inert, nanoporous supports that can host Cs atoms to form strong base catalysts.<sup>[35]</sup> The nanopores are narrowly distributed about a mode of 0.5 nm. Stevens and Foley<sup>[35]</sup> prepared Cs/CMS material by a vapor-phase deposition method in which

Cs metal was heated together with CMS in vacuum. A unique feature of this material is its lack of pyrophoricity, which offers a strong advantage over cesium metal and graphite Cs compounds. Despite their non-pyrophoric nature, the Cs/CMS materials still reduce liquid water to produce H<sub>2</sub>. Results from magnetic susceptibility measurements and EPR spectroscopy indicate that a significant number of unpaired electrons resided in Cs/CMS. Interestingly, the value of the *g*-factor for Cs/CMS suggests that the electrons from Cs were actually donated to the carbon support.<sup>[36]</sup>

The Cs/CMS materials were shown to be active in a variety of base-catalyzed reactions, including those requiring strong basicity typically associated with alkali metals. For example, side-chain alkylation of toluene with propene was observed at 4 bar and temperatures ranging from 423 to 673 K.<sup>[37]</sup> In addition, benzene coupling to biphenyl was measured over these materials at 2 bar and 723 K.<sup>[36]</sup> The catalysts have also demonstrated catalytic activity in double-bond isomerization of 1-butene at temperatures as low as 298 K.<sup>[35]</sup> It is important to note that a second pore system, with a center of distribution at ~10 nm, was needed to facilitate the transport of reactant molecules to the active sites in the nanopores.<sup>[35]</sup> Catalysts without this “transport porosity” were not very active.

Stevens, Chen, and Foley<sup>[38]</sup> purposefully exposed Cs/CMS to air to create a highly dispersed alkali metal oxide or hydroxide in carbon nanopores. They discovered new peaks in x-ray diffraction pattern that were attributed to a crystalline form of cesium hydrous oxide, but the pattern did not match known cesium oxides or hydroxides. These materials were also tested as catalysts in the aldol condensation of acetone to isophorone. Compared with an analogous catalyst prepared by wet impregnation of CsOH solution, the oxidized Cs/CMS was more active and more selective to isophorone. Apparently, a higher dispersion of active material was achieved with the vapor deposition method followed by oxidation.

**Table 2** Turnover frequencies of 2-propanol and 1-butene reactions over MgO, thermally treated hydrotalcites, and Al<sub>2</sub>O<sub>3</sub><sup>a</sup>

Catalyst <sup>b</sup>	TOF of acetone formation <sup>c</sup> (10 <sup>-3</sup> sec <sup>-1</sup> )	TOF of propene formation <sup>c</sup> (10 <sup>-4</sup> sec <sup>-1</sup> )	TOF of 1-butene isomerization <sup>d</sup> (sec <sup>-1</sup> )
MgO	2.6	0.82	0.22
Mg:Al, 5:1	3.3	2.1	0.18
Mg:Al, 3:1	2.3	4.4	0.10
Mg:Al, 2:1	2.7	11.5	0.093
Al <sub>2</sub> O <sub>3</sub>	1.9	750	0.0071

<sup>a</sup>Turnover frequency is the rate of product formation divided by the number of surface sites counted by CO<sub>2</sub> adsorption.

<sup>b</sup>Calcined for 4 hr at 823 K in flowing He.

<sup>c</sup>2-Propanol decomposition temperature was 593 K.

<sup>d</sup>Reaction temperature was 340 K.

## Hydrotalcite

Hydrotalcite is an anionic clay mineral with the structural formula Mg<sub>6</sub>Al<sub>2</sub>(OH)<sub>16</sub>(CO<sub>3</sub>) · 4H<sub>2</sub>O.<sup>[39]</sup> The structure consists of brucite-like layers (Mg(OH)<sub>2</sub>) that are positively charged because of the partial substitution of Al<sup>3+</sup> for Mg<sup>2+</sup>. To balance the positive layer charge, carbonate anions are located in the interlayer spaces, together with waters of hydration. The synthetic form of hydrotalcite can be prepared with a variable Al content and a variety of charge-compensating anions.<sup>[40]</sup> An interesting feature of hydrotalcite for base catalysis is the nature of the solid after thermal treatment. Reichle, Kang, and Everhardt<sup>[41]</sup> reported that heating hydrotalcite to about 723 K caused the loss of interlayer water and carbon dioxide, as well as dehydroxylation of the brucite-type layers. However, this thermal treatment neither changed crystal morphology, nor caused exfoliation of the layered structure. A large increase in surface area with heating was a result of the creation of small pores (2–4 nm radius) perpendicular to the crystal surface. Additionally, Rey, Fornes, and Rojo<sup>[42]</sup> reported that thermal treatment of hydrotalcite creates a substantial number of micropores with radius smaller than 1.75 nm.

Thermally-treated hydrotalcite is known to be active in a variety of base-catalyzed reactions.<sup>[39,43,44]</sup> The compositional variability that hydrotalcites afford suggests that these solid base catalysts can be “tuned” by direct synthesis methods. For example, Fishel and Davis<sup>[45]</sup> studied the reactions of 2-propanol and 1-butene over thermally activated hydrotalcites having different amounts of Al in the structure. Table 2 summarizes the turnover frequencies (TOFs), or rates of product formation normalized by the number of surface sites, for the various reactions. Because the TOFs were based on the adsorption capacity of carbon dioxide, the TOF of a structure-insensitive base-catalyzed reaction should be relatively constant at a given temperature and pressure. Indeed, the invariance of

the TOF for acetone formation from 2-propanol over MgO, Mg:Al mixed oxides (from thermal treatment of hydrotalcite) and Al<sub>2</sub>O<sub>3</sub> supports the idea of structure insensitivity. In contrast to the dehydrogenation results, the turnover rate for 2-propanol dehydration increased by three orders of magnitude as the catalyst was changed from magnesia to alumina. Apparently, the surface sites counted by CO<sub>2</sub> adsorption did not function equally well for alcohol dehydration. This trend is expected because dehydration is usually considered an acid-catalyzed reaction. In addition, the mechanism for secondary alcohol dehydration over basic oxides differs from that over alumina. It is of interest to note that the TOF of base-catalyzed isomerization of 1-butene (Table 2) was also a strong function of composition, with magnesia being the most active. As discussed earlier, adsorption of CO<sub>2</sub> does not provide an accurate measure of the active base sites for olefin isomerization. Nevertheless, the results in Table 2 clearly show the adjustability of catalytically active surfaces on thermally treated hydrotalcites.

## CONCLUSION

In a recent review of industrial processes catalyzed by solid acids and bases, Tanabe and Holderich<sup>[2]</sup> showed that commercial base catalysts consist mainly of alkali metal and alkaline earth metal oxides, hydroxides, and carbonates in bulk form, or supported on a common carrier such as alumina. In several cases, alkali metals are also supported on a basic carrier.

The porous nanostructure of zeolites, MCM-41, and CMS provides a unique, shape-selective reaction environment in which novel base catalysts can be prepared. Recently, Merck and Co. created a pilot plant scale process to synthesize 4-methyl thiazol using a catalyst composed of cesium sulfate impregnated into ZSM-5 zeolite.<sup>[46]</sup> As research progresses on basic species located on nanostructured supports, additional

base-catalyzed commercial processes that utilize these advanced materials will appear.

The compositional variability of hydrotalcites offers a tremendous opportunity to adjust the acid–base properties of Mg:Al mixed oxide surfaces for base catalysis. Indeed, Henkel KGaA developed a new heterogeneous catalyst, formed by roasting synthetic hydrotalcite at 773 K, for the production of narrow molecular weight distribution ethoxylates from etherification of ethylene oxide in the presence of fatty alcohols.<sup>[2]</sup> The presence of both acid and base sites on the materials introduces the concept of acid–base bifunctional catalysis, which is beyond the scope of this entry.

## INTRODUCTION

Bimetallic layered nanocomposites, composed of alternating layers of soft metals, are shown to possess ultrahigh yield strengths, often approaching the theoretical limits defined for perfect crystals. For example, nanolayered composites made from ordinary soft metals such as Cu, Ni, Nb, etc. each with strength on the order of a few tens of MPa in the bulk can achieve strengths in excess of 2–3 GPa. More importantly, the conventional descriptions relating mechanical properties to the microstructural dimensions do not extrapolate to nanometer dimensions. The mechanisms that determine strength and failure limits of nanoscale materials lie within new realms of behavior. This overview starts with a description of the synthesis methods and the microstructures of bimetallic layered nanocomposites. The layer thickness dependence of the yield strengths of the nanocomposites, in the length scale range of submicrometer to  $\sim 1$  nm, is shown for a variety of material systems. Different functional dependences of layer thickness on strength are interpreted using dislocation models of strengthening. Dislocation pileup based Hall–Petch (H–P) model is applicable at submicrometer to a few tens of nanometer length scales. At smaller thicknesses, confined layer slip (CLS) of single dislocations provides the strength increase with decreasing layer thickness. A peak in strength is usually achieved at layer thickness of around 2–5 nm. This peak is determined by the stress needed for single-dislocation transmission across interfaces. Atomistic modeling results that explore the slip transmission stress for unit dislocations across coherent and incoherent interfaces are described. We show that the mechanical properties of bimetallic layered composites can be tailored via length scales as well as interface properties.

## BACKGROUND

The ability to refine the microstructural length scales, such as grain size, twin spacing, or interphase spacing,

of materials creates opportunities to develop ultrahigh strength materials without suffering a corresponding loss in toughness.<sup>[1]</sup> Nanoscale design may allow the synthesis of materials with strengths approaching the theoretical limit. Although the theoretical strength limit may be determined in various ways, the theoretical shear strength for perfect crystals is estimated to be in the range of  $\mu/2\pi$  to  $\mu/30$ , where  $\mu$  is the shear modulus.<sup>[2]</sup> For many metals, this theoretical limit corresponds to stresses of 1–5 GPa. In contrast, the experimentally measured critical resolved shear strengths are about 5–50 MPa for pure, single crystal metals. This huge difference arises from the fact that perfect crystals contain no dislocations, the defects that transmit slip at very low applied stresses in typical metals.<sup>[2]</sup> Indeed, yield strengths in excess of 1 GPa have been observed in carefully synthesized metallic whiskers that are near-perfect crystals with no glide dislocations.<sup>[3]</sup> However, the initial yield of such whiskers is followed by catastrophic nucleation of many glide dislocations resulting in large drops in the stress needed to sustain plastic flow. Furthermore, whiskers have severe limitations with regard to the shapes and sizes that can be synthesized. Therefore, the traditional approaches to strengthen metals, have involved methods that impede the motion of dislocations by means of obstacles such as grain or phase boundaries, rather than attempting to produce dislocation-free materials. Grain size refinement to the micrometer range by thermomechanical treatments is effective in increasing the strength of typical metals above 100 MPa. Further increases in strength, of pure metals at room temperature, are achievable by reducing grain dimensions to the 100 nm ranges by severe plastic deformation (SPD) approaches such as equal-channel angular pressing or high-pressure torsion. Such methods are capable of producing high purity metals with yield strengths of several hundred MPa,<sup>[4,5]</sup> but microstructures with a uniform grain size in the nanometer range has not yet been achieved by SPD methods. For a discussion of mechanical properties of three-dimensional structural nanomaterials the reader is directed to another review entry of this Encyclopedia.<sup>[6]</sup>

Bimetallic layered nanocomposites, produced by deposition methods (described in the following section), serve as good model systems to investigate the mechanical behavior of metallic materials where the layer dimension can be refined, in a well-controlled manner, from hundreds of nanometers down to below 1 nm. The synthesis methods, microstructures and mechanical properties of this class of nanocomposites are reviewed in this article, with emphasis on correlating mechanical behavior with bimetallic interface properties and layer thickness.

## SYNTHESIS AND MICROSTRUCTURES

There are two commonly used synthesis methods that are discussed here. First, is a “top down” approach involving SPD of bulk sheets.<sup>[7–9]</sup> The starting materials are tens or hundreds of micrometers thick individual metal sheets that are alternately stacked and subjected to repeated hot pressing–cold rolling–annealing cycles to produce bulk nanolaminate sheets. A typical processing cycle employed for Fe/Ag multilayers<sup>[7,8]</sup> is described below. Hundred sheets (13 mm × 18 mm) each of 50 μm thick Fe and 30 μm thick Ag were stacked together and pressed in a controlled temperature and atmosphere to bond the metal sheets. The bonded stacked was then rolled in ambient atmosphere to reduce the thickness of the layers. The rolled sheets were then annealed at 873 K to reduce the hardness, while maintaining the layered microstructure, before the next pressing–rolling cycle. After the second pressing–rolling step, the average Ag layer thickness was 20 nm. Since annealing after cold rolling leads to some coarsening, an alternate procedure eliminating the annealing step, results in an average Ag layer thickness of 4 nm. Similar results were obtained for Fe–Cu<sup>[8]</sup> and Cu–Al<sup>[9]</sup> multilayers as well. This press–rolling synthesis approach could effectively reduce the metal layer thickness from tens of micrometers to a few nanometers (a factor of 10<sup>4</sup>), although the resulting nanolaminates do not have very uniform interlamellar spacing.

Deposition methods, either electrodeposition or physical vapor deposition (PVD) such as magnetron sputtering or electron-beam evaporation, are more commonly used to synthesize bimetallic layered nanocomposites. These “bottom-up” synthesis methods offer several advantages. First, any two (or more) metals (or ceramics) can be alternately deposited to produce a layered composite. Second, the individual layer thicknesses can be controlled to within an atomic layer (unlike many techniques that produce a distribution in grain sizes). Third, the products have high purity, and are porosity free. Fourth, self-supported samples with total thicknesses of tens of micrometers,

or more, are readily synthesized so that a variety of nanomechanical characterization may be performed such as nanoindentation, microtensile testing, and large strain deformation via cold rolling.

Electrodeposition synthesis of nanolaminates is accomplished by using an electrolyte from which two different metals can be deposited by varying the applied voltage.<sup>[10–12]</sup> For example, Cu–Ni nanolaminates with a total foil thickness of 50 μm and individual layer thickness down to ~1 nm are electrodeposited from a nickel sulfamate bath containing Cu.<sup>[11]</sup> The constraint of finding an electrolyte from which two different metals can be electrodeposited limits the number of nanolaminate systems that can be synthesized by electrodeposition.

Magnetron sputtering, ion-beam sputtering, and electron-beam evaporation are widely used to synthesize nanolaminates.<sup>[13–16]</sup> To synthesize a multilayered film, shutters are alternated, typically through a computer-controlled stepper motor, between two different sputtering targets or e-beam melted sources. In another design, the sample stage can be rotated to alternately face the two (or more) sputtering targets for sequential deposition of the individual layers that make up the multilayer stack. The typical deposition rates vary from 2 to 20 Å/sec. Thousands of bilayers can be easily deposited to produce samples with total thickness >10 μm in a few hours. To sputter metal nitride layers, reactive sputtering is used in an Ar/N<sub>2</sub> gas mixture while sputtering from the metal target. For sputtering of insulating materials, rf power instead of dc is applied to the target. In both evaporation and sputtering, the substrate can be either heated or cooled. Often elevated temperature deposition, at least of the seed layer, is needed to produce single crystal growth of deposited layers. Energetic particle bombardment of the growing film, at any temperature, provides an additional way to control the density, residual stress, and texture of the films. A separate ion-gun added in the evaporator can be used to bombard the growing film (ion-beam assisted deposition). For sputtering, a negative dc bias can be applied to the substrate (which is otherwise kept at ground potential) to induce Ar<sup>+</sup> bombardment of the growing film. Both sputtering<sup>[17]</sup> and evaporation<sup>[18,19]</sup> techniques have been used to prepare nanolaminates with total thicknesses of several hundred micrometers.

Typical microstructures of bimetallic layered composites synthesized via sputter deposition techniques are shown in Figs. 1 and 2. Using shadow masks during sputtering allows the synthesis of self-supported dog-bone shaped tensile samples (Fig. 1A) that are more than 10 μm thick but consist of thousands of nanometer thick alternating layers of the two constituent metals. An example of 1 nm thick Cu/Nb multilayer is shown in Fig. 1B. Room temperature

**Fig. 1** (A) Photograph of a 20  $\mu\text{m}$  thick sputter-deposited tensile sample of a Cu–Nb multilayer; (B) high-resolution TEM image showing the internal nanostructure of the bulk tensile sample, consisting of alternating 1 nm thick Cu and Nb layers.

deposition on substrates such as Si with an oxide layer typically produces a textured, nanocrystalline structure within the layers. An example of such a polycrystalline microstructure is shown in Fig. 2A for a 75 nm thick Cu/Nb multilayer, with the corresponding selected area diffraction pattern shown in Fig. 2B. For fcc/bcc systems such as Cu/Nb, the crystal of one layer is oriented relative to the adjacent layers by the Kurdjumov–Sachs orientation relationship:  $\{110\}\text{Nb} // \{111\}\text{Cu}$ ,  $\langle 111 \rangle \text{Nb} // \langle 110 \rangle \text{Cu}$ ,<sup>[20]</sup> and the interface plane is  $\{110\}\text{Nb} // \{111\}\text{Cu}$ . Elevated temperature deposition or room temperature deposition on carefully cleaned substrates such as HF etched Si is typically needed to produce single crystalline multilayer structures.<sup>[14,15,21–23]</sup>

### LAYER THICKNESS DEPENDENCE OF STRENGTH

The general trends in the dependence of strength on: 1) microstructural length scales; and 2) the physical properties of the constituents layers may be discerned

by studying a variety of model multilayered systems. Table 1 lists the systems investigated by the authors' team that largely form the basis of the following discussion. In all these multilayers, the individual layer thicknesses of the two constituents were equal. Thus, the mechanical behavior could be interpreted in terms of a single length scale: layer thickness ( $h$ ) that is one-half of the bilayer period. Note that two categories, fcc/fcc and fcc/bcc, of material systems are studied. For each category, systems were selected so as to cover a wide range of elastic moduli and lattice parameter mismatches.

Hardness, based on nanoindentation measurements, of the systems listed in Table 1 is shown in Fig 3. For all systems, hardness scales linearly with  $1/\sqrt{h}$  for  $h > \sim 50$  nm. This observation is consistent with slip involving groups of dislocations such as the dislocation pileup on which the H–P model<sup>[24]</sup> is based. Such pileups possess a mechanical advantage in which the stress available to transmit slip through a barrier is equal to the applied stress times the number of dislocations in the pileup. Equivalently, the  $1/\sqrt{h}$  dependence is clearly an indication that the stress near the head of

**Fig. 2** (A) Bright field TEM image and (B) corresponding selected area diffraction pattern of a 75 nm layer thickness Cu–Nb multilayer. Note the polycrystalline,  $\{110\}\text{Nb} // \{111\}\text{Cu}$  textured microstructure.

**Table 1** Summary of the multilayered systems for which mechanical properties are reported in Fig. 3

System (production method)	Crystal structure	Orientation relationship	Modulus ratio <sup>a</sup> , $E_X/E_{Cu}$	Lattice mismatch <sup>b</sup> (%)
Cu–Ag (evaporation)	fcc/fcc	$\langle 111 \rangle$ texture	0.64	12.1
Cu–Ni (evaporation)	fcc/fcc	$\langle 100 \rangle$ single crystalline	1.54	2.66
Cu–330SS (sputtering) <sup>c</sup>	fcc/fcc	$\langle 111 \rangle$ texture	1.51	0.92
Cu–Nb (sputtering)	fcc/bcc	Kurdjumov–Sachs <sup>d</sup>	0.80	11.1
Cu–Cr (sputtering)	fcc/bcc	Kurdjumov–Sachs	2.15	2.33
Cu–304SS (sputtering)	fcc/bcc	Kurdjumov–Sachs	1.5	2.9

<sup>a</sup>Ratio of the Young's modulus of the second phase to the modulus of Cu.

<sup>b</sup>Lattice mismatch =  $(d_1 - d_2)/\{(d_1 + d_2)/2\}$  where  $d_1$  and  $d_2$  are the spacings of planes forming the interface.

<sup>c</sup>330SS and 304SS are austenitic stainless steels 330 and 304 respectively; 304SS adopts a bcc structure when sputter deposited.

<sup>d</sup> $\{110\}bcc//\{111\}fcc$ ;  $\langle 111 \rangle bcc//\langle 110 \rangle fcc$ .

the pileup is proportional to the square root of the length of the pileup, a result that holds as long as there are many dislocations in the pileup. For smaller layer thicknesses (typically,  $h < \sim 50$  nm), the pileups contain too few dislocations for this scaling law to be applicable and critical slip events involve a very few or single dislocations. From Fig. 3, as the layer thickness is reduced below the H–P range, three kinds of functional dependence of hardness on  $h$  are observed: 1) at  $5 \text{ nm} < h < 50 \text{ nm}$  range, hardness increases with decreasing  $h$  but more slowly than  $1/\sqrt{h}$  scaling; 2) a peak in hardness is reached when  $h$  is on the order of 2 nm; and 3) at  $h < 2$  nm, some systems exhibit a small drop in hardness. The maximum strength achieved in all these systems, estimated from hardness divided by a factor of 3, are typically greater than 10 times the rule-of-mixtures estimates based on bulk properties.<sup>a</sup> In addition to establishing the functional dependence of strength on length scale, Fig. 3 also allows comparison of strengths of different systems at equal layer thicknesses. Such comparisons reveal significant differences in the maximum achievable strengths. These differences are elucidated in the molecular dynamics (MD) simulations described later.

The data shown in Fig. 3 are summarized in Table 2 along with information on other metallic multilayers.<sup>[26–38]</sup> The data compiled in Table 2 show that the peak strength for most systems is typically on the order of 1.5–2.5 GPa. When expressed as a fraction of the Young's modulus of the composite ( $E_c$ ), the peak strength is typically within a factor of 2–4 of a

lower-bound estimate of the theoretical strength of perfect crystals ( $\sim E_c/25$ ). For systems where data are available at larger bilayer periods where H–P behavior is observed, the H–P slope is calculated and shown in Table 2. For a given type of material systems, e.g., polycrystalline fcc-fcc such as Ag–Cu, Cu–Ni, and Cu–SS330, note that the H–P slope increases with  $E_c$ . Similar trend is observed in polycrystalline fcc-bcc systems (Cu–Nb, Cu–Cr, and Pt–Fe). A high H–P slope indicates a strong resistance of interfaces to transmission of piled-up dislocations. For a given layer thickness, material systems with a higher H–P slope have higher strength. The intrinsic resistance of interfaces to slip transmission is discussed in the section on atomistic modeling.

**Fig. 3** Nanoindentation measured hardness of a variety of Cu-based multilayers. Linear fit to the hardness vs.  $1/\sqrt{h}$  data, at  $h > \sim 50$  nm, is consistent with Hall–Petch model.

<sup>a</sup>The ratio,  $H/\sigma_y \sim 3$ , is a commonly used rule-of-thumb relating hardness ( $H$ ) to strength ( $\sigma_y$ ). For Cu–Nb we measured tensile strengths of  $\sim 1.1$  and  $\sim 1.4$  GPa for  $h = 75 \text{ nm}$ <sup>[25]</sup> and  $h = 40 \text{ nm}$ , respectively. The corresponding hardness of these composites were  $3.6 \pm 0.2$  and  $4 \pm 0.2$  GPa, respectively, consistent with the factor of 3 rule. We do not, however, espouse the universality of this rule as systems with very weak interfaces may exhibit a significantly different ratio.

**Table 2** Mechanical properties of bimetallic layered nanocomposites

$\sigma_{\max}$  is the maximum strength for that system estimated from nanoindentation measured hardness divided by a factor of 3.

$E_c$  is the rule-of-mixtures Young's modulus for the multilayer.

H–P slope refers to the Hall–Petch slope obtained from data where hardness scales with  $h^{-0.5}$ . nr (not reported).

<sup>a</sup>Slope from tensile data.

<sup>b</sup>Al<sub>3</sub>Sc is fcc-based ordered L1<sub>2</sub> structure.

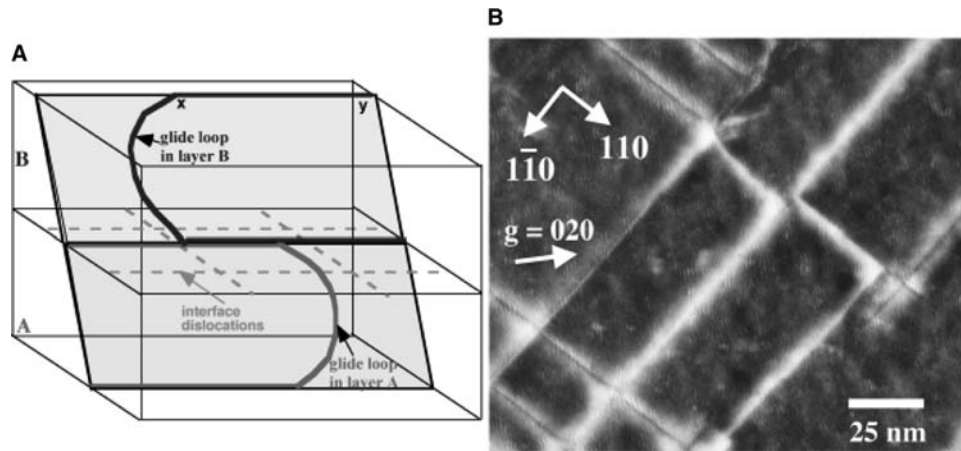

## SINGLE-DISLOCATION-BASED DEFORMATION MECHANISMS

As discussed above, at nanometer length scales when the dislocation pileup based mechanisms do not apply, three kinds of functional dependence of strength on layer thickness are observed: 1) strength increase with decreasing layer thickness; 2) a strength maximum independent of layer thickness; and 3) a drop in strength with decreasing layer thickness. The single-dislocation-based mechanisms that give rise to these behaviors are discussed below.

### Confined Layer Slip

Strength increase with decreasing layer thickness at length scales where dislocation pileups do not form is interpreted in terms of the confined layer slip mechanism that involves propagation of single-dislocation loops parallel to the interfaces.<sup>[36,39–45]</sup> For macroscopic yielding of the composite, both metallic layers must co-deform by CLS of Orowan loops, as shown in Fig. 4A. An example of CLS is the formation of misfit dislocations during coherency loss of very thin

epitaxial Ni layers on a thick Cu under layer. The misfit dislocation formation mechanism is the glide of existing threading dislocations, confined to the Ni layer. As a glide loop propagates, it deposits an interface dislocation in the Ni/Cu bilayer.<sup>[44]</sup> Such CLS was inferred from TEM studies<sup>[46]</sup> for Ni layer thickness  $\geq 3$  nm, while at lower thicknesses Ni was coherently matched with Cu. Glide on four  $\{111\}$  planes in the Ni layer produces two orthogonal sets of misfit dislocations at the  $\{001\}$  Ni–Cu interface [Fig. 4B]. The stress needed to glide a dislocation in the configuration shown in Fig. 4A depends on the self-energy of the deposited interface dislocations, and hence, for CLS, strength scales with layer thickness as:  $\sigma_{ys} \propto h^{-1} \ln(h)$ . An implication of this relation is that strength will continue increasing with decreasing  $h$ , but experimental results (Fig. 3) suggest that all multilayer systems exhibit a maximum strength at layer thickness on the order of 1–2 nm. At the very smallest  $h$ , the CLS stress exceeds the critical stress for dislocation transmission across the interface. Hence, dislocations cannot propagate as loops confined to individual layers, rather a dislocation loop must be transmitted across the interface first before it can spread in a direction parallel to the interfaces. The stress to transmit a single

**Fig. 4** (A) Schematic illustration of the confined layer slip in bimetallic layered nanocomposites. Glide of a dislocation loop confined to an individual layer results in deposition of dislocation segments (shown as dotted line) at the two interfaces confining the loop. (B) Plan view TEM image of a 5 nm thick Ni layer on a 100 nm (0 0 1) Cu. Confined layer slip in the Ni layer to partially relieve the coherency strain has resulted in a cross-grid of  $60^\circ$  misfit dislocations at the interface with Burgers vectors in the  $\{111\}$  glide plane.

dislocation across the interface is, therefore, the critical event that defines the nanolaminate yield strength, and this is discussed next.

### Atomistic Modeling of Glide Dislocation Transmission across Interfaces

In our discussion of the stress needed for single-dislocation transmission across interfaces, we consider two kinds of interfaces: *transparent* and *opaque*. The characteristic feature of interfaces in the fcc-fcc, Cu–Ni and Cu–Ag composites is that slip planes and slip directions are nearly continuous across the interfaces and both layers have the same crystal structure. Therefore, because of the continuity in slip across these interfaces, we refer to them as *transparent interfaces*. The second kind, *opaque interfaces*, apply to systems where the slip planes and slip directions are discontinuous across the interfaces and the two layers have different crystal structures, e.g., fcc-bcc Cu–Nb systems.

#### Transparent interfaces

For the coherent Cu–Ni case, in spite of the continuity of slip, dislocations are not able to easily move from one layer to the next because of coherency stresses. Fig. 5 shows the results of a MD simulation of slip transmission across  $\{001\}$  Cu–Ni interface under applied in-plane tension. A  $1/2\langle 011 \rangle$  dislocation on a  $\{111\}$  glide plane in the Cu layer, denoted BD in Thompson tetrahedron notation in Fig. 5A, dissociates into Shockley partials ( $\gamma D$  and  $B\gamma$  in Fig. 5B). In the simulation, the magnitude of the in-plane applied tensile stress needed to cause the lead partial  $B\gamma$  to

transmit across the coherent Cu–Ni interface into the Ni layer was 2.6 GPa.<sup>[47,48]</sup> Comparing this stress to the biaxial in-plane coherency stress in the Cu and Ni that are  $-2.4$  and  $+2.4$  GPa, respectively, we find that the critical applied stress to cross the interface is very nearly equal to the coherency stress. The small difference arises from contributions from non-linear elastic effects, dislocation image forces due to elastic moduli mismatch between the layers, and creation of a step at the interface during slip transmission. Assuming that we can neglect these small contributions, a very simple relation that predicts the dependence of the peak strength attainable in such multilayers on elastic moduli and misfit strain is obtained as

$$\sigma_f = \frac{C^A C^B}{C^A + C^B} \varepsilon_m \quad (1)$$

**Fig. 5** MD simulation of slip transmission across Ni–Cu interface. (A) A glide dislocation (labeled BD in Thompson tetrahedron notation) is placed in the Cu layer and the bilayer loaded in tension parallel to the interface plane. (B) At an applied stress of 2.6 GPa, the leading partial has transmitted to the Ni layer.

where  $C^A$  and  $C^B$  are the effective biaxial elastic constants for layers A and B respectively, and  $\varepsilon_m$  is the lattice mismatch strain between the two materials. For the Cu/Ni embedded atom method (EAM) potentials,  $C^{Cu} = 133$  GPa,  $C^{Ni} = 212$  GPa,  $\varepsilon_m = 0.0266$ , a strength of 2.2 GPa is calculated from Eq. (1) in reasonable agreement with the MD simulation results and in fair agreement with the experimentally observed (Fig. 3) peak strength values of 1.7 GPa for Cu/Ni at  $h \sim 5$  nm. Our TEM observations, Fig. 4B, of Ni–Cu interfaces at  $h = 5$  nm revealed a partial coherency loss that would result in a lower  $\sigma_f$ . Eq. (1) shows that higher strengths should be achieved in higher modulus materials, and combinations of materials with higher misfit strains. However, there are limits to the applicability of Eq. (1). For Cu/Ag the misfit strain is 0.12, significantly larger than for Cu/Ni. However, this misfit is too large to achieve coherency in this system because the misfit dislocations are so close together that the cores of the adjacent dislocations at the interface overlap. Consequently, coherency is lost and the maximum strength in Cu/Ag is less than that of Cu/Ni. Consistent with experiments that show a drop in strength as  $h$  is reduced below  $\sim 2$  nm, MD simulation results obtained from models with very thin layers also show a corresponding decrease in the stress needed to transmit slip across the interface as the layer thickness is reduced.<sup>[47–50]</sup> There are two explanations for this behavior: 1) the image forces on glide dislocations due to modulus mismatch decrease with layer thickness, and 2) the dislocation core size becomes a significant fraction of the layer thickness.

### Opaque interfaces

The transfer of slip across an interface between two different phases or between two misoriented crystals must, in general, involve dislocation multiplication because of discontinuity of slip planes and directions. Furthermore, the interface may have limited shear strength, a property that leads to attraction of glide dislocations to the interface and core spreading for dislocations in the interface. Such interfaces are typically incoherent, and, although periodic structures might occur, they may not be able to sustain the large coherency stresses that can develop in the transparent

interface systems. Consequently, in such materials, the interface itself is a barrier to slip, and we identify these interfaces as opaque.

Fig. 6A shows results from an unstressed Cu/Nb model in which a dissociated glide dislocation was placed in the Cu layer near the interface. In this particular case, the model is oriented such that one set of slip planes in the Cu and another set in the Nb are misoriented by a small tilt (although there is a large change in slip vector) and their traces on the interface are normal to the page. The lead partial of a dissociated glide dislocation in the Cu was attracted to the interface while the trailing partial remained some distance away. At a relatively small applied stress of about 0.2 GPa, the trailing dislocation also entered the interface. Disregistry analysis shows that the in-plane components of these dislocations spread significantly in the interface. Very large strains are required for the slip to transfer into the Nb. Fig. 6B shows a glide dislocation emerging in the Nb on a  $\{110\}$  slip plane at an in-plane strain of 3.5% (equal in both layers), producing an applied tensile stress of about 7 GPa in the Cu and 4.5 GPa in the Nb.<sup>[48]</sup> There is also evidence of a dislocation emerging on another  $\{111\}$  plane in the Cu layer at this huge stress. The results shown here derive from calculations near 0 K and it is very likely that at higher temperatures, thermal activation would assist dislocation nucleation into the Nb layer at lower stresses. In a different simulation, the shear strength of the interface in the Cu/Nb system was measured by applying an increasing homogeneous shear strain accompanied by energy minimization. The shear stress at which irreversible slip on the interface occurred was found to be about 0.55 GPa, much less than the stress to transmit slip across the interface. We have shown that this relative “weakness” of the interface is a key factor in core spreading of the glide dislocation along the interface.

### SUMMARY

The length scale dependence of strength of bimetallic nanolayered composites discussed in this article is shown schematically in Fig. 7.<sup>[36,51]</sup> As the layer thickness is decreased below around 200  $\mu\text{m}$ , strength becomes dependent on the length scale of the material

**Fig. 6** MD simulation of slip transmission across Nb–Cu interface. (A) A glide dislocation in Cu is approaching the Cu/Nb interface under applied in-plane tension. (B) The glide dislocation in Cu is absorbed, with its core spread, in the interface plane, and a glide dislocation is emerging on the Nb side.

Fig. 7 Schematic illustration of the length scale dependent deformation mechanisms in bimetallic layered nanocomposites.

via the H-P model,  $\sigma \propto h^{-1/2}$ . Dislocations pile up at the interfaces that are barriers to slip transmission and the stress concentration from the pileup eventually overcomes the interface barrier to propagate slip through the composite. With reducing layer thickness, the pileup length gets shorter and so does the stress concentration at the tip of the pileup, thereby resulting in a higher applied stress for slip transmission. This continuum model is applicable to submicrometer length scales. As the layer thickness in a bimetallic laminate is decreased below a few tens of nanometers, the H-P scaling law is no longer applicable implying that continuum-scale dislocation pileups cannot form in nanoscale multilayers, and the deformation behavior must be interpreted in terms of the nucleation and motion of single dislocations. For such nanolaminates, strength increase with decreasing layer thickness in the few to a few tens of nanometers range is interpreted as CLS of single Orowan loops (Fig. 7). As the layer thickness is decreased to a couple nanometers, the strength reaches a peak value independent of layer thickness. This peak strength is interpreted as the stress needed to transmit a single glide dislocation across the interface, and can be as high as  $\sigma_{th}/2$  where  $\sigma_{th}$  is the theoretical limit of strength for perfect crystals. The peak strength can be tailored by interface properties. For example, for coherent systems, the peak strength is determined by the magnitude of coherency stress. For incoherent interfaces between metals of dissimilar crystal structures, the crucial interface property is the interface shear strength. A weak interface shears in response to the glide

dislocation stress field leading to trapping of the dislocation in the interface plane via core spreading. Finally, as the layer thickness decreases below the typical dislocation core dimensions of  $\sim 1$  nm, the interface stress to single-dislocation transmission decreases.

The mechanical properties of bimetallic layered composites can thus be tailored by both length scales and by interface properties to achieve strengths approaching the theoretical limit for perfect crystals.

Structural transitions in bimetallic layered composites at layer thickness of a few atomic layers are not covered in this entry and the reader is referred to another review<sup>[52]</sup> on this topic published in the Dekker Encyclopedia of Nanoscience and Nanotechnology.

University of Stuttgart, Stuttgart, Germany*

## INTRODUCTION

Microarray technology is a key factor in today's biotechnology research. There already exists a variety of chip-based polynucleic acids analysis systems. DNA microchips are already commercially available and are widely used in laboratories worldwide. In contrast, new methods are needed for the starting era of proteomics—the investigation of function, structure, and molecular interaction among proteins. Protein microarrays are widely expected to play an outstanding role in this new field of research.

The change of scope from nucleic acids to proteins needs, by far, more than a little change in the technology to be applied. Especially, there is a tremendous need to develop new microarrays with a flexible surface chemistry. Proteins are, by far, more complex in their material properties than polynucleic acids. Whereas DNA is composed of only four different nucleotides, which are chemically quite closely related to one another, proteins consist of 21 different amino acids that can differ drastically in their chemical functionality. Additionally, posttranslational modifications on proteins within organisms create an even larger variety in the chemical properties of naturally occurring proteins and polypeptides. Therefore, intending to establish a protein-oriented microarray technology, there is an immense need for a large variety of different tailor-made surface chemistries.

In our approach described here, we provide a pre-structured microarray for the immobilization of proteins. By adsorbing a patterned layer of nanoparticles with various surface modifications to a substrate, we separate the two steps of chemical tailoring of the surface on a molecular level and the subsequent microstructuring of the chip in two fundamentally independent processes. Thereby, an extremely efficient microarray preparation is realized while providing notably high flexibility in chemical surface structures. In the first step, by means of chemical nanotechnology, tailor-made nanoparticles are prepared. The particle's surface is customized to match the specific demands for the immobilization of a certain kind or class of proteins. In a second step, the nanoparticles are deposited

on a chip to render a microstructured monolayer array of nanoparticles. This microstructure can be achieved by a choice of different lithographic processes. Either photolithography,<sup>[1]</sup> microcontact printing,<sup>[2–4]</sup> or micro-spotting<sup>[5]</sup> is applied for nanoparticle deposition only at well-defined areas of the substrate. The resulting system is a nanoparticle-based microarray ready for the selective binding of protein ligands.

## GENERAL SCHEME OF THE MICROSTRUCTURED SURFACE PREPARATION

To understand the flexibility of the practical approach of preparing nanoparticle-based microarrays, the overall process can be regarded as being composed of four different processes: 1) synthesis of functional nanoparticles; 2) substrate surface activation step; 3) nanoparticle deposition; and 4) lithographic process. Combining these processes in different ways provides the possibility to achieve the patterned deposition of nanoparticles in a direct or an indirect way. The performance of steps (2)–(4) will be described in “Surface Activation.” Subsequently, we will introduce a selection of functional nanoparticles (step 1), which are designed to determine the surface chemistry of the resulting microarray. Finally, we will give an example of a microarray based on functional nanoparticles.

### Surface Activation

The surface of the solid substrate has to be prepared to bind particles strong enough to withstand common washing procedures. In this approach, charged particles were fixed to an oppositely charged surface. Surface activation was achieved by self-assembly of ultrathin polyelectrolyte monolayers or multilayers on the substrate by applying a simple dipping process. The method used is referred to as layer-by-layer (LbL) technique<sup>[6,7]</sup> and was also used to deposit nanoparticles.<sup>[8–11]</sup>

According to the LbL technique, solid substrates were coated with ultrathin layers of positively and

negatively charged polyions by an alternating adsorption process. This process, in principle, can be repeated indefinitely; the only condition is a proper alternation of positively and negatively charged components [e.g., here, poly(diallyl-dimethyl ammonium chloride) (PDADMAC) was used as a polycation and the sodium salt of poly(styrene sulfonate) (SPS) was used as a polyanion]. The resulting polyelectrolyte layers then give rise to adhesive binding of charged nanoparticles by electrostatic forces. Most importantly, surface charge density is increased and homogenized by the LbL procedure (for experimental details, see “[Materials and Methods](#)”).

### Lithographic Microstructuring and Particle Deposition

Patterned nanoparticle deposition on the activated surface can be achieved either in a direct or an indirect way: Spotting or stamping the particles onto an activated surface directly generates a nanoparticle pattern on a homogeneous polyelectrolyte layer.

The photoablation of certain regions of polyelectrolyte layers by deep ultraviolet (DUV) irradiation through a mask leads to well-defined particle deposition only onto undamaged parts of the polyelectrolyte coating. Both methods to prepare a microstructured chip surface will be described in the following.

### Microstructuring of the Activated Surface by Photoablation

In structuring the activated surface, a photolithographic technique is employed (e.g., a homogeneously

activated surface is covered with a microstructured mask and is then irradiated with DUV light).<sup>[12]</sup> Thereby, the irradiated areas of the LbL film are transformed to become nonadhesive to the nanoparticles during the later nanoparticle adsorption step.

To characterize this photoablation process, first, irradiation of differently activated surfaces was performed without using a mask. The ablation kinetics and the change of the chemical composition of the polyelectrolyte layers during the photoablation process were monitored by ellipsometry and X-ray photoelectron spectroscopy (XPS), respectively.

Ellipsometric measurements showed that material degradation during DUV treatment depends on the duration of radiation. The layer thickness of the LbL polyelectrolyte film  $d_{\text{LbL}}$  decreased exponentially with the time of DUV irradiation  $t_{\text{DUV}}$ .

Here, three different samples were prepared: silica substrates coated with one layer of PDADMAC, with a double layer of PDADMAC/SPS, or with a triple layer of PDADMAC/SPS/PDADMAC, and then were exposed to DUV irradiation. Fig. 1 shows the decrease of the thickness of these polyelectrolyte layers plotted against the duration of radiation. In all cases, a simple exponential decrease of layer thickness with the duration of radiation was observed. After 45 min, the depth of the layers depreciated to about 20% of the starting value in each layer system.<sup>[13]</sup>

The chemical layer composition before and after exposure to DUV light was determined by XPS measurements (Fig. 2 and Table 1). After DUV irradiation for 45 min, the carbon measurement signal broadened significantly and shifted to a higher bonding energy (286.4–289.2 eV; Fig. 2). This higher bonding energy is the result of the chemical modification of carbon

**Fig. 1** Decrease of the layer thickness of polyelectrolyte layers on silicon wafer with DUV irradiation time. (★) Triple layer (PDADMAC/SPS/PDADMAC). (●) Double layer (PDADMAC/SPS). (◆) Monolayer (PDADMAC). Source: From Ref.<sup>[13]</sup>.

**Fig. 2** High-resolution carbon spectra of the XPS of a PDADMAC-coated silicon wafer before (above) and after (below) irradiation with DUV.

atoms via oxygen atoms. The broadening and displacement of the nitrogen signal (402.0–400.8 eV) originated both from the partial loss of quarternary nitrogen compounds and the loss of positive charges from polyelectrolytes (Table 1).<sup>[13]</sup>

Irradiation with DUV in our simple experimental setup does not result in a complete ablation of the polyelectrolyte film. However, the structuring of polyelectrolyte layers on silica functions excellently: Because of the combination of material ablation and chemical modification, the overall charge density

in the irradiated sectors of polyelectrolyte layers decreased substantially and thus electrostatic interactions (essential for the immobilization of particles) diminished decisively.

### Nanoparticle Monolayer Array by Dip Coating of Nanoparticles on a Microstructured Activated Substrate

A microstructured activated surface can be used as a substrate for the microstructured deposition of particles by a simple dipping process. Therefore, subsequent to the photolithographic treatment, the chip is dipped in a nanoparticle suspension, taken out, and simply rinsed with water. A microstructured nanoparticle array is thereby formed effectively. Fig. 3 shows a PDADMAC-pretreated and photolithographically patterned silica wafer after coating with silica nanoparticles. After the attachment of particles, a precise cutoff between the irradiated and nonirradiated sectors of the PDADMAC-coated silica surface was observed.

### Nanoparticle Monolayer Array by Microspotting or Microcontact Printing on a Nonstructured Activated Substrate

For direct or mask-free structuring of nanoparticle layers, a drop of particle suspension is deposited by a microarrayer at a defined position of the surface (microspotting), or a patterned particle layer is transferred by means of an elastomeric stamp (microcontact printing).

After vaporescence of the liquid phase, the particles stay as a microstructured film at the initially homogeneously coated substrate. Examples for both routes are described in the following sections.

### Microcontact Printing of the Nanoparticle Layer

Microcontact printing is a soft lithographic structuring method. In this technique, a microstructured elastomeric stamp is used to transfer a chemical “ink” to

**Table 1** Quantitative analysis of the XPS of a PDADMAC-coated silicon wafer for elements in question before and after DUV irradiation.

Silicon wafer	Element $E_B$ [eV]	Composition [at.%]							
		C 289.2	C 286.4	C 286.2	C 284.6	O 531.8	N 402.1	N 400.8	N 397.4
Hydroxylated and coated with PDADMAC		Tr	3.1	1.4	10.7	29.9	1.4	–	1.0
Hydroxylated with PDADMAC and UV-radiated (45 min)		1.8	2.9	–	3.6	35.8	0.7	0.5	1.1

**Fig. 3** Light micrograph (upper left) and atomic force microscopy (AFM) images (upper right, lower left and right) of a photo-lithographically structured PDADMAC layer on a silicon wafer with deposited silica nanoparticles.

some parts of a surface, which is so subdivided into areas of different chemical properties.

The stamps used here are made from polydimethylsiloxane (PDMS) (Fig. 4). According to the hydrophobic properties of the stamp material, the aqueous particle suspension does not spread uniformly over the surface of a freshly prepared stamp. Therefore the surface of the stamp was hydrophilized by an oxygen low-pressure plasma.<sup>[14]</sup> By this treatment, hydroxyl groups were generated at the PDMS surface, and the interaction of the stamp with water dipoles was substantially increased. The stamp was then coated with one layer of polyelectrolytes by a simple dipping

process in a polyelectrolyte solution, rinsed with water, and subsequently dipped into the particle suspension. When the stamp was brought into contact with the activated substrate surface, the particles were effectively transferred to the chip because of the stronger interaction of the charged particles with the activated surface of the substrate.<sup>[15]</sup>

### Microspotting of the Nanoparticle Layer

Microarrays are computer-driven robots that transfer dropwise a solution or a nanoparticle suspension

**Fig. 4** Light micrograph (left) and AFM image (right) of microcontact-printed silica nanoparticles on a PDADMAC-coated glass slide.

to precisely defined positions on a substrate. Herewith, any pattern composed of circular spots can be appointed on a planar surface.

The presented structures were printed with a pin-ring spotter. Here, a probe of a nanoparticle suspension was collected from a microtiter plate by dipping a steel ring in the suspension. Thus a thin film of the nanoparticle suspension was spread inside the ring, forming a reservoir for the subsequent spotting process. A steel needle (pin) passed through the liquid film is wetted by the nanoparticle suspension. At a defined position according to the coordinates chosen by the operator, the pin came in contact with the surface of the substrate, and thus a drop of the nanoparticle suspension was deposited. The evaporated liquid and a defined amount of nanoparticles were transferred to the activated substrate (Fig. 5).

### Nanoparticles Applied in the Microarray Preparation

A large variety of spherical nanoparticles, with a diameter from 50 to 300 nm and a molecularly defined surface, were generated and employed in microarray preparation e.g., surface-modified silica nanoparticles,<sup>[16,17]</sup> molecularly imprinted nanoparticles based on the monomer methacrylic acid (MAA) and the cross-linker ethylene glycol dimethacrylate (EGDMA),<sup>[18–20]</sup> or polymer nanoparticles providing an active ester surfmer for easy bioconjugation reactions.<sup>[21,22]</sup>

Surface-modified silica nanoparticles are receiving increasing attention in modern biotechnical and biomedical applications.<sup>[23–25]</sup> They provide an excellent model system for the development of nanoparticulate carrier systems as they are relatively simple tunable in particle size<sup>[17,23,26]</sup> and provide high flexibility in surface modification reactions by silanization (Fig. 6) (e.g., silica nanoparticles with a diameter of 100 nm were covalently modified at their surfaces by adjustable amounts of amine and carboxyl functional groups) (Fig. 7). The protein streptavidin was then conjugated

with nanoparticles, thus resulting in biofunctional hybrid particles with optimized protein density at the surface of nanoparticles.<sup>[27]</sup> Now the simple biotinylation of a protein prepares it for immobilization at the surface of silica particles, often conserving their full bioactivity.<sup>[28]</sup> In contrast, molecularly imprinted polymer nanospheres are examples of fully synthetic receptor nanoparticles. Here, highly crosslinked polymer nanospheres composed of poly(methacrylic acid)-co-(ethylene glycol dimethacrylate) were synthesized by miniemulsion polymerization in the presence of a chiral molecular template, L-Boc-phenylalanine anilid or D-Boc-phenylalanine anilid. By simple extraction of the template, polymer nanoparticles were obtained, which provided binding sites for the recognition of template molecules because of an imprinting process during polymerization. Because of the MAA content in copolymer particles, negative charges are disposed for attachment to polyelectrolyte layer systems. The present paper focuses on polymer nanoparticles composed of a copolymer formed by methylmethacrylate (MMA) with a special polymerizable surfactant bearing an active ester group.

### Protein Binding Polymer Nanoparticles Using Activated Ester Surfmers

Polymer nanoparticles with bioconjugation capabilities are an attractive solid-phase carrier system. For bioconjugation with a protein, the particles must provide a specific reactive function on their surface. These functions are traditionally introduced by surface modification of a preformed latex, often by formation of an activated ester.<sup>[21]</sup> Activated esters are valuable in bioconjugate chemistry as they react with nucleophilic groups of biomolecules (in proteins, peptides, or dyes) under mild conditions, hence usually preserving biomolecule activity. Here, we used a specific trifunctional active ester surfmer molecule to introduce the active ester function already during the formation of the polymer particle. A surfmer molecule is a

**Fig. 5** Left: Light micrograph of silica nanoparticle spots, deposited by a microarrayer on a glass slide. Lines: Different gap widths. Columns: 5, 2, and 1 droplet per spot. Right: Magnified image of a single spot with a diameter of 140  $\mu\text{m}$ .

**Fig. 6** Schematic of exemplary silanization (A) and derivatization (B) of silica nanoparticles.

polymerizable surfactant. In addition to the copolymerization of the molecule and its surface activity, here, active ester function is also disposed with the molecule *p*-(11(acrylamido)undecanoyloxy)phenyl dimethylsulfonium methylsulfate (AUPDS, **1**; Fig. 8). Thus nanoscopic polymer particles with a tunable diameter in the range from 120 to 160 nm with an activated ester surface were prepared by copolymerization with MMA (**2**; Fig. 8) in a one-stage reaction using emulsion polymerization.<sup>[22,29]</sup>

### Microarray Based on Patterned Monolayers of Functional Nanoparticles

The functionality of nanoparticles after deposition determines also the overall performance of the microarray. Qualitative assays of the functional properties of nanoparticles after microarraying were exemplarily performed with active ester surfmer nanoparticles deposited on glass substrates. In biochip technology, fluorescent labels are often used as markers and are detected with a fluorescence scanner. Thus for the

**Fig. 7** Scanning electron micrograph of silica nanoparticles. Bar, 100 nm.

demonstration of the reactivity of the active ester function of nanoparticles, a fluorescent dye (5,6-amino-fluorescein) was reacted with nanoparticles before or after deposition in a microarray.<sup>[13]</sup>

Glass slides were homogeneously activated by a double layer of polyanion and polycation, and the positively charged surfmer nanoparticles were deposited by a microspotter. The microarray was then incubated with a solution containing the fluorescent dye. Thereby, the amine group of the dye reacted covalently with the active ester group of the assembled surfmer nanoparticles. By scanning the microarray with a fluorescence scanner, the microstructure appeared very clearly, thus indicating effective binding of the marker (Fig. 9). The binding of the dye originated exclusively from the covalent binding of the dye, and the non-specific binding of the dye was negligible as was shown by a simple control experiment: When the active ester function was hydrolyzed and the microarray was incubated with the fluorescent dye solution in the same way, no fluorescence was observed.

In contrast, when surfmer ester nanoparticles were reacted with the fluorescent dye prior to deposition in a microarray, fluorescence activity was found again. The fluorescence scanner micrograph of the microarray formed with the fluorescently labeled nanoparticles appears the same as those reacted at the microarray surface (Fig. 9). Thus it was demonstrated that the (bio)conjugation reactivity of active ester surfmer nanoparticles was effectively conserved during the deposition in microarray.

When, instead of the fluorescence dye, for example, a protein receptor is immobilized by reaction with the active ester, or a protein biochip is realized by this simple bioconjugation reaction, all the surface chemistry for conserving the bioactivity of any protein receptor can be developed with the nanoparticles in solution and then a protein biochip can easily be prepared by the new route shown here.

**Fig. 8** Reaction scheme of nanoscopic polymer particles (diameter: 120–160 nm) with an optimized ester surface. AUPDS (1) is converted with MMA (2) as copolymer in a one-stage reaction using emulsion polymerization.

## MATERIALS AND METHODS

### Layer-by-Layer Technique

The substrates used for the immobilization of nanoparticles are glass slides (76 × 26 × 1 mm in size; Carl Roth, Germany), silica wafers, and gold-coated silica wafers. The polyions used are PDADMAC (low molecular weight) as polycation (Aldrich) and the sodium salt of SPS as polyanion (Sigma).

The slides were cleaned in 2 vol.% glass cleaner (Hellmanex, Germany) at 40°C for 90 min and placed in MilliQ water for ultrasonication for 5 min. Afterward, hydrolyzation took place in a 3:1 (vol/vol) mixture of ammonia (NH<sub>3</sub>, 25%; Fluka) and hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>, 30%; Merck) for 20 min at 70°C. The hydrophilic surface of slides was rinsed with MilliQ water and cleaned in MilliQ water in an ultrasonic bath for 5 min. The slides were now dipped into a solution of 0.02 M poly(diallyldimethyl ammonium chloride) and 0.1 M NaCl in MilliQ water for 20 min and rinsed with MilliQ water. To obtain a negatively charged surface, the glass slides were immersed into a solution of 0.02 M SPS and 0.1 M NaCl in MilliQ water for 20 min after the adsorption of the positively charged polycation. Finally, the slides were placed in MilliQ water in an ultrasonic bath for 5 min to homogenize the polyelectrolyte surface and again rinsed with MilliQ water.

### Photolithography

Photoablation of polyelectrolyte layers was performed using a mercury vapor UV lamp (UVP Ultra-Violet Products Limited, Cambridge, UK). The mask used was a copper transmission electron microscopy (TEM) grid “Identigrid M”: 400 mesh (400 bars per 25.4 mm; PLANO, Wetzlar, Germany).

After irradiation, the wafers were rinsed with MilliQ water and then incubated with a 0.5% particle suspension.

### Microcontact Printing

The elastomeric stamps were made from Sylgard 184 (Dow Corning GmbH, Wiesbaden, Germany). The stamps (line width: 2 μm; squares: 20 μm; gaps: 100 μm) used were from A. Offenhäuser of the Max-Planck Institute for Polymer-Research (Mainz, Germany; now Research Center Jülich, Germany).

### Microarrayer

The microarrayer used is the GMS 417 (MWG Biotech AG, Ebersberg, Germany). It has a fourfold pin-ring unit. The distance between pins is 9 mm. The diameter of the pintip is 125 μm. The spotter has a lateral error of 10 μm.

**Fig. 9** Illustration of structured and fluorescein–amine conjugated active ester surfmer nanoparticles on a PDADMAC/SPS-coated glass slide; here, cutouts from the 16-bit grayscale picture of the microarray laser scanner (GMS 417 Array Scanner) are shown as 256-color bitmap after color reverse. Left: Dye labeling of beads after spotted deposition. Right: Dye labeling of particles before spotted deposition. Bar, 400 μm.

## Analytical Methods

### Optical and atomic force microscopy

Optical micrographs are taken using a digital camera mounted on an optical microscope (Olympus BX 60). Scanning force microscopy is performed in noncontact mode with an Autoprobe cp (Park Scientific Instruments, USA).

### Photon correlation spectroscopy

Particle size is determined by dynamic light scattering using a Zetasizer 3000 HSA (Malvern Instruments, Herrenberg, Germany).

### Ellipsometer

The thickness of polyelectrolyte layers is detected with a computer-supported Multiscopie equipped with a HeNe laser (632.8 nm; Optrel GbR, Berlin, Germany).<sup>[30]</sup>

### X-ray photoelectron spectroscopy measurements

The atomic composition of layers is measured with the Axis Ultra system (Kratos Analytical Ltd., Manchester, UK; monochromatic Al K<sub>α</sub> pass energy: 160 eV for survey spectra, 40 eV for detail spectra). For peak integration and fitting, the shipped software is used.<sup>[31,32]</sup>

## CONCLUSION

A large variety of possible options and best fitting procedures were introduced to match the demands of an envisaged protein microarray structure in a most flexible way by employing functional nanoparticles. For a stable linkage of charged particles, the substrates were coated with polyelectrolytes by the LbL technique. For this purpose, hydrophilic or charged surfaces proved to be suitable.

The flexible route to a variety of nanoparticle-based microarrays allows for choosing the appropriate method for a certain kind of application. Spotting particles using a microarrayer allows for placing nanoparticles with different functionalities in different spots of the chip. Using the photolithographic or soft lithographic method, only one kind of particle can be transferred in one process, but user-defined and more complex structures can be generated more easily. However, multifunctional chips can be generated by step-and-repeat processes.

Each of the introduced methods generated microstructured monolayers of nanoparticles with high packing densities and homogenous distribution of

nanoparticles. The functional groups at the surface of the nanoparticles thus arrayed keep their functionality after deposition in a microstructure. Thus the large variety of nanoparticles optimized for the binding of a certain kind or class of proteins or peptides can be used for the relatively simple preparation of a biochip. Protein biochips allow for screening of complex interactions and are expected to play an outstanding role in upcoming proteome research (proteomics). One specific example of using these new kinds of protein biochips is to use them as substrates in affinity matrix-assisted laser desorption initiation turnover frequency (MALDI-TOF) mass spectrometry.<sup>[33]</sup>

# Biocatalytic Single-Enzyme Nanoparticles

Jay W. Grate

Jungbae Kim

*Pacific Northwest National Laboratory, Richland, Washington, U.S.A.*

## INTRODUCTION

Enzymes are useful biocatalysts of nanometer scale that regulate the chemistry of cells and organisms.<sup>[1]</sup> The potential application of enzymes as practical biocatalysts is well recognized and also growing.<sup>[2,3]</sup> The uses of enzymes have been realized in various fields, and are also being expanded in new fields: fine chemical synthesis, pharmaceuticals, commodity catalysts in food processing and detergent applications, biosensing, bioremediation, polymerase chain reaction, and protein digestion in proteomic analysis. The unique activities and specificities of enzymes play a key role in yielding a wide range of applications. However, the widespread application of enzymes is generally limited by their short lifetimes. As an innovative way of enzyme stabilization, we recently developed a new enzyme composite of nanometer scale that we call "single-enzyme nanoparticles (SENs)."<sup>[4]</sup> Each enzyme molecule is surrounded with a porous composite organic/inorganic network of less than a few nanometers thick. This approach represents a new type of enzyme-containing nanostructure. In this entry, we will describe the synthesis, characterization, and catalytic activity of SENs containing  $\alpha$ -chymotrypsin (CT).

## BACKGROUND

Many different approaches have been taken to stabilize enzyme activities, including various enzyme immobilization methods, enzyme modification, genetic modification, and medium engineering.<sup>[5–14]</sup> Genetic modification involves changing the amino acid sequence of an enzyme protein to yield an intrinsically more stable structure using molecular biology techniques such as directed evolution or random mutagenesis. However, medium engineering involves making the enzyme structure more stable by the effect of the medium around it, either by changing the salt composition of an aqueous solution, or by the use of non-aqueous solvents.

Chemically changing the structure of the enzyme through covalent reactions to the protein molecule defines enzyme modification. These reactions often

occur on the surface of the enzyme molecule. Covalent reactions have also been used to crosslink the peptide chains of enzyme molecules to reduce protein unfolding and denaturation. Addition of surface groups or polymers may be used to change the hydrophilicity or hydrophobicity of the molecule, and may result in an improvement in stability under certain solvent conditions. Alternatively, reactions may modify surface amino acids so that they no longer serve as the recognition site for proteolytic enzymes.

Enzyme immobilization entails attaching or incorporating enzyme molecules onto or into larger structures, including immobilization on surfaces, attachment within porous solids, or encapsulation in polymer, sol-gel, or composite materials. Especially in the case of multipoint attachment, immobilization reduces protein unfolding and hence improves stability. These conventional enzyme immobilization approaches often result in a final immobilization of micrometer scale, and the mass of support compared to that of the enzyme is often quite large. Encapsulating enzymes causes serious limitations on mass transfer of the substrate from the reaction medium to the enzyme active site.

The preparation of SENs represents a new approach that is distinct from immobilizing enzymes on the surfaces of solids, or from encapsulating them in sol-gels, polymers, or bulk composite structures. Converting free enzymes to SENs can result in significantly more stable catalytic activity, as we shall demonstrate for CT, whereas the nanoscale structure of the SEN does not impose a serious mass transfer limitation on substrates. At the same time, the synthesis of SENs is also different from conventional enzyme modifications such as surface amino acid modifications or polymer attachments, which generally do not provide as great a long-term enzyme stabilization. Fig. 1 provides a schematic comparison of various enzyme modification and immobilization approaches.

## SENS

### Synthesis

The process for the preparation of SENs begins from the surface of the enzyme molecule, with covalent

reactions to anchor, grow, and crosslink a composite organic/inorganic network around each separate enzyme molecule. The chemistry is shown in Fig. 2.<sup>[4]</sup> A vinyl group functionality is grafted onto the enzyme surface by covalently modifying the amino groups on the enzyme surface with acryloyl chloride. These modified enzymes are then solubilized in an organic solvent such as hexane. The solubilized enzymes are mixed with silane monomers containing both vinyl groups and trimethoxysilyl groups, such as methacryloxypropyltrimethoxysilane (MAPS) or vinyltrimethoxysilane (VTMS). Under suitable conditions, free radical-initiated vinyl polymerization yields linear polymers that are covalently bound to the enzyme surface. This represents the first polymerization. Careful hydrolysis of the pendant trimethoxysilyl groups, followed by condensation of the resulting silanols, yields a cross-linked composite network around each separate enzyme molecule. Hydrolysis and silanol condensation represent the second orthogonal polymerization.

The reactions are carried out so that crosslinking is largely confined to individual enzyme surfaces, yielding discrete nanoparticles, rather than the bulk solids that result from interparticle reactions. These enzyme-containing nanostructures are the structures we have called SENs. Using MAPS as the vinyl monomer, SENs containing CT (SEN-CT) as the enzyme have been prepared in synthetic yields of 38–73%.<sup>[4]</sup>

In the SEN structure, the enzyme is attached to the hybrid polymer network by multiple attachment points limited by the total number of amino groups on the

**Fig. 1** Schematic comparison of various enzyme stabilization approaches.

#### INITIAL ENZYME MODIFICATION

#### FIRST POLYMERIZATION: FREE RADICAL VINYL POLYMERIZATION

#### SECOND POLYMERIZATION: HYDROLYSIS AND SILANOL CONDENSATION

*Single Enzyme Nanoparticles (SENs)*

**Fig. 2** Synthesis of SENs. ENZ represents enzyme and it is understood that there are multiple amino groups around the enzyme that are modified as shown.

original enzyme surface. In addition, the thickness of the network around the enzyme is less than a few nanometers. The network is sufficiently porous to allow substrates to have access to the active site, as demonstrated in the catalytic studies below.

The synthetic parameters can be varied to control the thickness of the network and the likelihood of obtaining individual nanoparticles. Using VTMS as the vinyl monomer, which is less reactive to vinyl polymerization than MAPS, nanoparticles are obtained with thinner networks around the enzyme. The addition of vinyl crosslinkers such as trimethylpropane trimethacrylate (TMA) during the vinyl group polymerization with MAPS results in a thicker and denser network structure. The addition of crosslinker can also increase the formation of aggregates, rather than discrete nanoparticles containing single-enzyme molecules.

### Transmission Electron Microscopy

SENs were observed using high-resolution transmission electron microscopy (TEM). Individual nanoparticles with seemingly hollow centers and a contrasting outer structure could be resolved, as shown in Fig. 3A. The dimensions of the transparent core containing the protein are 4–8 nm across, which is consistent with the size and shape of CT (4 × 3 × 8 nm). The presence of silicon in the dark structure around

**Fig. 3** TEM images of SEN-CT (A) and biocatalytic silicates (B). The scale bars are 20 and 50 nm respectively.

the cores was confirmed by energy-dispersive X-ray analysis in the TEM instrument. In some images, nanoparticles are observed with sizes corresponding to two protein molecules, and in others, nanoparticles rest next to one another, either by chance or because of linkage during the synthesis. The use of crosslinkers under some conditions leads to larger size aggregates.

### Catalytic Stability

The activities of SEN-CT and free CT were measured by the hydrolysis of *N*-succinyl-Ala-Ala-Pro-Phe-*p*-nitroanilide (TP) in a buffer solution (10 mM phosphate buffer, pH 7.8). Whereas free CT is inactivated very rapidly by autolysis at 30°C, SEN-CT did not show any decrease in CT activity in a buffer solution for 4 days at the same temperature. Inactivations of

**Fig. 4** Kinetic results showing the inactivation of free CT and stability of SEN-CT at 30°C.

free CT and SEN-CT are compared in Fig. 4. Slight decreases in SEN-CT activity are observed in extended experiments, leading to an estimated half-life of up to 143 days.<sup>[4]</sup> Stored in buffer solution at 4°C, a sample of SEN-CT solution showed negligible decrease in CT activity over 5 months. Thus these enzyme-containing nanoparticles offer significant stabilization for this initial test case using the protease CT. It has also been demonstrated that trypsin can be stabilized in the SEN form.<sup>[4]</sup>

Modified CT, representing a preparation after vinyl group polymerization and before the second orthogonal polymerization, showed a marginal stabilization of CT activity. However, it did not come close to the impressive stability of SEN-CT prepared using sequential orthogonal polymerizations. For example, the relative activities after 1-day incubation, defined as the ratio of the residual activity to the initial activity, were 27%, 54%, and 100% for free CT, modified CT, and SEN-CT, respectively (Table 1). Thus the second orthogonal polymerization creating a hybrid network around the enzyme molecule is essential for achieving the observed high stability of SENs.

Although it is conceivable that the network surrounding the enzyme may interfere with biomolecular proteolysis, the fact that the CT molecules within SEN-CT retain their catalytic activity over extended periods of time also demonstrates that they are not losing activity by denaturation within the nanoparticle structure. Proteolysis of free CT by other active CT molecules is believed to occur by a mechanism entailing rate-limiting denaturation followed by

**Table 1** Stability of free CT, modified CT, immobilized CT (biocatalytic silicates), and SEN-CT<sup>a</sup>

CT preparation	Relative activity (%) after one-day incubation at 30°C
Free CT	27%
Modified CT <sup>b</sup>	54%
Immobilized CT <sup>c</sup>	≈100%
SEN-CT	≈100%

<sup>a</sup>The CT activity was determined by the hydrolysis of N-succinyl-Ala-Ala-Pro-Phe p-nitroanilide in an aqueous buffer (10 mM phosphate, pH 7.8) at room temperature (22°C). Each sample was incubated at 30°C in a standing position. After one-day incubation, the residual CT activity was measured, and the relative activity (%) was calculated from the ratio of the residual activity to the initial activity of each sample.

<sup>b</sup>Modified CT represent the preparation after the first vinyl-group polymerization and before the orthogonal silicate polymerization.

<sup>c</sup>Immobilized CT represents biocatalytic silicates. (From Ref.<sup>[15]</sup>.)

irreversible proteolysis of the denatured form.<sup>[15]</sup> In this mechanism, the observed rate of activity loss corresponds to the denaturation rate.

Stabilization of the SEN-CT against inactivation by denaturation likely results from multiple covalent attachment points within the nanostructure. Enzyme inactivation is usually considered as a two-step process,<sup>[16]</sup> as shown in Scheme 1.

In this mechanism, the species N, D, and I represent the active native, inactive reversibly denatured, and irreversibly inactivated forms of enzymes, respectively. Inactivation usually starts with a reversible unfolding of proteins (N → D) followed by secondary irreversible processes (D → I). Many strategies of enzyme stabilization generally aim at slowing down or inhibiting the first step (i.e., unfolding of enzyme molecule). To this end, enzyme immobilization, endowing the enzyme molecule with additional resistance to unfolding by attachment to a surface or encapsulation within a composite, seems to be one of the most promising methods for enzyme stabilization.<sup>[10,13]</sup> The use of multiple covalent attachment points is recognized as a method for improving stabilization.<sup>[13,17]</sup> Thus it is reasonable to expect that the multiple covalent attachment points created in the synthesis of SENs will lead to stabilization in the present test case, and also for other enzyme species that may be prepared as SENs in the future.

**Scheme 1**

## Kinetics and Mass Transfer Issues

In general, mass transfer effects are a fundamental issue in enzyme immobilization methods. Many immobilization methods, especially those that encapsulate the enzyme within a polymer, silica gel, or composite matrix, result in a serious mass transfer limitation of substrates and lowered volumetric activity because of the large mass of supports (in general, >90% by weight).<sup>[10]</sup>

Kinetic constants for the hydrolysis of TP by SEN-CT ( $k_{\text{cat}}$ ,  $K_m$ , and  $k_{\text{cat}}/K_m$ ) were determined.<sup>[4]</sup> The apparent binding constant ( $K_m$ ) of SEN-CT was 40 μM, which is almost the same as that of free CT (39 μM). This suggests that the nanostructure surrounding the enzyme did not cause a significant mass transfer limitation for the substrate (TP).<sup>[18]</sup>

These results can be compared with those for biocatalytic silicates previously prepared by Kim, Delio, and Dordick<sup>[19]</sup> These immobilized enzyme preparations yielded solid composites of micrometer scale (20–250 μm) (Fig. 3B) by a seemingly similar approach using two orthogonal polymerization steps. The stability of the CT activity in these biocatalytic silicates was also impressive (Table 1). However, the catalytic efficiency ( $k_{\text{cat}}/K_m$ ) of the enzyme in these bulk composites was lowered by a factor of 10, indicating a significant limitation on mass transfer of the substrate through the composite matrix.<sup>[19]</sup> Similarly, biocatalytic plastics isolated as micrometer-scale solids are subject to significant mass transfer limitations in an aqueous buffer.<sup>[20]</sup> The SEN nanostructures of single-enzyme scale significantly reduced the mass transfer limitation compared to these other microscale enzyme stabilization methods.

## CONCLUSION

We have developed a new nanostructure containing active and stable enzyme molecules. Dramatic activity stabilization was achieved with minimal substrate mass transfer limitation compared to enzymes entrapped in larger-scale particles. The development of stabilized enzymes as soluble individual enzyme particles provides the opportunity to further process these new nanomaterials, in contrast to enzymes entrapped in bulk solids. The SENs can be deposited as films or immobilized on solid supports. Given their small size, they can penetrate and be immobilized within nanostructured or nanoporous matrices, creating hierarchical architectures. They can potentially be linked with other nanoparticles or molecules as part of multifunctional nanoassemblies.

We are also optimistic that other enzymes may also be stabilized as SENs, using the approach described

above or other synthetic routes yielding crosslinked porous network nanostructures around them. Such hybrid enzyme nanostructures offer great potential to be used as prepared, or processed into other forms for a wide variety of applications such as biosensors, bioremediation, and bioconversions.

# Biological and Chemical Decontamination

Peter K. Stoimenov  
Kenneth J. Klabunde

*Department of Chemistry, Kansas State University, Manhattan, Kansas, U.S.A.*

## INTRODUCTION

A great deal of interest has been focused on nanomaterials in the last decade because of their unusual physical, mechanical, and chemical properties. They have found numerous applications, or are expected to find such applications in electronics, catalysis, composite materials, etc. The differences in their chemical properties, in particular, compared with the corresponding bulk material are mostly because of a largely increased surface area and a great increase in the number of active sites on the surface, such as corners, edges, and dislocations. Furthermore, nanomaterials are usually less thermodynamically stable than the corresponding bulk materials, which contributes to their enhanced chemical activity.

Decontamination of chemical and biological warfare is of considerable interest not only for eliminating the hazard of warfare agents on a battlefield, but also in cases of terrorist attacks, industrial accidents, demilitarization of warfare stockpiles, etc. The application of solid materials as decontaminants for both chemical and biological warfare agents has been severely limited by the incomplete and generally slow interaction of solid materials with warfare agents. Nanoparticles with their high surface area, enhanced chemical reactivity, and easy deployment allow the development of new perspectives regarding decontamination. In addition, generally, the products of these decontamination reactions are benign, mineral-like solids.

## CHEMICAL WARFARE AGENTS DECONTAMINATION

A component of a filtration system is always a high surface area solid, usually activated carbon, which adsorbs warfare agents physically but does not destroy them. The sorbed material is still highly toxic and the decontamination of the contaminated carbon is a problem. Nanoparticles offer surface areas comparable with active carbon, but at the same time high chemical reactivity toward the warfare agents, allowing their chemical decomposition and detoxification.

Several chemical warfare agents are noted as most important because of their very high toxicity, persistence, and large existing stockpiles.<sup>[1]</sup> Mustard gas or HD is a blistering agent, which can be lethal in high concentrations. It irreversibly alkylates key amines in organisms such as proteins, enzymes, and especially DNA, which causes cell malfunction and death. Another warfare agent with similar action and chemical structure is the arsine analog, Lewisite (Fig. 1).

Another large class of chemical warfare agents is the nerve agents class, which is based on phosphonic acid derivatives. Some of them feature a relatively stable bond with fluorine-like sarin (GB agent) or soman (GD agent) (Fig. 1). The later generation, such as VX, contains a more stable ester bond, which contributes to higher persistence, slower hydrolysis, and decontamination, which is more difficult. The VX generation of warfare agents is more toxic as well. The action of the nerve agent is based on its ability to selectively bind to the active centers of key phosphatase enzymes (such as acetylcholinesterases), which are responsible for nerve impulse propagation. Similar to nerve gases are certain widely used pesticides, such as paraoxon (Fig. 1).

## Physical Action

There are several requirements for successful decontamination,<sup>[1]</sup> the most important of which is that non-toxic by-products must be formed and the decontamination should be quick and complete. There is a requirement that the decontamination agent should not be corrosive to the surfaces to which it is applied. Nanoparticles do have excellent properties in this respect, as they are very easy to deploy and to clean up. In general, they are not corrosive, or not as corrosive as typical developed decontamination compositions and solutions. As such, nanoparticulate formulations should be applicable to all kind of surfaces, including the skin, metals, and sensitive equipment, including electronics. Most decontaminating compositions are liquids, which contain organic liquid, electrolytes, as well as corrosive oxidants.

**Fig. 1** Structures of the most common chemical warfare agents. (A) 2,2'-Dichloroethyl sulfide (mustard gas or HD); (B) soman or GD; (C) Lewisite; (D) VX agent; (E) sarin or GB; and (F) paraoxon (pesticide).

Nanoparticles are in the form of fine powder, which can be deployed by an inert solvent suspension such as freon or just by carrier gas under pressure. They can be removed by standard vacuum cleaning procedures. Alternatively, if an air-filtering or water-filtering approach is needed, nanoparticles can be used in the form of porous reactive pellets.

## CHEMICAL ACTION

It has already been mentioned that chemical warfare agents are usually alkylating agents. Usually their hydrolysis renders them non-toxic or much less toxic than warfare agents because the chemical groups that determine toxicity are usually the most reactive parts of the molecule.<sup>[1]</sup> Similarly, detoxification can be achieved by their oxidation<sup>[1-3]</sup> because both HD and nerve gases contain relatively easy-to-oxidize sulfur (HD and VX) and/or phosphorus atoms, which have a large contribution to their extreme toxicity.

Metal oxide nanoparticles are apparently a very good choice for detoxification of warfare agents because of the presence of a huge number of basic Lewis and Bronsted sites, as well as acidic sites, which can very significantly accelerate hydrolysis process. By-products, in the form of phosphonates and alcohols, have the tendency to bind strongly to solid surfaces and be retained there. Taking into consideration the high surface area of nanomaterials, this corresponds to a large amount of decomposed warfare agent and rapid reactions compared with bulk metal oxide surfaces because the rate of the interaction is

proportional to the contact area. It is additionally strongly facilitated on corners and edges, which have higher activity and lower activation energy barriers compared with normal surface sites.

Most interesting for this type of application are certain metal oxides that have high melting points and chemical stability. The nanomaterial form is thermodynamically less stable than the corresponding bulk material. The higher the melting point is (higher lattice energy), the more stable the nanomaterial will be. Based on this reaction, the best metal oxide nanoparticle systems are magnesium oxide and aluminum oxide nanoparticles,<sup>[4-9]</sup> although activity has also been found for other oxides, such as calcium oxide.<sup>[10]</sup>

## Detoxification of HD (Mustard Gas)

The toxicity of mustard gas (Fig. 1) is because of its capability to attach simultaneously and irreversibly to two biomolecules. The reaction takes place by an  $S_N^1$  mechanism with an intermediate sulfonium cation as a key reaction species.

Magnesium oxide has a considerable number of basic sites that interact with the HD by hydrohalogen elimination, forming vinyl chloroethyl sulfide, or by exchange of chlorine with a hydroxyl group from the magnesium oxide surface.<sup>[6]</sup> The reaction proceeds further to divinylsulfide and in the other case to the corresponding glycol. The final ratio between the two major products was found to be approximately 50:50. The half-life of HD in this first-order reaction is 17.8 hr.<sup>[6]</sup> According to a careful kinetic examination, the reaction actually starts much faster. However, it slows down when part of the surface becomes clogged with residues of the reaction, which are permanently bound to the surface. Thus the limiting step in the reaction is the diffusion of the viscous and relatively low-volatility HD among magnesium oxide aggregates. This study has shown that the half-life of warfare agents is proportional to their vapor pressure—the higher the vapor pressure is, the higher the diffusion rate and hence the reactions leading to decontamination will be.<sup>[6]</sup> When calcium oxide was tested instead of magnesium oxide, the ratio of the products changed significantly to 80:20 elimination/hydrolysis products.<sup>[10]</sup> Elimination was the preferred route for the reaction, although it depended significantly on the way the sample was pretreated: When the nanoparticles were dried in advance before their contact with HD, elimination to hydrolysis products changed completely to 5:95 elimination/hydrolysis products.<sup>[10]</sup> It is particularly important to note that a catalytic decomposition process was found for CaO nanoparticles.<sup>[10]</sup>

Additional experiments have shown<sup>[7]</sup> that dispersion of nanoparticulate magnesium oxides in a variety

of solvents with/without addition of small amounts of water can alter the rate as well as the product types and their ratio. The most prominent effect observed was that the solvent speeds up the reactions because it eliminates the diffusion problem caused by the relatively high viscosity of warfare agents. Another important feature is that Lewis and Bronsted acid sites work simultaneously with Lewis base sites to decompose HD and HD stimulants.<sup>[7]</sup>

Another oxide that can be synthesized with high surface area using an aerogel procedure is aluminum oxide (AP- $\text{Al}_2\text{O}_3$ ). Although aluminum oxide is not as basic as magnesium and calcium oxides, it possesses a large number of Lewis acid sites, which accelerate hydrolysis processes.<sup>[5]</sup> Because nucleophilic centers are much less abundant, elimination is less prominent and the ratio of the elimination/hydrolysis products is 17:83, with the major product being dithioglycol, as observed by solid-state nuclear magnetic resonance (NMR).<sup>[5]</sup>

#### Detoxification of nerve agents (VX, GD, GB, and paraoxon)

The interaction of nerve agents such as VX and GD (soman) (Fig. 1) with nanosized magnesium oxide particles (AP-MgO) was tracked by solid-state NMR.<sup>[6]</sup> It allowed the kinetics of interaction as well as the intermediate products to be determined. The width of the peaks was used to judge whether a particular product or intermediate was attached to the surface: Species attached to the surface have broader peaks because of anisotropic effects. In the case of GD, hydrolysis was the major process that took place, yielding GD acid (pinacolylmethylphosphonic acid) as a major product and methylphosphonic acid as a secondary product. According to NMR data, both products strongly interact with the surface, most probably by strong ionic interaction.<sup>[6]</sup> The basic surface of the magnesium oxide nanocrystals most certainly converts the products to their respective anions, which bind with the positively charged surface. A quick start of the reaction, followed by a slowing down to a constant rate of  $t_{1/2} = 28$  min, is observed, as in all cases of interactions of nanomaterials with viscous warfare agents.

The VX agent is a thioester with high viscosity and lower volatility compared with GD. It slowly hydrolyses to ethyl methylphosphonic acid and methylphosphonic acid. It is noteworthy to mention that the toxic hydrolysis product, EA-2192 (the VX toxin with the ethyl group replaced by hydrogen), which usually forms by hydrolysis in water, is not observed when contacted with AP-MgO nanoparticles. A very similar behavior was found in the interaction of VX and GD with nanosized calcium oxide.<sup>[10]</sup>

Nanoscale-sized aluminum oxide interacts with nerve agents with a very different rate: Although the

reactive and relatively volatile GD has a  $t_{1/2} = 1.8$  hr after a quick start-up, the VX agent's  $t_{1/2}$  is above 6 days. The difference from the MgO case is that the interaction with the warfare agents erodes the surface, allowing the "bulk" of  $\text{Al}_2\text{O}_3$  nanoparticles to participate in the detoxification process. This makes aluminum oxide a very promising material for warfare agent cleaning because this erosion behavior, coupled with its high surface area, allows a very high reaction capacity.

### BIOLOGICAL WARFARE DECONTAMINATION USING NANOMATERIALS

Biological warfare agents could be several completely different types: bacteria, fungi, viruses, or toxins. All these have major differences in their behavior, and their decontamination procedures can vary significantly. This makes creating a single total decontaminating material practically impossible.

There are several methods recognized so far in decontaminating biological warfare agents. The most widely applied method is disinfecting solutions, such as diluted bleach or chloramine T solution. They have the advantage of quick and complete disinfection of bacteria, viruses, and certain fungi. However, it has very significant disadvantages, such as aging, which deteriorates disinfecting activity. Another disadvantage is that the bleach solution exhibits a strong smell, is corrosive, and is safely applicable only for the most durable surfaces. There are studies which reveal that in some respects, bleach effectiveness can be overrated,<sup>[11]</sup> especially for aged solutions.

A limited method for decontamination is applying a gas such as chlorine or chlorine dioxide. It cannot be applied in open spaces and on sensitive equipment, and can permanently damage many surface types.

Another approach is the use of oil-in-water microemulsions, developed by Hamouda et al.<sup>[12,13]</sup> and Hamouda and Baker.<sup>[14]</sup> They have demonstrated good activity against certain spores and bacteria, but they have the disadvantage of being difficult to remove after the decontamination procedure. In addition, they cannot be used for filtering airborne pathogens.

An alternative to the aforementioned approaches is the application of very fine solid powders in the form of nanoparticles. They are advantageous for a decontamination procedure because they can be easily collected from surfaces by simple vacuum cleaning, and they can be applied on sensitive electronic and other equipment because no liquid is present; they are much less corrosive than any of the aforementioned methods as well.

Nanoparticles such as AP-MgO, ZnO, or CaO have limited bactericidal activity against most biological warfare agents, although they have decent activity

against vegetative bacteria such as *Escherichia coli*, *Bacillus cereus*, and *B. subtilis*.<sup>[15]</sup> An outstanding property of nanoparticles is the demonstration of their capability to remove powerful biological toxins such as aflatoxins.<sup>[15]</sup>

As was discussed in the “Introduction,” nanoparticles feature huge surface areas and higher surface reactivity compared with bulk materials. Thus nanoparticles have very high adsorption activity per mass adsorbent, which allows adsorption of potent bactericides such as elemental chlorine, bromine, or iodine. Halogens are excellent bactericides in general. However, their use is restricted because of their high volatility, corrosive action, and toxicity.

Nanoparticles are capable of adsorbing as much as 6–10 wt.% free chlorine, 13–15 wt.% bromine, and 20–30 wt.% iodine. The adsorbates are preserved as halogens on the surface, preserving their properties as oxidizers, including their excellent bactericidal and sporicidal properties.<sup>[16]</sup>

The halogen-loaded magnesium oxide nanoparticles were found to preserve their activity even in water suspension,<sup>[16]</sup> or in the dry state. If suspended, all types of halogen-loaded nanoparticles become positively charged, thus being attracted to the negatively charged (in general) bacteria or spores.<sup>[16]</sup> It was demonstrated by laser confocal microscopy that AP-MgO/X<sub>2</sub> (X = Cl, Br, none) coagulates spontaneously with the bacteria in clumps composed of both bacteria and nanoparticle aggregates. When observed with transmission electron microscopy (TEM) and atomic force microscopy (AFM), microbial spores (*B. subtilis*) and vegetative cells (*E. coli*) were severely damaged (Fig. 2). In the case of more vulnerable vegetative cells, nanoparticles were found to enter the cells through holes developed in the membrane, thus bringing the adsorbed halogen inside the cell. The cell membrane and the spore coat were significantly damaged and eventually killed the cell by allowing its internal content out of the cell envelope.

An important feature of nanoparticles for their sporicidal activity is their basicity: It was demonstrated that pretreatment of spores with basic solution removes partially or completely the thin outermost layer composed of base-sensitive proteins, which is a strong barrier for conventional sporicides, including free halogens.<sup>[17]</sup> Apparently, the nanoparticles of magnesium oxide have several properties, which render them as highly active bactericides and sporicides. They are abrasive (which is important for damaging the cell membrane), basic (important for partial spore coat removal), oppositely charged to the bacteria and spore cells, and carry a significant amount of oxidizing potential in the form of a potent bactericide (chlorine or bromine). For example, chlorine-loaded magnesium oxides carry as much as 10 wt.% active chlorine,

**Fig. 2** Nontreated *E. coli* (left) and *E. coli* treated with AP-MgO/Cl<sub>2</sub> nanoparticles (right). The dark matter in the right micrograph represents nanoparticles that penetrated inside the cell.

whereas in comparison, undiluted bleach contains 6 wt.% active chlorine.

## CONCLUSION

Nanoparticles constitute a new realm of the matter, which has properties very different from those of the bulk material. Because of higher surface-to-bulk ratios for the constituting atoms or ions and the much higher overall surface per unit weight, they exhibit outstanding chemical, physical, and biological properties. Their high surface area and activity may find use in “hasty” decontamination of warfare agents. Nanoparticles of metal oxides can be pelletized and used as an additional protective layer for standard activated carbon filters. Furthermore, nanoparticles detoxify adsorbed warfare agents. Nanoparticulate magnesium oxide and its halogen-loaded derivatives, in particular, were found to possess bactericidal, viricidal, and sporicidal properties as well as capabilities to adsorb and deactivate complex toxins such as aflatoxins.

Nanoparticles have the potential to be used as an “all-in-one” solution for both chemical and biological warfare decontamination.

## INTRODUCTION

Nanoscale biomaterials, in the form of nanostructures such as nanofibers and nanoparticles, have been extensively used in biomedical applications such as tissue engineering and drug delivery. As these nanostructures are subjected to physical stresses within the body during application, it is important to ensure that their structural integrity remains intact and that they do not fail in vivo. Thus, there is a need to mechanically characterize these nanoscale biomaterials. Here, techniques for characterizing these nanobiomaterials using tensile test, nanoscale bend test, and nanoindentation will be presented and the challenges involved highlighted. Most of these techniques involve the use of atomic force microscopy (AFM) or AFM cantilevers as a means to apply or measure force and displacement in the nanometer range. The current limitations in the mechanical characterization of nanoscale biomaterials and future work required will be briefly mentioned.

## BACKGROUND

Biomaterials can be defined as any biological or man-made materials that are used to construct prosthetics or medical devices for implantation in a human body for the purpose of performing, augmenting, or replacing a natural function.<sup>[1,2]</sup> Biomaterials in the form of nanostructures are often fabricated to mimic the body's extracellular matrix in the area of tissue engineering<sup>[3]</sup> and/or as drug delivery devices in the area of pharmaceuticals.<sup>[4]</sup> These nanostructures normally come in the form of nanofibers and nanoparticles. When the nanostructures are implanted in the body, it is essential that they do not buckle, deform permanently, or fracture when subjected to various stresses in the human body. Therefore it is important to obtain the mechanical properties of individual nanofibers and nanoparticles to ensure that these nanostructures are able to perform their designated functions in vivo.

In this entry, various mechanical characterization techniques of these nanostructures will be presented. These techniques include tensile test, bend test, and indentation done at the nanoscale for the characterization of nanofibers. Owing to the shape of nanoparticles, only nanoindentation or compression tests have been performed. The challenges of each technique and the methods of overcoming them will be mentioned in each section. Finally, the current limitations and future directions will be discussed.

## NANOFIBERS

The most common type of nanofibers used for biomedical applications are the biodegradable polymeric nanofibers. These fibers have been used to form tissue engineering scaffolds for the regeneration of tissues such as cartilage,<sup>[5]</sup> blood vessel,<sup>[6]</sup> and nerve.<sup>[7]</sup> The preferred method of fabricating such nanofibers is by electrospinning as it is simple and able to produce continuous nanofibers (Fig. 1A).<sup>[3]</sup> Phase separation has also been used to produce nanofibers in the form of a nanofibrous foam (Fig. 1B).<sup>[7,8]</sup>

Owing to the small size of the nanofibers, conventional testing methods of characterizing larger fibers cannot be directly applied to nanofibers. The difficulties of testing single nanofibers include preparing and handling single strand nanofibers, finding force transducers and actuators with nanoscale and subnanoscale resolutions, and finding a way to observe the deformation of nanofibers. Although methods for testing nanoscale materials have been established for materials such as carbon nanotubes (CNTs),<sup>[9–11]</sup> these methods cannot be easily applied to polymeric nanofibers as the tests have to be carried out inside a scanning electron microscope (SEM) or transmission electron microscope. Owing to the nonconductive nature of most polymeric nanofibers, such methods are not suitable. However, by modifying existing techniques for testing microscale fibers and CNTs, feasible methods of testing single polymeric nanofibers have been developed.

**Fig. 1** SEM images of biodegradable nanofibers. (A) Electrospun polycaprolactone (PCL) nanofibers and, (B) poly(L-lactic acid) (PLLA) nanofibrous scaffold produced by phase separation.

### Tensile Test

Some challenges unique to tensile tests in addition to those mentioned in the previous section include sample

gripping and fiber alignment. Conventional mechanical gripping methods may not be suitable for nanofibers owing to the small size of the fibers.<sup>[12]</sup> Fiber alignment is necessary as misalignment between fiber axis and loading direction may result in unwanted bending moment, which may lead to premature sample failure.<sup>[12]</sup> Two methods of performing tensile test of nanofibers are presented with these factors in mind.

AFM cantilevers have been used for tensile tests of CNTs within the SEM chamber.<sup>[11,13]</sup> Although this method is not suitable for nonconductive samples, it can be adapted for testing polymeric nanofibers. Tan et al.<sup>[14]</sup> performed tensile test of electrospun polyethylene oxide (PEO) nanofibers using a piezo-resistive AFM cantilever. Aligned electrospun nanofibers were produced<sup>[15]</sup> to obtain several aligned fibers across two parallel strings mounted on a wooden frame. One end of a selected nanofiber was attached to a motorized optical microscope stage and the other end to a piezo-resistive AFM cantilever tip (Fig. 2). The nanofiber was stretched by moving the microscope stage in the X-direction and the force was measured by the cantilever deflection. The stress-strain characteristics of the nanofiber can be obtained from this test. Although this method is feasible, it is time consuming and requires practice for successful attachment of nanofiber to the AFM tip and the microscope stage.

The conventional method of preparing tensile test samples of microfibers is to mount single fibers onto a paper or plastic frame with the fiber spanning across a hole in the frame.<sup>[16,17]</sup> A similar method of preparing single nanofibers for tensile test can be done for electrospun nanofibers.<sup>[18]</sup> Currently, a commercial nano tensile testing system (Nano Bionix System, MTS, U.S.A.) has the capability of testing polymeric nanofibers of as small as few hundred nanometers.<sup>[18,19]</sup> Electrospun polycaprolactone (PCL)<sup>[18]</sup> and poly(L-lactic acid) (PLLA)<sup>[19]</sup> nanofibers have been tested using this method. Polycaprolactone nanofibers were electrospun by directly depositing nanofibers across a cardboard frame (Fig. 3). After mounting the sample on the nano tensile tester, the cardboard frame was cut along the

**Fig. 2** Schematic diagram of the tensile test of a polyethylene oxide (PEO) nanofiber using a piezo-resistive AFM tip. *Source:* From Ref.<sup>[14]</sup>.

**Fig. 3** A single nanofiber sample (not visible) is first mounted vertically across a cardboard partition or frame. This cardboard frame is then mounted onto a nano tensile tester for the nano tensile testing of a single polymer nanofiber. (NanoBionix, MTS, U.S.A.). *Source:* From Ref.<sup>[18]</sup>.

discontinuous lines at the two sides of the frame before the fiber was stretched (Fig. 3). The stress–strain curves for the PCL fibers at different fiber diameters are shown in Fig. 4.

The mechanical properties were observed to vary with fiber diameter owing to the higher “draw ratio” that was applied during the electrospinning process for fibers with smaller diameter. Although many samples can be tested conveniently with this method, observation of the nanofibers during the tensile test is

**Fig. 4** Plot of stress vs. strain for electrospun polycaprolactone (PCL) ultrafine fibers with varying fiber diameters. *Source:* From Ref.<sup>[18]</sup>.

difficult as this system does not provide a suitable observation system to investigate the deformation and mode of failure.

### Bend Test

The AFM is able to apply forces in the nano- and pico-Newton range and measure deformation in the subnanometer range. Thus it is a very useful tool for mechanical testing of nanostructures. The AFM has been used for three-point bend tests of CNTs<sup>[20–22]</sup> by using the AFM tip to apply a point load at the mid-span of a CNT suspended over a hole or groove. Three-point bend test of nanofibers such as  $\beta$ -chitin,<sup>[23]</sup> PEO,<sup>[24]</sup> and PLLA<sup>[25]</sup> can be performed in the same way as the sample does not need to be conductive.

PLLA nanofibers produced by phase separation will be used to illustrate three-point bend test of single nanofibers.<sup>[25]</sup> The bend test was performed by using an AFM tip to apply a point load at the mid-span of a suspended nanofiber over an etched groove on the silicon wafer (Fig. 5).

The adhesion between the sample and substrate is usually sufficient for the bend test to be conducted successfully without slippage at the fixed ends. Young’s

**Fig. 5** Nanofibers suspended over etched grooves of silicon wafer. (A) SEM image of poly(L-lactic acid) PLLA nanofibers deposited onto the silicon wafer; (B) AFM contact mode image of a single nanofiber (300 nm diameter) suspended over an etched groove; and (C) schematic diagram of a nanofiber with mid-span deflected by an AFM tip. *Source:* From Ref.<sup>[25]</sup>.

modulus,  $E$ , is found from beam bending theory<sup>[26]</sup> for a beam with two ends fixed as

$$E = \frac{PL^3}{192\nu I} \quad (1)$$

where  $P$  is the maximum force applied,  $L$  is the suspended length,  $\nu$  is the deflection of the beam at mid-span, and  $I$  is the second moment of area of the beam (where  $I = \pi D^4/64$  and  $D$  is the beam diameter). The method of obtaining  $\nu$  from the force curves using AFM is shown in Fig. 6.  $E$  is found to be  $1.0 \pm 0.2$  GPa for PLLA nanofibers assuming that the fibers undergo pure bending.

The nanofiber was assumed to be an elastic string instead of a rigid elastic beam for the bend test of electrospun PEO nanofibers<sup>[24]</sup> as the force curves for suspended PEO nanofibers were best fitted with a cubic equation. In this case, the Young's modulus is given by

$$E = \frac{P}{8A(\nu/L)^3} \quad (2)$$

where  $A$  is the cross-sectional area of the fiber. It is necessary to ensure that there is no indentation made on the nanofiber by the AFM tip for the bend tests as this will result in underestimating the Young's modulus. This can be done by ensuring that no indentation is made when applying the same maximum force to portions of nanofiber on the substrate. This technique is useful for testing both continuous nanofibers and nanofibrous networks.

A novel way of performing bend test of single nanofibers was proposed by Gu et al.<sup>[27]</sup> Single electrospun

**Fig. 6** Plot of cantilever deflection ( $D$ ) vs. vertical displacement of the  $z$ -piezo ( $Z$ ). A reference curve is obtained by measuring the cantilever deflection over the  $Z$  piezo displacement on a silicon wafer. The loading and unloading curves are obtained by using the AFM tip to deflect the mid-span of the nanofiber. The deflection of the fiber,  $\nu$  is the difference between the loading and the reference curve. *Source:* From Ref.<sup>[25]</sup>.

**Fig. 7** (A) SEM image of a polyacrylonitrile (PAN) fiber attached to a contact mode cantilever and (B) schematic diagram of a nanofiber with one end attached to AFM tip and the other end deflected by silicon substrate. *Source:* From Ref.<sup>[27]</sup>.

polyacrylonitrile (PAN) nanofibers were cut before attaching one end to an AFM tip with epoxy (Fig. 7A). The free ends of the nanofibers were bent on the sharp edge of a silicon substrate (Fig. 7B). The dimensions of the nanofiber are obtained from SEM observation without coating the sample. The nanofiber was considered to be an ideal spring over the whole length and the Young's modulus is given by

$$E = \frac{4}{3\pi} \times \frac{P}{x} \times \frac{L^3}{r^4} \quad (3)$$

where  $r$  is the radius of the nanofiber and  $P/x$  is the product of the spring constant of cantilever and the slope of the approaching line of the force curve. This method may not be suitable for fibers that are sensitive to thermal treatments as the fibers need to be first cooled in liquid nitrogen before cutting them and then subsequently get heated up by electron beam in the SEM.

## Nanoindentation

Nanoindentation of nanofibers is performed by using an AFM tip to apply a load on the curved or sectioned

surface of the nanofiber, such that the nanofiber deforms elastically or elastic-plastically. Although the sample can be prepared for testing by simply depositing the nanofibers on a hard and flat substrate with sufficient adhesion between the substrate and the nanofiber, interpretation of nanoindentation results may vary based on the assumptions used.

### Elastic nanoindentation

The elastic modulus of the material is obtained during elastic nanoindentation, whereby the deformation of the sample by the AFM tip is recoverable. The use of AFM for nanoindentation requires careful consideration of the following factors:

1. The elastic modulus values can be overestimated if the diameter of the nanofiber is too small (<200 nm).<sup>[28]</sup> However, this can be overcome by using small penetration depths.
2. Actual tip radius and cantilever spring constants usually deviate from the nominal values provided by the manufacturer.
3. Surface roughness of the nanofiber will result in the reduction of contact pressure for a given load,<sup>[29]</sup> thereby resulting in an underestimated value of elastic modulus.
4. If nanoindentation is performed on the curve surface of the nanofiber, the curved surface of the nanofiber has to be taken into account especially when the radius of curvature of the AFM tip and the fiber diameter are of comparable size.
5. As the AFM tip is not perpendicular to the sample surface, slip and friction between the AFM tip and the sample surface may occur during indentation.<sup>[30]</sup> However, the non-perpendicular load factor is not significant.<sup>[31]</sup>
6. In a high-humidity environment (>70% relative humidity), the effects of adhesion owing to capillary effect of water condensation between tip and sample can be significant.<sup>[32]</sup>

AFM was used to perform nanoindentation of electrospun PAN nanofibers.<sup>[33,34]</sup> It was assumed that the indentation depth was of comparable size to the AFM tip, and the tip radius (5 nm) was small compared to nanofiber diameter (50–500 nm) such that the nanofiber curvature can be ignored. The reduced modulus is given by

$$\frac{P}{\delta} = 2\sqrt{\frac{A}{\pi}}E_r \quad (4)$$

where  $P$  is the normal force,  $\delta$  is the indentation depth,  $A$  is the contact area, and  $E_r$  is the reduced modulus,

which is given by

$$\frac{1}{E_r} = \frac{1 - \nu^2}{E} + \frac{1 - \nu_i^2}{E_i} \quad (5)$$

where  $E$  and  $\nu$  are the elastic modulus and Poisson's ratio, respectively, for the sample and  $E_i$  and  $\nu_i$  are the same quantities for the AFM tips. As the AFM tip is much stiffer than polymeric samples ( $E_i \gg E$ ), the last term in Eq. (5) is assumed to be zero.

A different assumption was used for the nanoindentation of PLLA nanofibers produced by the phase separation method.<sup>[35]</sup> Hertz's theory of normal contact of elastic solids was used to analyze the force-indentation data.<sup>[36]</sup> The nanofiber was assumed to be a cylinder and the AFM tip a sphere. The reduced modulus,  $E_r$ , is given by

$$E_r = \sqrt{\frac{9P^2}{16R_e\delta^3}} \quad (6)$$

where  $P$  is the force applied,  $\delta$  is the indentation depth, and  $R_e$  is the equivalent radius for a spherical indenter in contact with an infinitely long cylinder.  $R_e$  is given by

$$R_e = \sqrt{\frac{R_t^2 R_f}{R_t + R_f}} \quad (7)$$

where  $R_t$  is the AFM tip radius and  $R_f$  is the radius of the nanofiber. The elastic modulus of the nanofiber was then calculated assuming that  $\nu$  is 0.33.<sup>[37]</sup>

The root mean square (RMS) roughness<sup>[29]</sup> ( $R_q = 1.1 \pm 0.6$  nm) was taken from the AFM image of the nanofiber surface and used to determine the correction required for the calculated modulus values. The elastic modulus of PLLA nanofiber was found to be  $0.7 \pm 0.2$  GPa for fibers with diameter >250 nm. Higher values were obtained for fibers with smaller diameter owing to the effect of the underlying substrate. To determine if the effect of surface roughness on the calculated elastic modulus was significant, a nondimensional parameter,  $\alpha$ , has to be determined where

$$\alpha = \sigma_s \left( \frac{16R_e E_r^2}{9P^2} \right)^{1/3} \quad (8)$$

and  $\sigma_s$  is the RMS roughness. The Hertz's theory for smooth surfaces can be used with a few percentage of error if the parameter  $\alpha$  is less than 0.05.<sup>[29]</sup> Because  $\alpha$  for this study was calculated to be 0.28, correction has to be made to the elastic modulus values. A second nondimensional parameter,  $\mu$ , defined by Greenwood

and Tripp<sup>[38]</sup> is given by

$$\mu = \frac{8}{3} \eta_s \sigma_s (2R/\kappa_s)^{1/2} \quad (9)$$

where  $\eta_s$  is the asperity density and  $\kappa_s$  is the mean curvature of the summits of the asperities. Greenwood and Tripp obtained a range of  $\mu$  between 4 and 17, which encompass a wide range of practical rough surfaces. The two parameters,  $\alpha$  and  $\mu$ , are then used to determine the correction required. The ratio of effective contact radius  $a^*$  (experimental) to the Hertz radius  $a_0$  (theoretical) are influenced by the surface roughness as shown in Fig. 8. For  $\alpha = 0.28$  and  $4 < \mu < 17$ , the ratio of  $a^*/a_0$  is between 1.14 and 1.18. As  $E$  is proportional to  $1/a^3$ , the elastic modulus after roughness correction was found to be approximately 1 GPa. This result after roughness correction for the PLLA nanofibers agrees well with that of the three-point bend test.<sup>[25]</sup>

### Elastic–plastic nanoindentation

The elastic modulus can also be obtained from elastic–plastic nanoindentation. However, this type of nanoindentation is not suitable for very thin sections or very small fibers owing to the larger penetration depth. Typically, the elastic modulus from elastic–plastic indentation is obtained from the slope of the initial portion of the unloading curve ( $S$ ), which has been fitted by a power-law relation. This was first formulated by Oliver and Pharr<sup>[39]</sup> as shown in Eq. (10)

$$S = 2\beta \sqrt{\frac{A}{\pi}} E_r \quad (10)$$

where  $\beta$  is a constant that depends on the geometry of the indenter and  $A$  is the projected area of the indent. This model assumes that the nanofiber diameter is much larger than the AFM tip.

**Fig. 8** Influence of the surface roughness on the effective contact radius  $a^*$  compared with the Hertz radius  $a_0$ . Source: Adapted from Ref.<sup>[29]</sup>.

Elastic–plastic nanoindentation has been performed on electrospun silk nanofibers.<sup>[40]</sup> The uncertainties of cantilever stiffness and tip geometry of the AFM tip make it difficult to determine the exact value of modulus from Eq. (10). This problem was overcome by first making an indent on epoxy, which has a known value of elastic modulus ( $E_1$ ). The contact radius of the plastic indent ( $r_1$ ) and slope of unloading curve at maximum load for epoxy ( $S_1$ ) were then obtained. Another indent is made with the same loading force on the nanofiber using the same tip. The contact radius of the plastic indent ( $r_2$ ) and slope of unloading curve at maximum load for the nanofiber ( $S_2$ ) were obtained. All these values are substituted into Eq. (11) to calculate the modulus of the nanofiber ( $E_2$ ).

$$\frac{S_1}{S_2} = \frac{r_1 E_1}{r_2 E_2} \quad (11)$$

Viscoelastic creep may be significant for polymeric samples, which results in overestimation of modulus values. This is owing to the increase in the initial slopes of the unloading curves.<sup>[41]</sup>

### NANOPARTICLES

Nanoparticles such as polymeric and ceramic nanoparticles, polymeric micelles, liposomes, and dendrimers have been used as drug delivery devices.<sup>[42]</sup> An example of nanoparticles is shown in Fig. 9. Most nanoparticles used for drug delivery are in the form of nanocapsules or vesicles in which the drug is confined to a cavity surrounded by a membrane. Fabrication methods include microemulsification, supercritical fluids, aerosols, and reactive precipitation.<sup>[44]</sup> Owing to the size

**Fig. 9** SEM image of paclitaxel-loaded vitamin E D- $\alpha$ -tocopheryl polyethylene glycol 1000 succinate (TPGS) emulsified poly(lactic-co-glycolic acid) (PLGA) nanoparticles (bar = 1  $\mu$ m). Source: From Ref.<sup>[43]</sup>.

and geometry of nanoparticles, nanoindentation or compression using the AFM is the most suitable technique for probing the mechanical properties of single nanoparticles. Although other techniques such as micropipette aspiration have been used<sup>[45,46]</sup> to characterize microparticles, it cannot be easily applied to nanoparticles as it is challenging to fabricate pipettes with nano-sized openings. Mechanical properties such as elastic modulus, bending modulus, and buckling instability can be obtained from the AFM studies.

Hertz's theory of normal contact of elastic solids has been used to obtain the elastic modulus of egg yolk phosphatidylcholine (EggPC) liposome in the form of vesicles.<sup>[47–49]</sup> The size of the vesicles range from 40 to 70 nm in diameter. The aim of these studies was to investigate effects of modification on the stability and rigidity of the vesicles. The elastic modulus of the vesicles were found using Eq. (6). After substituting the relevant parameters for the reduced modulus  $E_r$ , the force applied  $P$ , and the equivalent radius for a spherical indenter in contact with a spherical object  $R_e$ , the indentation depth  $\delta$  is given by

$$\delta = 0.825 \left[ \frac{k^2 (R_{\text{tip}} + R_{\text{ves}}) (1 - \nu_{\text{ves}}^2)^2}{E_{\text{ves}}^2 R_{\text{tip}} R_{\text{ves}}} \right]^{1/3} \times (d - d_0)^{2/3} \quad (12)$$

where  $E_{\text{ves}}$  is the elastic modulus of the vesicle,  $R_{\text{tip}}$  and  $R_{\text{ves}}$  are the radius of the tip and vesicle, respectively,  $\nu_{\text{ves}}$  is the Poisson's ratio of the vesicle,  $k$  is the cantilever spring constant,  $d$  is the deflection of the AFM tip, and  $d_0$  is the noncontact deflection. The bending modulus of the vesicle  $k_c$  is deduced from the elastic modulus as

$$k_c = \frac{E_{\text{ves}} h^3}{12(1 - \nu_{\text{ves}}^2)} \quad (13)$$

where  $h$  is the bilayer thickness.

Owing to the small size of the vesicles, the force curves have to be interpreted carefully. Fig. 10 shows a typical force curve on a cholesterol-containing EggPC liposome.<sup>[48]</sup> Region I represents the non-contact region whereby the tip is far away from vesicle and the force between the tip and the vesicle is zero. Region II shows the elastic deformation of the vesicle under tip compression, which can be used to calculate the elastic properties. Region III corresponds to further tip compression after the tip penetrates the top bilayer of the vesicle. Region IV reflects the cantilever deflection when it is in contact with the hard mica substrate after penetrating through the vesicle's bottom bilayer. As mentioned in the section "Elastic Nanoindentation," elastic nanoindentation of thin

**Fig. 10** Force curve on an egg yolk phosphatidylcholine (EggPC)/cholesterol liposome. *Source:* From Ref.<sup>[48]</sup>.

samples requires the penetration depth to be shallow to avoid the influence of the hard substrate on the mechanical properties obtained. Therefore only data obtained in region II was used to deduce the elastic properties. It was found that addition of cholesterol<sup>[48]</sup> or Pluronic<sup>®</sup><sup>[49]</sup> copolymer resulted in a significant increase in bending modulus of EggPC vesicles. This increases the viability of this liposome as a drug carrier.

Mechanical properties of polyelectrolyte-multilayer capsules were studied using AFM in a similar

**Fig. 11** Typical force–deformation curve of a 20  $\mu\text{m}$  diameter capsule. Loading and unloading curves are shown in black and gray, respectively. Inset pictures are 11.4  $\mu\text{m} \times 11.4 \mu\text{m}$ . Reflection interference contrast microscopy (RICM) images were taken at different intervals during the experiment that can be separated in three parts: (A) small-deformation regime; (B) large deformations with an increase in contact area; and (C) buckling of capsule with an increase in contact area. The fringes inside the contact area show the buckling of the capsule (Box 4). *Source:* From Ref.<sup>[50]</sup>.

**Table 1** Summary of mechanical testing techniques for nanoscale biomaterials

Nanostructure	Test method	Instruments and techniques	Materials	References
Nanofiber	Tensile test	Atomic force microscope cantilevers	Polyethylene oxide (PEO)	[14]
		Commercial nano tensile tester	Polycaprolactone (PCL)	[18]
	Bend test	Three-point bend test using AFM	Poly(L-lactic acid) (PLLA)	[19]
			PEO	[24]
		Deflection of free end of nanofiber with fixed end attached to AFM tip	PLLA	[25]
	Nanoindentation	Elastic nanoindentation using AFM	Polyacrylonitrile (PAN)	[27]
PAN			[33,34]	
Nanoparticle	Nanoindentation	Elastic-plastic nanoindentation using AFM	PLLA	[35]
			Silk	[40]
		Nanoindentation/compression using AFM	Egg yolk phosphatidylcholine (EggPC) liposome	[47–49]
			Sodium poly(styrene sulfonate)/poly(allylamine hydrochloride) (PSS/PAH) capsule	[50,51]

manner.<sup>[50,51]</sup> These capsules consist of alternating layers of sodium poly(styrene sulfonate) and poly(allylamine hydrochloride). Although these particles are microscale in size, nanoscale particles can be fabricated using the same layer-by-layer method.<sup>[51]</sup> Therefore, this characterization technique can be applied for smaller particles. The indentation experiments were carried out with a micro-sized glass bead attached to the end of an AFM cantilever and under an inverted microscope operating in reflection interference contrast microscopy (RICM). The buckling behavior of the capsules could be observed under the microscope. The particles were assumed to be shells of radius  $R$ , of thickness  $h$ , and were made of an isotropic elastic material with Young's modulus  $E$  given by

$$E = SR/Ah^2 \quad (14)$$

where  $S$  is the slope of the force–displacement curve and  $A$  is a numerical prefactor around 0.6. The onset of buckling instability could be observed from both force curves of the AFM and from RICM (Fig. 11).

## CONCLUSIONS

Developing techniques for mechanical characterization of nanoscale biomaterials is essential for the design of the materials that match the *in vivo* requirement. The range of techniques presented here for nanofibers and nanoparticles are summarized in Table 1. It can be seen that most techniques involve the use of AFM or AFM cantilevers for imaging and/or force measurement. The main advantage of the characterization

methods presented is in most cases, direct manipulation of single nanofiber or nanoparticle is minimal, thus allowing nanomechanical characterization to be performed easily. Tensile test, bend test, and nanoindentation are used to characterize the mechanical properties of nanofibers. Only nanoindentation has been used to characterize nanoparticles.

Although nanostructured materials can be characterized using various methods, an effective mode of observing deformation is yet to be found. Most of the measurements also did not take into account the viscoelastic nature of the polymers used. In some techniques such as tensile test and bend test, it is difficult to perform the test in *in vivo* conditions as only dry samples can be tested conveniently. Therefore, future work would involve developing devices or methods of observing the deformation behavior of the various nanostructures and means of performing dynamic material characterization. A means of characterizing the nanostructures in *in vivo* conditions is required. It would also be interesting to determine the actual mechanism of deformation and failure of nanofibers or nanoparticles in relation to their nano and molecular structures.

## INTRODUCTION

Over the past nine decades of administering bioimplants to humans, most of the synthetic prostheses consist of material particles and/or grain sizes with conventional dimensions (approximately 1 to  $10^4 \mu\text{m}$ ).<sup>[1]</sup> Most of these early implants were made out of the following: vanadium steel (in the 1920s), stainless steel, cobalt alloys, titanium (in the 1930s), gold, and amalgams (a metal alloy containing mercury).<sup>[1]</sup> However, the lack of sufficient bonding of synthetic implants to surrounding body tissues and the inability to obtain mechanical characteristics (such as flexural strength, bending strength, modulus of elasticity, toughness and, ductility) as well as electrical characteristics (such as resistivity and even piezoelectricity) that simulate their human tissue equivalents have, in recent years, led to the investigations of nanomaterials.<sup>[2–12]</sup> Consequently, improving the biocompatibility of these implants remains the focus of many research groups around the world. Several nanobiomedical implants are being investigated, and are likely to gain approvals for clinical use. The critical factor for this drive is the increasingly documented, special, non-biological improved material properties of nanophase materials when compared to conventional grain-size formulations of the same material chemistry.<sup>[2–12]</sup>

This entry seeks to add another property of nanophase materials that makes them attractive for use as implants: bio- and cytocompatibility. Active works are focused in the domains of orthopedic, dental, bladder, neurological, vascular, and cardiovascular graft applications. The present level of advances was previously unimaginable with conventional materials possessing large micron-sized particulates. This entry will briefly articulate the seeming revolutionary changes and the potential gains of nanostructured implants in medical technology.

## RATIONALE AND DEVELOPMENTS

### The Problem—Fibrous Encapsulation of Newly Implanted Materials

For the replacement of dysfunctional and diseased tissues, millions of biomedical implants are used each

year around the globe. The characteristics vital for the effective functioning of these implants in the host animal tissue (usually, humans) include lack of any toxicity tendencies, resistance to corrosion by surrounding tissue fluids, sufficient strength against involuntary and normal physical motion or loading, resistance to bodily fatigue forces, ability to promote cellular adhesion that may lead to tissue regeneration, and, finally, biocompatibility (or cytocompatibility) with the host tissue or organs.

The healing response immediately following biomaterial implantation determines the long-term functionality of the device. This response is primarily affected by the chemical and physical characteristics of the bioimplant. Healing characteristics common of unsuccessful biomaterial wound healing include fibrous encapsulation and chronic inflammation. Inflammation and the subsequent processes involve recruitment of a variety of body fluids, proteins, and unwanted cell types to the tissue–implant interface.<sup>[13–15]</sup> Fibrous encapsulation—or callus formation, in the case of bone implants—at the interface or implant–body tissue site decreases the bonding effectiveness and often results in clinical failures.<sup>[13]</sup> Fig. 1 depicts the sequential events of cellular responses of soft tissues following an injury.<sup>[14–22]</sup> There exists a latent period for the collagen molecules to polymerize and align according to the principal direction of stress. This slows rapid attainment of the physical strength in the region that would be juxtaposed to that of normal tissue. Currently, most of the medical devices for cardiovascular or neural treatments, such as pacemakers, defibrillators, neural probes, etc., are routinely coated with parylene, a polymer with increased dielectric constant and coating depth, for better compatibility with body tissues. However, parylene degrades at temperatures above 125–140°C in the presence of oxygen, and a special grade of the polymer loses its optical clarity, becoming hazy at thickness levels above 5  $\mu\text{m}$ . Therefore, modulating the healing response may improve biomaterial compatibility to decrease unwanted fibrous tissue formation, and this is the role envisaged of nanostructured implants.<sup>[2,6–8,17]</sup>

### A Potential Solution—Nanostructured Implants

Nanotechnology embraces a system whose core of materials is in the range of nanometers ( $10^{-9}$  m). The

Fig. 1 Sequential events of soft tissue wound healing. Source: From Ref.<sup>[14]</sup>.

application of nanomaterials for medical diagnosis, treatment of failing organ systems, or prevention and cure of human diseases can generally be referred to as nanomedicine. The branch of nanomedicine devoted to the development of biodegradable or non-biodegradable prostheses or implants fall within the purview of nanobiomedical science and engineering. Although various definitions are attached to the word “nanomaterial” by different experts,<sup>[23]</sup> the commonly accepted concept refers to nanomaterials as that material with the basic structural unit in the range 1–100 nm (nanostructured), crystalline solids with grain sizes 1–100 nm (nanocrystals), individual layer or multi-layer surface coatings in the range 1–100 nm (nanocoatings), extremely fine powders with an average particle size in the range 1–100 nm (nanopowders), and fibers with a diameter in the range 1–100 nm (nanofibers).

Nanostructure science and technology create materials and products that potentially outperform, at several boundaries, the existing advanced materials (such as advanced/fine ceramics, advanced polymers and composites, and electronic and photonic materials).<sup>[24]</sup> For example, with the development of macromolecular complexes, modern technology enhances the secrets of biology and communicates to it. High-resolution instruments, such as scanning tunneling microscope, atomic force microscope, and high-resolution transmission electron microscope, are capable of atom-by-atom resolution in the structure of solids. Atom layer by atom layer structures can now be built using ion beam or molecular beam. Advanced instruments can also monitor processes in materials at atomic or subatomic levels on real time scales.

Assisted by these developments emerges, concurrently, nanotechnology, an endeavor able to work at the molecular level atom by atom to create large structures with fundamentally new molecular organization,

with at least one characteristic dimension measured in nanometers.<sup>[9]</sup> The commonly known nanostructures include carbon nanotubes, proteins, DNA-based structures, thin film and laser emitters, quantum wire and dots, and single-electron transistors that operate at room temperatures. The substances in the list that are significantly relevant to designing future implants are proteins and DNA-based structures. Scientific activities on nanobiomedical implants seek to mimic the nanomorphology that proteins create in natural tissue, mainly for efficient and effective cytocompatibility.<sup>[16]</sup> Clearly, cells in our body are accustomed to interacting with nanostructured surfaces. It is evident that nanotechnology-enabled increases in computation power will permit the characterization of macromolecular networks in realistic environments. Such simulation will be essential in developing biocompatible implants to mimic these novel topographies.

## CHARACTERISTICS, DEVELOPMENTS, AND POTENTIALS

### Characteristics

Functions of implants can benefit immensely from the manifold increase in size reduction, bonding potential, and mechanical and electrical characteristics of consolidated nanoparticles or nanofibers. The specific properties relevant for the synthesis and efficacy of these nanobiomedical implants are high surface energy of the discrete substances, increased surface roughness of the bulk material, strength, elastic modulus, ductility, and electrical conductivity.<sup>[5,6,16]</sup>

Surface properties (such as area, charge, and morphology) depend on the particulate (such as grain) or fiber size of a material.<sup>[10–12]</sup> The increased surface

**Fig. 2** Schematic representation of surface properties of (A) conventional materials and (B) nanophase materials. Nanophase materials have higher surface areas, possess greater numbers of atoms at the surface, and less acidic OH<sup>-</sup> groups (because of an increase in electron delocalization) in the hydroxide layer. *Source:* From Ref.<sup>[35]</sup>.

defects (such as at the edge/corner sites) and the high number of grain boundaries<sup>[10,11]</sup> in nanophase materials have special advantageous properties that are being exploited in the development of biocompatible implants. Because of their small size (1–100 nm), bioceramic or metallic particulates require less severe sintering conditions (temperature and pressure) to become fully consolidated. Thus, for complex inorganic ceramics, the likelihood of phase separation is reduced. For the particulate or hybrid composites, excessive interfacial reactions between the matrix and filler phases are reduced because process temperature is lower. Kinetics of reactions in the various systems are shorter. Thus, there are promises for nanophase materials from a material processing point of view.

To date, the increased surface reactivity of nanomaterials has been used for catalytic applications almost exclusively,<sup>[10,11]</sup> for example, compared with conventional (>100 nm average grain size) magnesium oxide (MgO), nanophase (4 nm average grain size) MgO possessed increased numbers of atoms at the surface, higher surface area (100–160 m<sup>2</sup>/g compared to 200–500 m<sup>2</sup>/g, respectively), less acidic OH<sup>-</sup> groups (because of a much higher proportion of edge sites for the nanophase MgO to cause delocalization of electrons) (Fig. 2), increased adsorption of acidic ions (such as SO<sub>3</sub><sup>2-</sup> and CO<sub>3</sub><sup>2-</sup>), and increased destructive adsorption of organophosphorous and of chlorocarbons.<sup>[10,11]</sup>

### Proteins—Control of Implant Biocompatibility

Living systems are governed by molecular behavior at nanometer scales.<sup>[5,6,16]</sup> The molecular building blocks of life—proteins, nucleic acids, lipids, carbohydrates, and their non-biological mimics—are examples of materials that possess unique properties determined by the size, folding, and patterns at the nanoscale. Most current in vivo implants are used for orthopedics (bone therapy or replacement), their fixation, or for dental (tooth therapy) purposes. An increasing number is also applied in vascular and cardiovascular organ systems. These implants are known to be of the

conventional structure (average grain size is in microns). Being in-body prostheses, most implants (such as orthopedic or vascular) are initially interfaced with soluble proteins (through biological fluids), as against insoluble proteins (which usually occurs through synthesis and deposition by cells after initial adhesion to implants).<sup>[13,14]</sup>

Protein interaction with surfaces is mainly by adsorption and orientation (conformation). Significant protein adsorption leads progressively—but not always—to an appropriate conformation (or orientation) and for subsequent cell adhesions.<sup>[15,16]</sup> These molecular activities, however, depend on the relative bulk concentration of each protein in solution and the properties of the surface that control protein reactivity.<sup>[15]</sup> As shown in Table 1,<sup>[13,17–22]</sup> solid surface features (such as specific surface, roughness, charge, chemistry, wettability, etc.) and the specific properties of each amino acid influence protein adsorption (ultimately affecting implant biocompatibility with host tissue). Fig. 3 presents the schematics on how cells interact with adsorbed proteins on a substrate.<sup>[15]</sup> For nanostructured substrate formulations (or nanoimplants), the surface grain size increases the number of grain boundaries at the surface to enhance material surface wettability for protein adsorption that, subsequently, promotes select cell function. Note, however, that proteins will adsorb to a material surface seconds after implantation. Thus, their interactions are imperative to controlling subsequent cell function and eventual implant success/failure.

The dimensions of proteins are at the nanometer level.<sup>[5,6,16]</sup> In addition, other inorganic constituents in natural bone, such as hydroxyapatite (HAP) fibers, possess nanometer dimensions between 2 and 5 nm in width, and lengths around 50 nm.<sup>[1]</sup> Several studies have positively correlated the adhesion and functions of various proteins with the nanoscale surface features of potential implants.<sup>[16,25–33]</sup> In fact, some of the best examples of how nanophase, compared with conventional, materials alter interactions with proteins are provided in the investigations of the potential use of nanostructured materials as the next generation of bone implants.<sup>[6,25–33]</sup> Following are presented the

**Table 1** Structural categories and specific properties of amino acids contained in proteins

Amino acid (three and one-letter abbreviation)	Charge	Hydrophobicity (values as kcal/mol to transfer from hydrophobic to more hydrophilic phase; increase positive value means more hydrophobic)	Surface tension (values as ergs/cm <sup>2</sup> /mol per liter lowering of the surface tension of water)
Isoleucine (Ile or I)	Neutral	0.73	-15.2
Phenylalanine (Phe or F)	Neutral	0.61	-17.3
Valine (Val or V)	Neutral	0.54	-3.74
Leucine (Leu or L)	Neutral	0.53	-21.9
Tryptophan (Trp or W)	Neutral	0.37	-9.6
Methionine (Met or M)	Neutral	0.26	-3.01
Alanine (Ala or A)	Neutral	0.25	0.96
Glycine (Gly or G)	Neutral	0.16	1.12
Cysteine (Cys or C)	0 to -1	0.04	0.69
Tyrosine (Tyr or Y)	0 to -1	0.02	-15.1
Proline (Pro or P)	Neutral	-0.07	-0.49
Threonine (Thr or T)	Neutral	-0.18	0.59
Serine (Ser or S)	Neutral	-0.26	0.76
Histidine (His or H)	0 to 1	-0.40	1.03
Glutamic acid (Glu or E)	0 to -1	-0.62	0.86
Asparagine (Asn or N)	Neutral	-0.64	1.17
Glutamine (Gln or Q)	Neutral	-0.69	1.21
Aspartic acid (Asp or D)	0 to -1	-0.72	0.96
Lysine (Lys or K)	0 to 1	-1.1	0.92
Arginine (Arg or R)	0 to 1	-1.8	1.03

Because of a wide range of amino acid properties, proteins have diverse properties.

significant milestones from current activities on protein or cellular interactions with ceramics, metals/alloys, polymers, or their composites.

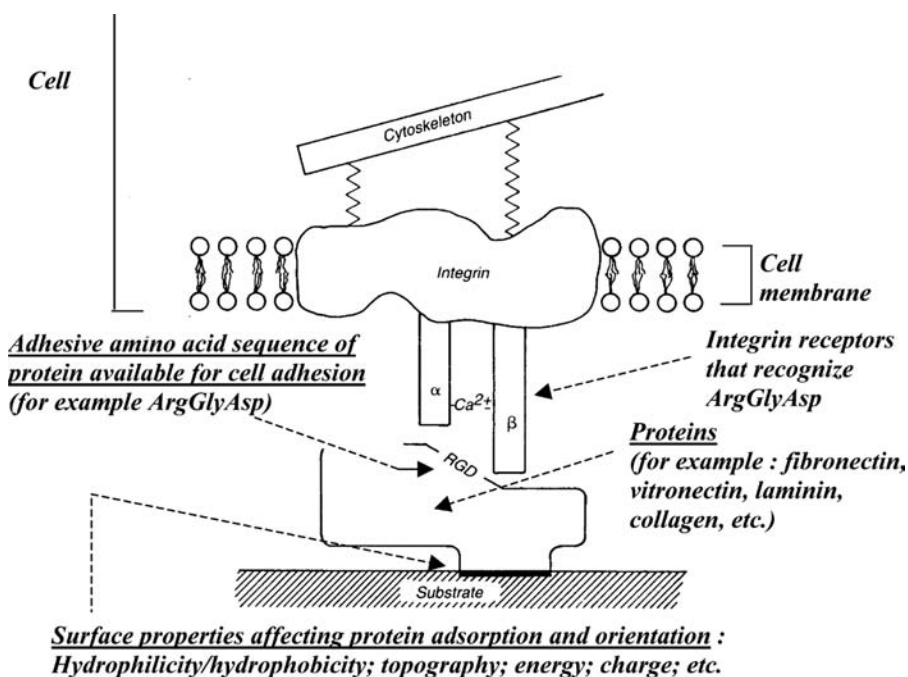

### Developments and Potentials of Nanophase Ceramics as Nanobiomedical Implants

Ceramic materials have been used for sometime in dentistry for dental crowns. Their high compressive strength, good esthetic appearance, and inertness to body fluids were responsible. Investigations of underlying mechanisms on tissue-implant interaction revealed that the initial adsorbed concentration,<sup>[27]</sup> conformation,<sup>[31]</sup> and bioactivity<sup>[31]</sup> of proteins contained in blood serum were responsible for the select, enhanced functions of osteoblasts (bone-forming cells). Notably, cumulative adsorption of proteins contained in serum was significantly higher on smaller, nanometer, grain-size ceramics.<sup>[27]</sup> In particular, the interaction of four proteins—fibronectin, vitronectin, laminin, and collagen—known to enhance osteoblast function, increased greatly on nanophase compared to conventional (micron-sized grains) ceramics.

Furthermore, a novel adaptation of the standard surface-enhanced Raman scattering (SERS) technique

has provided evidence of increased unfolding of the aforementioned proteins adsorbed on nanophase vs. conventional ceramics (Fig. 4).<sup>[31]</sup> This is important because unfolding of these proteins promotes availability of specific cell-adhesive epitopes that increased bone-cell adhesion and function.<sup>[34,35]</sup> In addition, nanophase ceramics have much greater surface reactivity because of increased numbers of atoms at the surface, greater amounts of grain boundaries at the surface, and higher proportions of edge sites (Fig. 2).<sup>[35]</sup>

Clearly, these novel properties of nanophase ceramics may be influencing interactions with proteins. In particular, nanophase ceramics have also been reported to have increased surface wettability over conventional ones.<sup>[26]</sup> Because proteins assume a tertiary structure with mostly hydrophilic amino acid residues on the exterior of globular shapes, it is believed that a material surface with increased wettability (or hydrophilic) properties should increase protein adsorption and possibly enhance unfolding of that protein to expose interior amino acids important for cell adhesion. Because of protein dimension being in the nanometer regime, biomedical implants with nanophase surfaces can now be engineered to manipulate adsorbed protein conformation for increased implant

**Fig. 3** Schematic representation of the interaction of cells with proteins adsorbed on a substrate such as an implant. *Source:* From Ref.<sup>[15]</sup>.

efficacies over a long time. For instance, compared to conventional (micron-size) ceramic formulations, nanostructured substrates made from spherical particles of alumina, titania, and hydroxyapatite provided evidence of enhanced adhesion of osteoblasts (bone-forming cells), decreased adhesion of fibroblasts (cells that contribute to fibrous encapsulation and callus formation events that may lead to implant loosening and failure), and decreased adhesion of endothelial cells (cells that line the vasculature of the body).<sup>[26]</sup> In addition, consolidated substrates formulated from nanofibrous alumina (diameter 2 nm, length >50 nm) have demonstrated a significant adhesion and proliferation of the bone-forming cells (osteoblasts) in comparison with similar alumina substrates formulated from nanospherical particles.<sup>[16]</sup> The study further reported enhanced calcium deposition (calcium deposition is an index of mineralization of the bone matrix) by osteoblasts as well as increased functions of osteoclasts (bone-resorbing cells) on the alumina nanoparticles. In a comparative study, Price et al. has determined a twofold increased adhesion cell density of the osteoblasts on alumina nanofiber vs. conventional titanium, following a 2-hr culture.<sup>[52]</sup> These findings consistently testify to unprecedented and excellent cytocompatibility of nanobioceramics with physiological bone.

Furthermore, other studies have reported the detrimental influences of wear particles (or debris) resulting from articulating components of conventional orthopedic implants that are subjected to physiological loading forces (such as friction).<sup>[36–38]</sup> These particles induce bone loss, which leads to implant loosening, and sometimes results in clinical failure of bone

prostheses (such as hip, elbow, knee, ankle, etc.). In a recent report, however, results of a more well spread morphology and increased cell proliferation in the presence of nanophase particles have demonstrated that wear debris resulting from bone prostheses composed of nanophase ceramics affects bone and cartilage cell functions less adversely in comparison to larger conventional ceramic wear particles.<sup>[39]</sup> In addition, the ductility and superplastic-forming capabilities of nanoceramic particles have now been demonstrated as favorable to initial cellular activities, indicating their potential for orthopedic nanobiomaterials.<sup>[16,39]</sup>

Following these significant discoveries, extremely fine bioceramic powders can be used as components in a wide range of biomedical implants, from hard sintered ceramic disk implants to porous bone grafts (bone replacement), controllable-setting calcium-phosphate-based bone cements (for implant fixation), and nanocomposites that have superior mechanical and biological properties in vitro. Phase-stabilized zirconia is used to make femoral heads of the implants in hip-replacement operations. With the improved ductility of nanoceramics, the synthesis of polycrystalline phase-stabilized zirconia from nanoparticles will allow the material to be made even stronger, with better fracture toughness and improved wear-resistance properties, compared to current-generation zirconia materials.<sup>[40]</sup>

### Developments and Potentials of Nanophase Metals as Nanobiomedical Implants

Whereas for dental applications conventional silver-tin amalgam is selected because of its plasticity and

cold-setting property, and micron-grain-sized gold often chosen because of its corrosion resistance as well as malleability and durability,<sup>[1]</sup> the conventional metallic materials—titanium, titanium alloys (such as Ti-6Al-4V), Co-Cr-Mo, and 316L stainless steel—are

selected for orthopedic implants based on their mechanical properties and ability to remain inert in vivo.<sup>[1]</sup> [Table 2](#) compares the elastic modulus property of select conventional metallic and ceramic materials currently applied in orthopedics with compact

**Table 2** Comparison of elastic modulus ( $E$ ) of major internal bone structures with select conventional metallic and ceramic materials currently used as orthopedic implants

	Material	Modulus of elasticity (GPa)
	Bone	12–18
	Trabecular bone	0.1
Ceramic/carbon	Calcium phosphate	40–117
	Carbon (pyrolytic) <sup>a</sup>	28
Metal/alloys	Titanium and Ti–6Al–4V	110
	Tantalum (cold-worked)	190
	Cobalt alloys	220–234
	316L stainless steel	193–200
	Aluminum alloy	70–77

<sup>a</sup>1.0 wt.% Si-alloyed pyrolytic carbon, Pyrolite (Carbomedics, Austin, TX).

and spongy bones. The choice of these materials as implants only satisfied physiological loading conditions but did not duplicate the mechanical, chemical, and morphological properties of the bone.<sup>[1,16]</sup>

Most importantly, to date the failures of conventional orthopedic and dental implant materials is often due to insufficient bonding with juxtaposed bone or tissue. Timely and desirable responses from surrounding cells and tissues are required to enhance deposition of the mineralized matrix at the tissue–implant interface, which provides crucial mechanical stability to implants. This requirement, in addition to the hardness and strength of metallic implants, can be greatly increased by nanostructuring. Metallic implants coated with conventional HAP have been tried with little success, causing stress shielding of the surrounding bone and experiencing a reduced durability of the HAP coatings over time.<sup>[1]</sup> It is therefore intriguing to ponder an alternative approach using nanostructured metals to promote interactions with juxtaposed bone to increase implant success. This objective remains largely uninvestigated to date.

## Developments and Potentials of Nanophase Polymers as Nanobiomedical Implants

Several micron-grain-sized polymers [such as hyaluronan-based polymer, Dacron, and poly(lactic-*co*-glycolic acid) (PLGA)] investigated as potential implants have been reported as either causing defects or unsuitable.<sup>[1]</sup> Solchaga et al. observed cracks and fissures in some biodegradable materials, e.g., hyaluronan-based polymers, within 12 weeks that followed implantation.<sup>[41]</sup> This investigation studied the polymer as a potential implant for the treatment of osteochondral defects on femoral condyles of rabbits. Messner had earlier reported improper cartilage morphology, early-stage debris formation, and synovitis when he implanted polyethylene terephthalate (Dacron), a non-degradable synthetic material in rabbits for similar treatment.<sup>[42]</sup>

Although much scientific activity is focused on it, the Food and Drug Administration (FDA)-approved PLGA does not mimic the nanometer morphology of biological tissues they are intended to replace. Fig. 5 shows the scanning electron images distinguishing the surface roughness of nanostructured from conventional PLGA. As could be observed, the nano-PLGA exhibits a finer surface morphology than the conventional PLGA. While the latter registers a roughness of 100 nm–1  $\mu$ m, the former has a surface roughness value within the range 50–100 nm. Recently, a synthesized nanostructured PLGA has been shown to lead to significant proliferation of chondrocytes in comparison with the conventional FDA-approved PLGA.<sup>[43]</sup> The study further provided evidence of preferred growth of chondrocytes along the aligned portions in the nanostructure. This discovery is of practical significance because articular cartilage has aligned nanostructures (i.e., the collagen fiber). Thus, by simulating the nanostructure and alignment topography of cartilage tissue in monolithic PLGA or in PLGA–matrix composite formulations, a more natural environment is created for chondrocytes to regenerate cartilage.

**Fig. 5** Scanning electron images depicting (A) surface roughness of conventional PLGA (100 nm–1  $\mu$ m) in comparison with (B) fine surface roughness of nanophase PLGA (50–100 nm). Bar represents 100  $\mu$ m in dimensions. Source: From Ref.<sup>[46]</sup>.

Also, a related study found a 23% and 76% increase in adhesion of both vascular and bladder smooth muscle cells on nanophase PLGA (average surface roughness: approx. 50 nm) and nanostructured polyurethane (PU), respectively, vs. their conventional formulations.<sup>[44]</sup> The potential application of these formulations as vascular graft implants was further demonstrated by the enhanced long-term biofunction (such as proliferation) of cells on the substrates and the “controllable” degradation rate of PLGA, within 1- to 5-day culture range.<sup>[44]</sup> These exciting and improved characteristics of the nanopolymers would very shortly form the basis for reducing health-related costs due to implant removals. Their commercial importance is further elevated by earlier conclusion that micron-sized tubular scaffolds of poly(glycolic acid) (PGA) physically support vascular smooth muscle and endothelial cell growth in vitro.<sup>[45]</sup>

Nanostructured topography of bioimplants may not always be the desired morphology for effective regeneration of human tissues. Miller et al. have recently demonstrated that in comparison with conventional PLGA, rat aortic endothelial cells adhered and proliferated less on PLGA substrates whose surface was transformed to nanodimensions through treatment with sodium hydroxide.<sup>[46]</sup> They concluded that the residual hydroxyl radical on the surface, and not the nanoscale roughness, might be responsible for decreased endothelial cell function on the nanophase polymer. This apparent anomaly can be of significance if scientists attempt to engineer vascular implants to influence cell localization in the host environment. However, once surface chemistry changes were eliminated using cast-mold procedures,<sup>[46]</sup> a greater endothelial cell function was achieved on the nanophase PLGA in comparison to the conventional one. Generally speaking, therefore, the different cellular responses elicited from varied surface features of current and potential implants can pave the way to modulating wound healing in relation to immunoactivity of the surrounding tissue.

### Developments and Potentials of Nanostructured Composites as Nanobiomedical Implants

Composites, as tissue scaffolds, are emerging owing to the need to engineer the high strength of monolithic ceramics or metals with known biocompatible polymers, notably, PLGA and poly(L-lactic acid) (PLLA).<sup>[47]</sup> On another note, some carbons have earlier found use in implants especially for blood interfacing applications such as heart valves. Hitherto, because of their anisotropic mechanical, surface, and electrical properties and relative biocompatibility, conventional-size carbon fibers are used in orthopedic

implants.<sup>[48–53]</sup> Combined with the prominent electrical conductivity of the fibers (reaching up to 2000 W/m K), these studies suggest a strong potential for the use of carbon nanofibers as neural prostheses. Not long ago, clinical studies have demonstrated that these micron-size fibers provide insufficient bonding to juxtaposed tissue, which leads to clinical failures.<sup>[50]</sup> This concern of biocompatibility prompted in vitro studies using multiwalled carbon nanotubes functionalized with a bioactive molecule, 4-hydroxynonenal. The functionalized nanosized carbon tubes resulted in increased extension of neurites in rat brain neurons.<sup>[51]</sup> Long neurites improve transmission and coordination of nerve responses to stimuli. In an effort to develop an efficient and effective material capable of minimizing gliotic scar tissue formation around regions of neural implants, a formulation of polycarbonate urethane (PCU) reinforced with 10–25 wt.% high-surface-energy carbon nanotubes (carbon tubes with no pyrolytic layer) was studied by McKenzie et al.<sup>[54]</sup> They reported a decreased adhesion of astrocytes by 50% on the composite in comparison with only PCU,<sup>[54]</sup> after a 1-hr culture. Astrocytes are neuroglial cells that, among other functions, respond to injury of brain tissue, forming a special type of scar tissue, which fills spaces and closes gaps in the central nervous system. A gliotic response that is mediated largely by astrocytes forms at implant/injury sites, impeding axonal regeneration<sup>[55–57]</sup> and electrical signaling between neurons and implanted probes.<sup>[58]</sup> Although silicon has good electrical properties, inhibited neural function is often reported with neural probes made out of micron-size structures of silicon.<sup>[58]</sup> The report by McKenzie et al. followed a previous study by the same group of scientists in which they demonstrated decreased astrocyte cell densities on nanophase carbon fibers (size: approx. 60 nm) in comparison with conventional ones (size: approx. 0.125  $\mu$ m), following adhesion and proliferation studies for 1 hr and up to 5 days, respectively. These carbon fibers in compact form are presented in Fig. 6.

Another study mimicked the nanometer dimensions of hydroxyapatite crystals (which are present in bones) in carbon fibers. The investigators used unfunctionalized carbon nanofibers (diameter: 60–200 nm), and they observed the first evidence of increased adhesion<sup>[52]</sup> as well as enhanced long-term functions (specifically, proliferation, synthesis of alkaline phosphatase, and concentration of calcium in the extracellular matrix) of osteoblasts in relation to the conventional fibers.<sup>[53]</sup> The positive behaviors, combined with the high specific strength of carbon nanotubes, can readily be exploited in using the fiber as a reinforcing component for composite implant materials and tensile loading applications, such as artificial tendon and ligaments. The clinical benefits from their desirable qualities and the ease of the fabrication of

**Fig. 6** Scanning electron images depicting (A) conventional carbon fibers (0.125  $\mu\text{m}$  diameter) in comparison with (B) nanophase carbon fibers (60 nm diameter). Bar represents 10  $\mu\text{m}$  in dimensions. *Source:* From Ref.<sup>[53]</sup>.

their composites make them attractive candidates for orthopedic and dental implants.

Nanostructured surface topography of PLGA substrates, in both aligned and non-aligned arrangements, significantly increased adhesion and proliferation of chondrocytes (cartilage-synthesizing cells) over the conventional substrate.<sup>[59]</sup> There was preferred alignment of the cells along the nanoscale ridges on the aligned surfaces of the polymer. Other investigators have observed increased adhesion and proliferation of chondrocytes on nanostructured synthetic ceramic/PLGA composites.<sup>[60,61]</sup> More recently, Ejiofor and coworkers studied the adhesion and long-term functions of chondrocytes and osteoblasts on conventional and nanophase titania/PLGA composites for use as bone prostheses.<sup>[43]</sup> Of the various size-classified titania/PLGA composites studied, nanostructured titania/nanophase PLGA demonstrated the highest adhesion of both bone-producing cells (by 150%) and cartilage-synthesizing cells (twofold) compared to their conventional composite equivalent. These composites are pictured in Fig. 7. In addition, following a 4- to 7-day culture, the total intracellular protein synthesized by chondrocytes on the nanocomposite was significant (>400%) vs. the conventional titania/conventional PLGA composite substrate. The increased surface roughness and specific surface area were thought to be responsible for the favorable results.<sup>[43]</sup> The above developments lend credence to

the positive influences of nanostructured composites on the synthesis of cartilage tissues.

On further investigations of the same material system, the researchers attributed fine grain size of nanocomposites as the major potential cause of the enlargement of the developing cartilage tissue, as indexed by their alkaline phosphatase activity. The activity level on the nanostructured titania/nanophase PLGA composites yielded 1.4 activity units/ $\text{cm}^2$  whereas the rest of the substrates investigated leveled off to 0.85 activity units/ $\text{cm}^2$ . Although further mechanical characterization is needed, materials such as this may allow for exciting alternatives in the design of more effective cartilage tissue engineering prostheses.

## POTENTIAL RISKS

Since the research on and the use of nanobiomedical implants using nanopowders or nanofibers is still at its infancy, risks to human health and environment must not be overlooked. Many issues relating to safe and healthy fabrication of nanobiomedical implants still need to be addressed. For example, small nanoparticles can enter the human body through pores and may accumulate in the cells of the respiratory or integumentary organ system, and the health effects are yet to be known. This would happen during commercial-scale processing of the nanoparticles as

**Fig. 7** Scanning electron images depicting PLGA composites containing: (A) conventional titania (4.120  $\mu\text{m}$  grain size) in comparison with (B) nanophase titania (32 nm grain size). 70/30 wt.% PLGA/titania. Bar represents 100  $\mu\text{m}$  in dimensions. *Source:* From Ref.<sup>[61]</sup>.

well as through the use of these materials as implants. According to Debra Rolison of Naval Research Laboratory (Washington, DC), because of humankind's history with viruses—and viruses are already nanobiotechnological—there should be a need for continuous monitoring of potential effects of newly designed and fabricated nanomaterials.

## FUTURE ACTIVITY

According to the U.S. government's research agenda, the current and future broad interests in nanobiomedical activity can be categorized as given in Table 3.<sup>[24,62]</sup> Marsch<sup>[62]</sup> further grouped the entire activity in three broad related fronts:

1. Development of pharmaceuticals for inside-the-body applications—such as drugs for anticancer and gene therapy.
2. Development of diagnostic sensors and lab-on-a-chip techniques for outside-the-body applications—such as biosensors to identify bacteriological infections in biowarfare.
3. Development of prostheses and implants for inside-the-body uses.

Whereas the European governments emphasize commercial applications in all three fronts above according to Marsch, the U.S. government—as can be seen in Table 3—tends to gear toward fundamental research on biomedical implants and biodefense, leaving commercial applications to industry. Both classifications identify nanobiomedical implants (item 8 in Table 3 and the third classification by Marsch) as potential interests. The biological and biomimetic nanostructures to be used as an implant involve some sort of an assembly in which smaller materials later assume the shape of a body part, such as hipbone.

**Table 3** U.S. government current and future broad interests in nanobiomedical research activity

U.S. Government Research Interests for Nanobiomedical Research
1 Synthesis and use of nanostructures
2 Applications of nanotechnology in therapy
3 Biomimetic nanostructures
4 Biological nanostructures
5 Electronic–biological interface
6 Devices for early detection of diseases
7 Instruments for studying individual molecules
8 Nanotechnology for tissue engineering

Source: Refs.<sup>[24]</sup> and<sup>[62]</sup>.

These final, biomimetic, bulk nanostructures can start with a predefined nanochemical (such as an array of large reactive molecules attached to a surface) or nano-physical (such as a small crystal) structure. It is believed that by using these fundamental nanostructured building blocks as seed molecules or crystals, a larger bulk material will self-assemble or keep growing by itself. Further research is needed in self-assembly of nanostructured materials.

Several developments on implants for clinical uses are ongoing, while just a few are at various clinical testing stages.<sup>[63,64]</sup> For instance, peripheral vascular grafts made out of polytetrafluoroethylene (PTFE) have been developed to serve as artificial arteries to restore blood flow to peripheral limbs of the body, and is already under clinical test.<sup>[63]</sup> Coronary artery bypass grafts made out of expanded polytetrafluoroethylene (ePTFE) is a potential material for supplying blood to the heart tissue, and this has been developed.<sup>[63]</sup> In addition, biologically hybridized polymeric immunoisolation devices are considered a biocompatible substitute capable of preventing rejection responses following immunosuppressant therapy. Clearly, nanomaterials as mentioned in this chapter are at their infancy and much more testing must be conducted before their full potential is realized.

## CONCLUSIONS

We would like to note that the scientific developments reported above do not exhaust the current global beehive research efforts on the biological potentials of nanoparticulates as implants. It is believed, however, that following the trends of these impressive application properties of the nanomaterials in the biomedical domain, there exists a bright future for therapies and treatments through prosthetic implantation.

Recent developments in modifying existing conventional materials to possess nanoscale dimensions without altering their chemistry would build upon the existing implant materials or clinical approvals by the various responsible agencies (for instance, the FDA in the United States). This is a much easier route to exploiting the beneficial properties of nanostructured materials as nanobiomedical implants than creating new chemistries that have not yet been recommended for inside-the-body use.

## INTRODUCTION

The emergence of nanoscale science and the materialization of consequent technologies have provided new avenues for engineering materials and devices that will revolutionize the way health care is administered. In particular, the ability to engineer with molecular to macromolecular precision has led to the creation of nanoscale materials and devices with inherent advantages relative to macroscale-structured counterparts.

In biological and medical applications, controlling interactions at the level of natural building blocks, from proteins to cells, facilitates the novel exploration, manipulation, and application of living systems and biological phenomena. Nanoengineered tissue scaffolds and nanostructured biomaterials and coatings for implants and prostheses are leading to better solutions in tissue design, reconstruction, and reparative medicine. Synthetic nanopores of tailored dimensions are probing, characterizing, and sequencing biological macromolecules. Nano- and microarrays are accelerating drug discovery and assessment of drug candidates. Self-assembly is creating new biomaterials with well-ordered structures at the nanoscale such as nanofiber peptide and protein scaffolds. Also, nanostructured materials and nanoparticulate delivery systems enable a wide range of materials for imaging and/or therapeutic purposes to be easily introduced or injected in the body.

Application of these techniques to create novel materials and devices for tissue engineering, diagnostics, and therapeutics will profoundly impact the practice of medicine. This entry reviews and discusses the emerging field of nanomedicine, where nanoscale science and technology are sculpting future innovations in medicine, and outlines the enormous potential of the field.

## FABRICATION, ASSEMBLY, AND VISUALIZATION AT THE NANOSCALE

In a recent perspective on nanobiotechnology, Whitesides<sup>[1]</sup> emphasizes the value of the microscale in the current enthusiasm of nanoscale science and technology. The scales encountered in biology, medicine, and biotechnology range from the micro- to nanometer and developments will continue to progress and expand on both levels. This overview is presented in much the same manner, with an analysis of exciting and novel technologies that are equally relevant to nanotechnology, but are not strictly classified as nanoscale.

The development of fabrication processes capable of manipulation at the micro- and nanoscale, such as electron-beam and ion-beam lithography,<sup>[2]</sup> nanoimprint lithography,<sup>[3]</sup> microcontact printing ( $\mu$ CP),<sup>[4]</sup> and dip-pen nanolithography (DPN),<sup>[5]</sup> enabled the creation of novel devices. In addition, self-assembly has been demonstrated to be a powerful method for creating well-defined nanostructures.<sup>[6–8]</sup> At the same time, visualization with submicron resolution has been essential in the implementation and utilization of these fabrication techniques. The development of nanoscale visualization techniques, such as scanning tunneling microscopy<sup>[9]</sup> and atomic force microscopy,<sup>[10]</sup> has facilitated manipulating and imaging at the atomic level. In recent years, micro- and nanoscale fabrication techniques have been utilized to construct micro-/nanoelectromechanical systems (MEMS/NEMS), microarrays, microfluidic devices, micro total analysis systems (i.e., lab-on-a-chip), and other micro-/nanodevices.

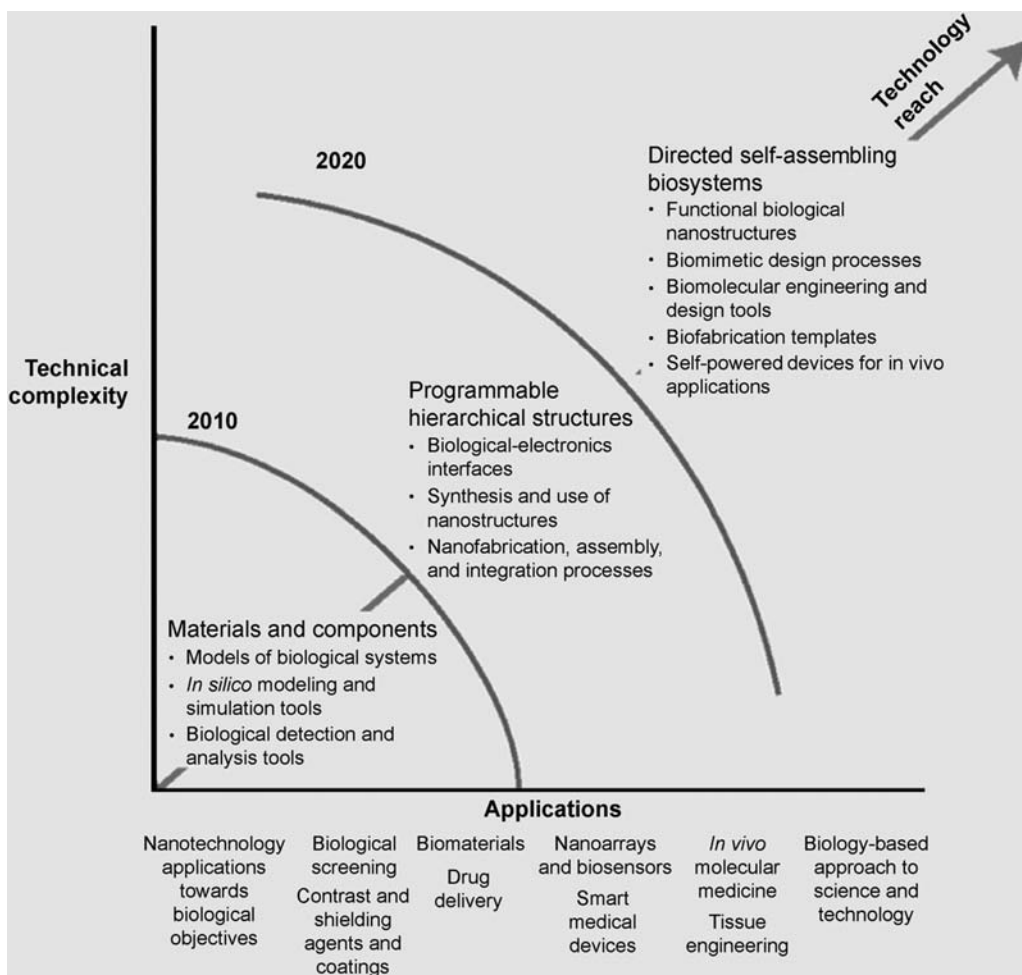

## NANOMEDICINE

Within the last century, technology has revolutionized the practice of medicine and drastically improved

quality of life. Two entries listed within the top 20 greatest achievements of the 20th century by the National Academy of Engineering were related to the field of medicine: imaging and health technologies, ranked at number 14 and 16, respectively.<sup>[11]</sup> The list included a number of technologies such as X-rays, the electron microscope, radioactive tracers, ultrasound and ultrasonic imaging, computer-aided topography, magnetic resonance imaging, endoscopy, pacemakers, the ventricular defibrillator, the blood-heat exchanger, contact lenses, heart valves, artificial kidney, etc. Slightly before the century began, W.C. Roentgen discovered X-rays in 1895, which dramatically changed medicine and allowed visualization inside the human body as never before.

At the transition into the 21st century, technology is becoming progressively controlled at the molecular level. Molecular understanding is driving the next generation of commercial diagnostic and therapeutic devices (Fig. 1).<sup>[12]</sup> The application of micro-/nano-

devices for biological and medical applications is leading to fundamental insights about the behavior and function of tissues,<sup>[13]</sup> intra- and intercellular communication,<sup>[13–15]</sup> forces and flows and the effects on individual cells,<sup>[16]</sup> the structure, function, and behavior of proteins, DNA, and other biological molecules;<sup>[17]</sup> and pharmacogenetics and genetic predisposition toward disease, etc. Similarly to X-rays in 1895, the two decades before the beginning of the 21st century had the discoveries of the atomic force and scanning tunneling microscopes, which allowed visualization and manipulation on a molecular and atomic level as never before. It is in this regard that nanoscale science and engineering has an unlimited potential to affect the diagnosis and etiology of a number of diseases with enhanced prognosis and rational treatment. Therefore this century is anticipated to be unparalleled in the progress of medical science and technology and lead to more technological innovation in medicine than any other in history.

## NANOTECHNOLOGY IN CELLULAR AND TISSUE ENGINEERING: REPARATIVE MEDICINE

Tissue engineering is a diverse and evolving field that focuses upon the regeneration, modification, and assembly of functional tissue, tissues, or organs using specific combinations of cells, extracellular scaffolds, and temporal supporting mechanisms (i.e., biochemical, mechanical, electrical signals, etc.) for tissue synthesis events.<sup>[18–20]</sup> The field can be classified into two main areas of relevance: *therapeutic relevance*, which covers tissue regeneration and organ replacement (in vivo or in vitro); and *diagnostic relevance*, where tissue is formed in vitro and used for toxicology studies, metabolism, drug discovery, etc.<sup>[21]</sup>

Based on a recent commentary by Yannas<sup>[22]</sup> and an overview by Sipe,<sup>[23]</sup> six methods have been practiced to address the problem of organ or tissue replacement: 1) transplantation (allograft or xenograft), which depends on a supply of available organs or tissue and appropriate histocompatibility; 2) autografting, removing a viable tissue or organ and placing it elsewhere in the body than the original site; 3) replacement with permanent prosthesis (synthetic material or device); 4) use of an external device to substitute or augment a poorly functioning organ; 5) in vitro synthesis (organ or tissue synthesized in culture and then implanted); and 6) in vivo synthesis (implantation of minimum constituents to induce organ or tissue regeneration in situ). The last two (5 and 6), and 7, when it includes cellular machinery in a bioartificial device, describe the field of tissue engineering.

The essential elements of tissue engineering as outlined in a recent NIH symposium<sup>[23]</sup> are as follows: 1) cells, 2) signaling, 3) extracellular matrix scaffold, 4) design principles, 5) vascular assembly, 6) bioreactors, 7) storage and translation, and 8) host remodeling and immune response. We direct the reader to the following reviews for a discussion on the challenges and obstacles within each element as well as the road ahead in the field.<sup>[19,20,23]</sup>

The hierarchical structure of human anatomy begins with the building block of cells. A collection of cells similar in structure and function form tissues (epithelial, connective, muscle, and nervous) and a collection of tissues that perform physiological tasks are organs. Consequently, multiple organs form systems such as the cardiovascular, respiratory, musculoskeletal, digestive, endocrine, reproductive, etc.

Each tissue and tissue system has unique biochemical composition, cellular components, mechanical/physiochemical properties, and extracellular matrix, etc., which vary over length scales. Of particular importance within the tissue or cellular framework (i.e., scaffold), as outlined by Griffith,<sup>[20]</sup> are the macroscopic shape and composition; the size, orientation, and surface chemistry of pores and interconnected pores or

channels (microscale); and the local substrate surface roughness, texture, and porosity (micro- to nanoscale).<sup>[24–27]</sup> Therefore the success of scaffold-based strategies depends highly on the substrate materials and material physiochemical properties, determined fundamentally by the material micro-/nanostructure and design.

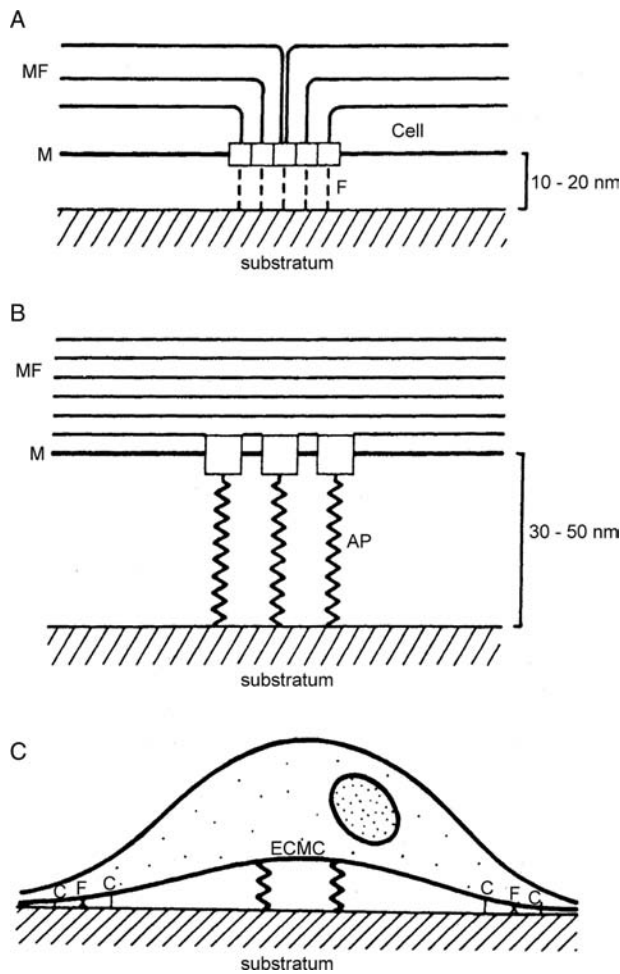

This section will focus on scaffolds for cellular and tissue engineering, specifically highlighting micro- and nanofabricated surfaces, matrices, and scaffolds; cellular spatial and function regulation by micro- and nanoscale features; and novel nanoscale science and engineering developments toward tissue regeneration.

### Micro- and Nanotechnology for Cellular Spatial and Function Regulation

Most mammalian cells are anchorage-dependent and therefore must adhere and spread on a substrate in order to live and remain functional. Cell spreading, locomotion, and active migration are primarily influenced by the physiochemical characteristics of the surface (substratum surface free energy and surface topography).<sup>[28]</sup> However, protein adsorption always precedes cellular adhesion<sup>[24]</sup> and extracellular matrix proteins regulate and promote cell adhesion, spreading, and motility (Fig. 2). Binding strength, conformation, and orientation of proteins on a biomaterial surface particularly influence subsequent cellular binding and motility. Functional cell behaviors include proliferation, differentiation (i.e., cellular specialization), migration, and secretion of their own extracellular matrix. For further information, we direct the reader to an excellent review of cell surfaces and interactions with materials.<sup>[24]</sup>

To induce cells to attach to certain areas or patterns of a particular biomaterial, one must alter the underlying substrate chemistry. The underlying surface chemistry has been modified to include hydrophilic or hydrophobic molecules or polymers,<sup>[29,30]</sup> polysaccharides,<sup>[31,32]</sup> stimuli-sensitive and responsive materials,<sup>[33–35]</sup> and proteins or growth factors.<sup>[36–39]</sup> The ability to pattern has enabled control over the adsorption or immobilization of adhesive proteins and, thus, the patterning or selective adhesion of cells on substrates.<sup>[40]</sup> These modifications change the ability of a cell to attach, but to some extent, regulate cellular functions such as growth, differentiation, and apoptosis.<sup>[41]</sup>

In order for a surface to be patterned in micro- or nanoscale dimensions, a means to spatially control a chemical modification of the surface is required at the resolution necessary to fit the design of the application or device. By patterning a surface, domains of a few microns or nanometers can be created, each able

**Fig. 2** Schematic of cell-substratum contact sites. In (A), focal adhesion sites are demonstrated. These are predominantly found at cell extension boundaries. The integrin connects the cytoskeleton with the substratum via fibronectin. In (B), close contacts, which are weaker adhesion sites, are illustrated. In (C), the localization of the different adhesion sites is demonstrated. MF, microfilaments; M, cell membrane; AP, adhesive protein; F, fibronectin; ECMC, extracellular matrix contact; C, close contact; F, focal adhesion. *Source:* From Ref.<sup>[24]</sup>—permission pending.

to maintain different interactions with the environment. Various techniques have been developed to achieve a fine level of control, which include lithographic techniques (e.g., UV, electron-beam, ion-beam lithography,<sup>[2]</sup> nanoimprint lithography,<sup>[3]</sup>), and soft lithographic techniques (e.g., microcontact printing ( $\mu$ CP),<sup>[4]</sup> micromolding in capillaries (patterning using microfluidic channels),<sup>[42]</sup> dip-pen nanolithography (DPN),<sup>[5]</sup> laminar flow patterning).<sup>[43,44]</sup> By integrating microcontact printing with microfluidics<sup>[42,45]</sup> a surface was patterned by pumping solution through channels formed when stamp and substrate were brought into contact. Reviews of these soft lithographic techniques discussing patterned surface creation<sup>[45,46]</sup> and also

their application for microfluidics devices<sup>[47]</sup> were recently published.

While the approaches above are adequate for a number of tissue types, the fabrication of thick complex tissues with complex vascularization remains difficult due to a limited diffusion distance of nutrients, gases, and waste products.<sup>[48,49]</sup> Various forms of three-dimensional (3-D) work are beginning to address these concerns.

Three-dimensional printing (3DP<sup>TM</sup>), which is a solid free-form fabrication method, creates physically joined structures in desired, very complex micro- and macroarchitecture.<sup>[50]</sup> Also, 3-D micromolding in capillaries (3D MIMIC) has been shown to pattern multiple cells and proteins in complex, discontinuous structures with close proximity and in well-defined structures.<sup>[51]</sup> Each allows understanding of tissue architecture at the resolution of individual cells.

Three-dimensional peptide scaffolds<sup>[52]</sup> and artificial amphiphilic protein scaffolds<sup>[8,53,54]</sup> have also shown promise to maintain functional, mature differentiated cells,<sup>[52]</sup> as well as to support the differentiation of progenitor cells.<sup>[55,56]</sup> For example, Zhang et al. recently demonstrated primary rat neuronal cells projecting axons along the contours of the peptide surface with active synaptic connections as well as neuronal progenitor cell migration.<sup>[52,56]</sup>

In a recent paper by Vacanti et al., a mold of a branched network of vascular channels (with capillary channels 10  $\mu$ m in diameter) was formed in silicon and Pyrex utilizing photolithographic and micromachining techniques (Fig. 3).<sup>[57]</sup> Three-dimensional units of tissue could be lifted from the mold after seeding and proliferation of endothelial cells. Including these branched vascular networks within layers of tissue has the potential to form 3-D conformations of living tissue for implantation.

**Fig. 3** Optical micrograph of a portion of a capillary network etched into a silicon wafer. *Source:* From Ref.<sup>[57]</sup>—permission pending.

## Micro- and Nanotopography: Structured Biomaterials

Experimental evidence exists that surface topography and texture of implanted materials have a large effect on the rate of success. It has been known for many years that grooved substrata of particular dimensionality induced cellular orientation, locomotion, and cell guidance.<sup>[58–60]</sup> It has also been shown that fibrous capsule formation and foreign body response can be greatly reduced by using microtextured materials.<sup>[61]</sup> For orthopedic and dental implants, a decrease in the grain size of ceramic formulations into the nanometer regime has demonstrated improved efficacy.<sup>[62]</sup> However, as discussed in the previous section, the underlying surface chemistry is a determining factor in cellular adhesion and function, and it is unclear as to the extent that chemical or topographical clues control.<sup>[63]</sup>

The length scale of basement membranes (i.e., the extracellular matrix in epithelium and endothelium) is of nanoscale dimension with a complex mixture of pores, fibers, and ridges.<sup>[25,27,64]</sup> For example, the corneal basement membrane of the Macaque monkey has average feature heights between 147 and 191 nm, average fiber width of 77 nm, and pores with an average diameter of 72 nm.<sup>[27]</sup> Recently, by matching of synthetic nanoscale topographies with feature dimensions similar to basement membrane, cell behavior and function was affected.<sup>[25]</sup> The authors demonstrate that endothelial cells respond strongly to topography in orientation, elongation, and cytoskeletal organization and that focal adhesions are narrower on substrates with regions of nanoscale dimensions than on smooth substrates. It has been demonstrated that focal adhesion assembly contributes significantly to cellular adhesion strengthening independent of cell morphology changes and redistribution of adhesive structures.<sup>[65]</sup> In this study, micropatterning methods were used to control focal adhesion size and position and to decouple integrin and focal adhesion assembly from gross changes in cell morphology.

An excellent review exists on the topic of micro- and nanoscale-substrate interactions, which highlights that micro- and nanoscale topographical cues, independent of biochemistry, generated by the extracellular matrix may have significant effects upon cellular behavior.<sup>[26]</sup> The effects of textured surfaces on cell behavior are listed for a number of systems, which includes a variety of cell types and substratum features such as grooves, ridges, steps, pores, wells, nodes, and adsorbed protein fibers.

Typically, grooves, ridges, and other shapes are fabricated in similar ways as discussed in the last section, but that various isotropic or anisotropic etching steps are added. Depending on the type of substrate and the corresponding etching scheme, a number

of different shapes of varying sizes can be produced. Recently, engineered surface textures such as micro- and nanoscale patterns (pillars, ridges, and complex shapes) were only superimposed on microscale features using nanolithography.<sup>[66]</sup> Pillars and ridges ranging in height from 1.5 to 5  $\mu\text{m}$  and separated by 5, 10, and 20  $\mu\text{m}$  were prepared. Nanoscale pillars and ridges ranged from 12 to 300 nm.

## NANOTECHNOLOGY IN DIAGNOSTIC SYSTEMS

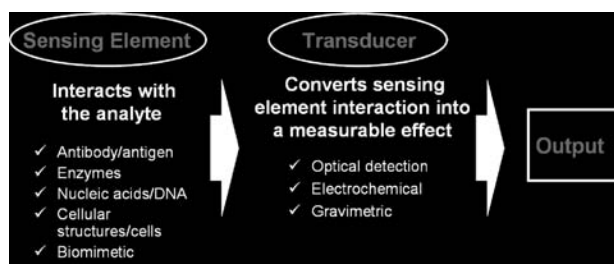

In medical diagnostics, the speed and precision with which a condition is detected determines patient prognosis. With the development of lab-on-a-chip and other miniature point-of-care (POC) devices, the speed and precision with which health care is administered can be radically enhanced. In addition, novel analysis techniques allowing for acquisition of previously unattainable information and, consequently, leading to improved diagnosis have been enabled by micro- and nanoscale technologies. For instance, DNA arrays have enabled for individual genetic analysis to become a reality, which can allow for early detection of diseases.<sup>[67]</sup> Furthermore, diagnostics by means of molecular imaging and profiling has been enabled with the maturation of quantum dot technologies.<sup>[68–72]</sup>

The administration of health care will always require a human provider, who is naturally subjective yet invaluable for the treatment of a patient. The role of this physician will likely be reduced with the advancement of diagnostic techniques, and patient outcomes will be greatly enhanced by eliminating much of the guesswork in diagnosing a condition. The ability to accurately assess the levels of specific analytes that are indicators for a disease or condition is the foundation of successful diagnostics. Therefore the sensitivity, selectivity, response time, and other key characteristics that define the quality of a sensor profoundly impact the quality of a diagnosis.

## Nanoscale Sensor Platforms—Fundamentals and Applications

A sensor is characterized by two key components, a sensing element, which has a specific interaction with an analyte or environmental condition, and a transducing element, which converts this interaction into a measurable effect (Fig. 4). For biomedical applications, the sensing element is designed to interact specifically with biologically significant conditions or target molecules. Natural receptors, such as antibody/antigen, enzymes, nucleic acids/DNA, cellular structures/cells, are the most common choice for sensing elements in biosensors, because of their evolved high affinity and specificity.<sup>[73,74]</sup> Biomimetic sensing

**Fig. 4** Illustration of the key components of a biosensor platform.

elements, such as biorecognitive polymer networks, can be advantageous over their biological counterparts because they can be designed to mimic biological recognition pathways and at the same time exhibit other abiotic properties that are more favorable, such as greater stability in harsh environments.<sup>[75,76]</sup> Common transducing elements, such as optical, electrochemical, gravimetric, and micromechanical, have been highlighted in recent reviews.<sup>[77–82]</sup>

By minimizing the sensor size, diagnostic devices can be fabricated that not only have a significant impact in *ex vivo* sensing applications, but can also be applied to *in vivo* and *in vitro* applications, where micro- or nanoscale dimensionality is imperative. These miniaturized sensors require small sample and/or reagent volumes, tend to be less invasive, and can be faster and more sensitive relative to macroscale technologies. Micro- and nanoscale sensor platforms, such as the ones that are discussed in the following paragraphs, will replace current laboratory methods and facilitate novel diagnostic analysis.

### Micro-/nanoelectromechanical sensors

In a seminal paper,<sup>[83]</sup> Peterson described the early efforts in developing MEMS that were based on the exceptional mechanical properties of silicon, which had been neglected relative to its well-established

electrical properties. In the years that have followed, MEMS have been successfully developed and made commercially available, such as pressure and acceleration sensors for medical and automobile applications.<sup>[84]</sup> In recent years, NEMS devices have received more attention, particularly with a focus on the creation of novel sensor devices.<sup>[85]</sup>

Microcantilevers, an example of a MEMS transducing element, have been integrated with a wide variety of sensing elements, such as intelligent polymer networks<sup>[86,87]</sup> and single-stranded DNA,<sup>[88]</sup> for application as ultrasensitive sensing devices. Recently, researchers have focused on developing techniques to fabricate nanocantilevers,<sup>[89–91]</sup> enabling for the enhancement of the inherent advantages associated with diminishing size.

### Nanopore sensors

Once knowledge of the genetic code of humans, bacteria, viruses and other organisms can easily be attained, diagnosis of many illnesses and diseases can be completed in a rapid and accurate manner. While microarrays, dubbed DNA arrays, DNA chips, and GeneChips, have been established as the preferred method for carrying out genetic analysis on a massive scale,<sup>[67]</sup> novel technologies, such as nanopore sequencing, have demonstrated the possibility to make the analysis faster and cheaper.<sup>[92]</sup>

Nanopores have been applied as a novel method for probing and characterizing the molecular structure of macromolecules (Fig. 5). A translocating molecule alters the ionic current through the pore relative to its open state, and this current change is monitored vs. time and then correlated to the specific characteristics of the target macromolecule. For the majority of studies,<sup>[93,94]</sup>  $\alpha$ -hemolysin has been applied as a model natural ion channel, and these promising results have been highlighted in a recent review.<sup>[95]</sup> Recently, nanofabrication methods have been applied to

**Fig. 5** Illustration of the principles and components of a high-speed device based on a nanopore for probing single molecules of DNA. Source: <http://www.mcb.harvard.edu/branton/>—permission pending.

reproducibly create more robust, synthetic nanopores that can be tailored to have desired dimensions.<sup>[96–100]</sup> With further progress in fabrication and analysis, this simple, yet powerful technique, will sequence biomacromolecules, such as proteins, nucleic acids, and polysaccharides, with molecular precision for cheaper and faster technologies.

### Optical nanosensors

Optical nanosensors, which are devices that transduce a chemical or biological event using an optical signal, have been shown to be an enabling technology for making quantitative measurements in the intracellular environment, demonstrating again the advantages of nanoscale sensors. In a recent review, the impact of this rapidly growing field was highlighted.<sup>[101]</sup> Probes encapsulated by biologically localized embedding (PEBBLEs), with diameters on order of 40 nm, have been utilized to measure intracellular values of pH, calcium, magnesium, potassium, and oxygen.<sup>[102,103]</sup> In other work, optical nanofibers, with a tip diameter of approximately 50 nm, were fabricated and then functionalized with antibodies, allowing for nanometer resolved spatial measurements of a target analyte.<sup>[15]</sup> In addition, other researchers have created a nanoscale optical biosensor based on monitoring the localized surface plasmon resonance (LSPR) spectrum of functionalized silver nanoparticles and demonstrated the ability to apply this device as a real-time immunoassay in physiological buffer.<sup>[104]</sup> In considering the above successes demonstrated with nanoscale optical biosensors, the near future technologies based on these platforms will be utilized for real-time quantitative measurement and imaging within single living cells.

### Point-of-Care Diagnostic Devices

The clinical diagnostics field presents numerous opportunities where micro- and nanoscale biosensor technology can be exploited.<sup>[105,106]</sup> In particular, POC diagnostic devices, which enable diagnostic testing (in vivo or ex vivo) at the site of care, can enhance patient outcomes by substantially abbreviating analysis times as a result of the intrinsic advantages of the miniature device and by eliminating the need for sample transport to an onsite or off-site laboratory for testing. These POC diagnostic devices rely on miniature biosensors as a fundamental component. In addition, the novel information that nanoscale sensors are able to probe provides a superior knowledge base, allowing the physician to accurately diagnose a condition. In critical care medicine, the need for rapid diagnosis and, thus, POC diagnostic devices is magnified, because a delay of even a minute or second can mean

the difference between patient survival and death.<sup>[107,108]</sup>

The development of micro or miniaturized total analysis systems ( $\mu$ S), also referred to as lab-on-a-chip devices, has profoundly impacted the corresponding development of POC diagnostic devices. These  $\mu$ -TAS devices integrate microvalves, micropumps, microseparations, microsensors, and other components to create miniature systems capable of analysis that typically requires an entire laboratory of instruments. Since introduced as a novel concept for chemical sensing devices,<sup>[109]</sup> reviews have been published illustrating the widespread applicability of  $\mu$ -TAS devices.<sup>[110,111]</sup> Of particular interest, other reviews have focused on the application of  $\mu$ -TAS devices as innovative biological devices<sup>[112]</sup> and POC diagnostic devices.<sup>[113,114]</sup> The advancements facilitating the creation of the micro- and nanosensor platforms introduced above have led to the corresponding maturation of POC diagnostic devices. Micro- and nanoscale sensors enable improved and novel analysis, and the consequent POC diagnostic devices will be fundamental to the future of medical diagnostics.

A number of medical conditions or treatments require the sensing and control of a particular biomolecule. In the insulin-dependent diabetes mellitus market, a wide array of sensors are available that operate in a variety of ways in the management of the disease (e.g., small sample sizes, multiple day averages, event markers, diabetes management software, data ports/access to transfer readings). However, many diseases still require a clinic visit to properly monitor the disease or adequately manage medication levels. The technology either does not exist for these sensors or cannot be technically or economically scaled down for POC use.

With nanotechnology and novel material design, the future of medical management will involve small, POC, and possibly disposable sensors that intermittently or continuously monitor the biological molecule of interest. This will translate into an informed patient with better overall hands-on control for disease management. Also, it may alert and aid patients in determining when a low-risk environment or high-risk situation exists and offer greater control. As such, the quality of life and term of life of a person with a chronic disease can be enhanced. Also, with the increase in wireless technology, data can be processed and transmitted to a variety of systems, as well as a family or specialist physician.

### NANOTECHNOLOGY IN THERAPEUTICS

In addition to the intrinsic activity of a drug, the delivery of it in a specific, controlled manner to the desired

site of action is critical to its overall therapeutic effect. For instance, the optimum therapeutic effect depends on a drug getting to the right place at the right time and then staying active for a certain time period. Consequently, advanced drug delivery formulations have been developed over the past 20 years that do not simply release a drug at a specific rate, but release the drug in a way that the pharmaceutical scientist and molecular designer have designed.<sup>[115,116]</sup> Additionally, because drug delivery can improve safety, efficacy, convenience, and patient compliance, novel delivery methods are a major focus of pharmaceutical companies.<sup>[117]</sup> Also, novel methods of delivery are prolonging patent protection.<sup>[118]</sup>

### Drug Development and Discovery

In the field of drug discovery, about half of drug development candidates fail due to problems with absorption, distribution, metabolism, elimination, or toxicity.<sup>[119]</sup> Recent technologies have not had much impact on reducing the cost of drug discovery within the pharmaceutical industry.<sup>[120]</sup> Rather than present an exhaustive history, we direct the reader to an excellent review on the history of drug discovery technologies.<sup>[120]</sup>

In the early 1990s, genomics became a commercial enterprise with high-throughput sequencing on an industrial scale.<sup>[67,121]</sup> As the automation, speed, and accuracy of sequencing results increased, it dramatically decreased the time to complete the Human Genome Project (HGP), which determined the sequences of the 3 billion chemical base pairs and identified approximately 30,000 genes in human DNA as well as patterns of variation across the genome. This was a tremendous accomplishment, but work is now beginning to probe the potential of the sequence code (Table 1).<sup>[122]</sup> This work is expected to have a profound influence on the genetic and mechanistic basis for disease and will lead to genotype- or phenotype-specific therapeutics.

With the knowledge of genome sequences and new high-throughput technologies (nanoarrays and nanoliter systems of increasingly smaller volumes and high degrees of parallelization),<sup>[123]</sup> problems can be attacked on a much larger scale than ever before (e.g., fast screening of focused chemical libraries for target molecules,<sup>[120]</sup> studying all the genes in a genome, and discovering how genes and proteins function in interconnected networks, etc.). The demand for increased sensitivity and throughput for genomics and proteomics<sup>[14]</sup> has companies such as Affymetrix (Santa Clara, CA) and Nanogen (San Diego, CA) looking for solutions at the nanoscale.<sup>[12]</sup>

Tissue microarrays have been developed that can have high-throughput validation of drug targets and

**Table 1** Research challenges that remain after sequencing the genome

---

#### Post-sequencing research challenges

---

Gene number, exact locations, and functions
Gene regulation
DNA sequence organization
Chromosomal structure and organization
Noncoding DNA types, amount, distribution, information content, and functions
Coordination of gene expression, protein synthesis, and post-translational events
Interaction of proteins in complex molecular machines
Predicted vs. experimentally determined gene function
Evolutionary conservation among organisms
Protein conservation (structure and function)
Proteomes (total protein content and function) in organisms
Correlation of SNPs (single-base DNA variation among individuals) with health and disease
Disease-susceptibility prediction based on gene sequence variation
Genes involved in complex traits and multigene diseases
Complex systems biology including microbial consortia useful for environmental restoration
Developmental genetics, genomics

evaluation of efficiency, distribution, and toxicity.<sup>[38]</sup> Using laminar microfluidic flows, delivery of membrane-permeable molecules into selective regions of a single cell and differential manipulation of regions within a single cell have been demonstrated. Specifically, Takayama et al. were able to selectively label subpopulations of mitochondria as well as disrupt actin filaments in selected cellular regions (Fig. 6).<sup>[14]</sup> The authors speculate that the technique may allow for the probing and manipulation of cellular metabolic and structural machinery and major applications include chemotaxis, spatially regulated signaling, drug screening, and toxicity studies.

### Miniaturization of Controlled Drug Delivery Devices

Advances in micro- and nanotechnologies have accelerated the development of new drug delivery vehicles that will transform biological potential into medical reality.<sup>[124]</sup> For instance, micro- and nanofabrication techniques have enabled the development of novel drug delivery devices that can improve the therapeutic effect of a drug, such as micro- and nanoscale needles, pumps, valves, and implantable drug delivery devices. The field of micro- and nanofabricated drug delivery

**Fig. 6** Differential manipulation of regions of a single bovine capillary endothelial cell using multiple laminar flows. *Source:* From Ref.<sup>[14]</sup>—permission pending.

devices, which is still in its infancy, has unlimited potential.

#### Micro-/nanoscale needles for cellular and transdermal delivery

For over 150 years, syringes and hypodermic needles have been utilized for the delivery of drugs bypassing the transport barriers that exist in other delivery routes. Currently, the smallest needles that are commercially available for injections are 30 gauge for conventional syringes and 31 gauge for pen injectors, having outer diameters of 305 and 254  $\mu\text{m}$ , respectively.<sup>[125]</sup> Microfabrication techniques have been utilized to create miniature needles, which are orders of magnitude smaller in diameter and capable of localized and painless delivery of drugs into cells or tissues. Recently, novel methods have been developed to fabricate nanoneedles, which have been proposed to enhance performance even further.<sup>[126,127]</sup>

Microscale needles have been applied for cellular delivery of membrane impermeable molecules. For example, arrays of microneedles were fabricated and utilized to deliver DNA into plant and mammalian cells, as a method for transforming cells.<sup>[128,129]</sup> Additionally, microneedles have been utilized to target

drug delivery to a specific region or tissue in the body, thus avoiding detrimental effects that can result from administering certain drugs systemically. This targeting can reduce side effects, minimize the dose of an expensive drug, and/or provide a means of delivery to a location that is difficult to treat.<sup>[117]</sup> For instance, a multichannel silicon microneedle has been microfabricated to deliver bioactive compounds into neural tissue while simultaneously monitoring and stimulating the neurons *in vivo*.<sup>[130]</sup> In addition, microneedles have been used to penetrate vessel walls of normal and atherosclerotic rabbit arteries *in vitro* demonstrating potential use for targeted delivery of antirestenosis drugs.<sup>[129]</sup>

Furthermore, microscale needles have been applied for transdermal drug delivery. In conventional transdermal drug delivery, the outer 10–20  $\mu\text{m}$  of skin, the stratum corneum, acts as a barrier to the diffusion of the drug molecules, thus limiting its applicability to small drug molecules. Because the stratum corneum does not have any nerves, needles that are long enough and robust enough to penetrate across this layer, but short enough to not stimulate the nerves in the deeper tissue, have the potential to make transdermal delivery a painless and much more viable option.<sup>[125,131]</sup>

**Table 2** Selected nanobiotechnology companies developing drug delivery and therapeutic applications

Focus	Company	Platform
Therapeutics	Alnis Biosciences (Emeryville, CA)	Polyfunctional nanoparticles
	ALZA (Mountain View, CA)	Lipid nanoparticles with PEG coating; Doxil on the market
	NanoCrystal Technologies (King of Prussia, PA)	NanoMill technology for creating nanocrystals
	NanoMed Pharmaceuticals (Kalamazoo, MI)	Nanotemplate engineering for drug and vaccine delivery systems
	StarPharma (Melbourne, Australia)	VivaGel anti-HIV dendrimer (phase I)
Drug Delivery	Advectus Life Sciences (British Columbia, Canada)	NanoCure system for delivery of anticancer drugs across the blood–brain barrier
	BioDelivery Sciences (Newark, NJ)	BioOral nanocochleates cigar-shaped structures composed of lipid bilayers
	BioSante Pharmaceuticals (Lincolnshire, IL)	Nanoparticulate platform (CAP) for drug delivery (phase I)
	C-Sixty (Houston, TX)	Fullerene-based drug delivery
	Cytimmune Sciences (College Park, MD)	Tumor necrosis factor bound to colloidal gold nanocrystals for targeting tumors; vector with docking site for gene therapy
	NanoCarrier (Chiba, Japan)	NanoCap micellar nanoparticle for water-insoluble drugs (under development)
	NanoBio (Ann Arbor, MI)	Antimicrobial nanoemulsions (phase II)
	NanoSpectra Biosciences (Houston, TX)	Nanoshells for optical therapies
	Targesome (Palo Alto, CA)	Injectable nanospheres for therapeutic or diagnostic agents

### Nanoscale polymer carriers for controlled drug delivery

Polymer nanoparticle and nanosphere carriers are very attractive for biomedical and pharmaceutical applications, because of their unique and tailorable properties. In the case of polymer networks, the release profile can be precisely controlled through the design of its molecular structure, such as degree of cross-linking and ionic characteristics of the pendent functional groups.<sup>[132,133]</sup>

Polymer nanospheres have been molecularly designed to be responsive to the pH of their environment, enabling for the protection of fragile therapeutic peptides and proteins in the harsh, acidic stomach environment and then release in the more amiable environment of the upper small intestine.<sup>[134–136]</sup> In addition, nanoparticle carriers have been designed to have stealth properties, allowing extended residence time without being recognized by the immune system.<sup>[137,138]</sup> In other efforts, synthetic delivery systems, including polymeric nanoparticles, have been developed for application in gene delivery.<sup>[139,140]</sup> By creating polymer drug delivery systems that are biodegradable, the need for removal of the system post-delivery is eliminated, as the polymer can be naturally resorbed by the body.<sup>[141]</sup> Also, a number of companies are reformulating insoluble drugs as nanoparticles and nanocrystals to control uptake through cellular

membranes.<sup>[12]</sup> Table 2 lists a few selected nanobiotechnology companies and platforms.

### Microchip-based delivery systems

Microchips have been created for the storage and then delivery of multiple drugs in a controlled manner. For instance, a solid-state silicon microchip that can provide controlled release of single or multiple chemical substances on demand was fabricated and demonstrated.<sup>[142,143]</sup> The release is achieved via electrochemical dissolution of the thin anode membranes covering the microreservoirs filled with chemicals in solid, liquid, or gel form. The advantages of this microdevice include that it has a simple release mechanism, very accurate dosing, ability to have complex release patterns, potential for local delivery, and possible biological drug stability enhancement by storing in a microvolume that can be precisely controlled. Recently, multipulse drug delivery from a resorbable polymeric microchip device was demonstrated.<sup>[144]</sup>

The aforementioned microdevices demonstrate only a few examples of the wide variety of novel applications that exist for integration of micro- and nanofabrication technologies with drug delivery, revealing the immaturity of the field. These novel drug delivery devices can enable efficient delivery that was unattainable with conventional drug delivery techniques, resulting in the enhancement of the therapeutic activity of a

drug. The future of drug delivery is assured to be significantly influenced by micro- and nanofabrication technologies.

## CONCLUSION

Nanoscale science and engineering has an unlimited potential to affect the diagnosis and etiology of a number of diseases with enhanced prognosis and rational treatment. Although this field is in its infancy, the unlimited potential is clear, especially for application in medical science and technology leading to technological innovations in medicine. In the near future, micro- and nanodevices will be created that will combine the diagnostic and therapeutic actions described in this review, enabling for comprehensive devices that can monitor conditions and administer therapy. As the interest and investment in this maturing field continues to grow, it is impossible to identify the full breadth and reach of the resulting technologies, yet it is unmistakable that the developments will dramatically influence the nature and practice of medicine.

## ACKNOWLEDGMENTS

We would like to acknowledge Prof. Nicholas A. Peppas and Prof. Rashid Bashir for insightful discussions regarding the subject matter. We would also like to acknowledge NSF and NIH for funding.

## INTRODUCTION

Interest in nanoparticles has grown rapidly in recent years because of their diverse applications in biomedicine and as novel materials for engineering and devices. Magnetic nanoparticles are of particular interest because of their potential application in areas such as magnetic separation, magnetic resonance imaging (MRI), targeted drug delivery, hyperthermia treatment of solid tumors, and high-density magnetic storage.

In this entry, we cover some of the synthesis methods (chemical reduction in reverse micelle, and solution, fabrication in hydrogels, thermal decomposition, seed-mediated growth, and precipitation from aqueous solution) and characterization of magnetic nanoparticles (transmission electron microscopy (TEM), X-ray diffraction (XRD), X-ray absorption spectroscopy (XAS), superconducting quantum interference device (SQUID), Mössbauer spectroscopy, and small angle neutron scattering (SANS)). We will also explore some of the biomedical applications such as magnetic separation, targeted drug delivery, hyperthermia cancer treatment, and MRI contrast agents.

## METHODS OF SYNTHESIS

Fabrication of nanoparticles can be grouped into three main synthetic methods: solid, gas, and solution.<sup>[1]</sup> The solid route involves the mechanical milling or the mechanochemical synthesis of raw powder to produce nanoparticles. This method has the disadvantage of introducing contamination to the products from the milling equipment as well as producing particles with wide size distribution. In gas and chemical routes, the synthesis can be considered as either “phase-transformation” or “phase-build-up.” The “phase-transformation” can be described as

the conversion of finely divided metal compounds into metals through thermal decomposition (see later) or chemical reduction. On the other hand, in “phase-build-up,” particles are “constructed” from building blocks (metal atoms). This process can take place from the gas phase (chemical or physical vapor deposition) or from the liquid phase (chemical precipitation). Gas-phase synthesis involves the formation of a supersaturated vapor of condensable gaseous species as a result of a chemical reaction that produces a new species or as a result of a physical process such as cooling that will reduce the vapor pressure of the condensable species. There are also several methods that use the solution route and are discussed in further detail later. These techniques produce uniform nanoparticles of different shapes by using appropriate precursors and by adding a surfactant or a capping ligand during the transformation. The addition of a surfactant/capping ligand can also prevent aggregation of the particles.

In the liquid phase, the chemical precipitation usually occurs from homogeneous solution. When the concentration of the constituent precursor reaches critical supersaturation, there is short burst of nucleation. This is followed by a period of uniform growth as the solutes diffuse from the solution to the surface of the nuclei until the final size is reached. To achieve monodisperse nanoparticles, this process requires the separation of the nucleation and growth phases, with no further nucleation occurring during the growth period. Multiple nucleation events can result in small particles aggregating to form much larger particles.<sup>[2,3]</sup> This process is known as Ostwald ripening and typically leads to the coarsening of the size distribution of the particles. Nucleation, particle growth, and particle interaction can be better controlled in a liquid medium, making chemical precipitation a more favorable method for producing uniform particles with well-controlled features (see Fig. 1).

## Chemical Reduction in Solution

Reduction is the transfer of electrons from reducing agent to oxidized metal species in a process driven by redox potential of the reaction,  $\Delta E^0$ . The value of  $\Delta E^0$  will indicate the likelihood of the reduction proceeding and can predict the rate of the chemical reaction. An increase in its value is associated with faster generation of atoms in the liquid phase. This leads to a higher supersaturation concentration of atoms and therefore faster nucleation. Thus, finely controlling the redox potential of the reacting species and the overall reaction is vitally important in controlling the properties of the metal particle produced. Complexing or precipitating the oxidized metallic species can alter their electrochemical potential. The degree of change is dependent on the stability constants or the solubility products of the resulting compounds.<sup>[4]</sup>

The reducing agent can form an intermediate with the oxidized metal species without altering its oxidation state. In this situation, the reduction process can be initiated by increasing the temperature, for example, and it can be conducted very slowly, producing conditions that lead to the formation of highly crystalline structures of regular shape.

An example of this is the reduction of iron (II) chloride and platinum acetylacetonate using superhydride ( $\text{LiBEt}_3\text{H}$ ) at high temperature ( $263^\circ\text{C}$ ) to produce 4 nm FePt magnetic nanoparticles.<sup>[5]</sup> Alternatively, 5 nm CoPt nanoparticles can be produced by coreduction of cobalt and platinum acetylacetonate in trimethylene glycol.<sup>[6]</sup> These particles are ferromagnetic at room temperature and by annealing above  $550^\circ\text{C}$ , the magnetic properties of the nanoparticles can be enhanced, owing to the induction of ordering.

## Redox Transmetalation

This process involves metal ions of the reactant metal complexes being reduced on the surface of metal (Me) nanoparticles with the simultaneous oxidation of the neutral  $\text{Me}^0$  to  $\text{Me}^{n+}$  via ligand migration to form a metal–ligand complex as a reaction by-product.<sup>[7–9]</sup> This process also means that the particle size remains the same during the reaction. Using redox transmetalation, Lee et al.<sup>[9]</sup> fabricated cobalt core nanoparticles with shells of gold, palladium, platinum, and copper. Of particular interest are Co@Au core-shell nanoparticles, because they can be transferred to the aqueous phase without losing any magnetism and the gold shell layer is very versatile.<sup>[9]</sup>

## Reduction in Reverse Micelles

Reverse micelles are spherical aggregates formed by surfactants dissolved in organic solvent. In the presence of small amount of water, which is readily solubilized in the polar core, monodisperse aggregates can be formed.<sup>[10]</sup> In contrast, microemulsions are formed with a larger amount of water. The reverse micelles can be used as microreactors for the synthesis of nanoparticles. Briefly, aqueous solutions of metal salts containing elements that formed the desired nanoparticle are added to the reverse micelle suspension. A reductant (e.g.,  $\text{NaBH}_4$ ) is added to the mixture and once the metallic nanoparticles are formed, the micelle solution is disrupted by the addition of an excess amount of polar solvent (e.g.,  $\text{CHCl}_3$ ; methanol) and the particles are collected.<sup>[11–15]</sup>

Reverse micelles provide unique reaction media as they can solubilize, concentrate, localize, and even

**Fig. 1** Formation mechanism of nanoparticles where, following a single burst of nucleation, a period of uniform growth leads to the formation of monodisperse nanoparticles by diffusion. Multiple nucleation events and growth via Ostwald ripening can lead to polydisperse suspensions of nanoparticles.

organize reactants. They also allow the nanoparticle synthesis to take place in aqueous solution. However, control of the size and shape of nanoparticles synthesized by this method is difficult as it reflects the interior of the micelles.

## Hydrogels

A hydrogel is a gel that will expand greatly in aqueous solution. They are usually composed of a hydrophilic organic polymer component that is cross-linked through either covalent or non-covalent interactions.<sup>[16]</sup> They can be synthesized to contain magnetic nanoparticles by using a two-step emulsifier-free emulsion polymerization. For example, bovine serum albumin (BSA) can be covalently attached to the particles to form thermosensitive magnetic immunospheres, which can be very useful in the immunoaffinity purification of anti-BSA antibodies from antiserum.<sup>[17]</sup>

## Thermal Decomposition

In this process, organometallic complexes are rapidly broken down in hot solvent containing surfactant, which can form a protecting layer around the nanoparticle, whilst acting as a dispersant. For example, the rapid pyrolysis of  $\text{Co}_2(\text{CO})_8$  in *o*-dichlorobenzene, in the presence of trioctyl phosphine oxide (TOPO) and oleic acid at  $185^\circ\text{C}$  will produce cobalt nanoparticles, whose size and shape can be controlled by varying the molar ratios of precursor and surfactant.<sup>[18,19]</sup> The protective layer can also consist of polymers, which can be tailored to improve the biocompatibility of the nanoparticles. For example, Stevenson et al.<sup>[20]</sup> used a poly[dimethylsiloxane-*b*-(3-cyanopropyl)methylsiloxane-*b*-dimethylsiloxane] (PDMS-PCPMS-PDMS) family of triblock polymers with controlled length to coat Co nanoparticles. The central block (PCPMS) is absorbed onto the nanoparticle surface and the hydrophobic end-blocks protrude into the carrier fluid (poly[dimethylsiloxane]), providing suspension stability. Alternatively, one can also use peptides as capping ligands for *in situ* synthesis of water-soluble Co nanoparticles with the aim to use these particles for biological applications.<sup>[21]</sup> The ability to tune the properties of the peptides (by varying the length, and sequence of amino acids) makes them a unique class of ligands for combinatorial nanomaterial synthesis. In addition to the 20 amino acids that occur naturally in proteins, over 100 unnatural amino acids are available for peptide synthesis, which provide access to a huge chemical combinatorial space. Like metallic nanoparticles, 13 nm monodisperse maghemite particles have been synthesized by injecting  $\text{Fe}(\text{CO})_5$  into

a solution containing surfactants and a mild oxidant (trimethylamine oxide).<sup>[22]</sup> Moreover, Park et al.,<sup>[23]</sup> using the same method, have been able to synthesize monodisperse iron oxide nanoparticles with extremely fine size control, producing particles with diameters of 6, 7, 9, 10, 12, 13, and 15 nm.

## Seed-Mediated Growth

Introducing “seeds” to a reaction mixture can increase the nucleation rate and thus the properties of the resulting nanoparticles.<sup>[4]</sup> The catalytic or surface properties of the small solid entities can trigger the reduction of the species and the nucleation process. This is of particular use in systems in which nucleation would otherwise not take place or would be too slow. It also has the advantage of artificially separating the nucleation and growth phases of the particle formation.

Seeds can be produced “in situ” by the rapid reduction of a different, more electropositive element or be in the form of a stable dispersed preformed nanosized particle of the same element. To form monodisperse nanoparticles, it is necessary for the nucleation process to be uniform throughout the entire solution, a condition that is difficult to achieve in rapid reductions. This has an effect upon reproducibility and scale up of the process.

To avoid this, it is favorable to use systems in which the electron transfer is inhibited when the reactant species are brought into contact, but can be induced by changing the conditions (e.g., pH, temperature, etc.) after the system is already homogenized. For example, the solvent used to dissolve the metal salts will become the reducing agent on changing the conditions. Wang et al.<sup>[24]</sup> used  $\text{Fe}_3\text{O}_4$  nanoparticles as seeding materials for the reduction of gold precursors to synthesize gold-coated  $\text{Fe}_3\text{O}_4$  nanoparticles ( $\text{Fe}_3\text{O}_4@\text{Au}$ ).

## Precipitation from Aqueous Solution

Precipitation routes from aqueous solution are widely used for the synthesis of iron oxide nanoparticles.<sup>[25]</sup> One method involves ferrous hydroxide suspensions that are partially oxidized, using a variety of oxidizing agents. The amorphous ferrous hydroxide is first precipitated and the aqueous gel is aged at  $90^\circ\text{C}$  over various time periods in the presence of a mild oxidant (e.g., nitrate ions). A study of the evolution of the precipitation with time has shown that minute primary particles, nucleated in the ferrous hydroxide gel, aggregate and then larger particles form by a contact-recrystallization mechanism. The aggregation of the primary iron oxide particles results from the Van der Waals and magnetic forces acting under the

conditions of weak repulsion, close to the isoelectric point, giving rise to spherical crystalline particles.<sup>[26]</sup>

An example of this is using an iron (II) chloride and iron (III) nitrate mixture (at a ratio of 1 : 1) in a basic aqueous solution to precipitate spherical magnetite ( $\text{Fe}_3\text{O}_4$ ) nanoparticles with an average diameter of 7 nm.<sup>[27]</sup> Alternatively, by adding polyelectrolytes, again at basic pH, to the iron salts during the precipitation, ferrite nanoparticles of nearly uniform size can be produced.<sup>[28]</sup> By varying the polyelectrolyte concentration in the solution, the size of the resulting iron oxide nanoparticles can be easily controlled.

## CHARACTERIZATION METHODS

For sample characterization, it is important to know the phase, morphology (size and shape), as well as the physical properties of the as-prepared magnetic nanoparticles. In the following, we will cover some of the most common techniques for this purpose.

### Phase and Morphology Characterization

#### Transmission electron microscopy

Transmission electron microscopy (TEM) is one of the most common techniques used to visualize and determine the morphology of the particles. In this technique, the specimen is illuminated by a beam of monochromatic electrons, some of which are

transmitted through the objective lens and then projected onto a viewing screen (for example, a layer of electron fluorescent material) to produce an image. In TEM, one can “see” particles as small as a few angstroms ( $10^{-10}$  m), which is near atomic levels. As an example, in Fig. 2 is shown the TEM image of a self-assembled sample of Co nanoparticles with the mean particle size of 4.5 nm; the particle size distribution is also shown in the left panel.

High-resolution transmission electron microscopy (HRTEM) can sometimes be used for complex structures such as core-shell or those consisting of an alloy. The HRTEM allows us to obtain information on the crystal planes of the particles and measure the lattice distance.

#### Scanning electron microscopy

A scanning electron microscope (SEM), like TEM, uses a beam of electrons aimed at a specimen; therefore, both instruments have similar features such as an electron gun, condenser lenses, and a vacuum system. However, the images are produced and magnified in different ways and while TEM provides information about the morphology of the nanoparticles, SEM is mainly used to study the surface or near surface structure of bulk specimens. The spatial resolution of SEM is approximately 15 nm, and therefore, not as good as TEM, which can have spatial resolutions in the sub-nanometer range; however, SEM images are generally much easier to interpret. Also SEM has the ability to

**Fig. 2** TEM micrograph of 4.5 nm Co nanoparticles with the size distribution graph (Bar 50 nm).

image a comparatively large area of the specimen; the ability to image bulk materials (not just thin films or foils); and the variety of analytical modes available for measuring the composition and nature of the specimen.

Field-emission SEM (FESEM) uses a field-emission cathode in the electron gun of a scanning electron microscope and provides narrower probing beams both at low and high electron energy; this results in both improved spatial resolution and minimized sample charging and damage. FESEM produces clearer, less electrostatically distorted images with spatial resolution down to 1.5 nm or better, i.e., several times better than the conventional SEM. High-quality, low-voltage images are obtained with negligible electrical charging of samples (accelerating voltages range from 0.5 to 30 kV).

### X-ray diffraction

Powder X-ray diffraction (XRD) is the most conventional technique that can be used to determine the structure, phases, and average size of the particles. In this technique, the structure and the lattice parameters are determined by fitting the X-ray patterns by means of the Rietveld profile procedure,<sup>[29]</sup> several software programs are available, such as FULLPROF.<sup>[30]</sup> The size of the particles can also be determined from the width of the X-ray peaks using the Scherrer formula.<sup>[31]</sup> The particle size estimated from the XRD is often found to be larger than that from TEM estimates because of the broadening of X-ray diffraction lines, which can be affected by many factors. In addition, the X-ray coherence length does not allow the technique to be applied to the study of particles that are too small (say less than 1 nm).

### X-ray absorption spectra

When a beam of X-rays passes a sample, it can be absorbed. A certain amount of energy of the incident X-ray photons is sufficient to cause excitation of a core electron of an absorbing atom, which causes it to pass into a continuum state, thus producing a photoelectron. This results in a drastic increase in the absorption, giving rise to an absorption edge. If one defines the electron binding energy as  $E_0$ , an X-ray absorption spectrum (XAS) is generally divided into four sections: (1) pre-edge ( $E < E_0$ ); (2) X-ray absorption near edge structure (XANES), where the energy of the incident X-ray beam is  $E = E_0 \pm 10$  eV; (3) near edge X-ray absorption fine structure (NEXAFS), in the region between 10 eV up to 50 eV above the edge; and (4) extended X-ray absorption fine structure (EXAFS), which starts approximately from 50 eV and continues up to

1000 eV above the edge. The analysis of the different spectrum sections is particularly useful. The XANES contains information about the electronic state of the X-ray absorbing atom and the local structure around it. The NEXAFS can give information relating to bond angles, bond lengths, and the presence of adsorbates. Finally, the EXAFS can give information on the atomic number, distance, and coordination number of the atoms surrounding the element.

### Magnetization Characterization

Magnetic particles with size smaller than few tens of nanometers can be considered as single magnetic domains, which display properties markedly different from the bulk. One of the interesting features of nano-size magnetic materials is the presence of the magnetic relaxation process that is due to the thermal effect and the existence of the energy barriers separating the local minima for different equilibrium states of the system. As a result, the magnetic behavior of a small particle depends on its relaxation time ( $\tau$ ),

$$\tau = \tau_0 \exp[KV/(k_B T)],$$

where  $\tau_0$  is of the order of  $10^{-9}$ – $10^{-13}$  s and weakly depends on temperature,  $k_B$  the Boltzmann constant,  $T$  the temperature; and  $K$  and  $V$  are the anisotropy and (average) volume of the particle, respectively. When  $\tau$  is smaller than the experimental time window ( $\tau_{\text{ex}}$ ), the magnetization vector is seen to change quickly between different states, i.e., the system is in a superparamagnetic state. By contrast, when  $\tau > \tau_{\text{ex}}$ , the thermal dynamic equilibrium state is very difficult to observe, since the energy barriers arising from the anisotropy obstruct the magnetization vector from switching to a lower energy state. This case is generally called the blocked state. The temperature at which  $\tau = \tau_{\text{ex}}$  is defined as the blocking temperature.

For magnetization characterization, it is important to determine the blocking temperature of the nanoparticle sample. From this, sometimes one can also obtain complementary information such as the monodispersity of the sample; size and anisotropy of the particles; formation of an oxide layer on the intermetallic sample, and the magnetic (dipole–dipole) interaction between particles.

One of the most common devices used in magnetization characterization is the superconducting quantum interference device (SQUID) in which the magnetization can be measured within an experimental window  $\tau_{\text{ex}}$  of about 20 s. Here, one can determine the blocking temperature  $T_B$  of the sample from a standard zero-field-cooled (ZFC) and field-cooled (FC)

**Fig. 3** Temperature dependence of the magnetization of 3.3 nm  $\text{CoFe}_2\text{O}_4$  nanoparticles measured in zero-field cooled (ZFC) and field-cooled (FC) conditions with an applied field  $H = 10$  Oe.

measurement of the magnetization. As an example, Fig. 3 shows the results measured on 3.3 nm  $\text{CoFe}_2\text{O}_4$  nanoparticles. The ZFC curve shows a peak at about 90.5 K, which corresponds to the blocking temperature  $T_B$ . This sample shows a good monodispersity with the sharp peak at  $T_B$  and the splitting between ZFC and FC curves occurs very close to the peak's position.

Another useful magnetization characterization can be realized on measuring the a.c. susceptibility at different frequencies ( $f$ ). Here, the experimental time window  $\tau_{\text{ex}} = 1/f$ . Fig. 4 shows an example for 3.3 nm  $\text{CoFe}_2\text{O}_4$  nanoparticles. It can be seen that

**Fig. 4** Temperature dependence of the in-phase component of the a.c. susceptibility of 3.3 nm  $\text{CoFe}_2\text{O}_4$  nanoparticles ( $\chi'_{\text{ac}}$ ) at different frequencies. The inset shows the logarithm of the experimental time window  $\tau_{\text{ex}}$  as a function of inverse blocking temperature ( $1/T_B$ ).

the blocking temperature  $T_B$  at the peak of the a.c. susceptibility shifts toward higher temperatures with increasing frequencies. The slope of the plot  $\ln \tau_{\text{ex}}$  vs.  $1/T_B$  in the inset of Fig. 4 gives information on the anisotropy ( $K$ ) and the volume of the particles ( $V$ ) through the relationship  $\ln \tau_{\text{ex}} = \ln \tau_0 + KV/k_B T_B$ .<sup>[32]</sup>

## Other Techniques for Characterization of Magnetic Nanoparticles

### Mössbauer spectroscopy

Mössbauer technique is a very useful tool for probing the properties of materials although it can be applied only to those consisting of elements (more than 40) that are Mössbauer-active of which  $^{57}\text{Fe}$  is the most prominent “Mössbauer nuclide.” For magnetic nanoparticles, the magnetic hyperfine field splitting in the Mössbauer spectra begins right below the blocking temperature  $T_B$  where the relaxation rate of particles has slowed down sufficiently for the reversal energy to exceed the thermal energy.<sup>[33]</sup> Note that because of very small experimental time window ( $\tau_{\text{ex}}$ ) in Mössbauer ( $\approx 10^{-9}$  s) when compared with other techniques such as SQUID ( $\approx 20$  s), the blocking temperature derived from the technique is higher. The analysis of the spectra close to  $T_B$  would give information on the size distribution of the particles. Spectra below  $T_B$  can give different information on the phase(s) of the sample, oxidation state, magnetic structure, dynamics effects as well as the interaction between the particles.

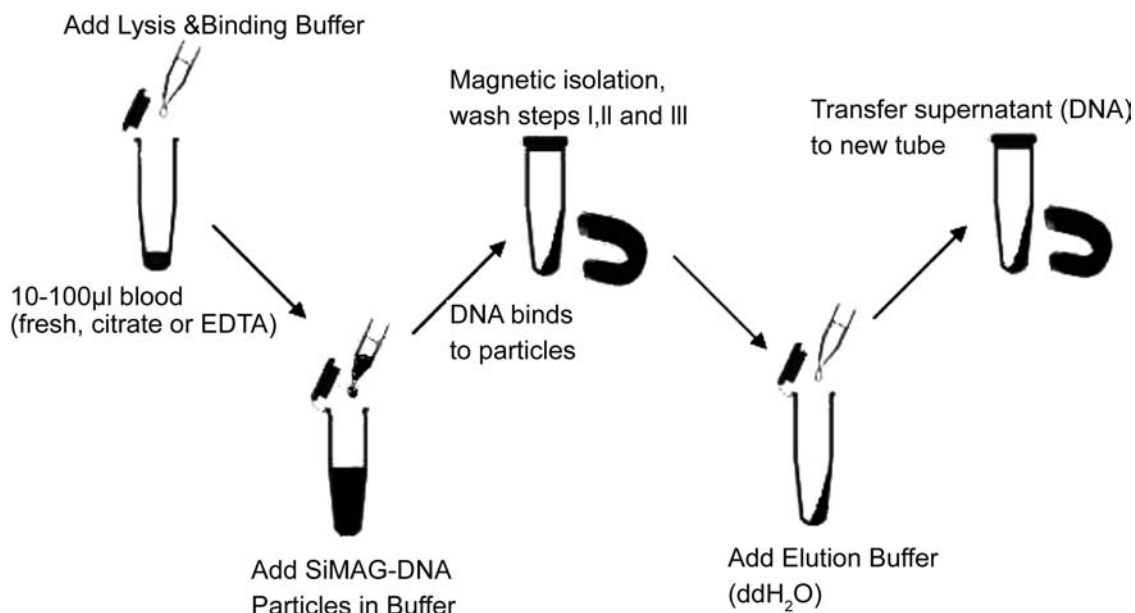

### Small angle neutron scattering

Small angle neutron scattering (SANS) is a useful tool to study magnetic nanoparticles. In contrast to light and X-rays, which are scattered by the electrons surrounding atomic nuclei, neutrons are scattered by the nucleus itself. In this technique, one can “see” the particle in the range between 1 and 500 nm. Several parameters can be evaluated from SANS data, including the radius of gyration, the particle surface area, shape of the scattering particles, magnetic structure, magnetic correlation, alignment of nanoparticles as well as their response to an external magnetic field.<sup>[34,35]</sup>

## BIOMEDICAL APPLICATIONS

### Magnetic Separation

Since magnetic nanoparticles can be quickly separated by magnetic forces, they are excellent candidates for purification and reuse in biotechnology. The special

**Fig. 5** Schematic view of the use of magnetic nanoparticles to separate the DNA from blood sample. *Source:* From <http://www.chemicell.com>.

advantages of magnetic separation techniques are the fast and simple handling of a sample vial and the opportunity to deal with large sample volumes. This is because intensive steps of centrifugation can be omitted. Therefore, biomagnetic separation is highly compatible for labor automatization systems that will play a very important role in the near future.

In magnetic separation, first the magnetic nanoparticles have to be tagged with a desired biological entity such as proteins, DNA, RNA, enzymes, blood cells, and cancer cells in the native solution. This tagging can be made possible by chemical coating of magnetic nanoparticles with biocompatible molecules such as dextran, peptides, and phospholipids. The magnetically labeled entities can then be separated using a permanent magnet and washed with water. Finally, the magnetic particles can be untagged and removed again by a magnetic field to obtain the desired biological product. An example of the use of magnetic nanoparticles for the separation of DNA from a blood sample is illustrated in Fig. 5.

### Drug Delivery

Most current chemotherapies are relatively non-specific and tend to attack normal healthy tissue leading to unwanted side effects that can lead to the discontinuation of their use. However, if such treatments could be localized, e.g., anti-inflammatory drug to arthritic joints, the dose and thus the side effects

could be minimized allowing prolonged use of these agents (see Fig. 6).<sup>[36]</sup>

One particular method of achieving this would be to attach a therapeutic drug to a biocompatible magnetic nanoparticle carrier that is injected into the patient via the circulatory system. Once in the blood stream, the drug-carrier complex can be concentrated at a specific site by applying a high-gradient, external magnetic field; the drug released via enzymatic activity or changes in the physiological conditions.<sup>[37]</sup>

**Fig. 6** Schematic view of the use of magnetic nanoparticles for guided drug delivery.

There are several physical parameters that govern the effectiveness of the therapy, including field strength, gradient, and volumetric and magnetic properties of the particles. Hydrodynamic factors, such as blood flow rate, carrier concentration, and infusion route and circulation time, will also play a major role if the carriers are administered via the circulatory system. Finally, physiological parameters such as tissue depth to the target site (i.e., distance from the magnetic field source), reversibility, and strength of the drug/carrier binding and, in cancer treatments, tumor volume are also very important.<sup>[38]</sup>

Generally, the carriers are magnetic particles coated with a biocompatible molecule (e.g., polymer, peptide, silica), which can be functionalized by adding carboxyl groups, biotin, avidin, and other molecules.<sup>[39–41]</sup> These molecules can then act as attachment points for the coupling of therapeutic drugs.<sup>[42]</sup>

### Therapeutic Hyperthermia

Hyperthermia treatment of cancers involves using a device to heat malignant cells. However, the majority of devices are restricted in their use owing to coincidental damage to surrounding healthy tissue. Magnetic nanoparticle hyperthermia provides a possible solution to this problem. Generally, magnetic particles can be dispersed into the target tissue and an AC magnetic field of sufficient strength and frequency is applied resulting in the heating of the particles. The heat is then transferred to the surrounding diseased tissue and if the temperature can be maintained above the therapeutic threshold of 42°C for a minimum of 30 min, the tumor is destroyed.<sup>[42]</sup>

However, to date, most laboratory and animal model based studies have used magnetic field strengths that would have deleterious effects on humans, such as peripheral and skeletal muscle stimulation, cardiac stimulation, and arrhythmia and non-specific heating of tissue. This may be overcome by direct administration of the magnetic material directly into the target site rather than via the circulatory system. This would allow far greater quantities of the material to be used, and therefore, lower field strengths could be applied.

### MRI Contrast Enhancement

Magnetic resonance imaging (MRI) utilizes the vast number of protons present in biological tissue as each has an extremely small magnetic moment, which together lead to a measurable response in a large magnetic field. The response is derived from the net magnetic moment of the protons in a radio frequency transverse field applied in a pulsed sequence. Pick-up coils within the MRI scanner measure induced currents

caused by the relaxation of the response from the instant when the pulse is switched off.

By using magnetic contrast agents, the relaxation times  $T_1$  (longitudinal or spin–lattice) and  $T_2$  (transverse or spin–spin) can be shortened. Paramagnetic gadolinium ion complexes are the most commonly used contrast agents, while superparamagnetic (SPM) iron oxide particles are available for the organ specific targeting of liver lesions. In the field strengths normally used in MRI scanners, SPM particles become magnetically saturated, leading to a considerable locally perturbing dipolar field, which has the effect of shortening the relaxation times.

Magnetic nanoparticles are selectively taken up by the reticuloendothelial system of cells lining blood vessels, which remove foreign substances from the body, the differential up-take of different tissues in the body is vital for MRI.<sup>[43]</sup> Particle size is also of great importance; smaller particles have a longer half life in the blood stream, accumulating in the reticuloendothelial cells throughout the body.<sup>[44,45]</sup> One of the drawbacks of using iron oxide nanoparticles as contrast agents is their relatively low saturation magnetization, requiring the use of larger particles. Transition metal nanoparticles, e.g., those made from cobalt, have a much higher saturation magnetization value, allowing the use of smaller particles (<8 nm), without compromising sensitivity, and research is currently ongoing to assess their effectiveness.

### CONCLUSIONS

We have attempted to present an up-to-date review of the synthesis, characterization, and biological application of magnetic nanoparticles. The synthetic methods currently used have to surmount the problem of producing particles that are not only soluble in aqueous solution but also able to withstand the specific environments present in a biological system (e.g., powerful electrolytes, etc.). Nanoparticles can be produced in aqueous solution, but tend to be polydisperse aggregates, whilst those produced in organic solvent are monodispersed but they do not readily dissolve in aqueous solution. In the future, new syntheses methods need to be developed that are designed with a specific biological application as the focus to overcome the problem of technology transfer as this is one of the major challenges in the biomedical application of magnetic nanoparticles.

# Biomimetic Design of Self-Assembling Systems

Mila Boncheva

George M. Whitesides

*Department of Chemistry and Chemical Biology, Harvard University,  
Cambridge, Massachusetts, U.S.A.*

## INTRODUCTION

Successful solutions to many problems in science and technology have emerged by extracting design or strategy from biology, and applying it in a nonbiological context.<sup>[1–16]</sup> The use of biomimetic approaches is particularly well suited when designing self-assembling functional systems because life—from single cells to complex, multicellular organisms—demonstrates an enormous number of successful, functional designs and because living systems assemble themselves. Cells and organisms consist of collections of molecular and supramolecular structures that perform a range of complex functions, including molecular recognition, ligand binding, signal transduction, information storage and processing, and energy conversion. The molecular organization of biological structures also underpins their mechanical properties. In addition, certain of these structures can self-heal, self-repair, and self-replicate.

## OVERVIEW

There are two reasons for studying self-assembly. First, self-assembly is centrally important for life. Biological systems form and are sustained as a result of self-organization. Therefore understanding life requires, among other things, understanding self-assembly. Second, self-assembly can generate ordered three-dimensional (3-D) aggregates of components, ranging in size from the molecular to the macroscopic. These structures often cannot be generated by any other procedure.

In the past, self-assembly has been best known as a synthetic strategy in the molecular size regime.<sup>[17]</sup> New examples of its application to nanoscale and microscale components are now beginning to emerge.<sup>[18,19]</sup> As a consequence, self-assembly is becoming increasingly important as a strategy for the formation of useful nanoscale and microscale structures.<sup>[20]</sup>

We discuss the characteristics of self-assembly in living systems and review self-assembled functional systems designed according to biological principles.

The examples include only systems that self-assemble from preexisting components larger than molecules; synthetic biomimetic approaches to molecular aggregates are reviewed elsewhere.<sup>[21–25]</sup>

## SELF-ASSEMBLY IN LIVING SYSTEMS

Self-assembly in living organisms has four distinct characteristics:

1. Programmed (coded) self-assembly: Self-assembly in living systems is based on information that is encoded into the components themselves (e.g., as sequences of nucleic acids in the genome, or of amino acid residues at the active sites of proteins). The order of monomers in these sequences and the environments they experience determine their “shape” (i.e., their 3-D atomic surfaces), patterns of electrostatic charge, hydrogen bonds, hydrophobicity, and other characteristics that determine their functions. Both these encoded instructions *and* features of the environment determine the outcome of self-organization in living organisms. For example, during embryonic development, cell differentiation is governed by the cell origin and by a multitude of environmental signals and cues. Neural circuits also assemble themselves from individual components (cells) following a combination of internal program and external guidance.<sup>[26]</sup>
2. Constrained (templated) self-assembly: Order and asymmetry in self-assembled aggregates of biological molecules are often achieved by imposing constraints (e.g., by “templating” the process of self-assembly). One mechanism that introduces constraints and is found throughout biology consists in using chains of monomers. The order of monomers in these sequences is fixed, and this constraint restricts possible 3-D structures that can form. Another mechanism that imposes constraints on biological self-assembly involves geometrical restrictions to self-assembly.<sup>[27]</sup>

Undesired contacts with other molecules that might occur during the folding of linear precursors into correctly folded 3-D structures can be prevented by geometrically restricting the volume in which the folding process takes place, as happens, for example, during chaperonin-assisted protein folding.<sup>[28]</sup> Local geometrical factors are also important at the supramolecular level (e.g., for templating crystal growth during biomineralization,<sup>[29]</sup> for regulation of cell growth and viability,<sup>[30]</sup> and for exchange of materials between cells and their environment).<sup>[31]</sup>

- Hierarchical self-assembly: Living organisms form by bottom-up, hierarchical self-assembly—the primary building blocks (molecules) associate into larger, more complex secondary structures, which are, in turn, integrated into increasingly more complex structures in hierarchical designs. Thus, the organization of biological structures is integrated across length scales from the molecular to the organismic. For example, tendons have six discrete levels of hierarchical organization, starting from the triple helices of tropocollagen, and proceeding through microfibriles, subfibriles, fibrils, fascicles, and tendons.<sup>[32]</sup>
- Static and dynamic self-assembly: Self-assembly in biological systems may generate equilibrium structures; examples include molecular recognition and folding of globular proteins. Other biological processes and systems are dynamic, that is, they exist out-of-equilibrium, and the systems maintain their characteristic order only

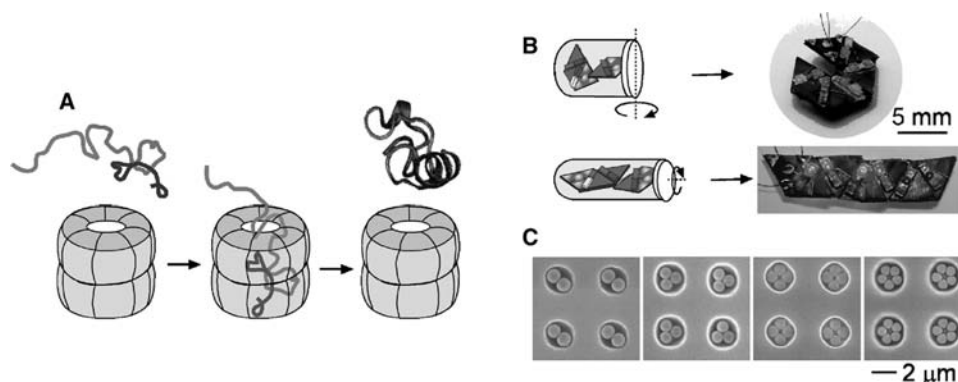

while dissipating energy.<sup>[19,33]</sup> Living cells and organisms are examples of such systems—they die when the flow of energy through them stops. In many animate systems, new properties and patterns emerge as a result of interactions between autonomously moving components (e.g., bacteria in swarming colonies, fish in schools, and birds in flocks).

## ARTIFICIAL SELF-ASSEMBLING SYSTEMS DESIGNED USING BIOLOGICAL PRINCIPLES

In analogy to biological self-assembled structures, the shape and functionality of artificial self-assembled aggregates are governed by the shapes of their components, by the interactions between them, and by the environments and constraints imposed on them (e.g., the degree of order and the symmetry of a crystalline lattice of microspheres determine its optical properties, and the shape and connectivity in aggregates that form electrical circuits determine the type of electronic functionality that they exhibit). Control over the structure—and, thereby, the properties—of self-assembled aggregates has been achieved in several ways by borrowing strategies from biological systems.

### Constrained Self-Assembly

Figure 1 illustrates templating of the structure of self-assembled aggregates using geometric restrictions. In

**Fig. 1** Templating of the structure of biological (A) and artificial (B, C) self-assembled aggregates using geometric restrictions. (A) Scheme illustrating chaperonin-assisted protein folding. The limited volume within a chaperonin molecule in which the folding process takes place ensures the correct folding of a polypeptide chain into a functional 3-D protein by preventing undesired contacts with other molecules. (B) Geometric templating of the structure and function of 3-D aggregates self-assembled from millimeter-sized components. Self-assembly in containers of different shapes generated topologically different 3-D structures—helices (top) or zigzags (bottom); these structures had different patterns of electrical connections among LEDs carried by the components. *Source:* From Ref.<sup>[34]</sup>. ©Wiley-VCH, 2003. The size and the shape of the assemblies were determined by the boundaries of the metal cavities used as templates. Source: From Ref.<sup>[40]</sup>. ©American Chemical Society, 2002. (C) Three-dimensional, spherical structure formed by self-assembly of hexagonal metal plates on the surface of a drop of perfluorodecalin in water. The surface of the liquid drop acts as a template for the structure. From Ref.<sup>[41]</sup>. ©American Chemical Society, 1998.

these systems, the geometry of the volume available for the self-assembly of components determined the morphology and the pattern of functional connections formed between self-assembled components. The same principle has been used in colloidal<sup>[36,37]</sup> and macroscopic<sup>[38]</sup> systems.

Figure 2 illustrates templating of the structure of self-assembled aggregates by preformed templates. In a system without constraints, self-assembly of micron-sized hexagonal plates resulted in the formation of sheetlike aggregates containing undefined numbers of components (plates). Self-assembly of the same plates in the presence of templates (holes with complementary shapes,<sup>[40]</sup> or drops of immiscible liquid),<sup>[41–44]</sup> led to the formation of new types of structures: planar aggregates with defined shapes, or spherical aggregates. In other examples, pre-assembled colloidal structures<sup>[45]</sup> chiral kernels,<sup>[38]</sup> encapsulating host molecules,<sup>[46]</sup> and micropatterned Scanning Auger Microscopy (SAM)<sup>[30,47,48]</sup> have also been used as templates.

Figure 3 illustrates templating of the structure of self-assembled aggregates by using sequence-restricted folding of linear precursors,<sup>[49–51]</sup> in analogy to the sequence-restricted folding of proteins and RNA into

3-D structures. In these examples, the sequence of millimeter-sized components in a chain and the properties (e.g., topology and flexibility) of the connections between them templated the structure and function of the self-assembled aggregates.

### Self-Assembly Based on Multiple Driving Forces

Biomolecular systems usually self-assemble by the concerted action of multiple types of weak interactions. In most artificial systems, self-assembly of the components involves not more than two types of interactions: fluidic and gravitational,<sup>[52]</sup> vibrational and gravitational,<sup>[53]</sup> magnetic and hydrodynamic,<sup>[54]</sup> or magnetic and electrostatic.<sup>[55]</sup> By using several types of interactions between the components, it is possible to form independently different types of connections between the components: structural connections, functional connections, or connections combining both tasks. Figure 4 shows one such system, modeled on the structure of tobacco mosaic virus.<sup>[56]</sup> The millimeter-sized components forming the helical aggregate interacted via two orthogonal capillary interactions: a

**Fig. 5** Biological (A) and artificial (B) self-assembling systems in which the components interact by 3-D complementary surfaces. (A) Scheme of interaction between an enzyme and its substrate. The binding pocket of the enzyme molecule adopts a geometrical shape complementary to the shape of the substrate. (B) Silicon chips self-assemble into indentations of complementary shapes on a substrate. *Source:* From Ref.<sup>[60]</sup>.

**Fig. 6** Biological (A) and artificial (B, C) self-assembling systems in which the components are organized at several hierarchical levels of structural complexity. (A) Hierarchical self-assembly of a viral capsid. Amino acids (shown as squares and circles) form a disordered polypeptide chain; the chain folds (self-assembles) into a functional protein; several protein molecules aggregate into the viral capsid. *Source:* From Ref.<sup>[66]</sup>. ©Wiley-VCH, 1999. (B) Hierarchical self-assembly of millimeter-sized spheres. The spheres are packed into rods, which subsequently self-assemble into 3-D structures (C). From Ref.<sup>[67]</sup>.

strong interaction based on drops of liquid solders was responsible for the growth of the aggregates and resulted in electrical connectivity between the components, and a weaker interaction based on drops of hydrophobic liquid stabilized the aggregates laterally.

### Recognition by Shape Complementarity

This principle has been used to design components that interact in both molecular<sup>[57]</sup> and mesoscale<sup>[58–60]</sup> self-assembling systems. Three-dimensional surfaces enable high specificity in recognition, and contribute to the structural stability of self-assembled aggregates. Figure 5 shows a mesoscale system in which polyhedral, micron-sized electronic components self-assemble onto a common substrate by shape recognition and shear forces.

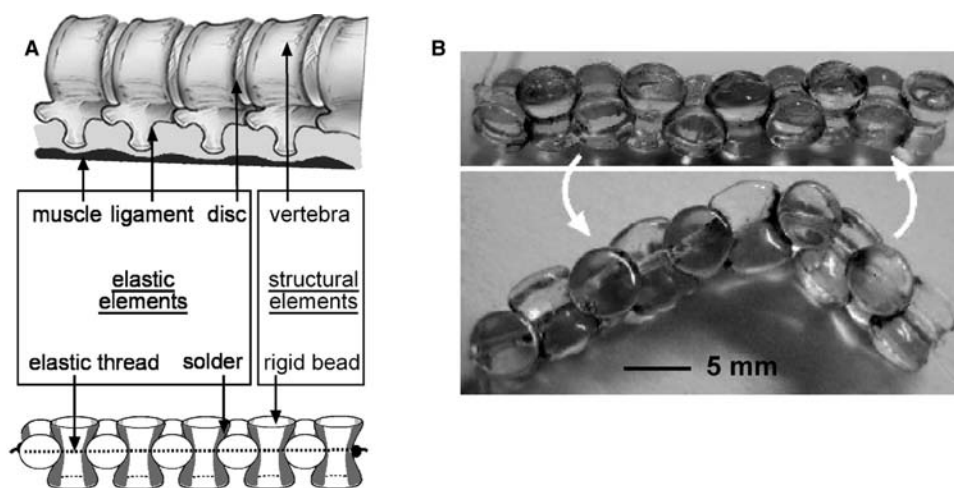

### Hierarchical Self-Assembly

Bottom-up, hierarchical self-assembly has been used to build nanostructures for application as optical and magnetic materials,<sup>[61]</sup> tunable nanoporous<sup>[62]</sup> and microporous<sup>[63]</sup> materials, nanomaterials with anisotropic properties,<sup>[64]</sup> metal nanostructures on diblock copolymer scaffolds,<sup>[65]</sup> and extended arrays of polymeric objects at a fluid–fluid interface.<sup>[66]</sup> Figure 6 illustrates the use of hierarchical self-assembly to form three-dimensional lattices of spheres.<sup>[67]</sup> Unrestricted and templated self-assemblies of spheres have been shown to give access to only a limited range of structures. The use of a hierarchical approach (i.e., the confinement of spheres in rods, followed by assembly of these rods) makes it possible to generate 3-D structures with a variety of 3-D lattices.

### Self-Healing Structures

Designing materials and structures that can self-repair in ways modeled on living systems is an emerging goal for materials science.<sup>[68]</sup> Self-healing in living systems

**Fig. 7** Self-healing structures in biology and engineering. (A) Common features of the design of a vertebrate spine (top) and a self-assembling system of millimeter-sized components (bottom). Both systems consist of rigid structural elements connected by elastomeric elements. (B) The structure loosely mimicking the organization of vertebrate spine spontaneously realigns and heals after breaking and dislocation. *Source:* From Ref.<sup>[69]</sup>. ©Wiley-VCH, 2003.

involves complex cascades of out-of-equilibrium processes that are impossible to reproduce in current man-made systems. However, self-assembly may offer an interesting alternative for the design of self-healing, steady-state systems. After disruption, equilibrium self-assembled systems return to their ordered state, provided that this state corresponds to a thermodynamic minimum. Figure 7 shows a self-healing system loosely mimicking the spine of vertebrates, based on self-assembly of a string of millimeter-sized components interacting via capillary forces.<sup>[69]</sup>

### Dynamic Self-Assembling Systems

The central importance of dynamic systems for life has prompted the development of simple out-of-equilibrium systems with which to model complex behavior and emergence.<sup>[54,55,70,71]</sup> Figure 8 shows two examples of dynamic, mesoscopic self-assembling systems. The first system consists of millimeter-sized metallic objects rotating at the liquid–air interface. The objects self-organize into a variety of patterns. The second system consists of polymer plates floating at the surface of an aqueous solution of hydrogen peroxide. The individual components can move autonomously and can interact with one another. Obviously, these systems are too primitive to mimic the complex biological dynamic systems; the studies of dynamic self-assembly are just beginning.

**Fig. 8** Biological (A) and artificial (B, C) dynamic self-assembling systems. (A) A flock of ibises (Image J. -M. Bettex). (B) Magnetized disks rotating on the top surface of a droplet of perfluorodecalin covered with water. *Source:* From Ref.<sup>[70]</sup>. ©Macmillan Magazines Limited, 2000. (C) A system of millimeter-scale objects that move autonomously across the surface of a liquid powered by the catalytic decomposition of hydrogen peroxide. The numbers indicate time elapsed during change between two positions of the objects at the fluid–air interface. From Ref.<sup>[71]</sup>. ©Wiley-VCH, 2002.

### CONCLUSION

Self-assembly is an efficient, and often, practical way to organize components ranging in size from molecular to macroscopic into functional aggregates. Biomimetic approaches to the design of self-assembling systems have been immensely stimulating in solving critical problems in the design of artificial self-assembling systems; they might be the key to many of the unsolved problems facing the future of self-assembled functional systems in different size regimes.

In the molecular size regime, supramolecular self-assembly based on biomimetic principles has delivered many types of complex molecules<sup>[17,46]</sup> and useful materials.<sup>[5,22,72]</sup> The synthesis and assembly of large molecules and molecular aggregates with intricate

structure and functionality (e.g., analogs of integrated circuits or viruses) remain unsolved problems.<sup>[73]</sup> Templated and hierarchical self-assembly—concepts familiar from many biological instances—may offer a solution.<sup>[46]</sup>

In the nanoscale size regime, principles extracted from biology have been applied to the fabrication of functional materials (e.g., photonic bandgap crystals and self-healing materials). Much of the current research in the nanoscale is focused on achieving electronic functionality, notably on the problems of electrically connecting the components, organizing them into arrays, and establishing the best architectures for nanoscale devices.<sup>[74]</sup> Biological systems have demonstrated the utility of templating and hierarchical self-assembly in ordering components of similar sizes (macromolecules and organelles) into functional entities (cells). Dynamic, reconfigurable biological systems offer examples of a different approach to self-assembly: dynamic systems are currently of purely academic interest, but may become useful in the future.<sup>[75]</sup>

In the microscale and macroscale size regimes, self-assembly can generate functions that are not possible at smaller scales (e.g., electric connectivity and electronic functionality).<sup>[20]</sup> In addition, self-assembling systems may be useful in solving problems in robotics and microfabrication. Biomimicry might help to solve the most significant problem in this size range—the fabrication of small, functionalized components. Self-folding and hierarchical self-assembly—two strategies widely used by biological systems—are among the most promising approaches to this problem.<sup>[76,77]</sup>

Some of the most important problems in current technology include: 1) better systems for information processing (i.e., systems that are fast, cheap, and can be cooled efficiently); 2) systems that use and store energy efficiently; 3) materials and structures with internal organization leading to valuable properties (e.g., capability to self-repair, self-heal, and self-replicate); and 4) small, three-dimensional, functional structures. All of the materials and functions in this list are found in biological systems.<sup>[78]</sup> The self-assembled, living world provides examples of some of the most efficient functional systems known. To the extent that one can understand and model the designs and strategies used in these systems, the biomimetic approach will stimulate new designs for self-assembled functional systems.

Università di Parma, Parma, Italy

## INTRODUCTION

Carboxylate anions are ubiquitous in nature and are involved in several biological processes. For example, the carboxylate group of the D-alanyl-D-alanine terminal part of the cell wall peptidoglycan is selectively recognized by the binding pocket of vancomycin-type antibiotics.<sup>[1]</sup> di- and tricarboxylates are involved in several metabolic processes,<sup>[2]</sup> and other carboxylate anions are known to be substrates or inhibitors of enzymes.<sup>[3]</sup> Moreover, chiral propionic acid derivatives are widely used in therapy as non-steroidal anti-inflammatory drugs<sup>[4]</sup> and carboxylate polyanions can form well-ordered self-assembled structures when mixed with complementary polycations or hydrogen bonding donor groups.<sup>[5]</sup> For all these reasons the synthesis of biomimetic receptors for carboxylate anions have been recently pursued in supramolecular chemistry,<sup>[6–8]</sup> with the aim of obtaining 1) useful models of the biological processes, 2) biologically active molecules, 3) selective chemosensors, and 4) selective separation systems.

The objective of this entry is to highlight the most successful approaches followed in the design and synthesis of biomimetic receptors for carboxylate anion recognition, with major emphasis on the results achieved in the last 5 years with macrocyclic compounds, and on our own work.

## CHARGED RECEPTORS

The most obvious way to bind anions, and therefore also carboxylates, is to use positively charged receptors that can cause strong electrostatic ion–ion interactions with the guests.<sup>[9]</sup> Quite often in positively charged receptors, besides electrostatic forces, also hydrogen bonds and hydrophobic interaction are exploited, especially to increase substrate selectivity.

The first examples of receptors for carboxylate anions were presented by Kimura et al.<sup>[10]</sup> and Dietrich et al.<sup>[11]</sup> in 1981. They showed that polyazamacrocycles

(e.g., **1** and **2**), when protonated, are able to form complexes with polycarboxylated guests in water solution. In some way they mimic the action of biogenic linear polyamines, such as spermine and spermidine, which are known to interact with the phosphate backbone of nucleic acid and with polycarboxylates.<sup>[12,13]</sup>

For protonated polyazamacrocycles the formation of hydrogen bonds with the anions strongly complements the most important electrostatic ion–ion interactions, because quaternary ammonium receptors (vide infra) usually show weaker binding.

Incorporation of one or two chiral (*R,R*)-1,2-diaminocyclohexyl units into a hexazamacrocyclic structure gives rise to receptors (e.g., **3**), which exhibit enantioselective discrimination toward dicarboxylates. They show clear selectivity for D-tartrate, *N*-Ac-D-aspartate and *N*-Ac-D-glutamate over their L-enantiomers.<sup>[14]</sup> However, this selectivity is strongly dependent on the degree of protonation of the receptor.<sup>[15]</sup>

The properties of vancomycin family of antibiotics are linked to their ability to bind the terminal part of L-Lys-D-Ala-D-Ala-COO<sup>-</sup> of the cell wall mucopeptide precursor of gram-positive bacteria via a combination of hydrogen bonds and hydrophobic interactions, which act cooperatively.<sup>[1]</sup> Hamilton tried to mimic the action of vancomycin carboxylate binding pocket,<sup>[16]</sup> synthesizing receptor **4**, which is able to bind carboxylic acid via a proton transfer from guest to host and the formation of a salt bridge. Carboxylates are held inside the cavity by hydrogen bonds with all free peptide NHs. The binding constant of cyanoacetic acid in CDCl<sub>3</sub> was estimated to be ca. 580 M<sup>-1</sup>. A similar system (**5a**) reported by Pieters, binds *N*-Ac-D-Ala in CDCl<sub>3</sub>, with association constants  $K_{\text{ass}} \approx 3 \times 10^4 \text{ M}^{-1}$ .<sup>[17]</sup> As in vancomycin, the protonated amino group does not seem to be essential for binding because **5b** or **5c** show approximately the same association constants.

With a quite different approach, we synthesized a series of macrobicyclic ligands **6** belonging to the class of *upper rim* *N*-linked peptidocalix[4]arenes and having  $\alpha$ -amino acids of different structure (Gly, Ala, Phe) and configuration (LL, DD, or DL).<sup>[18,19]</sup> The minimum inhibitory concentrations (MICs) of these macrocycles against gram-positive bacterial strands show that biological activity increases as the steric hindrance of *R* groups decreases. The L-Ala,L-Ala (**6**: R = CH<sub>3</sub>) receptor shows activity quite close to that of vancomycin and ability to bind carboxylate guests in organic solvents, as demonstrated by nuclear magnetic resonance (NMR) and electrospray ionization mass spectrometry (ESI-MS). Stability constants ( $K_{\text{ass}}$ ) increase in CDCl<sub>3</sub> from lauric acid (log  $K_{\text{ass}} = 3.0$ ) to *N*-lauroyl-D-Ala (log  $K_{\text{ass}} = 4.1$ ) and to *N*-lauroyl-D-Ala-D-Ala (log  $K_{\text{ass}} > 5.0$ ). NMR diffusion experiments in CDCl<sub>3</sub> + 3% dimethyl sulfoxide (DMSO-*d*<sub>6</sub>) show that *N*-Ac-L-Ala-L-Ala is bound more strongly (log  $K_{\text{ass}} = 3.4$ ) than *N*-Ac-L-Ala (log  $K_{\text{ass}} = 2.4$ ).<sup>[20]</sup> These data indicate that besides the most important electrostatic interaction between carboxylate and the ammonium headgroup, additional H bonding and possibly CH- $\pi$  interaction between the alanine methyl group of the guest and the calixarene cavity stabilize the complexes.

The water-soluble polyquaternary ammonium receptor **7** synthesized by Diederich is able to recognize mono- and dicarboxylates in D<sub>2</sub>O.<sup>[21]</sup> It binds *N*-Ac-D-Ala ( $K_{\text{ass}} = 74 \text{ M}^{-1}$ ) and less strongly *N*-Ac-D-Ala-D-Ala ( $K_{\text{ass}} = 51 \text{ M}^{-1}$ ) essentially through electrostatic interactions that take place outside the cavity. However, the cyclophane structure seems important for the efficiency of the anion binding, as the hexamethylammonium salt of 1,4,7-triazaheptane is not able to bind alanines under the same conditions.

The use of quaternary ammonium salts instead of protonated amines for anion recognition has the

advantage of rendering complexation independent from the pH of the solution, but also has the disadvantage of removing hydrogen bond contributions to the binding. In the complexation of a series of dicarboxylates to bisquaternary ammonium anion receptors, Schneider found a value of 8 kJ/mol in H<sub>2</sub>O for a single carboxylate–ammonium interaction, independently of the rigidity of the two partners.<sup>[22]</sup>

Guanidinium salts offer the great advantage of being protonated over a wide pH range and to bind carboxylates via a combination of electrostatic forces and bidentate H-bonding interactions (**8**).<sup>[23]</sup> The importance of the formation of hydrogen bonds for carboxylate recognition in DMSO is highlighted by the fact that the change from NH to NCH<sub>3</sub> groups causes a remarkable drop in the stability of the carboxylate–guanidinium complexes (**8**).<sup>[24]</sup>

Also in the case of guanidinium-based receptors, the most interesting results in terms of efficiency and selectivity have been obtained when this carboxylate binding group is used in cooperation with additional interactions (hydrogen bonding, hydrophobic, van der Waals, etc.). The 2-guanidiniocarbonyl pyrrole

receptors (e.g., **9**) bind carboxylates in 40% H<sub>2</sub>O/DMSO ( $K_{\text{ass}} \approx 10^3 \text{ M}^{-1}$ ), more than 30 times stronger than a simple acylguanidinium cation. This significant increase is due to the formation of additional H bonding with the pyrrole and amide protons, whereas selectivity is mainly given by steric repulsion or attractive cation– $\pi$  interaction between substituents on the host and on the guest. A fair enantioselectivity was found for *N*-Ac-L/D-Ala ( $K_{\text{ass}}$  1610 and 730 M<sup>-1</sup>, respectively).<sup>[25,26]</sup> Kilburn prepared a tweezer receptor having a guanidinium moiety in the middle and two arms made up of an N-protected tripeptide. By using a combinatorial library it was shown that **10** is able to complex N-protected tripeptides possibly via hydrophobic interactions and  $\beta$ -sheets like hydrogen bonds. Calorimetric titration allowed one to determine a  $K_{\text{ass}} = 4 \times 10^5 \text{ M}^{-1}$  in DMSO/H<sub>2</sub>O for *N*-Cbz-Glu(O<sup>t</sup>Bu)-Ser(O<sup>t</sup>Bu)-Val-OH.<sup>[27]</sup>

Bicyclic guanidinium salts, offering the advantage to protrude NH groups in only one direction, are particularly efficient in carboxylate binding. Chiral bicyclic guanidinium salts have been prepared by Schmidtchen,<sup>[28]</sup> de Mendoza,<sup>[29]</sup> and Davis<sup>[30]</sup> and

included in receptor structures especially with the aim to reach enantioselective binding.

de Mendoza proposed a receptor for  $\alpha$ -amino acids where a naphthalene unit and a crown ether moiety are linked to a chiral bicyclic guanidinium ion. The crown ether and guanidinium ion provide the two anchoring groups for ammonium and carboxylate ions, respectively, whereas the naphthalene ring, giving rise to stabilizing  $\pi$ - $\pi$  interaction with aromatic side chains, determines the observed selectivity for Phe  $\approx$  Trp  $\gg$  Val in extraction experiments (e.g., **SS-11**  $\times$  Trp). High enantioselectivity was observed in extraction into  $\text{CH}_2\text{Cl}_2$ , as no D-enantiomer could be detected in the organic phase, whereas the RR stereoisomer extracts D-Phe and D-Trp but not their L-enantiomers.<sup>[31]</sup>

A closely related receptor proposed by Schmidtchen<sup>[32]</sup> and having a hydrophobic silyl ether is also able to efficiently transfer to  $\text{CH}_2\text{Cl}_2$  hydrophilic amino acids such as Ser and Gly, but not charged ones, although the enantioselectivity is lower. de Mendoza developed a receptor (**12**) where two deoxycholic acids are linked to a bicyclic guanidinium and which complex glucuronic and galacturonic acids with nearly the same strength in  $\text{CD}_3\text{CN}/\text{CDCl}_3$  (98/2). Steroid units only weakly influence the binding because of intramolecular hydrogen bonding observed in the free host.<sup>[33]</sup> Davis reported on the enantioselective extraction from  $\text{H}_2\text{O}$  to  $\text{CHCl}_3$  of *N*-Ac-amino

acids by using steroidal guanidines. The most selective receptor (**13**) is based on cholic acid and bears a monocyclic guanidinium side arm plus two carbamate functions whose H-bonding NH groups are activated through electron-withdrawing *p*-trifluoromethylbenzene units. Selectivity is in the order Phe > Trp > Met > Val > Ala with enantioselectivity (L/D) in the range 7/1–10/1.<sup>[34]</sup>

Smukste, House, and Smithrud<sup>[35]</sup> synthesized the [2]rotaxane host **15** having two guanidinium ions of arginine converging toward the calix[4]arene lipophilic cavity. The host **15** strongly binds *N*-Ac-L-Trp ( $10 \times 10^4 \text{ M}^{-1}$ ) and zwitterionic L-Trp ( $1 \times 10^4 \text{ M}^{-1}$ ) in DMSO via inclusion in the calixarene cavity of the Trp aromatic side chain and electrostatic interaction of the guanidinium with the carboxylate headgroup. The aromatic ring of the guest provides most of the binding free energy, as indole is also strongly bound in DMSO ( $4.2 \times 10^4 \text{ M}^{-1}$ ). However, the advantage of having convergent functional groups in rotaxane **15** was demonstrated by the low binding ( $9 \times 10^2 \text{ M}^{-1}$ ) of *N*-Ac-L-Trp with calixarene **14** having divergent guanidinium ions.<sup>[35]</sup>

Anslyn introduced three monocyclic guanidinium side arms on the 1,3,5-triethylbenzene scaffold (**16**) and observed a strong binding of citrate anion ( $K_{\text{ass}} = 2.9 \times 10^5 \text{ M}^{-1}$ ) and good enantioselectivity.<sup>[36,37]</sup> Thanks to the steric barrier given by the three ethyl groups in **16**, guanidinium ions are preorganized on the same face of the benzene ring and can cooperate in the binding.

The amidinium cation, offering the possibility to coordinate carboxylate anions with a pair of hydrogen bonds strengthened by electrostatic interaction, shows a binding mode quite close to that of guanidinium cations. However, despite their stronger acidity they are much less used in anion binding. The bisamidinium receptors synthesized by Diederich using a 1,1'-binaphthalene scaffold (**17**) are efficient in the binding of dicarboxylates with selectivity for isophthalate and

glutarate anions. Calorimetric titration in MeOH evidenced that binding is mainly entropy driven because of the high solvent release from the charged species upon interaction.<sup>[38]</sup>

A tetramidinium resorcarenene receptor forms a 1:2 complex with an isophthalate and, in water solution, one of the aromatic rings of the guest is included in the lipophilic cavity of the host.<sup>[39]</sup> Calix[4]arenes functionalized at the lower rim with amidinium units (e.g., **18**) complex malonate and isophthalate anions in DMSO solution, where multiple host-guest stoichiometries are observed. In the X-ray crystal structure of the **18** × malonate 1:1 complex several different amidinium-carboxylate interactions are present, which

show the ability of these hosts to form an interesting hydrogen-bonding network.<sup>[40]</sup>

### CARBOXYLATE COORDINATION TO METAL CENTERS

Macrocyclic or cleftlike multidentate compounds having oxygen or nitrogen donor centers are able to bind metal ions in their cavity. In some cases, the complexed metal center is able to further interact with anionic species, giving rise to anion receptors. Most of the studies have been performed within the context of biomimetic catalysis of amide and ester bond cleavage because the transition state for these reactions have an anionic character and therefore the enzyme activity is also related to its ability to bind anions. One of the earliest examples of carboxylate anion recognition by metal-containing receptors was reported by Tabushi and coworkers.<sup>[41]</sup> The  $\beta$ -cyclodextrin ( $\beta$ -CD)-based receptor **19**, having a triazaalkane arm that binds zinc(II), forms stable complexes with adamantane-1-carboxylates ( $10^3 < K_{\text{ass}} < 10^5 \text{ M}^{-1}$ ) in  $\text{H}_2\text{O}$  at pH 10. Particularly interesting in this context are the transition metal complexes of polyazamacrocycles.

An early example of carboxylate anion binding was reported by Martell and Motekaitis.<sup>[42]</sup> The hexaaza-24-crown-8 (**20**) binds two  $\text{Co(II)}$  ions, and an oxalate dianion can bridge between the two metal centers. If two nitrogen atoms are protonated, the macrocycle binds to a single metal ion. However, the oxalate anion is bound to the  $\text{Co(II)}$  on one end of the macrocycle and to the protonated amine of the other end. In his extensive model studies for molecular recognition of carbonic anhydrases and carboxypeptidases, Kimura<sup>[43]</sup> produced several macrocyclic polyamines, which recognize anionic species when bound to  $\text{Zn(II)}$  ions. Although  $\text{Zn(II)}$ -1,5,9-triazacyclododecane<sup>[44]</sup> binds very strongly hydroxide anion (**21**) ( $\log K_{\text{ass}} = 6.4$ ) it also interacts with acetate anion ( $\log K_{\text{ass}} = 2.6$ ), which is an inhibitor of carbonic anhydrase.<sup>[45]</sup>

An interesting example of carboxylate anion recognition by a  $\text{Zn(II)}$  complex of a cyclen macrocycle having an acridine-pendant arm was reported by the same Japanese group.<sup>[46]</sup> Compound **22** is able to form a strong complex with benzoate anion in aqueous solution ( $\log K_{\text{ass}} = 2.25$ ).

Even more interesting is the observation that the terephthalate dianion forms an insoluble complex with this last host. The X-ray crystal structure of the complex shows that the terephthalate anion acts as a bridge between two macrocycles by interacting with two complexed  $\text{Zn(II)}$  ions (Fig. 1).

Inspection of the crystal lattice reveals that a well-organized chainlike self-assembled aggregate forms through the action of several supramolecular interactions such as metal coordination,  $\pi$ - $\pi$  stacking, and

**Fig. 1** X-ray crystal structure of complex **22** and terephthalate anion.

solvent stabilization. The phthalate and isophthalate anion form similar 2:1 host/guest complexes, which, however, are water soluble. This circumstance allowed an easy separation of the phthalate *para* isomer with respect to the *ortho* and *meta* by crystallization.

Lanthanide complexes have also been used as receptors for anions in general, and for carboxylates in particular. Parker and coworkers have used the 1,4,6,10-tetraazacyclododecane derivative with chiral side chains, which binds  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  through the four nitrogen atoms of the macrocycle and by the three amide oxygen atoms of the side arms. Two water molecules are also bound to complete the coordination sphere of the metal ion (**23**).<sup>[47,48]</sup>

Carboxylate anions can displace these bound water molecules giving complexes characterized by binding constants that can reach a value of  $K_{\text{ass}} > 40000 \text{ M}^{-1}$  for citrate and malonate anions.

## NEUTRAL, HYDROGEN BONDING RECEPTORS

Many proteins and natural polypeptides are known to bind anions via hydrogen bonding involving the NH amide groups. Therefore, the incorporation of these groups into cleftlike or macrocyclic compounds has been considered as the most promising biomimetic approach in designing new receptors for carboxylate anion recognition.<sup>[49,50]</sup> Ten years ago, Hamilton and coworkers<sup>[51]</sup> reported the first example of a multiple-hydrogen-bonding receptor family **24**. The investigation of the molecular recognition properties of **24** actually revealed that urethane NHs, and serine OHs in the case of **24c**, rather than amide NHs are involved in the carboxylate anion complexation, suggesting other possibilities for the binding of this species. The association constant between **24c** and acetate anion was  $2.7 \times 10^5 \text{ M}^{-1}$  in  $\text{CD}_3\text{CN}$ , three orders of magnitude higher than that of **24a** and **24b**.

A common amide-containing molecular motif is the pyridine derivative **25a** and its benzene analogue **25b**. In the bicyclic cyclophane **26** reported by Bisson et al.<sup>[52]</sup> six NH protons converge toward the center of the binding pocket, as evidenced also in the X-ray crystal structure of the receptor. The structure of the 1:1 complex in the solid state with acetate ( $K_{\text{ass}} = 770 \text{ M}^{-1}$ ) shows the involvement of four of the six available NHs in the binding process.

The identical pyridine moiety is found in the macrocyclic tetralactam **27**, which shows in DMSO a moderate selectivity for the acetate anion ( $K_{\text{ass}} = 2640 \text{ M}^{-1}$ ) over inorganic anions such as  $\text{F}^-$  ( $K_{\text{ass}} = 830 \text{ M}^{-1}$ ),  $\text{Cl}^-$  ( $K_{\text{ass}} = 65 \text{ M}^{-1}$ ), and  $\text{H}_2\text{PO}_4^-$  ( $K_{\text{ass}} = 1680 \text{ M}^{-1}$ ).<sup>[53]</sup> In solution the complex shows a 1:1 stoichiometry, whereas a 2:1 host:guest ratio is observed in the solid state. Note that only one oxygen atom of the carboxylate anion is interacting with each receptor molecule.

28b: X = CH

We exploited the dicarboxypyridine and the isophthalate units as rigid spacers bridging two alanine residues linked at the upper rim of a calix[4]arene.<sup>[54]</sup> The two peptidocalix[4]arenes **28a,b** present other two amide NH groups directly attached to the aromatic nuclei of the macrocyclic scaffold. The two macrobicyclic receptors show an interesting selectivity for the carboxylate over inorganic anions. The significant downfield shifts observed in  $\text{CDCl}_3$  for the signal relative to all NH protons by addition of substrates suggest their involvement in the binding.

The X-ray crystal structure of the free ligand **28a** shows the pyridine nucleus in the bridge to be tilted and almost parallel to one calix[4]arene aromatic nucleus. In this way a cleft is created and the host-guest interactions are maximized. This structure explains the great efficiency of these receptors toward the benzoate anion because the aromatic nucleus of the guest can interact with those of the host (**28a** × **benzoate**).

The preorganization of the two peptidocalixarenes plays an important role in determining the efficiency of their anion binding. In fact, the cleft-like analogue **29** shows the tendency to form intramolecular hydrogen bonds in  $\text{CDCl}_3$  and, as a consequence, it is a very poor anion receptor.<sup>[55]</sup>

One general way to increase the anion binding properties of amide receptors is to “activate” their hydrogen bonding donor ability through electron-withdrawing groups. Stibor and coworkers<sup>[56]</sup> introduced two pentafluorophenyl amide units at the upper rim of a calix[4]arene (**30**) and were able to observe in  $\text{CDCl}_3$  the complexation of dicarboxylate anions such as adipate ( $K_{\text{ass}} = 280 \text{ M}^{-1}$ ) and terephthalate

( $K_{\text{ass}} = 370 \text{ M}^{-1}$ ). Two pentafluorophenyl amides are also present in the calix[4]arene heteroditopic receptor **31** reported by our group.<sup>[57]</sup> The X-ray crystal structure of the complex obtained on addition of 1 equivalent of potassium acetate to a chloroform

**Fig. 2** X-ray crystal structure of the complex between **31** and  $\text{CH}_3\text{COO}^- \text{K}^+$ .

solution of the host shows an interesting 2:2:2 ligand:cation:anion stoichiometry (Fig. 2). This supramolecular structure is assembled by the simultaneous action of several non-covalent interactions, with each acetate ion bridging two host molecules through hydrogen bonding with their amide NHs.

In the simple 3-acetylaminopyridine **32a**, which interacts in  $\text{DMSO-}d_6$  with benzoate anion also through the more acidic protons in *ortho* and *para* position, the methylation of the pyridine nitrogen and the consequent introduction of a positive charge close to the hydrogen bonding donor groups enhances the affinity for the substrate.<sup>[58]</sup> Linking two **32b** units with a suitable spacer leads to interesting receptors able to complex adipate in 10%  $\text{D}_2\text{O}/\text{DMSO-}d_6$  with  $K_{\text{ass}} > 10^3 \text{ M}^{-1}$ .

A series of diamidopyrrole-based compounds (**33**) containing amide groups has been prepared and studied by Gale and coworkers.<sup>[59]</sup> The benzoate complex in the solid state shows the cleft mode of binding with

all the three NH groups donating hydrogen bonds.<sup>[60]</sup> The presence of strong electron-withdrawing groups in **33b** increases the association for this anion ( $K_{\text{ass}} = 4150 \text{ M}^{-1}$ )<sup>[61]</sup> with respect to **33a** ( $K_{\text{ass}} = 560 \text{ M}^{-1}$ ) in 0.5%  $\text{D}_2\text{O}/\text{DMSO}$ .<sup>[59]</sup>

Since 1992,<sup>[62]</sup> urea and thiourea groups have been extensively used as neutral binding groups for anions.

An impressive series of cleftlike receptors containing two of these units have been reported. In general, a strong competition by the dihydrogen phosphate anion  $\text{H}_2\text{PO}_4^-$  is observed and often this substrate turned out to be the most efficiently bound. Buhlmann et al.<sup>[63]</sup> synthesized bithiourea receptors with a different degree of conformational freedom, observing an interesting positive effect of the host preorganization on its recognition properties. An increase of the association constant with acetate from  $470 \text{ M}^{-1}$  for compound **34** to  $38,000 \text{ M}^{-1}$  for **35** underlines the importance of this factor, also with regard to the absolute values of  $K_{\text{ass}}$ , considering that the solvent used is DMSO.

We have used glycosyl thioureido groups to functionalize the upper rim of calix[4]arenes.<sup>[64]</sup> Di- (e.g., **36**) and tetraglycosylated derivatives have been obtained with the goal of developing novel molecular delivery systems that exploit the anion recognition properties of the urea groups and the specific recognition ability of the glycoside units toward biological targets. Besides carboxylates, phosphate-containing substrates are complexed to the same extent and the binding in

DMSO-*d*<sub>6</sub> is weaker than that found with simpler monothiourea receptors,<sup>[65]</sup> probably because of the steric crowding around the binding region. On the other hand, an interesting increase of the association constant is observed moving from acetate ( $K_{\text{ass}} = 17 \text{ M}^{-1}$ ) to benzoate ( $K_{\text{ass}} = 103 \text{ M}^{-1}$ ), suggesting a possible secondary interaction between the aromatic tail of the guest and the carbohydrate units. Furthermore, a specific interaction with selective carbohydrate-binding proteins discloses the possibility of vehiculate biologically active carboxylates toward relevant biomacromolecules. We have also explored the complexation properties of other calixarenes functionalized with urea and thiourea groups. The monothiourea **37** showed the best affinity with carboxylates ( $K_{\text{ass}} = 60\text{--}340 \text{ M}^{-1}$ ), over  $\text{H}_2\text{PO}_4^-$  and spherical anions ( $K_{\text{ass}} < 10 \text{ M}^{-1}$ ).<sup>[66]</sup> The higher values of association observed with benzoate, butyrate, and phenylacetate, compared with acetate, have been explained by the presence of additional weak interactions between the guest side groups and the cavity of the macrocycle. On the contrary, for acetate, an external binding mode was proposed. The opposite is observed with the bisurea receptor **38**, for which a significant preference for acetate ( $K_{\text{ass}} = 2200 \text{ M}^{-1}$ ) is evidenced because of urea-anion and  $\text{CH}_3\text{-}\pi$  interactions. The monourea **39** shows a behavior comparable with that of the thiourea analogue **37**, without a relevant decrease in efficiency despite the lower acidity of its NH protons. More efficient and with a remarkable selectivity for benzoate ( $K_{\text{ass}} = 1.61 \times 10^5 \text{ M}^{-1}$  in  $\text{CDCl}_3/\text{CD}_3\text{CN}$  4/1) is the bisurea **40** reported by Budka et al.<sup>[67]</sup> where the phenylthiourea groups are directly linked to the aromatic rings.

The insertion of the same binding group at the upper rim of a calix[4]arene tetramide gives rise to the ditopic receptors **41** and **42**.<sup>[68]</sup> When the thiourea NH is directly linked to the aromatic ring of the calixarene platform (**42**), the complexation of sodium ion at

37: X = S

42: R = CH<sub>2</sub>C(O)NEt<sub>2</sub>; X = S; n = 0

43: Y = CH<sub>2</sub>; X = CH  
44: Y = O; X = N

Another important class of receptors, with similar structural motifs, is that reported by de la Torre et al. and based on chromenones.<sup>[71]</sup> The central urea unit of **45** and **46** interacts with the carboxylate anion whereas the NH amide protons strengthen the complexation by coordinating the *anti* lone pair of the carboxylate oxygen atoms. A spirobifluorene moiety attached to the amide groups confers to macrocycle **45** an interesting enantioselectivity in recognizing the tetrabutylammonium salts of (*S*) and (*R*) lactic acid with  $K_{\text{ass}}$  of  $3.5 \times 10^3$  and  $3.5 \times 10^4 \text{ M}^{-1}$ , respectively.<sup>[72]</sup>

45

Substrates having more hydrogen bonding acceptor groups, such as carboxylates of  $\alpha$ -heterocyclic and  $\alpha$ -keto acids, get benefit by the presence of additional hydrogen bonding donor groups (e.g., **46**) in comparison with simple carboxylate anions.<sup>[71]</sup>

46

the lower rim determines a positive cooperative effect since the acidity of the NH groups increases.

In some receptors, a single thiourea unit is present in the structure accompanied by carboxamide groups, which actively cooperate in the complexation process. Important examples of these host molecules are the macrobicycles **43** designed by Kilburn.<sup>[69,70]</sup> The complexation studies toward a series of simple carboxylates and anions of *N*-acetyl *L*- and *D*-amino acids evidence the predominance of thiourea in the interaction with the substrates. In the case of the *D*-enantiomers, the data are quite consistent with an external 1:1 complex involving only the thiourea unit, but with the *L*-amino acids the complexation takes place within the cavity of the receptor involving also the amide groups, and this results in a higher association constant ( $1.3 \times 10^5 \text{ M}^{-1}$  in CDCl<sub>3</sub>) with the *N*<sup>ε</sup>-Ac-*L*-lysine. The presence of a pyridine unit in the bisaryl linkers (**44**) provides an additional hydrogen-bonding functionality that, in fact, seems to determine the mode of binding of *N*-Ac-*L*-asparagine, which interacts with its CONH<sub>2</sub> side chain ( $K_{\text{ass}} = 5.5 \times 10^4 \text{ M}^{-1}$  in CH<sub>2</sub>Cl<sub>2</sub>).

## CONCLUSION

Historically, the first supramolecular interactions to be exploited in synthetic receptors for anion recognition, and for carboxylate as well, were electrostatic or hydrogen bonds strengthened by positive charges as, e.g., in protonated macrocyclic amines. During the years, because of a growing interest in the biomimetic approach for the design of anion receptors, metal-containing macrocycles or hosts having only neutral, hydrogen bonding donor groups have been used more extensively, indicating a tendency that will probably continue in the near future. Besides representing interesting models for biological recognition involving carboxylates, these synthetic receptors constituted the active core of sensors and other supramolecular devices. Once the rules that control the specific molecular recognition of carboxylate anions are completely mastered, one can easily forecast that specially designed multivalent supramolecular systems will be synthesized and used, inter alia, to produce nanoscale, supramolecular functional devices based on carboxylate–receptor interaction.

## INTRODUCTION

Bionanoparticles are naturally produced entities that are of nanometer dimension. For aeons, nature has been an avid and extremely sophisticated exponent of nanoscience. Viruses and other protein assemblies such as the iron storage protein ferritin are examples of naturally occurring nanoparticles.<sup>[1]</sup> The branch of bionanotechnology in which naturally occurring nanoparticles are modified and manipulated for various applications is a rich and newly emerging field of research. The current research in this area can be broadly classified as host-guest chemistry (including biomineralization) and the bioconjugate chemistry of bionanoparticles.<sup>[2–7]</sup> Bionanoparticles have marvelous and complex structures. Understanding their basic structural arrangement is essential to appreciate how they may be exploited for chemical applications. A separate section is devoted in this review for each nanoparticle.

The host-guest chemistry based on bionanoparticles is discussed. Three systems—ferritin, cowpea chlorotic mottle virus (CCMV), and tobacco mosaic virus (TMV)—have recently been used to package hard and conducting inorganic materials. Hybrid conducting quantum nanodots can be selectively patterned on two-dimensional substrates by engineering recognition elements on the biomaterial component to recognize specific sites on the two-dimensional substrate. This is one of the most promising approaches for developing nanoelectronic devices. Some recent work using Filamentous Bacteriophage M13 to bind and align nanocrystals in an ordered array is described in the following section. In another section of the review, the bioconjugate chemistry of bionanoparticles, especially of the Cowpea Mosaic Virus (CPMV) system, the MS2 Bacteriophage, Tobacco Mosaic Virus, and the Hepatitis B Surface Antigen (HBsAg)

is covered. These have potential applications in both the areas of materials science and biomedical research. Several decades ago, Paul Ehrlich<sup>[8]</sup> pioneered the “magic bullet concept,” where he proposed that a drug could be targeted with the help of ligands having defined affinity for specific cells. His predictions are close to practical realization, an example of such a construct is a ligand-decorated bionanoparticle,<sup>[9]</sup> which can selectively target the receptors present on specific cell types, to package and deliver therapeutic genes/drugs to target cells. The last section of this review covers the recent development of using bionanoparticles, especially adenoviruses, for gene delivery.

The practical examples discussed in this entry serve as a tribute to the accuracy of many of Richard Feynman’s predictions in his classic talk titled “There is plenty of room at the bottom” on December 29, 1959, at the annual meeting of the American Physical Society at Caltech.<sup>[10]</sup>

## FERRITINS

Ferritins are iron storage protein cages belonging to the Class II diiron-carboxylate proteins.<sup>[11]</sup> All ferritins have the capacity to remove  $\text{Fe}^{2+}$  ions from solution in the presence of oxygen, and to deposit iron into the protein interior in a mineral form. Iron is stored as iron(III) oxy-hydroxide, mainly ferrihydrite ( $5\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$ ). The tertiary and quaternary structure of ferritins is highly conserved. All ferritins are composed of 24 subunits arranged in 432 symmetry, which self-assemble to form a 12 nm diameter cage with a 7.5–8 nm diameter cavity. About 4000 iron atoms can be stored in the central core. The crystal structure of Bullfrog M Ferritin at 2.8 Å resolution is shown in Fig. 1.<sup>[12]</sup> The protein has both hydrophilic and hydrophobic channels. Most ferritins are very stable particles, which can withstand 65°C and

**Fig. 1** Crystal structure of Bullfrog M Ferritin. *Source:* From Protein Data Bank.

tolerate a pH range between 4 and 9 (<http://metallo.scripps.edu/PROMISE/FERRITIN.html>).

Douglas, Clark, and Rothschild<sup>[1]</sup> have used the crystalline proteinaceous surface layers of some bacteria as biologically produced nanoscale templates for lithography. Individual protein complexes of ferritin have been selectively self-assembled onto the metal-coated template. Yamashita<sup>[13]</sup> produced a two-dimensional array of ferritin by self-assembly at the air–water interface, which was then transferred onto a silicon surface. The protein coat of the ferritin molecules was then eliminated by heating at 500°C. Scanning electron microscopy (SEM) of the surface showed a well-ordered array of iron nanocrystals on the silicon surface. Atomic force microscopy (AFM), Fourier-transform infrared spectroscopy (FTIR), and weight measurement studies confirmed that the protein shell was indeed eliminated by the thermal treatment, leaving only the iron cores on the silicon substrate. The size and repeat distance of the iron cores was 6 and 12 nm, respectively. The arrays of nanocrystals produced by this process could be used for the fabrication of quantum electronic devices.

Ferritin has also been used as a catalyst for the selective hydroxylation of phenol using hydrogen peroxide as the oxidant.<sup>[14]</sup> Douglas and Stark<sup>[15]</sup> have used horse spleen ferritin as a constrained nanoreactor for the oxidative hydrolysis of Co(II) to achieve site-specific mineralization within the protein cage. The

catalytic effect promoting the mineralization process is driven by complementary electrostatic interactions between the protein interface and the incipient mineral. Wong et al.<sup>[16]</sup> have coupled long-chain primary amines to the surface carboxylic acid residues of ferritin, and the resulting alkylated nanoparticles were soluble and stable in methylene chloride. Transmission electron microscopy (TEM) and analytical ultracentrifugation analysis confirmed that the protein cages were indeed intact after derivatization and that they possess a significantly modified surface charge. However, the degree of derivatization of the ferritin molecules varied considerably; both high-performance liquid chromatography (HPLC) and mass spectroscopy (MS) studies confirmed the polydisperse nature of the samples.

### COWPEA CHLOROTIC MOTTLE VIRUS (CCMV)

Viruses are both important biological entities and chemical assemblies of fascinating structures and diversities. The structures of many viruses have been solved to near-atomic resolution. From a materials science viewpoint, these programmable nanoblocks have many advantages: 1) many viruses can be isolated in gram quantities; 2) most plant viruses cannot infect human beings and are biocompatible; 3) viruses display reactive functional groups on both the inside and outside surfaces of their coat protein, and by

**Fig. 2** The collapsed (left) and swollen (right) forms of the cowpea chlorotic mottle virus (<http://mmtsb.scripps.edu/iper/iper.html>). Source: From Ref.<sup>[63]</sup>.

genetic manipulation, one can introduce amino acid residues with unique reactivity or even peptides with therapeutic properties in designated positions of the capsid protein. Biom mineralization studies based on viral scaffolds such as CCMV (in this section) is a mimicry of ferritin-based chemistry that nature has employed for aeons.

Douglas and Young used CCMV (Fig. 2) as a component to develop hybrid inorganic materials.<sup>[2,3]</sup> CCMV is an icosahedral virus composed of 180 identical 20 kDa protein subunits, which self-assemble around the viral nucleic acid to generate an intact icosahedral cage. The most important structural feature of CCMV is that it can undergo a reversible pH-dependent swelling, resulting in a 10% increase in virus size.<sup>[17,18]</sup> This transition is the result of an expansion at the pseudo threefold of the virus particle, which causes the formation of 60 separate openings, each ~20 Å in diameter, in the coat protein. The swollen virus allows free exchange between the virus cavity and the medium. In the non-swollen form, the pores are closed and no exchange of molecules takes place between the interior of the virus cavity and the bulk medium.

The inner surface of each protein subunit of CCMV presents nine basic residues (arginine and lysine) and this creates a highly positively charged interior, which presumably stabilizes the negatively charged nucleic acid. A wide variety of negatively charged poly-oxometallate species (vanadate, molybdate, and tungstate) were selectively mineralized within empty CCMV particles devoid of the nucleic acid; the size of the capsid cavity defines the size of mineralized particles.<sup>[2]</sup> The electrostatically driven mineralization was carried out at pH 5, at which the inorganic species underwent oligomerization and the viral pores closed. The mineralized viral particles were purified by sucrose gradient ultracentrifugation. Transmission electron microscopy images showed electron dense metal cores. Negative

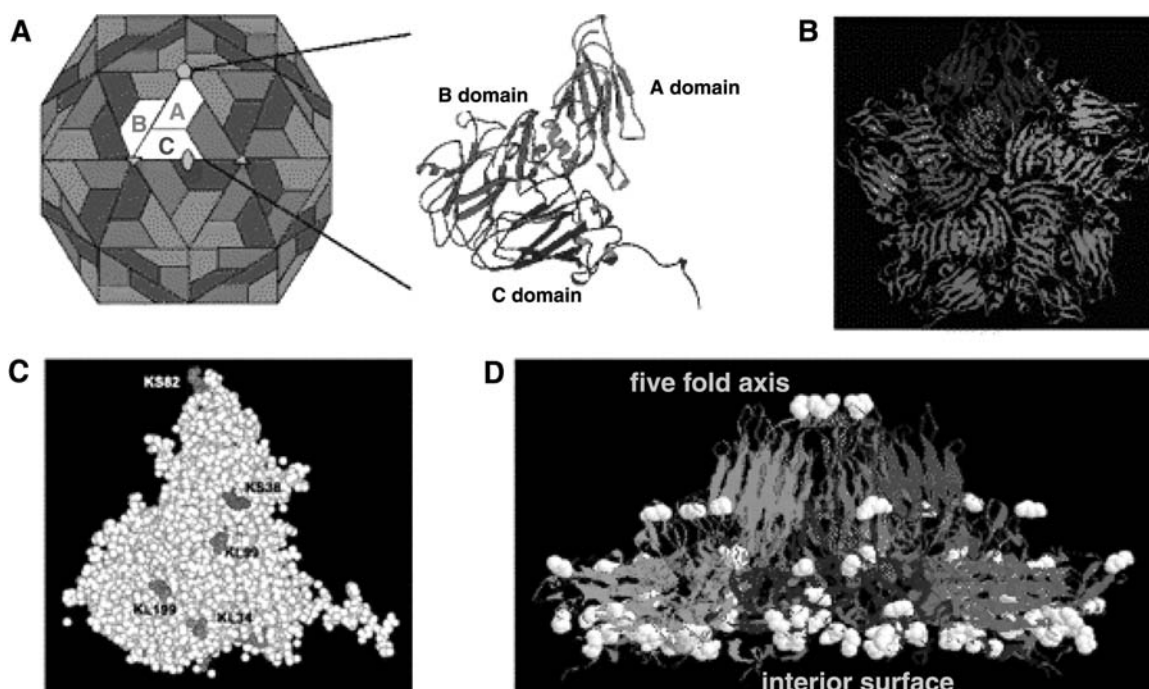

staining was performed to confirm that the viral capsid protein was indeed intact.

Other negatively charged species that serve as a surrogate nucleic acid, such as the anionic polymer polyanetholesulfonic acid, have been encapsulated in CCMV; the virus gating mechanism coupled with an electrostatically driven internalization of the polymer was exploited to produce organic polymer–CCMV hybrid materials.<sup>[3]</sup> The polymer–virus hybrid materials were purified by sucrose gradient ultracentrifugation. The presence of the polymer was confirmed by ultraviolet (UV) spectroscopy and the intact nature of the particles was confirmed by TEM.

A genetically engineered mutant CCMV particle with a negatively charged interior (the nine basic residues at the N-terminus of CCMV were replaced with glutamic acid) was used to sequester nanoparticles of iron-oxide through spatially constrained oxidative hydrolysis of Fe(II); this serves as a ferritin mimic.<sup>[19]</sup> These semiconductor/metallic hybrid materials have potential applications in nanoelectronics and bionanotechnology.

### COWPEA MOSAIC VIRUS (CPMV)

Cowpea Mosaic Virus is a non-enveloped icosahedral plant virus, approximately 30 nm in diameter, which can be isolated from infected black eye pea plant in yields of 1–2 g per kg of leaves by using a simple and convenient procedure.<sup>[20]</sup> The physical, biological, and genetic properties of CPMV have been well characterized.<sup>[21,22]</sup> It is non-infectious toward other organisms and presents no biological hazard. Its structure has been determined to a resolution of 2.8 Å,<sup>[23]</sup> showing a picorna-like ( $T = 1$ ,  $P = 3$ ) protein shell (termed as “capsid”) composed of 60 copies of the asymmetric units. Each asymmetric unit contains three jellyroll  $\beta$ -sandwich folds formed by two polypeptides

**Fig. 3** CPMV structure. (A) Left: A representation of CPMV showing the distribution of the two subunits comprising the “asymmetric unit,” 60 copies of which form the icosahedral particle. The trapezoids in red and green represent the two domains of the large subunit clustered around the threefold symmetry axes and the blue trapezoid represents the small subunit clustered about the fivefold symmetry axes. Right: Ribbon diagram of the two subunits. (B) Organization of five asymmetric units into the “pentamer” centered around a small hole at each fivefold axis. (C) Space filling model of the asymmetric units of coat protein showing the surface exposed lysines. (D) Side view of the ribbon diagram of the “pentamer” with all lysines highlighted. Most of the lysines are located at the interior surface of the protein cell to bind to the RNA inside.

termed as a “small” subunit, the A-domain; and a “large” subunit, the B + C-domains in Fig. 3. The CPMV particles are remarkably stable, maintaining their integrity at 60°C for at least 1 hr at pH range from 3.5 to 9. CPMV was the first virus to be treated as a natural analog of very large dendrimer<sup>[24,25]</sup> for organic reactions. It is also a powerful platform for bioconjugation and has been extensively studied as a model system.

Cowpea mosaic virus has five solvent exposed lysine residues per asymmetric subunit or 300 solvent exposed lysines per particle. Low molecular weight *N*-hydroxysuccinimide ester and isothiocyanate reagents have been employed to test the reactivity of the lysine residues of wild-type CPMV.<sup>[26]</sup> The pH of the reaction, the specific reagent employed, and the reagent/virus ratio used determine the number of dyes/reagent molecules attached per virion, at neutral pH the loading numbers reported are lower than that at higher pH. Loading numbers between 60 and 240 have been reported in literature depending on the ratio of reagent/virus and the pH of the buffer employed for bioconjugation.<sup>[26]</sup> The integrity of the reagent labeled virions was confirmed by sucrose gradient sedimentation and size exclusion fast performance liquid chromatography (FPLC).

The crystal structure of wild-type CPMV displays no free cysteine residue exposed on the exterior surface of the capsid. Chemically addressable cysteine residues have been introduced genetically at two solvent exposed sites on the exterior surface of CPMV.<sup>[27]</sup> Each of the virus mutants displays 60 of such insertions, arrayed in icosahedral symmetry on the 30 nm diameter capsid. The cysteine mutant viruses have been chemically labeled successfully with small molecule maleimide reagents and 1.4 nm monomaleimido-Nanogold<sup>®</sup>.<sup>[4]</sup>

The lysine residues of CPMV have been reacted with *N*-hydroxysuccinimide esters of poly(ethylene glycol) (5 kDa and 2 kDa) to give well-defined loadings of polymer on the outer surface of the virus. The intact nature of the polymer protein hybrids was confirmed by FPLC and TEM. The resulting conjugates have altered densities and reduced immunogenicity in the mouse model. These stealth viruses serve as a model system to further develop a tailored vehicle for drug delivery.<sup>[5]</sup> The attachment of biologically relevant ligands on CPMV was demonstrated by decorating the virus with lysine reactive phenylisothiocyanate derivatives of mannose, glucose, and galactose. These polyvalent constructs, which display carbohydrates at

**Fig. 4** Synthesis of "clicked" CPMV neoglycopolymer conjugate.

well-defined distances, were shown to bind strongly to complementary lectins such as concanavalin A.<sup>[28]</sup> Similar carbohydrate–virus conjugates can be used to develop vaccines.

To achieve both reduced immunogenicity and targeting, one needs a polymer that possesses ligands and simultaneously the ability to shield the virus from the immune system. Such a system was developed: a dense array of carbohydrates was generated by attaching glycopolymer chains to CPMV using two highly efficient chemical steps. Atom transfer radical polymerization of glucosyl acrylate using an azide-containing ATRP initiator provided a well-defined end-functionalized neoglycopolymer. Derivatization and attachment of this material to the virus scaffold was further accomplished by the copper-catalyzed azide–alkyne "click" cycloaddition (Fig. 4).<sup>[29]</sup> By employing a calibrated dye absorbance, the number of polymer chains attached to CPMV was determined to be 77 and 140 per particle, respectively, depending on the reaction conditions; this represents the addition of approximately 1.0 and 1.9 million daltons of mass to the 5.6 mDa virion. The resulting hybrid particles show unprecedented levels of polyvalent affinity for concanavalin A, which is a complementary lectin.

Transmission electron microscopy shows the virus conjugates to be more rounded in shape, to take on uranyl acetate stain differently, and to be distinctly larger in size than the wild-type CPMV (Fig. 5). The neoglycopolymers completely shield the protein assembly from the immune system; in the mouse model, this system was less immunogenic than the

PEG-CPMV hybrid. This is the first example in which a neoglycopolymer has been attached to either a protein or a bionanoparticle in a biorthogonal fashion. CPMV-MRI agent conjugates<sup>[30]</sup> and CPMV-DNA hybrids<sup>[31]</sup> have also been reported recently. CPMV assembles at the perfluorodecaline–water interface. Rhodamine and biotin labeled CPMV assembled at such interfaces have been cross-linked either using glutaraldehyde or by the biotin–avidin interactions to produce stable and ultrathin membranes consisting of assembled viruses.<sup>[32]</sup> CPMV has thus served as a workhorse for the development of new bioconjugation reactions, analytical methods, and applications. Also, many of these chemistries and techniques have been

**Fig. 5** (Left) Negative-stained TEM of polymer-CPMV conjugate. (Right) TEM image of a WTCPMV particle surrounded by particles of polymer-CPMV conjugate.

translated to other bionanoparticles such as the MS2 bacteriophage and the tobacco mosaic virus (TMV).

### M13 BACTERIOPHAGE

The M13 bacteriophage is  $\sim 880$  nm long and 6.6 nm in diameter. The high aspect ratio of the phage predisposes it to form lyotropic liquid crystalline phases. Long-range ordered films can be fabricated by using M13 phages.<sup>[33]</sup> Lee et al.<sup>[34]</sup> used genetic engineering to generate a large library ( $10^9$  peptide inserts) of phages displaying random peptides at one end of the M13 virus. The library was then screened to select the phage that selectively binds zinc sulfide crystal surfaces. The bacteriophage displaying the zinc sulfide binding peptide motif (Sel\*Phage) was then isolated, cloned, and multiplied to liquid crystalline concentrations. The Sel\*Phage was suspended in a ZnS solution to form a Sel\*Phage–ZnS nanocrystal liquid crystalline suspension. The Sel\*Phage–ZnS nanocrystal solution formed a self-supporting nanoscale and micrometer-scale ordered hybrid film, which was continuous over a centimeter length scale. This approach of exploiting evolution for selecting bacteriophages, which bind to inorganic materials (along with the advantage that phages form liquid crystalline systems), is a powerful technology for ordering quantum dots or other functional motifs on a large scale.

### TOBACCO MOSAIC VIRUS (TMV)

Tobacco mosaic virus, which is the first isolated virus, has been studied for a long time. As a rod-like virus, TMV is a fascinating supramolecular assembly.<sup>[35]</sup> Wild-type TMV is composed of a spiral of 2130 wedge-shaped protein (CP) subunits. The TMV RNA contains about 6400 nucleotides. The assembly of the TMV particle involves the interaction between the CP subunits and the RNA, resulting in a rigid helical rod of ca.  $300 \times 18 \text{ nm}^2$  with an interior channel having a diameter of 4 nm (Fig. 6).<sup>[36,37]</sup>

Tobacco mosaic virus forms ordered aggregates in the presence of divalent metal cations such as  $\text{Cd}^{2+}$ ,  $\text{Zn}^{2+}$ ,  $\text{Pb}^{2+}$ ,  $\text{Cu}^{2+}$ , and  $\text{Ni}^{2+}$ . These divalent metal cations promote the precipitation of TMV from solution at a critical concentration, and the precipitate behaves as a nematic lyotropic liquid crystalline phase.<sup>[38,39]</sup> Metal binding sites present on the surface of TMV form metal bridges, which serve as cross-linking points. Drying on a glass slide produces highly ordered, optically birefringent films.<sup>[40]</sup> The highly polar exterior surface of TMV has been used for surface mineralization of iron-oxyhydroxides, CdS, PbS, and silica.<sup>[3]</sup> These materials form a thin coating over

**Fig. 6** Structural representation of Tobacco Mosaic Virus.

the virus nanorod and result in inorganic nanofibrils of 20–30 nm diameter range, which are as long as 1  $\mu\text{m}$ . This is a result of the end-to-end assembly of TMV fibrils. These materials were characterized by energy-dispersive X-ray and transmission electron microscopy.<sup>[41]</sup>

Dujardin et al.<sup>[42]</sup> recently used TMV as a template for the alignment and controlled deposition of Pt, Au, and Ag nanoparticles. By varying the conditions of the deposition, they demonstrated that one can either specifically decorate the external surface with metallic nanoparticles via the chemical reduction of  $[\text{PtCl}_6]^{2-}$  or  $[\text{AuCl}_4]^{2-}$  or achieve constrained growth of Ag nanoparticles within the 4 nm internal channel present in the virus via the photochemical reduction of Ag-salts. In principle, one can thus prepare one-dimensional arrays of a wide range of quantum dots via molecular engineering of the internal or external surface of TMV.

At high concentrations, TMV particles form a nematic liquid crystal, which was employed as template to prepare mesostructured and mesoporous silica with periodicities of about 20 nm.<sup>[43]</sup> Silica nanoparticles consisting of a dense core surrounded by a radial array of mineralized TMV fragment has been synthesized. Chemical degradation of TMV yielded a stable fragment of about 50 nm in length, which was similar in size to those encapsulated in the silica shell of the nanoparticles. The general stability of TMV liquid crystals indicated that it should be possible to use a

similar approach to prepare a wide range of inorganic oxides, semiconductors, and metal-based mesophases and nanoparticles with mesostructured interiors. The exterior surface of TMV has been chemically modified by labeling tyrosine 139 and the interior has been modified by addressing glutamic acid residues 97 and 106.<sup>[44]</sup> Biotin, chromophores, crown ethers, and polyethylene glycol are some of the molecules successfully conjugated to TMV. TMV, thus, serves as a convenient bio-nanoscaffold for both biomineralization and bioconjugation.

## ADENOVIRUSES AND GENE DELIVERY

All adenovirus particles are similar: non-enveloped and 60–90 nm in diameter. They have icosahedral symmetry and are composed of 252 capsomers: 240 “hexons” + 12 “pentons” at vertices of the icosahedron (2–3–5 symmetry), which packages a DNA genome of approximately 36 kDa (Fig. 7).<sup>[45,46]</sup> Attachment to target cells is mediated by the binding of the fiber knob to its complementary receptor protein present on the cell. The viral penton base then interacts with cellular  $\alpha_v$  integrins to allow virus internalization.

Recombinant adenoviruses have been widely used as gene transfer vehicles.<sup>[47]</sup> Adenoviruses have been retargeted to specific cell types by displaying ligands (which are complementary to the receptors present on the cell type) on the surface of the virus. This has been achieved genetically and by other means. For instance, genetic modification of the fiber protein via the incorporation of small targeting peptide sequences, such as a polylysine sequence, has been developed to enhance muscle cell transduction.<sup>[48]</sup> Biospecific adaptor molecules consisting of cross-linked monoclonal antibodies have been used to bridge adenoviral vector protein to cell surface receptor molecules.<sup>[49]</sup>

An antibody/immunoglobulin (IgG) binding protein sequence (Z33) has been expressed on adenovirus fibers. The Z33-modified adenovirus particles were used to form antibody–virus complexes (the binding constant between the antibodies and the virus is

**Fig. 7** Cartoon representation of the structural features of adenovirus.

extremely high;  $K_D = 2.4$  nM) by preincubating them with monoclonal antibodies directed against neuronal cell-adhesion molecules or integrin  $\alpha_7$ . In targeting experiments with human muscle cells, up to a 77-fold increase in reporter gene transfer was achieved by this novel strategy. The approach is quite general and, by varying the cell-type-specific antibody one incubated with the Z33-adenovirus, a wide variety of cells can be targeted.<sup>[50]</sup> Adenoviruses have also been coated with polyethylene glycol (PEG) to avoid antibody-mediated neutralization of the virus in vivo.<sup>[51–53]</sup>

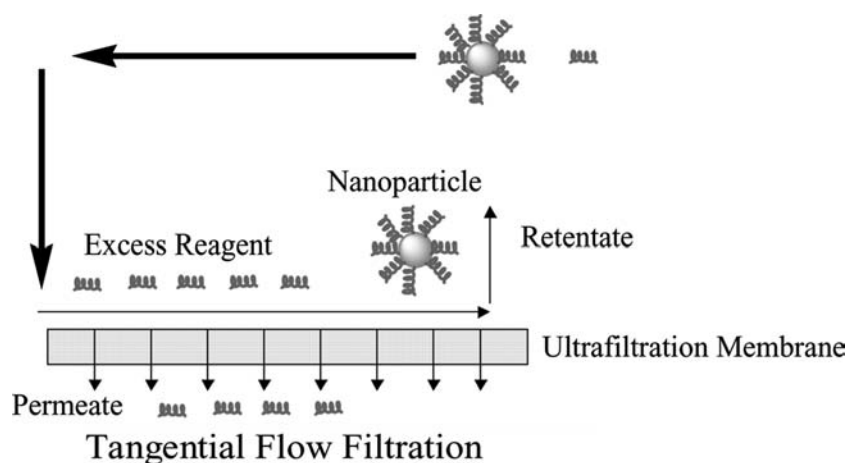

Retroviral vectors have also been used for targeted gene therapy. A targeting peptide along with trimerization domain has been linked on the N-terminus of the viral envelope glycoprotein using a linker, which is further cleaved by an enzyme (matrix metallo protease). These attachments shield the native receptor binding because of steric hindrance; the targeting peptide, which is on the exterior, mediates attachment to tumor cells displaying complementary receptors. After attachment to the tumor cells, the metalloprotease produced by the tumor cells cleaved the linker, thereby exposing the native viral envelope protein, which mediates cell entry into the tumor cells.<sup>[54–56]</sup>

## MS2 BACTERIOPHAGE

The MS2 coat protein consists of 180 copies of subunits, which self-assemble to form a 27.4 nm icosahedral capsid. The X-ray crystal structure of MS2 has

**Fig. 8** Refined structure of Bacteriophage MS2 at 2.8 Å resolution (picture courtesy Virus particle explorer). *Source:* From Ref.<sup>[63]</sup>.

**Fig. 9** Tangential flow filtration method for separation of bionanoparticles from excess conjugation reagents.

been solved to Ångstrom level resolution (see Fig. 8). Each particle has 1080 covalently addressable lysine residues.<sup>[57]</sup> Around 500 lysine residues of MS2 capsid have been covalently modified with gadolinium diethylenetriaminopentaacetic acid (MRI contrast agent) to produce a bionanoparticles contrast agent, which polyvalently displays MRI agents. The  $T_1$  bionanoparticle contrast agent gives reflexivities over three orders of magnitude greater than a single low molecular weight Gd-DTPA moiety.<sup>[58]</sup> MS2 has recently been double labeled with fluorescein (drug mimic) and polyethyleneglycol (shields the particle from the immune system) to develop a model drug delivery vehicle.<sup>[59]</sup>

### HEPATITIS-B SURFACE ANTIGEN (HBsAg)

Clinical grade HBsAg is composed of a mixture of bionanoparticles and small aggregates of particles formed by the self-assembly of 100–150 copies of 25.4 kDa protein subunits.<sup>[60]</sup> HBsAg is a therapeutically relevant protein, and has covalently accessible lysine residues that can be modified with lysine-specific reagents. The current commercial hepatitis B virus (HBV) vaccine consists of HBsAg adsorbed to alum, which acts as an adjuvant. The synthesis and characterization of a novel Hepatitis B Virus vaccine (HBsIC-ISS) composed of Hepatitis B surface antigen (HBsAg) bionanoparticles conjugated to multiple copies of immunostimulatory sequence oligodeoxynucleotides has been recently reported.<sup>[61]</sup> This HBsIC-ISS conjugate, which polyvalently displays multiple copies of ISS-DNA, shows promise as a therapeutic vaccine against hepatitis B virus. The current methods of separation of bionanoparticles from small molecule/polymer and conjugation reagents, like ultracentrifugation

over sucrose gradients, pelletizing and resuspension of the conjugates are multi-step two-day processes and requires expensive equipment. A faster and efficient method for purification of bionanoparticles conjugates is necessary for scale up and commercial exploitation of these constructs. A novel rapid tangential flow filtration (TFF) method was developed to synthesize, purify, and formulate the HBsIC-ISS vaccine (Fig. 9). A 300 kDa molecular weight cut-off cellulose ultrafiltration membrane was employed to retain the large nanoparticles; removal of DMSO, NEM, and Sulfo-SMCC (small molecules), and polymeric ISS (7500 MW) was demonstrated via TFF, with excellent recoveries and short run times of under 1 hr. This TFF technique could serve as a general method for the separation of excess small molecule/polymeric conjugation reagents from virus like particles, viruses, and nanoparticles.

### CONCLUSION

As discussed here, many inroads have been made into harnessing bionanoparticles for nanoscience applications. A vast number of programmable nanoblocks have not yet been explored in this rich, new, and exciting field at the confluence of nanotechnology, biology, chemistry, and materials science. Biology provides a vast resource of nanoparticles and exquisite control of the recognition motifs displayed on the surface of these particles. Organic/bioconjugate chemistry immensely expands the scope of useful functional units such as dyes, sugars, and polymers, which one can use to decorate bionanoparticles for a wide range of applications. Inorganic chemistry/biomineralization affords a convenient route to preparing hard-soft bio-hybrid starting materials for nanoelectronic applications and materials science,

which is the last component in developing this kind of technology. Technological breakthroughs occurring in this field are in two broad directions: nanoelectronics and biomedical applications of nanotechnology. The former has more of a materials science component to it, and the latter has more of a molecular biology component with chemistry contributing richly in both directions. Both directions hold great promise in bringing about an electronic and biomedical revolution. The number of components that go into nanotechnology is almost as complex as the primordial soup<sup>[62]</sup> and what emerges from it promises to be as complex, rich, and unpredictable as life on our planet.

## ACKNOWLEDGMENTS

We thank all the authors whose names are given in the references list. In particular, we sincerely thank Dr. M. G. Finn for many invaluable discussions, and Dr. John E. Johnson for organizing the Mondiego Symposium, which has been the platform for exchanging the latest breakthrough among all the groups pursuing research in the area of virus chemistry. K. S. Raja thanks the College of Staten Island/CUNY for a start-up package and the PSC CUNY grant for partly funding this work. We thank Dr. Vijay Reddy for making Fig. 9.

## INTRODUCTION

The use of microbes, indigenous or foreign, in the cleanup of contaminated sites is termed bioremediation. Bioremediation has shown great promise in the removal of a wide variety of contaminants, especially at sites where the contaminant is widespread or is present at lower concentrations. Many larger contaminated sites have remained untreated because of high costs associated with traditional cleanup methods. Bioremediation is an attractive alternative to traditional clean up methods, because it may be performed on site, is less invasive, of lower overall costs than conventional methods, and can have higher public acceptance than harsher treatments. Bioremediation techniques are relatively inexpensive because capital and operating costs are generally much lower than, e.g., techniques such as soil removal and replacement. A study performed by Alper<sup>[1]</sup> states that bioremediation is six times lower in cost than incineration and three times cheaper than entombment. Lower cost is a result of the lower energy and time requirements during the application phase of nutrient enhancements and the low cost of the nutrients because of their large-scale use in agriculture.

Bioremediation techniques are also safe and consistent with the natural processes occurring in the contaminated areas. As described later in this entry, naturally occurring or indigenous organisms have been used exclusively up to the time of this writing. Indigenous organisms are present at the contaminated site and are therefore not added. Use of foreign or non-indigenous organisms remains a challenge for future research and development. Bioremediation can be applied to many situations including soil remediation, groundwater remediation, oil spills, and others as described below. Multiple contaminants can be attacked such as petroleum hydrocarbons, industrial solvents, organic wastes, and removal of metals.

The use of bioremediation does have its problems because it is a relatively immature technology where fundamental data still needs to be gathered. Information such as changes in the microbial community as biodegradation takes place is still lacking, due mainly to the fact that many of the microbes used in bioremediation cannot be successfully cultivated in a laboratory setting. For this reason, it is difficult to ascertain just how much removal of a contaminant observed in a study is directly a result of biological processes as opposed to other abiotic processes.<sup>[2]</sup> We also do not know how the ecosystem is affected following the use of bioremediation except in the special case of the Exxon Valdez oil spill that has been extensively studied from the point of view of ecological impact. Bioremediation is still considered to be a new technology and thus many opt for using the more traditional and expensive cleanup methods. The role of government regulators in generating a favorable environment for introducing novel and effective treatments needs to be reassessed. Finally, although bioengineered microbes offer great promise for the removal of contaminants, public and regulatory acceptance of their use remains lacking. This situation is similar to the controversy surrounding the use of genetically engineered foods. This entry will briefly discuss the current use of bioremediation for the removal of different types of contaminants, as well as the difficulties and benefits associated with the use of bioremediation in the removal of each contaminant.

## POLLUTANTS IN THE ENVIRONMENT

### Hydrocarbons

Some microorganisms can completely degrade contaminants as exemplified by the bioremediation of hydrocarbons. Most commonly, *aerobic* organisms are found that add oxygen to the hydrocarbon, thus

starting the process of mineralization as indicated in the following example:

The process continues until the entire hydrocarbon is converted to carbon dioxide and the mineralization is complete, as exemplified in Fig. 1. In practice, only in simple hydrocarbons does complete mineralization occur rapidly. The process of bioremediation of higher hydrocarbons is more complex, as described later.

Hydrocarbon-degrading bacteria have been discovered in all marine environments and were originally discovered by Zobell.<sup>[3]</sup> Biodegradation, together with physical processes such as evaporation, is a major process by which petroleum is removed from the environment following an oil spill. The role of these processes for a large spill such as that of the Amoco Cadiz was described by Gundlach et al.<sup>[4]</sup> This study showed that biodegradation was acting as rapidly as evaporation even during the first days following the spill. It is thought that the high rate of biodegradation along the coast of Brittany was a result of the runoff of agricultural fertilizers from farms near the coast. The

**Fig. 1** Schematic diagram illustrating the breakdown of hydrocarbons by hydrocarbon degrading bacteria. In the case of aerobic microbes, oxygen along with nitrogen and phosphorous are required for this mineralization to occur.

addition of nitrogen and phosphorous from this agricultural runoff enhanced the biodegradation on the beaches, presumably by removing the nitrogen and phosphorous limitation resulting from low naturally occurring levels of these elements in sea water (Atlas, R.M., personal communication, 1990).

The above process requires that hydrocarbon-degrading organisms are present and that there is sufficient oxygen. In some cases, *anaerobic* organisms, organisms that do not require oxygen, can be used to destroy the hydrocarbons by a different route. However, *anaerobic* processes are thought to be slow and are not yet widely used but promise to be a fruitful future research area. If sufficient organisms are present along with sufficient quantities of oxygen, the degradation of the hydrocarbons proceeds and the contaminant is destroyed. During this process, the microorganisms are also increasing in number. This increase in the microbial community requires nitrogen and phosphorous as well as carbon and oxygen for new biomass to be generated. Thus, in many cases, the remediation can be limited by the availability of nitrogen and phosphorous. This can be remedied by addition of nutrients; this commonly used process is called “nutrient enhanced bioremediation” or *biostimulation*. In some cases, the indigenous organisms are grown in a culture under ideal conditions until their numbers are very high and are then added back to the remediation site. This is known as *bioaugmentation* and can be used when a rapid “kick-start” is desired. If the oxygen supply is limited, as can be the case in groundwater remediation, it can be added by “bioventing.” Hydrocarbon degraders are thought to make up less than 1% of microbial communities, but may rapidly increase to more than 10% of the community following exposure to pollutants present in oil.<sup>[3]</sup> In the case of marine oil spills, the contaminants may be tackled via two different options. The first option involves the addition of fertilizers so that the performance of indigenous hydrocarbon degraders may be improved, while the second option involves seeding (*bioaugmentation*). Seeding simply refers to the rapid increase in the population of indigenous hydrocarbon-degrading microbes, which is accomplished by the addition of seed cultures. In the case of hydrocarbon-contaminated terrestrial sites, one may opt for using in situ bioremediation, enhanced land treatment, and slurry bioreactors. In situ bioremediation involves the addition of nutrients and oxygen to increase the activity of the hydrocarbon degrading community. The addition of substances such as nutrients, electron acceptors, and primary substrates presents the factor most likely to affect the rate of in situ bioremediation as these must all reach the microbial community for the technique to be successful.<sup>[5]</sup> In some cases, in situ bioremediation may be ruled out. One might then

choose a method where the contaminated soil is placed in a closed reactor in an aqueous slurry. Microbes are then added in order to treat the soil. Slurry bioreactors may be chosen for sites where mass transfer limitations may occur, field temperatures adversely affect the activity of the microbes, or where the soil is predominantly composed of clay.<sup>[6]</sup> Regardless of the mode of treatment used, one important consideration for bioremediation involves the concept of bioavailability. This simply refers to the portion of the contaminant that is available for microbial treatment. Factors such as oil-phase partitioning, adsorption, and rate-limiting diffusion are most likely to affect bioavailability because all these lead to a decrease in the amount of contaminant found in the aqueous phase, where transformation of the contaminant is most likely to occur.<sup>[7]</sup>

Fig. 2 is an optical micrograph of hydrocarbon degraders grown in laboratory cultures. In most cases, the identification of the specific organisms in the hydrocarbon degrading cultures has not been accomplished. In fact, it is generally considered that indigenous hydrocarbon degraders exist in complex *consortia* that contain many codependent species. The study of *consortia* is an important research area because their control and optimization is of major importance for the future of bioremediation.

### Polycyclic Aromatic Hydrocarbons (PAHs)

The previous section considered the remediation of various hydrocarbons. In this section, we discuss a special class of hydrocarbons, the polycyclic aromatic hydrocarbons (PAHs). These are very difficult to remediate and present particularly difficult and widespread environmental issues. Polycyclic aromatic hydrocarbons are often referred to as polynuclear

**Fig. 2** Optical micrograph of a marine hydrocarbon-degrading consortia cultured in the laboratory. Each rodlike bacterium is approximately 25  $\mu\text{m}$  in length.

aromatics (PNA). They are a class of very stable organic molecules made up of carbon and hydrogen. These molecules are flat, with each carbon having three neighboring atoms much like graphite. Polycyclic aromatic hydrocarbons (PAHs) are released into the atmosphere as gases or particles during the incomplete combustion of organic material. PAHs have a number of sources, including mobile cars, trucks, ships and aircraft, industrial-power generation, oil refining and waste incineration, and domestic—primarily combustion for heating and cooking, especially solid fuel heaters using wood and coal. The Department of Health and Human Services (DHHS) has determined that some PAHs may be reasonably expected to be carcinogens. Three- to five-ring PAHs occur as particles in air. PAHs with five or more rings tend to be solids, which attach themselves to the surface of other particulate matter in the atmosphere. PAHs are found in air, water, soils, marine organisms, and plants.

Because of their potential toxicity, bioremediation of these compounds has been under study for more than 30 years.<sup>[8]</sup> During this period, many naturally occurring or indigenous bacteria, fungi, and algae have been discovered that attack the lower-molecular-weight species of three rings or lower.<sup>[9,10]</sup> However, as the PAH becomes larger, it becomes more recalcitrant to attack by organisms, probably because of bioavailability considerations. Some fungi and algae have been discovered that attack higher-molecular-weight PAHs but their applicability has been limited by the slowness of their action. Organisms can cometabolize the larger PAHs if given a cometabolite such as phenanthrene (a three-ring PAH);<sup>[11]</sup> however, the success of this approach has been limited. The addition of surfactants to increase bioavailability has also produced limited enhancement of degradation rates.<sup>[12]</sup>

Part of the difficulty in producing better bioremediation processes is attributable to the lack of knowledge regarding the degradation pathways and therefore, their inherent limitations. It is thought that the initial addition of oxygen to the aromatic ring is the most difficult aspect of the degradation process. This occurs through the action of a dioxygenase in the organism. However, the biodegradation of PAHs, the inherent limitations and the subsequent metabolic pathways, is an area that requires a substantial research effort. In particular, bioavailability, adsorption, and mass transfer limitations must be improved in processes using naturally occurring organisms for bioremediation to be effective.

Recent results have indicated that new xenobiotic organisms have great potential for bioremediation of PAHs.<sup>[13]</sup> Genetically engineered organisms (GEMS) are showing progress in modifying metabolic pathways to enhance the effectiveness of organisms in degrading the PAHs. However, although the molecular biology

approach promises to further improve the ability of organisms to degrade PAHs, considerable work remains to be performed and further modification of the relevant DNA is required. Additionally, GEMS have been excluded from practical remediation projects and will likely be limited in the future until more knowledge on the effects of introducing genetically modified organisms into the environment is attained.

## Metals

Metals, particularly heavy metals such as chromium, lead, and copper, are also major pollutants in soil and water. Microorganisms possess the ability to catalyze the transformation of both organic and inorganic pollutants. In the case of organic compounds, the materials is destroyed. However, in the case of metals, the microorganisms are only able to stabilize or remove metal contamination from the treatment site, and one is still left with the problem of getting rid of the metal-containing biomass.<sup>[14]</sup> In his review on the use of microbes for environmental restoration, Francis<sup>[15]</sup> outlines several mechanisms used by microorganisms to accomplish this: oxidation/reduction reactions, changing pH, synthesis of sequestering agents, accumulation or adsorption of metals by functional groups present on bacterial cell walls, or the active uptake of metals into the intracellular space.

In the case of biosorption, the microbial biomass simply acts in the same manner as an ion exchange resin. Live bacteria as well as biopolymers have been successfully used as biosorbents.<sup>[16,17]</sup> Studies have illustrated that, in certain cases, the biomass may be regenerated after alkali treatment for use in additional sorption-desorption processes.<sup>[18]</sup> The main drawback to the implementation of biomaterials for the sorption of heavy metal ions can be attributed to the use of synthetic ion exchange resins, which are more established and therefore more widely used. Biosorbents offer two very important advantages. First, they are superior to synthetic ion exchange resins, in that they are able to remove metal ions present at dilute concentrations.<sup>[19]</sup> Furthermore, because of their specificity, biosorbents are also able to avoid the problem faced by the synthetic ion exchange resins, whose binding sites tend to saturate when alkaline-earth metals are present.

Bacteria may also be used to transform a metal to a lower redox state, as seen with the conversion of the toxic and mutagenic hexavalent chromium to trivalent chromium and reduction/precipitation of Tc(VII), U(VI), and Mo(VI) by sulfate-reducing bacteria (SRB).<sup>[20-22]</sup> The main challenge facing the widespread use of sulfate-reducing bacteria is their susceptibility to low levels of Cd(II), Zn(II), or Ni(II), which are toxic to them at concentrations of 20–200  $\mu\text{M}$ .<sup>[23]</sup> Because

of this, current research is centering on the use of molecular biology techniques to transfer genes involved in the sulfate reduction pathway to more resistant bacterial strains, such as was carried out when the thio-sulfate reductase gene from *Salmonella enterica* was transferred to *Escherichia coli* strains. This led to the production of one recombinant strain with the ability to take out 98% of the available cadmium.<sup>[24]</sup>

In addition to the more traditional metal ions, bacteria have illustrated their ability to enzymatically transform metalloids such as arsenic to methylarsenic, its less toxic form by biomethylating the metalloid. Methylarsenicals are thought to be less toxic than inorganic arsenic because they tend to be more easily excreted and less likely to bind to biomolecules and cell walls.<sup>[25]</sup> An example of genetically engineered bioremediation of arsenic involves the use of bacterial genes, which are then introduced into the *Arabidopsis thaliana* plant.<sup>[26]</sup> These plants are now able to accumulate lethal levels of arsenic in their leaves. In this case, the oxy-anion, arsenate, is transported by the plant above-ground and then reduced to arsenite, which is then sequestered in thiol-peptide complexes. It is hoped by the authors that the same scheme can be applied to larger and faster growing plants for the bioremediation of arsenic.

## BIOREMEDIATION TECHNIQUES

### Groundwater Bioremediation

The quality of groundwater in industrialized and developing countries has been rapidly deteriorating in recent years. This deterioration is closely related to industrial growth and the associated disposal of all kinds of wastes, uncontrolled spills of fuels and lubricants in shops, service stations and industrial plants, and the disposal of industrial wastewaters into open sewers, particularly in countries that are rapidly developing. A large variety of technologies have been developed for remediation of contaminated soils and aquifers including physical, chemical, thermal, and biological procedures. In the remediation of groundwater, the most widely used technology is the pump-and-treat technology. This consists of a pumping-treatment-recharging cycle that comprises extraction of the groundwater for treatment at the surface followed by reinjection into the aquifer. One study indicated that over 3000 “pump and treat” systems existed in the United States.<sup>[27]</sup> In spite of the widespread use of “pump and treat” technology, constraints exist that can limit the success of the process. For example, contaminants may be strongly adsorbed in certain soils making their removal difficult. Thus, when “pump and

“pump and treat” is used to successfully clean the water at the surface, reinjection of the treated water often leads to recontamination after a period of time as a result of contact with contaminants that are strongly adsorbed in the soil. In other situations, the soil may be of low permeability, inducing mass transfer constraints. Finally, the mechanical and energy requirements of “pump and treat” can become quite costly. Bioremediation techniques have recently shown promise in ameliorating groundwater contamination. Bioremediation is safe and economical compared with other technologies. If indigenous or naturally occurring organisms are used, reasonable public acceptance of such a “natural” process is achieved. Contaminants are transformed and degraded to carbon dioxide and water when the technology is properly applied by the mineralization process. The use of microorganisms in one site may not guarantee their success in a different site because microorganisms removed from their habitat and exported to a new environment with different characteristics are not likely to survive in this new environment. In situ bioremediation may be an option for the cleanup of aquifers contaminated with chlorinated solvents or metals. In both cases, nutrients would be pumped to the subsurface to stimulate the activity of organisms that biodegrade the contaminants, or in the case of metals, organisms that change the chemical forms of the metals. There is also promise for the use of sulfate-reducing bacteria (SRB) in the aboveground treatment of heavy metal contaminated groundwater.<sup>[28]</sup> Another variation of groundwater bioremediation is the passive barrier concept, in which contaminated groundwater passes through a permeable reactive zone where bioremediation takes place. Here the contaminants may be degraded or scavenged, thus resulting in the release of uncontaminated groundwater in the downgrade direction of the reactive zone. Advantages of the passive barrier option include the following factors: no aboveground facilities are required and no groundwater reinjection is needed.<sup>[29]</sup>

### Biofiltration

Biological treatment in air pollution control is a new and promising technique that is finding increasing use in many industries.<sup>[30]</sup> This use is fueled by an increasing concern regarding the release of volatile organic compounds (VOCs) into the atmosphere. Volatile organic compounds released in the atmosphere not only cause bad odors but can also have long-term toxic effects over extended periods of time.<sup>[31]</sup> VOCs such as acetone, methanol, toluene, methyl ethyl ketone, and other commonly used solvents are released during manufacturing processes. There is an increasing

move toward replacing these solvents with “environmentally” friendly processes such as “supercritical carbon dioxide” in the semiconductor industry. Nevertheless, processing release from industrial processes remains a major problem. Many food-processing industries also release VOCs into the atmosphere but these VOCs are primarily a concern because of the production of odors.

Recently, biological techniques for waste air treatment have gained interest.<sup>[32]</sup> There has been an increase in both research activity and in application of biofilters for the treatment of either odors or volatile organic compounds (VOCs) in process waste air. The two types of biofilters usually considered for air pollution control are biofilters and biotrickling filters. Both types use naturally occurring indigenous organisms converting the hydrocarbon pollutant to carbon dioxide and water. In a *biofilter*, a humid stream of contaminated air is passed through a damp packing material, usually compost mixed with wood chips or any other bulking agent, on which pollutant degrading bacteria are naturally immobilized. Biofilters are simple and cost-effective, requires low maintenance, and are particularly effective for the treatment of odor and volatile compounds that are easy to biodegrade. These factors have led to the increased use of *biofilters* in industrial applications. *Biotrickling filters* work in a similar manner to *biofilters*, except that an aqueous phase is trickled over the packed bed, and the packing usually consists of some synthetic or inert material (Fig. 3). Inorganic nutrients are added to the trickling solution, which is usually recycled. *Biotrickling*

**Fig. 3** Schematic layout of a biotrickling filter. Top arrow indicates movement of contaminated air stream. Interaction of the pollutant with the biofilm leads to biological degradation of the pollutant; bottom arrow indicates the release of clean air.

filters are more complex than biofilters, yet are more effective, especially for the treatment of compounds that generate acidic by-products, such as  $H_2S$ . Because they are more complex and a more recent development, they have not been as widely commercialized. A review by Cox and Deshusses<sup>[33]</sup> provides more information on the potential of biotrickling filters, as well as areas where data remains lacking such as those of biofilm architecture, the population dynamics taking place within these filters, and the potential of using fungi instead of bacteria. The review also touches on the problems encountered with the use of these filters such as the clogging of filters that takes place when biomass accumulation is not controlled.

*Biofilters* and *biotrickling* filters are cost-effective and an environmentally friendly alternative to incineration, adsorption onto activated carbon, or chemical scrubbing. Potential applications include treatment of exhaust air processing industries, printing and painting shops, electronic and materials manufacturing, furniture and metal production, farming and food manufacturing, wastewater treatment operations, etc. They will become more effective as research leads to a better understanding of microbe/support interactions and other factors that determine the size and operating conditions of these filters. Companies such as Biorem, Haase, and Bohn are leaders in biofiltration.

## Phytoremediation

Although bioremediation is generally thought of as the use of microorganisms to remove chemical wastes, the use of plants to remove metal contaminants from soils or even from wetlands is a significant new application of bioremediation. The use of plants for this purpose is called *phytoremediation*. In this application, plants that naturally occur in the contaminated regions may sequester heavy metals such as chromium or lead, which are removed with great difficulty and expense by other methods. Plants that are effective in phytoremediation must take up substantial amounts of metals and are called *hyperaccumulators*. The removal of heavy metals by plants has been demonstrated. However, the contaminated biomass must then be disposed of in an alternate way. For example, the leaves roots and stems of a plant that is removing lead from a contaminated site must be disposed of in a landfill after being ashed to reduce volume. Fig. 4 illustrates a schematic layout of a plant taking up metal from contaminated soil. The first line of defense is to keep the metal out of the plant. The insert in Fig. 4 shows a lead carbonate deposit on the root of a mustard plant exposed to lead. If this first line of defense fails and the lead enters the plant, the metal may accumulate in vacuoles where it is stored or excreted in dead

**Fig. 4** Schematic layout of metal uptake by plants. Arrows indicate movement of metals. Bioavailable metals are first excluded from the root. Insert shows scanning electron micrograph (SEM) of a *Brassica* (mustard plant) root following exposure to lead.

leaves or in dripping sap. In any case, the detritus must be removed with the plant for complete disposal of heavy metals. Phytoremediation using water lilies has been attempted to clear radioactive metals as a result of the Chernobyl disaster. In this case, the alternatives of removing hundreds of square miles of soil is not feasible.

## BIOREMEDIATION OF THE EXXON VALDEZ OIL SPILL: THE LARGEST SUCCESSFUL BIOREMEDIATION PROJECT

### Background

The Exxon Valdez spill of approximately 11 million gal of Alaskan North Slope crude oil in Prince William Sound, Alaska, in March 1989 resulted in the contamination of approximately 1300 miles of rocky intertidal shorelines within Prince William Sound and the Gulf of Alaska. Bioremediation was extensively used to accelerate the natural degradation of beached oil. This example is described in some detail because many aspects of instituting a successful project of large magnitude were encountered, including both technical and political obstacles. These obstacles were overcome, resulting in the largest bioremediation project ever attempted.<sup>[34]</sup>

Nitrogen-containing fertilizers were applied to stimulate the growth of indigenous hydrocarbon-degrading microorganisms within the intertidal zones. Shorelines were treated with Inipol EAP 22 (7.4% N, 0.7% P), an oleophilic liquid fertilizer, and Customblen (28% N, 3.5% P), a slow-release granulated fertilizer.

Approximately 50,000 kg of nitrogen and 5000 kg of phosphorus were applied to shorelines over the summers of 1989–1992.

In 1989, field tests on Exxon Valdez beached oil were carried out by the US Environmental Protection Agency (EPA) and Exxon. These tests provided evidence for the success of bioremediation in the cleanup of these beaches.<sup>[35]</sup> Treated areas were visibly cleaner than adjacent untreated areas within a few weeks of fertilizer application.<sup>[36,37]</sup> However, gravimetric analyses on heterogeneous sediments were statistically unconvincing. Laboratory testing confirmed that Inipol EAP 22 was not an effective agent for physically removing oil from sediments, and that oil removal occurred through biological activity.<sup>[38,39]</sup>

The Exxon Valdez bioremediation effort occurred in an extremely rapid crisis atmosphere. Controlled studies that were statistically valid were not performed in the initial year of the spill. However, in 1990, a statistically designed field test was conducted that included extensive chemical analyses of the oil. Results demonstrated that measured changes over time in the oil composition, relative to a stable, high-molecular-weight hydrocarbon present in the oil, allowed the quantification of the rate and extent of the oil biodegradation with high levels of statistical confidence. The authors found that hopane, a multiring saturated hydrocarbon, was not biodegraded and was thus a useful conserved standard. Monitoring hydrocarbon losses relative to hopane provided benchmark confirmation of oil biodegradation, and showed that adding fertilizers could accelerate the rate of oil removal by a factor of 5 or more. It was also found that the rate of oil biodegradation is a function of the nitrogen concentration maintained in the pore water of the intertidal sediments. These results suggested that bioremediation application could be further improved by monitoring nutrient level in real-time and maintaining the nutrient level at an optimum and safe level.<sup>[40]</sup> On-site monitoring of nutrients in sediment pore waters would provide practical, real-time guidance on amounts and frequency of fertilizer applications.

A concurrent monitoring program conducted in Alaska jointly by the EPA, Alaskan Department of Environmental Conservation (ADEC), and Exxon, incorporated comprehensive environmental monitoring, including tests for toxicity and potential stimulation of photosynthetic plankton.<sup>[41]</sup> No adverse effects were found, supporting the safety of bioremediation techniques and illustrating that more frequent fertilizer application would have been equally safe and even more effective. The ultimate rate of nutrient bioremediation will be limited by the amount of nutrients, which may be added without adversely affecting the indigenous biota.

## Lessons from the Exxon Valdez Oil Spill

Bioremediation has inherent limitations. Bioremediation is not likely to be effective on extensively degraded oil. Once the polar content of the oil residue reaches 60–70% of the total mass, nutrient availability will no longer be the limiting factor. This calls for a rapid response in case of an oil spill. Furthermore, adequate oxygen must be available; bioremediation within anaerobic fine sediments such as mud flats or marshes would probably be effective only at shallow depths, but oil penetration in such sediments is also restricted. Nevertheless, based on the statistically significant field tests along with a substantial body of laboratory testing, bioremediation is an important treatment for oil spills on rocky intertidal shorelines of the type found in Alaska.

The effectiveness of this approach was further confirmed and extended by the effectiveness of nutrient enhanced bioremediation on sandy beaches.<sup>[42]</sup> The study concluded that significant intrinsic biodegradation of petroleum hydrocarbons can take place naturally if sufficient nutrients already exist in the impacted area. The study also demonstrated that statistically significant rate enhancement occurs in the presence of an already high intrinsic rate by supplementing natural nutrient levels with inorganic mineral nutrients. It was also shown that bioaugmentation did not significantly contribute to the cleanup of an oil spill. The study developed first-order biodegradation rate constants for the resolvable normal and branched alkanes and two- and three-ring aromatic hydrocarbons present in light crude oil. This study also connected relative biodegradation rates in the field to those measured in the laboratory. The literature, which connects laboratory studies to field studies, is sparse, and considerably more work needs to be carried out. The difference between closed vessel studies, which are usually performed in the laboratory, and open systems, which occur in the field, has been discussed by Oudot.<sup>[43]</sup>

Of primary concern here is the fact that, in laboratory experiments, the products of biodegradation often inhibit microbial activity and retard degradation, whereas these products can be removed by tidal action or large volume dispersion in field environments.

The Exxon Valdez project and the Delaware project cited above demonstrated that bioremediation is an effective and safe technology for beached petroleum hydrocarbons in appropriate areas. Areas appropriate for this technology include those areas in which it can be demonstrated that hydrocarbon degraders are present and active. It is also necessary to demonstrate that the selected area is nutrient-limited. This is not always the case, as demonstrated by the “Amoco Cadiz” spill, in which fertilizer runoff from nearby

farms enhanced nutrition on oil-covered beaches. This also appears to be the case at the head of the Persian Gulf, where the Tigris and Euphrates rivers enter the Gulf, delivering nutrients washed from farmlands in Iraq. If the oil spill affected area receives a large input of nutrients, further addition maybe counterproductive.

Experience in the “Exxon Valdez” spill also indicated that bioremediation was perceived as a “natural technology,” yielding higher public acceptance. Adding nutrients, especially familiar agricultural products, gave the appearance of “helping nature.” Thus, higher public acceptance resulted in more rapid attainment of required approvals from public regulatory agencies for the application of bioremediation. Addition of non-indigenous organisms is ineffective and receives negative public scrutiny. Genetically modified organisms have not been demonstrated to yield any advantage at this point, and are often viewed with alarm by segments of the public. One great advantage in the “Exxon Valdez” project was the use of “town hall meetings” to respond to public concerns regarding bioremediation. These meetings were used to describe the bioremediation process and to answer any questions from those in the community. A frequently asked question was “what happens to the bacteria after they consume the oil”? The answer to this question is that the bacteria are consumed by higher organisms and safely converted to biomass, thus increasing “food” available to local species. This question is illustrative of the concerns expressed by the public. Bioremediation is a relatively inexpensive technology using available nutrient additives. Application involves low-impact application techniques and a low degree of labor intensity. Low-impact application techniques are an advantage in addressing the problem of beached hydrocarbon remediation with minimal disturbance of the beaches themselves. Nutrient enhancement bioremediation techniques are not only applicable to oil spills but also to soil remediation of weathered hydrocarbons, which widely occur in refineries and transportation terminals, although the case studies are not common in the open literature and mostly occur within the affected companies.

## FUTURE OF BIOREMEDIATION

Bioremediation is inexpensive, safe, and effective. However, many obstacles exist that prevent its wider use. Two of these obstacles are the lack of information on the application of bioremediation techniques, and research and policy issues that need to be addressed both in the short term and in the longer term. A major obstacle to the application of bioremediation techniques during an oil spill has been a lack of agreement

among all appropriate international, national, and local regulating agencies regarding the use of bioremediation techniques after the occurrence of an oil spill. This delays or, in some recent cases, eliminates the applicability of bioremediation as a tool for oil spill clean up. Because of the lack of agreement regarding the application of nutrient-enhanced bioremediation techniques, there has not been a general effort or plan in place for dealing with oil spills. Agreement followed by preparedness could greatly mitigate the effect of oil spills that will inevitably occur, especially in high-traffic areas. The same limitations apply as we go from the international to the national and regional level. Often, local environmental agencies are not prepared to allow for the use of novel bioremediation techniques because field demonstrations are required and the time and funding to perform them are not available. There is an urgent need for federally funded field demonstration of novel bioremediation technologies.

Application of nutrient-enhanced bioremediation techniques to problems of soils contaminated with weathered hydrocarbons has been hampered by the existence of published examples demonstrating success. This makes it difficult for regulators to approve the process for cleanup without extensive demonstration projects. The connection between published bioremediation projects that have been accomplished on “freshly spilled oil” and bioremediation of “weathered oil” has not been demonstrated. A particularly difficult point is the determination of an acceptable endpoint for the application. It is clear that bioremediation never fully mineralizes the oil leaving a residue. Therefore what is an acceptable endpoint for bioremediation? One answer appears to be that after limitations such as nutrients and oxygen are removed, the bacteria will proceed until no more hydrocarbons are “available.” By definition, if the hydrocarbons are not available to the bacteria, they are probably now in “safe” condition, and this may be an acceptable endpoint.

More research and field demonstrations need to be performed to overcome technological limitations. Foremost among these limitations is analytical determination of the agreed endpoint of bioremediation. Currently, established techniques such as the determination of “biomarker” molecules (e.g., hopanes that occur in small quantities) require costly mass spectrometry/gas chromatography. These techniques are very expensive and time-consuming. It is estimated that, in the case of the “Exxon Valdez,” the cost of application of these analytical techniques required to demonstrate effectiveness was of the same order as the nutrient-enhanced application itself. This fact is probably a major factor in preventing the occurrence of more bioremediation projects and the concurrent publication of scientifically sound results. Additionally,

the application of these techniques requires removal of the samples to remote facilities, elaborate chemical separation, and ensuing time delays. It would seem the development of a rapid technique based on molecular genetics that could be applied in the field would represent a major advance. Many questions exist, which are not only scientifically important but, if answered, will greatly advance the usefulness and applicability of bioremediation.

Insight into fundamental processes of bioremediation will be gained by pursuing the objectives described below:

1. *Development of strong laboratory/field connections:* Fundamental understanding of microbial transformations, which can be studied in the laboratory, are often difficult to connect to field bioremediation studies. In addition, expensive and time-consuming field experiments are required. When laboratory, macrocosm, and field experiments are strongly connected via proper statistical design of each, the time and cost required to demonstrate field effectiveness is greatly reduced. The utilization of controlled laboratory experiments having direct meaning to real environmental field situations would lead to advances in the use of bioremediation techniques.
2. *Development of strong connection between biological growth rates and rates of molecular transformation:* The work of microbiologists studying hydrocarbon degrading organisms and bioremediation scientists studying the rates of molecular destruction are often only weakly connected. Development of rates of transformation, which are strongly connected to biological dynamics, would greatly assist scientists and engineers to design, accelerate, and control bioremediation processes. For example, hydrocarbon destruction is most rapid when microbes are in the growth phase. Developing rate models, which directly relate the number of microbes in the growth phase with the rate of destruction of hydrocarbons, would greatly enhance our understanding of the process and ways to accelerate and control it. Greater control could be provided by biological assays (perhaps based on RNA/DNA), which would more easily and rapidly indicate the state of the bioremediating population, allowing for quicker intervention for the adjustment of unfavorable conditions.
3. *Development of an understanding of the microbial ecology of soil microorganisms:* Bioremediation experiments often slow down or accelerate in the field for reasons that are not well understood and are not related to the chemical composition of the substrate. Understanding of the relationship of the degrading organisms and their relation to physical surroundings is an important next step in controlling the delivery of nutrients and the removal of products. Such an understanding can lead to new treatments, which could greatly accelerate the rate of destruction and the completeness of remediation.
4. *Understanding predator/prey relations in bioremediation experiments:* As biomass accumulates during hydrocarbon destruction, higher organisms begin to feed on the microbes. If this occurs too rapidly, bioremediation may be slow. If it occurs too slowly, bioremediation may also slow because the microbes may fill available niches and stop growing. Understanding and control of predation could lead to new ways of accelerating bioremediation by removing biomass from the available niches, allowing more organisms to grow.
5. *Understanding of chemical endpoints of bioremediation processes:* In the destruction of spilled and/or aged hydrocarbons by microbial degradation, not all hydrocarbons are mineralized. The reason for this is not completely understood, although it is usually attributed to "bioavailability." However, there is evidence that microbes may participate in cross-linking heavier fractions of hydrocarbons via oxygen addition. This process has been termed "bioasphalting" by analogy to chemical asphaltting. If this can be demonstrated, it is good news for the bioremediation community because this could lead to the determination of a natural endpoint for the process. Bioasphalting renders that fraction which is not mineralized safe and inert.

Progress is being made in the areas described above. Longer-term research progress that will assure future improvements in the success of bioremediation will depend, to a large degree, in understanding how consortia survive and thrive in their natural environments. Furthermore, introduction of foreign organisms into the environment requires an understanding of the genetics that allow an organism to fit into its "niche" successfully. This understanding is not trivial and most introductions of foreign organisms into the environment fail because the introduced organisms are simply outcompeted by the indigenous organisms. This knowledge is essential whether the habitat is lakes, rivers, or soils; or whether we are asking the organisms to thrive in a bioreactor.

Bioremediation by anaerobic organisms continues to be of major interest especially in destroying

molecules that are recalcitrant to oxidative methods. Recently, it has been shown that anaerobic communities can destroy chlorinated benzoates, phenols, benzenes, and some pesticides. This includes PCBs, one of the most recalcitrant and ubiquitous pollutants. Ye et al.<sup>[44]</sup> reported that the dechlorination reaction is carried out by a previously unknown anaerobe that grows best in a consortium with other organisms; together, they create a food chain yielding methane and chloride. This finding emphasizes the importance of understanding the consortia and underscores the complexity contained therein. The reductive dechlorination reactions are among the very few ways that the chlorinated hydrocarbons can be destroyed. There is considerable interest in developing an anaerobic process based on this discovery. However, many hurdles need to be overcome for practical application.

Acceptance of introducing foreign organisms or genetically modified organisms into the environment requires more knowledge in understanding how genetic material is exchanged between organisms. DNA probe techniques are being developed for use in soil to detect specific gene sequences in the total soil population.<sup>[45]</sup> This allows for the study of naturally occurring gene exchange, rearrangement, and regulation. This approach will require years of research before we are able to say with certainty that we understand the processes, and that genetically modified organisms can be introduced into the environment with confidence.

## INTRODUCTION

The development of rapid, label-free methods for detecting pathogenic organisms is of intense interest, both because of the scientific challenge it represents and because of its potential importance to society. Recently, several groups have begun examining the suitability of nanocrystalline silicon (or, simply, “porous silicon”) as a substrate material for the construction of such sensors. Our own efforts have focused on the photoluminescence of porous silicon microcavities, appropriately derivatized with probe molecules for a variety of model biopolymers, viruses, and bacteria.

## BACKGROUND

Optical biosensing has traditionally required labeling a probe molecule with a soluble reporter group, typically a dye or fluorescent molecule. In microbiology, one of the most venerable techniques uses just such a scheme. In 1860, Hans Christian Joachim Gram, a Danish physician, observed that certain bacteria turned purple when exposed to crystal violet, a common dye. This observation turned out to have medical significance (for underlying molecular reasons we will discuss later),<sup>[1]</sup> and the Gram stain became a key component of microbial analysis.<sup>[2]</sup> The Gram stain is illustrative of the difficulties inherent in any label-based analytical scheme: Correct preparation of the smear, involving an initial thin film deposition of the bacteria on a glass slide followed by a heat fixing step, is crucial for an accurate reading. Failure to precisely follow the steps leads to staining artifacts or the

complete washing away of the bacteria. Furthermore, although this procedure can be rapidly carried out by those “skilled in the art,” it is not suitable for broad deployment (i.e., to be carried out by those lacking extensive training), nor is it readily generalizable to a broad range of targets.

Likewise, many solid-supported assays (i.e., sensors) rely on a labeling step to produce a signal in the presence of a target. For example, microarray systems such as those developed by the Affymetrix group<sup>[3,4]</sup> and Iyer et al.<sup>[5]</sup> rely on fluorescence tagging of oligonucleotide sequences during a polymerase chain reaction (PCR) amplification step. In this example, and in many analogous systems, the substrate material serves only a passive role. An attractive alternative is for the substrate onto which the probe is attached to play an active role in sensing, transducing a signal generated by the binding event. The construction and testing of such devices is currently an area of intense research, and has produced some notable successes (for a review, see Ref.<sup>[6]</sup>).

## RECENT DEVELOPMENTS

Over the past several years, nanoporous silicon has generated considerable interest as a substrate material for the production of active biosensors. Produced via an electrochemical etching procedure, four primary advantages make porous silicon an attractive material for biosensing applications. First, its enormous surface area ranges from 90 to 783 m<sup>2</sup>/cm<sup>3</sup>.<sup>[7]</sup> Second, its photophysical properties are responsive to environmental changes, e.g., the presence of gases. Third, a rich body of chemistry exists for the attachment of a

wide range of probe molecules. Finally, the biocompatibility of porous silicon has been demonstrated, suggesting that the production of biosensors for continuous *in vivo* monitoring is a possibility.

In general, porous silicon optical biosensors may be divided into two broad classes: those that make use of changes in reflectance and those that rely on changes in luminescence. Reflectance-based examples include the detection of organic phosphines,<sup>[8]</sup> ethanol,<sup>[9]</sup> and streptavidin–biotin interactions.<sup>[10]</sup> In the remainder of this article, we will discuss our efforts to produce porous silicon biosensors capable of specifically detecting (or, sensitively differentiating) pathogenic viruses and bacteria.

In particular, our efforts have focused on the use of microcavity structures. Porous silicon microcavity resonators possess the unique characteristics of line narrowing and luminescence enhancement. The emission peak position is completely tunable by changing the properties of the central layer. Increasing the thickness of the central active layer introduces multiple narrow peaks in the luminescence spectrum.<sup>[11]</sup> The microcavity structure is highly sensitive and any slight change in the effective optical thickness modifies the reflectivity spectra, causing a spectral shift in the interference peaks. The characteristic luminescence spectrum of a single porous silicon layer has a full width at half maximum (FWHM) value of approximately 150 nm centered at a wavelength of 750 nm. This relatively broad band emission can be narrowed by confining the luminescence between two distributed Bragg reflectors.<sup>[12–14]</sup> This microcavity-resonating structure narrows the luminescence in the forward direction to a single peak with a FWHM value of 10 nm.<sup>[15]</sup> When the cavity thickness increases, the number of luminescence peaks also increases. The porosity of the cavity is kept relatively low (<70%), which allows the formation of thick films without stress-related instabilities. For a microcavity resonator, the FWHM values for each of the photoluminescence peaks can be as narrow as 3 nm and any slight shift in the peak positions is readily observable.

## DNA DETECTION

As an initial demonstration of the utility of porous silicon microcavities as biosensors, we decided to examine the ability of appropriately functionalized devices to detect DNA. (Portions of this section are adapted from Ref.<sup>[16]</sup>). Microcavities were prepared using a highly boron-doped substrate ( $p^+$ , 0.008–0.01  $\Omega$  cm), chosen because of the wide range of porosities that can be prepared using this substrate. A programmed etching sequence was used to produce alternating layers of low (43%) and high (62%) porosity flanking a thick

“active layer” of high porosity (Fig. 1). Construction of such three-dimensional structures is possible because etching only occurs at the interface between unetched silicon and the HF bath. As visualized by electron microscopy, pore diameters in these structures are in the range of 50–75 nm. This dimension is critical in that it must be well above the predicted size of the target analytes. As the diameter of double-stranded DNA is approximately 1.8 nm, this falls well within the needed range. Following the etching process, microcavities were subjected to thermal oxidation in ambient oxygen at 900°C for 10 min. In addition to stabilizing the optical properties of the microcavity,<sup>[17]</sup> this provides a surface layer of silicon oxides (Si-O-Si and Si-OH) ideal for attachment of probe molecules.

Several different chemistries have been employed for the attachment of probe molecules to glass, ranging from simple non-specific adhesion of polyanionic oligonucleotides to a polycation such as polylysine,<sup>[18,19]</sup> to significantly more complex schemes.<sup>[20,21]</sup> We chose to first silanize the oxidized porous silicon microcavity with 3-glycidoxypropyltrimethoxy silane, providing the surface with an electrophilic site in the form of an epoxide (Fig. 2). We next treated the sample with a DNA sequence (5'-TAG CTA TGG AAT TCC TCG TAG GCA-3') bearing a 3'-amino group. This acts as a nucleophile, opening the epoxide and providing a covalent attachment between the silicon surface and the DNA probe. After allowing the epoxide-functionalized microcavity to incubate with a solution of the amino-terminated DNA for 12 hr, it was washed with glass-distilled water and dried under a stream of nitrogen. Fourier-transform infrared (FT-IR) analysis, as well as parallel experiments with radiolabeled [<sup>32</sup>P]DNA, provided evidence that this procedure yielded a microcavity with the probe DNA sequence covalently immobilized.

Fig. 3 shows the photoluminescence spectrum of the resulting DNA-functionalized chip. When the chip is incubated with a 1- $\mu$ M buffered solution of the complementary DNA strand (5'-G CCT ACG AGG AAT TCC ATA GCT-3') for 1 hr, followed by a rinsing step, the luminescence spectrum red shifts (Fig. 3, middle). This 7-nm shift is particularly observable in the difference spectrum (Fig. 3, bottom). We attribute the red

Fig. 1 Porous silicon microcavity.

Fig. 2 Attachment chemistry of DNA to epoxide-derivatized silicon.

shift, which can be interpreted as a slight change in the optical thickness of the device, to binding of the solution-phase complementary DNA strand to the surface-immobilized sequence. Control experiments, including simple treatment of the chip with buffer, and incubation of the chip with a random DNA sequence, produced no change in the photoluminescence spectrum. Together, these results provided initial support for the idea that microcavity structures fabricated in porous silicon could have utility for detecting biological molecules.

## VIRUS DETECTION

For the detection of a more complex organism such as a virus, we next decided to examine the ability of the microcavity biosensor to detect  $\lambda$ -bacteriophage. Lambda is a double-stranded DNA bacteriophage that infects *Escherichia coli* (*E. coli*).<sup>[22,23]</sup> From the 48,502-base-pair genome of  $\lambda$ -bacteriophage, we selected the 30-base sequence 5'-TCG GAG AGC CTT CCT GTT CAA TAT CAT CAT-3'. This sequence, once again bearing a 3'-amino group, was obtained from a commercial vendor and covalently attached to the silicon surface as described above. The high base-pairing specificity of DNA is an advantage here with regard to specific identification of an organism; for example, a 16- to 18-base oligonucleotide is sufficient to uniquely define a sequence within the human genome. Likewise, we anticipated that this 30-base sequence would prove capable of uniquely identifying  $\lambda$ -bacteriophage. However, potentially more troublesome was the fact that  $\lambda$ -bacteriophage, such as all double-stranded DNA, exists in solution in a highly supercoiled (folded) conformation. In addition to potentially blocking access to the base sequence of interest, we were concerned that this large particle of DNA might not be capable of penetrating into the porous structure of the microcavity. To ameliorate both of these problems, the chip was heated to 89°C in a water bath, then exposed to a 194 fM solution of  $\lambda$ -bacteriophage (obtained from New England Biolabs, Inc.). At this temperature, the DNA uncoils, and the two strands of the double helix separate. Incubation was continued at this temperature for 1 hr. In addition to keeping the DNA uncoiled and separated into complementary strands, this also presumably provides thermodynamic assistance in the penetration of the target into the pores. The temperature was then reduced to 37°C, allowing hybridization of complementary DNA strands to occur.

Fig. 4 shows the results of this experiment. As with detection of the synthetic DNA oligomer, exposure of

Fig. 3 Top: 50  $\mu$ M of DNA attached to a porous silicon microcavity structure. Middle: 1  $\mu$ M of complementary DNA is exposed to the DNA-attached porous silicon. A 7-nm red shift is observed, consistent with DNA binding. The difference spectrum is shown at the bottom.

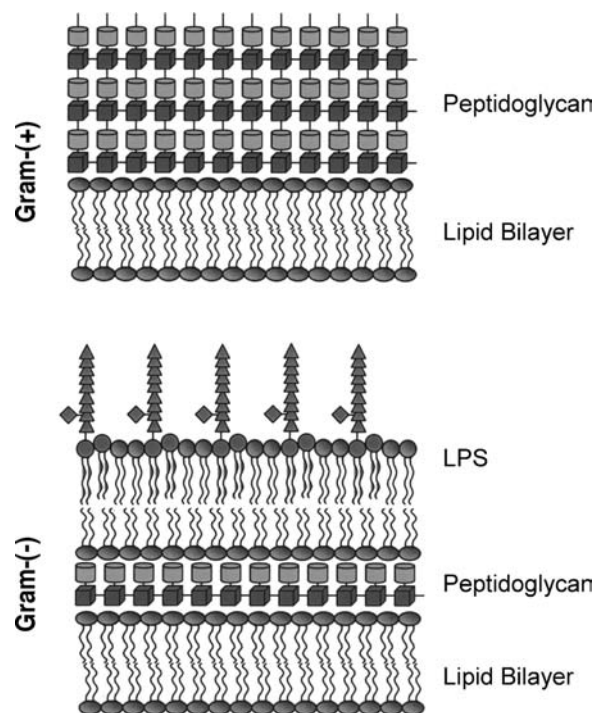

**Fig. 4** Room temperature photoluminescence spectra taken before (dotted line) and after (solid line) recognition and binding of bacteriophage lambda to a 30-nucleotide complementary DNA sequence immobilized in a porous silicon microcavity structure. A 12-nm red shift is observed for a sensing bacteriophage lambda concentration of 194.2 fM.

the probe-functionalized chip to  $\lambda$ -phage causes a red shift in the photoluminescence spectrum, presumably because of the binding of the probe sequence to the complementary  $\lambda$ -DNA. In this case, a 12-nm shift was observed. While it is tempting to relate the magnitude of the red shift to the size and concentration of the DNA sequence detected (consistent with prediction and essential to establishing the porous silicon microcavity as both a *quantitative* as well as a *qualitative* sensor), significant additional experimentation will be necessary before making such a claim.

## BACTERIUM DETECTION

Following the successful demonstration of purified DNA oligonucleotides and  $\lambda$ -phage, we were next ready to examine the suitability of the porous silicon microcavity sensor as a detector for a bacterium. (Portions of this section are adapted from Ref.<sup>[24]</sup>). One could envision functionalizing the porous silicon structures with oligonucleotides unique to the genomic sequence of the target bacterium by direct analogy to the work described above. However, although targeting genomic DNA provides inherent advantages of *specificity*, and the molecular recognition entailed is relatively straightforward, it has inherent disadvantages

of *sensitivity*. Given that each bacterium has only a single copy of its genomic DNA sequence, unless the sensor is sensitive enough to detect single-copy-number targets, it is necessary to introduce an intermediate amplification (or bacterial culture) step. An alternative strategy is to target higher-abundance molecules. In essence, this is what the Gram stain does (Fig. 5). Gram (+) bacteria are so designated because their cell walls are largely made up of peptidoglycan, a polymeric molecule to which crystal violet adheres. In contrast, the cell wall of Gram (-) bacteria is more complex, including little peptidoglycan but an outer leaflet of lipopolysaccharide (LPS, Fig. 6). Lipopolysaccharide is a primary constituent of the outer cellular membrane of Gram (-) bacteria,<sup>[25]</sup> and is commonly known as bacterial endotoxin, the causative agent of sepsis.<sup>[26]</sup> The precise structure of LPS varies among bacterial species, but is overall composed of three parts: a variable polysaccharide chain, a core sugar, and lipid A.<sup>[27]</sup> As lipid A is highly conserved among LPS subtypes, this seemed a natural target. While molecules such as LPS and peptidoglycan do not provide species-level differentiation of bacteria, but rather separate bacteria into one of two broad classes, their inherent advantage is their extraordinarily high copy number per cell. Thus we have chosen to pursue a strategy of building bacterial biosensors in stages, constructing devices capable of detecting the highest-abundance (but, perhaps, lower specificity) molecules

**Fig. 5** The molecular makeup of Gram (+) and Gram (-) bacterial cell walls.

**Fig. 6** Structure of lipopolysaccharide (LPS). *Source:* From Ref.<sup>[27]</sup>.

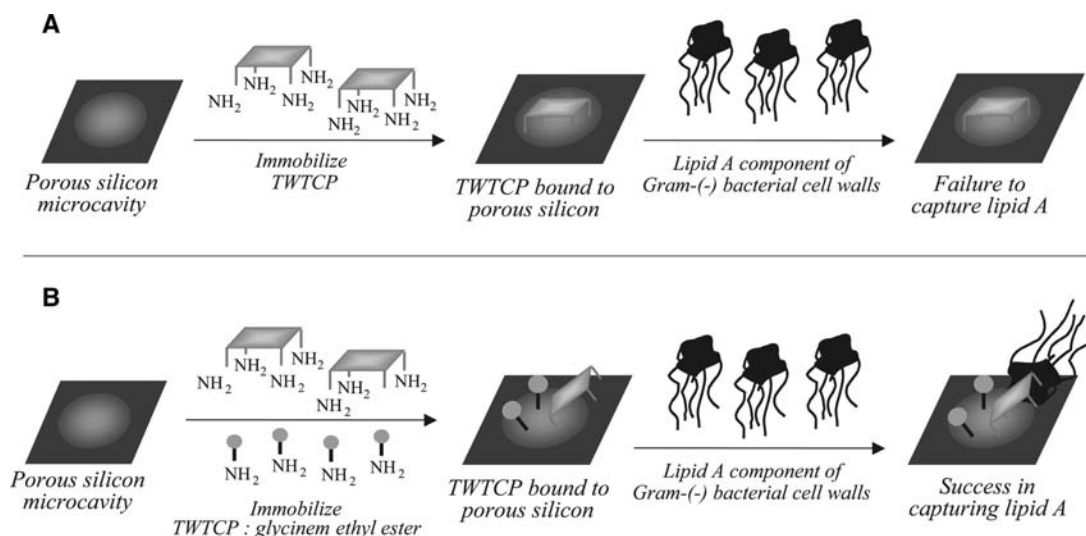

first, and then progressing to lower-copy-number/higher-specificity targets. Fig. 7 schematically shows how this might be carried out: First, a sensor capable of detecting LPS and/or peptidoglycan would provide an initial indication that bacteria were present, and differentiate them based on their Gram category. Subsequent sensors would “hone in” on the species-level identification of the bacterium present, by differentiating Gram (-) bacteria (for example) based on differences among LPS subtypes, or based on the presence of species-specific, cell-surface proteins.

We designed and synthesized an organic receptor, tetratryptophan *ter*-cyclopentane, designated TWTCP, which binds to diphosphoryl lipid A in water with a dissociation constant of  $0.6 \mu\text{M}$ ,<sup>[28]</sup> as measured by UV-Vis spectrometric titration. Confirmation of

binding was provided by NMR and fluorescence titration experiments. While one could envision employing an antibody to LPS or lipid A as the probe molecule, several potential advantages attracted us to the use of an organic compound. First, although antibodies typically have exquisite binding selectivity and affinity, as proteins they are subject to a variety of environmental factors (e.g., thermal degradation and proteolysis) that might degrade the long-term stability of the device.<sup>[29]</sup> Second, because TWTCP can be produced via a relatively short synthetic sequence, it is potentially available in very large quantities. Third, it was anticipated that covalent attachment of TWTCP to the porous silicon matrix would be more straightforward than the analogous attachment of a complex antibody. However, it should be noted that

**Fig. 7** Schematic depiction of targets for bacterial biosensor development.

**Fig. 8** Functionalization of porous silicon microcavities with TWTCP and glycine methyl ester.

antibody-based porous silicon sensors also have considerable promise, and are an object of active research in our laboratories.

Detailed fabrication steps for the porous silicon microcavity resonator, including the electrochemical preparation and postthermal oxidation treatment, were as described above. As before, to provide functionality capable of forming a stable bond between the organic probe molecule and the inorganic silicon surface, the porous silicon microcavity resonator was treated with an aqueous solution of 3-glycidoxypropyltrimethoxy silane. Subsequent exposure of this epoxide-terminated surface to an aqueous solution of TWTCP in 6% dimethyl sulfoxide (DMSO), provided a surface functionalized with the lipid-A-binding receptor. To our surprise, we found that exposure of this device to purified diphosphoryl lipid A did not produce a shift in the photoluminescence spectrum of the chip. A consideration of our working model for the interaction of TWTCP with lipid A suggested that this could be due to a reaction of all four amino groups of the receptor reacting with the porous silicon surface, thus blocking access to the binding face of the receptor molecule, as shown in Fig. 8A. A second possibility is that binding of lipid A to the sensor is precluded if sufficient interstitial space between receptor molecules is not present, a problem that has been observed in some surface-immobilized DNA binding assays.<sup>[30]</sup> If either of these were indeed the case, we hypothesized that exposure of the epoxide-terminated surface to a mixture of TWTCP and a “blocking” amine would allow for the generation of a functional sensor (Fig. 8B).

Using glycine methyl ester as the blocking amine and examining the response of the sensor to purified lipid A, we found that the optimal ratio of receptor to blocker molecules was 1 : 10 TWTCP/glycine methyl

ester (Fig. 9). In this case, incubation of the sensor with a solution of lipid A produces an 8-nm red shift in the photoluminescence peak wavelength. When a 100% solution of TWTCP, or a 100% solution of glycine methyl ester, was immobilized in the porous matrix, no shifting of the luminescence peaks was detected after exposure to lipid A. To determine the ability of this sensor to differentiate between two classes of bacteria, independent overnight cultures of Gram (–) bacteria (*E. coli*) and Gram (+) bacteria (*Bacillus*

**Fig. 9** Dependence of lipid A recognition on the use of glycine methyl ester as a blocking group.

**Fig. 10** Response of TWTCP-functionalized porous silicon microcavities to Gram (+) bacteria (*B. subtilis*, left) and Gram (–) bacteria (*E. coli*, right).

*subtilis*) were grown up, centrifuged, and then individually lysed following resuspension in phosphate buffer solution. Upon exposure of the lysed Gram (–) cells to the immobilized TWTCP biochip, a 4-nm photoluminescence red shift is detected, (Fig. 10). The equilibrium recognition and binding time of TWTCP to lysed Gram (–) bacterial cells is an important variable to determine. It dictates the time it takes for the cells containing lipid A to diffuse into the pores to seek and bind to the receptors. Experimental results reveal that the minimum time it takes to red shift the photoluminescence peaks by 4 nm is 1 hr. Prolonged time exposures of up to 5 hr show no additional shifting.

However, when the microcavity sensor is exposed to a solution of lysed Gram (+) bacteria, no shifting of the luminescence peaks is observed, depicted by the left spectra of Fig. 10. While we attribute the large shift to the recognition and binding of the TWTCP receptor with the lipid A present in the bacterial cell wall, it is also conceivable that some other factor is responsible for the differential signal. Nonetheless, these results demonstrate the ability of a porous silicon biosensor to distinguish Gram (–) from Gram (+) bacteria through changes in the refractive index of the microcavity layers. Similarly, lysed solutions of *Salmonella minnesota* and *Pseudomonas aeruginosa*, both Gram (–) organisms, produced red shifts in the photoluminescence spectra of TWTCP-functionalized porous silicon microcavities. In contrast, lysed solutions of *Lactobacillus acidophilus*, a Gram (+) organism, did

not cause any detectable change in the photoluminescence spectrum.

## CONCLUSION

We have constructed a series of porous silicon microcavity devices functionalized with probes for synthetic oligonucleotides, viral genomic DNA, and bacterial lipopolysaccharides. In each case, exposure of the microcavity to a solution of the target molecule produces a specific change (a red shift) in the photoluminescence spectrum of the device. These early results are encouraging, given the potential advantages of porous silicon as a biosensing platform. Current efforts in our laboratories are focused on optimizing sensitivity and detection speed by modifying the geometry of the microcavity.

## Abstract

The aim of this review is to give an overview of the trends in surface modification for biosensor applications. We focused this review on developments in the past decade, describing the progress both in analytical techniques for detection of biomolecules and in the methods of receptor molecule immobilization on the surface of a transducer. The review is divided into several parts that characterize different approaches of surface modification, including local surface patterning, immobilization on self-assembled monolayers, and hybrid nanostructures bioengineering.

## INTRODUCTION

There has been a recent trend toward device miniaturization and functionalization for simultaneous analysis of multiple samples in the field of biotechnology. This trend can offer various advantages to the researchers because the devices are able to provide tools to handle ultra-small sample volumes and improve detection limit of nano-biosensors and -biochips by increasing the density of receptor elements. It is also possible to control the reactivity of the receptors by engineering them with molecular precision. In this entry, we will briefly characterize methods for biomolecular recognition on the surface and surface modification methods, such as Langmuir–Blodgett (LB), Layer-by-Layer (LbL), and Self-Assembly Monolayer (SAM) approaches. The most important step for successful surface engineering for biomolecules, which demands proper orientation, is also reviewed in details. The main goal of this entry is to show the trends in local surface patterning and subsequent receptor design on the solid surface for biosensor applications.

## OUTLINES

Biosensors are perspective tools in various fields such as medical diagnosis, drug screening, environmental monitoring, and defense applications.<sup>[1–4]</sup> Bioengineering on solid surface is essential for the surface development of biosensors and is a multi-disciplinary research field including biotechnology, chemistry, physics, microelectronics, material science, etc. The technologies for the production of protein microarrays are still

under development.<sup>[5–7]</sup> For application of biosensors, it is essential to immobilize receptors on sensor surfaces, which are directly attached to solid substrates and used to detect specific target molecules. Various biomolecules, such as antibodies, nucleic acids, proteins, or catalytic ones like enzymes, microorganisms, and biomimetic catalysts have been used as receptors.<sup>[6,7]</sup>

Biosensor devices have advantages over the enzyme-linked immunosorbent assay since molecular interactions can be monitored in real time by the biosensors without labeling. There has been a strong demand for miniaturization of the biosensors, since recently it has been more important to analyze hundreds to thousands of samples in parallel.<sup>[8]</sup> Scanning Probe Microscopy (SPM) has been widely used in life science for the researches of deoxyribonucleic acid (DNA) and protein structures with the molecular resolution.<sup>[9]</sup> It is now possible to handle molecular assemblies and to pattern monolayer films because of the constant progress of SPM technologies.<sup>[10]</sup> Scanning probe microscopy methods allow to pattern sensor surfaces in a molecular level with the precise control of structure and location. The resulting nanostructures will provide promising applications in the development of biochips in the nanometer scale.

## Analytical Techniques for Detection of Biomolecules

Instrumentation for bioanalytical purposes is now well elaborated and includes various techniques,<sup>[11]</sup> such as mass spectrometry, X-ray photoelectron spectroscopy, imaging ellipsometry, infrared reflection–absorption,

fluorescence spectroscopy, and SPM methods (atomic force microscopy (AFM), scanning tunneling microscopy (STM), near-field scanning optical microscopy (NSOM), etc.). These methods can provide the essential tools to analyze the presence of proteins on solid surface, to register the morphology changes, and to measure the biospecific interactions at the molecular level. Detection of molecular interactions by biosensors is mainly based on the optical and electrochemical techniques, such as surface plasmon resonance (SPR), total internal reflection fluorescence, time-resolved fluoroimmunoassay, the displacement flow immunoassay, and electrochemical impedance spectroscopy.<sup>[12–18]</sup>

Surface plasmon resonance is one of the prevalent methods for analysis of biomolecular interactions<sup>[12,13]</sup> because of its direct detection of analytes in real time. Surface plasmon resonance biosensors have been widely used for the analysis of antigen–antibody interactions,<sup>[17,19]</sup> and also used to characterize the conformational changes of protein molecules.<sup>[12]</sup> Recently, there has been an intensive investigation on the imaging of protein arrays by spectral SPR biosensors based on wavelength-interrogation (Fig. 1). One

drawback of SPR biosensors is the detection limit of low concentration or low molecular weight analytes, but the detection limit has been improved by oriented immobilization of proteins, enhancing the response signal by streptavidin-biotinylated protein complex,<sup>[13]</sup> or using modified colloidal gold particles.<sup>[14,20]</sup>

Quartz crystal microbalance,<sup>[15]</sup> electrochemical,<sup>[16]</sup> capacitive,<sup>[17]</sup> and microcantilever biosensors<sup>[21–23]</sup> can be also widely used by the integration with microelectronic chip technology. For example, the microcantilever-based sensors are suitable for “label-free” detection of biomolecules<sup>[21]</sup> and can be operated either as microbalances (using dynamic mode of AFM) or as surface stress sensors (static bending cantilever). This cantilever vibration or bending is caused by the forces involved in the adsorption process at the cantilever surface. A femtogram mass sensing biosensor can be designed using the resonance frequency shifts of cantilevers.<sup>[22]</sup> The cantilevers produced in silicon technology can also be scalable into arrays for the differentiation of the biochemical interactions.<sup>[23]</sup> Undoubtedly, these methods will play an important role in future, specially, in the microcircuit development.

### Methods of Surface Modification: LB, LbL, and SAM Approaches

These methods produce uniform and well-organized thin films with monomolecular thickness, which may be followed by a big variety of post-patterning modification. Appropriate molecules should be used for each method.

LB method is operated with amphiphilic molecules (Fig. 2) on the water interface and used for transferring monolayer films onto solid substrates.<sup>[24]</sup> Monolayer films are typically transferred onto substrates by dipping vertically the substrates through the interface. Some proteins form well-ordered monolayers at the water phase and can be transferred onto solid surfaces using the LB technique.<sup>[25]</sup> This technique can be used to design biosensor surfaces<sup>[26]</sup> because the orientation and surface density of biomolecules can be controlled.<sup>[27,28]</sup> Indeed, the LB method gives an opportunity to design functional biological systems with appropriate orientation in lipid monolayers.<sup>[29]</sup> Such an approach has been applied to the binding of histidine-containing peptides<sup>[30]</sup> and proteins<sup>[31]</sup> to chelator-lipid monolayers at the air-water interface. As a result, using determined receptor units inside the monolayer, e.g. calix[4]arene derivatives,<sup>[32]</sup> nanomolar concentrations of the proteins can be selectively detected. Various functionalized biomimetic

**Fig. 3** Typical polyelectrolyte molecules for LbL method. (1) Poly(diallyldimethylammonium) chloride (PDDA), (2) poly(sodium 4-styrenesulfonate) (PSS), (3) polyacrylic acid (PAA), (4) polyallylamine hydrochloride (PAH).

nanostructures oriented recognition site can be constructed<sup>[33]</sup> to study artificial cell membranes in an effort, for example, to speed up the discovery of new drugs for a variety of diseases.

LbL method consists of the step-by-step electrostatic adsorption of anionic and cationic polyelectrolytes (Fig. 3) on a charged surface in solution, which has been introduced by Decher,<sup>[34]</sup> and it provides a way to fabricate ultrathin functional films on solid surfaces with nanometer resolution. By the LbL method, it is possible to change the property of inorganic surfaces and create “friendly” monolayer environments (hydrocarbon, charged, etc.) for non-specific protein binding. The method has been extended and successfully applied to the surface formation with various biomolecules such as globular proteins,<sup>[35]</sup> enzymes,<sup>[36]</sup> and even viruses.<sup>[37]</sup>

Self-assembly monolayers provide an alternative means by which molecules are self-organized into densely packed structures on a surface.<sup>[38,39]</sup> This method was pioneered by Sagiv,<sup>[40]</sup> who has introduced the hydrophobization of silicon surface with octadecyltrichlorosilane molecules. A similar approach was successfully developed especially for organic thiolate molecules (Fig. 4) on gold surface.<sup>[41]</sup> The gold-thiol reaction may be regarded as an oxidative reaction of the S-H bond with gold surface followed by a reductive elimination of hydrogen.<sup>[41]</sup> The sulfur-to-gold bond is strong and the bond strength has been reported as 40 kcal/mol. Now, SAMs of organothiols on gold have been used as a spacer layer for biomolecule attachment to the gold surface.<sup>[38]</sup> In addition, SAMs can be further modified by subsequent treatments, for example, the photochemical addition of H<sub>2</sub>S to the terminal double bond of vinyl-terminated 18-nonadecyltrichlorosilane film and attachment of new molecular layers.<sup>[42]</sup>

**Fig. 4** Organothiols for SAM film formation. (1) NTA-terminated tetra(ethylene glycol) undecylthiol, (2) biotin-capped tetra(ethylene glycol) undecanoat, (3) 1-mercapto-11-undecyl tetra(ethylene glycol), (4) 11-mercaptoundecanoic acid.

## PROTEIN IMMOBILIZATION

### Protein–Surface Interaction

Surface modification is a key technique for biosensor elaboration. However, protein–substrate and protein–protein interactions are quite complex. Protein

properties, especially, their conformation, can be changed by the contact with sensor surface, since proteins are affected at the sensor surface by van-der-Waals hydrophobic and electrostatic interactions, interfacial perturbations by multipoint attachments to the surface, pH environment, surface charge, co-adsorption of low molecular weight ions, and isoelectric points of proteins.<sup>[43]</sup> Bound proteins may lose their activity resulting from the immobilization chemistry or inappropriate orientation. Hence, the biological activity of biomolecules on immobilization on the chip surface should be preserved. Immobilized molecules must retain their native conformation to ensure proper function at the surface without denaturation. That is why, during the last few years, special interest has been paid to the studies on the nature of the protein–surface interaction to control the biomolecule adsorption process.<sup>[44]</sup> Biomolecules can be immobilized on the surfaces by other methods, for example, physisorption or chemisorption, copolymerization, covalent chemical coupling, and supramolecular interactions.<sup>[45,46]</sup> Immobilization of antibody molecules from immunoliposomes has been also used in several biotechnological applications.<sup>[47]</sup> In addition, protein solutions can be applied to the surfaces by inkjet printing or electrospray.<sup>[48]</sup> However, the deposition of liquid samples followed by drying can result in protein aggregation and loss of biological activity.

Simplest approach includes incorporation of antibodies<sup>[49]</sup> or enzymes<sup>[50]</sup> into thin films. This approach is quite promising because repeated assays by regeneration is possible. A whole range of antibodies with different specificities can be bound to and dissociated from the surfaces simply by lowering the pH of the solutions.<sup>[51]</sup> It has been reported<sup>[52]</sup> that the structure and orientation of adsorbed proteins is dependent on the charge of the film. For example,

**Fig. 5** AFM-images of transferrin molecules (1 mg/ml) immobilized on (A) PDDA/PSS/PDDA and (B) (PDDA/PSS)<sub>2</sub> on mica surface.

transferrin bound to the negative charged surface displayed normal morphology and behavior, whereas the protein unfolded on the strongly positive-charged surface did not (Fig. 5).

The advantage of protein immobilization by physico-sorption method on film surfaces is reversible reaction. Indeed, protein interactions on surfaces have physical nature and the interactions are easily disturbed by salt concentration (phosphate buffered saline (PBS) solution, for example), pH environment, and competitive reactions in the solution. However, the immobilized biomolecules can be susceptible to the reduction of biological activities by inappropriate orientation of the biomolecules caused by physical adsorption.

### Covalent Immobilization

Covalent coupling of molecules, on the other hand, is irreversible and thus stable. Glass, quartz, or silicon surface can be modified with aminopropyltriethoxysilane or mercaptopropyltrimethoxysilane for biomolecule coupling. In particular, siloxy linkage can be applied for the activation of glass or silicon surface by aminopropyltriethoxysilane in dry toluene, resulted in the formation of covalently bound siloxane film.<sup>[53]</sup> However, majority of works have been focused on the gold surface immobilization due to its better-elaborated chemistry based on thiols.<sup>[54]</sup> The antibodies are usually linked to gold substrates using bifunctional reagents with a thiol group on one side.<sup>[55]</sup> Representative bifunctional molecules are shown in Fig. 6.

*N*-hydroxysuccinimide/ethylcarbodiimide cross-linking is one of the most popular methods for immobilization of proteins and nucleic acids on sensor surfaces.<sup>[56,57]</sup> The NHS/EDC covalent coupling results in the formation of mainly amide bonds between enzymes and SAM molecules.<sup>[58]</sup> However, immobilization by the covalent coupling may result in the random orientation of biomolecules because the functional groups used for the attachment can be found in more than one location of the biomolecule surfaces. So, the biomolecules may lose their biological activities by the random orientation on their support surfaces.<sup>[59]</sup>

The best approach to control the orientation of immobilized biomolecules is to selectively attach a pre-determined site of the protein on the sensor surface. There have been reports on the methods to control the orientation of immobilized proteins on the surface,<sup>[60–63]</sup> such as i) site-specific oriented attachment of biomolecules to gold surfaces through thiol- or cysteine-containing enzyme, ii) orientation with hetero-bifunctional photoactivatable cross-linking agents, and iii) oriented immobilization of antibodies by the use of immobilized protein A or G, or biotin–streptavidin interaction. Indeed, it is possible to genetically

**Fig. 6** Chemicals commonly used for silicon (1,2) and gold surface modification (3–7). (1) Octadecyltrichlorosilane (OTS), (2) aminopropyltriethoxysilane (APTES), (3) *N*-hydroxysuccinimide (NHS), (4) di(*N*-succinimidyl)-3,3'-dithiodipropionate (DTSP), (5) 3-(2-pyridyldithio)propionic acid *N*-hydroxysuccinimide ester (SPDP), (6) 4-maleidobutyric acid *N*-hydroxysuccinimide ester, (7) *N*-(3-dimethylaminopropyl)-*N'*-ethylcarbodiimide (EDC).

incorporate functional coupling site(s) into the protein structure<sup>[60,61]</sup> or to implement reductive splitting of antibodies by 2-mercaptoethylamine<sup>[62]</sup> with subsequent immobilization to solid surfaces. Specific binding of antibodies against antigens was successfully observed by using splitted immunoglobulins<sup>[62]</sup> or cysteine-modified antibodies.<sup>[60]</sup>

The universal tools to properly orient antibody molecules are protein A and G from *Staphylococcus*, which specifically bind to the Fc regions of antibodies. After immobilizing protein A or G to the surface by NHS/EDS or SPDP/EDS cross-linking reaction, it is possible to attach antibodies with the desired orientation for the antigen binding. In addition, avidin and biotin can be used as a cross-linking bridge between proteins and surfaces. Indeed, avidin and streptavidin are tetrameric proteins and their binding

sites are located in pairs on either side of the protein molecule. Thus, when avidin or streptavidin is attached to gold surface via one or two binding sites, the other binding sites are exposed to the solution.<sup>[64]</sup> Hence, the appropriate binding of streptavidin or avidin to the solid surface<sup>[65]</sup> can produce an oriented protein film.

At last, there have been reports on heterobifunctional, photoactivatable cross-linking agents for protein conjugation,<sup>[66]</sup> which are commercially available. Most of these compounds contain aryl azides as the photophore. The major problem for patterning the substrates with photolithography is the chemicals involved in the process, which may denature the immobilized proteins and then reduce their activity.

### Immobilization on SAMs

Self-assembly monolayers prepared by bifunctional compounds (Fig. 4) are extremely important and promising for bioengineering of sensor surfaces. SAMs can be used for both adsorption of biomolecules and appropriate orientation of macromolecules. Covalent coupling of proteins and peptides is achieved by the conjugation of COOH-terminated SAMs with NHS esters. Such cross-linkers can be used to covalently attach biomolecules to the surfaces that are coated with thin films of hydrophilic polymers, e.g., poly(ethylene glycol) (PEG) or pluronic triblock copolymers.<sup>[67]</sup> Polynucleotides are also anchored to preformed alkanethiol SAMs via NHS/EDC cross-linking reaction.<sup>[68]</sup>

Quite perspective is the use of mixed SAMs for biomolecules. The mixture of two molecules allowed the creation of a range of surfaces with varying hydrophilicity and different functions.<sup>[39,69]</sup> In this approach, mixed monolayers, consisting of biotinylated alkanethiols and an ethylene glycol-terminated alkanethiol, were used. The latter helps to optimize the density of binding sites and to reduce non-specific binding to the surface.<sup>[69]</sup> Indeed, long-chain alkylthiols, terminated by PEG (Fig. 4), effectively prevent non-specific binding of proteins.<sup>[70]</sup> Minimization of non-specific interactions can also be obtained by covering gold- or glass-surfaces with thin layers of dextrans.<sup>[71]</sup>

In addition, protein immobilization on SAM can be achieved through chelating interactions. Indeed, gold surface can be modified by SAMs with metal-chelating alkanethiols<sup>[72]</sup> as well as oxide surfaces with metal-chelating silanes.<sup>[73]</sup> The free coordination sites of the chelator-metal complex subsequently react with histidine residues of proteins. The binding of proteins to the NTA derivative (Fig. 4) is highly specific and fully reversible on addition of a competitive ligand (histidine or imidazole), reprotonation of the histidine residues, or removal of the metal ion via EDTA.

### Hybrid Nanostructures for Bioengineering

Nanocrystals derivatized with biological molecules have been applied in biological research in recent years.<sup>[74,75]</sup>

There is a possibility that the conjugation of nanoparticles (NP) to different biomolecules such as DNA,<sup>[76]</sup> proteins,<sup>[77]</sup> antibodies,<sup>[78]</sup> short peptides<sup>[79]</sup> with subsequent conjugate targeting to receptor sites of analyte.

Self-assembly of chemically constructed hybrid metal-organic nanostructures from solution onto solid surface with molecular precision may be extremely useful for the fabrication of nanodimensional biosensors in future as an alternative to the conventional microfabrication techniques. Recent advances in this area are based on the use of ligand stabilized gold nanoparticles.<sup>[80,81]</sup> It has been reported that the conjugation of DNA oligomer-Au nanoparticle conjugates with complementary sequences are selective and reversible.<sup>[82]</sup> And there have been reports on a variety of Au nanoparticle-based DNA assays. Other standard system for the preparation of DNA-gold conjugates has used the biotin-streptavidin coupling method, in which biotinylated DNA binds to streptavidin-coated gold colloids.<sup>[83]</sup> In addition, DNA hybridization has been used to assemble Au nanoparticles onto patterned substrates prepared by the lithographic approach.<sup>[84]</sup> Gold nanoparticles emit light, so intense that it is easily possible to observe a single nanoparticle at laser sub-100 fs pulses of 790 nm light.<sup>[85]</sup> Hence, the NP conjugates are a viable alternative to fluorophores for biological labeling and imaging.

The biomolecule-nanoparticle hybrid systems can be also used for bioelectronic applications provides a high surface area matrix with excellent charge transport properties for the electrical contacting of enzymes with the electrode.<sup>[86]</sup> The fluorescent conjugates NPs with antibodies yields biomarkers, which can compete and even replace the traditional organic fluorescent tags in terms of biocompatibility, excitation, and photostability.<sup>[74,75]</sup> Nanoparticles have a broad excitation spectrum, but emit only at a characteristic emission wavelength. Some of them were bright enough to visualize even a single dot, and their subsequent conjugation with proteins do not affect the yields much. Various organic and inorganic materials have been utilized as capping materials on the surface of nanoparticles through covalent or ionic interactions.<sup>[38,87]</sup> These capping agents stabilize nanocrystals in solution. For example, CdSe NPs are often overcoated with ZnS layer; these improve the fluorescence quantum yield and decrease NC toxicity.<sup>[87]</sup> Cadmium selenide nanoparticles coated with zinc sulfide can then be functionalized with a bifunctional SAM either directly or via ligand exchange to tune a surface charge of the nanocrystals and incorporate any of the most relevant biological functional groups

**Fig. 7** Fluorescence image of a cell culture decorated with “CdSe/ZnS/ligand” nanoparticles.

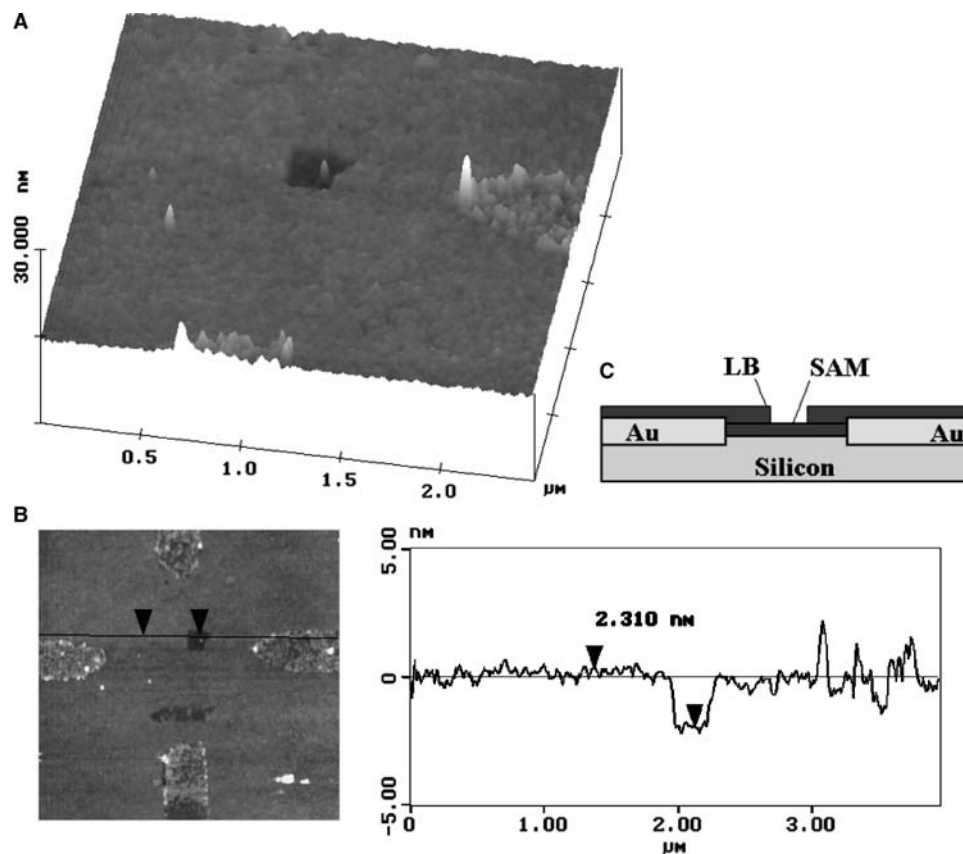

(-COOH, -NH<sub>2</sub>, -OH) for the generation of shells with biocompatible surfaces. Fluorescence image of cancer and living cells after treatment with the NPs shows selective NP penetration through outer membrane of living cells only (Fig. 7). Obviously, capping

molecules play a determined role as the connecting media of the NPs to the biological probe. As an ideal case, immobilization strategy should be based on specific interactions between the biological target molecule and tailored modifications of the NP surface.

## SURFACE PATTERNING

In biosensor technology, surface patterning has been increasingly perspective for the elaboration of high-density multianalyte chips. Surfaces can be chemically patterned using a number of techniques, such as photolithography,<sup>[88]</sup> microcontact printing ( $\mu$ CP),<sup>[89]</sup> and microfluidic patterning.<sup>[90]</sup> These techniques can also be sorted into two categories: i) indirect methods and ii) direct active placement. The active methods include inkjet and pipette deposition.<sup>[91]</sup> It is also possible to directly pattern biomolecules on a solid substrate by  $\mu$ CP without loss of biological activity.<sup>[89]</sup>

Photolithography creates protein patterns on the substrates by using chemical linkers to conjugate proteins.<sup>[66]</sup> Photochemical patterning uses chemically labile species, which can be activated on irradiation to target proteins for binding.<sup>[92]</sup>

**Fig. 8** Result of mechanical scratching of topmost LB monolayer on SAM sub-layer. (A) 3D view, (B) cross-sectional analysis, and (C) schematic diagram of the sample.

Templates with variable surface chemical properties can be patterned on SAMs.<sup>[93]</sup> A patterned SAM can be fabricated by decomposition of UV light or an electron beam,<sup>[94]</sup> or etching the SAM by a SPM tip.<sup>[95]</sup> Argon ion or electron beam lithography can produce smaller patterns (down to tens of nanometers), but requires a high-vacuum environment. In addition, surface properties can be worse by photoresistance used. On the contrary,  $\mu\text{CP}$ <sup>[96]</sup> is a simple, flexible, and efficient patterning technique, which was introduced by Whitesides and coworkers in 1993 for patterning SAMs of alkanethiols onto gold substrates.  $\mu\text{CP}$  makes molecule-based patterns with sub-100-nm resolution and is well combined with the formation of microfluidic networks.  $\mu\text{CP}$  can transfer proteins onto a variety of substrates (hydrophilic or hydrophobic) including glass, gold, silicon, polymer surfaces, and monolayers on gold.

Microcontact printing of a pattern of hydrophobic alkanethiols can generate sites where proteins will deposit from solution after blocking the unprinted parts of the gold substrate with thiolated PEG.<sup>[56]</sup> In the process of surface patterning, proteins should selectively bind to the active surface and have strong repulsion from other regions of the substrate. This method provides a possibility to deposit proteins from solution into patterns.<sup>[97]</sup>

Recently, a new strategy to fabricate the SAM nanopattern by “dip-pen” nanolithography (DPN) has been reported.<sup>[98]</sup> Tips of microscope may have an influence on samples and commonly modify the sample surface on the molecular level. Because of this reason, SPM methods have been evolved into so-called Scanning Probe Lithographic (SPL) methods, which may be applied to the protein surface patterning. By SPL methods, it is possible to scratch SAM, LbL, or LB films mechanically (Fig. 8), and to derivatize electrode surfaces by STM.<sup>[99]</sup> It is also possible to transport organic molecules from the AFM tips to the surface in the area specifically defined by the tip/surface interaction by DPN,<sup>[98]</sup> and to incorporate reactive sites into SAMs by “nanoshaving”.<sup>[100]</sup>

In particular, DPN is a technique to fabricate patterns of chemical functionality like organothiols on gold,<sup>[101]</sup> and even gold particles on silicon.<sup>[102]</sup> It is shown that the molecular transport from the AFM tip with adsorbed molecules to substrates is determined by the probe geometry, water meniscus properties, and the chemical nature of the “ink”.<sup>[98]</sup> However, the mechanism of the DPN process is more complex. In particular, it was proved with octadecanethiol as an example that the water meniscus is not universally responsible for DPN molecular transport between the AFM tips and substrates.<sup>[103]</sup>

Reversible translocation has been observed in the hybrid CdTe/behenic acid composites, which is dependent on the applied force to the AFM tip.<sup>[104]</sup> Since monolayer films are easily self-reorganized on the surface,<sup>[105]</sup> it is reasonable to consider the DPN transfer as the local self-organization process, pushing molecules into energetically more favorable state on the surface. Hence, DPN process can be expanded on a big variety of surface-active molecules and considered as an extremely perspective technique for surface modification.

In addition, electrooxidation of terminal groups of alkylsilane SAMs seems quite promising, since only a few nanometer lines could be drawn by conducting AFM tip in inert matrix.<sup>[106]</sup> Subsequent self-assembly of organic and inorganic building blocks can be developed on the activated part of the SAM surfaces by surface chemistry.<sup>[42]</sup>

## CONCLUSION

It is clear that miniaturization and simultaneous analysis of multiple samples are the general tendency in the development of biosensors. Progress in nanotechnology will require approaches from various research fields of science and engineering. Indeed, SPM methods can not only visualize the surface of protein layers, but also recognize biomolecules. For example, by the methods, it is possible to quantify immunological reactions and to probe the adhesive forces of antigen–antibody interactions. In the near future, high-speed AFM imaging in solution may provide a tool to analyze biomolecule interactions on the sensor surface in real time.

Well-defined immobilization schemes and technological approaches have already been elaborated. Their combination will allow the construction of desired functions on the determined area of sensor surfaces. Indeed, it is possible to directly replace SAM molecules onto the sensor surface because the SAM molecules under AFM tip can be removed and replaced by the new adsorbate molecules into solution. This method can provide a new approach for site-directed attachment of functional molecules to the sensor surface. In addition, hybrid multi-structures can be constructed by the combination of patterning techniques with LB method on LbL or SAM films.

Thus, there has been a constant progress for nanotechnological development of biosensors, and continuous development will provide promising and powerful tools for the analysis of biomolecules in the near future. Nanoarrays are the next stage in the evolution of the miniaturization of microarrays.

## ACKNOWLEDGMENTS

We thank Dr. Thierry Ondarcuhu and EM team from CEMES, CNRS for the mutual work in the framework of Nanomol project. We also thank Drs. Jong Seol Yuk and Sun-Ju Yi for their works on the construction of SPR biosensor and protein microarray analysis. This work was supported in part by research grants from the Vascular System Research Center of KOSEF and the Advanced Backbone IT Technology Development Project from the Ministry of Information and Communication.
