and  $B^{III}$  is a Group 3B (B, Al, Ga, In) cation or transition metal ion in +3 oxidation state]. As a unit cell has 32  $O^{2-}$  ion and only 4 are present per molecule (from the formula), then spinel structure has 8 (64/8) tetrahedral and 4 (32/8) octahedral vacancies per molecule of  $AB_2O_4$ . When  $A^{2+}$  ions occupy one eighth of a tetrahedral (1 out of available 8) hole and  $B^{3+}$  ions occupy half (2 out of available 4) of an octahedral hole, the structure is called “normal” spinel, e.g.,  $MgAl_2O_4$ . This is a very stable arrangement even in terms of coordination, having tetrahedral arrangement about a divalent cation and octahedral arrangement about a trivalent cation. In some cases, one half of  $B^{3+}$  ions exchange their positions with  $A^{2+}$  ions. This is called “inverse” spinel, e.g.,  $NiFe_2O_4$ . In this arrangement, one eighth of tetrahedral sites are occupied by half of  $B^{3+}$ , whereas the rest of  $B^{3+}$  ions along with  $A^{2+}$  ions occupies half of the octahedral sites. If the general formula for “normal” spinel is written as  $(A)[B]_2O_4$  to suggest ( ) and [ ] representing tetrahedral and octahedral coordination, then the general formula for “inverse” spinel is written as  $(B)[AB]O_4$ . Many MMOs

also have intermediate cation distribution between these two extremes. The general formula for these structure is then written as  $(A_{1-x}B_x)[B_{2-x}A_x]O_4$ , where  $x$  is the “inversion parameter” ( $0 < x < 1$ ).<sup>[58,59]</sup>

Nanocomposites of  $ZnFe_2O_4$  and  $TiO_2$  were studied by Yuan and Zhang.<sup>[51]</sup>  $TiO_2$  (anatase phase) and  $ZnFe_2O_4$  (spinel phase) with broad diffractions were recorded (Fig. 5A). This means that in the composite,  $TiO_2$  and  $ZnFe_2O_4$  crystallite phases separate each other, having small size. Fig. 5B and C shows composite begins to form at 600°C. Anatase to rutile transformation takes place at 700°C. (Fig. 5D and E). The strongest peak ( $2\theta = 25.3^\circ$ ) disappears and, simultaneously, two new peaks of phases  $ZnTiO_3$  and  $Fe_2TiO_5$  appear. This shows the following solid-phase reaction might be taking place at annealing temperature.

Measurement of grain sizes in comparison with values of  $TiO_2$  and  $ZnFe_2O_4$  shows the following: (1) As

**Fig. 5** XRD patterns of the  $\text{ZnFe}_2\text{O}_4/\text{TiO}_2$  composite with a molar ratio of  $\text{Zn}:\text{Ti} = 0.1$  after annealing at various temperatures for 2 hr. A = anatase, R = rutile, S = spinel, \$ =  $\text{Fe}_2\text{TiO}_5$ , # =  $\text{ZnTiO}_3$ . Source: Reprinted with permission from Ref.<sup>[51]</sup>.

annealing temperature increases, the grain size of  $\text{TiO}_2$  increases. (2) In composite, an increase in temperature has the same effect of growth of  $\text{ZnFe}_2\text{O}_4$  as it does on pure  $\text{ZnFe}_2\text{O}_4$ . TEM analysis proved particles are distributed homogeneously and particles grow with uniform sizes.

### Perovskite Structures

Perovskite-phase MMO ceramics are important because of changes in their physical properties on application of an external electrical stimulus. These properties include ferroelectric, pyroelectric, piezoelectric, and dielectric behavior. These have led to numerous applications in electromechanical transducers, light modulation, charge storage, nonvolatile memory applications, etc.<sup>[23,24]</sup> The class of MMOs having the formula  $\text{ABO}_3$  (such as  $\text{CaTiO}_3$ ) is called perovskite. The structure of this mineral was first thought to be cubic but later confirmed as orthorhombic. The truly cubic form is referred to as “ideal perovskite” having a unit cell edge of  $\sim 4 \text{ \AA}$  containing one  $\text{ABO}_3$ . In perovskite structure, large cation A is surrounded by 12 oxide ions to form cuboctahedral coordination, while B cation is surrounded by 6 oxide ions in an octahedral coordination.

Nanophase powders of  $\text{Y}_x\text{Zr}_{1-x}\text{O}_{2-x/2}$  have been prepared from a mixture of  $\text{ZrO}_2$  and  $\text{Y}_2\text{O}_3$  powders.<sup>[60]</sup> It is shown that depending upon the starting powder mixture composition, the yttrium content in nanophases can be controlled to obtain tetragonal or

cubic phases. Tetragonal or a mixture of tetragonal and cubic were observed for low yttria content (3.5 mol% yttria), and cubic for higher yttria contents (19, 54, and 76 mol% yttria). These powders were found to have a most probable grain size of about 10–12 nm, and the grains appeared as isolated single crystals with polyhedral shape. The grain shape appeared to be polyhedral and not too anisotropic. Lattice figures were parallel to surfaces, showing that (100) and (111) face dominates.<sup>[17]</sup>

### PROPERTIES AND APPLICATIONS OF MIXED METAL OXIDE NANOPARTICLES

Properties of MMO nanoparticles are mainly size dependent, and their chemical and physical properties are unique in comparison to corresponding bulk materials. The study of physical and chemical properties is interesting as it allows gradual transition from atomic or molecular to condensed matter systems. As the particle size decreases, the percentage of atoms residing on the surface increases. This makes MMO nanoparticles more reactive, as atoms/ions are more reactive than their bulk counterparts because of coordinative unsaturation. Because of this and high surface-to-volume ratio, it is not unusual to see unique behavior and characteristics of MMO nanoparticles, including insulating oxides. When strong chemical bonding is present, delocalization varies with size; this in turn can lead to different chemical and physical properties.<sup>[17]</sup>

### Acid–Base Behavior (Catalysts)

Several oxide composites have been found to be potential catalysts for a variety of important reactions because of different centers present in the same material and their basicity or acidity.<sup>[61,62]</sup> This behavior varies from one MMO to another. Some exhibit surface basic behavior and some surface acidic behavior, whereas mixtures show unusual properties. The mixing of two oxides can enhance the catalytic activity many fold because of synergistic effects, as seen in the mixed aerogel of titania/zirconia. The acid strength increases and active sites are more than pure titania and zirconia. This is probably because of oxide–oxide interaction at molecular level, suggesting that co-gelling two metal oxides is an effective way to bring two oxides in close contact.<sup>[17]</sup>

### Unusual Adsorptive Properties

Perhaps one of the greatest promises of MMO nanoparticles in chemistry is their ability to chemically adsorb a wide range of organic molecules or inorganic gases that are considered as hazardous environment pollutants. They not only adsorb but also dissociate these to nonhazardous substances on their surface. Carnes, Kapoor, and Klabunde<sup>[46]</sup> studied the adsorption of CCl<sub>4</sub>, SO<sub>2</sub>, and paraoxon on both Al<sub>2</sub>O<sub>3</sub> and Al<sub>2</sub>O<sub>3</sub>/MgO.

#### Reaction of Al<sub>2</sub>O<sub>3</sub> and (1/1) Al<sub>2</sub>O<sub>3</sub>/MgO with CCl<sub>4</sub>

The reaction of CCl<sub>4</sub> with Al<sub>2</sub>O<sub>3</sub> and Al<sub>2</sub>O<sub>3</sub>/MgO was carried out to understand the destructive adsorption abilities of the metal oxides toward a model chlorocarbon at elevated adsorption temperatures.

Thermodynamics predicts that the samples containing or being made of MgO will be more reactive than the Al<sub>2</sub>O<sub>3</sub> samples.<sup>[31]</sup> However, surface area, crystallite size, and morphology play important roles.

#### Sulfur dioxide adsorption on aluminum and aluminum/magnesium oxide

Adsorption of SO<sub>2</sub> was carried out to learn if the adsorption properties are different for nanocrystals (NC) when compared to commercial microcrystals (MC).<sup>[46]</sup> The experimental results showed that at atmospheric pressure and room temperature, SO<sub>2</sub> adsorbed onto NC-Al<sub>2</sub>O<sub>3</sub> up to 3.5 molecules

SO<sub>2</sub>/nm<sup>2</sup>; similarly, on CM-Al<sub>2</sub>O<sub>3</sub> there were 3.5 molecules SO<sub>2</sub>/nm<sup>2</sup> adsorbed, and on NC- (1/1) Al<sub>2</sub>O<sub>3</sub>/MgO there were 6.8 molecules SO<sub>2</sub>/nm<sup>2</sup>, whereas on CM-MgO there were only 0.68 molecules SO<sub>2</sub>/nm<sup>2</sup> adsorbed. These data indicate that NC-Al<sub>2</sub>O<sub>3</sub>/MgO efficiently adsorb SO<sub>2</sub> in slightly more than one layer. After adsorption, the samples were subjected to dynamic vacuum to remove the physisorbed species. The vacuum treatment removed most of the adsorbed SO<sub>2</sub> from the CM-MgO, whereas the NC-Al<sub>2</sub>O<sub>3</sub>/MgO sample retained 3.9 chemisorbed molecules of SO<sub>2</sub>/nm<sup>2</sup>.

### CONCLUSION

Mixed metal oxide nanoparticles can provide great diversity of substances and phenomena. Different metals in their various oxidation states can combine in different ratios to produce a variety of materials. These new materials with variation in physical, chemical, and morphological properties can be exploited in various fields of science and technology. The compression of nanoscale ceramic particles yields more flexible solid objects, apparently because of the multitude of grain boundaries that exist. After further development of compression techniques so that highly densified nonporous MMO nanomaterials can be prepared, these may find uses as replacements for metals in many applications including electrochemistry. These materials, beyond doubt, would be environment friendly, not only by themselves but also as future water purifiers and destructive adsorbents. These MMO nanoparticles are finding use in antichemical/biological warfare, in air purification, and as an alternative to incineration of toxic substances. Mixed metal oxide nanoparticles would also be replacing many heterogeneous catalysts known today because of high surface area, which increases their efficiency many fold. Research on the effect of particle size (percent dispersion as a measure of the fraction of metal atoms on the surface and thus available to incoming reactants) and shape (crystal faces, edges, corners, defects that lead to enhanced surface reactivity) has been and continues to be a potential field. In general, the ability to prepare MMO nanoparticles for use in high surface area catalysis has certain inherent advantages, and further progress is sure to come in the near future. It has been proposed that further work in the area of nanophase ceramics may lead to increased flexibility, less brittleness, and greater strength. It may also be possible to form materials with a large fraction of atoms at grain boundaries, maybe in unique arrangements. It may also be possible to produce binary materials of normally immiscible oxides. This entry has explored the synthetic, structural, and application

prospects that MMO nanoparticles provide. Although relatively few examples have been chosen, all relevant areas have been covered.

## INTRODUCTION

Biopolymers such as nucleic acids and proteins encode biological data and may be viewed as strings of chemical letters. While electronic computers manipulate strings of 0's and 1's encoded in electric signals, biologically encoded data might, in principle, be manipulated by biochemical means. During the last decade, several approaches to compute with biomolecules were developed, and the field has become known as biomolecular or DNA computing. The approaches varied widely with respect to the model of computation they employed, the problems they attempted to solve, and the degree of human intervention. One approach focused on the application of the Turing machine model and, more generally, string-processing automata to biomolecular information processing. Its goal is to construct computers made of biomolecules that are capable of autonomous conversion of an input data-encoding molecule to an output molecule according to a set of rules defined by a molecular program. Here we survey the field of biomolecular computing machines and discuss possible future directions.

## BACKGROUND

The seminal work of Adleman<sup>[1]</sup> demonstrated that commonly used biochemical manipulations of DNA can be utilized to solve real-world computational problems and initiated the field of biomolecular computing. In the biomolecular approach to computing, the computational paradigm is chosen to fit the capabilities of biomolecules, rather than adapting the biomolecular machinery to computational schemes borrowed from electronic computers.<sup>[2]</sup> The problems initially solved by DNA computing were so-called “combinatorial problems.” An example of such a problem is the traveling salesman problem, which is to find the most efficient route through several cities given a distances chart between them, passing through each city exactly once. Solving the problem can be performed by calculating all possible routes that pass

exactly once through each city, comparing them and choosing the shortest one. As the number of potential routes is exponential in the size of the problem, this computation may require an exponential number of steps. More efficient solution methods are not known for the traveling salesman problem and for similar such problems, termed NP-hard. It was hoped that the potential massive parallelism of DNA manipulation could speed up the solution of NP-hard problems. The DNA computing technique employed to solve the traveling salesman problem included 1) generation of all possible solution candidates (e.g., various routes) encoded in DNA strands and selection of the correct ones, 2) their amplification and detection by known molecular biology techniques, and 3) isolation and characterization of the shortest one. Computational problems solved in vitro with variations of this approach encompassed instances of Hamiltonian Path,<sup>[1]</sup> SAT,<sup>[3]</sup> maximal clique,<sup>[4]</sup> and “knight move”<sup>[5]</sup> problems. The computer, i.e., the physical system that produced a solution, comprised the biomolecules themselves, the laboratory equipment required to realize their biochemical manipulation, and the laboratory personnel who operated the laboratory equipment, performing the operations required to execute the computation. Therefore while these computing systems used biomolecules for computation, they realized laboratory-scale, rather than molecular-scale, computers.

A second direction in DNA computing, proposed by Winfree,<sup>[6,7]</sup> uses self-assembly of DNA tiles.<sup>[8,9]</sup> It relies on the mathematical theory of tiling. One result of this theory discovered by Wang<sup>[10]</sup> is that aperiodic assembly of appropriately designed tiles emulates the operation of a Turing machine, a universal computer. The tiles have colored edges, and they may be assembled once two adjacent tiles have edges of the same color. DNA tiles<sup>[8]</sup> are relatively rigid flat constructs with four sticky ends, with one sticky end emulating one edge of a tile and different sticky ends emulating different colors. DNA tiles make contact through complementary sticky ends, emulating recognition by the same color. Initial breakthrough in this area was achieved by constructing a periodic

two-dimensional crystal from DNA tiles, based on Wang assembly rules. The first actual computation performed by this technique was a cumulative XOR (exclusive OR) logical operation on a string of four binary bits.<sup>[9]</sup> In this experiment, an input string was built from alphabet tiles (either “0” or “1”) and then a second row of tiles self-assembled upon it. The first tile of the second row contained the result of the XOR operation between the first two bits, and each subsequent tile performed the operation between the intermediate cumulative result and the next unprocessed bit. Besides the potential to realize universal computation through Turing machine emulation, the technique of DNA tiles self-assembly may become a basis for fabrication of smart, aperiodic materials on a nanoscale, as suggested by several recent results.<sup>[11,12]</sup>

A third direction in DNA computing is an attempt to realize the vision,<sup>[13]</sup> recalled by Adleman in the conclusion to his seminal paper of a programmable, autonomous, molecular-scale computer: “In the future, research in molecular biology may provide improved techniques for manipulating macromolecules. Research in chemistry may allow for the development of synthetic designer enzymes. One can imagine the eventual emergence of a general purpose computer consisting of nothing more than a single macromolecule conjugated to a ribosomelike collection of enzymes that act on it.” This paradigm of biomolecular computers is the focus of our review. It views a DNA strand as a string or a tape that functions as the input as well as the memory storage for *automata* such as a finite automaton or a Turing machine.<sup>[13]</sup> This paradigm is inspired by the realization that some biomolecular machines in the living cell are essentially simple automata operating on digital information encoded in directional biopolymers.<sup>[14,15]</sup> An automaton operates by scanning a tape of symbols one symbol at a time, possibly modifies one symbol in each step, moving to an adjacent symbol and changing its state according to a predefined set of the transition rules. The tape of symbols may be naturally encoded in a polar biopolymer such as DNA or RNA. The transition rules of the machine may be encoded by transition molecules similar to tRNA. A transition, i.e., the physical modification of the input according to the transition rules, may be accomplished, in principle, by a combination of different processing enzymes. Taking this viewpoint, DNA and RNA polymerases, the ribosome, and recombinases can all be viewed as simple molecular automata. For example, RNA polymerase is, mathematically speaking, a so-called finite state transducer, which translates a string over the alphabet {A, T, C, G} into a string over the alphabet {A, U, C, G} according to a simple translation table. An artificial molecular automaton may be able to operate autonomously, realizing a truly molecular-scale

computer. Such a computer could have several important applications, discussed below.

The concept of a biomolecular computer was first introduced by Bennett<sup>[13]</sup> in 1982 as a hypothetical design for an energy-efficient computer. In this conceptual design, a set of artificial enzymes encoded the transition table of the machine and operated on RNA-based data tape. The design did not include any concrete implementation details. Several detailed designs were proposed since then. Rothmund<sup>[16]</sup> and Smith<sup>[17]</sup> proposed models for molecular implementations of Turing machines. Garzon et al.<sup>[18]</sup> designed a model of finite automata and Sakamoto et al.<sup>[19,20]</sup> implemented a semiautonomous state machine that could perform state transitions.

## MOLECULAR AUTOMATA

### Automata

Generally, an automaton consists of 1) a data tape divided into cells, each containing a symbol selected from the tape alphabet, and 2) a finite-state device driven by transition rules. The device is positioned over one of the cells and is in one of a finite number of internal states. Depending on the symbol read and the internal state, a transition rule instructs the device to write a new symbol, change state, and move one cell to the left or to the right. The Turing machine<sup>[21]</sup> is the most general automaton, capable of writing on the tape as well as moving in either direction. Fig. 1A demonstrates a Turing machine with two symbols and two states, with the upper part of the panel showing the application of one transition rule. Each rule is of the form *initial state, current symbol* → *new state, new symbol, direction of movement* (R = right, L = left). A more restricted, yet important, class of automata is called finite-state acceptors (finite automata for short).<sup>[22]</sup> A finite automaton is a unidirectional read-only Turing machine. Its input is a finite string of symbols. It is initially positioned on the leftmost input symbol in a default initial state and, in each transition, moves one symbol to the right, possibly changing its internal state (Fig. 1B is an example of a computation step of a finite automaton). Each of its transition rules specifies a next state based on the current state and current symbol. The computation terminates after the last input symbol is processed. Alternatively, it may suspend without completion when no transition rule applies. Some states are deemed accepting and the automaton accepts an input if there is a computation with this input that ends in an accepting final state. Otherwise, it is said to reject the input.

A finite automaton with two states and an alphabet of two symbols is shown in Fig. 1C. It determines

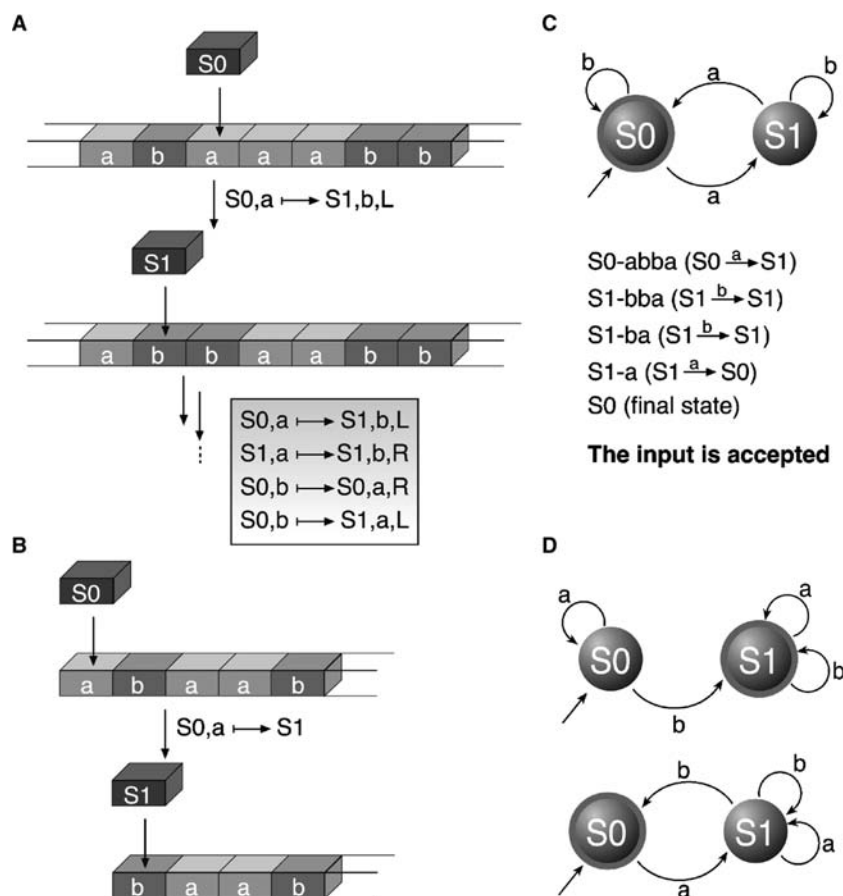

Fig. 1 Examples of automata.

whether a string of symbols over the alphabet  $\{a, b\}$  contains an even number of  $a$ 's. On a diagram, an incoming arrow represents an initial state, and a double circle represents an accepting state. Below the diagram, a sample computation over an input  $abba$  shows the intermediate configurations obtained during the sequential application of the transition rules.

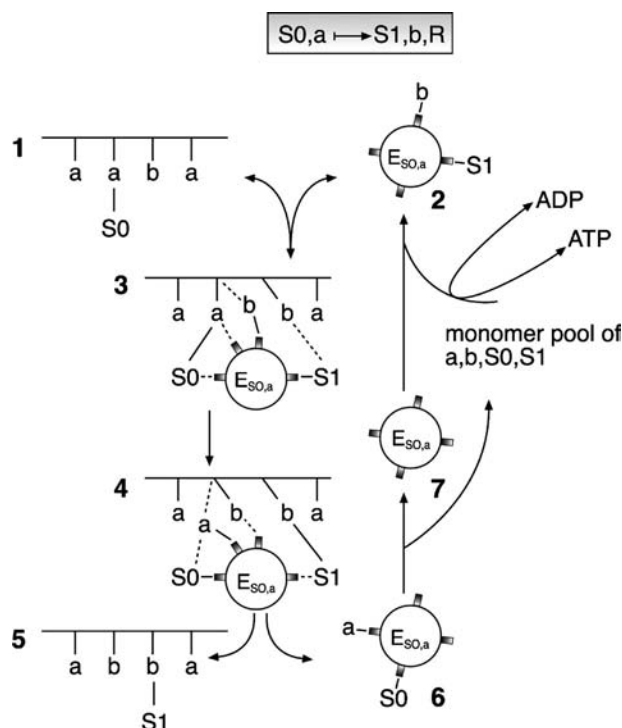

A two-state, two-symbol automaton can have eight possible transition rules. The programming of such an automaton amounts to selecting the transition rules and determining the accepting states. Figure 1D shows some examples of additional final automata. The top-most automaton determines whether an input string contains at least one  $b$  symbol. A second one determines if an input string begins with  $a$  and ends with  $b$ . It is an example of a non-deterministic automaton with two transitions ( $S1, b \rightarrow S0$  and  $S1, b \rightarrow S1$ ) applicable to the same configuration. A computation ending in an accepting state uses  $S1, b \rightarrow S1$  for all  $b$  symbols except the last, and uses  $S1, b \rightarrow S0$  for the last  $b$ .

### Early Designs of Molecular Automata

Bennett<sup>[13]</sup> described a “truly chemical Turing machine” with a linear tape analogous to RNA, where

the internal state and head location are realized by a special chemical modifier attached to one of the nucleotides. Each transition rule is realized by a hypothetical “enzyme” that exclusively recognizes a unique combination of a nucleotide and its modifier, replaces a nucleotide by an output symbol, and attaches a next-state modifier to one of the adjacent nucleotides, according to the desired head movement (Fig. 2).

In Fig. 2, a transition molecule **7** that recognizes a combination of the symbol  $a$  and the state  $S0$  loads itself with the molecule for the symbol  $b$  and a molecule for the state  $S1$ . The loaded molecule **2** reversibly attaches itself to a data tape **1**. An intermediate complex **3** forms through new chemical bonds between the transition molecule and the symbol  $a$  and state  $S0$ , between the new symbol  $b$  and the data tape, and between the adjacent symbol  $b$  and the new state  $S1$  (dotted lines). In the next intermediate **4**, the old symbol  $a$  and state  $S0$  become attached to the transition molecule and are detached from the data tape; the new symbol  $b$  is inserted into the data tape; the new state  $S1$  attaches to the symbol  $b$  that lies to the right of the site of newly inserted symbol. The transition molecule **6** dissociates from the completely modified data tape **5** and is subsequently stripped of the attached old state and symbol.

**Fig. 2** An example of a single transition performed by Bennett's hypothetical chemical Turing machine. The rule implemented is  $S0, a \rightarrow S1, b, R$ . Source: From Ref.<sup>[13]</sup> © Kluwer Academic/Plenum Publishers.

Bennett introduced several logical elements that remain relevant till this day. First, he proposed to encode a data tape in a single biopolymer, using a natural "alphabet." Second, he introduced the important concept of a "transition molecule," i.e., representation of each transition rule by a separate molecule or molecular assembly.

Following work on molecular automata dealt with realizing this concept. Different ways to encode tape symbols and machine states and to build transition molecules were proposed and various biochemical transition mechanisms were considered.

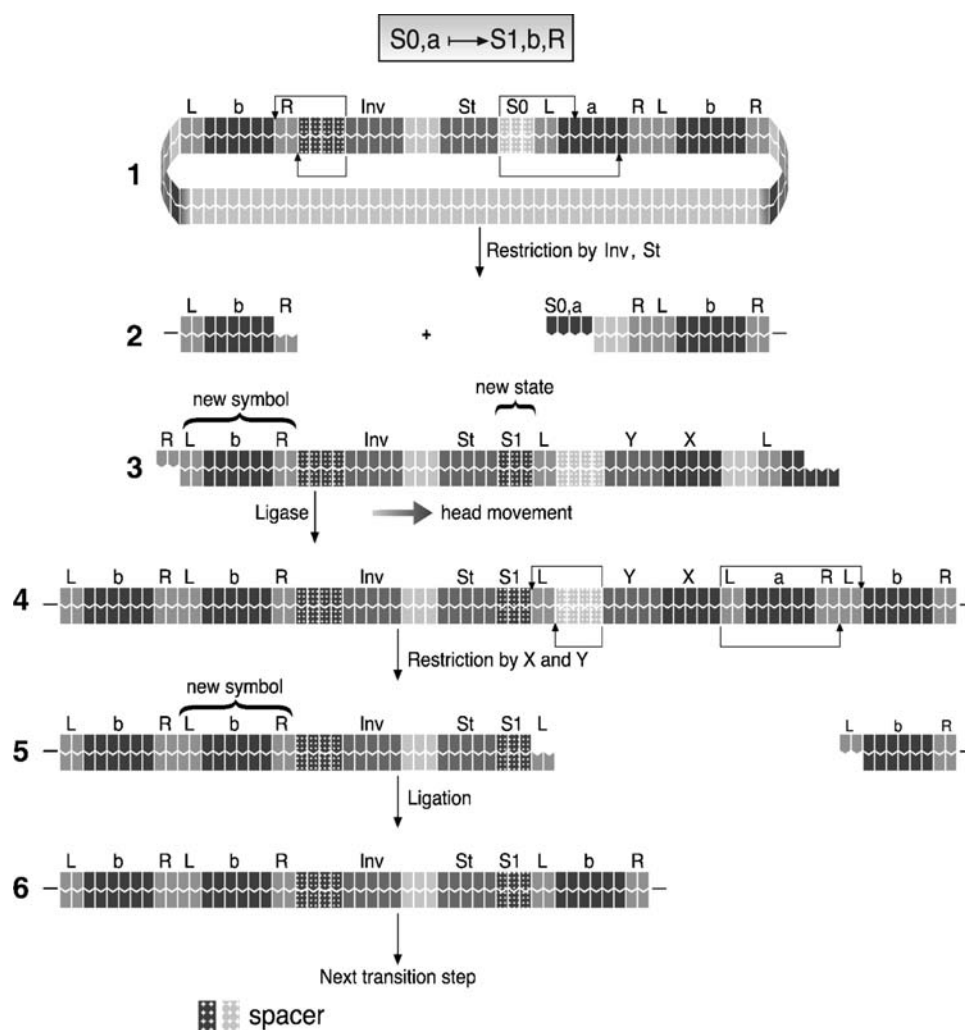

Rothemund<sup>[16]</sup> proposed a detailed design for a molecular Turing machine that utilized a common DNA structural motif known as a "cohesive terminus" or a "sticky end." A sticky end is a short (one to six nucleotides) stretch of single-stranded DNA emerging from the double-stranded DNA molecule of a potentially unlimited length. The advantage of a sticky end as compared with the dsDNA is that it is reactive and may interact once the DNA sequences of their sticky ends are complementary, irrespective to the sequence of their double-stranded part. This technique is extensively used in recombinant DNA technology. Rothemund's hypothetical computer comprised a data tape and transition molecules made of DNA

and hardware containing DNA ligase and restriction enzymes. Ligase is an enzyme that may glue together fragments of DNA that have complementary sticky ends. Restriction enzymes recognize specific locations in the double-stranded DNA and cut inside or near this location, forming two fragments with complementary sticky ends. Rothemund pioneered an encoding system of "frame shifts," where a long stretch of double-stranded DNA encoded a symbol while shorter sticky ends derived from this stretch encoded state-symbol combinations. This entailed a particular design of the transition molecules, using SII-type restriction enzymes that cut DNA outside their recognition sequence. The machine was not designed to be autonomous as it required a number of manual steps to perform a single transition (Fig. 3).

Figure 3 describes a single transition  $S0, a \rightarrow S1, b, R$  as implemented by Rothemund's hypothetical Turing machine. In this design, each data symbol is represented by a stretch of dsDNA flanked by invariant left (**L**) and right (**R**) short sequences. The starting circular double-stranded DNA structure **1** represents a data string  $bab$  and a Turing machine head, located at a symbol  $a$ . Inside a "head," there are two SII-type enzyme recognition sites. One is denoted **Inv** and another **St** for "state enzyme." **Inv** enzyme invariantly cuts in the **R** region of a symbol that lies to the left of the head. **St** enzyme cuts inside the current symbol  $a$ , and the exact restriction site is determined by the length of a spacer between the **St** recognition site and an **L** region of the current symbol. This spacer is denoted as **S0**.

After double restriction by **Inv** and **St**, the enzymes are removed and a modified data tape **2** with two sticky ends is formed. One is inside the **R** region of the leftmost  $b$  symbol. Another lies within the coding sequence of a current  $a$  symbol. Because the exact structure of this sticky ends depends on both the current symbol and the current state. This sticky end is recognized by the transition molecule **3**, which encodes a rule  $S0, a \rightarrow S1, b, R$ . It contains two sticky ends: one recognizes the current state-symbol sticky end of the data tape, and another one recognizes the sticky end within the **R** region of the left-hand symbol. Its dsDNA region contains, from left to right, an encoding for a new symbol  $b$ , a spacer and a recognition site of the **Inv** enzyme, a recognition site of the **St** enzyme, a new state spacer (**S1** in this case), **L** region, another spacer, two recognition sites of the auxiliary SII-type enzymes **X** and **Y**, and another **L** region.

The solution containing the transition molecules is added to the cleaved data tape **2**. Because real computation would require many different kinds of transition molecules, the existence of an invariant sticky end in a data tape would allow it to react non-selectively with

**Fig. 3** A single transition  $S_0, a \rightarrow S_1, b, R$  as implemented by the Rothemund's hypothetical Turing machine. *Source:* From Ref.<sup>[16]</sup> © American Mathematical Society.

different transition molecules. Therefore the original design contained only right-hand state-symbol specific sticky end. The left-hand sticky end was exposed by yet another restriction enzyme after correct ligation to the state-symbol sticky end and washout of the useless transitions (not shown on the figure). Following double ligation and insertion of the transition molecule, an intermediate structure **4** is formed. At this stage, the new symbol  $b$  is inserted into the tape. The head is also inserted, with the new state encoded by the new state spacer. However, the previous symbol  $a$  is regenerated. It needs to be excised by means of the enzymes  $X$  and  $Y$ . The enzymes form two complementary sticky ends in the intermediate **5**: one in the  $L$  region of the right-hand symbol  $b$ , and another one in the  $L$  region preinserted in the transition molecule. After their ligation, the next legal configuration **6** is formed. The  $St$  enzyme is now positioned at the correct distance from the next symbol  $b$ . Thus this multistep

transition process results in an insertion of a new symbol  $b$ , excision of a previous symbol  $a$ , and change of the machine state from  $S_0$  to  $S_1$ .

Sakamoto et al.<sup>[19,20]</sup> described a different approach to biomolecular state machines. While their system implemented only a fixed state-to-state transition scheme, which is not dependent on any input, it had the advantage of semiautonomous operation. The system was experimentally verified and shown to perform several transitions (Fig. 4).

Figure 4A shows a set of transition rules. Panel B depicts the molecular transition table. Each state is encoded by unique sequence of a ssDNA of 20–30 nt long. A transition between  $S_1$  and  $S_2$  is represented by a concatenation of two sequences, one complementary to  $S_1$  and another one—to  $S_2$ . The “stop” segment does not allow DNA polymerase to pass through. Figure 4C shows the initial configuration of the machine. A transition table is concatenated to the

**Fig. 4** A molecular state machine of Sakamoto et al.

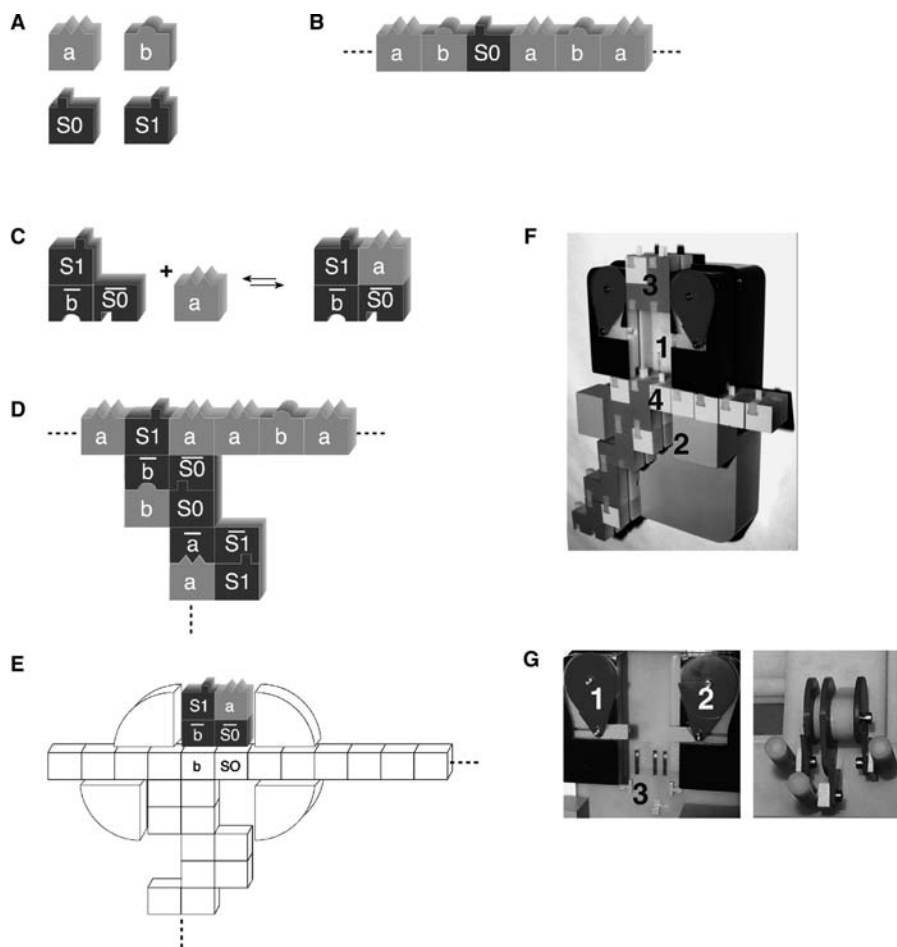

initial state S1. Figure 4D describes a sample computation. Initial state S1 is annealed to its complementary counterpart in the rule  $S1 \rightarrow S2$  of the transition table and then extended by DNA polymerase to form a DNA stretch for S2. After denaturation and another annealing, the S2 stretch is annealed to its counterpart in the rule  $S2 \rightarrow S3$  and extended to S3 stretch. The whole process is performed in the PCR-like manner, termed “Whiplash PCR” with cycles of denaturing, annealing, and polymerase extension.

Shapiro<sup>[14,15]</sup> proposed a detailed logical design for a molecular Turing machine, with an emphasis on a general-purpose programmable computer that may operate in vivo and interact with its biochemical environment. The design was realized in a working mechanical implementation.

The structural blocks of the design proposed by Shapiro are depicted in Fig. 5. The mechanical computer employs a chain of basic building blocks (Fig. 5A), referred to as *alphabet monomers*, to represent the Turing machine’s tape (Fig. 5B), and uses another set of building blocks (Fig. 5C), referred to as *transition molecules*, to encode the machine’s transition rules. The computer operates on two polymers simultaneously: the *tape polymer*, representing the Turing machine’s tape, and the *trace polymer*, which is a byproduct of the computation constructed incrementally from displaced transition molecules and displaced alphabet monomers and has no analog in

the theoretical Turing machine. A transition molecule loaded with an alphabet monomer specifies a computational step of the computer similarly to the way an aminoacyl-tRNA specifies a translation step of the ribosome.<sup>[23]</sup> The transition encoding is similar to a Wang tile construction<sup>[10]</sup> which is also at the basis of DNA computing via self-assembly.<sup>[6–9]</sup> The set of loaded transition molecules constitutes the computer *program* (Fig. 1A). A description of the design and mechanism of operation is shown in Figs. 5 and 6. Figure 5C shows the formation of a transition molecule and Fig. 5D shows an active transition molecule. An active transition molecule joins the two data polymers. It is embedded in the tape polymer and represents the location of the Turing machine’s read/write head as well as the machine’s internal state. At the same time, the active transition molecule is the terminal molecule of the trace polymer, representing the most recent transition of the computation. Figure 5E schematically depicts the computer (hardware). The computer is made of two subunits, referred to as *small* and *large*, each with a tunnel called the *small tunnel* and the *large tunnel*, respectively. The small tunnel provides incoming loaded transition molecules with access to the active transition molecule and to its adjacent alphabet monomer. Access is controlled by gating mechanisms that block transition molecules that are ill-formed or do not match the current state and current tape symbol. These mechanical analogs of

**Fig. 5** Structural blocks of the Shapiro's mechanical Turing machine.

allosteric conformational changes open the channel only when a valid incoming transition molecule approaches. The large tunnel holds the active transition molecule and the tail of the trace polymer being constructed.

The actual mechanical computer is  $18 \times 29 \times 9$  cm as shown in Fig. 5F. The small tunnel **1** is part of the small subunit and is 2 units wide. The large tunnel **2** is part of the large subunit and is 3 units wide, so that it can accommodate the displaced transition molecule and the new active transition molecules. The small and large subunits can move one unit sideways relative to each other. Such movement is necessary following a change of direction of the computation. An incoming transition molecule **3** is approaching the active transition molecule **4** and the alphabet molecule to its right. The tape polymer can move left or right 1 unit, aligning the active transition molecule to the left or to the right side of the large tunnel. Such movement is necessary to accommodate consecutive transitions in the same direction. The hardware as well as the data tapes and the incoming transition molecule are shown.

Figure 5G shows the mechanical implementation of the gating mechanisms, front (left) and back views.

Five mechanisms in the small tunnel prevent erroneous transitions from occurring. All mechanisms are based on a spring-loaded bell crank/cam which is connected to a linkage which, in its free state, blocks passage of the approaching transition molecule. Each bell crank/cam checks for a certain condition and, if the condition is met, is rotated. The connected linkage then moves out of the way of the approaching transition molecule, essentially effecting a conformational change in the tunnel. Two mechanisms **1** and **2** detect that the (left or right) transition molecule is loaded with an alphabet molecule. Mechanism **3** detects that the recognition site of the incoming transition molecule matches the state side group of the active transition molecule and the alphabet symbol to its right. Additional two mechanisms check for the blank transition.

The computer operates in cycles (Fig. 6), processing one transition molecule per cycle. In each cycle, an incoming loaded transition molecule **2** that matches the current state and its adjacent alphabet monomer of the data polymer **1** becomes the new active transition molecule and its accompanying alphabet monomer is incorporated into the tape polymer via the intermediate **3**. This is achieved by displacing the

**Fig. 6** Operational cycle of the Shapiro's mechanical Turing machine.

currently active transition molecule and the matched alphabet monomer, effectively editing the tape polymer, and elongating the trace polymer by the displaced molecules to form the next configuration 4. Specifically, when processing a left transition molecule, the computer moves left to accommodate the molecule, if necessary, and displaces the currently active transition molecule and the alphabet monomer to its left by the new molecule. The computer processes a right transition molecule similarly by moving right and displacing the alphabet monomer to the right of the active transition molecule.

The trace polymer created during the computation represents past state changes and head movements, as well as the symbols that were “erased” from the tape during each transition, and as such has several important advantages. First, the trace polymer renders the computer reversible. Because the trace polymer embodies a complete record of the computation, a molecular implementation of the computer will be

subject to the speed/energy consumption tradeoff of reversible devices. Second, computation traces, in general, and the trace polymer, in particular, enable many “software” program analysis and debugging tools,<sup>[24]</sup> which are critically needed for large-scale applications. Third, the trace polymer enables “hardware” error detection and correction. One expects that any biomolecular implementation of the computer may exhibit non-negligible error rate. Such errors can be detected, and possibly also corrected, by cascading several computers along the same trace polymer, each detecting, and possibly also correcting, errors produced by its predecessor.

The most important property of the mechanical computer is that it is reactive:<sup>[25]</sup> it can have an ongoing, program-controlled, interaction with its environment. This capability is a result of the biologically inspired architecture of the computer rather than inherited from the theoretical Turing machine, which was conceived as a “batch” computing device that receives its input at the beginning of the computation and produces an output if and when the computation ends. The ribosome, for example, suspends the construction of a polypeptide chain when a required amino acid is unavailable. Similarly, this computer can be “programmed” to suspend until a specific molecule is available. The availability of such a control molecule can be tied to other relevant environmental conditions, thus triggering a computation only when these conditions prevail.

The Turing machine is a non-deterministic computing device in that it can make choices during a computation, and so is the mechanical computer. In a biomolecular implementation, this capability can be used to have the environment affect the course of a computation, based on the relative concentrations of molecules that enable one computational step compared with molecules enabling a different computational step. Using these two capabilities, the computer can be programmed so that both the timing and the course of a computation are affected and controlled by the biochemical environment.

The computer is endowed with an output device as follows. A simple extension to the Turing machine design is an instruction that erases the tape segment to the right of the read/write head. This instruction would mean in this context: “cleave the tape polymer to the right of the active transition molecule and release this tape polymer segment to the environment.” With this instruction, the computer can create and release any effectively computable polymer of alphabet monomers, in any number of copies, in the course of a computation. A cleaved tape polymer segment released by one computer can serve as the initial tape for the computation of another computer, or it can be ligated under certain conditions to the tape of

another computer, thus enabling parallel processing, communication, and synchronization among multiply operating computers.

The computer design allows it to respond to the availability and to the relative concentrations of specific molecules in its environment and to construct program-defined polymers and release them into the environment. Hence if implemented using biomolecules, the computer can be part of biochemical pathways. In particular, given a biomolecular implementation of the computer that uses ribonucleic acids as alphabet monomers, one can envision how cleaved tape polymer segments can function as messenger-RNA, effecting program-directed synthesis of proteins in response to specific biochemical conditions within the cell. Such an implementation can provide a family of computing devices with broad biological and pharmaceutical applications.

### Molecular Finite Automata

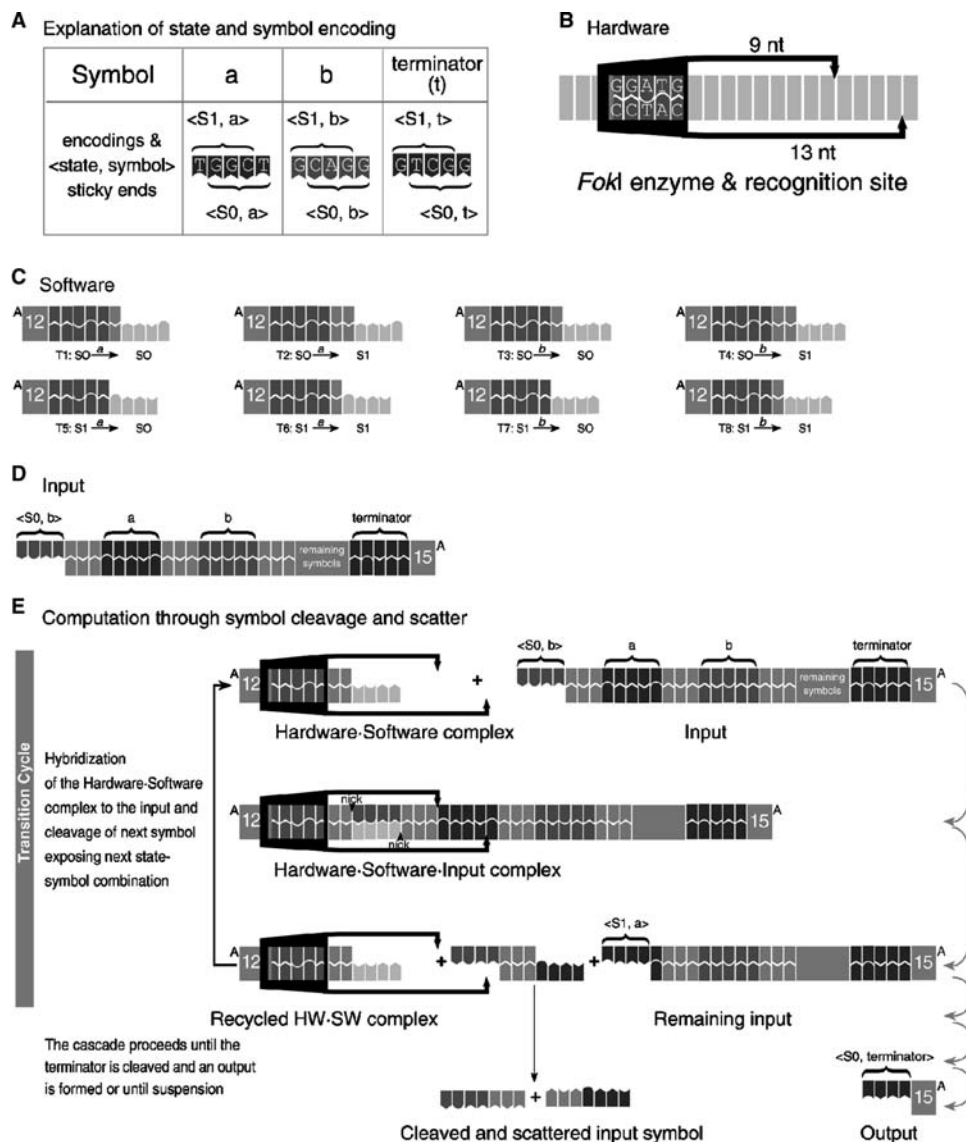

Two programmable, autonomous finite automata made of biomolecules were demonstrated by Benenson et al.<sup>[26,27]</sup> Both use a DNA molecule as input, DNA molecules as software, encoding the automaton transitions, and DNA-manipulating enzymes as hardware. The differences between the two are the source of energy for the computation and the reuse of software molecules. The first automaton relies on ATP as an energy source and consumes its software molecules during computation, while the second utilizes solely the energy stored in the chemical bonds of its DNA input molecule and its software molecules are reusable. While having similar logical structures, these versions differ in the implementation details. The design of the molecular finite automaton incorporates ideas from designs for molecular Turing machines.<sup>[15,16]</sup> The hardware of the first automaton consists of a mixture of the class IIS restriction nuclease *FokI*, T4 DNA ligase, and ATP, while the second automaton utilizes only *FokI*.

The structure of the latter automaton is shown in Fig. 7. Figure 7A shows the encoding of *a*, *b*, and terminator (sense strands) and the <state, symbol> interpretation of exposed 4-nucleotide sticky ends, the leftmost representing the current symbol and the state S1, similarly the rightmost for S0. Fig. 7B shows the hardware: the *FokI* restriction enzyme, which recognizes the sequence GGATG and cleaves 9 and 13 nucleotides apart on the 5' → 3' and 3' → 5' strands, respectively. The software comprises eight short double-stranded (ds) DNA molecules, the transition molecules encoding the eight possible transition rules (Fig. 7C). It consists of a <state, symbol> detector (light gray), a *FokI* recognition site (dark gray), and a spacer

(intermediate gray) of variable length that determines the *FokI* cleavage site inside the next symbol, which, in turn, defines the next state. Empty spacers effect S1 to S0 transition, single base-pair (bp) spacers maintain the current state, and 2-bp spacers transfer S0 to S1.

A dsDNA molecule encodes the initial state of the automaton and the input (Fig. 7D), with five to six base pairs (bp) coding for one input symbol (Fig. 7A), with the exposed sticky end at the 5'-terminus encoding the initial state and the first symbol. The ligase-based system may also contain "peripherals," two output-detection molecules of different lengths, each of which can ligate selectively with a different output molecule to form an output-reporting molecule that indicates a final state and can be readily detected by gel electrophoresis. In the ATP-free system, the output is detected by examining the length of the remainder of a processed input molecule. The computation starts when the hardware, software, and input are all mixed together and runs autonomously, if possible till termination. The automaton processes the input as shown in Fig. 7E. The computation proceeds via a cascade of transition cycles. In each cycle, the sticky end of an applicable transition molecule may ligate to the sticky end of the input molecule, detecting the current state and the current symbol. Alternatively, it may hybridize non-covalently. In both cases, the product is cleaved by *FokI* inside the next symbol encoding, exposing a new four-nucleotide sticky end. The design of the transition molecules ensures that the encodings of the input symbols *a* and *b* are cleaved by *FokI* at only two different "frames",<sup>[16]</sup> the leftmost frame encoding the state S1 and the rightmost frame encoding S0 (Fig. 7A). The exact next restriction site and thus the next internal state are determined by the current state and the size of the spacers (Fig. 7C, intermediate gray) in an applicable transition molecule. The computation proceeds until no transition molecule matches the exposed sticky end of the input or until the special terminator symbol is cleaved, forming an output molecule that has a sticky end encoding the final state. In a step extraneous to the computation and analogous to a "print" instruction of a conventional computer, this sticky end may ligate to one of two output detectors and the resultant output reporter may be identified by gel electrophoresis.

The ATP-free automaton has several advantages over the ligase-based version. First, the software molecule used in a transition is recycled because it undergoes no modification. Thus a finite number of software and hardware molecules may, in principle, process an input of any length. Second, much better performance characteristics may be achieved with the ATP-free automaton because the processing does not involve the usually slow ligation step. Using stoichiometric amounts of the software and the hardware

**Fig. 7** Design details and mechanism of operation of the molecular automata of Benenson et al. *Source:* From Ref.<sup>[27]</sup> © PNAS.

molecules, it is possible to process a single symbol in a few seconds. On the other hand, the ligase-based automaton is less structurally restricted. It may utilize different SII-type restriction enzymes as a hardware, including those that require a covalently bonded substrate. More importantly, it was found<sup>[27]</sup> that the ability of *FokI* to cleave DNA with its recognition and cleavage sites attached by sticky-end hybridization was limited to specific hybridization complexes. Long spacers and low GC content often resulted in cleaving only one of the input strands, producing a computationally illegal configuration. Correct performance was achieved with short spacers and high GC content of the sticky ends. The final design used the shortest possible spacers of 0, 1, and 2 bp (Fig. 7C), which dictated a particular symbol encoding (Fig. 7A) and the introduction of spacers between the symbols

(Fig. 7D). Using ligase may relax some of these constraints.

These molecular automata may be viewed from two perspectives. On one hand, the computations were performed with bulk amounts of the input molecules. Each molecule was processed independently and in parallel, thus the inputs could potentially be distinct. The parallel character of the computation could be employed in a hypothetical process of screening of DNA libraries. Large libraries of molecules could be filtered through the same software, for a search of certain sequence feature. Traditional approach to the same problem would require (non-parallel) sequencing of the whole library and then running non-parallel computer algorithms on the sequences. To analyze parallel performance of our system, the cumulative number of unit operations in a unit time per unit

volume was measured. This would represent an upper limit on the complexity of the libraries that could be analyzed. The parallel performance of the ligase-based version was in the order of  $8.3 \times 10^6$  operations/sec/ $\mu\text{L}$ , while in the ATP-free case, the performance was improved almost 8000-fold and reached  $6.6 \times 10^{10}$  operations/sec/ $\mu\text{L}$ .

Another approach is to try and scale down the system to run it in a very small compartment such as living cell. Then the question is what are the minimal requirements from the operational system. It is not unfeasible that a mixture of a single input molecule, four software molecules, and one or two *FokI* molecules could form a functioning computer while placed in a sufficiently small volume (to avoid dilution). While such possibility still requires experimental demonstration, it is possible to estimate its characteristics from the process performed in the bulk. Scaling down the concentrations, such a “minimal computer” would fit in a cube with a side length of 100 nm. The size of each component is in the range of several nanometers, with long inputs being tens of nanometers long. Such a computer would be a truly nanoscale computer. A computation on a single input molecule would proceed at a rate of 1000 sec per step in the ligase-based version and about 20 sec in the ATP-free version. While such rates seem slow compared with the electronic computers, they reflect the properties of biological systems. Once these computers would be able to operate in a cell, their performance would be competitive with respect to other cellular processes.

## CONCLUSION

The notion of a biomolecular computing machine has evolved gradually over the past decades. Theoretical designs proposed for such machines eventually led to simple molecular computing machines functioning in the test tube. The field may develop in several directions. First, more complex computing machines could be designed and built. This includes general finite automata, string transducers, stack automata, and, ultimately, the Turing machine. Currently, progress in this direction seems to be hampered by the lack of DNA- and RNA-manipulating enzymes; we hope that an eventual progress in enzyme engineering may supply the tools required to develop more complex machines. Another important issue relevant to many machine designs is symbol encoding. Current experimental realizations utilize artificial alphabet of pre-designed DNA sequences. However, the computer should “understand” natural alphabets of either single nucleotides or amino acid codons to be biologically relevant. Designing even the simplest finite automaton that would operate on an arbitrary DNA sequence

remains a major challenge. A third future direction is a search for application that would clearly demonstrate qualitative edge of a molecular computer over competing technologies.

We believe that the application potential of autonomous biomolecular computers is not to surpass electronic computers with performance; in fact, it is hard to believe they ever will. The advantage is that biomolecular computers process information encoded in molecules rather than in electric signals. Any *direct* computing over biomolecular inputs could only be performed by the computers of the same format, i.e., made of biomolecules. As we already mentioned, running sequence analysis algorithms on DNA libraries without actually sequencing all library members could be conveniently performed by a molecular state machine whose alphabet is composed of single nucleotides or codons. Another broad range of application may emerge once the molecular computer is successfully “plugged into” cellular molecular environment. By “plugging into” we mean that some of the computer components would be able to respond to certain changes in the environment, affecting the result of the computation. While the most obvious component to communicate with the environment seems to be the software, both the hardware and input could be affected as well. Once the communication between the intracellular compounds and the computer is established, the computer may, in principle, perform complex analysis of the environmental conditions. The complexity of such analysis would increase with the complexity of the computing machine and the sensitivity of the communication channels. However, even the simplest finite automata seem to provide enough computational power to make rather complex diagnostics.

# Molecular Electronics: Logic and Memory

Dustin K. James

James M. Tour

Chemistry Department, Rice University, Houston, Texas, U.S.A.

## INTRODUCTION

Electronic logic chips are used in many products today, from cell phones to robotic toys to automobiles and trucks, dishwashers and freezers, thermostats, and coffee makers. The most visible application of course is in our desktop and laptop computers. To enable further miniaturization of the circuitry used in these devices, recent research has focused on developing molecular-based logic and memory. In this entry, we will review the state of the art in the development and characterization of molecular electronic logic and memory, with discussions of the quantum cellular array approach (QCA) (and the related electrostatic repulsion architecture) and the crossbar approach to building molecular circuits followed by a more in-depth look at very recent results from our laboratory concerning the NanoCell approach to molecular logic and memory.

## MOLECULAR ELECTRONICS

The rapidly developing field of molecular electronics is one of the driving forces behind the interest in molecular-based circuits.<sup>[1–9]</sup> The limitations of the present “top-down” method of producing semiconductor-based devices have been the subject of debate and conjecture since Gordon Moore’s prediction that the number of components per integrated circuit would double every 18 months.<sup>[10]</sup> It is thought that the inherent limitations of the present technology will lead to a dead-end in the next few years. For instance, silicon’s band structure disappears when silicon layers are just a few atoms thick. Lithographic techniques that are used to produce the circuitry on the silicon wafers are limited, in part, by the wavelengths at which they work. However, leaders in the semiconductor manufacturing world are still making advances that appear to be pushing “Moore’s Law” beyond its prior perceived limits. In the commercial technology of 2001, the copper wires in Intel’s Pentium® 4 logic chip

are 0.13  $\mu\text{m}$  wide.<sup>[11]</sup> Intel is developing technology to create logic chips with wires 90 nm wide to be commercialized in 2003.<sup>[12]</sup>

For comparison’s sake, a typical molecular electronics candidate synthesized in our laboratory is calculated to be 0.3 nm wide and 2.5 nm in length (Fig. 1).<sup>[5]</sup> It would take 300 of these molecules, positioned side by side, to span the 90-nm metal line in the most advanced logic chip in development. The small size of these molecules is emphasized when one considers that 500 g (about 1 mol) would contain  $6 \times 10^{23}$  molecules, or more molecules than the number of transistors ever made in the history of the world. This amount of material could be produced by using relatively small 22-L laboratory reaction flasks. Changing the physical characteristics of this molecule is as easy as changing the raw materials used to make it. The small size, the potential of synthesizing huge numbers in small reactors, and the ease of modification of the physical characteristics of the molecules are good reasons for pursuing molecular electronics research. As an example of how far the technology has come, molecular electronics is discussed in the “Emerging Research Devices” section of the most recent International Technology Roadmap for Semiconductors<sup>[13,14]</sup> and molecules that may act as wires are a large part of the emerging technology. Molecular electronics was named the “breakthrough of the year” by *Science Magazine* for 2001.<sup>[15]</sup> Instead of replacing the present silicon-based technology, nanoelectronic architectures could prove to be a complement to traditional solid-state devices.<sup>[1,5,16,17]</sup>

To take advantage of the ultrasmall size of molecules, one needs an interconnect technology that 1) scales from the molecular dimensions; 2) can be structured to permit the formation of the molecular equivalent of large-scale diverse modular logic blocks as found in very large-scale interconnect (VLSI) architectures; and 3) can be selectively connected to mesoscopically (100 nm scale) defined input/output leads.

The first approach to molecular computing is based on quantum cellular automata (QCA) and related

**Fig. 1** The dimensions of a typical molecule studied in molecular electronic applications are calculated to be 0.3 nm in width and 2.5 nm in length using molecular mechanics to determine the energy-minimized structure. *Source:* From Ref.<sup>[5]</sup>.

electrostatic information transfers.<sup>[18–20]</sup> This method relies on electrostatic field repulsions to transport information throughout the circuitry. One major benefit of the QCA or electrostatics approach is that heat dissipation is less of an issue because only a few or fractions of an electron are used for each bit of information.

The second approach is based on the massively parallel solid-state Teramac computer developed at Hewlett-Packard (HP),<sup>[9,21]</sup> and involves building a similarly massively parallel computing device using molecular electronics based on crossbar technologies that are proposed to be defect-tolerant. A Teramac-like crossbar-based approach called the “NanoFabric” architecture deals more effectively with the numbers of wires emanating from the array.<sup>[22]</sup> When applied to molecular systems, the crossbar approaches propose to use single-walled carbon nanotubes (SWNTs)<sup>[23–27]</sup> or synthetic nanowires (NWs)<sup>[28–31]</sup> for the crossbars. Logic functions are performed either by sets of crossed and specially doped nanowires, or by molecular switches placed at each crossbar junction.

The third approach involves using molecular scale switches as part of a NanoCell.<sup>[32]</sup> The NanoCell relies on disordered arrays of molecular switches to perform logic functions. It does not require that each switching molecule be individually addressed, and furthermore

utilizes the principles of chemical self-assembly in construction of the logic circuitry, thereby reducing complexity. While fabrication constraints are greatly eased, programming difficulties increase dramatically.

## QUANTUM CELLULAR AUTOMATA (QCA) AND ELECTROSTATIC ARCHITECTURES

Quantum dots have been called “artificial atoms” or “boxes for electrons”<sup>[33]</sup> because they have discrete charge states and energy level structures that are similar to atomic systems and can contain from a few thousand to one electron. They are typically small, electrically conducting regions, 1  $\mu\text{m}$  or less in size, with a variety of geometries and dimensions. Because of the small volume, the electron energies are quantized. No shell structure exists; instead, the generic energy spectrum has universal statistical properties associated with quantum chaos.<sup>[34]</sup> Several groups have studied the production of quantum dots.<sup>[35]</sup> Heath et al. discovered that hexane solutions of Ag nanoparticles, passivated with octanethiol, formed spontaneous patterns on the surface of water when the hexane was evaporated,<sup>[36]</sup> and has prepared superlattices of quantum dots.<sup>[37,38]</sup> Lieber has investigated the energy gaps in “metallic” single-walled carbon nanotubes<sup>[23]</sup> and has used an atomic force microscope to mechanically bend SWNT to create quantum dots less than 100 nm in length. He found that most metallic SWNT are not true metals, and that by bending the SWNT, a defect was produced that had a resistance of 10–100 k $\Omega$ . Placing two defects less than 100 nm apart produced the quantum dots.

In the QCA approach toward molecular electronic computing systems, four quantum dots in a square array are placed in a cell such that electrons are able to tunnel between the dots but are unable to leave the cell.<sup>[39]</sup> Coulomb repulsion will force the electrons to occupy dots on opposite corners. The two ground state polarizations are both energetically equivalent and can be labeled logic “0” or “1.” Flipping the logic state of one cell, for instance, by applying a negative potential to a lead near the quantum dot occupied by an electron, will result in the next-door cell flipping ground states in order to reduce Coulomb repulsion. In this way, a line of QCA cells can perform computations.<sup>[40]</sup> A QCA fan-out structure has been proposed; however, when the ground state of the input cell is flipped, the energy imposed into the system may not be enough to flip all the cells of both branches of the structure, producing long-lived metastable states and erroneous calculations. Switching the cells using a quasiadiabatic approach prevents the production of these metastable states.<sup>[41]</sup>

**Fig. 2** Three compounds that were synthesized for studies in computing using electrostatic potentials. **1** is a molecular three-terminal junction that could be used as a molecular interconnect. **2** is a molecular-sized switch for which there is a corresponding equivalent of a source, drain, and gate terminals of a bulk solid state FET. **3** can be an active OR or a passive NOR gate if positive logic is used, or an AND or NAND gate if negative logic is used.

While the use of quantum dots in the demonstration of QCA is a good first step in reduction to practice, the ultimate goal is to use individual molecules to hold the electrons and pass electrostatic potentials down QCA wires. We have synthesized molecules that were shown by ab initio computational methods to have the capability of transferring information from one molecule to another through electrostatic potentials (Fig. 2). The potentials use a millionth of an electron per bit of information. This is quite attractive because a major consideration in molecular devices is the energy consumption/dissipation needs. Considering the fact that there are  $10^8$  gates/cm<sup>2</sup> (in presently sized silicon-based systems) functioning at the rate of  $10^{-9}$  sec (present speeds), those gates afford  $10^{17}$  electrons/sec ( $\sim 0.02$  A/cm<sup>2</sup>) if only one electron per gate is used to transport, indicate, fetch, or represent a binary digit. At this point, heat considerations are already extreme: if the average resistance of the circuit is  $30\ \Omega$ , this represents  $20\ \text{W}/\text{cm}^2$ . If an increase of several orders of magnitude in performance is expected with molecular circuits, this would imply a proportional increase in power dissipation. Such levels of power dissipation rule out most conventional current or electron transfer methods for practical molecular devices wherein large numbers of devices are densely configured.

Electrostatic interactions are produced by small reshapes of the electron density as a result of the input signals. In turn, electrostatic potential interactions between molecules could transport the information throughout the central processing unit (CPU). When this approach is used, there is no need for electron currents or electron transfers as in present devices; a small change in the electrostatic potential of one molecule could be enough to send the information to another molecule. These perturbations of the electrostatic

potential imply a very small amount of charge transfer, substantially less than one electron.

Although we synthesized molecules that included three-terminal molecular junctions, switches, and molecular logic gates to demonstrate the electrostatics methodology, none of the molecules were incorporated into an actual assembly. Because the electrostatics method has major obstacles to overcome before even simple laboratory tests can be attempted, all results were based on computation only. While relatively large quantum dot arrays can be fabricated by using existing methods, a major problem is that placement of molecules in precisely aligned arrays at the nanoscopic level is very difficult to achieve with accuracy and precision. Another problem is that degradation of only one molecule in the array can cause failure of the entire circuit. There has also been some debate about the unidirectionality (or lack thereof) of QCA designs.<sup>[42–44]</sup> Examples of two-dot QCA arrays have yet to be demonstrated using molecules, because addressing the molecular-sized inputs and the recording of a signal based on fractions of an electron are enormous hurdles.

## CROSS-BAR ARRAYS

Heath et al.<sup>[9]</sup> reported on a massively parallel experimental computer that contained 220,000 hardware defects yet operated 100 times faster than a high-end single processor workstation for some configurations. The solid-state-based (not molecular electronics) Tera-mac computer, built at HP, relied on its fat-tree architecture for its logical configuration. The minimum communication bandwidth needed in the fat-tree architecture was determined by utilizing Rent's rule, which states that the number of wires coming out of a region of a circuit should scale as the power of the number of

devices ( $n$ ) in that region, ranging from  $n^{1/2}$  in two dimensions to  $n^{2/3}$  in three dimensions. The HP workers built in excess bandwidth, putting in many more wires than needed. The reason for the large number of wires can be understood by considering a simple city map. To get from point A to point B, one can take local streets, main thoroughfares, freeways, interstate highways, or any combination thereof. If there is a roadblock at any point C between A and B, then renavigation can be assessed by using the map to arrive to point B. In the Teramac computer, “street blockages” are stored in a defect database; when one device needs to communicate with another device, it uses the database and the map to determine how to get there. Therefore the Teramac design can tolerate defects.

In the Teramac computer (or a proposed molecular computer based on the Teramac design), the wires that comprise the address lines controlling the settings of the configuration switches and the data lines that link the logic devices are the most important and plentiful part of the computer. It is logical that a large amount of research has been performed to develop NWs that could be used in the massively parallel molecular computer. This approach is dependent on precise order in devices with exact arrays of nanostructures, including nanowires or nanotubes, sometimes bridged by molecules, and interfaced with microstructure in order to communicate with the outside world.<sup>[9,18,45]</sup> Advancements have been made in the art since our last review,<sup>[3]</sup> many of which have been reviewed by Luo et al.<sup>[46]</sup> and by us. (See the entry “Molecular Wires,” for our review of this related area.)

Lieber has reviewed the work carried out in his laboratory to synthesize and determine the properties of NWs and nanotubes.<sup>[23]</sup> He used Au or Fe catalyst nanoclusters to serve as the nuclei for NWs of Si and GeAs with diameters of 10 nm and lengths of hundreds of nanometers. By choosing specific conditions, Lieber was able to control both the length and the diameter of the single crystal semiconductor NW.<sup>[28]</sup> Silicon NWs doped with B or P were used as building blocks by Lieber to assemble semiconductor nanodevices. Active bipolar transistors were fabricated by crossing n-doped NWs with p-type wire base. The doped wires were also used to assemble complementary inverter-like structures.

Lieber used Langmuir–Blodgett (LB) techniques to transfer multiple layers of nanowires onto planar substrates, followed by spin coating a photoresist layer onto the lattice.<sup>[47]</sup> The photoresist was patterned and developed, and the exposed nanowires were removed by sonication in deionized water. The remaining photoresist covering the nanowire arrays was dissolved in acetone. Large arrays were built.

Yu, Chung, and Heath<sup>[48]</sup> reported the synthesis of silicon NWs by chemical vapor deposition using  $\text{SiH}_4$  as the Si source and An or Zn nanoparticles as the

catalytic seeds at 440°C. The wires produced varied in diameter from 14 to 35 nm, and were grown on the surface of silicon wafers. After growth, isolated NWs were mechanically transferred to wafers and Al contact electrodes were put down by standard e-beam lithography and e-beam evaporation such that each end of a wire was connected to a metallic contact. In some cases, a gate electrode was positioned at the middle of the wire. Tapping-mode atomic force microscopy (AFM) indicated the wire in this case was 15 nm in diameter.

Heath found that annealing the Zn–Si wires at 550°C produced increased conductance attributed to better electrode/nanowire contacts. Annealing Au–Si wires at 750°C for 30 min increased current about  $10^4$ , an effect attributed to doping of the Si with Au, and lower contact resistance between the wire and Ti/Au electrodes.

More recently, Melosh et al.<sup>[49]</sup> reported on a method of obtaining aligned metal and semiconductor nanowires, based on the process of first growing nanowires in a selectively etched GaAs/ $\text{Al}_{0.8}\text{Ga}_{0.2}\text{As}$  superlattice, and then releasing them onto a 10-nm epoxy adhesion layer on an oxidized silicon wafer. After heat curing of the epoxy layer, the GaAs template was removed by treatment with  $\text{KI}/\text{I}/\text{H}_2\text{O}$ . The wafer was then rinsed with ultrapure water and dried, and the exposed epoxy adhesion layer was removed by using an  $\text{O}_2$  plasma etch. This process produced nanowire arrays with center-to-center distances as small as 16 nm and high aspect ratios (up to  $10^6$ ). Multiple cycles produced crossed nanowires with a junction density  $>10^{11}$  per  $\text{cm}^2$ . No molecules were placed at the junctions of the nanowires.

Much research has been performed to determine the efficacy of SWNTs as NWs in molecular computers. One problem with SWNTs is their lack of solubility in common organic solvents. In their synthesized state, individual SWNTs form ropes,<sup>[50]</sup> from which it is difficult to isolate individual tubes. In our laboratory, a measure of the solubility of the tubes was seen in 1,2-dichlorobenzene.<sup>[51]</sup> An obvious route to higher solubility is to functionalize SWNTs by attachment of soluble groups through covalent bonding. Mickelson et al.<sup>[52]</sup> found that fluorinated SWNTs were soluble in alcohols, while Chen et al.<sup>[53]</sup> were able to dissolve SWNTs by ionic functionalization of the carboxylic acid groups present in purified tubes.

We have found that SWNTs can be functionalized by electrochemical reduction of aryl diazonium salts in their presence.<sup>[54]</sup> Using this method, about 1 in 20 carbon atoms of the nanotube framework are reacted. We have also found that the SWNTs can be functionalized by direct treatment with aryl diazonium tetrafluoroborate salts in solution, or by in situ generation of the diazonium moiety using an alkyl nitrite reagent.<sup>[55]</sup> These functional groups give us handles

with which we can direct further, more selective derivatization (Fig. 3) and we recently reviewed the area of covalent sidewall derivatization of SWNTs.<sup>[56]</sup>

From an electronics perspective, the good thing about SWNTs is that all the carbons on the sidewalls are essentially the same; therefore, there is no location for an electron to localize during electronic transport. However, most of organic synthetic chemistry is predicated upon the ability to distinguish different carbon atoms in a molecule based on their subtle electronic and/or steric differences. Thus, from a synthetic perspective, the bad thing about SWNTs is that all the carbons on the sidewalls are essentially the same; therefore, one cannot use the plethora of synthetic techniques that favor formation of one type of carbon-carbon bond over another. However, if one did have a crossbar array of nanotubes, where the voltage between the two tubes could be selectively addressed at discrete locations, then the bridging on the specified cross-junctions might be possible; this has not yet been demonstrated.

Unfortunately, fluorination and other sidewall functionalization methods can perturb the electronic nature of the SWNT. An approach by Smalley et al.<sup>[50,57]</sup> and Stoddart and Heath<sup>[27]</sup> to increasing the solubility without disturbing the electronic nature

**Fig. 3** Reaction of SWNTs with aryl diazonium compounds. Shown are the electrochemical reactions with pre-formed diazonium salts, and the thermally activated reaction with in situ generated diazonium compounds. Also shown are a number of specific moieties that have been attached via these methods.

of the SWNTs was to wrap polymers around the SWNTs, but leave individual tubes' electronic properties unaffected. Stoddart and Heath found that the SWNT ropes were not separated into individually wrapped tubes; the entire rope was wrapped. Smalley found that individual tubes were wrapped with polymer; the wrapped tubes did not exhibit the roping behavior. Although Smalley was able to demonstrate removal of the polymer from the tubes, it is not clear, however, how easily the SWNTs can be manipulated and subsequently used in electronic circuits. In any case, the placement of SWNTs into controlled configurations has been, for the most part, a top-down methodology. Significant advances will be needed to take advantage of controlled placement at dimensions that exploit a molecule's small size.

Lieber proposed a SWNT-based non-volatile random access memory device comprising a series of crossed nanotubes, wherein one parallel layer of nanotubes is placed on a substrate and another layer of parallel nanotubes, perpendicular to the first set, is suspended above the lower nanotubes by placing them on a periodic array of supports.<sup>[24]</sup> The elasticity of the suspended nanotubes provides one energy minima, wherein the contact resistance between the two layers is zero, and the switches (the contacts between the two sets of perpendicular NWs) are OFF. When the tubes are transiently charged to produce attractive electrostatic forces, the suspended tubes flex to meet the tubes directly below them, and a contact is made, representing the ON state. The ON/OFF state could be read by measuring the resistance at each junction, and could be switched by applying voltage pulses at the correct electrodes. This theory was tested by mechanically placing two sets of nanotube bundles in a crossed mode and measuring the  $I(V)$  characteristics when the switch was OFF or ON. Although nanotube bundles with random distributions of metallic and semiconductor properties were used, the difference in resistance between the two modes was a factor of 10, enough to provide support for their theory. In another study, Lieber used scanning tunneling microscopy (STM) to determine the atomic structure and electronic properties of intramolecular junctions in SWNTs samples.<sup>[25]</sup> Metal-semiconductor junctions were found to exhibit an electronically sharp interface without localized junction states, while metal-metal junctions had a more diffuse interface and low-energy states.

A major problem with using SWNTs or NWs is how to guide them in formation of the device structures, i.e., how to put them where you want them. Lieber has studied the directed assembly of NWs by using fluid flow devices in conjunction with surface patterning techniques, and found that it was possible to deposit layers of NWs with different flow directions for

sequential steps.<sup>[28]</sup> For surface patterning, Lieber used  $\text{NH}_2$ -terminated surface strips to attract the NWs; in between the  $\text{NH}_2$ -terminated strips were either methyl-terminated regions or bare regions, to which the NW had less attraction. Flow control was achieved by placing a poly(dimethylsiloxane) (PDMS) mold, in which channel structures had been cut into the mating surface, on top of the flat substrate. Suspensions of the NWs (GaP, InP, or Si) were then passed through the channels. The linear flow rate was about 6.40 mm/sec. In some cases, the regularity extended over mm length scales, as determined by scanning electron microscopy (SEM).

In a similar fashion, the assembly of individual SWNTs onto substrates was realized by functionalizing substrate surfaces with polar and non-polar chemical groups in adjacent areas.<sup>[58]</sup> SWNTs deposited from a suspension tended to self-assemble into the polar regions of the substrate, with a lateral-directional force, probably as a result of electrostatic interactions, rotating the SWNTs so that they were confined with the polar area of the substrate. At low concentrations of 0.02 mg/mL, only single nanotubes were found at the center of each microscale polar molecular pattern. Although there was room for more than one SWNT on each patterned area, it was postulated that the hydrophobic surface of the first SWNT prevented additional SWNTs from being attracted to the underlying hydrophilic functionality. A problem with using carbon nanotubes is that they are always formed as mixtures of conducting tubes (0 eV bandgaps), semimetallic or “mod-3” tubes ( $\sim 1$  meV bandgaps), and semiconducting tubes (1 eV bandgaps). Most protocols form semiconducting tubes as  $\sim 60$ – $70\%$  of the mixture, therefore, one has to hope that the desired tube type would form or assemble in the desired device region. Of course, for a large array, the formation of the desired structure with the proper tube type is statistically prohibitive. Collins, Arnold, and Avouris at IBM have developed a method of engineering both multiwalled nanotubes (MWNTs) and SWNTs using electrical breakdown methods.<sup>[59]</sup> Shells in MWNT can vary between metallic or semiconductor character. Using electrical current in air to rapidly oxidize the outer shell of MWNTs, each shell can be removed in turn because the outer shell is in contact with the electrodes and the inner shells carry little or no current. Shells are removed until arrival at a shell with the desired properties. We recently published a process for selectively reacting the metallic and semimetallic tubes to the exclusion of the semiconducting tubes.<sup>[60]</sup> Therefore there is the hope, within a few years, that macroscopic quantities of homogeneous tube types will become available.

While Lieber has shown that it is possible to use the crossed NWs themselves as switches, Stoddart and

Heath have synthesized molecular devices that would bridge the gap between the crossed NWs and act as switches in memory and logic devices.<sup>[61]</sup> The UCLA/Caltech researchers have synthesized catenanes and rotaxanes that can be switched between states using redox chemistry. For instance, LB films were formed from the catenane, and the monolayers were deposited on polysilicon NWs etched onto a silicon wafer photolithographically. A second set of perpendicular Ti NWs were deposited through a shadow mask, and the  $I(V)$  curve was determined. The data, when compared to controls, indicated that the molecules were acting as solid-state molecular switches. As yet, however, there have been no demonstrations of combining the Stoddart switches with NWs.

The defect-tolerant approach to molecular computing using crossbar technology faces several hurdles before it can be implemented. Large numbers of nano-sized wires are used to obtain defect tolerance. How are each of these wires going to be accessed by the outside world? Multiplexing, the combination of two or more information channels into a common transmission medium, will have to be a major component of the solution to this dilemma. The directed assembly of the NWs and attachment to the multiplexers will be complicated, nonetheless, HP and CalTech researchers are making strides in this arena. Another hurdle is signal strength degradation as it travels along the NWs. Gain is typically introduced into circuits by the use of transistors. However, placing a transistor at each NW junction is an untenable solution because the silicon transistor would be much larger than the NW junction. Likewise, in the absence of a transistor at each cross point in the crossbar array, molecules with very large ON:OFF ratios will be needed. For instance, if a switch with a 10:1 ON:OFF ratio were used, then 10 switches in the OFF state would appear as an ON switch. Hence isolation of the signal via a transistor is essential. Researchers are hoping to insert diodes to sidestep this hurdle.

Additionally, if SWNTs are to be used as crossbars, connection of molecular switches via covalent bonds introduces  $\text{sp}^3$ -hybridized carbon atom linkages at each junction, disturbing the electronic nature of the SWNT and possibly rendering the SWNTs useless in the first place. Non-covalent bonding of the device molecule to the SWNT will probably not provide the conductance necessary for the circuit to operate. Therefore continued work is being carried out to devise and construct crossbar architectures that address these challenges.

## THE NANOCELL

This NanoCell architecture involves an approach where molecular switches are not specifically directed

**Fig. 4** SEM image of the NanoCell after assembly of the Au nanowires and **4**. The top image shows the five juxtaposed pairs of fabricated leads across the NanoCell, and some Au nanowires are barely visible on the internal rectangle of the discontinuous Au film. The lower image is a higher magnification of the NanoCell's central portion showing the disordered discontinuous Au film with an attached Au nanowire that is affixed via the OPE-dithiol (not observable) derived from **4**.

to a precise location and the internal topology is generally disordered. A NanoCell is a two-dimensional (three-dimensional models could also be considered) network of self-assembled metallic particles or islands connected by molecules that show reprogrammable (can be turned ON or OFF) switching and/or memory properties. The NanoCell is surrounded by a small number of lithographically defined access leads at the edges of the NanoCell. Unlike typical chip fabrication, the NanoCell is not constructed as a specific logic gate and the internal topology is, for the most part, disordered. Logic is created in the NanoCell by training it postfabrication, similar in some respects to a field-programmable gate array (FPGA). Even if this process is only a few percent efficient in the use molecular devices, very high logic densities will be possible. Moreover, the NanoCell has the potential to be reprogrammed, thereby creating a real-time dynamic reconfigurable hard-wired logic. The CPU of the computer would be composed of arrays of NanoCells, wherein each NanoCell would have the functionality of many transistors working in concert. A regular array of NanoCells is assumed to manage complexity, and ultimately, a few NanoCells, once programmed, should be capable of programming their neighboring NanoCells through bootstrapping heuristics. Alternatively, arrays could be programmed one NanoCell at a time via an underlying complementary metal oxide semiconductor (CMOS) platform.

Within the fabricated NanoCell, the input and output leads could be repetitively interchanged based on the programming needs of the system, thereby demonstrating the pliability of the architecture. Naturally, issues of gain will eventually have to be addressed through either an underlying CMOS layer or clocked circuits programmed into the NanoCell.<sup>[62]</sup> Even if one CMOS transistor were used for gain at the output from each NanoCell, enormous space savings could be attained because a NanoCell could possess the functionality of numerous transistors working in concert

to produce a specified logic function. Furthermore, by capitalizing on the NDR properties of the molecular switches, internal gain elements based on NDR/nanoparticle/NDR stacks (Goto pairs) could be efficacious.<sup>[63,64]</sup>

The functionality of a NanoCell depends largely on the  $I(V)$  characteristics and placement of its molecular switches with respect to the nanoparticles. We have demonstrated NDR with a large ON:OFF ratio from several types of molecular switches based on nitro-containing OPEs (similar to **4** in Fig. 4). We will exploit this switching behavior (rise, then decline in the current with increased voltage) to build logic devices that exhibit negating functionality such as NAND or XOR responses from these two-terminal devices because two voltage inputs that are high could set the device into an OFF state (right side of the  $I(V)$  curve). Switches that do not exhibit the NDR characteristic cannot provide the negating functionality needed for the NanoCell approach.

The object in programming or training a NanoCell is to take a random, fixed NanoCell and turn its switches ON and OFF until it functions as a target logic device. The NanoCell is then trained postfabrication by changing the states, ON or OFF, of the molecular switches by imposing voltages at the surrounding input/output leads.

## NANOCELL MEMORIES

The NanoCell approach, as previously described and simulated,<sup>[1,32]</sup> is not dependent on placing molecules or nano-sized metallic components in precise orientations or locations. The internal portions are, for the most part, disordered and there is no need to precisely locate any of the switching elements. The nano-sized switches are added in abundance between the micron-sized input/output electrodes, and only a small percentage of them need to assemble in an orientation

suitable for switching. The result of the NanoCell architecture is that the patterning challenges of the input/output structures become far less exacting because standard micron-scale lithography can afford the needed address system. Also, fault tolerance is enormous.<sup>[32]</sup> However, programming is significantly more challenging than when using ordered ensembles. We describe here an example in which a NanoCell has been successfully assembled and tested. Remarkably, the NanoCell exhibits reproducible switching behavior with excellent peak-to-valley (PVR) ratios,<sup>[65]</sup> peak currents in the milliamperage range and reprogrammable memory states that are stable for more than a week with substantial 0:1 bit level ratios.

A NanoCell is a two-dimensional unit of juxtaposed electrodes fabricated atop a Si/SiO<sub>2</sub> substrate. In the embodiment described here, five Au electrode pairs were patterned on opposing sides of the NanoCell (Fig. 4, top). A discontinuous gold film was vapor deposited onto the SiO<sub>2</sub> in the central region (Fig. 4, bottom). The chips were always treated with UV ozone and ethanol-washed immediately prior to use to remove exogenous organics. Electrical measurements of up to 30 V DC confirmed there was  $\leq 1$  pA conduction across the discontinuous Au film between the five juxtaposed pairs of  $\sim 5$ - $\mu\text{m}$  spaced electrodes. In this study, each juxtaposed pair serves as an independent memory bit address system.

The assembly of molecules and nanowires in the central portion of the NanoCell was then carried out under N<sub>2</sub> to provide a current pathway across the NanoCell. Compounds similar to the mononitro oligo(phenylene ethynylene) (OPE) **4**<sup>[66]</sup> have been previously shown to exhibit switching and memory storage effects when fixed between proximal Au probes.<sup>[66,67]</sup> Au nanowires (diameter of 30 nm and length of 300–2000 nm, grown in a polycarbonate membrane by electrochemical reduction at 1.2 Coulombs)<sup>[68]</sup> were added to a vial containing **4** in CH<sub>2</sub>Cl<sub>2</sub>. The vial was agitated for 40 min to dissolve the polycarbonate membrane and to form **4**-encapsulated Au nanowires via chemisorption of the thiols to the nanowires.<sup>[69]</sup> Because the thiol groups are far more reactive toward Au than thioacetyl groups,<sup>[70]</sup> this procedure leaves the latter projecting away from the nanowire surfaces. NH<sub>4</sub>OH and ethanol were added, and the vial was agitated for 10 min to remove the acetyl group.<sup>[71]</sup> A chip containing 10 NanoCell structures was placed in the vial (active side up), and the vial was further agitated for 27 hr to permit the nanowires to interlink the discontinuous Au film via the OPEs (Fig. 4). The chip was removed, rinsed with acetone, and gently blown dry with N<sub>2</sub>.

The assembled NanoCells were electrically tested on a probe station with a semiconductor parameter analyzer at room temperature (297 K) under vacuum

**Fig. 5**  $I(V)$  characteristics of the NanoCell at 297 K. The curves for a, b, and c are the first, second, and third sweeps, respectively ( $\sim 40$  s/scan). The PVRs in C are 23:1 and 32:1 for the negative and positive switching peaks, respectively. The arrow indicates the sweep direction of negative to positive.

( $10^{-5}$  mm Hg). Typical  $I(V)$  characteristics of the NanoCell devices are shown in Fig. 5. Two stable and reproducible switching peaks are observed in a bias range of  $-10$  and  $+10$  V. The shape of the  $I(V)$  curve is asymmetric because the molecule, as a result of the nitro-group orientation, is asymmetrically oriented, and/or the contacts are likely to be slightly different on each end. After about 300 scans, the switching responses further stabilized in peak voltage; the device showed no degradation to  $>2000$  scans over a 22-hr period of continuous sweeping. Also, after testing, an assembled NanoCell was stored in a capped vial (air) for 2 months with little, if any, signal variations relative to the readings recorded at the initial testing.

A juxtaposed pair of electrodes, as described above, showed little variation in its behavior over several thousand scans. However, there were notable differences when comparing different electrode pairs in that they showed variations in peak current position (occurring typically within a range of 3–15 V), peak current (typically 0.1–1.7 mA), and PVR (typically 5–30). The differences are undoubtedly related to the variations in the conduction pathways of these disordered arrays.

If a voltage sweep is conducted on a NanoCell in a bias range that is up to or not far beyond the peak of the  $I(V)$  curve (switching event), a pseudo-linear trace is observed, as shown by curve **a** (0-state) in Fig. 6. However, if three voltage pulses at  $-8$  V (100 msec width, 104 msec period) are then applied to the same pair of leads, a peak appears (1-state) in the first scan after the voltage pulses, as shown by curve **b** in Fig. 6. Apparently, the voltage pulses set the system into a new state that is then read by the bias sweep **b**. This is being termed the switch-type memory effect. However, the following scans **c** and **d** produced  $I(V)$

**Fig. 6**  $I(V)$  characteristics of the NanoCell before (a) and after (b–d) three voltage pulses at  $-8$  V at 297 K. Curves b, c, and d were the first, second, and third scans (after the  $-8$  V reset pulses), respectively. Scans a–d were run at  $\sim 40$  s/scan. The results here are from the same device used to generate the  $I(V)$  curve in Fig. 5.

responses similar to curve **a**, the scans before the voltage pulses, suggesting that the state set by the voltage pulse was erased after reading it by scan **b**. In other words, the switch-type memory effect has a destructive-read property [as seen with present-day dynamic random-access memory (DRAM)]. A positive voltage pulse, i.e.,  $+8$  V, can also set the system into the 1-state. Voltages higher than  $\pm 8$  V always worked, but voltages lower than  $\pm 8$  V did not reset this particular NanoCell into the 1-state. All of the active NanoCells showed this rewritable behavior, although the magnitudes and set voltages varied between different NanoCells as described above.

On the same device as shown in Figs. 5 and 6, another type of memory effect was found which has a non-destructive-read, the so-called conductivity-type memory, which operates by the storage of a high- or low-conductivity ( $\sigma$ ) state. The difference between the switch-type memory and the conductivity-type memory is based on the voltage-sweep range:  $-4$  to  $0$  V for the former and  $-2$  to  $0$  V for the latter. An initially high conductivity state (high  $\sigma$  or 0-state) was observed in a bias range of  $-2$  to  $0$  V as shown in Fig. 7, curves **a–c**. The high  $\sigma$  state is changed (written) into a low  $\sigma$  state (1-state) upon application of three voltage pulses at  $-8$  V (100 msec width, 104 msec period), as shown by curves **d–f**. The low  $\sigma$  state persists as a stored bit, which is essentially unaffected by successive read sweeps. There is a 400:1 0-state/1-state ratio in current levels between the high and low  $\sigma$  states recorded at  $-2$  V for this NanoCell device. The ratios may vary between different electrode pairs but the ratio here is representative. The highest observed 0:1 ratio was 12,500:1 ( $198 \mu\text{A}$ :  $16$  nA at  $-2.0$  V) for a  $5\text{-}\mu\text{m}$  gap electrode pair, and the lowest observed ratio was 10:1 at the same voltage.

**Fig. 7**  $I(V)$  characteristics of the NanoCell before (scans a–c) and after (scans d–f) three voltage set-pulses of  $-8$  V at 297 K. The initial high  $\sigma$  state (0-state) is represented by curves a, b, and c, which are the first, second, and third scans before the set-pulse, respectively. The low  $\sigma$  state (1-state) is represented by curves d, e, and f, which are the first, second, and third scans after the  $-8$  V set-pulses, respectively. The inset shows scans d–f in the  $\mu\text{amp}$  range. Scans a–c were run at  $\sim 40$  s/scan. Scans d–f were run at  $\sim 50$  s/scan. This is the same device depicted in Figs. 5 and 6.

The conductivity-type memory effect is independent of bias sweep directions. Once set into the low  $\sigma$  state upon application of voltage-set (write) pulses, the system holds the low  $\sigma$  state regardless of negative bias sweep from  $0$  to  $-2$  V or positive bias sweep from  $0$  to  $2$  V. Several routes were investigated to erase the stored low  $\sigma$  state (written bit). Voltage pulses at  $-3$  to  $-4$  V ( $\sim 20$  pulses at 1 msec pulse width, 10-msec pulse period) reset the memory into the original high  $\sigma$  state (use a voltage pulse that comes near the peak of the switching event, but not far past the peak). Although the overall write, read, erase sequence used in the screening of these devices was rather slow because of the resetting time of the probing electronics, the inherent switching may be on the order of milliseconds, or faster, for each operation if customized electronics were used. The switch-type and conductivity-type memory effects are shown here in the negative bias regions; however, they apply in the positive bias region as well.

The bit retention time for the switch-type memory is at least 11 days and with  $\sim 10\%$  change in the voltage peak position of the curves when compared to the read-tests run seconds after setting the written state; however, there was no decline in the magnitude of the response. The conductivity-type memory persisted for at least 9 days. Over this period, the 0:1 signal magnitudes interestingly increased, although the reset voltages also drifted higher ( $\sim 10\%$ ) over this period. Therefore the two types of memory effects can have

much longer retention times, but these are merely the time periods over which they have been tested. Longer durations were not studied. During waiting periods over which these retention times were recorded, the NanoCells had been occasionally exposed to air at 1 atm for periods of up to 30 min, as more samples were moved through the testing chamber. Therefore the stored written states are robust even with short exposure to air. Yields of functioning NanoCells that have been prepared via the protocol described here seemed to be electrode gap-dependent. A NanoCell produced by using the described protocol chip showed 100%, 65%, and 30% yields for devices with 5-, 10-, and 20- $\mu\text{m}$  spacings between the juxtaposed electrodes, respectively.

The assembled chips were tested in the probe station both in the dark, by covering the observation window with aluminum foil, and in the presence of the room light with the station's fiber optic observation light projected through the observation window  $\sim 10$  cm above the chip. The same electrical responses were obtained regardless of the lighting, thereby excluding a photoconductive mechanism.

Several control experiments were conducted to investigate the mechanism of action for the NanoCell memories. When the same assembly process was conducted but **4** was not added, all the leads were "open" and no switching behavior was observed over the tested 15 juxtaposed electrodes (5 pairs at 5- $\mu\text{m}$  spacings, 5 pairs at 10- $\mu\text{m}$  spacings, and 5 pairs at 20- $\mu\text{m}$  spacings). Therefore the process is **4**-dependent. When the assembly procedure was conducted but the nanowires were not present (only **4**, polycarbonate devoid of nanowires,  $\text{CH}_2\text{Cl}_2$ ,  $\text{NH}_4\text{OH}$ , and ethanol were added), two out of three juxtaposed 5- $\mu\text{m}$  spacings showed switching between them; however, the switching effect signal degraded nearly completely after 3–10 scans. Therefore some molecules may have bridged the discontinuous Au film, but the connections were not as abundant or stable. A similar behavior was observed at 10- $\mu\text{m}$  spacings between the electrodes. When an alkyl system,  $\text{AcS}(\text{CH}_2)_{12}\text{SH}$  (**5**),<sup>[72]</sup> was substituted for **4** in the standard assembly process, and 30 juxtaposed electrode pairs were studied, 28 showed no device behavior. Interestingly, however, one 5- $\mu\text{m}$  electrode pair showed the characteristic switching that dissipated after three scans, while a second electrode pair showed reproducible switching behavior but the onset and peak currents occurred at 14 V. Therefore **1** is not unique among molecule types.

Concerning the mechanism underlying the programmable memories, a molecular electronic effect was first considered. Several mechanisms were proposed for molecular electronic switching<sup>[73–75]</sup> based upon charging of the molecules, which results in changes in the contiguous structure of the lowest unoccupied molecular

orbital (LUMO). This can be accompanied by conformational changes that would modulate the current based on changes in the extended  $\pi$ -overlap. Conversely, as some have pointed out, the so-called "molecular-based" switching might not be an inherently molecular phenomenon, but may result from surface bonding rearrangements that are molecule/metal contact in origin. For example, a sulfur atom changing its hybridization state, or subangstrom shifts between different Au surface atom bonding modes, or molecular tilting.<sup>[76,77]</sup> An estimate of the number of molecular junctions between a set of juxtaposed electrode pairs is difficult to gauge; however, based on the size of the nanowires and the Au islands, which can be 0.3–1  $\mu\text{m}$  long, the number of molecular junctions could be as few as four in a 5- $\mu\text{m}$  electrode gap. The number of molecules in parallel, per junction, could be as few as 30 or as many as several thousand, based on the nanowire diameters and lengths. Note that the quantum conductance of each molecule is  $\sim 0.08$  mA/V.

In addition to a molecular electronic process, electrode migration was considered as a cause for the high currents and reset operations that are analogous to filamentary metal memories.<sup>[78–81]</sup> To investigate this possibility, the exposed organic material was stripped from a working NanoCell by treating the assembled chip with UV ozone for 10–30 min. Remarkably, the device behavior of the NanoCell remained and often improved. In some cases, the 0:1 bit level ratios for the conductivity memory even increased up to  $10^6:1$  (2.53 mA:0.76 nA at  $-3.0$  V). This could suggest that the ozone was not able to reach the small amount of active organic molecules in the key nanodomains that are sandwiched between the nanowires and the Au islands, and that the more exposed leakage routes were destroyed by the ozone. Conversely, it could suggest that, indeed, filamentary metal had grown along the molecules and that these metal filaments were causing the observed switching behavior, with any molecular leakage routes being destroyed by the ozone. It was previously shown by modeling that the NanoCell should exhibit extraordinary defect tolerance because of the abundance of molecules available for switching; furthermore, if one molecule degrades, another could slip into place from the self-assembled monolayers that cover all the surrounding metal surfaces.<sup>[32]</sup> Consider also that, at the atomistic level, a molecular change in either conformation or hybridization at the metal–molecule interface, due to voltage changes or charging, could give electronic response characteristics that are analogous to filamentary metals (atoms moving in and out of alignment for current flow), and thereby resemble negative differential resistance-like behavior. In other words, metallic nanofilaments forming during a voltage sweep, then on increasing the voltage, they could exhibit a sudden break, causing a decline in the current.

Additionally, a mechanical motion involving the molecule-covered nanowires was considered. However, it was deemed less likely because of the highly cross-linked nature of the micron-sized matrix.

None of the former data was conclusive enough to exclude either the molecular electronic-based mechanism or the nanofilament mechanism. However, a later finding pointed toward the nanofilament-based mechanism being the dominant or exclusive pathway. As described above, we had never seen the switch-like behavior from the bare chips; they just showed open circuits. As customary to ensure open circuits before we begin the molecule/nanowire assembly, while probing an older chip (4 months storage at room temperature in a Fluoroware™ container) from the same lot of chips that was used to prepare the NanoCell described here, we notice switching with magnitudes similar to the levels outlined in Fig. 5. Neither nanowires nor molecules had been added; it was merely the aged discontinuous Au film vapor-deposited between electrodes. Possibly, while the film had aged, the islands migrated across the gaps sufficiently close together to form nanofilaments upon voltage scanning, and then metal filament breakage occurred at higher voltages, giving responses similar to that shown in Fig. 5. The metallic island migration was not obvious by microscopic analysis of the discontinuous Au films because the resolution needed within the topologically non-planar arrays cannot be achieved with either SEM or AFM. We carried out  $I(V,T)$  (current as a function of voltage and temperature,  $-2$  to  $2$  V,  $280$  to  $80$  K and back to  $280$  K) measurements to assess the possible conduction mechanism of the high  $\sigma$  conductivity-type memory state on the bare chip. The data suggested “dirty” or modified-metal conduction: metallic conduction with trace impurities. However, in the low conductivity state, only thermionic emission was observed. The same type of  $I(V,T)$  measurements on a molecule/nanowire assembled NanoCell showed both a temperature dependence and a non-temperature dependence based on the particular juxtaposed electrode set studied. Albeit confusing, there may be a duality of mechanisms coexisting on the same chip, namely, metallic filaments in the high  $\sigma$  state and molecular phenomena in the low  $\sigma$  state. Further studies are ongoing to better discern this process. Fabrication of NanoCells with more refractory metals such as Pt or Pd will be carried out to further test this point. Additionally, we are currently making chips with a  $193$ -nm stepper to yield juxtaposed electrode gap spacings of  $<1\ \mu\text{m}$  with smaller Au-film islands and appropriately sized nanowires, with the hope of attaining higher degrees of consistency between electrode pairs. With the presently sized embodiments, write/erase speeds, and the lack of isolation and fan-out, the NanoCell is not a harbinger for DRAM, flash,

or magnetic random access memory (MRAM) replacements. However, it demonstrates the first fabrication of a disordered nanoscale ensemble for high-yielding switching and memory, while mitigating the painstaking task of nanoscale lithography or patterning; thereby furthering the promise of disordered programmable arrays for complex device functionality.

## CONCLUSION

Of the three basic approaches to building a molecular computer—QCA, crossbar array, and NanoCell, two approaches appear to be at the forefront of the advancing science—the crossbar array approach and the NanoCell approach. The crossbar approach has seen many advances in the fabrication and assembly of nanowire arrays on surfaces. The NanoCell approach has also been swiftly advanced, and includes molecules in its assembly, but whether the device properties are due to the molecules themselves or to the formation of metal nanofilaments facilitated by the molecules remains unknown at this time. Work continues on many fronts to advance the idea of using molecules to meet the future computing needs of an ever more complex world. We are amazed and delighted to see this research unfold around us.

## INTRODUCTION

The process of scaling down modern semiconductor devices faces serious obstacles, mainly because of device-addressing problems. Practical limitations in fabrication and extraordinary increases in production costs will also be limiting issues. Small molecules, easy to tailor, are the natural candidates to complement semiconductor components in the generation of hybrid circuits, giving birth to a completely new area of electronics, molecular electronics or Moletronics. Experimental characterization is highly challenging, and only a few experiments in which only one molecule is addressed have been performed,<sup>[1–3]</sup> because technical possibilities of success become greatly diminished with the minuscule system size. Fortunately, modern quantum-chemistry-theoretical-based computational techniques are able to accurately solve molecular systems using precise natural laws, and this ability increases substantially as systems become smaller.

This entry investigates recent results on molecular systems that can potentially be used as electronic devices. It is particularly focused on molecules that can behave as controllable switches (a characteristic that allows programmability) and the theoretical techniques available for their analysis, design, and simulation. Switching has been studied before but not with the purpose of programmability. For instance, Collier et al.<sup>[4]</sup> studied switching based on the translation degrees of freedom of mechanical bonds, and more elaborate molecular circuits have been proposed, such as a flash-like, single-electron memory cell,<sup>[5]</sup> however, they are hardly useful for a paradigm of a chemically random assembly of molecules governed mostly by thermodynamic and some kinetic controls where programmability features at the level of devices are of paramount importance.<sup>[6]</sup> The studies cited focused on electrical features and their correlation to

conformational properties, the metallic contacts characterization, and the metal–molecule interface. Determining the correlation between transport characteristics and molecular electronic and geometrical configuration is particularly important, because this correlation provides a mechanism to control electron transport in molecular and atomistic systems.

## THEORY-BASED APPROACHES FOR THE CALCULATION OF MOLECULAR SYSTEMS

In this section, we describe several approaches used for the analysis of molecular electronic systems. We briefly summarize the common methods and tools that allow researchers to theoretically characterize, design, model, and simulate moletronics systems.

### Methods

The main methods used in moletronics are borrowed from quantum chemistry and solid state physics, and in particular, density functional theory (DFT) is used for discrete and extended systems as well as their interconnection using the Green function (GF) scattering technique.

#### Ab initio density functional theory for molecules

In the study of molecules presenting highly non-linear features, the Kohn–Sham molecular orbitals (MOs) can provide a qualitative picture of the molecular mechanisms of operation and how they are affected by its boundaries. The solution of the Schrödinger equation for the system under consideration should provide an exact solution if an exact Hamiltonian is used; however, such a solution is very tedious because

of the massive computational resources it demands. One way to bypass this difficulty is to use DFT where the solution of the wave function replaces the solution of the electron density. Electron density is obtained from auxiliary systems of non-interacting electrons whose total electron density is forced to be identical to the electron density of the interacting or real electrons. The advantage of this approach is that the system of non-interacting electrons can be easily separated into individual one-electron MOs, also called Kohn–Sham MOs. Each MO is associated to individual energies that can be roughly correlated with the excitation energies of the molecular system. The shape and energy of these MOs have been widely used in the qualitative explanation of electron transport (vide infra) in single molecules. However, the use of MOs is only for qualitative purposes. MOs from DFT, or any other theory, can never precisely describe the exact wave function of a real system because real electrons are not independent particles. For most practical purposes, DFT calculations using functionals based on ab initio approaches and beyond the local approximation have been very successful in describing the main features of molecular systems with acceptable precision. This fact has converted DFT into the main computational tool in modern quantum chemistry, and into the preferred tool for the study of molecular electronics.

Integration of several tools is often necessary. Single molecules are first treated by using ab initio density functional theory (DFT) as implemented in the Gaussian-98 program,<sup>[7]</sup> or its recent version, Gaussian-03.<sup>[8]</sup> The molecular geometry is optimized with no constraint (except for special cases) until all eigenvalues of the Hessian matrix are positive, ensuring that the molecule is in a minimum energy configuration. The Becke-3 Perdew–Wang 91 (B3PW91) procedure, which consists of the Becke3 hybrid exchange functional combined with the generalized gradient approximation (GGA) Perdew–Wang-91 correlation,<sup>[9–11]</sup> is used in combination with different basis set selected according to the system. In general, systems with metallic atoms are treated using LANL2DZ,<sup>[12–14]</sup> an effective core potential and basis set. The LANL2DZ basis set explicitly considers all the valence electrons, rather than just those in last electronic shell. Core electrons are treated in an approximate way by using pseudopotentials that include relativistic effects allowing an excellent description of heavy metal atoms.<sup>[15]</sup> The level of theory B3PW91/LANL2DZ has been used in several works, and further details can be found in Refs.<sup>[16–20]</sup> In some cases, where no metallic atoms are present, 6-31G\* basis or higher sets are also used.

Atomic charges are estimated by using Mulliken population analysis, which associates charge to each atom by integrating the basis functions assigned to each

individual atom and assigning equally to each atom of each pair their overlap contributions. Mulliken charges can only provide complementary information. Mulliken values do not support conclusions, but provide a qualitative picture of the quantitative results; atomic charges are not expectation values but mere indicators highly dependent on the method and basis set used to solve the Schrödinger equation. Nevertheless, if properly balanced basis sets are used, Mulliken analysis can provide an excellent tool for qualitative analysis and interpretations of charge transfer effects.

## Green functions

*I*–*V* characteristics are calculated by combining the DFT results with a Green function technique originally designed for mesoscopic systems.<sup>[21–27]</sup> This approach considered the molecule attached to infinite contacts that modify its electronic structure, the new modified electronic structure is, in turn, used to calculate the system (molecule plus contacts) *I*–*V* characteristic. The electron transport properties of a molecule under a bias voltage *V* are described by its Green function,  $G_M$ , obtained from the molecular Hamiltonian,  $H(V)$ , which is obtained by reoptimizing the molecular electronic structure under the presence of an external electrical field. The transport of electrons takes place through the MOs, which are affected by interaction with the contacts and with the applied voltage.<sup>[28,29]</sup> MOs may be affected by an applied external field or by the charge state on the molecule. For instance, delocalized MOs can become localized, or vice versa, when the molecule traps one electron. The molecule is in a conducting state (low impedance) if delocalized MOs are available in the energy range for which one contact has occupied levels and the other unoccupied ones. The molecule is in a non-conducting state (high impedance) if those MOs are localized, i.e., they do not connect both ends of the molecule to the contacts. When the molecule is open shell (electrons are unpaired), both  $\alpha$  and  $\beta$  spin states are considered to obtain the molecular *I*–*V* characteristics.

The Green function is obtained from Eq. (1),

$$G_M = [E\mathbf{1} - H_{MM} - H_{M1}g_1H_{1M} - H_{M2}g_2H_{2M}]^{-1} \quad (1)$$

where subscripts *i* and *j* in  $H_{ij}$  [submatrices of *H* in Eq. (2)] refer to the molecule (M), contact 1 (1), and contact 2 (2).

$$H = \begin{bmatrix} H_{11} & H_{1M} & H_{12} \\ H_{M1} & H_{MM} & H_{M2} \\ H_{21} & H_{2M} & H_{22} \end{bmatrix} \quad (2)$$

Information about the macroscopic nature of the contacts is introduced by a Green function for a semi-infinite medium ( $g_i$ ), whereby  $s$ ,  $p$ , and  $d$  contributions<sup>[30]</sup> to the density of states (DOS) of the Au metal are explicitly considered. Derosa and Seminario represented the metallic contacts by assuming a density of states with  $s$ ,  $p$ , and  $d$  contributions, but energy-independent. This approach, although not perfect, was an improvement compared to available applications (see, for example, Refs.<sup>[31,32]</sup>) that considered only an  $s$ -character, also energy-independent DOS. These descriptions of the contacts were finally improved by calculating at DFT level, the DOS of a metallic system extended using periodic boundary conditions (vide infra).<sup>[33]</sup>

From the molecular Green function, the transmission function (TF), which is the sum of the transmission probabilities of all channels (MOs) available at energy  $E$ , is obtained, as described by Eq. (3), and the current is obtained from Eq. (4),<sup>[25]</sup> where  $f_i$  is the Fermi–Dirac function for a voltage  $V_i$  at contact  $i$  ( $V = V_2 - V_1$ ).

$$T(E, V) = \text{trace}[\Gamma_1(V)G_M(E, V)\Gamma_2(V)G_M^+(E, V)] \quad (3)$$

$$I(V) = \frac{2e}{h} \int_{-\infty}^{\infty} dE T(E, V)[f_1(E, V_1) - f_2(E, V_2)] \quad (4)$$

As a first approximation, the experimental work function of the metal making the contact,  $-5.31$  eV for Au, was used for some calculations of neutral systems.<sup>[34]</sup> In previous works,<sup>[29,35]</sup> this value was also used to study the anions. An average of the highest occupied molecular orbital (HOMO)–lowest unoccupied molecular orbital (LUMO) midgap energy from several neutral organic molecules attached to Au atoms yielded an energy of  $-5.2$  eV, which is in excellent agreement with the experimental work function of Au. However, the midgap average energy for the single anions and dianions is  $-1.55$  and  $0.88$  eV, respectively. The HOMO and LUMO energies obtained from DFT is an approximation (with a minus sign) of the ionization potential and the electron affinity of the molecule, respectively. Thus it is not surprising that both energies are higher (in absolute value) for anions than for neutral; however, this situation will not reflect the position of the HOMO–LUMO gap (HLG) relative to the metal Fermi level. This shift in position of the HLG, which was not considered in our original model, was later accounted for to estimate the electrical characteristics of the anion and dianion.

The density of states (DOS) is also obtained from the Green function formalism,<sup>[25]</sup> as shown by Eq. (5).

$$\text{DOS}(E, V) = \text{trace}[(i[G_M(E, V) - G_M^+(E, V)])] \quad (5)$$

A full description of this procedure is published elsewhere,<sup>[29]</sup> where more detailed information and useful references can be found.

### Ab initio calculations for crystals and extended systems

CRYSTAL-98<sup>[36]</sup> is used to study the metallic contacts within the linear combination of atomic orbital approximations. Macroscopic properties (band structure, DOS, etc.) are obtained by reproducing the unit cell to infinite, following the rules of the corresponding crystal structure. CRYSTAL-98 is a suite of programs that can calculate the electronic structure, total energy, and wave functions, including its band structure, density of states, electron charge distribution, electron momentum distribution, Compton profile, Mulliken charges, electrostatic potentials, and X-ray structure factors<sup>[37]</sup> by using a DFT approach for periodic systems.<sup>[38]</sup> The basis set expands the Bloch functions built  $\Psi_k(r)$  by using  $s$ ,  $p$  and  $d$  Gaussian functions, as can be observed in Eq. (6).

$$\Psi_k(r + g) = \Psi_k(r) \exp(ik \cdot g) \quad (6)$$

The electron density of the  $N$ -electron system<sup>[38]</sup> is given by Eq. (7), where  $\theta$  is the Heaviside step function, and  $\varepsilon_i(k)$  is the eigenvalue of the  $i$ th crystalline orbital.  $\varepsilon_F$  is the Fermi energy.

$$\rho(r) = \int_{\text{Brillouin zone}} dk \sum_i^{\text{Occupied bands}} |\varphi_{ki}(r)|^2 \theta(\varepsilon_F - \varepsilon_i(k)) \quad (7)$$

The Bloch functions described above are used to expand the crystalline orbitals that are linear combinations of atom-centered Gaussian-type functions,  $\varphi_{ki}(r)$ . The coefficients for the linear expansion are adjusted such that  $\varphi_{ki}(r)$  are the solutions of the one-particle equations [Eq. (8)],

$$\hat{h}_i \varphi_{ki}(r) = \varepsilon_{ki} \varphi_{ki}(r) \quad (8)$$

where  $\hat{h}$  is the single particle Hamiltonian operator shown in Eq. (9), which includes the contributions from kinetic, external potential, Coulomb, and

exchange-correlation potential operators, respectively.

$$\hat{h}_{\text{KS}} = \hat{t} + \hat{v} + \hat{J}[\rho(r)] + \hat{v}_{\text{xc}}(r) \quad (9)$$

The exchange-correlation operator is expanded in a basis of Gaussian-type functions, as seen in Eq. (10), where  $g$  is the cell (vectors) containing the  $j$ th basis function centered at the atomic position  $s_j$ .

$$v_{\text{xc}}^{i,jg} = \int dr \chi_i(r - s_i) v_{\text{xc}}(r) \chi_j(r - s_j - g) \quad (10)$$

This integral is solved analytically because the exchange-correlation potential is expanded with Gaussian auxiliary basis functions,  $G_a(r)$ ; thus the integral is transformed into a linear combination of integrals of the form given by Eq. (11), which is solved only once then stored for subsequent use.

$$g_a^{i,jg} = \int dr \chi_i(r - s_i) G_a(r) \chi_j(r - s_j - g) \quad (11)$$

At each step, the coefficients are recalculated so the exchange-correlation potential fits the analytic form that depends on the charge density. In addition, the exchange potential is calculated by using the Hartree–Fock prescription, yielding a fully non-local functional, and when combined with the PW91 correlation functional, yields one of the so-called hybrid functionals. We use the hybrid functional approach with the gradient-corrected PW91 functionals<sup>[10]</sup> for the correlation potential together with the SBKJC VDZ ECP (8s 8p 6d)/[4s 4p 3d]<sup>[39,40]</sup> ECP and basis set. The Au bulk is treated as an infinite periodic system with face centered cubic (fcc) crystalline structure, thus realistic density of states for a metal is obtained to construct the Green function for the contacts.

## Tools for Molecular Calculations

This section describes tools employing the ab initio based techniques described in the last section.

### Nonlinear circuit solver

Recently, an algorithm able to calculate the current–voltage characteristics of combinations of single molecules has been developed.<sup>[6]</sup> In general, the algorithm is able to determine all possible solutions of an electrical circuit with devices having highly nonlinear characteristics, such as negative differential resistance or resonant tunneling. The solutions to these circuits are multivalued functions, which cannot be obtained with the traditional programs to solve electrical circuits.

The DFT, GF, and their combination, DFT–GF, provide quantitative information needed for the design and testing of programmable molecular circuits. Once the molecule is characterized, the  $I$ – $V$  curve is used as the device characteristic. The analysis is systematically applied branch by branch, such as sweeping a suitable range of currents and determining all compatible voltages from the  $I$ – $V$  of the device in the branch, then all possible voltage drops in the branch (each configuring one possible state) are determined by combining voltage drops on each device.

The method does not scale very well at this stage of development; the scaling depends on the number of solutions for each branch and the number of branches. However, this method can systematically solve any combination of molecular devices irrespective of the particular  $I$ – $V$  characteristic and provide all possible solutions; this feature is not available in any current software for circuit solution.

### Interpretation using molecular orbitals

A powerful technique for the analysis of molecular circuits, i.e., the use of the quantum chemistry techniques, including MOs and their energies, as indexes for the estimation of electron transport was recently introduced into the field of molecular electronics.<sup>[28,29,35]</sup> Delocalized MOs are expected to provide a more suitable path for electron transport, because they simultaneously connect the molecule to the metallic atoms at both ends. Thus analyzing MO qualitative predictions on how easy it is for a molecule to conduct electrons can be inferred. MOs can explain, without calculating the currents, the behavior of several oligomers and the effect of their substituents. Furthermore, using MOs can identify groups in the molecule responsible for a particular observed behavior, information that can be used in the design of new molecular devices; for instance, using them to explain the electrical behavior of  $\pi$ -conjugated organic molecules resembling a resonant tunneling diode.<sup>[28]</sup>

Figure 1 shows some of the conformations studied using DFT. The HOMO–LUMO gap (HLG) energy for planar and rotated  $\pi$ -conjugated organic molecules is reported in this figure at the bottom of the corresponding case. Calculations were extended to include gold clusters at both ends of these molecules. This work determined the mechanism of operation of the molecular resonant tunneling diode (MRTD),<sup>[28]</sup> where the electron transport occurs through the lowest unoccupied molecular orbital and so the shape of the LUMO determines the transport characteristics of the molecule presenting negative differential resistance (NDR). These analyses explained qualitatively<sup>[28]</sup> the peak found experimentally at 2.1 V at a temperature of 60 K,<sup>[41]</sup> and explained the observed reduction in

	A	B	C	D
Q = 0

Q = -2				
HLG $\tau$	1.30/1.59 0°	0.10 <sup>a</sup>	0.80/1.02 0.1°/1.7°	0.36 <sup>a</sup>

**Fig. 1** LUMO plots, HLG energies (in eV), and torsion angles ( $\tau$ ) for the optimized neutral and for the vertical and adiabatic structures of the anions. Only one LUMO is shown if the vertical and adiabatic shapes are similar. *Source:* See Ref.<sup>[28]</sup> for further details.) <sup>a</sup>Only vertical HLG is shown because the structure becomes planar during the optimization.

peak voltage as temperature increases. One of the key findings of this research is that Seminario and Derosa analyzed single molecules providing the effect of amplification.<sup>[42]</sup> Subsequently, electronic transport was fully investigated, and it was concluded that the molecular chemical potential determines the conduction barrier, and that the molecule becomes charged as the external potential increases.<sup>[33]</sup> In earlier studies, Seminario, Zacarias, and Tour<sup>[28]</sup> were able to explain the non-linear character of the current–voltage ( $I$ – $V$ ) characteristic of the molecule and its temperature dependence.

The effect of the bias voltage on the electron transmission of a molecular device, negative differential resistance

A bias voltage applied to a molecule attached to metallic contacts has two effects. On one hand, it changes the Fermi level in the contacts; electrons lower their energy on the positive electrode and increase their energy in the negative electrode and, as a result, electrons are available on the negatively polarized contact at energies for which empty states are available in the

positive electrode. If these electrons find a delocalized molecular level that connects both ends, electron transport occurs. On the other hand, the electric field created across the molecule affects MOs and can change not only their energy, but also the degree of localization; thus a MO that is localized at zero voltage may become delocalized by the electric field and vice versa.

One of the most interesting effects observed in some of the molecules studied is the negative differential resistance (NDR). NDR means negative slope in the  $I$ - $V$  curve. NDR can occur for two main reasons. One is charge or conformational-induced NDR; at a given voltage, the molecule can become charged, or change its structure such that current decreases after the voltage is increased. The other, intrinsic NDR, is produced by a change in the molecular electronic structure that reduces the electron transport capabilities of the MOs involved in conduction. Intrinsic NDR cannot be predicted if a bias voltage is not included in the calculations and cannot be predicted if the correct chemistry of the molecule is not considered. The current is calculated via Eq. (4) (in the section "Green functions"), where  $T$ , the transmission function, would only depend on  $E$  if a field is not applied to the molecule to account for the effect of the voltage. In such a case,  $V$  only enters in the Fermi factors that control the "window"; as a consequence, the current can only monotonically increase with  $V$ , and NDR would not be predicted.

Figure 2 shows the current-vs.-voltage curve for two test molecules; both molecules have three benzene rings separated by a C-C triple bond group. Molecule **1** ( $\text{NO}_2$  in Fig. 2) has two nitro groups as substituents in the central ring; molecule **2** ( $\text{NH}_2$ ) has one nitro and one amino group in the central ring. We used density functional theory (DFT) calculations to explain the electrical behavior of these  $\pi$ -conjugated organic

molecules with current-voltage characteristics resembling a resonant tunneling diode.<sup>[33]</sup>

Considering the behavior of the neutral of these molecules (blue curve solid and dotted, respectively, for **1** and **2**), intrinsic NDR is observed for **2** at around 1.3 V, while no NDR is observed for **1**. Figure 3 shows the transmission function at voltages relevant for the observed NDR effect. The NDR is observed between 1 and 1.5 V; the integration range to obtain the current at 1 V is from  $-5.81$  to  $-4.81$  eV [Fig. 3 and Eq. (3)], and from  $-6.06$  and  $-4.56$  eV for 1.5 V.

For **2**, a peak in the TF observed between  $-6.06$  and  $-5.81$  eV increases in height and approximately maintains its width when the voltage rises from 1 to 1.3 V (position of the NDR peak). Then the area below TF decreases considerably as the voltage increases further, thus explaining the decrease in the current (NDR). No similar effect is observed for **1**. This effect would have gone unnoticed if an electrical field had not been considered; the observed effect on the TF is entirely attributable to the changes in the molecular electronic structure (changes in MO localization and energy) due to the effect of an external field.

The need to implement the present methods is attributable to the impossibility of using simple model barriers able to represent the potential of small molecules acting on the conducting electrons. There are two ways that NDR and RT can be obtained from a single molecule. 1) The first is by charging the molecule or changing its geometry. Because the ion of a molecule has totally different characteristics than its neutral, charging a molecule is equivalent to substituting a molecule for another in the circuit. 2) Changing the shape of a molecule, for instance, by rotating a ring with respect to the other, which will very likely change the electron transport characteristics of molecule **2** via the intrinsic resonant tunneling (IRT) inherent to most

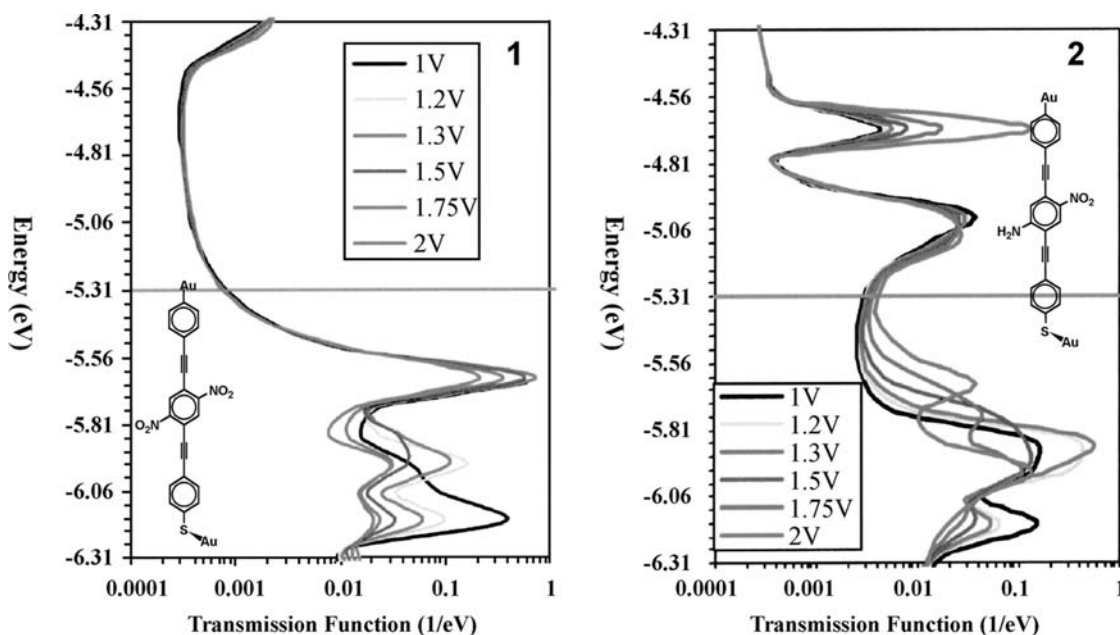

Fig. 2 Current-voltage of the neutrals (blue), anions (red), and dianions (green) for **1** (continuous lines) and **2** (dashed lines).

**Fig. 3** Transmission function vs. energy of incoming electrons at several bias voltages for the neutral of **1** and **2**. *Source:* Adapted from Ref.<sup>[33]</sup>.

molecular systems. The former yields sharp changes in the currents, and the latter yields smoother and symmetric curves, such as those in a typical resonance case.

### Molecular electrostatic potentials

Molecular electrostatic potential (MEP) is another important piece of information needed to understand the electronic properties of molecules. Areas of the molecule with specific properties (such as electron donation or electron-withdrawing capabilities) can be easily identified from an MEP map; this information is extremely useful in understanding molecular interactions and in molecular design. With MEPs, the

well-exploited electronic configuration analysis is able to accurately explain a switching experiment,<sup>[43]</sup> complementing the conclusions drawn by experimentalists, with a further explanation that include concepts and all the factors influencing the switching of the molecule, and raising research goals for subsequent experiments.

MEP does not show a smooth behavior across the molecule. For instance, when a bias voltage is applied, the voltage profile shows a complicated topology, which is very different from monotonous decrease that is expected from simple linear or bilinear devices. An example of an MEP profile across a molecule is shown in Fig. 4. Figure 4A shows the MEP profile across a single benzene ring at 2 Å above the benzene plane,

**Fig. 4** Molecular electrostatic potential profile at 2 Å above the molecular plane. (A) No voltage applied across the molecule; (B) side view of the MEP profile when 2 V are applied across the molecule; (C) like (B) but from a different view angle: view of the MEP profile showing the distribution on the plane.

while (B) and (C) are two different views of the MEP topology when a bias potential of 2 V is applied across the molecule. This picture dramatically changes the idea that molecules are simple barriers, and indicates that more precise studies should be performed to properly describe electron transport properties in molecules.

Tour, Kosaki, and Seminario<sup>[44,45]</sup> have also theoretically determined the first precise electrostatic potential profile obtained on a single molecule in the presence of an external potential source.

Seminario and Derosa have heavily investigated the behavior of benzene rings substituted with nitro and amine groups. It has been already determined that these groups render the negative ions of the ring stable with respect to the neutral state of the same molecule, thus they are able to exist as single, stable molecules. In addition, for some of these molecules, electron transport characteristics are different for the anion than for the neutral state. If this is the case, these molecules are able to behave by themselves as memory devices. Our calculations indicate that some of these molecules are able to store a second electron when bonded to metallic atoms.<sup>[28,33,35]</sup> The main advantage of this behavior for molecular electronics is that these molecules present storage characteristics at three levels (charge = 0, -1, and -2), therefore they could behave as devices without the need for a control gate because

we have one extra state available forming a two-terminal, three-state device that could be substituted for a three-terminal, two-state device.<sup>[35,46]</sup>

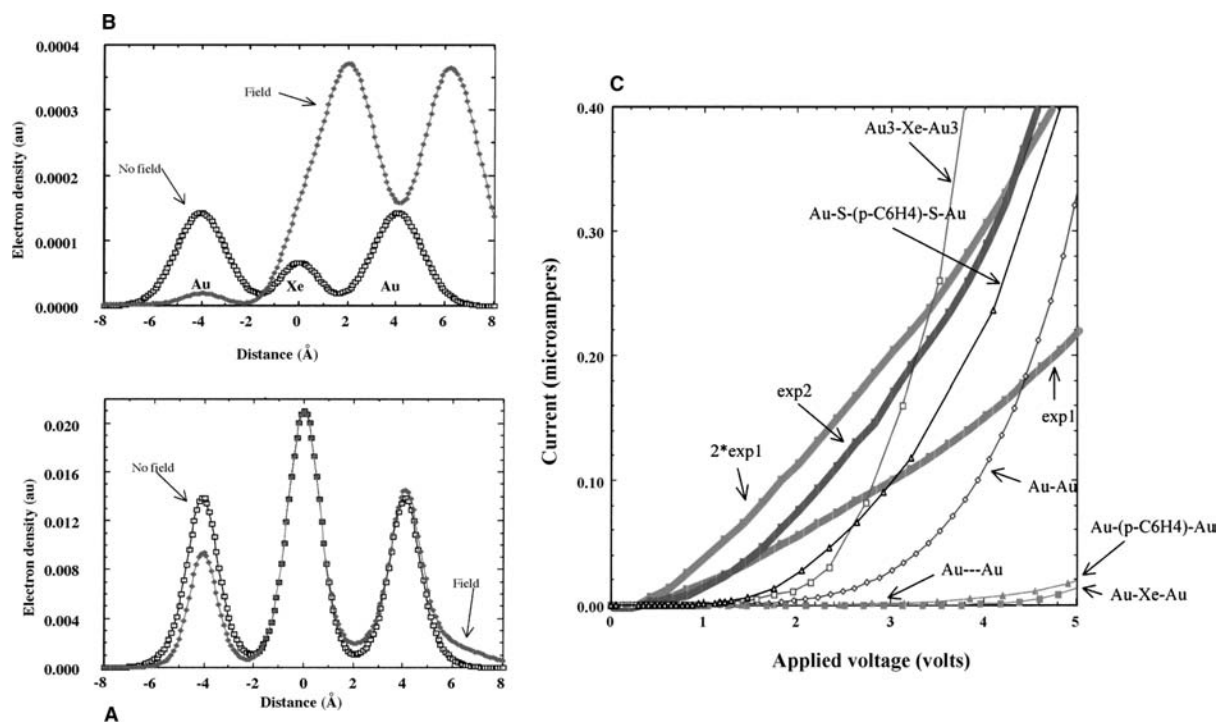

## APPLICATIONS

The following discussion reviews several applications of the tools and techniques described above.

### DFT-Based $I$ - $V$ Calculations

As a preliminary approach to calculating the  $I$ - $V$  characteristic of single molecules, a purely ab initio approach for the calculation of molecular current-voltage characteristics was developed.<sup>[17]</sup>

This method only uses molecular calculations to estimate the  $I$ - $V$  through a molecule, thus formulating a new prescription can obtain current-voltage characteristics via the use of precise quantum chemistry techniques. As shown by the results in Fig. 5, the agreement of calculations<sup>[17]</sup> with the experiments on single molecules<sup>[1]</sup> is very encouraging. Figure 5 shows results labeled as Au-S-(p-C<sub>6</sub>H<sub>4</sub>)-S-Au to be within the two experimental curves exp1 and exp2. This technique does not require any experimental feedback to predict

**Fig. 5** Panels (A) and (B) show electron densities along parallel axes to the molecule (Au-Xe-Au) axis at 1.5 and 3 Å, respectively. Cases when the external applied field is able to transfer one electron from the Au atom on the right side of the junction to the Au atom on the left side are shown. (C) Molecular  $I(V)$  characteristics. exp1 and exp2 correspond to the experimentally determined values of  $I(V)$ . Source: Adapted from Ref.<sup>[17]</sup>.

the  $I$ - $V$  characteristics. In addition, these studies have determined that the position of the molecule with respect to the metal tips has a strong effect on the charge transfer process.

### NDR and Memory

Some molecules have been found to present a particular response, such as NDR, to an applied voltage. This simply means that above a certain voltage, the current through the device decreases when the applied voltage increases. It is experimentally<sup>[41,47]</sup> and theoretically<sup>[28]</sup> known the nitroamine molecule **1** shows a strong negative differential resistance; its  $I$ - $V$  is characterized by a threshold at low voltage, followed by a steady and pronounced increase in the current until it reaches a maximum, then it sharply decreases. The steady increase in current is partly attributable to the increase in the TF of the neutral molecule, but is mainly a result of a simultaneous charge of the molecule to  $-1$ . The current for the negative ion is relatively small compared to the corresponding current that could be obtained with the neutral state; however, this is in qualitative agreement with the experiment where only 1 nA is obtained at the peak of the curve through  $\sim 1000$  molecules. The sharp drop observed in the experiment is attributable to a second electron charging the molecule, and yielding a current lower

than the currents for neutral and anion as shown in Fig. 2. These characteristics, together with the fact that the presence of Au atoms stabilizes the first two anions, make this molecule suitable for use as a memory device. Based on experimental observations,<sup>[41,47]</sup> the molecule probably charges with one electron at a voltage between 0.5 and 1.5 V, and most likely one electron is stored at a voltage closer to 0.5 V as a result of the position of the LUMO (Fig. 6), which is accessible for conduction at a bias voltage of 0.6 V, while the second electron is stored at a voltage closer to 1.5 V.

A bias voltage charges (writes) the neutral, and a pulse below 0.5 V allows reading the state of the molecule without altering its charge state—thus the “memory” can be read. If uncharged, the molecule will be in a low impedance state; but if charged, it will be in a high impedance state. The predicted position of the NDR peak is not exactly identical to the experimental observation, probably because of temperature effects<sup>[28]</sup> that we had not considered, and the fact that the experimental setting corresponds to a statistical average of ca. 1000 molecules in parallel.

Molecule **2** (dinitro) had not been experimentally tested (to the best of our knowledge); therefore, its characteristics were inferred from this study. Its anion and dianion were also predicted to be stable against electron ejection. If we assume that the molecule remains uncharged for low voltages, a threshold for conduction is observed. The LUMO of this molecule

**Fig. 6** Density of states (A) and transmission function (B) for the neutral of **1** (blue) and **2** (red). The position of  $E_F$ , i.e., the interface between the occupied and unoccupied levels, is a 5.31 eV (light blue). *Source:* Adapted from Ref.<sup>[33]</sup>.

is accessible for conduction of electrons from the metal contacts at bias voltage of 2V, thus this molecule will not become charged for lower bias voltages. The storage of one electron in this molecule yields a sharp increase of current. If another electron is stored, a sharp decrease takes place.

NDR is expected in the dinitro molecule, although with a different mechanism than for the nitroamine. Unlike the latter, a range of voltages might be predicted in which the dinitro molecule is in a high conductance state, rather than just a peak. As a result, charged and uncharged states can be easily identified. The dinitro molecule can also perform as memory device. Its neutral shows high impedance, while its single ion shows low impedance. A read pulse should be lower than 2V, the conductance of the neutral and the single charged state are perceptibly different in that range, and the applied voltage is insufficient to charge the molecule if it is uncharged. However, if the write pulse is large enough to doubly charge the molecule, an ambiguity can result, because both neutral and double charge states of the molecule show high impedance.

The nitro groups are known to be electron-withdrawing groups; therefore, when the dinitro is connected to macroscopic tips, electrons are available in the contact flow and could charge the molecule even without an applied voltage, resulting in a current-voltage characteristic that is different from what is expected for the neutral. High conductance is expected at low voltages, with a sudden drop when a second electron is stored. This molecule is stable under the ejection of the second electron, thus keeping the charge until it is forced to discharge. A voltage pulse of more than 2 V writes a nonconducting state in the molecule, and a low voltage pulse will read the molecule statically, i.e., without changing its charge state.

### Molecular Gain

An interesting manifestation of molecular gain was discovered,<sup>[48]</sup> and later calculated by using high levels of theory<sup>[42]</sup> considering two different modes of operation of a single molecule with two phenyl rings. The relative position of these rings, perpendicular or parallel with respect to each other, determines the magnitude of the impedance.

The observed rotational barrier for this molecule is about 0.05 eV, which is the energy needed to shift from the parallel conformation to the perpendicular one. However, when such a shift occurs, the HLG increases to 0.85 eV—in other words, by investing 0.05 eV, the transmission barrier can be changed to 0.85 eV, which corresponds to an amplification factor of 17.

Another important finding of this calculation is the switching capabilities of this molecule, the coplanar

Fig. 7 Demonstration of molecular gain in a thiolane system.

conformation present an impedance of  $\sim 50 \text{ K}\Omega$  at 1 V, whereas for the perpendicular conformation, the impedance is almost  $3 \text{ M}\Omega$ , i.e.,  $\sim 60$  times greater (Fig. 7).

Figure 7 shows the  $I$ - $V$  for both conformations, the planar and rotated conformations. The solid line corresponds to the  $I$ - $V$  obtained after the application of an electric field to the molecule, the dotted line represents the zero-field approximation, i.e., the Hamiltonian at zero bias is used for the entire voltage range. No significant difference between the two approaches is observed for this molecule up to 1 V. Thus the zero-field approximation, unlike that for other molecules, works fairly well here.

### Conducting and Insulating Molecular Devices

Seminario, DeLa Cruz, and Derosa<sup>[49]</sup> demonstrated that molecules of nanometer sizes could still be characterized as low- and high-impedance devices by using quantum ab initio techniques. Low-impedance and high-impedance devices are needed as building blocks for circuits and systems in molecular electronics. Small alkanes and polyene chains with  $\sigma$  and  $\pi$  bonding, respectively, yield a high-low impedance relation of 2 orders of magnitude for changes of 1 nm in length, of 3 orders of magnitude for changes of 1.3 nm in length, and with exponential growth after 0.9 nm. A substantial difference between polyenes and alkanes is observed at small lengths; this difference is unpredictable from what is known about the larger chains.

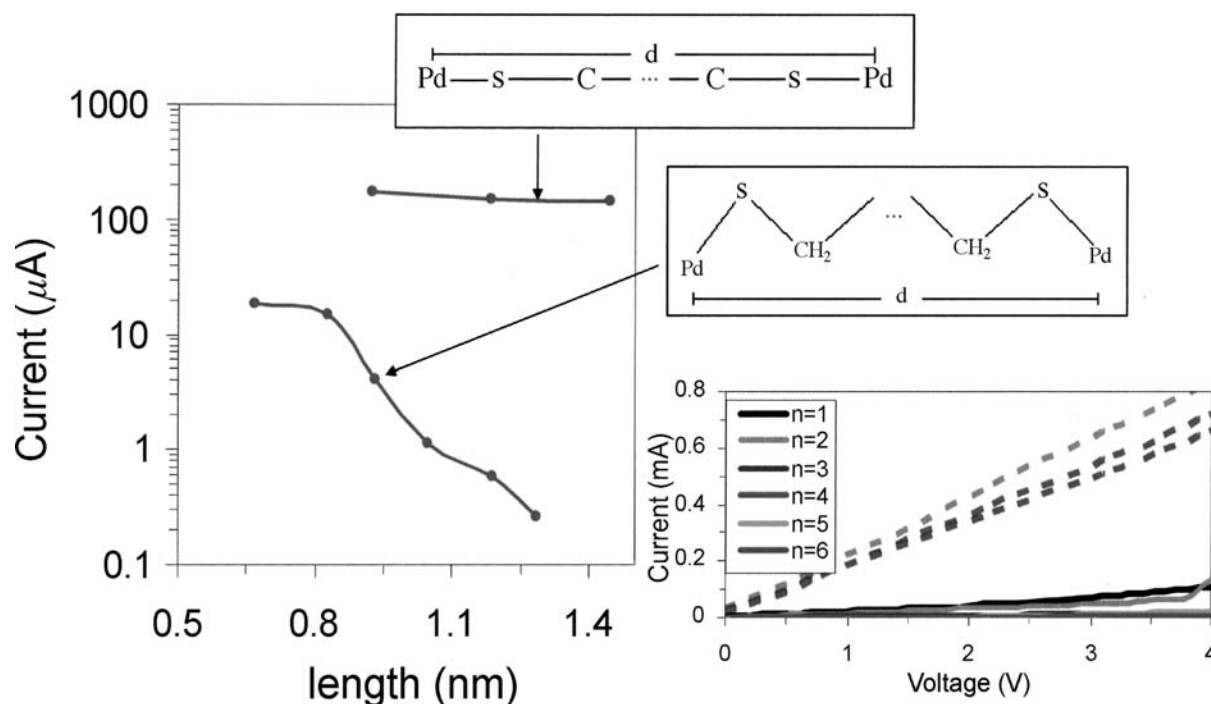

Fig. 8 Variation of the current in the alkanes and polyynes.

The current in the alkanes is relatively low compared with the current in the polyynes. The current in the polyynes increases linearly with the voltage, as shown in Fig. 8, but it does not change too much with the size of the polyyne.

On the other hand, the current through the alkanes is smaller and it decreases very rapidly with the number of C atoms in the chain. Figure 8 also shows, in logarithmic scale, the current at 1 V for all cases. While polyynes do not show a significant change with the size of the chain, the current through alkanes decreases rapidly and almost exponentially for the larger alkanes.

### A Programmable Diode

In searching for new possible molecular devices, Derosa, Guda, and Seminario<sup>[50]</sup> studied the molecule depicted in Fig. 9, the molecule 3-nitro-2-(3'-nitro-2'-ethynylpyridine)-5-pyridinethiol (DNNDP) has two pyridine rings with a nitro group each in a meta position with respect to the N atom in the pyridine. The two rings are separated by a phenylene group. The neutral state of this molecule has a stable configuration for which the rings are almost perpendicular to each other ( $\sim 87^\circ$ ).

To the best of the author's knowledge, this molecule is the only six-member-rings-based molecule separated by phenylene groups that presents a stable configuration for which the rings are not coplanar. Even more interesting, the anion and dianion for the DNNDP are

coplanar, thus the same molecule has a stable state with planar and nonplanar conformations. Figure 10 depicts a comparison with other similar molecules: A) is the DNNDP, B) shows the same molecule but without the nitro groups, i.e. two pyridine rings separated by a phenylene, C) shows a molecule similar to DNNDP but with two phenyl rings instead of pyridines, and D) shows the tolane. The only case where the rings are not parallel is A), the DNNDP.

Provided the anion (or the dianion) are low impedance states, a molecule with this characteristic is desirable as a controllable switch—in which switching can be achieved by controlling the charge or the conformation in the molecule. It can also be used as a

Fig. 9 The dinitro dipyridine molecule. Neutral (left), anion (center), and dianion (right) are shown. Au, C, H, N, and O atoms are green, gray, white, blue, and red respectively.

**Fig. 10** Comparison between related molecules, all of them consisting of two six-member rings separated by a phenylene group: (A) both rings are pyridines and each has a nitro group, (B) both rings are pyridines, (C) both rings are phenyls and each has a nitro group, (D) a toluene molecule. Au, C, H, N, and O atoms are green, gray, white, blue, and red respectively.

memory device when connected to two contacts—the molecule can be written by using an external field to control the relative rotation of the rings; this is possible because the presence of the nitro group gives the rings a dipole moment that will interact with the external field. To write a *zero*, we need to induce the non-coplanar conformation; to write a *one*, we need to force the rings to be coplanar and the molecule will grab a charge from the contacts because it is energetically favorable. To read the molecule, we need to sense its current by attaching the molecule ends to contacts: high impedance means zero (rings noncoplanar and the molecule is neutral), low impedance means one (rings coplanar, and the molecule is ionized). Alternatively, this molecule can be a nanoactuator, if we control the charge state; we can induce rotation by charging or discharging the molecule.

The  $I$ - $V$  for this molecule was calculated by attaching two Au atoms on one end to a S atom, and attaching another two Au atoms to the other end, directly bonded to the pyridine ring. The  $I$ - $V$  curves are shown in Fig. 11, as expected, the neutral is a poor conductor

**Fig. 11** Current-vs.-voltage curves for the neutral (black), anion (orange), and dianion (blue). The inset shows details at the low voltage range.

while the anion and dianion conduct very well for positive bias (“+” on the vapor deposited end-top in the figure, and “-” on the self-assembly end) and poorly for negative bias. The different nature of the contacts provides this system with an even more attractive application—it can work as a programmable diode; it will behave as a diode if charged, but it can be turned off if we uncharge the molecule.

The idea of using an external field to induce switching was not born with this molecule, molecules with three phenyl rings were modified by attaching substituents to give this central ring a finite dipole moment to interact with the external field.<sup>[41,51]</sup> Switches based on this idea are schematically represented in Fig. 12.

### Metal Alligator Clip Interactions

Several works were devoted to understand the nature of the molecule–contact interface, and several other models have been proposed.<sup>[23,52–57]</sup> Through the characterization of different metallic contacts as they interact with the molecular device through different alligator clips, it was demonstrated that the best alligator clip corresponds to S, which is, however, not much better than the isonitryl (NC) alligator clip. It was predicted that the best metal for the metal–molecule interface corresponds to Pd, followed by Ni and Pt. Cu can be considered intermediate, and the worst cases correspond to Au and Ag (Fig. 13).

The impact of this study has been accepted at several research environments, including experimental ones, in which Pd and Pt have been considered as main substituents for Au, the metal that had been extensively used as contact for many nanotechnology approaches.<sup>[58]</sup>

A benzene ring bonded through a S or CN group to six different metallic atoms (Ni, Cu, Pd, Ag, Au, and Pt) at each end was fully studied. The  $I$ - $V$  curves were compared with each other, and conclusions were drawn about the best clip–metal combination. For this particular calculation, no electric field was applied to

**Fig. 12** Complementary molecular field effect transistors (CMolFETs): The current through molecules is controlled by an external electric field able to rotate the central part of the molecule. To perform an electronic function, complementary types of molecules are required: Type I are ON when no field is applied and OFF when a field is applied, whereas the opposite takes place for type II molecules.

the molecule, and complementary calculations indicated that frontier MOs of a single benzene ring are hardly affected by the external field, thus unimportant differences would have been found if a field had been applied.

### The Metal–Molecule Interface

Derosa and Seminario also provided the theoretical proof that solved a controversial issue for both experimentalists and theoreticians, which involved the metal–molecule interface geometry.<sup>[29,33]</sup> They demonstrated through the geometrical optimization of different systems that the interaction between the clip and the gold surface is achieved through only one Au atom, rather than through two or three Au atoms, i.e., S tends to bond to one Au atom only. The system analyzed was a single benzene ring attached through a S clip to Au

**Fig. 13** The study of the molecule–contact interfaces provided information about the best way to interconnect molecular systems.

atoms (we considered from one Au atom to five Au atoms). Benzene was chosen because it represents the end group of many molecules very commonly used for molecular electronics, a series of phenyl-based oligomers, and provided an insight into the nature of the metal–molecule interface on a self-assembled monolayer, and the metal–molecule interface on a vapor-deposited metal from *ab initio* DFT.<sup>[59]</sup> The analysis is based on the ability of the Kohn–Sham MOs to determine the electron transport characteristics of single molecules when they are attached to metallic contacts. The geometry optimization performed for all the studied systems used a high-accuracy convergence criterion, and one of the best tradeoffs between precision and cost. Furthermore, the theoretical results reasonably reproduce available experimental evidence.

The self-assembly process consists of the deposition of the molecules over a Au surface; thus, the metallic surface suffers minimal perturbations by the presence of the deposited structure. Accordingly, results show that the interaction between the clip and the gold surface is achieved through only one Au atom, rather than through two or three Au atoms. We predicted a S–Au bond of  $\sim 2.45$  Å and a C–S–Au of  $\sim 105^\circ$ . Considering S in a hollow site attached to three Au atoms in the exact center of the triangle, it is not compatible with the geometry we predicted; if S–Au is 2.45 Å, then the angle C–S–Au is  $137^\circ$  (Au–Au distance in a crystal is 2.88 Å). On the other hand, if the angle C–S–Au is considered  $105^\circ$ , in agreement with our predictions, then the S–Au distance should be  $\sim 1.7$  Å. Either way, we end up with a very high strain configuration, thus a very unstable bond, which is incompatible with the experimental finding that S is a good clip to attach organic molecules to metal surfaces. S, even when it can be above a triangle of Au atoms, cannot be in the center but mainly attached to one of the Au atoms. In short, even if S is above a triangle of three metal

atoms, it will not be in the bare center, but closer to one of the atoms in the triangle; such a Au atom is the one with the highest interaction with the S alligator *clip*. In some cases, the S clip is bonded to two Au atoms; however, the structure becomes energetically less favorable.

### Charge Effect on the Contacts

In a study of the dinitro and nitroamine molecule, Seminario, Zacarias, and Derosa<sup>[33]</sup> determined that all the charge transferred from the Au atoms to the molecule is taken from the Au directly connected to the phenyl ring, and almost no charge is taken from or added to the Au bonded to the S. Therefore, there will be substantial differences when S connects the molecule to the Au atoms at both ends. A calculation of nitroamine molecule, but with two Au atoms in the upper ring instead of one, yields a total charge of 0.38 in the two Au atoms. When three Au atoms are connected at each end of the molecule, the S–Au<sub>3</sub> group at the S end is neutral, while the Au<sub>3</sub> group at the other end bears a total charge of 0.48. This structure has two Au atoms directly connected to the S on one end, and one Au atom connected to the aryl ring on the other end. On the S side, the Au atom not directly connected to S has a charge of –0.2, while the S is positive by the same amount. The Au atoms directly attached to the S are neutral. On the other end, the Au directly attached to the C in the ring holds almost all the charge at that end (+0.46), while the other two Au are almost neutral. This indicates that, even when each nitro group can store up to half an electron, the molecule only takes less than half an electron from the contact with no S. When the nitroamine and the dinitro molecules are charged, part of the charge is stored in the Au atoms rather than in the molecule. For dianions, almost one electron for the dinitro and over one electron for the nitroamine are stored in the Au atoms, plus the sulfur. The fact that the Au atoms adsorb part of the charge does not imply that the molecule cannot become charged with two electrons; in fact, there is no definite limit in the real system where we can distinguish the molecule from the contacts. Certainly, the few first Au atoms making contact to the molecule have to be considered part of the molecule. Most of the charge transferred to the molecule comes from the Au atoms directly attached to the upper ring, irrespective of how many Au atoms are directly connected to the upper ring, or whether there are other Au atoms connected to them. Independently of how the molecule is connected to Au, the amount of charge in the molecule is half of an electron. The Au atoms attached to the upper ring are positive, and compensate the charge in the rest of the molecule.

Even if the molecule is not intrinsically charged at 0 V, it can be easily precharged before its use by applying a bias voltage, and therefore this molecule can operate in another mode with two charge states, –1 and –2.

### Geometry Effects of the Metallic Contacts

To make sure that a more detailed representation of the interface geometry does not strongly affect the electrical characteristics of the molecule, the original geometry in the dinitro and nitroamine molecules, described in the previous sections, was modified by adding one H atom bonded to the C on the vapor deposited end and two more Au atoms on the self-assemble monolayer (SAM) side, such that the S atom is on a hollow site of three Au atoms. The geometries for Au–(2'-nitro-4-ethynylphenyl-4'-ethynylphenyl-5'-nitro-1-benzenethiolate)–Au<sub>3</sub> (**1''**) and Au–(2'-amino-4-ethynylphenyl-4'-ethynylphenyl-5'-nitro-1-benzene thiolate)–Au<sub>3</sub> (**2''**) were partially optimized in the following manner: one Au atom is placed randomly close to a fully optimized benzene ring; then the calculation runs until a local minimum is obtained and it is confirmed by a second derivative calculation of the energy. This full benzene ring plus Au atom system is substituted into the molecules. This forms molecules that are most likely more realistic than those used before. For the S-ended side of the molecule, a triad of Au atoms is optimized and an S atom is placed on the hollow site and optimized with a constraint of C<sub>3v</sub> symmetry. Such a structure is unstable, thus the constraint is needed to represent a possible (111) surface hollow site of an Au crystal. Next, a benzene ring is attached to the S of the Au<sub>3</sub>S system, keeping the Au<sub>3</sub>S base fixed and letting the benzene ring to reach its most stable configuration with respect to the Au<sub>3</sub>S system.

The addition of a C–H bond to the system does not change the frontier MOs or those around them, as shown in Fig. 14. Therefore electrical characteristics, such as the *I*–*V* curve, are not affected. As long as the electronic structure around the Fermi level is the same, drastic changes in the geometry of the system only slightly affect the results. The metal geometry at the interface may add impedance, but the main features, such as NDR, are mostly governed by the molecular conformation in the central ring. This is supported by experiments, which show good reproducibility in the electrical characteristics when measuring several samples of the same molecule. It is expected that the geometry of the vapor deposited Au is different from sample to sample; however, results are reproducible as shown in Ref.<sup>[46]</sup>. On the other hand, it has been shown that the shape of the *I*–*V* curves changes radically when the substituents in the central ring,

**Fig. 14** MOs of **1** and **1''** showing the effects of adding one H and two Au atoms to **1**. (A) LUMO + 3 of **1** and HOMO of **1''**, (B) HOMO of **1** and **1''**, (C) LUMO of **1** and **1''**. Source: Adapted from Ref.<sup>[33]</sup>.

which are those that strongly modify the frontier MOs, are changed. The substituents determine the nature of the molecular device. Thus the contacts do not affect the main characteristic of the device. Conduction is practically attributable to antibonding orbitals, rather than bonding ones, which are much more stable and much lower in energy than the Fermi energy of the metallic contacts. Neither the H bonded to a C nor the addition of more Au atoms contribute to the main channels of conduction through the molecule, because they only contribute with very stable bonding or very unstable antibonding MOs, all of them well localized. Nevertheless, the presence of the C–H or C–Au bonds provides marked and contrasting suggestions on how the contacts were created. A cleavage of the C–H bond could lead to strong damage of the nanopore, and this is certainly of paramount importance for a study of metal vapor deposition. On the other hand, the addition of more gold atoms simply increases the number of localized MOs, but they do not contribute to electron conduction.

Although the correct geometry in the experiment is unknown, the authors believe that the geometry with the S symmetrically centered on a hollow site, sometimes used in theoretical calculations, is chemically and physically impossible. This assertion is based on experimental<sup>[1]</sup> information and theoretical calculations,<sup>[29]</sup> which determine that S should be bonded to just one Au atom. Notice that constraining the geometry is the only way a S atom can be kept in the geometric center of Au triangle—thus confirming our affirmation that this geometry is not realistic. The extended nature of the surface may not be really relevant because the attachment of the molecule to the surface is strongly dominated by local effects. Even assuming that the SAM was performed on a perfect (111) surface, there is evidence that the angles are the correct ones. For instance, an angle of 107° is reported for the bond angle of Au–S–C when alkanes are used.<sup>[60]</sup> This is in agreement with calculations yielding 102° in a slightly different environment. There is experimental evidence indicating that the metal–S–C

angle is 104°,<sup>[61]</sup> which agrees with the theoretical predictions described in this section. Angles on the order of ~150° are certainly a possibility, but they yield substantially less stable structures as observed experimentally<sup>[60]</sup> and theoretically.<sup>[29]</sup>

In summary, interpreting that S is in a hollow site might lead to confusion. The fact is that S does not position itself symmetrically above the center of an Au<sub>3</sub> triangle. The geometry suggested in this section is compatible and in perfect agreement with the experimental findings that S is on a hollow site. However, the S atom does not remain at the center of the triad. We assume two possible and realistic bond angles for S, 90° and 100°, connecting an oligomer chain, thus making a tilt angle of 30° with the normal to the surface, as is already established experimentally for some alkanes.<sup>[60,62]</sup>

### Search for Minimum Molecular Programmable Units

Molecular electronics can be developed if we are able to program a RANDOM arrangement of molecules or a field programmable molecular random array. Preliminary simulations have shown that programming this molecular arrays is possible,<sup>[63–65]</sup> however, schemes for implementing these programming techniques still need to be realized and that starts by characterizing the smallest molecular system with programmable features. Present programs for the calculation of current–voltage characteristics of electronic circuits, needed for such demonstrations, are only able to predict single-valued characteristics. A procedure exists to incorporate molecular physics procedures with a practical analysis of molecular circuits having strong non-linearities.<sup>[6]</sup> The highly non-linear current–voltage (*I*–*V*) characteristics shown by some molecules open up a complete new set of possibilities for operational circuits. However, the engineering design becomes more complex and new approaches should be developed because traditional tools for circuit analysis are prepared to deal mostly with linear

components. Combinations of nonlinear systems yield circuits with multivalued characteristics. Thus determining all the possible states of the circuits is of fundamental importance to characterize operational modes defined as set of states allowed under normal operation. A special signal, usually large in magnitude, above a threshold, can be used to drive this system from one operational mode to another. This flexibility allows more than one  $I$ - $V$  curve for each device, facilitating the programming of molecular circuits.

The first step in the design flow of moletronics systems is to determine the electrical properties of single molecules. Theoretical methods allow scientists to study systems comprising a molecular system interconnected by small metal clusters. Triangular patterns made of gold clusters interconnecting molecules are expected to be the building blocks of moletronics functional units, for which all of their possible functional states need to be characterized. The analysis of possible configurations allowed by self-assembly procedures needs to be performed to find possible programmable units. When programmable molecular units of a given geometrical structure are found, the candidate molecule goes through the simulation loop until the simulated system yields programmable characteristics, otherwise the molecule is discarded and another, with different  $I$ - $V$  characteristics, is chosen. Molecules with

highly non-linear current–voltage ( $I$ - $V$ ) curves are preferred because of their ability to create switchable states. The simulation loop, looking for a programmable molecular unit, begins with the proposal of new single molecular devices and their characterization utilizing ab initio principles. The next step is the characterization of simple combinations of series and parallel circuits of a few units, then functional units can be studied. These minimum programmable units are then combined in larger circuits with more versatility, leading to field programmable molecular random arrays.<sup>[65]</sup>

### Testbed for Molecular Architectures

Having made a considerable effort to characterize the molecular device, a design paradigm for molecular electronics is simulated to demonstrate that clusters of devices showing negative differential molecular impedance can be used as minimum programmable units.<sup>[6,64,66]</sup> These molecular-scale resonant tunneling devices show features of multiple-valued logic and memory. The plausibility of programmability of minimum molecular units arranged in triangular structures, which are similar to the (111) surface of a face centered cubic crystal, are shown in Fig. 15. In general,

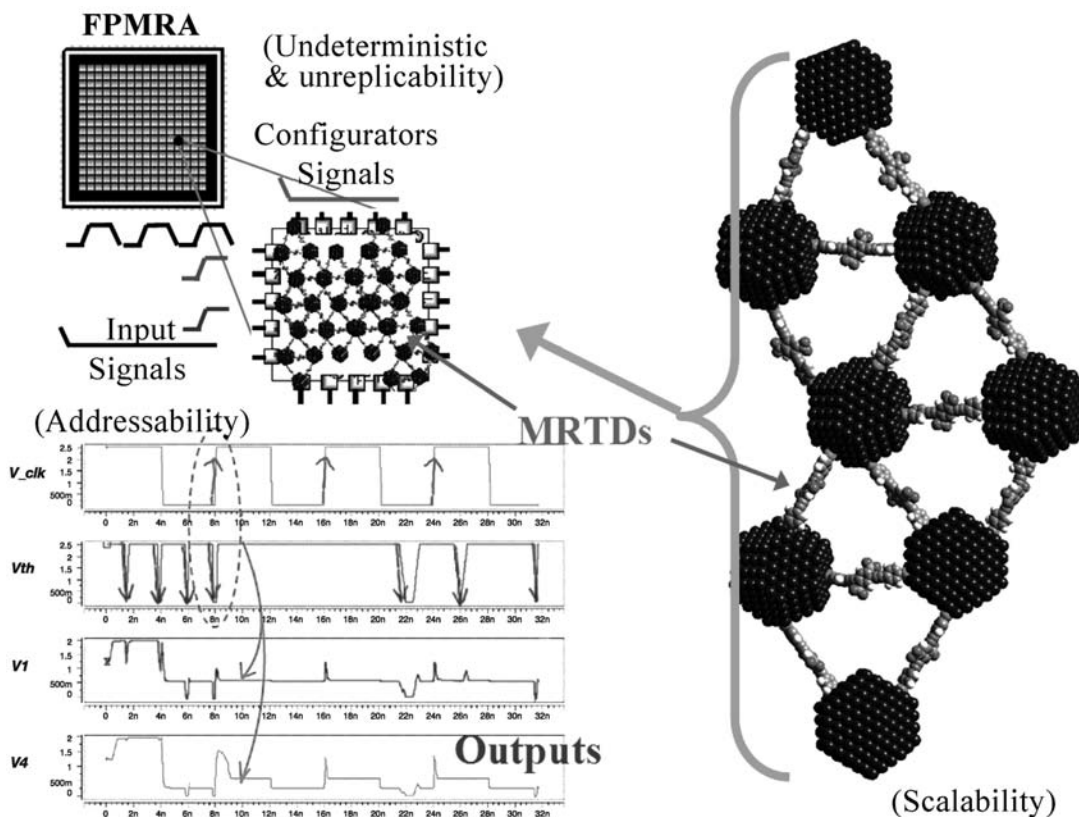

Fig. 15 Design of configurable random molecular logic units.

minimum units can be used as multivalued logic blocks.<sup>[64,66,67]</sup> Input, output, and control signals can be used to program the molefabric to a specific function, which can be accomplished by using artificial intelligence techniques such as neural networks and evolutionary techniques. Future work is needed to test other individual molecules until an optimum molecule, with adequate  $I$ - $V$  characteristics, is found for an efficient learning process of the molefabric.

## CONCLUSION

The field of moletronics is certainly exciting. Modern semiconductor devices are already facing complications with further size reduction, and are now forced to consider quantum mechanical effects as transistor sizes become increasingly smaller. It is believed that the semiconductor industry will soon hit a practical device size limit, and at that point, it will be necessary to pursue alternate computing strategies to further reduce size and power consumption, while providing increased computing power. Moletronics is one such alternative. Because molecules are on the nanometer scale, using them as electrical switches will provide an innate reduction in size, and the high molecular densities that can be achieved should lead to increased computing power. However, it is not expected that moletronics will replace conventional electronics; rather, it will complement it. The small molecular size also introduces many difficulties that must be overcome before moletronic devices can become a reality.

In this entry, we have discussed the methods used to calculate the electronic and electron transport properties of moletronic systems with programmability characteristics, as well as some applications of these methods. Theoretical results showed excellent consistency with experiments and explained experimental phenomena that were observed prior to these simulations, and recently theory was also able to predict experimental outcomes before the actual experiment were performed. This predictive capability enables molecular simulations to actually design molecular components and recommend to experimentalists the most appropriate systems to be tested. Finally, the search for minimum molecular programmable units and how these units may be used for computing purposes were discussed to explain the analysis and design flow of molecular devices.

## ACKNOWLEDGMENTS

We acknowledge Angelica Zacarias, Luis Cordova, Cecilia de la Cruz, Suneel Guda, Hernan Figueroa, and Jimena Bastos, who participated in an earlier work

being reviewed in this article. We also thank David McClard, Nagendra Vadlamani, and Sridhar Bingi for their assistance with the details of the manuscript. We thank James Tour from Rice University for his invaluable contribution to some of the work referred to in this manuscript. We highly appreciate the support of ARO under grants DAAD19-00-1-(0154, 0592, 0634) and DAAD19-99-1-0085, DARPA/ONR under grant N00014-01-1-0657, and the USC NanoCenter.

# Molecular Manipulator: Dynamic Design Criteria

Andrés Jaramillo-Botero

School of Engineering, Pontificia Universidad Javeriana, Cali, Colombia

## INTRODUCTION

The ability to intentionally manipulate three-dimensional (3-D) irregular-shaped matter with atomic precision, abiding to physical laws, is considered as one of the ultimate goals of nanoscience and engineering. Nature has given us a vast assortment of biological molecular machines that demonstrate the viability of this goal, including, among others, the ribosome (which can translate mRNA instructions into proteins) and kinesin, an enzyme that acts as a molecular motor which pulls things toward the outer reaches of the cell. In nerve cells, it is kinesin that pulls vesicles or other cellular materials from the cell body to the nerve endings. These biological systems are primarily “application-specific molecular machines.” They are not universal assemblers that could, in principle, be used in a programmable fashion to perform alternate functions at the molecular level. Self-replicating programmable manufacturing systems able to arrange atoms for multiple “applications” would require a universal assembler with an appropriate end-effector and a corresponding controller. The scope of this entry explores design criteria for such a universal assembler (Fig. 1).

This entry reviews the literature on the creation of nanometer-scale spatial positioners, from a kinematic and dynamic standpoint, as one of the basic building blocks for an atomic-scale manipulator (to arrange differently functionalized molecular building blocks into a lattice or any other nanometer-scale object in a specified and complex pattern, it is necessary to introduce positional control). The development of theoretical criteria for the design of reduced constrained dynamic complexity of a nanoscale positioning device (nanomanipulator), based on the equations of motion (EOM) for spatial serially articulated rigid multibodies, is presented in this entry. By using a rigid-body semiclassical mechanics approach, it is shown how dynamic complexities, such as coupling and non-linearities introduced by high-speed operation, complicate the control task and deteriorate performance. The first section of the entry introduces the reader to appropriate state space forms of the EOM for a serially coupled set of rigid bodies using internal

coordinates. This allows a compact mathematical description of the problem at hand and exposes the intended solution by permitting concise physical insight. The second section develops the complete set of EOM for both the Newton–Euler and Lagrange–Euler formulations. From the state space equivalence of both methods, the EOM are then expressed as a function of the articulated body inertia operator for the multibody, leading to a highly dependent form of the EOM on this operator. The internal matrix structure of the articulated body inertia is then revealed. The third section presents the analysis that leads to a reduced set of EOM from the structural simplification of the articulated body inertia matrix and develops the general kinematics and mass distribution criteria for doing so. From the resulting analysis, a set of compliant manipulator configurations that could, in principle, be built from carbon nanotubes, linked by direct-driven rotational molecular joints, is shown. Finally, the last section concludes on the obtained results and describes current and future work.

## NEED FOR A UNIVERSAL MOLECULAR ASSEMBLER

Today, atomic force microscopy (AFM) provides capabilities that allow scientist to characterize matter at the nanometer-scale (e.g., electrically, mechanically, and chemically) while correlating it to structure.<sup>[1]</sup> But perhaps its most notable capability is that of allowing the manipulation of nanometer-scale objects efficiently on 2-D surfaces,<sup>[2,3]</sup> making it possible to explore substrate–sample interactions<sup>[4]</sup> or the creation of devices incorporating nanometer-scale objects.<sup>[5]</sup> Atomic force microscopy is indeed an important tool for the study of nanodevices, but as impressive as it may be, it is not likely to become the type of atomic manipulator expected to permit the aforementioned goal, leading to the shift in paradigm proposed by molecular manufacturing: bottom-up atomic-scale construction. For this, a new set of devices is required to allow for atomic level manipulation in 3-D space, autonomous/commanded self-replication,

Fig. 1 Universal molecular assembler.

nanometer/submicrometer-scale size, increased spatial dexterity, and higher operational energy efficiency, among others.

Currently proposed nanoscale molecular devices inherit their design, for the most part, from macroscopic counterparts.<sup>[6,7]</sup> Little regard is taken to consider atomic-scale effects (in particular, non-bonded interactions or the discrete nature of the atoms spherical contact surfaces)<sup>[6]</sup> other than mere static structural stability of the molecular components or the undesired dynamic properties being ported from the macroscopic systems to the nanoscale that increase controller complexities and, in some cases, impose serious constraints on performance. Nanometer-scale manipulator designs tend to favor particular characteristics (e.g., force magnitude at the end-effector or stretching stiffness—refer to Fig. 2) while sacrificing other properties that are also fundamental at the nanoscale, such as dexterity (for molecular obstacle avoidance), reachable workspace, or operational speed, among others.

## New Approach

This entry is concerned with the theoretical criteria for the design of a nanoscale positioning device (nanomanipulator), based on the equations of motion (EOM) for spatial serially articulated rigid multibodies, in particular, by using a rigid-body semiclassical mechanics approach. The resulting equations for the corresponding microcanonical or canonical ensembles make it evident that the key operator affecting the complexity of the EOM is the articulated body inertia of the system.

This entry analyzes the necessary conditions under which the spatial articulated body inertia operator for the system can be made decoupled (diagonal) and configuration-invariant (independent of joint coordinates). Simplifying its structure via design, by considering the kinematics and mass distribution of the system, proves to be a major advantage for reducing the complexity of the forward dynamics solution (used in molecular simulations) and the inverse dynamics solution (used in the design of appropriate controllers). The proposed devices are presumed to be fully actuated; that is, joint motion depends on an individual actuator, located directly or remotely on the joint origin.

Although some research has been devoted in the past to highly speculative designs and concepts,<sup>[7,9,10]</sup> some with adequate functionality (evaluated via molecular simulations using first principles), it is worth pointing out that advances into the design of robust modular mechanosynthesis nanodevices are still very limited. This work provides a new direction in this

Fig. 2 Nanometer scale Stewart platform manipulator (left picture—©K.E. Drexler, Institute of Molecular Manufacturing—<http://www.imm.org>) and macroscopic commercial counterpart (right picture—by Physik Instrumente GmbH). Both designs trade off controllability (highly coupled designs that limit speed), dexterity (useful in obstacle avoidance), and reachable workspace for higher payload.

**Fig. 3** Rigid body (atomic clusters) molecular system representation.

quest by proposing novel designs for a positioning device for molecular mechanosynthesis with high dexterity, large workspace (ratio to manipulator size), and improved dynamic performance at high speed that could, in principle, be synthesized from modular self-assembled parts. Furthermore, the proposed designs can be actuated at the corresponding joints by existing polymeric muscles at the nanometer scale. It is assumed that arbitrary positioning of atoms in 3-D space requires at least 3 degrees of freedom, while that of complex macromolecules requires a minimum of 6 degrees of freedom to account for the added complexity of arbitrary orientation of manipulated bodies.

The approach presented here considers a semiclassical dynamics formulation of the constrained EOM for a serial set of articulated rigid molecular bodies, analogous in structure to a human manipulator arm. The notion of rigid body is employed at the molecular level in the context of clusters of atoms (refer to Fig. 3) that make up the primary components of the nanoscale positioning device (e.g., a single atom, a phenyl ring, an alpha helix, or even an entire protein domain). In turn, the notion of constrained dynamics comes from introducing constraints on molecular structural properties such as bond lengths and bond angles to shift focus onto the dihedrals that distinguish conformations, in this way reducing the number of atomic degrees of freedom (DOF).

Consequently, the description and analysis of the molecular system are simplified without losing nanoscale properties, and the real-time requirements for control or simulation of the device are significantly reduced (intracluster motions are neglected). Articulated motion comes from clusters interconnected via

hinges or joints. Joints do not have to be bonded atomically as shown in Fig. 3.

## STATE SPACE REPRESENTATION OF THE EQUATIONS OF MOTION

Assume that the state of the system is known and defined by the collection of generalized coordinates ( $Q$ ,  $\dot{Q}$ ,  $\ddot{Q}$ ) corresponding to effective joint positions, velocities, and accelerations, respectively. Furthermore, assume that the mass distribution of each rigid element of the multibody is completely characterized, given a localized center of mass and a known inertia tensor. It then follows that for a constrained molecular dynamics model, the EOM under Newton's formulation are represented in state space as

$$F(Q) = M(Q)\ddot{Q} + C(Q, \dot{Q}) + N(Q, \dot{Q}) \quad (1)$$

where  $F$  denotes the vector of generalized forces (e.g., torques) applied at the joint,  $N$  are any other conservative forces (e.g., potential) acting on each generalized coordinate,  $M$  denotes the articulated body inertia matrix, and  $C$  denotes the non-linear velocity-dependent terms of force (e.g., Coriolis, centrifugal, and gyroscopic forces). Solving Eq. (1) leads to a direct calculation of joint actuator forces required for the system to follow a specific spatial trajectory. On the other hand, the dynamics of motion are obtained by solving Eq. (1) for effective joint accelerations,

$$\ddot{Q} = M^{-1}(Q)[F(Q) - C(Q, \dot{Q}) - N(Q, \dot{Q})] \quad (2)$$

This entry explores the dependence of both Eqs. (1) and (2) on the articulated body inertia operator  $M$  and particular forms of this operator that lead to reduced complexities in both the inverse and forward dynamics solutions expressed above.

## Canonical Ensemble

Standard Newtonian dynamics leads to conservation of total energy along a motion trajectory; thus the collection of points for this type of molecular dynamics (MD) describes a microcanonical ensemble (NVE: number of particles, volume, and energy are conserved). To deal with normal experimental conditions, it is necessary to add contact with a heat bath at constant temperature. An appropriate ensemble to simulate these conditions (NVT and NPT) is the canonical ensemble. The corresponding extensions to support a canonical ensemble were carried out by Nosé<sup>[11]</sup> and Hoover<sup>[12]</sup> for Cartesian dynamics. Nosé introduced an additional time-scaling variable, and

its conjugate momentum, into the system to represent its interaction with the heat bath. The resulting EOM drive the velocity changes with time which, in turn, drive the changes in thermal energy (kinetic), leading to its proper canonical description. However, Nosé's EOM involve virtual time, which implies unequal time steps in real time. This is inconvenient for the analysis of dynamic properties of the system (e.g., Fast Fourier Transform (FFT)), so Hoover proposed transforming the Nosé EOM into real variables. A concise form of the Hoover dynamics EOM follows,

$$F(Q) = M(Q)\ddot{Q} + C(Q, \dot{Q}) + \Phi_X^{\text{nb}} + \xi M(Q)\dot{Q} \quad (3)$$

where  $\Phi_X^{\text{nb}}$  is the sum of gradients of the non-bond and external potentials  $\Phi$  with respect to Cartesian coordinates and  $\xi$  denotes the baths friction coefficient. For simulation purposes, the friction coefficient,  $\xi$ , is integrated for each time step using a modified leap frog verlet from the relation between the ratio of instantaneous temperature to bath temperature and the inescapable of relaxation of the bath variables.<sup>[13]</sup>

It should be noted that Eq. (3) has the same form as that for the microcanonical ensemble [Eq. (1)], except that it includes one additional term: a friction term as a result of the atomic interaction with a heat bath.

### The Articulated Body Inertia Using Spatial Operator Algebra

This section presents an overview of the development of the EOM for a serial chain multibody (Fig. 3) using spatial operator algebra. For additional detail on spatial algebra in multibody dynamics, see Refs.<sup>[14,15]</sup>. From the equivalence between the Newtonian and Lagrangian formulations, a particular form of the EOM is found to express the non-linear velocity-dependent terms in  $C$  [Eq. (1)] as a function of the articulated body inertia of the system,  $M$ . This form of the EOM conduces to a straightforward explanation of why altering the structure of  $M$ , by design, is critical for the dynamic complexity of the system.

### Spatial Transformations

To operate and manipulate 6-D physical quantities on a common coordinate reference frame, 6-D spatial transformation operators are required. For any generic 3-D distance vector from point 1 to point 2,  $t_{1,2}$ , the translation operator is defined as

$$\hat{T}_{1,2} = \begin{bmatrix} U & \tilde{t}_{1,2} \\ 0 & U \end{bmatrix} \quad (4)$$

where

$$\tilde{t}_{1,2} = \begin{bmatrix} 0 & -t_z & t_y \\ t_z & 0 & -t_x \\ -t_y & t_x & 0 \end{bmatrix} \quad (5)$$

is the skew symmetric equivalent to the vector cross product and  $U$  is the 3-D identity matrix.

To simplify notation, a coordinate free form representation of the EOM is adopted, hence the orientation transformation is not made explicit. For an actual implementation of the solution, such an operator is required.

### Newton–Euler Formulation

Assuming a base to tip propagation of kinematic parameters (refer to Fig. 3), the spatial (translational and rotational components stacked in a single 6-D operator) velocities ( $V$ ), from body  $i = 1 \dots n$ , are expressed as

$$V_i = \hat{P}_{i-1,i}^T V_{i-1} + H_i \dot{Q}_i \quad (6)$$

where  $H_i$  denotes the projection matrix onto the joint ( $i$ ) DOF. Differentiating with respect to time results in the spatial accelerations ( $\dot{V}$ ),

$$\dot{V}_i = \hat{P}_{i-1,i}^T \dot{V}_{i-1} + H_i \ddot{Q}_i + \dot{\hat{P}}_{i-1,i}^T V_{i-1} + \dot{H}_i \dot{Q}_i \quad (7)$$

A reverse (or downward) propagation from body  $i = n \dots 1$  of the spatial forces follows to complete the EOM,

$$F_i = \hat{P}_{i,i+1} F_{i+1} + I_i \dot{V}_i + [\dot{I}_i + I_i \dot{\hat{S}}_{O_i,cm}^T] V_i \quad (8)$$

where the spatial inertia matrix for body  $i$ ,  $I_i \in \mathfrak{R}^{6 \times 6}$ , is obtained from the scalar mass and the moments of inertia with respect to a point of interest on the body. Boundary conditions are set accordingly for the type of base (floating/fixed) and for the existence of external forces. Assuming for body  $i$  a mass  $m_i$  and a tensor of inertia  $J_{i,cm}$  about its center of mass, cm, the spatial inertia operator is defined as

$$I_{i,cm} = \begin{bmatrix} J_{i,cm} & 0 \\ 0 & m_i U \end{bmatrix} \in \mathfrak{R}^{6 \times 6} \quad (9)$$

It then follows from the parallel axis theorem that the spatial inertia of the body about the hinge origin,

O<sub>i</sub>, I<sub>i</sub> is given by

$$I_i = \begin{bmatrix} J_{O_i} & m_i \tilde{s}_{O_i,cm} \\ -m_i \tilde{s}_{O_i,cm} & m_i U \end{bmatrix} \quad (10)$$

Finally, spatial forces are projected onto the DOF of each joint to obtain the effective forces,

$$F_i = H_i^T F_i \quad (11)$$

By assuming, for notational simplicity, that EOM are found at the center of mass and by defining higher level physical operators as follows,

$$I = \text{diag}[I_n, I_{n-1}, \dots, I_1] \in \mathfrak{R}^{6n \times 6n}$$

$$H = \text{diag}[H_n, H_{n-1}, \dots, H_1]^T \in \mathfrak{R}^{6n \times m}$$

$$V = [V_n, V_{n-1}, \dots, V_1]^T \in \mathfrak{R}^{6n \times m}$$

$$\dot{Q} = [\dot{Q}_n, \dot{Q}_{n-1}, \dots, \dot{Q}_1]^T \in \mathfrak{R}^{n \times m}$$

$$\dot{V} = [\dot{V}_n, \dot{V}_{n-1}, \dots, \dot{V}_1]^T \in \mathfrak{R}^{6n \times m}$$

$$\ddot{Q} = [\ddot{Q}_n, \ddot{Q}_{n-1}, \dots, \ddot{Q}_1]^T \in \mathfrak{R}^{n \times m}$$

$$F = [F_n, F_{n-1}, \dots, F_1]^T \in \mathfrak{R}^{6n \times m}$$

$$S = \text{diag}[\hat{S}_n, \hat{S}_{n-1}, \dots, \hat{S}_1] \in \mathfrak{R}^{6n \times 6n}$$

$$P = \begin{bmatrix} U & 0 & 0 & \cdots & 0 \\ -\hat{P}_{n,n-1} & U & 0 & \cdots & 0 \\ 0 & -\hat{P}_{n-1,n-2} & U & \cdots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & -\hat{P}_{2,1} & U \end{bmatrix} \quad (12)$$

where  $m$  is the number of DOF per joint and  $U$  is the 6-D identity matrix. Then, Eqs. (6–8) and 11 are rewritten in indexless spatial notation.

$$P^T V = H \dot{Q} \quad (13)$$

Solving for spatial velocities in Eq. (13)

$$V = P^{T^{-1}} H \dot{Q} \quad (14)$$

where

$$P^{-1} = \begin{bmatrix} U & 0 & 0 & \cdots & 0 \\ \hat{P}_{n-1,n} & U & 0 & \cdots & 0 \\ \hat{P}_{n-2,n} & \hat{P}_{n-2,n-1} & U & \cdots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ \hat{P}_{1,n} & \hat{P}_{1,n-1} & \cdots & \hat{P}_{1,2} & U \end{bmatrix} \in \mathfrak{R}^{6n \times 6n} \quad (15)$$

Because  $P^{T^{-1}}$  (upper triangular) is nilpotent,  $P_{0,n}^{T^{-1}} = 0$ , then  $P^{T^{-1}} = P^{-1}$ . For simplicity, let  $\rho \equiv P^{-1}$ , then,

$$V = \rho^T H \dot{Q} \quad (16)$$

From the above equation, it follows that the manipulator Jacobian ( $J$ ), relating the joint state with the end-effector position and orientation, is given by

$$J = \rho^T H \quad (17)$$

In turn, spatial accelerations are written as follows,

$$\dot{V} = \dot{\rho}^T H \dot{Q} + \rho^T \dot{H} \dot{Q} + \rho^T H \ddot{Q} \quad (18)$$

and the spatial forces expressed with respect to joint origin,

$$PF = \dot{I}V + I\dot{V} - \dot{S}IV \quad (19)$$

Solving for spatial forces,

$$F = \rho[\dot{I}V + I\dot{V} - \dot{S}IV] \quad (20)$$

and from projecting onto the axes of motion from Eq. (11), the effective forces are obtained,

$$F = H^T \rho[\dot{I}V + I\dot{V} - \dot{S}IV] \quad (21)$$

Replacing Eqs. (14) and (18) in Eq. (21),

$$F = H^T \rho[\dot{I} \rho^T H \dot{Q} + I[\dot{\rho}^T H \dot{Q} + \rho^T \dot{H} \dot{Q} + \rho^T H \ddot{Q}] - \dot{S} I \rho^T H \dot{Q}] \quad (22)$$

Grouping terms of  $\ddot{Q}$  and  $\dot{Q}$ ,

$$F = [H^T \rho I \rho^T H] \ddot{Q} + H^T \rho \times [\dot{I} \rho^T H + I \dot{\rho}^T H + I \rho^T \dot{H} - \dot{S} I \rho^T H] \dot{Q} \quad (23)$$

Recognizing that Eq. (23) is equivalent, in state space, to Eq. (1), then the articulated body inertia operator for the system is given by

$$M = H^T \rho I \rho^T H \quad (24)$$

Clearly,  $M$  is strictly dependent only on the kinematics and mass distribution of the multibody. Note that it can also be written in terms of the manipulator Jacobian, from Eq. (17)

$$M = JIJ^T \quad (25)$$

The non-linear-dependent (quadratic in velocity) terms (Coriolis, centrifugal, and gyroscopic) in Eq. (23) are extracted as

$$C = H^T \rho [I \dot{\rho}^T H + I \dot{\rho}^T H + I \rho^T \dot{H} - \dot{S} I \rho^T H] \dot{Q} \quad (26)$$

### Lagrange–Euler Formulation

Using the same operators already found, we will express the EOM in terms of the Lagrangian operator,  $L = T - U$ , where  $T$  is the kinetic energy and  $U$  is the potential energy.

#### The kinetic energy of the serial multibody

The kinetic energy for the entire system is the sum of the kinetic energy of each of the links, equivalent to

$$T_i = \frac{1}{2} \sum_{i=1}^n V_i^T I_i V_i \quad (27)$$

This can be expressed in simplified spatial form from the higher level operators in Eqs. (12) and (16), using the above equation,

$$T(Q, \dot{Q}) = \frac{1}{2} \dot{Q}^T H^T \rho(Q) I \rho^T(Q) H \dot{Q} \quad (28)$$

From Eq. (18), it then follows that the kinetic energy is given as a function of  $M$  by

$$T(Q, \dot{Q}) = \frac{1}{2} \dot{Q}^T M(Q) \dot{Q} \quad (29)$$

#### The potential energy of the serial multibody

The potential energy of each link is a function of the geometry of the manipulator. Let  $h_i(Q)$  be the height of the center of mass of the  $i$ th link (position of the center of mass opposing the direction of gravity). The total potential energy for the manipulator is given by the sum of contributions from each link:

$$U(Q) = \sum_{i=1}^n m_i g h_i(Q) \quad (30)$$

where  $m_i$  is the mass of the  $i$ th link and  $g$  is the gravitational constant. For simplicity, the systems potential energy is denoted in spatial notation as

$$U(Q) = \Phi(Q) \quad (31)$$

No gravity pull is assumed at the nanoscale.

The Lagrangian operator for the serial articulated multibody is then written as

$$L(Q, \dot{Q}) = T - U = \frac{1}{2} \dot{Q}^T M(Q) \dot{Q} - \Phi(Q) \quad (32)$$

Yang and Tzeng<sup>[16]</sup> proposed a simple method to “linearize” serial chain robot manipulators based on the Lagrange–Euler formulation. The method consists of eliminating by design the terms in  $T$  and  $U$  that depend on joint coordinate variables. By doing so, differentiation of both kinetic and potential energy leads to complete independence of the EOM on joint rates (velocity-dependent terms) for simple manipulators of up to 3 DOF and simplified dynamics for higher DOF. Nonetheless, the resulting configurations are still joint-coupled.

Applying variational principles to the Lagrangian operator results in the Lagrange–Euler dynamic EOM,

$$F_i = \frac{d}{dt} \frac{\partial L}{\partial \dot{Q}_i} - \frac{\partial L}{\partial Q_i} \quad (33)$$

where  $F_i$  represents the spatial forces acting on the  $i$ th joint.

It will be convenient to express the kinetic energy as a sum,

$$L(Q, \dot{Q}) = \frac{1}{2} \sum_{i,j=1}^n M_{ij}(Q) \dot{Q}_i \dot{Q}_j - \Phi(Q) \quad (34)$$

From Eqs. (29–31), the first term in Eq. (33) is given by

$$\begin{aligned} \frac{d}{dt} \frac{\partial L}{\partial \dot{Q}_i} &= \frac{d}{dt} \left( \sum_{j=1}^n M_{ij} \dot{Q}_j \right) \\ &= \sum_{j=1}^n (\dot{M}_{ij} \dot{Q}_j + M_{ij} \ddot{Q}_j) \end{aligned} \quad (35)$$

On the other hand, the first partial derivative of the Lagrangian operator with respect to joint variables is

$$\frac{\partial L}{\partial Q} = \frac{1}{2} \sum_{j,k=1}^n \frac{\partial M_{kj}(Q)}{\partial Q_i} \dot{Q}_k \dot{Q}_j - \frac{\partial \Phi(Q)}{\partial Q_i} \quad (36)$$

Subtracting Eq. (36) from Eq. (35) results in the EOM. Because the potential energy is dependent only on  $Q$ , these are not expanded (our interest lays on non-linear

velocity-dependent terms)

$$F_i = \sum_{j=1}^n (\dot{M}_{ij} \dot{Q}_j + M_{ij} \ddot{Q}_j) - \frac{1}{2} \times \sum_{j,k=1}^n \frac{\partial M_{kj}(Q)}{\partial Q_i} \dot{Q}_k \dot{Q}_j + \frac{\partial \Phi(Q)}{\partial Q_i} \quad (37)$$

This is expressed in higher-level spatial operators as

$$F = M\ddot{Q} + \dot{M}\dot{Q} - \frac{1}{2}\dot{Q}^T M_Q \dot{Q} + \frac{\partial \Phi}{\partial Q} \quad (38)$$

where  $M_Q$  corresponds to the partial derivative of  $M$  with respect to joint variables.  $\dot{M}_{ij}$  in Eq. (37) can be expanded in terms of partial derivatives to yield

$$\sum_{j=1}^n \dot{M}_{ij}(Q) = \sum_{j,k=1}^n \frac{\partial M_{ij}(Q)}{\partial Q_k} \dot{Q}_k \quad (39)$$

Rewriting Eq. (37) using the above result yields

$$F_i = \sum_{j=1}^n M_{ij}(Q) \ddot{Q}_j + \frac{\partial \Phi(Q)}{\partial Q_i} + \sum_{j,k=1}^n \left( \frac{\partial M_{ij}}{\partial Q_k} \dot{Q}_j \dot{Q}_k - \frac{1}{2} \frac{\partial M_{kj}(Q)}{\partial Q_i} \dot{Q}_k \dot{Q}_j \right) \quad (40)$$

From Eq. (37), the non-linear velocity-dependent terms are given by

$$C(Q, \dot{Q}) = \dot{M}\dot{Q} - \frac{1}{2}\dot{Q}^T M_Q \dot{Q} \quad (41)$$

By inspection, Eq. (37) is equivalent in state space to Eq. (1). It must then follow that Eq. (41)  $\equiv$  Eq. (26),

$$H^T \rho [\dot{I} \rho^T H + I \rho^T \dot{H} + I \rho^T \dot{H} - \dot{S} I \rho^T H] \dot{Q} \equiv \dot{M}\dot{Q} - \frac{1}{2}\dot{Q}^T M_Q \dot{Q} \quad (42)$$

The proof of this equality is reached in a straightforward manner from the time derivatives of the spatial operators.

The key issue here is noting the dependence of  $F$  on  $M$  in Eq. 40. By doing so, the following can be said about simplifying the complexity of  $F$  via careful structural design of the multibody.

1. Obtaining a decoupled form of the articulated body inertia operator (i.e., a diagonalized form of it) eliminates joint actuator interactions.
2. Obtaining a configuration-invariant form of the articulated body inertia operator eliminates the dependence of  $M$  on joint coordinates ( $Q$ ), hence non-linear velocity-dependent terms in

the EOM ( $C$ ) vanish, except non-bonded potential components and friction term.

## STRUCTURAL SIMPLIFICATIONS ON $M$ THAT LEAD TO SIMPLIFIED CONSTRAINED DYNAMICS

The existence of a diagonalized composite body inertia form for serially articulated rigid-body spatial manipulators can be proven given that the representing mass operator for the system defines a metric tensor.<sup>[17]</sup> If this tensor is made to be metric Euclidean (i.e., with constant coefficients) by design, based on kinematic and mass distribution characteristics, then its configuration manifold is flat and the associated curvature tensor vanishes<sup>[21]</sup> (i.e., global diagonalizing transformation exists).

$$R_{hijk} = \frac{1}{2} \times \left[ \frac{\partial^2 M_{hk}}{\partial Q_i \partial Q_j} + \frac{\partial^2 M_{ij}}{\partial Q_h \partial Q_k} - \frac{\partial^2 M_{hj}}{\partial Q_i \partial Q_k} - \frac{\partial^2 M_{ik}}{\partial Q_h \partial Q_j} \right] + \sum_l \left[ \left\{ \begin{matrix} l \\ ij \end{matrix} \right\} [hk, l] - \left\{ \begin{matrix} l \\ ik \end{matrix} \right\} [hj, l] \right] = 0 \quad (43)$$

where  $R$  is the curvature tensor of  $M$ ,  $R_{hijk}$  is the corresponding  $n(n+1)/2$  Riemannian symbols of the first kind,<sup>[18]</sup> and the quantities

$$[ij, k] \text{ and } \left\{ \begin{matrix} k \\ ij \end{matrix} \right\}$$

are the Christoffel symbols of the first and second kind,<sup>[18]</sup> respectively, which are computed from the corresponding first derivatives of the mass matrix operator with respect to the joint angles.

On the other hand, the existence of a configuration-invariant form of the articulated body inertia can be proven and the corresponding criteria can be derived when the first-order partial derivative of the corresponding metric tensor with respect to joint coordinates vanishes ( $M_Q = 0$ ),

$$M_{Q_i} = \frac{\partial H^T}{\partial Q_i} \rho I \rho^T H + H^T \frac{\partial \rho}{\partial Q_i} I \rho^T H + H^T \rho \frac{\partial I}{\partial Q_i} \rho^T H + H^T \rho I \frac{\partial \rho^T}{\partial Q_i} H + H^T \rho I \rho^T \frac{\partial H}{\partial Q_i} = H^T \rho [\tilde{H}_\delta^i \rho I - I \rho^T \tilde{H}_\delta^i] \rho^T H \quad (44)$$

where the matrix  $\tilde{H}_\delta^i$  is the  $6n \times 6n$  matrix whose elements are all zero, except for the  $6 \times 6$  block corresponding to the  $\tilde{H}_i$  at the  $i$ th location on the diagonal. The index  $i$  corresponds to the joint-angle  $Q_i$  with respect to which the sensitivity derivative of the mass matrix  $M_Q$  is being taken.

An alternate approach comes from the structure of  $M$ . By analytically determining the joint

Fig. 4 Schematic of two rotational DOF arm and corresponding kinematic and mass parameters (cylinders indicate rotating joint).

coordinate-dependent terms in  $M$  and explicitly eliminating these, or inducing their constancy, through design criteria, configuration invariance can be achieved. Additionally, the off-diagonal terms in  $M$  can be explicitly removed by design. Expanding the spatial operator form of  $M$ , found in Eq. (24), into its diagonal and off-diagonal components leads to

$$M_{i,i} = H_i^T \left[ I_i + \sum_{k=i+1}^n \hat{P}_i^k I_k \hat{P}_i^{kT} \right] H_i \quad (45)$$

$$M_{i,j} = H_i^T \left[ \hat{P}_j^i I_j + \sum_{k=j+1}^n \hat{P}_i^k I_k \hat{P}_j^{kT} \right] H_j \quad i > j \quad (46)$$

For a serial chain,  $M$  is symmetric positive definite, then,  $M_{j,i} = M_{i,j}^T, j < i$ . Clearly, Eq. 45 cannot be null because of the principal moments of inertia.

**Structural Manipulator Building Blocks**

Simple two DOF cases can serve as building blocks for more complex articulated multibodies. For 2 DOF arms with open kinematic chain structure, the articulated body inertia cannot be decoupled unless the joint axes are orthogonal to each other (refer to Fig. 4). Possible mass distribution properties for decoupledness assuming joints with a rotational single degree of freedom,  $r$  as the distance vector between the two joints,  $b_i$  as the direction cosines of the joint axes ( $z_i$  as the joint axis), and a tensor of inertia given by

$$J = \begin{bmatrix} I_{xx} & I_{xy} & I_{xz} \\ I_{yx} & I_{yy} & I_{yz} \\ I_{zx} & I_{zy} & I_{zz} \end{bmatrix} \quad (47)$$

are shown in Fig. 5.

Fig. 5 Decoupled configurations resulting from Fig. 4.

For arms with open kinematic chain structure, the articulated body inertia can only be invariant iff one of the conditions expressed in Fig. 6 or Fig. 7 is met.

The necessary and sufficient conditions for a 2 DOF open kinematic chain structure and mass distribution to possess a decoupled and invariant articulated body inertia are given in Fig. 8. For higher DOF, the above 2 DOF cases can be used as building blocks. On the other hand, one way to relax the orthogonality condition for decoupling is to relocate the actuators to reduce the reaction torques exerted by an actuator. The above configurations assume actuators acting directly on each joint, hence reaction torques are present. From the conditions for decoupling, it can be deduced that decoupling the inertia tensor for more than 2 degrees of freedom requires modification of the structure of the arm mechanism. This was also demonstrated by Asada and Youcef-Toumi<sup>[20]</sup> and Youcef-Toumi<sup>[24]</sup> for macroscopic manipulators with fixed base. Fig. 8 shows a possible 4 DOF multibar spatial mechanism configuration that can be controlled

Fig. 6 Invariant configurations resulting from Fig. 4.

Fig. 7 Decoupled and/or invariant configurations resulting from Fig. 4.

**Fig. 8** Four DOF decoupled and invariant inertia manipulator for simultaneous motions involving  $\theta_{2-4}$ .

in a single plane (fixed waist rotation during motion of  $\theta_2$ ,  $\theta_3$ , and  $\theta_4$ ) with full decoupled and invariant inertia. The rotation of any link is a result of 1 and only 1 actuator [i.e.,  $\theta_1(1,4,6)$ ,  $\theta_2(2,5,8)$ ,  $\theta_3(3,7,9)$ ].

### Thermal Noise and Positional Variance (Uncertainty)

Thermal noise at the molecular level affects the positional accuracy. One of the key issues in achieving good positional accuracy at the nanoscale is controlling temperature or conversely controlling the structural stiffness of the elements that make up the manipulator. The latter is preferred, given the need to operate these nanodevices at room temperature. Because the presented designs have bending forces applied to their structural elements, we wish to evaluate their stiffness with respect to deflection of their ends as a consequence of thermal noise.

This has been shown by Ref.<sup>[19]</sup> from classical statistical mechanics. Let the probability density function for one position coordinate of a particle, say  $x$ , subject to the potential energy function  $V(x)$  be  $f_x(x)$ .

$$f_x(x) = \frac{\exp[-V(x)/k_B T]}{\int_{-\infty}^{\infty} \exp[-V(x)/k_B T] dx} \quad (48)$$

where  $k_B = 1.38 \times 10^{23}$  J/K is the Boltzmann constant and  $T$  is the temperature. From the potential energy for a simple case, say the harmonic potential,

$$V(x) = \frac{1}{2} k_s x^2 \quad (49)$$

it is shown that the probability density function is Gaussian:

$$\begin{aligned} f_x(x) &= \frac{\exp[-k_s x^2 / 2k_B T]}{\int_{-\infty}^{\infty} \exp[-k_s x^2 / 2k_B T] dx} \\ &= \frac{1}{\sqrt{2\pi\sigma_{\text{class}}^2}} \exp\left(\frac{-x^2}{2\sigma_{\text{class}}^2}\right) \end{aligned} \quad (50)$$

Yielding the classical value for the positional variance (=standard deviation squared = mean square displacement = RMS positional error squared),

$$\sigma^2 = \frac{k_B T}{f_R} \quad (51)$$

showing clearly that thermal noise can be controlled by decreasing the temperature  $T$  or by increasing the restoring force  $f_R$  (measured by the stiffness  $k_s$ ).

The positional uncertainty in quantum statistical mechanics for a harmonic oscillator shows that “quantum effects” do not pose a fundamental problem either,

$$\sigma^2 = \frac{\hbar\omega}{k_s} \left[ \frac{1}{2} + [\exp(\hbar\omega/kT) - 1]^{-1} \right] \quad (52)$$

Describing the frequency,  $\omega$ , in terms of the mechanical parameters ( $\omega = \sqrt{k_s/m}$ ) leads to

$$\sigma^2 = \frac{\hbar}{\sqrt{k_s m}} \left[ \frac{1}{2} + [\exp(\hbar\omega/kT) - 1]^{-1} \right] \quad (53)$$

Applying Eq. (51) to a cylindrical rod of radius  $r$ , length  $L$ , and traverse stiffness given by

$$k_s = \frac{3\pi r^4 E}{4L^3} \quad (54)$$

where  $E$  is the material’s Young modulus (e.g.,  $E = 10^{12}$  Pa for diamond), we can deduce that the positional error squared is given as

$$\sigma^2 = \frac{k_B T 4L^3}{3\pi r^4 E} \quad (55)$$

For a rod at room temperature (300 K) of  $E = 10^{12}$  N/m<sup>2</sup> (diamond),  $r = 8$  nm, and  $L = 50$  nm, the RMS positional error is  $\sigma = 0.007$  nm, much less than an atomic diameter. For the quantum mechanical version in Eq. (53), positional variance is again acceptable.

Single-wall carbon nanotubes (SWCN) are good candidates as structural elements. In general, diamond-oid structures are favored for nanomechanical systems because of their fundamental physical properties (strength and stiffness, among others).

Consequently, the structural elements that make up the manipulator must be chosen according to the systems kinematics and the calculated positional error of the end-effector. A simple kinematic analysis shows the calculation of the RMS positional error at the end-effector as a function of the propagation of deflections of the composing structural elements because of thermal noise. Using the cylindrical rods defined previously as structural elements for the kinematic configuration found in Fig. 8, and assuming an equal positional variance in all Cartesian coordinates, the worst-case RMS positional error of the manipulator's end-effector can be computed from Eq. (16) for a joint differential change on all 4 degrees of freedom. Using Denavit–Hartenberg's (DH) convention for coordinate frame assignment and parameterization,<sup>[22]</sup> the Jacobian for such a configuration can be computed algebraically from the kinematics equations,

$$A_1^0 A_2^1 A_3^2 A_4^3 = T_4^0 \quad (56)$$

where

$$A_i^{i-1} = \begin{bmatrix} \cos \theta_i & -\cos \alpha_i \sin \theta_i & \sin \alpha_i \sin \theta_i & a_i \cos \theta_i \\ \sin \theta_i & \cos \alpha_i \cos \theta_i & -\sin \alpha_i \cos \theta_i & a_i \sin \theta_i \\ 0 & \sin \alpha_i & \cos \alpha_i & d_i \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (57)$$

where  $a_i$  and  $d_i$  represent the Cartesian distance between joint axes  $i$  and  $i-1$ ,  $\alpha_i$  is the angle between adjacent joint axis,  $\theta_i$  is the  $i$ th joint angle, and  $T_4^0$  represents the orientation and position of the end-effector with respect to the inertial reference frame.

$$T_4^0 = \begin{bmatrix} n_x & o_x & a_x & p_x \\ n_y & o_y & a_y & p_y \\ n_z & o_z & a_z & p_z \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (58)$$

where  $n$ ,  $o$ , and  $a$  represent the 3-D vectors associated with the orientation of the manipulators' end-effector with respect to the inertial frame  $x$ ,  $y$ , and  $z$  and  $p$  represents the position of the end-effector with respect

**Table 1** Denavit–hartenberg parameters for the manipulator shown in Fig. 8

$a_i$ (rad)	$a_i$ (nm)	$\theta_i$ (rad)	$d_i$ (nm)
$\pi/2$	0	$\theta_1$	50
0	50	$\theta_2$	0
0	50	$\theta_3$	0
0	0	$\theta_4$	0

to the same reference frame. For this particular configuration, the DH parameters are given in Table 1.

The Jacobian can then be calculated from the column vectors that relate the differential Cartesian change of the end-effector with the differential change in each  $i$  joints,

$$\frac{dT_n}{d\theta_i} = \begin{bmatrix} -n_x p_y + n_y p_x \\ -o_x p_y + o_y p_x \\ -a_x p_y + a_y p_x \\ n_x \\ n_y \\ n_z \end{bmatrix} \quad (59)$$

Solving Eq. (16) for  $V$ , the maximum end-effector differential translational deviation in any given coordinate is 0.028 nm (still less than an atomic diameter). This does not account for the additional error introduced by joint backlash.

## CONCLUSION

Two and three DOF configurations with movable base are currently being designed at the molecular level, from modular parts (carbon nanotubes). Decoupled inertia is achievable for manipulators of up to 3 DOF, via structural redesign of the serial chain, while configuration-invariant inertia is manageable for higher DOF systems. These results become the basis for designing manipulators with reduced complexity dynamics, improved stability, and controllability, given that 1) for a hypothetical fully decoupled system, the dynamic control equations could then be computed under strict parallelism in  $O(1)$  with  $O(n)$  processors using a single input single output (SISO) controller (given precomputation of  $\Phi_X^{nb}$ ) and/or 2) for a configuration-invariant system, the computation of the inverse mass matrix does not need to be explicitly addressed at every control/integration time step. Having both conditions met results in the following simplified EOM,

$$F = M\ddot{Q} + \Phi_X^{nb} + \xi M\dot{Q} \quad (60)$$

$$\ddot{Q} = M^{-1}[F - \Phi_X^{nb} - \xi M\dot{Q}] \quad (61)$$

where  $M$  is diagonal and can be precalculated only once.

## INTRODUCTION

Although the biophysical and biochemical properties of motor proteins have been well studied, only recently have attempts been made to develop them as mechanical components in hybrid nanoengineered systems.<sup>[1–4]</sup> The motor protein  $F_1$ -ATPase is the smallest rotary motor known and can generate forces compatible with currently producible nanomechanical structures; we have previously fabricated and operated hybrid organic–inorganic nanodevices powered by  $F_1$ -ATPase (Fig. 1).<sup>[4]</sup> Control of device activity is a critical aspect in the engineering and deployment of integrated nanomachines. There are a variety of possible control mechanisms, including mechanical, optical, electrical, and chemical. We have previously implemented chemical controls into  $F_1$ -ATPase.<sup>[5]</sup> These controls followed from the design and construction of allosteric metal-binding sites that constituted a reversible and repeatable on/off switch of motor activity which was demonstrated in the bulk and at the single molecule level. For biomolecular motor-powered hybrid devices to fully realize their potential, progressing beyond scientific experiments and low-functioning curiosities, the devices and device components should be entirely reimagined from an engineering perspective. Development of a library of controls acting directly on motor proteins, their fuel, the components interfaced with them, or a combination of all of these will be highly useful toward increasing the utility, applicability, and range of operation of engineered biomotors.

In this entry, we will address these issues, describing the results of current research in which control of mechanical proteins incorporated into hybrid devices has been addressed for the first time. We will also discuss our recent work in which chemical controls were incorporated into the  $F_1$ -ATPase, able to reversibly start and stop the mechanical motion at the single molecule level. We will conclude with an outlook of the field as a whole and future directions.

## MECHANISMS AND STRATEGIES FOR CONTROL OF MOTOR PROTEINS

The  $F_1$ -ATPase is a biomolecular rotary motor deriving its mechanical energy from the hydrolysis of ATP. The loaded motor has been measured at the single molecule level to generate a constant torque of  $\sim 40$  pN nm while operating at high (50–100%) efficiency.<sup>[6,7]</sup> The no-load rotational velocity of  $F_1$ -ATPase has been measured to be over 7800 rpm.<sup>[8]</sup> In addition, genetic modification of  $F_1$ -ATPase has allowed the precise (sub-50 nm) positioning of single  $F_1$ -ATPase molecules on engineered nanofabricated substrates of nickel-capped posts.<sup>[4,9]</sup> Such advantageous natural and engineered characteristics of  $F_1$ -ATPase make it an ideal candidate for precision orientation and attachment to nanomechanical structures.<sup>[4,10,11]</sup>

Potential applications of devices using the  $F_1$ -ATPase and other motor proteins are currently limited because of the lack of control over the motor motion. The capability of the motor to reversibly turn on and off in response to an external signal represents an important first step in rational and useful device design for the next generation of biomolecular devices. Motor activity must be directed for device manipulation and efficient use of fuel. In natural biological systems such as the cell, thousands of proteins work interdependently, regulating themselves and others to ensure that the cell can adapt to changing external conditions, wasting no resources and ensuring that essential functions are carried out. These natural biological control mechanisms of proteins and protein complexes regulate their function in response to a variety of external stimuli: chemical, thermal, and mechanical, among others.

Commonly occurring natural controls include conformational changes in some proteins occurring in certain ranges of pH or ionic strength. These shape changes can alter the catalytic or hydrolytic activity of the protein, slow it down, or affect its interactions

**Fig. 1** Depiction of the hybrid nanodevice constructed previously.<sup>[4]</sup> Electron beam lithography was used to construct 50-nm Ni-capped SiO<sub>2</sub> posts on which individual 10 × His-tagged F<sub>1</sub>-ATPase motors were mounted. Ni rods, 75 × 750 nm, were linked to the rotor of the motor through a peptide/biotin/streptavidin/biotin bond. Upon addition of ATP, the rods were observed to rotate using conventional optical microscopy.

with other proteins. These conformational changes can also be induced through the application of electric fields. The advantages of engineering these kinds of responses in motor protein-based hybrid devices draw upon the capability of micro- and nanoelectromechanical systems, MEMS and NEMS, fabrication to place arrays of electrodes at arbitrary positions on a substrate surface. Electric fields produced by such electrodes would give the power to individually address single motors. Electrical control has been shown to exist naturally in the family of porins. Porins are pore proteins that transport water and other solutes across cell membranes, controlling concentration-dependent properties such as osmolarity and acidity. Some porins have been shown to open and close physically in response to an applied voltage, a shape change that activates and deactivates the proteins' transporting ability.<sup>[12–14]</sup> These shape changes are a result of charged or polar groups in the protein responding to an external electric field and, on a small scale, occur in every ligand-receptor binding event. It may be possible to engineer similar responses on other proteins using polar or charged residues to enhance these responses. Proteins not containing the necessary functional groups to respond to the applied fields can be engineered to contain the groups or to further tune their response, much in the same way as the chemical binding sites discussed above were created. Electrical control mechanisms have the promise of addressability, control of activity, and easy interfacing with external instrumentation.

Motor activity can also be controlled without changing the protein conformation. Attachment of cargo presenting variable loads resulting from viscous, electric, or magnetic forces will result in a change of the

motor speed for molecular motors with constant torque output, such as F<sub>1</sub>-ATPase. Although this will not be possible in every case, it is a powerful and flexible method of motor control. Any moving part attached to the motor, if susceptible to an external field, may be used to increase controllably the drag force experienced by the motor. Work by Noji et al.<sup>[15]</sup> have used this principle to study the rotation characteristics of F<sub>1</sub>-ATPase. In these experiments, magnetic beads were attached to F<sub>1</sub>-ATPase motors lying on a substrate while observed by optical microscopy. As the rotary shaft of the motor turned, the bead turned with it. An external magnetic field with controllable direction and magnitude was applied to this system, creating a counterforce opposing the rotation of the motor. Fields large enough to slow and stall the motor were used, with the result that the rotary energy potential of the motor was determined.

There are several different strategies for the implementation of controls into hybrid biomotor devices. In contrast to natural systems, primitive engineered hybrid nanosystems to date have contained only a few proteins removed from their natural environments and therefore also removed from their natural control mechanisms. As a consequence, much regulation of the function of motor proteins is often possible only through regulation of the fuel supply. Fuel-based control techniques are able only to activate motors, with the motors functioning until the fuel is exhausted. In the regime of Michaelis–Menten kinetics (i.e., in a steady state when the substrate concentration is much greater than the enzyme concentration),  $V = V_{\max}[S]/(K_M + [S])$ , where  $V$  is the catalytic turnover rate,  $V_{\max}$  is the maximum rate,  $[S]$  is the substrate concentration, and  $K_M$  is the Michaelis constant. Therefore the enzyme velocity can be controlled by the substrate concentration, for substrate concentrations small compared with  $K_M$  ( $K_M$  for unloaded F<sub>1</sub>-ATPase is 15 μM). There are significant shortcomings with an approach based on the regulation of the fuel supply: other ATP-utilizing molecules will also be affected, there is no differential motor control, and fine control of operational parameters such as speed is not possible.

Recent work in chemical control mechanisms has utilized light-activated “caged” ATP, a chemical derivative of ATP in a non-hydrolyzable form, which is able to release a defined amount of ATP related to the intensity, duration, and location of optical illumination.<sup>[16]</sup> This technique has controlled the operation of kinesin motors for proscribed periods of time as they proceeded along microtubule tracks (Fig. 2).<sup>[1]</sup> Alternative mechanisms of fuel-based control include myosin mutants with engineered binding sites having sensitivities for analogs of ADP with bulky side

**Fig. 2** Average speed of microtubules after exposure of caged ATP to UV light for 30, 60, and 60 sec converting 20%, 30%, and 20% of the initial caged ATP into free ATP. The presence of the ATP-consuming enzyme, hexokinase, leads to a rapid decline of the microtubule velocity. The inset shows the structure of DMNPE-caged ATP. *Source:* From Ref.<sup>[1]</sup>.

chains such as *N*<sup>6</sup>-(2-methylbutyl) ADP, allowing differential control between specific motor types.<sup>[17]</sup>

Alternatively, chemical control of the motors apart from fuel regulation may be effected through chemical modification of the motor itself. By engineering peptides which bind directly to each other, the motor can be stopped in the presence of the appropriate chemical reagents, as in reversible disulfide cross-linking of kinesin.<sup>[18]</sup> Alternatively, enzyme activity may be altered by engineering metal ion-binding sites (e.g., the addition or substitution of histidine, aspartate, or lysine residues)<sup>[19]</sup> into appropriate regions of the protein. The presence of these metal-binding sites can fix adjacent regions of the protein to each other by introduction of metal ions into these binding sites. This induces strong bonding between the ions and adjacent residues. Because ions can bind several amino acids simultaneously, it is possible to attach two separate, independent regions to the ion—in effect, altering the local elasticity of these subunits by fixing them to each other. If movement of these regions is necessary for protein activity, this activity can be impaired or entirely halted. This is an illustration of an allosteric control mechanism, a mechanism in which enzyme function is controlled without affecting substrate availability or reactivity. With this aim, we genetically modified the F<sub>1</sub>-ATPase, engineering pockets in the enzyme with high affinity for binding zinc ions. When the protein binds the zinc, it is incapable of performing the conformational changes necessary for rotation of its central shaft, the  $\gamma$  subunit, therefore stopping the motor from further motion.

## IMPLEMENTATION OF ALLOSTERIC CHEMICAL CONTROLS INTO F<sub>1</sub>-ATPASE

Isolated F<sub>1</sub>-ATPase is composed of five different subunits with stoichiometry of  $\alpha_3\beta_3\gamma\delta\epsilon$ . The  $\alpha_3\beta_3\gamma$  sub-complex of F<sub>1</sub>-ATPase has been identified as a minimum ATPase-active complex with characteristics and stability similar to native F<sub>1</sub>-ATPase.<sup>[20–22]</sup> The X-ray crystallographic structures of the F<sub>1</sub> fragment of the bovine mitochondrial ATPase (BF<sub>1</sub>) have revealed the nature of the conformational changes involved in ATP hydrolysis in atomic detail.<sup>[23]</sup> The crystal structures of BF<sub>1</sub> show that three  $\alpha$  and three  $\beta$  are arranged alternately forming a hexameric aggregate having one nucleotide binding site each, with the long coiled-coil structure of the  $\gamma$  subunit inserted into the central cavity of the ring. There are three catalytic sites, located on  $\beta$  subunits at  $\alpha/\beta$  interfaces, and three non-catalytic sites, located on  $\alpha$  subunits at different  $\alpha/\beta$  interfaces. The  $\beta$  subunits assume two conformations in the crystal structures, an open and a closed state, that interconvert via a hinge-bending motion. In the closed state, the  $\beta$  subunit binds ATP ( $\beta_T$ ) or ADP ( $\beta_D$ ); in the open state, the active site is empty ( $\beta_E$ ). The corresponding conformations of the  $\alpha$  subunits are designated as  $\alpha_T$ ,  $\alpha_D$ , and  $\alpha_E$ . The conformations of  $\alpha_T$ ,  $\alpha_D$ , and  $\alpha_E$  are nearly identical. In contrast, the structures of  $\beta_T$  and  $\beta_D$ , which are quite similar to each other, are completely different from that of  $\beta_E$ . The  $\beta_T$  and  $\beta_D$  are in the “closed” conformation, the C-terminal domain of which is elevated, closed to the nucleotide binding domain, while the  $\beta_E$  is in the “open” conformation, with its substrate binding site open.<sup>[23–25]</sup> Although  $\beta_T$  and  $\beta_D$  adopt the same overall state, there are structural differences in several surface loops related to the critical role of these states in the rotary motion of this complex.

During ATP synthesis, the three non-catalytic sites are homogeneously liganded with MgAMP-PNP (an ATP analog), whereas the three catalytic sites are heterogeneously bound to ligands during normal enzyme operation. These structural features, in addition to the direct observation of  $\gamma$  rotation in F<sub>1</sub>-ATPase,<sup>[26]</sup> strongly support the binding change model established by Boyer.<sup>[27]</sup> The rotary mechanism postulated by this model assumes that the sequential participation of the three catalytic sites and alternate interchange of their roles during ATP hydrolysis drive the counterclockwise rotation of the  $\gamma$  subunit.<sup>[28,29]</sup> In other words, the intrinsic conformational changes induced by the heterogeneous nucleotide affinities to catalytic sites, coupled with the rotation of  $\gamma$ , are crucially necessary for the catalysis of ATP hydrolysis.

The binding change mechanism suggests that F<sub>1</sub>-ATPase activity can be controlled by blocking the conformational changes necessary for ATP hydrolysis.

Because the six  $\alpha/\beta$  interfaces (three interdimer and three intradimer) are all different, and the rotation of the  $\gamma$  subunit relies on sequential interchange between different conformational and substrate ligation states, we hypothesized that reversible inhibition of the catalytic and rotation cycle may be achieved through insertion of secondary metal binding site capable of interfering with the sequential cycle (Fig. 3). When the open/closed conformational interconversion of the  $\beta$  subunits is hindered, the nucleotides that have been bound (MgATP or MgADP) are trapped and free nucleotides are prevented from entering the binding sites. Because the conformational states of  $\alpha_T$ ,  $\alpha_D$ , and  $\alpha_E$  are identical, they provide an immobile substrate to which the  $\beta$  subunits can be fixed, physically preventing switching between cooperative nucleotide binding sites and the rotational movement of the  $\gamma$  subunit. The effect of this hypothetical conformational lock is to fully inhibit the operation of F<sub>1</sub>-ATPase. Such a site is therefore predicted to function as a classic allosteric inhibitor of enzyme activity<sup>[30]</sup> and should provide a chemical switch for the control of motor activity in a nanomechanical device.

Obviously, a strong permanent binding of the  $\alpha$  and  $\beta$  subunits directly to each other would permanently immobilize the protein, possibly irreversibly. However, binding them each to a multivalent ligand in effect

binds them to each other, accomplishing the same immobilization. Furthermore, removal of the ligands restores the protein to its initial state and reverses the immobilization. With this in mind, we modeled bovine mitochondrial F<sub>1</sub>-ATPase and designed binding sites in the protein intended to have high affinities for zinc ions. We chose to construct an allosteric control element based on a zinc-binding site, as these domains are relatively compact, consisting of three or four amino acids that chelate the metal.<sup>[31]</sup> Moreover, computational design methods have been developed that reliably predict and construct de novo metal centers into proteins of known structure.<sup>[32–34]</sup> Reversible inhibition of the enzymatic activity may be readily achieved by the addition of extrinsic metal chelators (e.g., 1,10-phenanthroline) that sequester zinc, but not the Mg<sup>2+</sup> required for ATP binding and hydrolysis. The bovine protein was modeled because the crystal structures of the F<sub>1</sub>-ATPase in empty, ATP-bound, and ADP-bound states are known. Such structures of the F<sub>1</sub>-ATPase from thermophilic *Bacillus* PS3 (TF<sub>1</sub>), used in our previous experiments, are not available. However, TF<sub>1</sub> also has a functional asymmetry among the three catalytic subunits, although it does not contain any endogenously bound nucleotide.<sup>[35]</sup> Therefore the binding change model-based design for the fixation of conformational change in bovine F<sub>1</sub>-ATPase

**Fig. 3** Model for zinc switch-controlled ATPase. Counterclockwise rotation of the  $\gamma$  subunit from  $\alpha_E$  to  $\beta_D$  initiates a conformational change. Blue circles represent  $\alpha$  subunits liganded with MgATP (omission of ATP for clarity). Green circles represent  $\beta$  subunits at different states: circles represent  $\beta$  liganded with MgATP, ellipses represent  $\beta$  in the transition from closed to open conformation, and hexagons represent  $\beta$  in open conformation. [ATP] represents the transition state of  $\beta_D$  converting from closed to open conformation.  $\sim$  represents the energy released during the hydrolysis. While the zinc binds to the engineered additional binding site, the conformation of  $\alpha_3\beta_3\gamma$  is locked in one state, so that neither ATP nor ADP can enter in or exchange out.

is suitable to be applied to TF<sub>1</sub>. The binding sites were produced through the replacement of selected glycine, glutamine, and aspartate residues with histidine.

To design locations for allosterically active zinc-binding sites in BF<sub>1</sub>, we first identified regions in the interfaces that undergo local conformational changes, but are not part of the active site. In collaboration with Hellinga et al.<sup>[36]</sup> at Duke University, protoallosteric sites were identified using C<sub>α</sub>-C<sub>α</sub> double-difference distance maps comparing β<sub>E</sub> and β<sub>T</sub> structures. These binding sites were placed at locations in each α/β interface having large relative motions during catalytic activity but separate from nucleotide binding sites. The DEZYMER algorithm protein design program<sup>[32]</sup> was used to carry out the calculations and refinement of site design for the construction of a tetrahedral zinc center at the interface between each pair of α and β subunits. The idealized tetrahedral zinc primary coordination sphere consists of three histidines and a water molecule. The zinc is allowed to coordinate with either the N<sub>δ</sub> or N<sub>ε</sub> nitrogens of the histidines and is constrained within the plane of the imidazole rings.<sup>[33,37,38]</sup>

The algorithm predicted a set of sites that were then rank-ordered and examined by inspection. The geometry of the interaction between the metal and the histidine side chains is derived from visual inspections of natural protein structures.<sup>[39]</sup> We chose a site located in the interdimer interface between β<sub>D</sub> and α<sub>E</sub>. This designed site replaces glutamine α405, glycine β392, and aspartate β400 in BF<sub>1</sub> with histidine residues. The initial design phase yielded a site with approximate tetrahedral geometry. This site was then optimized using a combination of molecular dynamics and conjugate gradient energy minimizations to satisfy the metal coordination geometry resulting in movement of the loop in this region. Mutations were chosen to satisfy both the desired metal binding geometry and the steric compatibility of the protein folding (Fig. 4).

Using site-directed mutagenesis, the peptide replacements were made to the gene encoding a mutant F<sub>1</sub>-ATPase (named DEMHZ) with 10 × His tags on the β subunits and a lone cysteine on the γ subunit, described previously.<sup>[4]</sup> The modified α, β, and γ coding sequence of TF<sub>1</sub>, DEMH, which contains five additional mutations as a working wild type, was cloned into the expression plasmid pETBlue<sup>TM</sup> (Novagen) with a T7 lac promoter. The vector-encoded *Nhe*I site (3434) was eliminated (gctagc to gcgagc). Three histidines for creating the zinc binding sites were introduced by standard PCR oligonucleotide-directed mutagenesis techniques using Pfu DNA polymerase (Stratagene). Specifically, they are Gln-397-His on α and Gly-398-His and Asp-406-His on β (calculated with the inclusion of the 10 × His tags). Expression of the recombinant protein, DEMHZ, was conducted in *Escherichia coli* Tuner<sup>TM</sup> (λDE3) pLacI (Novagen).

**Fig. 4** Molecular model of the computationally designed Zn<sup>2+</sup> binding site in BF<sub>1</sub> ATPase. The histidines in the three interdimer interface locations are shown in red. The circle indicates the site in the β<sub>D</sub> / α<sub>E</sub> interface predicted to form a tetrahedral Zn<sup>2+</sup>-binding site (left insert). The ovals indicate that the sites in the other two interdimer interfaces do not form a geometry predicted to favor metal binding (right insert).

The mutations on pETBlue-DEMZHZ were checked by restriction enzyme digestion and confirmed by DNA sequencing, which failed to reveal any additional mutations or frameshifts. DEMHZ protein was over-expressed in *E. coli* Tuner<sup>TM</sup> (λDE3) by IPTG induction and purified to homogeneity by Ni-NTA affinity chromatography. There was some concern about the endogenous ATPase genes in the host strain Tuner<sup>TM</sup> (λDE3) pLacI. However, because the recombinant protein was stable to 100°C, and the crude lysate was prepared by heating the extracts at 60°C for 45 min, the native protein subunits should have denatured completely under such conditions. Moreover, the use of Ni-NTA affinity chromatography also ensured the purification of His-tagged constructs only. So it was very unlikely that chimeric F<sub>1</sub>-ATPase was purified.

Following the generation of the mutant, the motor was grown in large quantities in a bacterial expression system, harvested, and purified. *E. coli* Tuner<sup>TM</sup> (λDE3) pLacI containing the F<sub>1</sub>-ATPase mutant expression plasmid, pETBlue-DEMZHZ, was cultured at 37°C in LB medium (with 1% glucose, 50 μg/ml carbencillin, and 34 μg/ml chloramphenicol). When the growth of this transformant reached the mid-logarithmic phase (OD<sub>600</sub> = 0.6), 1 mM of

isopropyl- $\beta$ -thiogalactopyranoside (IPTG) was added to induce endogenous T7 polymerase, and the cells were cultured successively for 4 hr. Purification of the mutant  $\alpha_3\beta_3\gamma$  subcomplex was carried out following the methods by Matsui and Yoshida<sup>[40]</sup> with some minor modifications. Cells were harvested by centrifugation at  $6000 \times g$  for 20 min at 4°C. The collected cells (7.5 g out of 2 L culture) were resuspended in buffer A (50 mM Tris-SO<sub>4</sub>, 1 mM EDTA), incubated with lysozyme on ice for 30 min. The suspension was disrupted by sonication, and then heated at 60°C for 15 min. The precipitate was removed by centrifugation at  $105,000 \times g$  (Beckman JA-30.50) for 15 min. The supernatant was saved and heated at 60°C for 30 min and then centrifuged at  $105,000 \times g$  for another 45 min. The supernatant fraction was applied to HiPrep<sup>®</sup> 16/10 DEAE column (Pharmacia) that was pre-equilibrated with buffer A. The column was washed with 200 mL of buffer A containing 150 mM NaCl and eluted with 80 mL of a 300–330 mM linear NaCl gradient. The eluted fractions were concentrated by adding ammonium sulfate to a final concentration of 75% saturation. The resuspended pellet was mixed with nickel-nitrilotriacetic acid (Ni-NTA) Superflow<sup>™</sup> resin (QIAGEN), following a batch purification procedure.<sup>[41]</sup> After washing the unbound proteins, the bound proteins (with  $10 \times$  His tags) were eluted out with 1 M imidazole. The purity of the DEMHZ was analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) using a 12% polyacrylamide gel. Protein concentrations of the  $\alpha_3\beta_3\gamma$  complex were determined by measuring the absorbance at 280 nm using coefficient factor 0.45 of absorbance for 1 mg/mL of F<sub>1</sub>-ATPase. Steady-state ATPase activity was determined spectrophotometrically at 25°C in the presence of an ATP-regenerating system.<sup>[42]</sup>

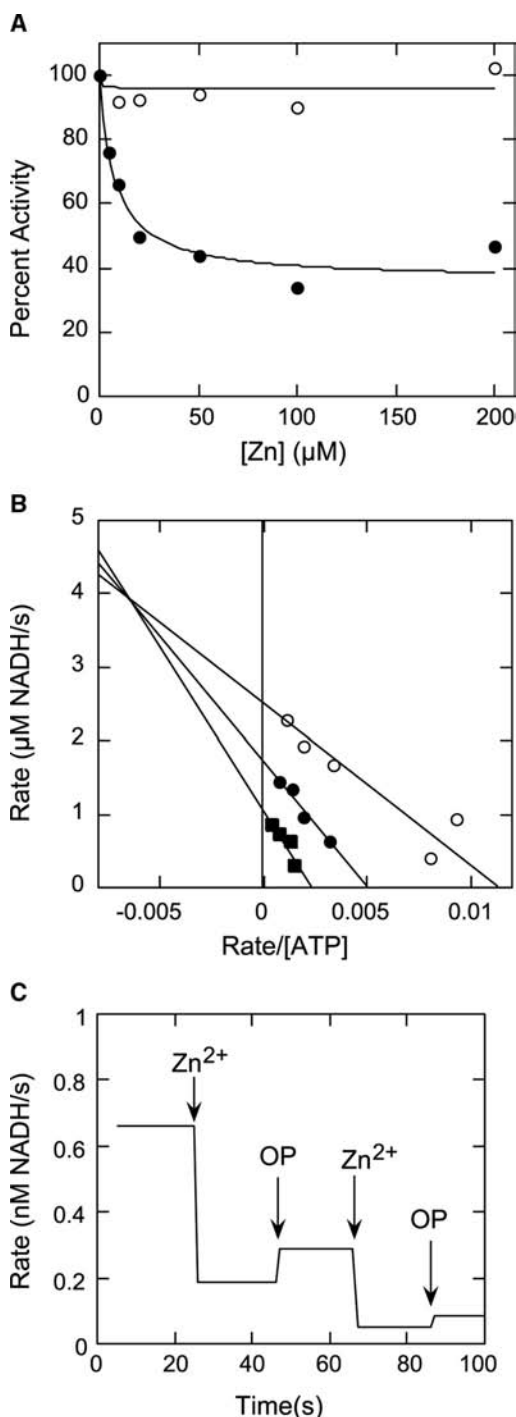

Bulk ATPase activity assays using an ATP-regenerating coupled enzyme system were performed to determine if Zn(II) could effectively inhibit the activity of the engineered ATPase, as well as the minimum Zn(II) concentration for full activity inhibition. To investigate the zinc effect on the DEMHZ, the indicated amount of ZnSO<sub>4</sub> was added to the assay mixture, which contained 50 mM Tris-HCl (pH 7.4), 100 mM KCl, 2.5 mM phosphoenolpyruvate, 50  $\mu$ g/mL double enzyme composed of pyruvate kinase and lactate dehydrogenase (Roche), 0.2 mM NADH (Sigma), 2 mM Na<sub>2</sub>ATP, and 4 mM MgCl<sub>2</sub>. One unit of activity was defined as the activity that hydrolyzed 1  $\mu$ mol ATP/sec/ $\mu$ mol ATPase. Assessment of zinc effect on ATP binding affinity to catalytic sites was carried out in the same assay system, except with a fixed concentration (800  $\mu$ M) of zinc that could effectively inhibit ATPase activity, and various concentrations of ATP. An experiment reversibly activating and deactivating the F<sub>1</sub>-ATPase was carried out by

adding 800  $\mu$ M of zinc and about 10% excess of the specific metal ion chelator 1,10-phenanthroline.

A summary of our previous work comparing ATPase activity of the mutant and wild-type<sup>[5]</sup> is shown in Fig. 5. In the absence of Zn<sup>2+</sup>, DEMH and DEMHZ exhibited similar specific activity, indicating that the histidine mutations did not affect catalysis. Addition of Zn<sup>2+</sup> to DEMHZ reduced the activity by 60% at saturating concentrations, but did not affect wild-type TF<sub>1</sub>. Zn<sup>2+</sup> bound hyperbolically with an apparent dissociation constant of  $8.6 \pm 1.2 \mu$ M. The Scatchard plot was linear (not shown) and consistent with noncooperative binding of Zn<sup>2+</sup>. An Eadie-Hofstee transformation of the steady-state kinetics with respect to ATP at various Zn<sup>2+</sup> concentrations revealed a pattern that is consistent with a linear mixed inhibition mode, in which both  $K_m(\text{ATP})$  and  $V_{\max}$  are affected by Zn<sup>2+</sup>. This finding is consistent with binding of Zn<sup>2+</sup> to both the free enzyme and the enzyme-substrate complex,<sup>[43]</sup> as expected. Repeated cycles of Zn<sup>2+</sup> addition followed by chelation with 1,10-phenanthroline demonstrated that the Zn<sup>2+</sup> inhibition of the enzyme's hydrolytic activity was reversible. This deactivation/reactivation cycle could be repeated many times. Taken together, these data suggest that we have successfully designed a Zn<sup>2+</sup>-dependent allosteric effector site that reversibly modulates TF<sub>1</sub> activity, as predicted.

Enzyme kinetics derived from these studies indicated that the mutant DEMHZ  $\alpha_3\beta_3\gamma$  has much higher propensity than wild type to bind Zn(II). However, quantification of the effect of the zinc on the mutant and wild-type protein was complicated by the discovery that the coupled enzyme assay itself was affected by the addition of zinc. We also conducted phosphorus colorimetric detection assays, an alternative method of measuring ATPase activity, and found possible effects on wild-type activity, but the sensitivity of that technique was poor and formed a precipitate at certain reagent concentrations. We did not use the P<sub>i</sub> release method for measuring ATPase activity because it is not able to monitor rate fluctuations.<sup>[44]</sup>

Several conclusions can be made from the data. 1) Zn(II) did not alter the affinities of catalytic sites of the wild-type  $\alpha_3\beta_3\gamma$  complex for ATP significantly, suggested by  $K_m = 210 \mu$ M in the presence of zinc vs.  $K_m = 159 \mu$ M in the absence of zinc. 2) Zn(II) has a strong effect on the ATPase activity of the mutant complex. In the presence of Zn(II), the activity was nearly fully inhibited; however, it was noticed that at low ATP concentrations, a precipitate formed upon addition of Zn(II), complicating the measurement of ATP hydrolysis rate. Therefore it remains unclear whether Zn(II) alters the ATP affinity to the mutant  $\alpha_3\beta_3\gamma$  complex, apart its direct effect on hydrolysis. 3) ATP hydrolysis of both the mutant and wild-type

**Fig. 5** Steady-state kinetics of ATP hydrolysis in the wild-type and mutant TF<sub>1</sub> enzymes. (A) The effect of Zn<sup>2+</sup> addition on the activity of wild-type (DEM<sub>H</sub>; open circles) and mutant (DEM<sub>HZ</sub>; closed circles) enzymes. For DEM<sub>HZ</sub>, Zn<sup>2+</sup> binding is modeled with a hyperbolic binding isotherm 19, with <sup>app</sup>K<sub>d</sub> = 8.6 μM. (B) Eadie-Hofstee transformation of the steady-state kinetics of DEM<sub>HZ</sub> with respect to ATP concentration in the presence of different Zn<sup>2+</sup> concentrations (open circles, 0 μM; closed circles, 5 μM; squares, 200 μM). (C) Two cycles of successive additions of 100 μM Zn<sup>2+</sup> and 150 μM 1,10-phenanthroline (OP). Source: From Ref.<sup>[5]</sup>.

$\alpha_3\beta_3\gamma$  complex exhibited negative cooperativity as a function of ATP concentration, as indicated by the Eadie-Hofstee plots, consistent with reported literature.<sup>[24,40]</sup> 4) This zinc switch mutant had a  $K_m$  (1490 μM) over 9 times bigger than wild-type  $K_m$  (159 μM) in the absence of Zn(II), which might be a result of some intrinsic changes made by introducing the zinc-binding site in the mutant  $\alpha_3\beta_3\gamma$  complex. 5) It is possible that Zn(II) substitutes in a functional manner for Mg<sup>2+</sup>. If this was true, Zn(II) competitively bound to ATP as well as to the mutant  $\alpha_3\beta_3\gamma$  complex, which led to a full inhibition of ATPase activity of the mutant. The actual number of bound Zn(II) equivalents to the mutant  $\alpha_3\beta_3\gamma$  complex remains to be determined.

To overcome the shortcomings of the bulk activity assays and also demonstrate the ability of the engineered mutation to enable control of the motors on the single molecule level, we observed fluorescent actin filaments attached to individual molecules of TF<sub>1</sub>. A flow chamber was constructed consisting of one (22 × 40 mm #0) coverslip attached to a microscope slide using double-sided tape. In buffer A (50 mM KCl, 5 mM MgCl<sub>2</sub>, 10 mM MOPS-KOH, pH 7) (1:10), 0.1% Ni-NTA-coated polystyrene beads<sup>[45]</sup> (0.22 μm) was infused into the flow cell and incubated for 15 min, resulting in a bead density of several beads in a 5 × 5 μm<sup>2</sup> area. Nonadherent beads were removed through rinsing 3 times with 2 volumes of buffer B (buffer A + 10 mg/mL BSA). The His-tagged biotinylated ATPase (28 nM) in buffer B was then incubated for 5 min and rinsed 3 × with 2 volumes of buffer B. Streptavidin (180 nM) in buffer B was incubated for 12–15 min and rinsed 3 × with 2 volumes of buffer B. Actin filaments (fluorescently labeled with Phalloidin-TRITC, polymerized, and biotinylated<sup>[26]</sup>) were diluted to 50 nM in buffer B and incubated in the flow chamber for 12–15 min. The chamber was washed twice with 2 chamber volumes of buffer B and a third wash of 2 chamber volumes of buffer C [buffer B with an oxygen scavenger (0.5% 2-mercaptoethanol, 30 U/mL catalase, 6 mg/mL glucose, and 0.2 mg/mL glucose oxidase) and an ATP regenerating system (2 mM Na<sub>2</sub>ATP, 0.2 mg/mL creatine kinase, and 2.5 mM creatine phosphate)]. The actin filaments were observed using a Nikon E800 upright optical microscope in epifluorescent mode. ZnSO<sub>4</sub> (800 μM) in buffer C was added to measure any inhibition on the mutant and wild-type protein. 1,10-Phenanthroline (800 μM) in buffer C was added to determine the reversibility of the zinc switch.

Upon addition of ATP, some filaments were observed to rotate clockwise (as expected because the motors were attached to the top surface and viewed from the motor side “upside-down”), although the majority were stationary or fluctuated around a central

**Fig. 6** Measurements of single molecule rotation and control. The movements of rotating fluorescent actin filaments were recorded and digitized. The rotation angle vs. time is shown for eight filaments attached to the mutant ATPase and two filaments attached to motors without the zinc mutation (black lines). The filaments rotated continuously in the presence of ATP. After the addition of  $800\ \mu\text{M}$   $\text{ZnSO}_4$  (blue arrow), the filaments attached to the mutant motor stopped, whereas the filaments attached to the wild-type motor continued rotating at the same rate. 1,10-Phenanthroline ( $800\ \mu\text{M}$ ) was added to the stopped filaments (red arrow), restarting the motor motion. There was an interval of about 3 sec after the addition of both the  $\text{Zn}^{2+}$  and the phenanthroline in which the filaments were unfocused because of disturbance of the stage position, preventing a more precise determination of the times of cessation and reinitiation of motion. Some filaments dislodged from the surface during the replacement and so rotation data following the PNT addition is not available (green lines). The data for all filaments have been shifted in time to synchronize the  $\text{Zn}^{2+}$  addition times. There appear to be no lasting effects of the  $\text{Zn}^{2+}$  on the motors. The rotational rates before  $\text{Zn}^{2+}$  addition and after  $\text{Zn}^{2+}$  removal are similar, as linear fits of each of the pink traces show: (1) before  $\text{Zn}^{2+}$  0.96 rotations/sec, after  $\text{Zn}^{2+}$  0.97 rotations/sec; (2) 0.61, 0.61; (3) 0.36, 0.32; (4) 0.27, 0.19. The differences between the numbers are within the variations of rotational rate of each before Zn addition. The lengths of filaments 1–4 are 1.75, 2.0, 2.25, and 2.25  $\mu\text{m}$ , respectively.

position. There were no filaments observed rotating in the counterclockwise direction. The rotating filaments were then incubated with  $800\ \mu\text{M}$   $\text{ZnSO}_4$  and 2 mM ATP. Some filaments detached from the surface during this buffer exchange, but all rotating filaments (and some fluctuating filaments) remaining were observed to stop after introduction of the Zn. After several minutes, the filaments remained immobilized and  $800\ \mu\text{M}$  1,10-phenanthroline, a Zn chelator, and 2 mM ATP were introduced in the chamber. The filaments which were formerly rotating and were not dislodged during the fluid exchange restarted their motion (likewise with the formerly fluctuating filaments). Experiments with the wild-type motor showed no effects resulting from the presence of zinc; rotating filaments continued their motion at the same rate both before and after Zn addition. To verify that the rotation mechanism of the filaments was because of the motor proteins, introduction of 0.5 M imidazole resulted in the detachment of all moving actin filaments in both the wild type and mutant experiments. In addition, although the wild-type motors were not inhibited by zinc, addition of 10 mM sodium azide halted filament rotation. Plots of the rotation angle vs. time for several filaments are shown for both the mutant and wild type

in Fig. 6. The process of Zn addition and removal from the mutant protein does not appear to have any permanent effect on the mechanical properties of the mutant ATPase; that is, the rotation rates before zinc addition and after zinc removal are very close. Furthermore, the mutation to the ATPase has not appeared to alter its mechanical characteristics when compared with the wild type; that is, the motors rotate filaments of the same length at the same rate, indicating that the torque output and efficiency of the motor are unchanged.

## CONCLUSION

In summary, we have genetically engineered a zinc switch in the  $\alpha_3\beta_3\gamma$  complex of  $\text{TF}_1$ . Through introducing or removing the Zn(II), the conformations of the  $\alpha_3\beta_3\gamma$  complex were correspondingly fixed or freed, such that the  $\text{F}_1$ -ATPase activity could be turned on and off. This allowed us to switch the nanodevice coupled with this genetically modified  $\text{F}_1$ -ATPase on and off in a well-controlled way. Regarding the creation and implementation of control mechanisms in general, each type of control mechanism has unique advantages and disadvantages relative to the intended

application. Chemically controlled motors could result in devices that respond to their environment variables, such as pH, ionic concentration, and temperature, and are not tied to any specific location, although all engineered motors would be affected. Immobile substrate-bound devices may be best served by electrical contacts integrated into the surface; this allows for differential control, in which some devices are operational while others are not. These contacts have the advantages of easy and configurable connections to the outside world and rapid conveyance of signals from the controller to the device. Some proteins can be both electrically and chemically controlled. This flexibility in choices allows the design and application requirements to dictate the components and not vice versa. Exploration and development of artificial protein binding sites, determination of optimal electrode configurations, electric field magnitudes and frequencies, and buffer compositions utilize computational calculations and simulations. These techniques are necessary for screening large numbers of variables and exploring regions of parameter space prohibitive from a cost and time perspective. Establishment of a library of controls and control techniques is a crucial step toward a wider array of useful hybrid bionanodevices.

## ACKNOWLEDGMENTS

The tireless work of Haiqing Liu resulted in the successful generation of the mutant, biochemical assays, and single molecule measurements. We also thank Homme Hellinga, Loren Looger, and Shahir Rizk at Duke University for their assistance in binding site design and biochemical assays.

# Molecular Orientation at Interfaces: Vibrational Spectroscopy

Zhan Chen

Department of Chemistry, University of Michigan,  
Ann Arbor, Michigan, U.S.A.

## INTRODUCTION

Sum frequency generation (SFG) vibrational spectroscopy has been developed into a powerful technique to detect molecular conformation and chemical group orientation at different interfaces. This entry will focus on recent SFG research of interfacial polymers and proteins. Understanding of molecular structures and conformations at interfaces involving polymer and/or protein molecules is widely desired because they determine the interfacial properties that play crucial roles in many important applications.<sup>[1–5]</sup> For example, the interfaces between polymer implants and proteins determine the biocompatibility of such devices. Consequently, improved control of these interfaces can increase human life expectancy.<sup>[3]</sup> The interfaces between antibiofouling polymer coatings and underwater glue proteins secreted by marine organisms such as mussels and barnacles dictate the performance of these coatings. Characterization of the molecular structures of such interfaces can aid in the design of environmentally benign polymer coatings with better antifouling properties, saving energy required to operate marine vessels.<sup>[4]</sup> The use of polymer-based adhesives is of major importance in a variety of modern microelectronic and photonic applications.<sup>[5]</sup> Understanding the molecular structures of these adhesives at interfaces is essential for the design of better adhesive materials.

The molecular-level understanding of structures of surfaces/interfaces involving polymers and/or proteins has been a challenge, as such structures are usually considered to be complicated and hard to examine in situ. Here we will present recent advances in characterizing molecular conformations and chemical group orientations of polymer surfaces and protein molecules at various interfaces using SFG. We will introduce the SFG technique, discuss SFG studies on buried polymer interfaces, and show SFG detection of interfacial protein conformations.

## EXPERIMENTAL: SUM FREQUENCY GENERATION TECHNIQUE

Sum frequency generation is a process in which two input beams at frequencies  $\omega_1$  and  $\omega_2$  mix in a medium and generate an output beam at the sum frequency  $\omega = \omega_1 + \omega_2$ . As a second-order non-linear optical process, it is forbidden under the electrical dipole approximation in media with inversion symmetry. At surfaces or interfaces where inversion symmetry is broken, SFG is naturally allowed, and can therefore be used as an effective surface probe. Typically, SFG vibrational spectroscopy uses a tunable infrared (IR) input  $\omega_2$  overlapping with a fixed visible input  $\omega_1$  on a surface/interface to generate a surface/interface vibrational spectrum by plotting SFG intensities vs. the IR input frequency.<sup>[6–22]</sup> Using different input/output polarization combinations with respect to beam and sample geometries, orientation information on surface/interfacial molecules can be obtained.<sup>[23–26]</sup>

A representative experimental arrangement for SFG is depicted schematically in Fig. 1. In our laboratory, the visible beam at 532 nm was generated by frequency-doubling fundamental output pulses of 20 psec pulse width from an EKSPLA Nd:YAG laser. The IR beam, tunable from 650 to 4300  $\text{cm}^{-1}$ , was generated from an EKSPLA optical parametrical generation/amplification and difference frequency system based on LBO and AgGaS<sub>2</sub> or GaSe crystals. Both beams were focused on the sample with diameters of about 0.5 mm. The sum frequency signal from the polymer surface was collected by a photomultiplier tube and processed with a gated integrator. Sum frequency generation spectra with different polarization combinations including ssp (s-polarized sum frequency output, s-polarized visible input, and p-polarized IR input), ppp, pss, and sps were collected. There are variations of SFG setups used in different research laboratories, depending on the types of lasers employed.<sup>[21]</sup>

### A second order, nonlinear optical Process

Fig. 1 Sum frequency generation experimental geometry.

Various experiments show that SFG is indeed a submonolayer surface-specific polymer surface probe. Such experiments include comparing reflected and transmitted SFG spectra, modifying a polymer surface by immersing it in liquids or by exposing it to plasma treatment for a short time, and evaluating SFG spectral intensity from polymer films with different thickness.<sup>[7]</sup> The surface specificity of SFG studies on interfacial proteins will be discussed later.

## RESULTS AND DISCUSSION

### Polymer/Water Interfaces

It is important to study polymer/water interfaces because many polymers such as biomedical or bio-fouling control polymers are used in aqueous environments. Unfortunately, most surface science techniques are operable only with the sample under ultrahigh vacuum.<sup>[27,28]</sup> Freeze-drying X-ray photoelectron spectroscopy (XPS) has been developed to study polymer surface restructuring in water, but it cannot provide molecular conformational information.<sup>[29]</sup> Contact angle measurements show that many polymer surfaces reconstruct in liquid, but they cannot show how the polymer surfaces change at the molecular level.<sup>[30]</sup> Here, we report our SFG studies on interfaces between polymethacrylates, which are widely used as biomaterials, and water.

Three polymethacrylates with different lengths of alkyl side chains—poly(methyl methacrylate) (PMMA), poly(*n*-butyl methacrylate) (PBMA), and poly(*n*-octyl methacrylate) (POMA)—were investigated. Their glass transition temperatures are 105°C, 17°C, and -70°C, respectively,<sup>[12]</sup> showing that the molecules have different bulk mobilities. Through this study, we hope to correlate the surface restructuring behavior of these three polymethacrylates in water to their bulk mobility or glass transition temperatures.

Both ssp and sps SFG spectra of PMMA in water are dominated by the signals from ester methyl groups, similar to those of the PMMA/air interface, although they are much weaker.<sup>[12]</sup> Analysis of the spectra shows that the weaker spectra are mainly because of the changes of the Fresnel coefficients for the two interfaces. There is little structural change for the ester methyl, alpha methyl, and methylene groups at the PMMA surface after contacting water.

Experimental and fitted SFG spectra indicated that PBMA surfaces in both air and water are dominated by the methyl groups of the ester side chains (Fig. 2). The average orientation and orientation distribution of these methyl groups at the PBMA/air and PBMA/water interfaces can be deduced by the SFG absolute intensity and intensity ratio measurements (Fig. 3).<sup>[14]</sup> Fig. 3 shows that methyl groups have different orientation distributions on PBMA surfaces in air and water, indicating that surface restructuring occurs when the PBMA sample contacts water. Methyl groups tend to stand up on the PBMA surface in air, and tend to lie down on the surface in water. The orientation distribution of side chain methyl groups

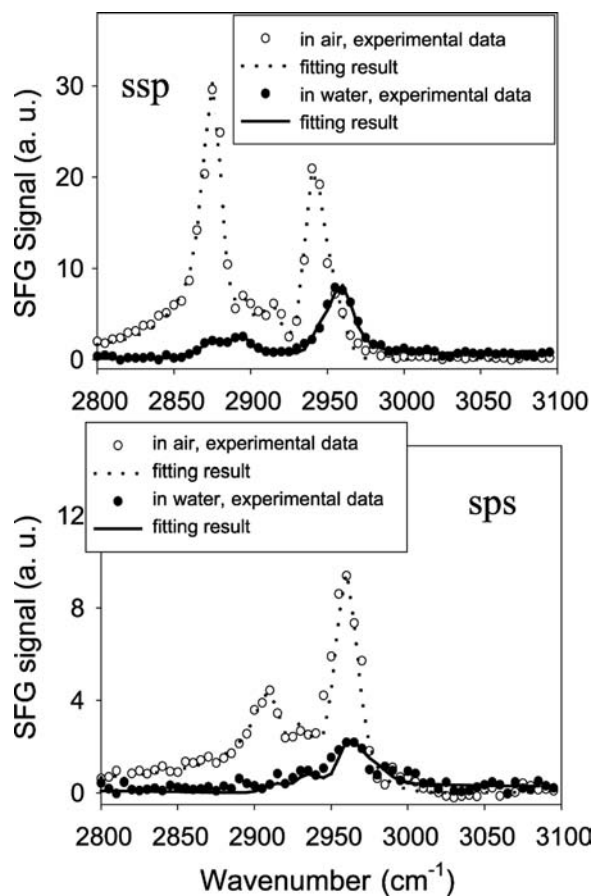

Fig. 2 Sum frequency generation spectra collected from the PBMA / air and PBMA / water interfaces. Source: From Ref.<sup>[14]</sup>; © American Chemical Society, 2002.

**Fig. 3** Orientation distribution of methyl groups on the PBMA surface in air and water. *Source:* From Ref.<sup>[14]</sup>; © American Chemical Society, 2002.

on the PBMA surface is narrower in water than that in air, indicating that the PBMA surface can be more ordered in water. To our knowledge, this is the first time that quantitative comparisons between molecular surface structures of polymers in air and water have been made. It has been found that the orientation angle distribution function deduced by the Gaussian distribution and the maximum entropy distribution are quite similar, showing that the Gaussian distribution is a good approximation of the angle distribution. When the PBMA surface was removed from water, the SFG spectra recovered, indicating that restructuring of the PBMA surface in water is reversible.

Sum frequency generation spectra of POMA show that the POMA/air interface is dominated by the methyl and methylene groups.<sup>[12]</sup> When POMA makes contact with water, its SFG spectra immediately disappear. With the sample out of water and dried, the spectra reappear, but are very different from those before contacting water. We believe that the polymer backbones of POMA change immediately after contacting water because POMA has a very low  $T_g$  ( $-70^\circ\text{C}$ ) and thus the backbones are very mobile. The molecules on the surface in water become randomly oriented so that no SFG signal can be detected.

We showed here that different polymers can have different surface restructuring behaviors in water. The PMMA surface has no detectable changes in water because of its rigid surface structures and hydrophilic surface-dominating ester methyl groups.<sup>[11]</sup> For PBMA, the surface had a reversible side group reorientation in water. Poly(*n*-octyl methacrylate) has a low glass transition temperature and thus molecules are very mobile. Its surface exhibited irreversible restructuring after contact with water.

In addition to these three polymethacrylates, surface restructuring of another polymethacrylate, cross-linked poly(2-hydroxyethyl methacrylate) (PHEMA), a widely used contact lens material hydrogel, has been studied using SFG.<sup>[31]</sup> Sum frequency generation measurements demonstrate that PHEMA can adopt two

discrete surface states depending on the environment. When PHEMA is exposed to air, polar side chains turn into the bulk, leaving the nonpolar methyl groups to project out of the surface to form a “hydrophobic conformation.” In water, polar ethylene glycol groups migrate to the surface and coexist with methyl groups at the surface, creating a “hydrophilic conformation” (Fig. 4).

Sum frequency generation studies on polymer surfaces in water demonstrate that it can provide molecular conformation and chemical group orientation information about polymer molecules at polymer/water interfaces in situ. Both qualitative and quantitative understanding of surface restructuring behaviors of polymer surfaces in water can be achieved.

### Solid/Liquid Polymer or Polymer Solution Interfaces

In addition to buried polymer/water interfaces, SFG has also been applied to study polymer/polymer interfaces. We will first report the SFG research on polymer structures at the solid/liquid interfaces. The polymers that will be examined here include poly(ethylene oxide) (PEO), poly(propylene oxide) (PPO), and PEO–PPO–PEO block copolymers.

Poly(ethylene oxide)–PPO–PEO block copolymers or pluronics are well-known non-ionic and water-soluble macromolecular surfactants. Their behavior in micelle formation, emulsification, drug stabilization, or drug delivery is determined by different interfacial conformations of PEO and PPO blocks at various solid/liquid interfaces. The adsorption behavior of pluronic surfactants at the solid/solution interface has been studied by several different techniques such as ellipsometry, total internal reflectance fluorescence (TIRF), XPS, and surface plasmon resonance (SPR).<sup>[32]</sup> However, it is still not clear how the polymer chains and chemical groups are arranged at different interfaces and how these molecules interact with the

**Fig. 4** Schematics describing surface structures of PHEMA in air and water. *Source:* From Ref.<sup>[31]</sup>; © American Chemical Society, 1999.

contacting media. Here we want to elucidate the interfacial structures of pluronics at various interfaces. Before that, we first discuss the conformations of various components of pluronics, including PEO and PPO, at various interfaces.

#### Conformation of poly(ethylene oxide) and poly(propylene oxide) at different solid/liquid polymer interfaces

Sum frequency generation spectra were collected from interfaces between PEO or PPO liquid and several solid materials, including fused silica, deuterated polystyrene (d-PS), and deuterated PMMA (d-PMMA) (Fig. 5). We found that the intensity of the dominating peak (symmetrical C–H stretch for both PEO and PPO) decreases from the d-PS interface to the d-PMMA interface and drops to zero for the fused silica/liquid polymer interface. At the d-PS/polyether interfaces, strong SFG signals show that polyethers should have ordered conformations, with CH<sub>2</sub> (for PEO) or CH<sub>3</sub> groups (for PPO) oriented along the interface normal. This indicates that the hydrophobic polystyrene (PS) surface, which is dominated by phenyl groups, interacts favorably with CH<sub>2</sub> groups on PEO or methyl groups on PPO molecules, forming ordered conformations of PEO and PPO at the interface. At the fused silica/polyether interface, no SFG signal can be detected, showing that both polyethers have random conformations. This shows that the interactions between fused silica and CH<sub>2</sub> groups on PEO

molecules or methyl groups on PPO molecules are unfavorable. Because of the surface-dominating ester methyl groups,<sup>[11]</sup> the hydrophobicity of d-PMMA is between d-PS and fused silica, thus polyethers have intermediate conformations compared to those contacting d-PS and fused silica, evidenced by SFG spectra with intermediate intensities. Sum frequency generation studies of solid/polyether interfaces clearly demonstrate that polyethers can have different conformations while contacting different solid materials.

#### Interfacial activity and conformation of poly(ethylene oxide) and poly(propylene oxide) at solid/solution interfaces

Poly(ethylene oxide), PPO, and their copolymers are mostly used in aqueous solutions. Similar to the solid/pure liquid polymer interfaces mentioned above, SFG spectra (ssp) were collected from solid/polymer solution interfaces. No SFG signals corresponding to PEO molecules were detected for any solid/PEO solution interface. Further research indicated that PEO molecules do not segregate to the interfaces.<sup>[16]</sup> Because of strong hydrogen bonding between PEO and water, PEO tends to interact with the water phase, is surrounded by water molecules, and stays in the bulk.

Poly(propylene oxide) is more surface-active or interface-active than PEO. Sum frequency generation spectra collected from a solid/PPO solution interface is quite similar to the solid/PPO liquid polymer interface.

**Fig. 5** Sum frequency generation spectra collected from solid/PEO interfaces (left) and solid/PPO interfaces (right). *Source:* From Ref.<sup>[17]</sup>; © American Chemical Society, 2002.

For example, SFG signals of PPO collected from d-PS/PPO solution interfaces are very similar to those of d-PS/pure PPO liquid interfaces, showing that the d-PS/PPO solution interface is covered by a layer of PPO molecules, with ordered methyl groups standing up along the interface normal. Compared to those at the d-PS/PPO solution interface, the molecules at the d-PMMA/PPO solution interface are less ordered. At the fused silica/PPO solution interface, no SFG signal is detected. Further research indicated that this is because of the fact that PPO has a random conformation at this interface.<sup>[17]</sup>

#### Molecular structures of copolymers at the solid/solution interface

The interfacial SFG spectra of various pluronic copolymers with different block lengths of PEO and PPO (PEO ratio varying from 20% to 80%) have been collected from the d-PS/solution and d-PMMA/solution interfaces.<sup>[32]</sup> Plurionics with different PEO ratios show similar interfacial spectra. It was found that interfacial structures of plurionics at solid/solution interfaces are dominated by PPO blocks and the orientation of methyl groups varies with different solid contacting media. A stronger signal is detected when the liquid contacts d-PS, showing that the methyl groups are more ordered at the d-PS/solution interface. However, at the d-PMMA/solution interface, the methyl groups are not very ordered as shown by the weak signals from the SFG spectra. Different conformations of the copolymers at different interfaces are related to molecular interactions at these interfaces (Fig. 6). The favorable interactions between hydrophobic surfaces with phenyl groups and hydrophobic methyl groups on PPO blocks cause more ordered conformations with these groups preferentially orientated along the interface normal. The interactions between less hydrophobic media with ester methyl or C=O groups and hydrophobic methyl groups are not very favorable, causing a less ordered methyl group arrangement at the interface. Through this research, we have demonstrated that SFG is an appropriate technique to observe molecular-level structures such as chain conformation and group orientation of plurionics at solid/solution interfaces.

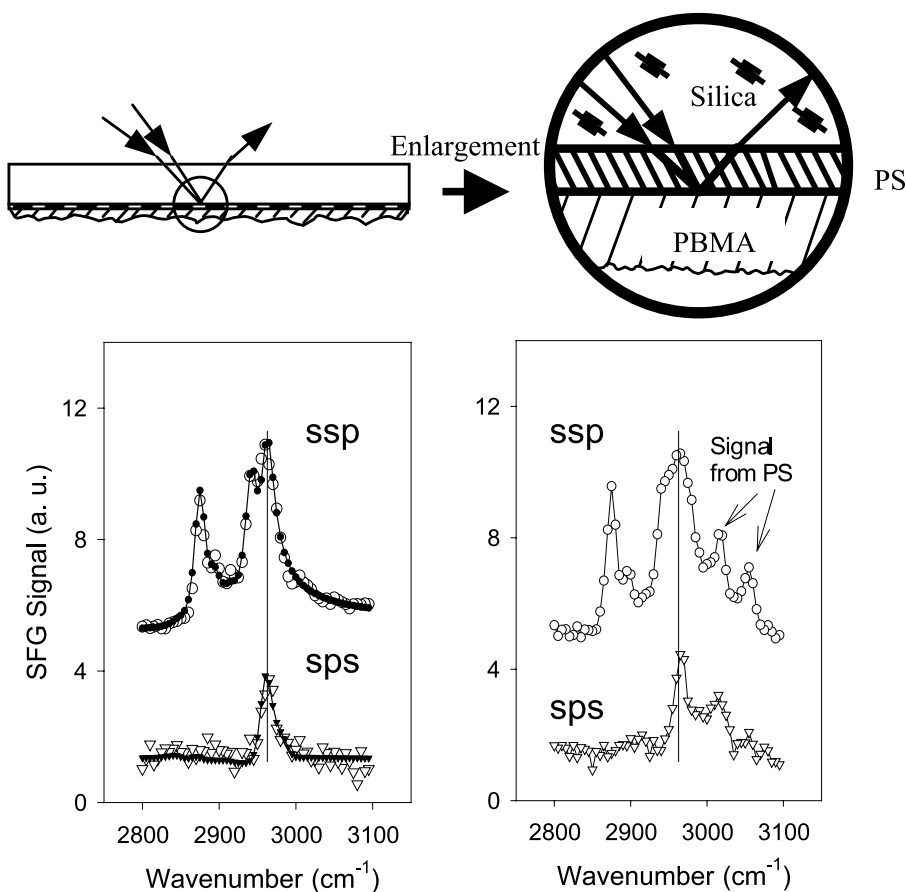

#### Solid Polymer/Solid Polymer Interfaces

Understanding interface structures between solid polymer materials is crucial to evaluate the miscibility and bulk properties of polymer blends, and adhesion at polymer/polymer interfaces. Such knowledge of polymer/polymer interfaces can be applied to many important industrial applications including coatings, lithography, microelectronic devices, and liquid crystal displays. In this section, we investigate the PBMA/PS interface as an example to demonstrate that SFG is a powerful technique to elucidate molecular-level structures of buried interfaces between solid polymers in situ.

The SFG spectra were collected with two input laser beams traveling through the substrate and the thin PS (or d-PS) film to the PS/PBMA interface (Fig. 7). We have ensured that the spectra we collected came from the polymer/polymer interface, not from the PS/substrate or PBMA/air interfaces.<sup>[16]</sup> As with the PBMA/air and PBMA/water interfaces,<sup>[14]</sup> orientation information of ester side chain methyl groups at the “buried” PBMA/PS (or d-PS) interface can be deduced after fitting these SFG spectra. Our detailed analysis clearly shows that the range of possible orientation of ester side chain methyl groups at the PBMA/PS (or d-PS) interface is between the two extremes of the PBMA/air and PBMA/water interfaces. On the PBMA surface in air, the ester side chain methyl groups have greater freedom and tend to extend into the air, leading to a small average orientation angle vs. the surface normal. Upon contacting water, the strong repulsion between the methyl groups and water molecules directs the methyl groups away from the surface normal, resulting in a larger average orientation angle. At the PBMA/PS (d-PS) interface, the ester side chain methyl groups interact with the phenyl groups, but the repulsion must be weaker compared to the situation in water. Therefore the orientation of ester side chain methyl groups is between the two extremes of the PBMA/air and PBMA/water interfaces. The repulsion force between the side chain methyl groups and the phenyl groups also directs the phenyl groups away from the interface normal compared to the PS/air interface, shown by different aromatic C–H signals at the PS/PBMA and PS/air interfaces.

**Fig. 6** Schematics of group interactions at plurionics solution/solid interfaces. *Source:* From Ref.<sup>[32]</sup>; © American Chemical Society, 2003.

**Fig. 7** Sum frequency generation spectra collected from the PBMA/d-PS interface (lower left panel) and the PBMA/PS interface (lower right panel). Both ssp and sps spectra collected from the two interfaces are shown. The upper panel shows the experimental geometry.

Research has also been conducted on the structure of the PS/PMMA interface using SFG, showing ordered ester methyl groups at the interface.<sup>[18]</sup> Sum frequency generation studies on the

poly(vinyl-*N*-octadecylcarbamate-co-vinyl acetate) (Comb)/PS interface indicated that features of SFG spectra collected from this interface are broader than those from the Comb/air interface.<sup>[19]</sup> Phenyl,

**Fig. 8** Left: Sum frequency generation spectra of BSA solution/air interfaces with different bulk concentrations. Right: Proposed schematics of different surface structures of BSA at the solution/air interfaces with different bulk concentrations.

methylene, and methyl groups were detected. Analyses of the SFG spectra indicate that Comb alkyl side chains are more disordered with a large population of gauche defects, and the crystallinity of the alkyl side chains is disrupted at these interfaces.

### Polymer/Inorganic Solid Interfaces

The PS/sapphire interface was studied using SFG in a total internal reflection geometry.<sup>[13]</sup> By carefully choosing the incident angles of the input beams, PS conformation at the PS/air surface and the buried PS/sapphire interface can be explored separately. Analyses of the spectra show that the phenyl rings are orientated approximately parallel to the surface normal at the PS/air interface, in comparison to nearly perpendicular to the surface normal at the PS/sapphire interface. Similarly, SFG was applied to investigate molecular structures of poly(*n*-alkyl acrylates)/sapphire interfaces as a function of temperature.<sup>[33]</sup> Upon heating, SFG spectral intensity decreased and one sharp transition close to bulk melting temperature was observed, showing that interfacial melting occurs at the same bulk melting temperature.

A different method was developed using SFG to detect the buried PS/spin-on-glass (SOG) interface by spin coating a thin layer of SOG on a gold film. A PS film was spin-coated on top of the SOG surface.<sup>[34]</sup> By varying the SOG thickness, the PS/air interface or the buried PS/SOG interface can be probed. The phenyl groups at the buried interface point away from the PS film toward the SOG/Au substrate, with an almost identical orientational distribution as that of the PS/air interface. In addition, the hydrophobic SOG surface was modified by UV ozone to create a hydrophilic SOG surface. Sum frequency generation studies on the PS/hydrophilic SOG interface show that the interface has a different structure from the PS/unmodified hydrophobic SOG interface.<sup>[20]</sup> Such structural differences can be correlated to the different adhesion properties of the two interfaces.

### Polymer/Protein Interfaces

Protein adsorption is the first process that happens when a biomaterial interacts with a biological system; the structure of adsorbed proteins determines finally whether an implanted material will be accepted or rejected by the body (biocompatible or not). Because of its critical importance, protein adsorption has been studied by a myriad of surface-sensitive methods for decades.<sup>[35–37]</sup> However, it is still difficult to determine chemical and structural information about adsorbed protein molecules, and details about how protein

molecules respond to different interfacial environments are still not clear. Recently, SFG has been shown to be a powerful technique to elucidate interfacial protein structures at the molecular level in situ.

We have studied structures and conformations of bovine serum albumin (BSA) at various interfaces including BSA solution/air, BSA solution/fused silica, BSA solution/d-PS, and BSA solution/d-PMMA interfaces.<sup>[15,38–40]</sup> Sum frequency generation is used mostly to study simple surfaces/interfaces and small molecule adsorptions, and models have been developed for the interpretation of such SFG spectra. Because BSA is a large protein (~65 kDa), a new interpretation model is needed. Instead of using a simple interface, we have successfully applied the more general thin film model to interpret protein

**Fig. 9** SFG spectra collected from A. d-PS/BSA solution interface; B. d-PS/air interface after the sample was removed from solution and washed by water; C. d-PS/water interface after the sample contacted water; D. d-PS/air interface again; E. d-PS/FC-75 interface after procedures a and b and contacting the sample with FC-75; F. d-PS/BSA solution interface in the wide spectral range. The spectral intensity in 2e has been multiplied by 2.

SFG spectra.<sup>[38,39]</sup> Using theoretical calculations as well as experimental results, we demonstrated that SFG spectra can be used to determine interfacial protein structure and conformation. The thin film model considers that SFG signals are contributed from functional groups in the whole adsorbed protein film, as long as inversion symmetry is broken.<sup>[38,39]</sup>

### BSA solution/air interfaces

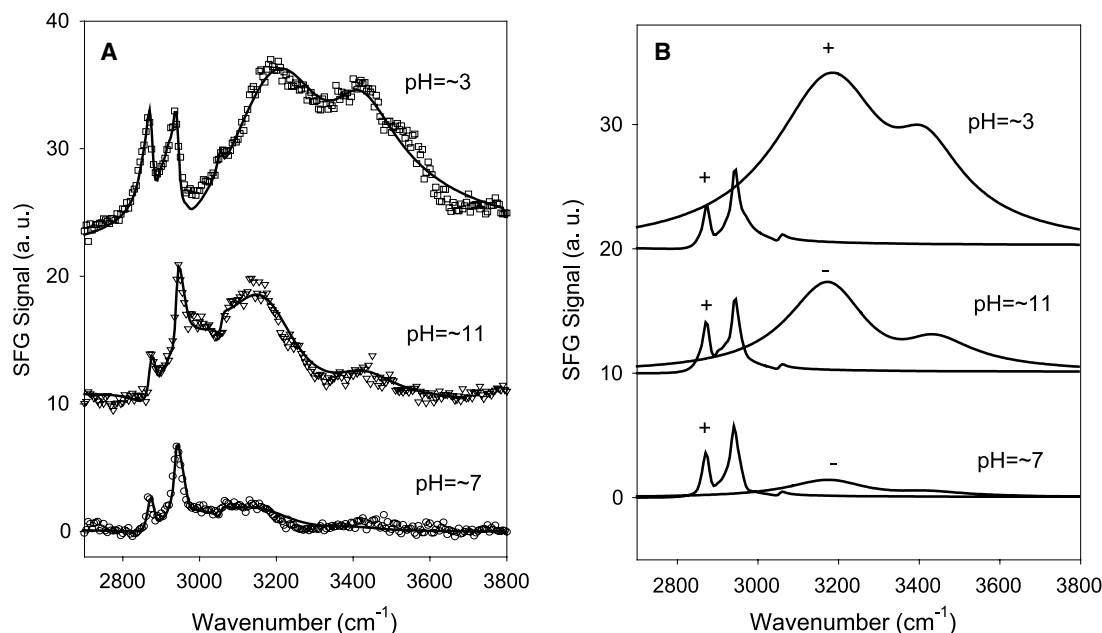

Extensive research has been done regarding the dependence of BSA adsorption at the solution/air interface on bulk protein concentration. However, no investigations in this area have determined the bulk concentration's effect on molecular interfacial protein structure. Fig. 8 displays SFG spectra collected from BSA solution/air interfaces in situ. The peaks in the range from 2800 to 3100  $\text{cm}^{-1}$  are indicative of aliphatic and aromatic C–H stretches from hydrophobic side chains on BSA. The broad peaks at higher wavenumbers are O–H stretches of surface water molecules. We have confirmed that these SFG signals come from the adsorbed interfacial BSA, not from BSA in bulk solutions.<sup>[15,38]</sup> Using SFG intensity measurements, we have elucidated structural changes of BSA molecules at solution/air interfaces with different BSA bulk solution concentrations (Fig. 8).<sup>[40]</sup> Bovine serum albumin molecules are denatured more at the solution/air interface of lower concentration solutions.<sup>[40]</sup>

### BSA solution/fused silica interfaces

We have collected SFG spectra directly from BSA solution/solid interfaces. The solid media that we investigated include fused silica, d-PS, and d-PMMA. Our SFG results show clearly that the conformation of adsorbed BSA molecules at different interfaces can be varied.<sup>[15,38]</sup> No C–H stretching signals from albumin molecules are detected from the BSA solution/fused silica interface because of the lack of a net alignment of protein C–H groups at the fused silica/BSA solution interface. At this interface, the adsorbed BSA adopts a hydrophilic conformation; the hydrophobic groups tend to stay inside the BSA film with no net alignment. Thus no SFG signal is detected. We have contacted the BSA adsorbed on fused silica with different chemical environments, including air, water, and hydrophobic solvents. Sum frequency generation spectra collected from various interfaces indicate that BSA has different conformations when interfacial environments are changed.<sup>[15,38]</sup>

### BSA solution/polymer interfaces

An SFG spectrum was collected from the d-PS/BSA solution interface (Fig. 9A and F). In this spectrum, strong C–H signals are detected, demonstrating that the adsorbed BSA molecules do not adopt the hydrophilic conformation as found in the case of fused silica.

**Fig. 10** Sum frequency generation experimental spectra (A) and fitting spectra (B) of the PS/BSA solution interface with different solution pH values. *Source:* From Ref.<sup>[38]</sup>; © American Chemical Society, 2002.

**Fig. 11** Schematic plot of the orientation of surface water molecules at different solution pH values. The water molecules at the interface have varying orientations because the surface BSA molecules have different charges at different pH levels above or below the BSA isoelectric point.

Bovine serum albumin adopts a conformation that allows for its hydrophobic components to maximize the favorable interaction with the surface. When the sample is removed from the BSA solution, washed by water, and exposed to air, SFG signals are still visible (Fig. 9B). When the sample is exposed to water again, strong C–H signals are detected (Fig. 9C), with different features as compared to the spectrum collected from the d-PS/air interface. C–H signals repeatedly change as we continue to alternately contact the sample with water and air (e.g., Fig. 9D). This phenomenon shows that the changes are reversible. When the sample is in contact with a hydrophobic fluorinated solvent FC-75 instead of water, C–H signals are still detected (Fig. 9E), but with weaker intensity. This research shows that BSA on PS can adopt different conformations in different chemical environments.

The SFG spectra of BSA solution/d-PS interfaces at different solution pH values are displayed in Fig. 10A, shown as dots. The detailed fitting results shown in Fig. 10B indicate that the C–H stretching signals collected from solutions of different pH values are quite similar, but spectral features in the O–H stretching region are different from spectrum to spectrum.<sup>[38]</sup> In addition, the relative phases between the C–H and O–H signals are quite different, resulting in distinct spectral differences in Fig. 10A. The phase differences between C–H and O–H signals at different solution pH values are because of opposite relative orientations between methyl or phenyl groups of BSA molecules and water molecules at the interface (Fig. 11).

#### Comparison of protein conformation at various interfaces

Our results show that BSA molecules have different conformations at various interfaces. The behavior of BSA on d-PS is totally different from the case of BSA on fused silica, showing the dependence of the protein conformations on material surface properties. We have also studied BSA structures at other polymer/BSA

solution interfaces. For example, the results at the d-PMMA/BSA solution interface are intermediate to those from interfaces involving fused silica and d-PS. This result is reasonable because the surface of d-PMMA is dominated by ester methyl groups and thus is more hydrophilic than d-PS but not as hydrophilic as fused silica. The adsorbed BSA film can form a “hydrophilic” conformation between two hydrophilic media (fused silica/BSA solution), and a “hydrophobic” conformation between two hydrophobic media (polymer/air or polymer/hydrophobic solvent) (Fig. 12). Nevertheless, such “hydrophobic” or “hydrophilic” characterization of interfacial protein structure is too crude. More molecular details of different “hydrophobic” or “hydrophilic” conformations need to be addressed in the future.

Sum frequency generation supplemented by fluorescence microscopy has also been applied to investigate different proteins including lysozymes, fibrinogen, and BSA adsorbed on fused silica and PS surfaces after removing the samples from solution and exposing

**Fig. 12** Schematics of different structures of BSA in contact with surfaces of different hydrophobicities. *Source:* From Ref.<sup>[15]</sup>; © American Chemical Society, 2002.

**Fig. 13** Sum frequency generation amide spectra collected from the PS / BSA solution interface in situ.

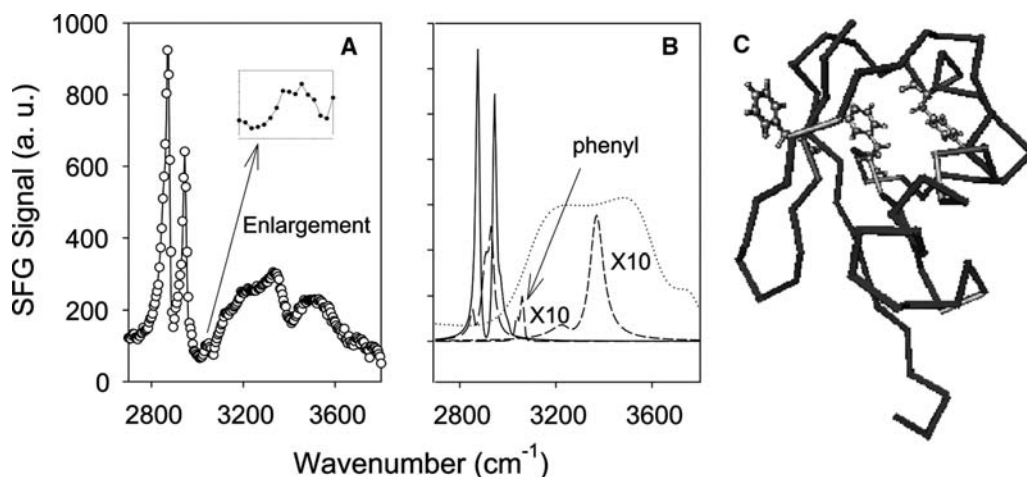

them to air.<sup>[41]</sup> Research shows that these proteins have different adsorption behaviors and conformations on various surfaces. On hydrophilic surfaces, the orientation of methyl groups in lysozymes is concentration-independent, but those of BSA and fibrinogen become less tilted with respect to the surface normal with increasing protein concentration. However, methyl groups in proteins adsorbed on hydrophobic PS surfaces appear more randomly

oriented and produce a weaker SFG signal. Sum frequency generation studies on lysozymes at fused silica/water interfaces with various water pH values indicate that when the pH value of water was varied, lysozymes changed conformations at the interface. At low pH, lysozymes have a hydrophilic conformation, whereas at high pH, they have a hydrophobic conformation.<sup>[42]</sup>

**Future direction: sum frequency generation studies on amide bands and isotope-labeled proteins**

The results shown above demonstrate that SFG is a powerful technique to deduce protein conformations at various interfaces. All the SFG signals shown above are signals from the C–H stretching region, which provide some structural information about interfacial protein molecules. However, for the determination of more detailed protein structures, the amide I band is more useful because it provides more specific information on the protein's secondary structure. We have demonstrated the feasibility to detect amide SFG signals of interfacial proteins at the solution/polymer interface in situ (Fig. 13). Research on correlating SFG amide signals to detailed conformation of proteins at various interfaces is underway.

Sum frequency generation C–H stretching signals and amide bands are generated from many functional groups in many amino acid residues of a protein molecule. To acquire conformation details of an interfacial protein, we need to know the orientation of every small segment of the protein. We have proven that SFG is sufficiently sensitive to detect even a few amino acid

**Fig. 14** (A) Sum frequency generation spectrum collected from ubiquitin on fused silica in air. Dots: Experimental data. The enlarged phenyl signal is shown at the upper right corner. Lines: The overall fitted spectrum. (B). Fitted results of various functional groups for the entire spectrum shown in (A). These various functional groups include CH<sub>3</sub>, CH<sub>2</sub>, phenyl, N–H, and O–H groups. The fitted result for the phenyl group was multiplied by a factor of 10. (C). Ubiquitin structure: three phenyl groups are clearly indicated. This figure shows that it is feasible to detect SFG signals from three phenyl groups of ubiquitin molecules at the interface.

residues at the interface. Fig. 14A shows the SFG spectrum collected from ubiquitin adsorbed on the fused silica prism in air using a total reflection optical geometry. There are only three phenyl groups in a ubiquitin molecule (Fig. 14C). Both original and fitted spectra in Fig. 14 show clearly the SFG signal from three phenyl groups. Various isotope labeling techniques can be used to label different parts of a protein. Sum frequency generation can be developed into a powerful technique to provide detailed protein molecular interfacial structures by studying such isotope-labeled proteins.

## CONCLUSION

Sum frequency generation has been developed into a powerful technique to reveal conformations and orientations of polymer and protein molecules at various interfaces at the molecular level in situ. Sum frequency generation studies on polymer/water interfaces indicate that different polymers can have different surface changes in water. Quantitative surface restructuring behavior, such as surface functional group orientation distribution change, of polymers in water can be understood by SFG measurements. Polymer conformations at different solid/liquid polymer or solution interfaces observed by SFG provide more insights in understanding the interfacial performance of polymer surfactants. Sum frequency generation studies on solid polymer/solid interfaces show polymer conformation and chemical group orientation at various interfaces, elucidating interfacial interactions and polymer adhesion at the molecular level. Different conformations of interfacial proteins at various interfaces have been determined using SFG in situ. The effect of solution concentration, hydrophobicity of contacting surfaces, and pH value of protein solutions on interfacial protein conformation has been revealed. Sum frequency generation has been proven to be a unique and powerful submonolayer surface-sensitive molecular spectroscopy to examine conformations and orientations of large molecules such as polymers and proteins at various buried interfaces in situ.

# Molecular Probes of Cation–Arene Interactions

George W. Gokel

Departments of Molecular Biology and Pharmacology and Chemistry, Washington University  
School of Medicine, St. Louis, Missouri, U.S.A.

## INTRODUCTION

The three phases of matter are gas phase, liquid (or condensed), and solid state. In recent years, the stunning advances in computational studies have led some to refer to it in a jocular sense as the fourth: “the computational state.” Some of the studies discussed in this entry concern gas phase results determined by mass spectrometry and by calculation. Additionally, data have been derived from solution and solid-state studies. Important inferences can be drawn from computations, work undertaken in the gas phase, in solution, and in the solid state. Significant as all of these methods are, only X-ray crystallographic data permit unambiguous analysis and comparison of structural information. The emphasis of this entry is therefore on the evidence for cation– $\pi$  interactions that is available from solid-state structures.

## ISSUES AND INTERACTIONS

The three major species considered in chemistry are anions, cations, and neutral species. Anions are negatively charged and therefore Lewis-basic. Arenes are electron-rich and also considered to be Lewis bases. The interaction between two Lewis bases is usually repulsive rather than attractive. The term “neutral” means uncharged, but a neutral compound may be either Lewis-basic (e.g., dimethyl ether) or Lewis-acidic (e.g., aluminum chloride). Our major concern in this entry will be with interactions of the type illustrated in the lower panel of Fig. 1. Such interactions involve the arene’s  $\pi$ -cloud as a Lewis (base) donor and the cation as a Lewis acid. The cation is represented as  $M^+$ , and most of the discussion herein will concern metallic cations. Other cations are certainly possible and will be noted where appropriate (Fig. 1).

Although this article is limited to interactions of cations with arenes, there is much to be considered. Arenes may possess sigma-donors in addition to the  $\pi$ -system that is the primary focus of the present discussion. Sigma-donors may be substituents on the

arene or they may be an integral part of the arene. They may enhance the arene’s Lewis basicity or they may detract from it. The top row of Fig. 2 shows benzene, the archetype aromatic, at the left, followed by pyridine, nitrobenzene, and methoxybenzene (anisole). The nitro group is electron-withdrawing and the methoxy group is electron-donating. Thus nitrobenzene is a weaker  $\pi$ -base than is benzene and anisole is stronger. In both cases, however, the oxygen atoms can function as sigma-donors in their interactions with cations.<sup>[1]</sup> The pyridine nitrogen atom is also a good sigma-donor, and its presence in the heterocycle makes the aromatic ring about as weak a  $\pi$ -base as nitrobenzene.

The second line of Fig. 2 shows, from left to right, furan, thiophene, imidazole, and cyclopentadienide anion. The latter is formed by deprotonating cyclopentadiene. When two cyclopentadienide (Cp) anions react with ferrous ion [Fe(II)], ferrocene (third line of Fig. 2) is formed. Ferrocene is the prototype for cyclopentadienyl- $\pi$  complexes, whether they involve a sandwich structure or only one Cp ring. Organometallic structures of this general type number in the thousands (Fig. 2).

The remaining two structures shown on the third line of Fig. 2 are indole and phenol. Neither is a “simple” arene. Both are important in nature as the side-chain arenes of tryptophan (Trp, W) and tyrosine (Tyr, Y), respectively. The other two arenes that occur as side chains of the common amino acids are imidazole (second line) and benzene (first structure). These arenes are side-chain elements of histidine (His, H) and phenylalanine (Phe, F), respectively. Imidazole is electron-poor and has two potentially sigma-donating nitrogen atoms. As a result, it has not generally been of interest, as a  $\pi$ -donor has not been explored. Interest in the arenes benzene, phenol, and indole, however, has been high. The amino acids phenylalanine, tyrosine, and tryptophan comprise about 8.5% of the amino acids in all known protein structures. Thus along any given protein chain, one amino acid out of every dozen is capable of interacting with ubiquitous sodium, potassium, or other cations (Fig. 3).

**Fig. 1** Lewis acid-base interactions. Top panel: The Lewis acid  $\text{AlCl}_3$  interacts with the Lewis base chloride of  $\text{NaCl}$  while  $\text{Na}^+$  interacts with dimethylether. Bottom: Two representations of a cation-pi interaction between a metal cation ( $\text{M}^+$ ) and benzene.

## GAS PHASE AND COMPUTATIONAL STUDIES

Pioneering studies of the cation–arene interaction were reported by Sunner, Nishi Zawa, and Kebarle,<sup>[2]</sup> in 1981. They used mass spectrometric methods to show that the interaction of  $\text{K}^+$  with benzene in the gas phase was similar energetically to the interaction of this cation with either a molecule of water or of methanol. Similar results were disclosed for  $\text{Na}^+$  by Castleman et al.<sup>[3,4]</sup> and by Cabarcos, Weinheimer, and Lisy,<sup>[5,6]</sup> some time later. Fig. 4 shows the presumed orientation of a benzene ring (shown in the CPK i.e., Corey-Pauling-Koltunorspace-filling metaphor) and  $\text{Na}^+$  (left) and  $\text{K}^+$  ions. Benzene is symmetrical and the ion's position with respect to the pi-cloud is predictable. This is not necessarily the

**Fig. 2** The top row shows from left to right benzene, the archetype aromatic, pyridine, nitrobenzene, and methoxybenzene (anisole). The second line shows, from left to right, furan, thiophene, imidazole, and cyclopentadienide anion. When two cyclopentadienide (Cp) anions react with ferrous ion  $[\text{Fe(II)}]$ , ferrocene (third line) forms. It is shown with indole and phenol.

**Fig. 3** The four "essential" amino acids that have aromatic side chains. The amino acids are phenylalanine (F), tyrosine (Y), histidine (H), and tryptophan (W).

case with more complex arenes such as phenol or indole.

In recent years, a number of computational studies have been conducted,<sup>[7–11]</sup> in some cases, in concert with mass spectral analyses<sup>[12–14]</sup> (Table 1). In general, the conclusions are the expected and reasonable findings. Smaller cations of like charge, e.g.,  $\text{Na}^+$  compared with  $\text{K}^+$ , interact more strongly with an arene. Likewise, more electron-rich arenes, e.g., indole compared with benzene, are better donors for the same cation.

An example of how mass spectrometry may be used to study cation–pi interactions may be found in the study of pyxophanes.<sup>[15]</sup> The diacetylene, **1**, shown in Fig. 5 was prepared so that it would have a pi-rich interior of a size appropriate to bind  $\text{Na}^+$  but too small to bind  $\text{K}^+$ . These size notions were confirmed by a solid-state structure of **1**. The intriguing pyxophane has a molecular weight of 320 Da, but its  $^1\text{H-NMR}$  spectrum shows only two types of protons.

When the electrospray mass spectrum of the pyxophane was determined in the presence of equimolar

**Fig. 4** The presumed orientation of a benzene ring (shown in the CPK metaphor) and  $\text{Na}^+$  (left) and  $\text{K}^+$  ions.

**Table 1** Values reported for sodium and potassium cation interactions with benzene

Interaction	$-\Delta H$ (kcal/mol)	Method(s) used	Reference
$\text{Na}^+ + \text{C}_6\text{H}_6$	$28.0 \pm 0.1$	Mass spectrometry	[17]
$\text{Na}^+ + \text{C}_6\text{H}_6$	24.7–28.1	Computational methods	[9]
$\text{Na}^+ + \text{CH}_3\text{OH}$	26.6	Mass spectrometry	[17]
$\text{Na}^+ + \text{H}_2\text{O}$	24.0	Mass spectrometry	[17]
$\text{Na}^+ + \text{C}_6\text{H}_6$	21.5–21.8	Mass spectrometry and computational methods	[9][14]
$\text{K}^+ + \text{C}_6\text{H}_6$	18.3	Mass spectrometry and computational methods	[2]
$\text{K}^+ + \text{H}_2\text{O}$	17.9	Mass spectrometry and computational methods	[2]

$\text{Na}^+$  and  $\text{K}^+$ , a peak corresponding to  $[\mathbf{1}\cdot\text{Na}]^+$  was observed at  $m/e$  343. No peak corresponding to  $\mathbf{1} + \text{K}^+$  was observed at  $m/e$  359. This suggested selective pi-complexation of the smaller  $\text{Na}^+$  ion by  $\mathbf{1}$  and exclusion of larger  $\text{K}^+$ . These structural conclusions are reasonable based on known shapes, sizes, and interactions. Details cannot be known because they simply are not revealed in a mass spectral study. Notwithstanding, a structure was proffered shortly after the results appeared.<sup>[16]</sup> The conclusion was based on computational analysis, which is useful and, in this case, seemed reasonable. Thus one gains insight from both studies but actual structural data from neither.

### ARENE INTERACTIONS WITH NON-METALLIC CATIONS

Ammonium ( $\text{R}_4\text{N}^+$ ), phosphonium ( $\text{R}_4\text{P}^+$ ), sulfonium ( $\text{R}_3\text{S}^+$ ), and some others are common in nonmetallic cations. Their chemistry is both extensive and important. From the biological perspective, however, ammonium cations are the most important of these. The amine side chain of lysine (Lys, K) is protonated at physiologic pH as is the guanidinium residue of arginine (Arg, R). The potential of nonmetallic cations to interact with arenes was recognized in the early 1980s. Meot-Ner and Deakyne<sup>[17]</sup> used mass spectrometric studies to explore the interaction between -onium salts and arenes. At about the same time, Burley and Petsko<sup>[18]</sup> surveyed the Protein Data

**Fig. 5** Diacetylene,  $\mathbf{1}$ , has a pi-rich interior of a size appropriate to bind  $\text{Na}^+$  but too small to bind  $\text{K}^+$ .

Bank (PDB) to see if -onium ion interactions with arenes could be identified. They were successful in identifying such interactions, but the structural database was limited.

### SOLUTION STUDIES OF ORGANIC CATION–PI INTERACTIONS

Solution studies involving synthetic receptor molecules have also been reported, which confirmed cation–pi interactions in aqueous solution.<sup>[19]</sup> These have involved several types of receptors, and their function has been studied in various solvents. The receptor shown at the right incorporates the essential elements for studies of this type. It is shown with an included adamantanyltrimethylammonium cation. Receptor  $\mathbf{2}$  is cyclic and contains an internal cavity. It is soluble in water by virtue of its 4 carboxylate anions that are present as cesium salts. The four sides of the receptor system are composed of pi-surfaces. The carboxylates are potential sigma-donors, but they are turned outward. The four oxygen atoms are also potential sigma-donors, but their attachment to an aromatic system enhances the pi-donicity of the arene at the expense of sigma-donation by the oxygen.

The use of water as a solvent has the potential advantage of driving together the organic receptor and substrate. The concern in such systems is that water will so strongly solvate one or both of the components that complexation between them will prove to be too weak to detect. Gas phase studies (mass spectrometry or computation) are unencumbered by solvation issues but may be criticized as unrealistic. This is especially true if inferences in the chemistry are to be applied to biological systems, which function in water.

Modern NMR techniques permit structural information to be obtained from these complexation studies. Nuclear Overhauser enhancements (NOEs) indicate proximity of certain atoms or groups. The aromatic receptors are especially amenable to study by NMR methods as the arenes have shielding and deshielding zones that affect adjacent nuclei. Numer-

**Fig. 6** This figure shows a cyclic receptor (2), with an adamantyltrimethylammonium cation included in its internal cavity.

ous examples of and additional details concerning organic receptor molecules that have been studied in solution may be found in a review by Ma and Dougherty (Fig. 6).<sup>[20]</sup>

### SOLID-STATE STRUCTURAL STUDIES OF CATION–PI INTERACTIONS INVOLVING ANIONIC ARENES

The salt potassium tetraphenylborate [ $K^+B^-(C_6H_5)_4$ ] has been known for many years.<sup>[21]</sup> When it crystallizes, it forms a repeating unit that is packed to maximize the

**Fig. 7** Rendering of two molecules of  $KB(C_6H_5)_4$  showing the cation–anion contacts. The boron atom's negative charge is shared among the four benzene rings in each salt, making each arene a stronger donor than it would be if neutral.

stabilizing forces and to minimize any unfavorable steric and electronic interactions. A two-molecule segment of its crystal structure, rendered in mixed ball and stick and CPK metaphor, is shown in Fig. 7. The  $K^+$  ion is nestled in an electron-rich pocket created by two benzene rings of one anion and two from an adjacent anion. The lines at the left of the figure from  $K^+$  to the arene indicate the line of contact between the cation and the arene's centroid. The distance from  $K^+$  to the centroid is 2.986 Å, and the centroid–K–centroid angle is  $\sim 100^\circ$ .

The boron atom's negative charge is shared among the four benzene rings in each salt, making each arene a stronger donor than it would be if neutral. The packing of the arenes is such that the space between them would probably be empty if the spherical cation failed to occupy it. This structure illustrates many of the issues of interest in cation–pi complexation. It is also clear that such precise distance and angle information cannot be gleaned from other analytical methods.

A number of other salts have been studied that reveal similar results. These include  $NaBPh_4$  and  $RbBPh_4$ . The latter was reported in 1962<sup>[22]</sup> and is recorded in the Cambridge Structural Database (CSD) using their six-letter code<sup>a</sup> as “RBPBOR.” The structure of  $NaBPh_4$ , which is similar to the  $K^+$  and  $Rb^+$  structures, is recorded in the CSD as ZZZUPI<sub>10</sub>.

Early efforts to demonstrate cation–pi interactions involved using an alkali metal cation as a reducing agent for an arene. Brooks et al. treated 1,4-dihydronaphthalene with *n*-butyllithium to afford dilithium naphthalenide as a dark purple solid. Its solid-state structure (CSD code: NAPLIM) is shown in Fig. 8A.<sup>[23]</sup> The arene is in contact with two lithium ions, which are present on opposite sides of the naphthalenide (Fig. 8). The lithium ions are  $\sim 2$  Å from the benzene ring centroids, and each cation is stabilized by tetramethylethylenediamine. It is interesting to note in this case that the van der Waals thickness of a benzene ring is  $\sim 3.5$  Å and the ionic radius for  $Li^+$  is  $\sim 0.7$  Å, suggesting that a Li–arene contact should be about  $(1.75 + 0.7 =) 2.45$  Å. In this structure, the distance is  $\sim 2$  Å, suggesting a very strong cation–pi interaction.

A similar approach involved treating fluorene with *n*-butylsodium and pentamethyldiethylenetriamine to give orange crystals of the sodium fluorene complex

<sup>a</sup>Each of the CSD's more than 250,000 crystal structures is assigned a unique code, usually consisting of six letters but sometimes followed by a number. Where possible, and especially for early structures, the code was suggestive of the structure as RBPBOR suggests rubidium and tetraphenylborate. As expected, most of the burgeoning number of structures do not have identifiable or suggestive names.

**Fig. 8** Dilithium naphthalenide's solid-state structure (CSD code: NAPLIM) is shown in Fig. 7A. The arene is in contact with two lithium ions, which are present on opposite sides of the naphthalenide. A similar approach gives orange crystals of the sodium fluorene complex shown in Fig. 7B.

shown in Fig. 7B.<sup>[24]</sup> The solid-state structure is recorded in the CSD as VOKPUG. It is interesting that the cation– $\pi$  interaction occurs with the central ring rather than either of the benzene rings. The Na-centroid distance is 2.562 Å. The ionic radius of Na<sup>+</sup> is about 1 Å, so the observed distance is once again shorter than the calculated value of (1.75 + 1 =) 2.75 Å.

### SOLID-STATE STRUCTURAL STUDIES OF CATION– $\pi$ INTERACTIONS INVOLVING NEUTRAL ARENES

The importance of an early and revealing structural study by Hrcir, Rogers, and Atwood<sup>[25]</sup> was not generally recognized at the time it appeared. The K–benzene distance is 3.369 Å. The ionic radius of K<sup>+</sup> is approximately 1.35 Å, giving an expected K<sup>+</sup>–arene contact distance of (1.75 + 1.35 =) 3.1 Å. In this

**Fig. 9** Crystal structure of potassium cation complexed by dibenzo-18-crown-6- and axially-solvated by neutral benzene. The K<sup>+</sup> ion is pulled out of the plane formed from the 6 oxygen atoms in the crown ether.

example, the K–arene contact is longer than the sum of the van der Waals distances, but the arene is not charged in this case. An interesting feature of this structure is that the K<sup>+</sup> ion is pulled out of the plane formed from the 6 oxygen atoms in the crown ether (Fig. 9).

Many solid-state structures show close contacts between arenes and cations.<sup>[26]</sup> One example is found in zeolites, which trap cations and arenes within their intricate molecular structure.<sup>[27]</sup> Another is found in numerous calixarene complexes<sup>[28]</sup> in which one or more cations are in proximity to the numerous arenes in the receptor molecule.<sup>[29,30]</sup>

### LARIAT ETHERS AS MOLECULAR PROBES OF CATION–ARENE INTERACTIONS

Examples of designed cation– $\pi$  receptor molecules are not yet common. A number of such compounds have been developed for gas phase and solution studies, but these do not provide definitive structural information. On the other hand, a solid-state structure is always suspected on the grounds that packing forces may exert an unexpected influence on the molecular arrangement. Even so, crystal structures are generally persuasive and provide details not available by other methods.

Lariat ethers are crown ethers that have flexible side chains attached to the macroring. Donors present on the side chains may further stabilize cations bound in the macrocycle's cavity. In principle, both sigma- and pi-donors may be incorporated to serve this purpose. Four bibracchial (two-armed) lariat ethers are shown as compounds **3–6** (Fig. 10). Each is a diaza-18-crown-6 macrocycle that has an arene-terminated ethylene sidearm. The arenes on **3**,<sup>[31]</sup> **5**,<sup>[32]</sup> and **6**<sup>[33]</sup> correspond to the side-chain residues of phenylalanine, tyrosine, and tryptophan, respectively. Compound **4**<sup>[34]</sup> is structurally very similar to **3**, but the arene is electron-deficient owing to the strong electron-withdrawing effect of fluorine (Fig. 10).

The solid-state structures of **3–6** as their KI complexes are shown in Fig. 11A–D, respectively. In all cases, K<sup>+</sup> is complexed in the crown's central cavity or hole. From the electrostatic perspective, the iodide ion should be the best anionic donor and it should be in essentially direct contact with the ring-bound cation. Instead, the sidearm arenes appear to be the axial donors in **3**-KI, **5**-KI, and **6**-KI. Such a result might be caused by crystal packing forces. Note that the iodide ion is in approximately the same position in a, c, and d, although H-bond interactions with hydroxyl (c) or amino (d) groups are possible only with **5** and **6**,

**Fig. 10** Bibracchial (two-armed) lariat ethers having arene-terminated side arms: 3, benzene; 4, penta fluoro benzene; 5, phenol; and 6, indole.

respectively. The concern about packing forces is dispelled by the result shown in Fig. 9B. In this case, the benzene ring of **3** has been replaced by pentafluorophenyl groups. These are only slightly larger than benzene, but they may be considered pi-acids rather than pi-bases. Thus they are expected *not* to interact with bound  $K^+$ . As shown in Fig. 11, panel b, the two arenes are turned away from the macrocycle and the cation interacts directly with the iodide anion. Two iodide ions are shown in Fig. 11B. They actually comprise part of an infinite chain of  $(-K-I)_n$  ion pairs within the crystal (Fig. 11).

To further clarify these interactions, the diaza-18-crown-6 compound (**7**) was prepared that has 2-methoxyethyl and 2-phenylethyl side chains.<sup>[35]</sup> The compound and the complex observed by X-ray crystallography are illustrated schematically in Fig. 12. The complex possesses no obvious H-bonding residue in the sidearms, but iodide anion in **7**·KI is excluded from the cation's solvation sphere. Because there is only one arene available to serve as an axial donor, the other site is occupied by the ether oxygen. When a single sidearm is present (*N*-2-phenylethylaza-18-crown-6), iodide occupies the axial position opposite the single arene.<sup>[36]</sup>

**Fig. 11** The solid state structures of **3–6** complexing KI are shown as A–D, respectively. In panel B, the two Lewis acidic arenes are turned away from the macrocycle and the cation interacts directly with iodide anion whereas iodide is excluded from the solvation sphere in A, C, and D.

An interesting feature of the solid-state structural studies is that the bound cation in **6** was closer to the 5-membered ring instead of the more electron-rich 6-membered ring. Computational studies showed a clear preference for the benzo, rather than the pyrrolo subunit, of indole to serve as the pi-donor. Similar experimental results were observed for both  $Na^+$  and  $K^+$  in concert with a variety of counteranions. When the position of attachment between the macrocycle and the arene was moved, benzene became the cation's axial donor.<sup>[37]</sup> This suggests that indole is indeed a versatile pi-donor.

**Fig. 12** The diaza-18-crown-6 compound (**7**) was prepared to have 2-methoxyethyl and 2-phenylethyl side chains.

## CONCLUSION

Arenes are predicted by computational methods to bind cations. The first evidence for such interactions came from mass spectrometric studies conducted in the gas phase. Subsequent studies undertaken with designed receptor molecules gave evidence for cation–arene interactions in various solvents. Recently, numerous solid-state structural data have confirmed these interactions and have provided distance and angle information upon which to base more sophisticated receptor design efforts.

# Molecular Receptor-Modified Metal Nanoparticles

Jian Liu

Department of Chemistry, Michigan Technological University, Houghton, Michigan, U.S.A.

## INTRODUCTION

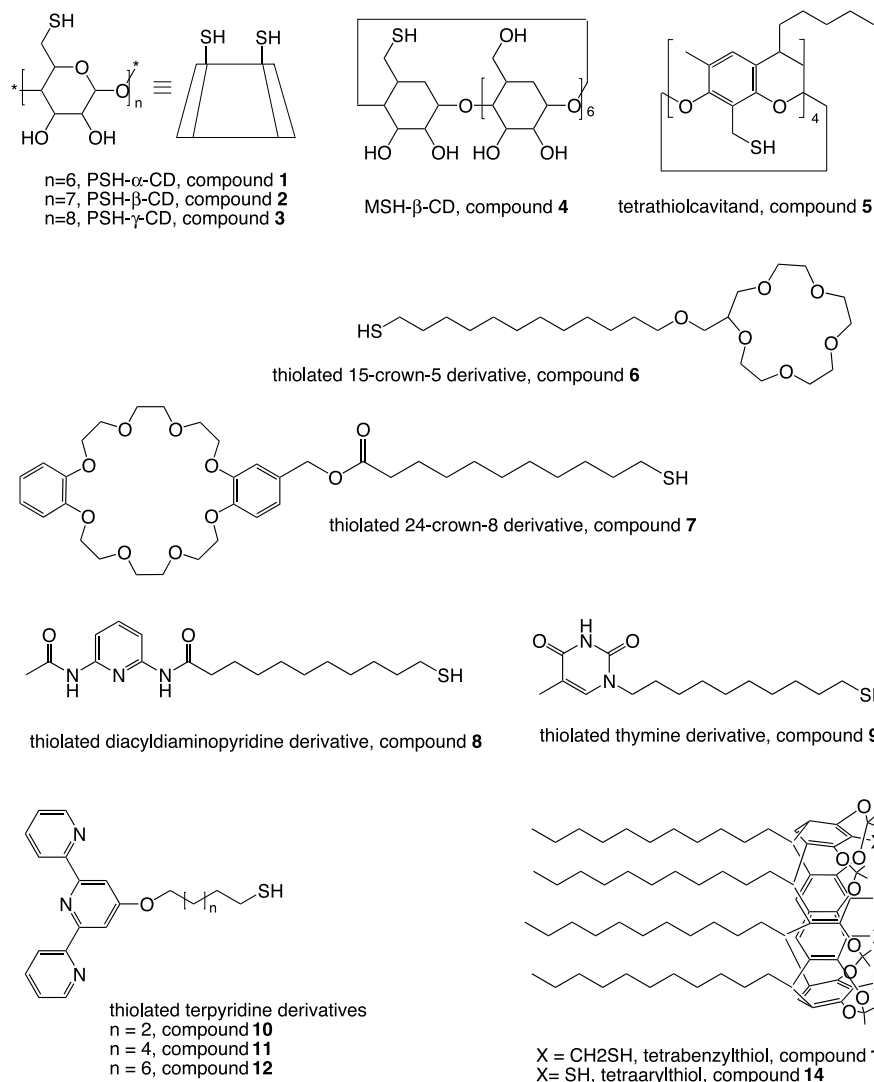

Presently, monolayer-protected metal nanoparticles (MPNPs) are the subjects of some exciting and very active interdisciplinary research because of the rapid development of preparation methods using organic thiols as stabilizers. The organic monolayer not only protects the particles from agglomeration, but also furnishes a scaffold for the construction of different functional entities on their surfaces leading to a broad range of interesting applications. Among these studies, the attachment of molecular receptors capable of engaging in well-defined host–guest interactions is receiving considerable attention.<sup>[1]</sup> This article summarizes recent advancements in the development and applications of artificial receptor-modified metal nanoparticles. The research work on metal nanoparticles modified with biological species, such as DNA, was reviewed recently,<sup>[2]</sup> thus this topic will not be included here.

## PREPARATION OF RECEPTOR-MODIFIED METAL NANOPARTICLES

There has been a great advance<sup>[3]</sup> in the development of synthetic methodology for the preparation of MPNPs after a seminar report from Brust et al.<sup>[4]</sup> In their approach, metal nanoparticles were prepared by chemical reduction of corresponding salts under a mild condition using NaBH<sub>4</sub> as the reducing agent. The presence of thiol ligands with various stoichiometries to metal salt in the reaction resulted in metal nanoparticles ranging in size between 2 and 8 nm. Molecular receptors on metal nanoparticles can be introduced by directly using the thiolated receptor as the capping agent during the particle formation. An alternative approach uses the ligand-exchange<sup>[3]</sup> method to further elaborate the preformed MPNPs with thiolated receptors. In the first case, a crucial consideration is the solubility of the receptor in the reaction media because metal salts are not soluble in nonpolar organic solvents. For example, Kaifer et al. developed a special method to prepare the water-soluble Au,<sup>[5]</sup> Pt,<sup>[6]</sup> and Pd<sup>[6,7]</sup> nanoparticles modified with perthiolated cyclodextrins (PSH-CDs, Chart 1). In this approach, the

special solvent, dimethyl sulfoxide (DMSO) or dimethylformamide (DMF), was used as the reaction media to bring all reacting components, the PSH-CD, the corresponding metal salt, and NaBH<sub>4</sub> in the same phase. This one-phase, one-step (1P-1S) approach eliminates the use of phase transfer reagents in a typical two-phase, one-step (2P-1S) method.<sup>[4]</sup> In the 1P-1S method, the final particle size is influenced not only by the concentration of thiols<sup>[5]</sup> but also by the nature of these molecules. For instance, a “macro-cyclic effect” was observed during the preparation of Ag nanoparticles in DMF.<sup>[8]</sup> Perthiolated  $\beta$ -CD (PSH- $\beta$ -CD) was found to be more efficient as a capping ligand than monothiolated  $\beta$ -CD (MSH- $\beta$ -CD, Chart 1). Similarly, a tetrathiol cavitand derivative (Chart 1) was also more efficient than a simple monothiol model compound. This sort of “macro-cyclic effect” probably results from an increased probability of surface attachment for the multidentate thiols, as they possess more functional groups capable of initiating their chemisorption process. In addition, once the surface attachment starts, their multidentate character may lead to a more robust, multipoint anchoring of the ligand. Therefore, this macrocyclic effect in metal nanoparticle capping reactions may have both a kinetic and a thermodynamic origin.

PSH-CD-modified metal nanoparticles prepared by 1P-1S approach have a diameter less than 10 nm. To obtain PSH- $\beta$ -CD-modified gold nanoparticles (PSH- $\beta$ -CD-Au) larger than 10 nm, a 2S method was applied. Preprepared, citrate-stabilized gold nanoparticles (13 nm in diameter)<sup>[9]</sup> were further modified with PSH- $\beta$ -CDs by ligand exchange with citrate on the particle surface in the aqueous solution.<sup>[10]</sup> A similar strategy was used by Lin et al.<sup>[11]</sup> to prepare Au nanoparticles (18 nm in diameter) modified with thiolated crown ether derivatives (Chart 1). Interestingly, surface-modified gold nanoparticles with even larger size (16–87 nm in diameter) were prepared by extracting citrate-stabilized particles in aqueous solutions into toluene or chloroform with thiolated resorcinarene derivatives (Chart 1),<sup>[12]</sup> the compounds relevant to some macrocyclic receptors. These tetrathiolated resorcinarenes improved the dispersion and robustness of midnanometer-sized gold nanoparticles in organic solvents. However, the authors clearly demonstrated that

the tetraaryltiol adsorbed on the surface is much weaker as compared to tetrabenzylthiol. This is another case that shows how the nature of the thiol compound affects the passivation on metal nanoparticles. Direct modification of Au particles (4 nm in diameter) with another type of crown derivative (Chart 1) was also achieved<sup>[13]</sup> by adapting Brust's 2P-1S approach.<sup>[4]</sup> Rotello et al.<sup>[14–16]</sup> introduced their organic receptors (Chart 1) by using ligand exchange approach to preformed, alkanethiol-modified Au particles in organic solvents. Multivalent receptors were also introduced by the same group on Au particles with similar methodology.<sup>[17]</sup> In the sense of practical application, the ligand exchange approach provides an easier way to control the number of receptors on each particle, which is one of the key factors for molecular recognition at particle surfaces.

Particle size characterization is usually carried out by transmission electron microscopy (TEM). The

solubility of MPNPs in various solvents affords a unique opportunity to characterize them by using standard solution-phase techniques such as nuclear magnetic resonance (NMR) and UV-vis spectroscopies. For example, a <sup>1</sup>H NMR spectrum of gold nanoparticles modified with perthiolated  $\gamma$ -CD (PSH- $\gamma$ -CD-Au) in D<sub>2</sub>O affords the broadened proton resonances from surface-immobilized  $\gamma$ -CDs (Fig. 1).<sup>[18]</sup> Such phenomenon is consistent with the observation obtained by Templeton and coworkers.<sup>[3]</sup> In these systems, the resonances of those protons closer to the metal surface are more seriously broadened, whereas the effect is less pronounced for the protons that are farther away. Fast relaxation and environmental heterogeneities are thought to be responsible for these line-broadening effects. The UV-vis spectroscopic study revealed that PSH- $\beta$ -CD-AuNPs with small size (3 nm in diameter) presented a relatively weak surface plasmon band (SP band) around 520 nm. In contrast, the bigger particles

**Fig. 1**  $^1\text{H}$  NMR spectra (400 MHz,  $\text{D}_2\text{O}$ ) of (A) free  $\gamma$ -CD and (B) PSH- $\gamma$ -CD-Au. Source: From Ref.<sup>[29]</sup>. © 2001, American Chemical Society.

(13 nm in diameter) gave a strong SP band, which may serve as a signal for visibly probing chemical and biological species in the solution.

### MOLECULAR RECOGNITION AT THE SURFACES OF RECEPTOR-MODIFIED METAL NANOPARTICLES

The purpose of introducing molecular receptors on metal nanoparticle surfaces is to endow these nano-scale entities with the capability of engaging molecular recognition. Electrochemistry and UV-vis spectroscopy are the two common techniques used to study the molecular recognition events on particle surfaces in various solutions. Several aspects in this scenario are addressed as follows.

#### Recognition of Redox-Active Species

An important feature of cyclodextrin (CD)-modified metal nanoparticles is their excellent aqueous solubility.

This property is probably contributed by the polarity of the secondary hydroxyl groups on CD receptors, which afford a polar character to the surface of nanoparticles. Surface attachment of the CD hosts through their primary faces necessarily leaves the wider, secondary faces exposed to the solution phase, a configuration that favors binding between the immobilized CDs and appropriate guests in the solution.

Liu et al. used some water-soluble, electroactive molecules (Chart 2) to study the complexation ability of surface-immobilized  $\beta$ -CDs on metal nanoparticles in aqueous solutions. For example, addition of PSH- $\beta$ -CD-Au led to two pronounced effects on the electrochemical response of ferrocenemethanol.<sup>[5]</sup> 1) it decreased the current of the voltammetric wave, and 2) it shifted the apparent half-wave potential to more positive values. Both effects clearly indicated that ferrocenemethanol was forming inclusion complexes with the CD receptors immobilized on the gold nanospheres. This was further verified by addition of 1-adamantanol to the same solution. Adamantanol, being also an excellent guest for inclusion complexation by  $\beta$ -CD,<sup>[19]</sup> competed effectively with ferrocenemethanol for the available CD binding sites on the surface of the gold particles (Scheme 1). As a result, most of the ferrocenemethanol molecules were displaced from their binding sites and released back to the bulk solution, giving rise to a voltammetric response very similar to that recorded in the absence of the  $\beta$ -CD-Au.

The host-binding ability of  $\beta$ -CD immobilized on gold nanoparticles was further verified using compound 17 as guest probe in a  $^1\text{H}$  NMR study.<sup>[18]</sup> The displacement and broadening of the ferrocene proton resonance in the presence of PSH- $\beta$ -CD-Au were attributed to the formation of the inclusion complexes on the nanoparticle surfaces, as they were similar to those observed upon the addition of free  $\beta$ -CD to solutions of ferrocene derivatives. The substantial line broadening must have resulted also from the association of the ferrocene guest to the massive nanoparticles, and was probably related to chemical exchange (free ferrocene going to bound ferrocene and back), as well as to relaxation effects in the bound state. Note that when the ferrocene guest was bound to a CD cavity, it became a part of a rather large supramolecular assembly.

A similar redox-controlled recognition event on receptor-modified metal nanoparticles was also demonstrated by Boal and Rotello in a different nanoparticle

**Scheme 1** Competitive binding of ferrocenemethanol and 1-adamantanol to the  $\beta$ -CD hosts immobilized on a gold nanoparticle.

system. Reversible complexation between flavin ( $\text{Fl}_{\text{ox}}$ ) and diaminopyridine (DAP) tethered on gold nanoparticles was successfully controlled electrochemically in chloroform (Scheme 2).<sup>[14]</sup> Moreover, the same group investigated the multitopic recognition at gold nanoparticles by creating multivalent recognition sites through tethering both DAP and pyrene on the same particle surface. A stronger recognition of electron-deficient  $\text{Fl}_{\text{ox}}$  on particle surfaces was achieved through hydrogen bonding to DAP units and favorable  $\pi$  stacking with the electron-rich pyrene units.<sup>[17,20]</sup>

### Recognition of Cations

Lin et al.<sup>[11]</sup> reported an efficient recognition of  $\text{K}^+$  by 15-crown-5-modified gold nanoparticles (18 nm in

**Scheme 2** Recognition of flavin by surface-immobilized diacyldiaminopyridine.

diameter) in aqueous solution containing physiologically important cations, such as  $\text{Li}^+$ ,  $\text{Cs}^+$ ,  $\text{NH}_4^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ , and an excess amount of  $\text{Na}^+$ . Upon exposure to  $\text{K}^+$ , the color of the nanoparticle solution changed from red to blue corresponding to the surface plasmon absorption of dispersed and aggregated nanoparticles. The authors postulated that one potassium ion efficiently bound to two crown moieties tethered to two different nanoparticles forming a sandwichlike 2:1 complex, which led to the aggregation of nanoparticles.

### Recognition of Anions

Gold nanoparticles modified with a mixed monolayer of alkanethiols and amidoferrocenylalkanethiol were used as effective exoreceptors for electrochemically sensing  $\text{H}_2\text{PO}_4^-$  and  $\text{HSO}_4^-$ .<sup>[21]</sup> The authors found that the redox potential of amidoferrocenyl group was perturbed by the synergy among the hydrogen bonding, electrostatic interaction, and topology of mixed monolayer to recognize  $\text{H}_2\text{PO}_4^-$  and  $\text{HSO}_4^-$  on particle surfaces. However, the potential change is much smaller for  $\text{HSO}_4^-$  than for  $\text{H}_2\text{PO}_4^-$ , showing certain selectivity of the recognition of these particles. The same group extended this work to gold nanoparticles modified with thiol dendrons containing three redox-active amidoferrocenyl or silylferrocenyl units.<sup>[22]</sup> These surface-functionalized particles could effectively recognize  $\text{H}_2\text{PO}_4^-$ . More insights about the stereoelectronic effect of amidoferrocenyl group on the recognition of oxoanions at gold nanoparticle surfaces were reported recently from the same group.<sup>[23]</sup> The recognition properties were weakened by permethylation of one Cp ring (electron releasing and sterically demanding) on amidoferrocenyl moiety but enhanced by acetylation of the same ring (electron withdrawing). Thus, the authors claimed, the stereoelectronic property of the amidoferrocenyl group acted as the key role for the recognition by the amidoferrocenium form through the hydrogen bonding between the  $-\text{NH}-$  amido group and the charged terminal oxygen atom of the oxoanions. The recognition properties of gold nanoparticles functionalized with metallodendrons were further discussed in a recent report.<sup>[24]</sup> Gold nanoparticles modified with up to 360 silylferrocenyl units on each particle were achieved. These dendronized gold nanoparticles combine the advantages of dendrimers and nanoparticles as sensors for the selective recognition of  $\text{H}_2\text{PO}_4^-$  and adenosine-5'-triphosphate ( $\text{ATP}^{2-}$ ) even in the presence of other anions. A dendritic effect on the recognition properties was clearly observed; in other words, the shift of the ferrocenyl redox potential upon introduction of the anion became larger as the generation number of dendrons increased.

Watanabe et al. developed amide-functionalized gold nanoparticles as a prototype for optical recognition of various anions, such as  $\text{H}_2\text{PO}_4^-$ ,  $\text{HSO}_4^-$ ,  $\text{AcO}^-$ , and  $\text{NO}_3^-$ , in organic solvents.<sup>[25]</sup> Interestingly, the addition of anions initially caused a decrease in the surface plasmon absorption of gold nanoparticles. However, the intensity of this SP band increased when excess anion existed in the  $\text{CH}_2\text{Cl}_2$ . The authors reasoned that initial decrease of the SP band was because of the anion-induced aggregation of gold nanoparticles. Further addition of anion caused the disaggregation of the suprananoparticles composed of particles and anions.

### RECEPTOR-MODIFIED METAL NANOPARTICLES AS BUILDING BLOCKS IN THE SELF-ASSEMBLY OF ORGANIC-INORGANIC NANOCOMPOSITES

Metal nanoparticles modified with molecular receptors are excellent candidates as “building blocks” for the bottom-up construction of organic/inorganic hybrid nanocomposites in solution phase by using the non-covalent molecular interactions at particle surfaces. Such nanoscale systems may serve as the initial prototypes in the fabrication of nanoelectronic devices. Several aspects of this scenario will be summarized in this section. A detailed discussion about the research work on this topic from Shenhar and Rotello can be found in a recent review.<sup>[26]</sup>

#### Receptor-Modified Metal Nanoparticles as Templates for the Construction of Micellar Structures

In a recent report, Liu et al.<sup>[18]</sup> reasoned that the introduction of molecular species by molecular recognition at PSH-CD-Au might lead to reversible functionalization of particle surfaces. Therefore, a series of ferrocene derivatives with different lengths of aliphatic chains (Chart 3) were used to examine this idea.

Mixing a chloroform phase containing **22** with an aqueous solution containing PSH- $\beta$ -CD-Au caused a color change of the organic phase from initial yellow to brown. The visible absorption spectrum of this solution clearly revealed two distinct bands residing at 430 and 510 nm, corresponding to the absorptions

by the ferrocene residues and the nanoparticles (SP band), respectively. The obvious conclusion from these results was that compound **22** acted as an efficient phase transfer agent for the water-soluble PSH- $\beta$ -CD-Au and enabled their solubilization in the chloroform phase. Further study showed that only compounds **20**, **21**, and **22** (with aliphatic chains of 12, 16, and 22 carbon atoms) effectively promoted the solubilization of the PSH- $\beta$ -CD-Au in the chloroform phase; compounds **18** and **19** (with shorter aliphatic chains of 3 and 7 carbon atoms) were ineffective. This finding strongly suggested that the long aliphatic chains of ferrocene derivatives could effectively cover the particle surfaces after the complexation with surface-immobilized  $\beta$ -CDs leading to more hydrophobic aggregates, which favored organic solvents. The effectiveness of phase transfer was enhanced when the initial concentration of either ferrocene derivatives or PSH- $\beta$ -CD-Au increased, which perfectly matched the transfer mechanism that involved the formation of interfacial complexes between the CD hosts on the nanoparticles and the ferrocene residues of the amphiphilic guests. Notably, PSH- $\beta$ -CD-Au were more effectively solubilized in the organic phase than PSH- $\alpha$ -CD-Au under identical experimental conditions. This finding was in excellent agreement with the well-established selectivity of ferrocene derivatives for  $\beta$ -CD hosts compared to  $\alpha$ -CD (or  $\gamma$ -CD) and provided additional support to the proposed involvement of nanoparticle/CD-ferrocene complexation in the phase transfer mechanism. Photon correlation spectroscopy (PCS) measurements verified that no aggregation happened after the phase transfer of PSH-CD-Au in chloroform. Gold nanoparticles still stayed individually in the solution with long-term stability.

Based on these findings, such phase transfer was believed to be accomplished by host-guest complexation between surface-immobilized CDs and ferrocene derivatives at gold nanoparticle surfaces. As the formation of inclusion complexes took place in the aqueous solution, water molecules were also transferred along with the nanoparticles into the chloroform solution leading to the stable complex in this organic solvent. The presence of the positively charged nitrogen atoms near the ferrocene subunits probably assisted in transferring water molecules and counterions to the organic phase. Further experiments supported this proposed mechanism. Thus, the proposed idealized structure of the nanoparticles after their transfer to the chloroform phase had some similarities with the structure of reverse micelles. Liu et al.<sup>[18]</sup> concluded that these nanoparticle-centered assemblies were conceptually similar to *gold-filled reverse micelles* (Scheme 3).

A similar micellar structure was also fabricated in Frankamp's group.<sup>[16]</sup> The hydrogen bonding between

**Scheme 3** Proposed structure for the assemblies formed upon transfer of the PSH- $\beta$ -CD-Au into chloroform solution.

the thymine tethered on gold nanoparticles and the complementary diaminotriazine on a copolymer yielded a polymer/nanoparticle composite in which the polymer blocks bearing the diaminotriazine closely interacted with nanoparticles resulting in a spherical core, whereas the polystyrene units acted as the hydrophobic tails projecting out into the solution. Lala et al.<sup>[27]</sup> also reported a relevant result in which gold nanoparticles capped with inclusion complexes of  $\alpha$ -CD and alkanethiols were transferred into the chloroform phase by using a similar strategy discussed above.

### Fabrication of Rotaxanes on Metal Nanoparticles

One of the fast-growing research fields in nanochemistry is the construction of molecular architectures on nanoparticle surfaces. By employing the well-known host-guest chemistry between CDs and organic molecules, Liu, Xu, and Kaifer built, for the first time, a nanoparticle-supported rotaxane system,<sup>[28]</sup> which provides an interesting example of molecular structure for the further development of the functional nanoscopic systems at nanoparticle scaffolds. Ligand exchange of a thiolated ferrocene derivative solubilized by  $\alpha$ -CD with the citrate on citrate-stabilized gold nanoparticle (13 nm) in an aqueous solution led to the attachment of this compound on the particle surfaces. Further study of these materials revealed that some  $\alpha$ -CDs were trapped on particles. On the other hand, when long-chain aliphatic thiols were used under identical conditions for the preparation of thiol-modified gold nanoparticles, no  $\alpha$ -CD was detected

**Scheme 4** Nanoparticle-supported rotaxane.

after the necessary purification. These data suggested that the dynamic character of the complex between CD and alkanethiol allowed dissociation to take place after attachment to the gold surface, whereas the bulky ferrocene group at one end of the thiolated ferrocene derivative precluded  $\alpha$ -CD dissociation from the complex after its attachment on the particle. Thus, a novel molecular structure obtained in this study was a “gold-supported rotaxane” in which one of the rotaxanes’ stopper groups was the gold nanosphere itself (Scheme 4). Interestingly, Fitzmaurice and coworkers reported<sup>[13]</sup> a pseudorotaxane system on gold nanoparticles by binding dibenzylammonium cation in a crown derivative tethered on particle surfaces.

### Fabrication of Nanoparticle Networks in Solutions

Host-guest chemistry has been used as the general strategy to self-assemble receptor-modified metal nanoparticles in aqueous solutions. Liu et al. reported their first attempt in this research direction by using PSH- $\beta$ -CD-Au (12.5 nm) as building blocks and ferrocene dimers (Scheme 5) as “linkers” in aqueous solutions.<sup>[10]</sup>

It was found that the addition of a ferrocene dimer to an aqueous PSH- $\beta$ -CD-Au solution initially caused a red shift of the SP band. Almost immediately, slow precipitation of a red solid took place, accompanied by the attenuation of the intensity of the SP band. After several control experiments, the authors verified

**Scheme 5** Gold nanoparticle aggregate driven by molecular recognition between surface-immobilized PSH- $\beta$ -CD and ferrocene dimer.

that such flocculation was driven by the host-guest interaction between  $\beta$ -CDs anchored on gold nanoparticle surfaces and the ferrocene dimers in the aqueous solution. In the process of complexation, two ferrocene sites in the same molecule bound with two  $\beta$ -CDs on different particles resulting in the network nanoparticle aggregates. Thus, the ferrocene dimer acted as the linker in self-assembly of nanoparticles in aqueous solutions. In addition, such aggregation process could be tuned by the addition of free host or guest molecules in the solution. For instance, introduction of  $\beta$ -CD in the same solution slowed and even shut down the aggregation process as free CD competed with surface-attached CD hosts for the available ferrocene groups. Thus, the flocculation was hindered because the dimers could not form a significant number of linkages between nanoparticles. Temperature also played an important role. Increasing the temperature diminished the extent of flocculation, resulting from the decrease in binding constant between the ferrocene residues and the  $\beta$ -CD hosts.

By using similar host-guest chemistry, another type of interesting organic/inorganic nanocomposites was constructed in the aqueous solution.<sup>[29]</sup> Direct mixing of PSH- $\gamma$ -CD-Au (3 nm) and solid  $C_{60}$  in water led to large nanoparticle aggregates with average size of around 290 nm as characterized by PCS analysis and TEM measurement. In an alternative approach, mixing a toluene phase of  $C_{60}$  with a PSH- $\gamma$ -CD-Au aqueous solution at 0°C also yielded similar nanoparticle aggregates in aqueous media. It is known that  $\gamma$ -CD can form stable 2:1 complex with  $C_{60}$  in aqueous solution.<sup>[30]</sup> Therefore, the authors reasoned that the solubilization of  $C_{60}$  in aqueous solution was attributed to its complexation by the nanoparticle-attached  $\gamma$ -CD hosts. Interestingly, the 2:1 stoichiometry of this complex suggests that the fullerene molecules may behave as *non-covalent linkers* between the nanoparticles, leading to their aggregation (Scheme 6).

Boal's group developed a "brick and mortar" approach in the fabrication of three-dimensional organic/inorganic nanostructures using receptor-modified gold nanoparticles as building blocks and polymers tethered with complementary recognition units as the glue. The three-point hydrogen bonding between the thymine-functionalized gold nanoparticles and diaminotriazine-functionalized polystyrene poly-Triaz yielded microspheric structures  $97 \pm 17$  nm in diameter.<sup>[31]</sup> The temperature had a profound effect on the assembly process. At -20°C, the largest micro-scale clusters were obtained, which were 10 times larger than the aggregates formed at 23°C. Each of these clusters was composed of 0.6–5.0 million individual gold nanoparticles representing the most complex synthetic structures known. Norsten's group also reported a

**Scheme 6** Fullerene-induced network of PSH- $\gamma$ -CD-Au in aqueous solution.

nanoparticle network system by using metal ions as the linkage. The chelation of various metal ions, Fe(II), Zn(II), Cu(II), and Ag(I), with two terpyridines that were tethered to separate nanoparticles resulted in the network aggregates.<sup>[15]</sup> The stability of these structures could be controlled by changing the solvent, adding excess terpyridine, or through the choice of bridging metal.

Ryan and coworkers reported that silver nanocrystals stabilized by chemisorption of a mixture of an alkane thiol and a thiolated dibenzo-24-crown-8 could form the nanoparticle aggregates by adding a small amount of bis-dibenzylammonium through the formation of crown-ammonium pseudorotaxane assembly.<sup>[32]</sup> It was also shown that the addition of excess dibenzylammonium cation or dibenzo-24-crown-8 inhibited further aggregation. This novel demonstration of controlled nanocrystal aggregation pointed the way toward the programmed assembly of complex nanocrystal architectures in solution. In a subsequent work, the same group reported the first example of binary nanostructures composing two different types of inorganic nanoparticles by using a similar recognition-directed templating strategy.<sup>[33]</sup> Dibenzo-24-crown-8-modified Ag nanoparticles (7 nm in diameter) recognized and bound to dibenzylammonium cation modified silica nanosphere (180 nm in diameter) via pseudorotaxane formation. Such templating process was proved to be reversibly controlled.

## RECEPTOR-MODIFIED METAL NANOPARTICLES AS NOVEL CATALYSTS

The increasing interest in using metal nanoparticles as catalysts is due to their high surface to volume ratio. In a recent and elegant work, Crooks and coworkers have prepared catalytically active metal nanoparticles encapsulated inside dendrimers.<sup>[34]</sup> The dendrimer effectively stabilizes the nanoparticles without passivating their surfaces, and its branched structure acts as a “molecular filter” imparting selectivity to the catalyst assembly. Recently, Kaifer et al.<sup>[6,7]</sup> reported several research works on the development of CD-modified Pt and Pd nanoparticles for catalytic reactions in aqueous solutions. Special effort has been made in tuning the catalytic activity of these CD-modified nanoparticles through introduction of host-guest interactions on their surfaces.

In an initial attempt,<sup>[6]</sup> water-soluble PSH- $\beta$ -CD-modified Pt and Pd nanoparticles (13 to 15 nm in diameter) were prepared in DMSO-H<sub>2</sub>O mixed solvents by reducing corresponding metal salts using borohydride as reducing agent. Both Pt and Pd nanoparticles prepared here could successfully catalyze the

hydrogenation of allylamine to propylamine in aqueous solutions. The ease of recovering the metal catalysts through precipitation with ethanol from the reaction medium provided an opportunity to recycle the catalyst for the hydrogenation reactions. The authors then focused their attention on the “selectivity” in the catalytic process. In this case, smaller Pd nanoparticles (3 nm) modified with  $\beta$ -CD were made in DMF. These  $\beta$ -CD-modified Pd nanoparticles (PSH- $\beta$ -CD-Pd) behaved as efficient catalysts for the selective hydrogenation of different substrates (Chart 4) in aqueous media. Interestingly, adding millimolar concentrations of **25** to the reaction mixture substantially decreased the rate of hydrogenation of **23**. However, the addition of similar concentrations of tetramethylammonium bromide or tetraethylammonium bromide had a much smaller effect on the rate of hydrogenation of **23**. Similarly, the negatively charged ferrocene derivative **26** and adamantanol (a neutral  $\beta$ -CD guest) were considerably less effective than **25** as catalyst inhibitors. All these data support the idea that **25** acts as an effective inhibitor of the catalytic activity of the PSH- $\beta$ -CD-Pd because of (1) its ability to act as a guest with the CD cavities and (2) its positive charge.

Further evidence of the strong correlation between inhibition by **25** and its binding ability with the CDs that decorated the Pd nanoparticles was obtained by investigating the concentration dependence of the reaction rate. The data obtained showed the saturation behavior that was clearly associated with the binding isotherm of the ferrocene derivatives in the binding sites (CD cavities) on the surface of the nanoparticles. The authors also found out that the actual effect of compound **25** to inhibit the hydrogenation of substrates **23** and **24** differed. Compound **25** was a more effective inhibitor with **23** than **24**. This was probably because of the ferrocene group present in **24**, which increased its affinity to the CD-modified nanoparticles.

**Scheme 7** Complexation control of the accessibility of reacting sites on PSH- $\beta$ -CD-Pd for hydrogenation reaction. Source: From Ref.<sup>[7]</sup>. © 2001, American Chemical Society.

Thus, **25** competed with the substrate itself (**24**) for the available binding sites, and its overall inhibition effect was strongly curtailed. The results presented in that work clearly showed that (1) PSH- $\beta$ -CD-Pds were active catalysts for the hydrogenation of water-soluble alkenes **23** and **24**, (2) catalytic activity could be substantially decreased by addition of the cationic ferrocene derivative **25**, and (3) the inhibiting character of **25** was due to its ability to create Coulombic barriers for the approach of the positively charged substrates (Scheme 7), resulting in the decrease in the surface density of catalytic active sites. These Pd nanoparticles served as heterogeneous catalysts while their small sizes and solubility properties approach those of homogeneous catalysts. These Pd nanoparticles were further used as the efficient catalysts for Suzuki reactions in aqueous media.<sup>[35]</sup>

## CONCLUSION

This article summarizes the recent advancement on the preparation and applications of molecular receptor-modified metal nanoparticles. Although, substantial progress has been achieved in these past years, this research field is still in its infancy. More work needs to be done in the future to reveal fundamental insights and explore more applications for these

nanoscale materials. For example, water solubility of these receptor-modified metal nanoparticles is the key factor for the development of chemical and biological sensors. To make three-dimensional nanocomposites self-organized by molecular recognition with long-range order and the controllable interparticle space is still a big challenge. High stereoselectivity provided by molecular receptors on metal particle surfaces is desired for the development of ecoefficient, environmentally benign heterogeneous catalysts. The author expects a great advancement in this research field in the next few years.

## INTRODUCTION

In the last decade, we have witnessed many exciting new discoveries in the ability to manipulate and measure matter at the nanometer scale—honeycombed pores structures, spheres, icosahedra, nanotubes and nanorods, and self-assembled structural hierarchies; the esthetics of the nanometer regime offers Nature's elegance in its purest form. Understanding the driving forces behind these shapes and the self-assembly processes provides key understanding for this chemistry to be exploited for positive impact on our daily lives. For this to take place, we must not only understand how the nanoscopic structures impact the structural and chemical properties of these novel new materials, but we must also understand the critical problems that we face today and how these nanoscopic properties can be tailored to address these specific needs and critical problems. The purpose of this entry is to show how this understanding can be applied to the synthesis of nanostructured hybrid materials that can address needs in the areas of drinking water purification, environmental remediation, and enhancing the sensitivity of analytical methods for detecting heavy metal contamination.

## DIMENSIONS OF THE PROBLEM

The most important factor in determining quality of life in human society is the availability of pure, clean

drinking water. Wars have been fought, and will continue to be fought, over access and control of clean water. Drinking water has two major classes of contamination: biological contamination and chemical contamination. Bacterial contamination can be dealt with by a number of well-established technologies [e.g., chlorination, ozone, ultraviolet (UV), etc.], but chemical contamination is a somewhat more challenging target. Organic contaminants, such as pesticides, agricultural chemicals, industrial solvents, and fuels, can be removed by treatment with UV/ozone, activated carbon, or plasma technologies. Toxic heavy metals such as mercury, lead, and cadmium can be partially addressed by using traditional sorbent materials such as alumina, but these materials bind metal ions non-specifically and can be saturated with harmless, ubiquitous species such as calcium, magnesium, and zinc (which are actually nutrients, and do not need to be removed). Another weakness of these traditional sorbent materials is that metal ion sorption to a ceramic oxide surface is an equilibrium process, meaning they can easily desorb back into the drinking water supply. Heavy metal contamination can also be removed via flocculation/precipitation, but these methods are far more effective at high contaminant concentrations, and commonly fail at lower metal concentrations, which is where most drinking water problems are found.

Heavy metal contamination comes from many sources, both natural and industrial. Geological contamination of drinking water with arsenic is a

major problem in Bangladesh<sup>[1-3]</sup> and in North America (e.g., the central valley of California<sup>[4,5]</sup> and New Hampshire.)<sup>[6]</sup> Industrial arsenic contamination has been found in New England<sup>[7]</sup> and the Pacific Northwest.<sup>[8]</sup> Stringent new Environmental Protection Agency (EPA) guidelines for arsenic in drinking water<sup>[9,10]</sup> make this a high-priority issue. Industrial activity has led to mercury contamination in many parts of the world.<sup>[11-13]</sup> Lead contamination from lead-based paints and burning leaded gasoline resulted in significant blood lead concentrations for children in the United States.<sup>[14]</sup> Aboveground nuclear weapons testing by the United States and the Soviet Union in the early 1960s and nuclear accidents (e.g., Chernobyl) have spread low levels of radioactive actinides and radiocesium throughout the world environment.<sup>[15]</sup>

## NANOSCIENCE AND ITS ROLE

Clearly, all these toxic metals form a significant threat to the water supplies of the world. How can nanoscience address this problem? A chemically specific sorbent material capable of permanently sequestering these toxic metal ions from groundwater supplies is needed to purify contaminated drinking water. Because we consume vast quantities of drinking water every day, the kinetics of heavy metal sorption need to be fast, allowing for high throughput in the process stream. A high binding capacity for the target heavy metal is clearly of value. In addition, as acceptable drinking water contamination limits becomes

increasingly lower, more sensitive analytical methods are needed in order to detect such contamination.

## Nanostructured Materials

There has been a great deal of recent developments in the synthesis of nanostructured materials, particularly in the area of surfactant templated synthesis of mesoporous ceramic materials.<sup>[16,17]</sup> Synthetic methods have been developed to prepare these materials in a variety of morphologies (lamellar, cubic, hexagonal, etc.) with structural features ranging from about 20 Å up to 300 Å.<sup>[18]</sup> The micelle shape and structure dictates pore size and structure (Fig. 1).<sup>[19,20]</sup> A huge amount of surface area is condensed into a very small volume in these nanoporous ceramics, making them well suited for catalytic, sorbent, and sensing applications. In addition, the rigid ceramic backbone precludes solvent swelling and allows facile diffusion throughout the entire porous matrix. The ceramic backbone is also structurally more robust than a polymer-based ion exchange resin, so particle attrition is less of an issue.

## Functionalization of Mesoporous Ceramics

Recently, a great deal of research has been performed exploring the synthetic elaboration of the pore surfaces of mesoporous materials.<sup>[21]</sup> Generally, these efforts fall into three approaches: cocondensation, surfactant displacement (or extraction), and postcalcination modification.<sup>[22]</sup> When a suitable metal precursor

Fig. 1 Micelle templated synthesis of mesoporous ceramics.

(e.g., metal salt, alkoxide, etc.)<sup>[23]</sup> or alkyl siloxane is included in the original sol–gel mixture and subjected to hydrolysis, this is referred to as “cocondensation.”<sup>[24]</sup> In this case, the dopant is entrapped within the mesostructured greenbody, and because most of the ceramic material is at, or very close to, an interface, the dopant is also usually close to an interface. For metal dopants, the surfactant can be removed by calcining the greenbody, resulting in an anchored metal silicate. Alkyl siloxanes will not survive calcination conditions, and therefore the surfactant template must be removed by low-temperature methods such as acid extraction. Doping levels as high as 40% have been reported.<sup>[24]</sup> However, it is important to recognize that the dopant represents a defect in the wall structure of the nanoporous ceramic, and therefore, higher doping levels result in weaker and more defective materials. The advantages of the cocondensation strategy are its simplicity and the direct access it provides to functionalized mesoporous materials; the disadvantages include the relatively high defect density and somewhat limited doping levels of the functionalized products.

A second method for the preparation of functional mesoporous materials is by surfactant displacement. In this method, the surfactant laden greenbody has the quaternary ammonium surfactant molecules displaced by a suitable cationic species<sup>[25,26]</sup> or by acid extraction (which is simply displacement by a proton).<sup>[27]</sup> This route provides easy access to functionalized mesoporous materials, especially those involving cationic transition metal complexes. Displacement by a proton affords a native silica surface that is not dehydrated, or silanol-depleted, and is therefore highly receptive to silanation. Like cocondensation, the advantages of surfactant displacement/acid extraction are the simplicity of the procedure and the direct access to functionalized nanomaterials. The disadvantage of these approaches is that, by avoiding the calcination phase of the procedure, the silicic acid backbone is never fully condensed (crosslinked) to form a robust ceramic, and hence these materials are susceptible to structural degradation over time.

Most commonly, the mesostructured greenbody is calcined to burn off the surfactant template and the interface modified thereafter.<sup>[28–32]</sup> This strategy has the advantage of providing a well-defined, structurally robust, rigid pore structure. Unfortunately, calcination drives off most of the surface silanols and all of the surface water, leaving the interface poorly suited to functional elaboration. As a result, direct silanation of this desiccated interface leads to very limited surface coverage because there is only small fraction of the original surface silanols left to be capped. For catalytic applications requiring high turnover numbers and minimal steric congestion, this limited surface coverage can be highly beneficial.

## Self-Assembled Monolayers

The self-assembly of a monolayer is the spontaneous aggregation of molecules into an ordered, organized macromolecular array a single molecule thick. The self-assembly process is driven by the attractive forces between the molecules themselves (e.g., van der Waals interactions, hydrogen bonding, or dipole–dipole interactions), as well as the attractive forces between the molecule and interface (e.g., hydrogen bonding, acid/base interactions, etc.). It is important to recognize that the molecular spacing in a self-assembled monolayer is dictated by the aggregation efficiency and the molecular “footprint” of the monomer. In the silanol capping chemistry discussed above, the molecular spacing of the monomer on the surface is dictated by the number and distribution of hydroxyl groups on the ceramic surface. At first glance, self-assembly and surface capping are very similar processes, but in the final analysis, self-assembly is controlled by the chemistry and behavior of the monomer component, while surface capping chemistry is ultimately controlled by the hydroxyl population of the surface. Each reaction pathway can be favored by suitable choice of the reaction conditions. If the solvent chosen swamps out the attractive forces between the monomer molecules, then self-assembly is kinetically disfavored and surface capping chemistry tends to dominate, leaving vacancies between the individual silanes. In addition, there must be sufficient water on the interface to hydrolyze the silane, but if the water is present in solution and not at the interface, then this leads to bulk solution polymerization of the silane, which precludes organized assembly on the surface. Inadequate amounts of water at the interface prevent silane hydrolysis. Because tris(hydroxy)silane is the active species in this self-assembly, if it is not formed then self-assembly (and crosslinking) is retarded, and once again the surface chemistry is limited to silanol capping reactions. Only through the judicious choice of reaction conditions (i.e., solvent identity, water concentration, water location, and reaction temperature) can self-assembly take place, resulting in a dense, uniform coating of the surface (Fig. 2).

Supercritical fluids are a particularly powerful reaction medium in which to carry out silane self-assembly within mesoporous ceramics.<sup>[33]</sup> Supercritical carbon dioxide (SCCO<sub>2</sub>) effectively solvates the siloxane monomers, but it also does not inhibit the attractive (van der Waals) forces between the hydrocarbon chains because CO<sub>2</sub> is a small linear molecule, allowing self-assembly to proceed smoothly. In addition, any associative process can be accelerated by carrying it out under conditions of high pressure.<sup>[34]</sup> Self-assembled monolayer formation is an associative process and is significantly accelerated when carried

**Fig. 2** The marriage of self-assembled monolayers with mesoporous supports has created a powerful new class of heavy metal sorbent materials.

out in  $\text{SCCO}_2$ . In addition, the monolayers so formed have a lower defect density as a result of some novel annealing mechanisms that come into play under these conditions.<sup>[35]</sup> The low viscosity of  $\text{SCCO}_2$  also facilitates mass transport of silane throughout the nanoporous ceramic matrix. When the monolayer deposition is complete, the pores of the self-assembled monolayers on mesoporous supports (SAMMS) are clear and dry, and not filled with residual solvent that must be removed before the materials can be used.  $\text{SCCO}_2$  is such a powerful functionalization protocol that it has even been successfully applied to the subnanometer pores of zeolites!<sup>[35]</sup>

## SAMMS AS SORBENT MATERIALS

### Soft Heavy Metals

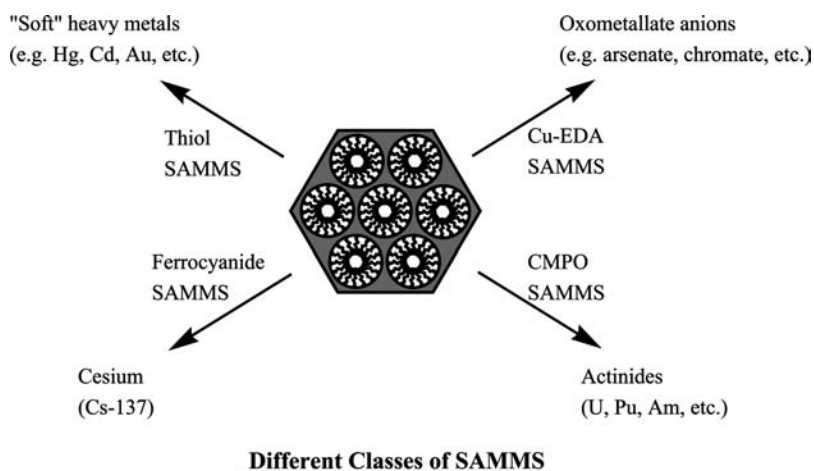

Our initial forays into developing SAMMS as a metallic sorbent focused on the sequestration of mercury because of its impact on the environment and human health. Because Hg is a “soft” Lewis acid,<sup>[36]</sup> we targeted the installation of “soft” Lewis bases, in particular alkyl thiols, to take advantage of the thiol’s legendary affinity for mercuric species. Preparation of thiol SAMMS is straightforward, and creates a powerful new class of mercury sorbent. The distribution coefficient ( $K_d$ ) is defined as a mass-weighted partition coefficient and provides a way of gauging the effectiveness of a sorbent material. Sorption distribution coefficients are determined by the following equation, where  $C_0$  is the initial concentration of the target analyte,  $C_f$  is the final equilibrium concentration,  $V$  is the volume of the testing solution (mL), and  $M$  is

the mass of SAMMS used (g).

$$K_d = [(C_0 - C_f)/C_f](V/M) \quad (1)$$

The  $K_d$  values obtained in our studies of thiol SAMMS binding mercury were typically in the  $10^7$  range.<sup>[37]</sup> This means that, for a solution/solids ratio of 10,000, at equilibrium there is 1000 times as much mercury in the small amount of SAMMS as there is in the supernatant solution. The  $K_d$  values were found to not vary significantly over a pH range from about 3 to 9. Below 3, the  $K_d$  values started to drop off significantly because of protonation of the ligand, and above pH of 10, the mesoporous silica begins to breakdown. The loading capacity is greater than 500 mg Hg, per gram of SAMMS (or 2.5 mmol/g). The sorption kinetics are quite fast, generally reaching equilibrium in about 3 min. Existing commercially available polymer systems require several hours to reach equilibrium. Extended X-ray absorption fine structure (EXAFS) characterization of the SAMMS–Hg adduct indicates that Hg is predominantly found bridging between two thiol groups.<sup>[38]</sup> Ubiquitous cations such as Na, K, Ca, Mg, Fe, and Zn were found to provide no competition for the thiol binding sites, as predicted by hard–soft acid/base theory. The binding affinity of thiol SAMMS for Hg is so high that even complexants such as ethylenediaminetetraacetic acid (EDTA) cannot compete!<sup>[39]</sup>

Other “soft” heavy metals of environmental concern, such as Cd, Cu, and Pb, are also bound by thiol SAMMS, although not as steadfastly as Hg ( $K_d$ ’s of several thousand to tens of thousands). Tl is also a suitable target for thiol SAMMS (Fig. 3).

**Fig. 3** By tailoring the chemical nature of the monolayer interface, it is possible to selectively sequester a variety of metallic contaminants of environmental concern.

### Oxometallate Anions

The beauty of the SAMMS concept is that it arises from a convergent synthesis, one branch leading to the mesoporous backbone, one branch forms the monolayer support, and conceivably, a third branch to form the functional interface. As a result, modification to tailor the sorbent material for a different target species is very easily accomplished. By lining the pore surfaces of SAMMS with cationic metal complexes, a powerful new class of anion exchange material has been realized (Fig. 3).<sup>[40]</sup> By judicious choice of the metal center and ligand field, it is possible to create chemical selectivity not only at the stereochemical level, but also a level of selectivity based upon the solubility of the metal–anion adduct. For example, copper (II) is known to have a very high affinity for amine ligands; however, being a  $d^9$  species, it tends to undergo Jahn–Teller distortion to alleviate orbital degeneracy, distorting its geometry away from an ideal octahedral coordination sphere. Thus, a monolayer interface composed of a copper (II)–ethylenediamine (Cu–EDA) complexes has a firmly bound metal center, but the third EDA ligand (or water molecule) is readily displaced by an incoming anion to take the Cu (II) center to a trigonal bipyramidal geometry. If the copper–anion salt is soluble (e.g., copper (II) sulfate), then this ligand displacement is reversible, and the anion can be displaced. If not, however, then the anion is effectively sequestered. The latter condition holds true for anions such as chromate and arsenate, both of which are of significant environmental concern.  $K_d$  values for chromate are commonly  $10^5$  or higher, with a loading capacity of 130 mg (or 1.12 mmol) chromate per gram of Cu–EDA SAMMS. Similar loading capacity is observed for arsenate anion (140 mg/g or 1.0 mmol/g). Given the 3:1 stoichiometry of the initially Cu(II)EDA complex, this correlates quite well with the initial silane population density on the mesoporous silica, indicating that

all of the Cu (II) binding sites are effectively utilized. The kinetics of arsenate sorption are quite fast with equilibrium being reached in about 5 min. Clearly, diffusion into the mesoporous matrix is not a significant limitation.

### Radiocesium

Cesium-137 is a radioactive by-product of weapons-grade Pu production and fallout from aboveground nuclear weapons testing. Once released into the environment, Cs is quite mobile. Methods to sequester Cs include calixcrown-modified supports<sup>[41,42]</sup> and the crystalline silicotitanates (CST).<sup>[43]</sup> The crown ethers offer modest selectivity for Cs over other monovalent cations, but are sensitive to reaction conditions (pH, competing ions, etc.) and are sensitive to radiolytic breakdown of the polymer backbone. The CSTs provide excellent selectivity and high binding affinity, but sorption kinetics may be quite slow (because of diffusion through the microporous matrix), and once the Cs is bound it cannot be removed, making the CSTs a single-use-and-dispose technology. Transition metal ferrocyanides form insoluble Cs salts, and this was exploited by modifying support materials with ferrocyanides.<sup>[44–46]</sup> Treatment of the Cu–EDA SAMMS described above with ferrocyanide provides unprecedented Cs binding capability (Fig. 3).<sup>[47]</sup> Binding affinities, even in the presence of huge excesses of Na or K ion, are greater than  $10^5$ . The Cs loading capacity of the ferrocyanide SAMMS is 179 mg per gram of SAMMS (or 1.35 mmol/g), once again indicating that almost all of the ferrocyanide binding sites are effectively used to sequester the Cs target [X-ray photoelectron spectroscopy (XPS) analysis reveals that some of the ferrocyanide groups are bridging between two adjacent Cu–EDA complexes, which slightly limits the Cs capacity; however, the metathesis of Cs for Na

is quantitative]. Sorption kinetics are facile, with equilibrium being reached in approximately 20 min.

## Actinides

The Cold War led to 40 years of weapons-grade plutonium production. In the wake of this massive chemical production effort, the United States has been left with millions of gallons of highly radioactive waste. Currently, the ultimate plan is to combine this waste with a suitable silica source, melt the mixture to glassify it, and store the glass logs in a suitable subterranean repository, such as Yucca Mountain, Nevada. The majority of this waste is relatively innocuous (e.g., sodium nitrate, sodium aluminate, tributyl phosphate, etc.), and does not need to be glassified for long-term disposition. Clearly, it would save much time, effort, and money if the small amount of radioisotopes could be removed from the bulk of the waste and only the small amount of radionuclides is subjected to vitrification. Thus, the need to selectively sequester actinides from complex mixtures exists, and sorely needs to be addressed. Actinide separations have historically been accomplished by solvent extraction methods, and much has been learned in terms of ligand design from these efforts. One of the most effective ligands for actinide extraction is the carbamoylphosphine oxide (CMPO) class of ligands.<sup>[48–51]</sup> We have decorated the monolayer interface of SAMMS with CMPO analogs to make acetamidophosphonate SAMMS, and found an exceptional new actinide sorbent material (Fig. 3).<sup>[52]</sup> The acid form of this sorbent not only has excellent binding affinities for actinides such as Pu (IV) and U (VI) ( $K_d$  values are usually in excess of 20,000, and sometimes as high as 300,000), but there is no competition from transition metal cations, or common complexants (e.g., EDTA). The binding affinity is dependent on pH, but the phosphonic acid SAMMS are still effective sorbents down to below a pH of 0.5. Sorption kinetics are very rapid, with equilibrium being achieved in about 1 min. An added advantage of using SAMMS to extract actinide from Department of Energy (DOE) nuclear waste is that SAMMS is a silica-based sorbent system, and is therefore directly compatible with glassification.<sup>[53]</sup>

## PRECONCENTRATION FOR ANALYTICAL APPLICATIONS

What we know is typically bound by what we can confidently measure. Consequently, there are ongoing efforts to improve the sensitivity, selectivity, and speed of analytical methods. One approach to improving any analytical method is to separate the analyte(s) for the sample matrix and concentrate them into a smaller

volume prior to measurement. When this preconcentration is carried out with small quantities of sorbents, the method is typically referred to as a solid-phase microextraction (SPME). Another method is to preconcentrate the analyte directly upon the transducer of the detector. In either case, the amount of extracted analyte is limited by the magnitude of the partition coefficient of the analyte between the sample matrix and the sorbent material.

Self-assembled monolayers on mesoporous supports can be ideal materials for selective preconcentration and SPME. The mesostructure endows SAMMS with high surface areas and short diffusional path lengths. The monolayer provides a high density of complexation sites. This combination results in a sorbent material with rapid uptake kinetics and very large loading capacities. The wide range of monolayer chemistries allows significant flexibility in the target analyte(s). However, application of SAMMS for preconcentration and SPME must coordinate the monolayer chemistry with the target analyte and sample matrix.

The target analyte(s) must have a high partition coefficient from the sample matrix to enable significant preconcentration. Moreover, the analyte partition coefficient must be much higher than any competing material(s) commonly occurring in the sample matrix, or equilibrium processes will displace it. The morphology of the SAMMS material must be matched to the analytical application. The SAMMS material must be available to extraction or analysis and the mesoporous structure is not immune to fouling issues (i.e., suspended sediments, organics, etc.) that plague other preconcentration methods.

## X-Ray Fluorescence and Heavy Metal Assay

X-ray fluorescence (XRF) spectroscopy involves the measurement of characteristic elemental X-rays emitted from an atom after bombardment by higher energy photons. The technique is not capable of direct trace level assay but can quickly perform part per million (ppm)-level multielemental analyses of solids. SPME with SAMMS provides not only a mechanism to preconcentrate the target (significantly enhancing detection limits) but also mitigates two primary factors limiting XRF sensitivity: the heterogeneity of the sample matrix and the particle sizes. The typically small, and potentially uniform, SAMMS particles (<200  $\mu\text{m}$ ) allow the excitation radiation and subsequent characteristic X-rays to efficiently and uniformly pass through the silica SAMMS structure.

As mentioned in a previous section, the partition coefficient for mercury with thiol SAMMS is over  $10^7$  for typical aquatic pHs ranging from 5 to 8, and the material has no affinity for common ions

such as sodium, calcium, and iron. This selectivity enables effective SPME from complex environmental matrices. We have found that, for high  $K_d$  and high capacity systems, such as mercury uptake with thiol SAMMS, trace analyte uptake is linear over very large preconcentration ranges. Selective SPME preconcentration from actual river and aquifer water up to a factor of  $10^6$  has been demonstrated. Sorbent material morphology can be very important for uptake dynamics. Small particulates ( $<5\ \mu\text{m}$ ) can block flow in packed microfluidic SPME columns. The hydrophobic nature of some mesostructured monolayers can create difficulty in wetting the surfaces of the nanopores and reduce analyte uptake. Humic acids, suspended organics, and colloids in surface and ground waters can significantly reduce analyte uptake by plugging the SPME column. However, these problems can be resolved with intelligent application of techniques such as particle sorting, sequential solvent washing, and in-line filtration methods.

X-ray fluorescence coupled with SAMMS SPME enable the rapid detection of trace levels of toxic metals. Table 1 shows the concentration of trace metals in an SPME thiol SAMMS column (15 mg) after only 200 mL of river water (pH 8) spiked with of 1 ppb of selected metals was pumped through at 1 mL/min. The difference in the preconcentration of the metals in the SPME SAMMS column is a result of the competitive equilibrium processes between the sample solution and monolayer surface. However, the SAMMS SPME clearly preconcentrated all the metals from a level (1 ppb) well below their EPA drinking water limits (listed in the right column) to a range easily measurable by the XRF. Using Cu-EDA SAMMS, we have obtained similar results for the toxic chromate and arsenate anions. The actual limit of detection for metals in environmental samples with this approach will depend upon a number of variables including the target metal, the sample matrix, the type of SAMMS,

the relative volumes of sample and sorbent, and the sensitivity of the XRF system. However, it is clear the SPME with SAMMS-type materials can be a powerful tool for environmental assay.

### Electrochemical Heavy Metal Detection

Electrochemistry is a well-established method for the measurement of ionic species. Concentration of the target analytes upon the electrode followed by voltammetric stripping is one of the most sensitive electrochemical methods. Chemical modification of the electrode can produce improvements in both sensitivity and selectivity. The voltammetric response of a carbon paste electrode modified with thiol SAMMS has been found to provide an effective electrochemical sensor for the in-situ detection of  $\text{Pb}^{2+}$  and  $\text{Hg}^{2+}$  in aqueous solutions. Factors affecting the performance of the chemically modified electrodes include electrode activation and precondition, electrode composition, preconcentration time, electrolysis time, as well as electrolysis and stripping mediums. To date, the best electrode contained 20% thiol SAMMS in the carbon paste and the optimum operating conditions were a 120-sec preconcentration period followed by a 60-sec cathodic electrolysis of the preconcentrated species in 0.2 M  $\text{HNO}_3$ . This was followed by a square wave anodic stripping voltammetry in 0.2 M  $\text{HNO}_3$ . Under these conditions, the areas of the peak responses were linear to metal ion concentrations in the within a range of 1–1000 ppb  $\text{Pb}^{2+}$  and 500–5000 ppb  $\text{Hg}^{2+}$  (of the original solution). The detection limits for  $\text{Pb}^{2+}$  and  $\text{Hg}^{2+}$  were 0.5 ppb  $\text{Pb}^{2+}$  and 100 ppb  $\text{Hg}^{2+}$  after a 20-min preconcentration period.

### Enhancement of Nuclear Assay Methods

SPME with SAMMS provides the same advantages to nuclear assay techniques as it has been shown to provide for chemical measurement methods. Coupling high-performance chemical sorbents with nuclear detection systems enhances the selectivity and sensitivity for detection of radioactive materials. In addition to concentrating the target radionuclide(s), the sorbent can exclude interferents and provide a uniform, well-defined sample geometry, which can be a critical issue for isotopic assay. The detection scheme employed depends on the type of radiation (alpha, beta, gamma, neutron) emitted from the radionuclide and whether or not isotopic information is desired. To date, we have found SPME with SAMMS very effective for determination of gamma-, beta-, and alpha-emitting radionuclides in environmental samples.

**Table 1** Performance of thiol SAMMS and XRF

Metal	SAMMS concentration <sup>a</sup> (ppm)	XRF LOD <sup>b</sup> (ppm)	EPA DWS <sup>c</sup> (ppm)
Hg	7.2	2	0.002
Cu	57.5	2	1.3
Pb	7	2.4	0.015
Ag	16.3	7	0.1
Cd	18.7	7	0.005

<sup>a</sup>200 mL of river water spiked with 1 ppb of metals and flowed through a 15 mg SPME thiol SAMMS column.

<sup>b</sup>Limit of detection (LOD) for XRF system utilized.

<sup>c</sup>EPA drinking water standards (DWS) from [www.epa.gov/safewater/mcl.html](http://www.epa.gov/safewater/mcl.html).

Because gamma radiation can pass through a significant amount of mass without attenuation, the configurations of the SAMMS material is not particularly critical for assay. As previously discussed, the ferrocyanide SAMMS is a very effective sorbent for radiocesium. Measurement of the  $^{137}\text{Cs}$  and  $^{134}\text{Cs}$  isotopes is significant for environmental monitoring and treaty compliance issues associated with the Cold War nuclear legacy. In addition to improving the sensitivity of standard assay methods, using ferrocyanide SAMMS for SPME enables several novel options for detection of radiocesium isotopes. Detectors with no spectral resolution [such as the ubiquitous Gieger–Muller (GM) counters] or detectors with limited resolution [such as NaI(Tl) scintillators] can be used for rapid and sensitive assay of radiocesium—if ferrocyanide SAMMS is used first for selective SPME. Second, small, portable, room-temperature semiconductor detectors (such as CdZnTe) with limited sensitivity due to their size become capable of environmental level assay when combined with SAMMS SPME.

Alpha radiation is composed of heavy, energetic, highly charged particles that interact strongly with surrounding matter. Consequently, alpha radiation is quickly attenuated by surrounding material and has very short ranges. Therefore, accurate assay of alpha emitters typically involves extensive matrix separation and sample preparation to eliminate interfering material. SPME with SAMMS selective for actinides, such as those with AcPhos and PropPhos monolayers, have been found to be a fast, single-step preparation method for the radiochemical assay of alpha emitters in aquatic samples.

Fig. 4 shows the alpha energy spectrum of an electrostatically immobilized particulate layer of Ac-Phos SAMMS that was exposed to a solution

**Fig. 4** Alpha energy spectrum of electrostatically immobilized particulate layer of Ac-Phos SAMMS after exposure to a solution of  $^{230}\text{Th}$  and  $^{239}\text{Pu}$ . The films were dried and data directly collected with a standard laboratory alpha spectrometer (under vacuum).

with  $^{230}\text{Th}$  and  $^{239}\text{Pu}$ . The film was dried and spectra directly collected with a standard laboratory alpha spectrometer (under vacuum) with a diode detector. This data demonstrates SAMMS materials can be clearly used to rapidly preconcentrate actinides from liquid samples and then directly analyze for isotopic content by using standard laboratory equipment. The spectral resolution for this sample is approaching the quality of many electroplated sources and exceeds that of many standard sample preparation methods based on precipitation. Spectral resolution could no doubt be improved with a true mesoporous thin film of uniform thickness.

Actinide-loaded SAMMS can also be measured with other nuclear counting methods. For SAMMS materials with small particle sizes (less than a  $10\ \mu\text{m}$ ), liquid scintillation counting (LSC) was found to be easy, effective, and efficient. Consequently, selective preconcentration by SAMMS materials followed by direct LSC is a rapid, convenient, extremely sensitive, and somewhat selective method for nuclear assay.

Portable alpha monitors (PAMs) are ubiquitous survey devices in all radiation facilities with actinides. Despite the loss of spectral capability and reduced efficiency, there are advantages to using PAM devices for alpha screening of SAMMS materials including low cost, universal availability, and scalable surface area. Moreover, actinide selectivity is not necessarily lost because the SAMMS materials can provide significant chemical selectivity. We found that PAMs could very effectively measure the activity of actinide-loaded SAMMS materials. Accounting for differences in instrument efficiency, the count rate of actinide-loaded SAMMS thin films was the same when measured with PAMs or with the more sophisticated silicon diode-based spectrometers.

Unlike alpha and gamma radiation, beta radiation does not have any peak structure in the energy continuum. This increases the advantages of using a chemical selectivity SPME sorbent because spectral discrimination between isotopes is not possible. We have found that beta radiation from radionuclides selectively sorbed into SAMMS materials can be measured with many standard methods including silicon diodes, plastic scintillators, standard survey equipment (GM), and liquid scintillation counting (LSC). Of particular interest is using Cu–EDA SAMMS for the extraction of  $^{99}\text{Tc}$ , a beta-emitting fission product isotope. This long-lived isotope exists in groundwater, principally as the pertechnetate anionic species that is highly mobile in aquifers. Cu–EDA SAMMS has been found to be effective for SPME and assay of  $^{99}\text{Tc}$  with all of the aforementioned mentioned nuclear assay methods.

Nanostructured sorbent materials coupled with the selected detection methods can be used for either real-time analysis of the signature species or as a rapid screening method to flag which samples require more detailed analysis, or as archival samples. SAMMS coupled with rugged, compact instrumentation will provide portable, highly sensitive field analyzers/samplers that could be quickly reconfigured for new analytes simply by changing the sorbent material. Sorbents used may be reusable, renewable, or disposable, depending on the configuration and chemistries involved.

## CONCLUSION

Novel synthetic methodologies in the area of templated nanomaterials and molecular self-assembly have created a powerful new class of sorbent materials that can make a significant impact on environmental remediation and analytical sensing and detection. The rigid open pore structure of SAMMS allows for facile diffusion of the target analyte into the mesoporous matrix, providing for fast sequestration kinetics. Self-assembled monolayers terminated in highly specific ligands allow the sorbent to be tailored to the specific environmental target, providing excellent chemical selectivity. The close proximity of the ligands to one another allows for multiple analyte/ligand interactions, enhancing binding affinity and specificity. Novel SCCO<sub>2</sub> synthetic methodology allows us to make SAMMS substantially faster, and clearly enhances the stability of these hybrid nanomaterials toward alkaline conditions. By varying the interface of the self-assembled monolayer, it has been possible to tailor these sorbent materials to selectively sequester a variety of different environmental targets such as mercury, plutonium, arsenate, and cesium. This exact same chemistry can be used to enhance the selectivity and sensitivity of analytical methodology by using the SAMMS as a preconcentrating interface. This enhancement has been demonstrated via X-ray fluorescence, electrochemical sensing, and radioanalytical methods. Further work developing SAMMS for environmental remediation and analytical enhancement is currently underway.

## ACKNOWLEDGMENTS

This research was supported in part by the Department of Energy (DOE) Environmental Managed Science Program. This work was performed at Pacific Northwest National Laboratory, which is operated for the DOE by Battelle Memorial Institute under contract DE AC06-76RLO 1830.

# Molecular Simulations of DNA Counterion Distributions

Alexander Lyubartsev

Stockholm, Sweden*

## INTRODUCTION

One of the remarkable physical properties of a DNA molecule is that it is a strongly charged polyelectrolyte. In solution, DNA dissociates, forming a negatively charged polyion surrounded by an atmosphere of mobile, positively charged counterions. Although positive counterions are attracted to DNA, they screen the negative charge of DNA, decreasing the attractive force for other positive counterions. Additionally, ions of different valency and size interact with DNA in a different manner, leading to effects of competition between ions of different species. There is always a delicate balance of forces forming the equilibrium ion distribution around DNA. The functionality of DNA in the cell is, in a decisive degree, determined by electrostatic forces, which in turn are dependent on the presence of different charged components in the surrounding solution. It is clear that understanding of DNA functionality is impossible without an understanding of electrostatic interactions of DNA with the environment.

The aim of the present review is to show how molecular computer simulations can contribute to our understanding of the basic features of the interaction of DNA with its ionic environment, what kind of information can be obtained by computer simulations, and how this information can be used to bridge experimental and theoretical studies of DNA. First, some common polyelectrolyte models of DNA will be briefly reviewed, and a survey of available computer simulation techniques will be given. Then, applications of computer simulations to describe the ionic environment of DNA on different levels of precision will be discussed: Monte Carlo (MC) and Brownian dynamics (BD) simulations within the continuum dielectric models, molecular dynamics (MD) simulations with explicit treatment of solvent, as well as a combination of these techniques, giving rise to the “multiscale modeling” approach.

Several reviews devoted to different aspects of DNA-ion interactions and computer simulations of DNA have recently appeared.<sup>[1–3]</sup> A more general and detailed review of the computer simulation of polyelectrolytes is presented in Ref.<sup>[4]</sup>

## DNA POLYELECTROLYTE MODELS AND THEORIES

A theoretical description of the ionic environment of DNA is not a simple task. In fact, in any condensed matter system, the more detailed and closer to reality the molecular model is, the more complicated (and often including even more approximations) is the theory that has to be applied to obtain meaningful results. There exist several levels of theoretical descriptions of polyelectrolyte systems. In the simplest approach (the so-called “primitive model”), a DNA is presented as a rigid cylinder, and mobile ions as point charges or small rigid charged spheres. Within the primitive model, the solvent is described as a uniform dielectric continuum, described by a dielectric permittivity of this solvent. The interaction between ions is described by the Coulombic potential scaled by the value of the dielectric permittivity.

The most commonly used approach to describe the properties of polyelectrolyte solutions at this level is the Poisson–Boltzmann (PB) (mean field) theory.<sup>[5]</sup> This approach implies a Boltzmann distribution of the mobile ion species in the average field of other ions. For a simple cylindrical geometry, the PB equation can be rather easily solved by numerical methods. If the electrostatic potential is small, the exponent term in the standard PB equation may be linearized, resulting in the linearized PB equation that allows an analytical solution. In this context, the counterion condensation (CC) model formulated by Manning<sup>[6]</sup> can also be mentioned. According to the CC model, for a highly charged cylindrical polyion, a certain amount of counterions remains in close proximity to the polyion. These counterions neutralize a given fraction of the total polyion charge, whereas the remaining counterions reside in the bulk phase. Because most of the charge of the polyion (76% in the case of DNA) is neutralized, the distribution of ions in the bulk phase may be described by the linearized PB equation. Because of its simplicity, the Manning CC model has had a profound impact on practical, as well as theoretical, studies of polyelectrolyte solutions.

The major problem with theories based on the PB approximation is that the Boltzmann expression for

the ion density cannot be strictly derived from the statistical-mechanical theory; therefore the accuracy of the PB theory should be checked by more rigorous theories, or by simulations. The PB theory neglects the small ion correlations within the model. The effect of correlations can be explained as follows. If a counterion is present at some point near the polyion surface, it will decrease the probability for other counterions to be around it. Therefore near this point, the counterion density will be lower than that given by the PB theory. The decrease in local counterion density causes an effective attractive force (in addition to the mean force) that draws the counterions closer to the polyion surface. Clearly, the effect becomes stronger with increase of the ion valency. Ion correlation effects can considerably change the behavior of the polyelectrolyte systems in quantitative as well as qualitative ways.

There exist a number of liquid state theories, based on integral equations, which go beyond the PB approximation: the hypernetted chain approximation (HNC),<sup>[7,8]</sup> the BBGY chain equations,<sup>[9,10]</sup> the mean spherical approximation,<sup>[5]</sup> the modified PB theory,<sup>[11]</sup> as well as some others. A discussion of these theories and a comparison of predictions of such models to both the PB model and that of computer simulations can be found in a recent review.<sup>[12]</sup>

More elaborate DNA models may include specific details of its structure. One example is the so-called "grooved" model of DNA,<sup>[13]</sup> in which the charged groups of DNA are located outside the cylindrical hard core, on the sites corresponding to the phosphate groups of DNA. In addition, full-atomic molecular models of DNA or other polyelectrolytes in continuum solvent have been considered. In such cases, the PB equation becomes three-dimensional, but its solution is still rather straightforward.<sup>[14,15]</sup> Sometimes effects of polarization and hydration are included by considering a distant-dependent and field-dependent dielectric constant. The relevant theory to treat this class of models is the modified PB equation.<sup>[16]</sup> Stricter statistical-mechanical theories become too complicated to be of any practical use in this case.

The above-discussed analytical theories have to resort to approximations already at the level of the primitive model. Comparison of theory with experiment is, in such cases, inconclusive; if discrepancies occur, it may be difficult to attribute them to the approximations within the model, or to approximations during the mathematical treatment of the model. Computer simulations can help to answer the questions because they may provide an accurate, asymptotically exact, statistical-mechanical solution for a given model. Moreover, computer simulations allow to treat even more accurate and detailed models, with a proper account of effects caused by hydration,

dielectric saturation, and the molecular structure of the solvent by considering explicit solvent molecules.

The main computer simulation methods are MC and MD. The MC method<sup>[17]</sup> is based on a stochastic procedure, which generates molecular configurations with probabilities equal to that in the canonical (or another statistical) ensemble. By calculating simple arithmetic averages over generated molecular configurations, it is possible to define average values of physical properties in the canonical ensemble and to obtain exact (in statistical sense) answers to a statistical-mechanical problem. An important kind of MC simulation technique is the grand canonical Monte Carlo (GCMC) method, which allows to perform simulations in the grand canonical ensemble at constant chemical potential.<sup>[18]</sup>

The MC method is very suitable for a description of electrolyte and polyelectrolyte systems within the frame of continuum solvent models (i.e., when solvent molecules are not explicitly included in the simulations). However, for models with explicit solvent molecules, the MC method is not so efficient. The main reason is that in the liquid state, the molecules are closely packed and the fraction of the accepted MC steps becomes too small. For molecular all-atom models of the solvent, the MD simulation scheme is then more efficient.

The MD simulation technique implies a numerical solution of the Newtonian equations of motion for all atoms in the simulated molecular system. At each step of the MD simulation, the coordinates and velocities of the particles are recalculated according to equations of classical mechanics where forces are computed from some predefined expressions, called the force field. The time step is usually chosen at about  $10^{-15}$  sec and a typical MD simulation covers a time interval of  $10^{-8}$ – $10^{-10}$  sec. In addition to structural and thermodynamic properties, the dynamics of the molecular system can be studied, including time correlation functions, diffusion, and other transport properties.

At present, MD simulation is the most commonly used simulation method for studying molecules and molecular interactions in the liquid state. However, because MD implies simulation of all atoms in the system including solvent molecules, it becomes too expensive for studies of polyelectrolytes. A simplified description of polyelectrolyte systems, in terms of continuum solvent models, is still a preferable option. For such models, either the MC method or the stochastic analogue of MD-BD is used. In BD, the solvent molecules are not explicitly accounted for, but enter the equations of motion for solute molecules by two terms: a friction force and a random force. The third term in forces describes interactions with other solute particles in the system (e.g., other ions or polyions). Because the

solvent molecules are not treated explicitly in BD, it allows simulation of substantially larger systems than full-atomic MD simulation. Moreover, compared with MC simulations, the dynamic properties of the ions can be determined. For example, the effect of polyions on ion diffusion can be studied.

## SIMULATION OF COUNTERIONS AROUND DNA WITHIN CONTINUUM SOLVENT MODELS

### Evaluation of Analytical Theories

The first attempts of computer simulations of DNA-like polyelectrolytes were made in the beginning of the 1980s using the MC method.<sup>[19,20]</sup> More systematic studies, with varying salt concentrations and/or ion type, have been carried out later.<sup>[21–27]</sup> The primary objective of these earlier computer simulation studies was to evaluate the applicability of analytical theories describing ionic distributions around DNA. In most of these works, the primitive model was used [i.e., the DNA was modeled as a hard body (cylinder) with a uniform distribution of surface charge, and the ions were represented as point charges or charged hard spheres]. In some of these works, a soft short-range ion–ion or ion–DNA interaction potential,<sup>[23]</sup> or a specific location of the charges on the polyion surface<sup>[22]</sup> has been used. The main outcome of the early simulations was that the PB approximation is generally valid if only monovalent ions are present in the solution. In subsequent works with more detailed and more accurate (in the sense of longer runs) simulations, it was shown that deviation of the PB theory from the simulations does not exceed 10% for the ion distribution or the electrostatic potential in the relevant range of ion concentrations.

For ions of higher valency and their mixtures, the PB approximation often fails. The typical behavior is that the PB approximation underestimates the ion density in the nearest layer next to the polyion surface, which is a result of neglecting ion–ion correlations. An example is given in Fig. 1, which shows the ion density distributions for a cylindrical model of DNA in the presence of a mixture of divalent counterions and monovalent coions. One can see an increased simulated concentration of counterions compared with the PB result within about 5 Å from the polyion surface. This feature may seem not large on the figure, but given the facts of the logarithmic scale of *Y*-axis and steep slope of the curve, it results in a noticeable higher affinity of divalent ions to DNA.

An additional attraction of counterions to DNA can be seen more clearly in the “integrated charge” curve, which represents ion distribution integrated from the surface of polyion to some distance *r*. The sense of this

**Fig. 1** Ion distribution profile around a cylindrical DNA model for a mixture of divalent and monovalent counterions and monovalent coions, obtained in MC simulation (solid lines) and PB approximation (dashed lines). Radius of all ions in MC simulations, 2 Å. The simulation was set up as in Ref.<sup>[37]</sup>.

curve is the total counterion charge (per length of the polyion) within the cylinder of radius *r* around the polyion. An example of the integral charge curve is shown in Fig. 2 for the mixture of monovalent and divalent counterions with monovalent coions.<sup>[23]</sup> It is seen that for the given case (0.022 M MgCl<sub>2</sub> and 0.155 M NaCl mixture), the amount of divalent ions within 5 Å from the DNA surface in the PB approximation is underestimated by about 20%. In other cases (e.g., higher concentrations) deviations may reach 40% or even more.

Besides quantitative differences, computer simulations can, in some cases, predict a qualitatively different behavior as compared with the PB model. An example is the so-called “charge reversal” or “overneutralization,” which may happen if the total charge of the counterions in the close vicinity of a polyion exceeds the charge of the polyion itself, which then leads to an alternating sign of the electrostatic potential. Such behavior is typically observed for divalent or higher-valence counterions under certain thermodynamic conditions,<sup>[25]</sup> but it may happen even for monovalent ions if the salt concentration is high enough.<sup>[13]</sup> The charge reversal cannot be obtained in the PB theory. There is no clear experimental evidence of the charge reversal, except perhaps for a rather old work by Strauss et al.,<sup>[28]</sup> who observed a cationic polyion (poly-4-vinylpyridine) moving against the electric field at high salt concentration.

More accurate statistical–mechanical theories, such as the HNC or the modified PB theory, were found to reproduce properties of the ion distributions relatively well even for multivalent ions.<sup>[8,11,23]</sup> Fig. 2, reproduced from the work of Murthy, Bacquet, and Rossky,<sup>[23]</sup> shows the integral charge computed for a

**Fig. 2** Radially integrated counterionic ( $q_{2+}$  and  $q_{+}$ ) and total ( $q$ ) charge for a 0.155 M NaCl and 0.022 M MgCl<sub>2</sub> salt mixture around a cylindrical model of DNA. Points are MC simulation result; dash-dot lines and solid lines are PB and HNC theories, respectively. *Source:* From Ref.<sup>[23]</sup>. © American Chemical Society, 1985.

mixture of divalent and monovalent ions by the PB and HNC theories as well as by MC simulations. Clearly, the HNC result is much closer to the simulation data than that obtained by the PB theory. The HNC theory, as well as some other more elaborated theories, are able to reproduce even such effects as charge reversal.<sup>[8]</sup> However, these theories are difficult to apply in the case of more complicated (non-cylindrical) geometries (e.g., for a model with specific location of the charges on the polyion).

Manning condensation theory is often considered as a further simplification of the PB theory. Still, it catches some basic features of ion distributions. Lamm, Wong, and Pack<sup>[27]</sup> compared the fraction of electrostatically bound ions using the MC, PB, and CC methods. If the bound fraction of counterions is determined as those residing within a region around the DNA where the electrostatic potential is less than  $kT$ , the MC results are found to quantitatively reproduce the bound fraction predicted by the Manning condensation theory. Another interesting feature of ion distribution, also related to the CC theory, is that the concentration of counterions just next to the DNA surface depends very weakly on the salt

concentration, and remains high (a few molars per liter) even at very low salt concentrations. According to the CC theory, a fraction of DNA counterions remains condensed to DNA even at infinite dilution. This feature was also confirmed by the computer simulations.

### Dielectric Effects

MC computer simulations within the primitive electrolyte model imply uniform continuum dielectrics with dielectric permittivity of liquid water ( $\epsilon \approx 80$ ). In fact, dielectric permittivity of DNA itself is substantially lower. It is also often argued that because the water molecules around the DNA are strongly oriented in the electrostatic field of DNA, their reorientation mobility is reduced, which must make the dielectric permittivity lower than in the bulk solution. Some estimations show that the effective dielectric constant may be as low as 6–30 in the first one to two molecular layers near a DNA surface<sup>[29,30]</sup> compared with the bulk value of about 80. Non-uniform dielectric permittivity is a source of polarization forces, and their effect on ionic distribution is a priori unclear.

MC simulations, incorporating the effect of dielectric discontinuity<sup>[31,32]</sup> at the polyion surface and using alternative dielectric saturation models,<sup>[33]</sup> have investigated the effects of the assumption of a constant dielectric permittivity, finding minor effects on the counterion distributions. Moreover, the effect may be different—it may drive ions out of the DNA grooves,<sup>[31]</sup> or, at the opposite, increase their concentration near the DNA surface,<sup>[32]</sup> depending on the details of the DNA model (shape) and the way how the dielectric effects are incorporated.

In fact, at distances on the order of a few angstroms, the concept of dielectric permittivity is not well defined. Within the primitive model, the interaction potential is the Coulombic potential scaled by the value of the dielectric constant. This potential is an approximation of the exact solvent-mediated potentials between the ions in the solution, which in fact represents the free energy of ion–solvent interactions. From this point of view,  $\epsilon$  in the interaction potential can be regarded as a parameter of the potential, which may differ from the local dielectric constant related, for example, to the water dipole fluctuation or the dielectric response. Evaluation of solvent-mediated potentials may be performed from the all-atom MD simulations, which showed that the effective dielectric constant—as a parameter of the effective potential—remains high even at high-enough salt concentrations and near the DNA surface.<sup>[33,34]</sup> The effects caused by an explicit account of the solvent in computer simulations on ion distribution around the DNA will be discussed in more detail below.

### Effect of Specific Distribution of Charges

The effects caused by a specific distribution of charges on the polyion surface were studied in a number of works<sup>[13,31,35–38]</sup> with applications to DNA. Quite evidently, a different structure of the charge distribution on the polyion may cause a rather different distribution of the ion density in the close vicinity of the polyion. Typically, one puts charges of  $-1$  on the sites corresponding to the phosphate groups of DNA. Additionally, helical grooves may be set, mimicking the minor and major grooves of DNA. In some cases, the DNA is presented with all-atom resolution.<sup>[39]</sup>

A detailed study of different ways to mimic helical grooves on DNA was presented by Montoro and Abascal.<sup>[13]</sup> These authors observed that specific interactions of ions with DNA (soft repulsion potential), the incorporation of the discrete charge distribution, and the grooved nature of the DNA surface may change the ion density profile around DNA considerably (Fig. 3). For example, in a “groove model” of DNA, in which explicit grooves on DNA were introduced, a double hump on the counterion density profile was observed,

**Fig. 3** Ion distribution profiles at 0.05 M monovalent salt, calculated in MC simulations for different DNA models. HH is “homogeneous hard cylinder,” HS is “homogeneous soft cylinder” (ions interact with the polyion with repulsive  $1/r^9$  potential), HS1 is homogeneous soft cylinder with a displaced axis of short-range repulsion, DS is discretely charged, soft repulsion model with charges located on sites of phosphate groups, GP is grooved DNA model with explicit grooves. *Source:* From Ref.<sup>[13]</sup>. © American Institute of Physics, 1995.

which even transformed to a double maximum at higher concentrations. This is in agreement with BD simulations of a full-atomic description of DNA.<sup>[40,41]</sup> In addition, substantial penetration of counterions in the minor and major grooves was observed.<sup>[36]</sup> Enhanced concentration of counterions in the grooves (with stronger effect in the minor groove) has been observed also in several works.<sup>[37,38]</sup> However, distribution of counterions far from the DNA depends only weakly on the structure of the DNA surface.

An MC study of a DNA model with an all-atom resolution in a continuum solvent was carried out by Mills, Rashid, and James<sup>[39]</sup> for different forms of DNA. It was found that the grooved structure of both A-DNA and the B-DNA affects the details of the ion distribution in the center region of the polyion dramatically. However, the total number of bound ions at a particular added salt value differs only slightly among the conformations.

A general conclusion from the studies on the effect of the specific charge location on DNA is that although it may affect strongly the details in ion distribution near the polyion, the distribution of counterions far from the polyion (at distances more than 20 Å from the DNA axis) remains largely invariant. Furthermore, the integral properties of the ion distribution, such as the amount of ions within a certain distance around the polyion, depend very little on how the charges are located on the polyion surface. This is illustrated in Fig. 4, where the integrated charge is displayed for the same ion distributions as shown in Fig. 3. The integrated charge curves are determined

**Fig. 4** Integrated charge (charge compensation) function, calculated in MC simulations for different DNA models. Notations are the same as in Fig. 3. *Source:* From Ref.<sup>[13]</sup>. © American Institute of Physics, 1995.

mostly by the total charge density of the polyion and by the ion composition. The primary reason for the weak sensitivity of the global properties of the ion distribution to the details of charge location is the long-range character of electrostatic interactions, which effectively averages contributions from all the charges of the polyion and makes the total electrostatic field similar to that of a uniformly charged cylinder.

### Ion Competition

The interaction of mobile ions with polyions depends strongly on the ion type, charge, and size. Counterions of higher valency are more strongly attracted to polyions than monovalent ions—that is why they force low-valency ions out from the nearest vicinity of the polyelectrolyte. The size of the ions additionally plays a role and becomes especially important in the discussion of the competition of ions of the same valency. Smaller ions can come closer to the polyion surface and lower the electrostatic energy as compared with larger ions. However, within the primitive electrolyte model, the size of ions in simulations is not directly related to their real “crystallographic” sizes. Rather, it is a parameter that, in an average way, takes into account the effective hydration shell of water molecules around the ion. Reasonable values of the ion hydration radii can be obtained by fitting to available experimental data on ion osmotic and activity coefficients.<sup>[42]</sup> Other ways of choosing effective ion radii are discussed in a recent work by Banavali and Roux.<sup>[43]</sup>

The problem of ion competition has received much attention because of its importance in biological and technological applications. (For more information, see, for example, Ref.<sup>[44]</sup>.) Typically, one determines a “competition coefficient,” which has a sense of an equilibrium constant of the ion exchange process.<sup>[45]</sup> The competition coefficient may be determined experimentally from nuclear magnetic resonance (NMR) relaxation measurements,<sup>[45]</sup> or from direct ion exchange experiments.<sup>[46,47]</sup> The competition parameter may be also determined from computer simulations, or other theoretical approaches in a standard manner: For a given concentration of ions of different species, the ion density profiles are calculated and from these data, the amount of ions of each species within some distance from the polyion surface is obtained. Some uncertainty arises when one tries to define which ions are “bound” and which are “free.” Usually, one considers ions within some cutoff distance  $r_B$  from the surface of DNA (which is on the order of a few angstroms) as “bound.” Paulsen, Anderson, Record<sup>[45]</sup> analyzed the dependence of the competition coefficient on the cutoff radius and found that it is almost independent of  $r_B$  if  $r_B$  is chosen in reasonable limits.

In this way, the competition of ions of several divalent counterions with  $\text{Na}^+$  around the DNA was studied in the work<sup>[45]</sup> where a comparison of the PB model, MC simulations, and NMR experiments has been made. It was found that simulation results were closer to the experimental data than the PB results. Other studies of the ion competition effects are reported in a number of more recent MC simulations.<sup>[38,48,49]</sup> It was shown that the PB approximation underestimates binding of higher-valency ions and that this underestimation increases with ion valency.<sup>[38,45]</sup>

In the case of concentrated polyelectrolyte systems (e.g., oriented DNA fibers in equilibrium with a bulk electrolyte solution), the situation is different. The simulation cell, in this case, cannot include the “bulk” solution, so the concentration of the ions in the bulk is not directly known. The problem can be solved by performing GCMC simulations both in the polyelectrolyte gel phase and in the bulk solution (without polyions), at the same chemical potential.<sup>[50]</sup> The GCMC approach has been applied for studying the competition of monovalent, divalent, and trivalent ions in a series of works by Korolev et al.<sup>[46,47,51]</sup> In these works, competition coefficients of different ions, computed in GCMC simulations, were compared with the experimental ones measured by ion exchange experiments for DNA fibers, which were stabilized by the presence of ethanol. In computer simulations, the presence of ethanol was modeled as a lower (than in pure water) dielectric constant. The competition coefficients for the ions of different valencies and sizes have been computed and a good agreement with the ion exchange measurements has been observed.

### Interaction of DNA with Multivalent Ligands

Studies of DNA interacting with complex multivalent molecular ions is of considerable interest because of the role of such ions (e.g., polyamines) in living systems. Additionally, polyamines are often used as condensing agents in the preparation of condensed samples of DNA. Other interesting and important applications are related to binding of charged intercalative drugs to DNA and to protein–DNA binding.

Application of standard polyelectrolyte theories to complex multivalent ions faces additional difficulties related to the spatial distribution of the ion charges and the internal degrees of freedom. In analytical theories, these additional features are usually either ignored<sup>[52]</sup> or treated in some approximate manner.<sup>[53,54]</sup> In computer simulations, on the contrary, inclusion of the internal structure of the ionic ligand does not pose any principal complications. In Ref.<sup>[37]</sup>, the polyamine spermidine<sup>3+</sup> was modeled as a chain of three monovalent ions connected by harmonic bonds. It was

shown that because of the effects of the non-local charge distribution and internal degrees of freedom, the binding affinity of spermidine to DNA was reduced compared with that of a simple trivalent (metal) ion. The binding was reduced even below the predictions of the PB theory, which generally underestimates the binding affinities of higher valency ions for simple ions. Existing NMR diffusion studies qualitatively confirm this result.<sup>[55]</sup>

The binding of an octavalent rodlike ligand to DNA in the presence of monovalent salt has been studied by Olmstedt et al.<sup>[56]</sup> using GCMC simulations. Such highly charged ligand binds strongly to DNA, forming a stable complex. A strong reduction in the surface counterion (e.g., Na<sup>+</sup>) concentration over a region including—but extending well beyond—the location of the ligand binding site has been observed.

### Brownian Dynamics of Counterions Around DNA

BD simulations allow, alongside ion distribution, computation of dynamic and transport properties of ions. The presence of a polyion makes the diffusion of ions slower than in the bulk solution, because of both the steric obstacles imposed by the polyion and the electrostatic interactions. Thus the retardation of the diffusion provides information on the binding of ions to the polyelectrolyte. An advantage of diffusion studies is that the self-diffusion coefficient is a quantity that is directly available from experiments measuring macroscopic self-diffusion.

The diffusion properties of counterions in the presence of DNA were studied by BD simulations in a number of works.<sup>[40,57,58]</sup> The self-diffusion coefficient can also be obtained within the PB mean field approximation, using the PB–Smoluchowski diffusion model.<sup>[59]</sup> A comparison of lithium counterion diffusion coefficients determined in BD simulations, in the PB–Smoluchowski model, and in the experiment was performed in Ref.<sup>[57]</sup>. The comparison of the two polyelectrolyte theories with the experiment clearly demonstrated the effect of ion correlations included in the BD simulations, which substantially improve agreement with the experiment.

Apart from the general interest as to how the presence of DNA affects ion dynamics, such simulations provide valuable information for the interpretation of NMR relaxation experiments. For example, BD may provide data on the time correlation function of the electric field gradients<sup>[40,58]</sup> experienced by Na<sup>+</sup> counterions associated with DNA, for which the NMR quadrupolar relaxation of the <sup>23</sup>Na nuclei is determined by the time-dependent fluctuation of these field gradients.

## SIMULATIONS OF COUNTERIONS AROUND DNA WITH EXPLICIT ACCOUNT OF SOLVENT

### Molecular Dynamics of DNA

The studies of the ionic environment of DNA discussed above have been carried out within continuum solvent models. The effects of solvent and hydration can be taken into account rather straightforwardly in computer simulations by introducing explicit solvent (water) molecules. However, an all-atom description makes the simulations very time-consuming and reduces the size of the system that can be considered. At the present level of computer power, the maximum number of atoms that can be simulated long enough to obtain meaningful results is on the order 10<sup>4</sup>, which corresponds to a simulation box size of 50–60 Å. This size is not enough to study polyelectrolyte aspects of ion distribution. Still, all-atom simulations are extremely important for understanding ion–DNA interactions in close proximity to the DNA.

The preferable method in all-atom simulations is MD, although the first attempt to simulate such model was performed by the MC method.<sup>[60]</sup> Earlier MD simulations of DNA<sup>[61–63]</sup> were too short to produce information on ionic distribution. Given the diffusion of counterions around DNA on the order 10<sup>−6</sup> cm/sec<sup>2</sup>, at least nanosecond time scale is needed for the counterions to sample the space around DNA. Such simulations became possible from the second part of 1990s, when a large number of works on MD simulations of DNA, with full-atomic description of solvent and ions, appeared.<sup>[64–71]</sup> In the majority of these studies, the main interest was in the DNA molecule itself, investigating DNA backbone structure and dynamics, base stacking, phosphate orientation, overall nucleic acid structure, and so on. (For more information on these issues, the reader is referred to recent reviews.)<sup>[3,72]</sup> Below, we shall concentrate on works dealing with MD simulations of ion distributions around DNA. Note first that results on MD simulations are dependent on the force field used. The force fields used in macromolecular simulations are usually empirically parameterized to reproduce some set of experimental results. At present, the most often used force fields for DNA simulations are AMBER<sup>[73]</sup> and CHARMM.<sup>[74]</sup> It was found that these force fields may give somewhat different DNA structures.<sup>[70]</sup> However, the hydration structure and ion distribution are very similar in AMBER and CHARMM simulations.<sup>[71,75]</sup> This is because of the fact that these force fields differ mainly by parameters describing intramolecular DNA interactions, whereas parameters describing forces between water, ions, and DNA are almost the same.

## Specific Binding of Ions

A major issue in molecular dynamic studies of the ionic environment of DNA is the problem of specific ion binding to different sites on the DNA surface. Whether this binding is sequence-specific or purely electrostatic is still to be determined. X-ray experiments carried out in the 1980s have suggested that there exists a “spin of hydration” of DNA,<sup>[76]</sup> which is a sequence of water molecules in the minor and major grooves that is impenetrable to cations. Cations, according to this picture, form a diffuse cloud around, which is defined by electrostatic interactions. However, MD simulations, made in the 1990s, have shown that Na<sup>+</sup> counterions may intrude the spin of hydration of DNA and substitute for water molecules.<sup>[66–68,77]</sup> This was also confirmed by newer, high-resolution X-ray data.<sup>[78]</sup>

The question of sequence-specific counterion binding to DNA has a principal importance to our understanding of mechanisms of DNA recognition. When counterions bind to DNA in a sequence-specific manner, they form a mosaic of non-uniform charge distribution depending on the DNA sequence. Moreover, it was supposed that direct ion binding to DNA affects the DNA structure,<sup>[78]</sup> although this point of view is under debate.<sup>[79]</sup> Molecular computer simulation can provide valuable information to this discussion.

Most of the mentioned MD simulations of DNA have been carried out with Na<sup>+</sup> counterions. In some works, other counterions were also studied. In Ref.<sup>[68]</sup>, a comparative study of Li<sup>+</sup>, Na<sup>+</sup>, and Cs<sup>+</sup> around DNA was performed. It was found that these monovalent alkali ions interact with DNA in a very different manner. Li<sup>+</sup> ions bind almost exclusively to the phosphate groups of DNA. Na<sup>+</sup> ions bind prevailing bases in the minor groove through one water molecule, although a smaller fraction of ions binds directly to the bases at some specific sites (AT step in the minor groove and guanine bases in the major groove). Cs<sup>+</sup> ions bind directly to sugar oxygen in the minor groove. It was shown also that the specific character of ion bonding is, to a large extent, determined by the hydration structure of water around DNA. A stronger binding of Li<sup>+</sup> ions to DNA was also confirmed by NMR studies of the diffusion of Li<sup>+</sup> and Cs<sup>+</sup> ions in oriented DNA fibers.<sup>[80]</sup>

DNA oligomers d(TpA)<sub>12</sub> in the presence of K<sup>+</sup> counterions were simulated in Ref.<sup>[81]</sup>. Comparing with Na<sup>+</sup> counterions, a stronger preference of K<sup>+</sup> ions to the major groove has been observed.

MD of DNA with divalent ions Mg<sup>2+</sup> and Ca<sup>2+</sup> was performed in some recent works.<sup>[63,64,82]</sup> However, the slow diffusion of Mg<sup>2+</sup> ions makes it difficult to perform a reliable estimation of distribution of these ions around the DNA.

Recently, some works appeared on the distribution of multivalent polyamine ions around DNA.<sup>[83–85]</sup> It was found that flexible polyamine molecules (spermine or spermidine) have several binding modes, interacting with different sites on the DNA in an irregular manner. That is why polyamine molecules are not seen in X-ray diffractions of DNA. Spermine<sup>4+</sup> ions compete with Na<sup>+</sup> ions and water molecules in binding to bases in the minor groove, and they influence the structure of the DNA hydration shell in different ways.<sup>[85]</sup>

## Comparison with Continuum Solvent Models

An interesting question that MD simulation could answer is: How reliable are computations within the continuum solvent model, for example, in the prediction of overall ion density around DNA? The angularly averaged density profile of counterions (Na<sup>+</sup> mostly) has been calculated in some recent works.<sup>[66–68]</sup> At short distances (within 5 Å from the DNA surface), these density profiles are defined mainly by the details of DNA structure and hydration forces. Naturally, the distributions are very different from the density profiles calculated for the cylindrical model of DNA within the continuum solvent model (both in analytical approaches and MC simulations). Such comparison, from Ref.<sup>[68]</sup>, is shown in Fig. 5, where angularly averaged distributions of different monovalent counterions around the DNA are displayed, together with the PB theory result. Introducing details of the DNA structure within the continuum dielectric model may make the counterion distribution closer to

**Fig. 5** Density profile of different ions around DNA obtained in all-atom MD simulations. The results marked with (\*) are from a simulation with a larger simulation cell than the other data. The thin dotted line shows the PB results with a cell radius corresponding to the system marked (\*). Source: From Ref.<sup>[68]</sup>. Adenine Press.

**Fig. 6** Integral charge for  $\text{Na}^+$  and  $\text{Cl}^-$  ions per phosphate obtained in all-atom MD simulations and PB approximation. Source: From Ref.<sup>[68]</sup>. Adenine Press.

that obtained in MD simulations. For example, a maximum in ion density is observed at about 8 Å from the DNA axis, corresponding to a high probability for counterions to be inside the DNA grooves.<sup>[38]</sup>

On larger distances from the DNA, the ion distribution, computed in MD simulations, became more similar to that calculated in the PB theory, or obtained in continuum solvent simulations. In addition, the integral charge for  $\text{Na}^+$  ions turned out to be very similar already on distances greater than 12 Å from the DNA surface (Fig. 6). This means that cylindrical PB equation, despite many inherent approximations, is still able to evaluate amounts of ions that are attracted (or “non-specifically” bound) to DNA.

### Multiscale Simulation Approach

However, direct simulation of ion density in MD simulation is a tedious task and can be performed only at relatively small distances from the DNA surface. These distances do not include the true “bulk” phase, where neither water nor ions are affected by the electrostatic field of DNA. On the other hand, the problem of finding the ion distribution in the whole range (from the DNA surface to the bulk solution) is the important one. The “bulk” ion concentration in the living cell is determined by the work of ion channels in the membrane; however, only ions that are in close proximity to DNA affect their properties. Although continuum solvent models allow to compute for the ion distribution in the whole range, they contain adjustable parameters, such as the effective ion radius, and are unable to describe the effects of specific ion binding (e.g., specific binding of  $\text{Li}^+$  ions to the phosphate groups).

In Refs.<sup>[33]</sup> and <sup>[34]</sup>, an approach was suggested to link together the two levels of simulations of electrolyte or polyelectrolyte systems (i.e., the all-atom MD simulations and the MC simulations without explicit solvent). The main idea is that detailed all-atom MD simulations provide information on how to parameterize parameters for the continuum solvent model. In practice, as a first step, an MD simulation of size as large as can be afforded is performed. From this simulation, the radial distribution function (RDF) between ions as well as between ions and some sites of DNA is determined. Then, an inverse MC procedure is performed,<sup>[34,86]</sup> which finds the effective interaction potentials that match the RDF obtained in the MD simulations. The great benefit of effective potentials is that they can be used for simulation of the very same system but of substantially larger scale because the solvent molecules are not included. The typical behavior of the effective potentials is that they have a few oscillations at short distances, reflecting the molecular structure of the solvent, and then—at distances of more than 10 Å—approach the Coulombic potential with the dielectric constant of water.<sup>[33,34]</sup> The short-range part of the effective potentials is rather ion-specific, thus the specific features of ion–DNA interactions are automatically included in the model.

In Ref.<sup>[34]</sup>, the effective potentials between different alkali ions and DNA have been determined and used for MC simulations of the ion environment of DNA. The computed ion distributions are shown in Fig. 7. One can notice clear similarities with the ion distribution obtained in all-atom MD simulations in Fig. 5. Another interesting observation is that for  $\text{Na}^+$  and  $\text{K}^+$  ions, the density profiles follow very closely the

**Fig. 7** Density profile of different ions around DNA obtained by MC simulation with effective solvent-mediated potentials. The notations for the curves are the same as in Fig. 5. Source: From Ref.<sup>[34]</sup>. American Institute of Physics. Simulation details are given in this reference.

solution of the PB equation for distances larger than 15 Å from the DNA axis (of course, they were rather different at closer distances). For two other ions, Li<sup>+</sup> and Cs<sup>+</sup>, the deviations from the solution of the PB equation were more significant because of specific interactions of these ions with DNA. From the simulations, the relative binding affinity of these ions to DNA was determined as Cs<sup>+</sup> > Li<sup>+</sup> > Na<sup>+</sup> ≥ K<sup>+</sup>, in agreement with the experimental results.

The multiscale modeling approach may be used to take into account solvent and hydration effects in studies of ion binding and competition, as well as of the interaction of DNA with other ligands and proteins. Work in this direction is now in progress.

## CONCLUSION

The aim of the present review has been to show that computer simulation techniques are becoming increasingly important in the description of the ionic environment of DNA as well as other properties of biomacromolecular systems. Computer simulations allow us to follow the motion of every atom in the studied system, thus providing very detailed information and contributing to our general understanding of the physical mechanisms that govern the behavior of these biologically, as well as technologically, important systems. With the rapid development of computer technology, allowing larger systems to be studied on a longer time scale and enabling also a more accurate and detailed description of molecular interactions, the importance of molecular simulations in this area will grow further. Furthermore, new developments in experimental techniques including “single-molecule” experiments, as well as an interest in more and more complicated systems related to new areas of biotechnology, biomaterials, and nanotechnology additionally enhance the importance of computer simulation methods.

## ACKNOWLEDGMENTS

The author is thankful to Jose Abascal for providing electronic copies of the figures. Many thanks to Lars Nordenskiöld, Aatto Laaksonen, and Nikolai Korolev for stimulating discussions. This work was supported by the Swedish Research Council.

## INTRODUCTION

A switch is an ensemble of pieces whose function is to stop and/or establish the electrical current in a circuit.<sup>[1]</sup> This 19th century definition of a switch continues to be valid in our days. But because of the requirement of better communication means during the 20th century, the pieces of our modern switches are no more mechanical or electromechanical in nature. In our information society era which uses plenty of communication and computation machines, the many switches constituting those machines are now made of solid-state semiconducting materials. After the relay and the vacuum tube, the microfabricated transistor is the modern reference of an integrated switch at the surface of a silicon wafer. Furthermore, not only electrical current, but also photons flux, magnetic flux, etc. have now their own switches, expanding the possibility of miniaturizing a switch to other types of material, such as dielectrics and ferromagnets.

A human operator was supposed to operate a switch in the 19th century. The increasing complexity of circuitry made this operator to disappear to the benefit of a third electrode per switch. In electronics, a switch is now a three-terminal device. The “on/off” triggering information is generally provided to a given switch by another one inside the circuit, without involving the operator. Taking the transistor as reference for switch performances, there is now a continuous demand for a further reduction of the weight, the size, the power consumption, and the switching time of the solid-state switches.

One solution is to reduce the amount of material required to fabricate a transistor by improving the lithographic technique, engraving a transistor on an always smaller and smaller portion of the surface of a semiconductor wafer. A radically new approach was proposed by Aviram and Ratner in 1974.<sup>[2]</sup> Instead of continuing the miniaturization of the transistor at the surface of a wafer by inventing new lithography techniques, why not go all the way down to the atomic scale. Here the next big step is to create switches whose

pieces are simple organic molecules and even a few atoms bound together to form a single molecule. Those switches are called molecular switches. In principle, they can control an electron flux or, for example, a photon flux in a photonic circuit.

What remains unchanged is the kernel of the definition of a switch: whatever the amount of material assembled or bonded to fabricate a switch (a condensed phase, a macromolecule, a few molecules, a single molecule), a switch must have two states (the “on” and “off” states) well separated to ensure the stability of both the “on” and the “off” states. Behind the scene, there is often an internal physical or chemical variable to describe the state of the material assembled to constitute the switch. This is independent of the physical or chemical effect triggering the switch and whatever the flux to be controlled. Along a reaction coordinate proper to each kind of switch, a double-well energy curve can often be plotted (Fig. 1) defining the “on,” the “off” states of the switch, and the transition region. But in simple monostable molecular switches, only one well is existing. The well is simply deformed or displaced by the triggering effect. The double-well case gives rise to bistable molecular switches: in a few examples, the same value of the triggering parameter can maintain both the “on” and the “off” state depending on the history of the switching event, i.e., there is a memory effect (note that conventional switches for domestic applications are usually bistable, but electronic switches such as transistors are only monostable). The memory corresponds to a hysteresis effect related to a cooperative phenomenon often obtained with molecular material molecular switches.<sup>[3]</sup>

In practice, mainly molecular electronic switches are explored. The reason is that the exchange of information between a given molecular switch and other molecular switches in the same circuit requires communication and interconnections means adapted to the size of ultimately a single molecule. Electrons have a much more practical wavelength than photons for this purpose. Furthermore, a tunnel junction is a very useful source of tunneling electrons where a

**Fig. 1** Topology of a switch.  $R$  is the response and  $X$  the switching action. (A) Monostable switch: the response comes back to its original value as soon as the switching action ceases; (B) bistable switch: the response remains modified after the end of the switching action (memory effect). Inserts: energy curves describing the state of a switch as a function of an internal coordinate. In the case of the bistable switch, an energy barrier separates the two states, permitting the memory effect.

molecule can be positioned on, like a jumper. Of course, such positioning is still very delicate to perform experimentally, taking into account the necessity to know exactly at the atomic scale the conformation and the exact position of the molecule in the junction. The invention of the scanning tunnel microscope (STM) in 1981<sup>[4]</sup> arrived exactly on time to show experimentally as early as in 1988<sup>[5]</sup> that such electrical interconnection between a single molecule and a macroscopic operator was possible.

Many experiments on molecular switches are still performed by averaging the answer of the molecules over many and even billions of the same type. This increases the signal-to-noise ratio and amplifies the signal to be measured. In those experiments, each molecule is supposed to be non-interacting with the others, so that the switching ability depends only on one class of molecules. Using many instead of one is not only a matter of convenience. This approach can speed up the exploration of new molecular switches, by separating two otherwise intricate problems: obtaining a switching effect and positioning one molecule on a surface.

In this entry, we shall consider first “chemical switches,” i.e., systems based on a chemical reaction, or on a cooperative process involving many molecules. Thus although the change in properties between the “on” and “off” states can be spectacular, it is not, in principle, possible to reach the truly monomolecular scale. Then we shall see the case of monomolecular switches, this latter goal being now strongly boosted by technological and fundamental purposes. There will be two variants: first “intrinsic” molecular switches, i.e., molecules which present a special sensitivity to an external perturbation, with a bistable character, and can be studied in solution, in particular for screening purposes; the second variant will be “surface bound” molecular switches, really interconnected to an electrical circuit, which implies a strong interaction with the surface, so that the switching effect comes actually from the molecule–surface ensemble.

## CHEMICAL SWITCHES

### Simple Chemical Conversions

A frequently encountered concept of molecular switch in chemistry is based on the abrupt variation of a property linked to a chemical concentration of some species, that could be detected by various optic or electrochemical measurement. In the most common approach, this is achieved by selecting a reversible chemical reaction for which the two processes back and forward are kinetically very fast compared to the time scale of the experiment. This is strongly reminiscent of colored indicators used in classic analytical chemistry. If we consider a set of species  $A$ ,  $B$ , and  $X$ , the concentrations of which are controlled by the following equilibrium  $A = B + X$ , then one can easily show that the concentrations of species  $A$  and  $B$  (and thus any macroscopic property linked to their concentrations, such as color, etc.) will vary quickly over a limited domain of  $-\log [X]$  values. Thus the latter parameter can be used as a control parameter. It is usually  $\text{pH}$  ( $X = \text{H}^+$ ), it can also be  $\text{pX}$  for another ion or the potential of an electrode. The switching effect is obtained by circulating around the “threshold” value  $-\log K$  (Fig. 2).

Sophisticated systems have been designed in order to exploit the output signal. One can indeed read out the switching by light (either in absorption, i.e., a color change, or in emission, i.e., a luminescence change) or by an electrochemical way, or by both. Many molecules have been proposed<sup>[6–8]</sup> for which an output signal, typically fluorescence, is triggered by chemical stimuli (Fig. 3). When several input conditions must be fulfilled, such systems even behave as logical gates.<sup>[8]</sup>

**Fig. 2** Abrupt variation of the concentration of a species (and thus of the related macroscopic property) around the threshold value.

However, as these switches are based on a quantitative conversion of a macroscopic population of molecules, in practice one has to add a sufficient amount of species X to the solution in order to read the signal related to compound A, then to add a chemical that has a better affinity toward X to set free the compound B. Thus a “switching cycle” involves an *ordered* sequence of *irreversible* mixing steps and reversible chemical reactions steps. This leads to the accumulation of the products resulting from the necessary second chemical reaction and of solvent. Thus the

**Fig. 3** Switching of fluorescence by either  $H^+$ , (From Ref.<sup>[7]</sup>) or a combination of  $H^+$  and  $Ca^{2+}$  Source: From Ref.<sup>[8]</sup>.

intervention of an operator is absolutely necessary, to open or close taps to add chemicals, playing the same role as ancient telephone operators from the 19th century, before the introduction of the third terminal on each switch.

Ways to suppress the use of an external operator have been proposed. First, the states of different switches or molecules can be coupled by the exchange of another chemical species, for instance  $H^+$ .<sup>[9]</sup> In addition, it is possible to devise systems based on chemical reactors with reactions far from equilibrium, where several steady states can exist. For instance, in the case of “kinetic bistability,”<sup>[10]</sup> an abrupt variation can occur when the system passes through a bifurcation. Finally, the most spectacular developments would be the control of the state of the switch by an oscillating reaction. Such reactions have been used as a way to design logic gates, based on the propagation of chemical waves in a two-dimensional (2-D) non-stirred reactor containing an excitable media.<sup>[11]</sup> This would represent an archetype of a neuronal computer, because a living cell such as a neuron can be viewed as an out-of-equilibrium reactor.

### Molecules in Interaction: Cooperativity

A large class of works is related to switching effects involving molecules in interaction, constituting a molecular material. In some circumstances, one can achieve appealing characteristics for information storage, such as a sharp transition and even a hysteresis. The most typical example is given by spin-transition systems.<sup>[3]</sup> They involve paramagnetic coordination complexes with two possible states, a low-spin one and a high-spin one, the high-spin situation being favored by temperature. If the molecules are without interaction, the state of an individual molecule is governed by Boltzmann statistics, and only a gradual transition occurs when the temperature is raised. But an interesting situation arises when a positive cooperativity occurs, i.e., when the high-spin state of a molecule is favored by the presence of other high-spin molecules in its vicinity. Then, as shown by a simple model, the transition from low-spin to high-spin can be very sharp, and in some cases, a hysteresis appears, corresponding to a memory effect (Fig. 4). This has been the basis of a number of propositions to realize memory devices. In particular, the possibility to switch the system state by light, and not only temperature, has greatly expanded the potential for applications.<sup>[3]</sup>

However, in such systems, the switching effect relies inherently on the cooperativity parameter, i.e., the presence of many molecules. There is strictly no way to downsize the device to one molecule.

**Fig. 4** Cooperativity and abrupt transition. Up: array of interacting molecules, each presenting two states, for instance  $\circ$  = low-spin state (L), and  $\bullet$  = high-spin state (H).  $W_{LH}$ ,  $W_{HH}$ , and  $W_{LL}$  designate the interaction energies between molecules. Bottom: response (proportion of  $\bullet$ ) as a function of temperature. An abrupt transition occurs, as shown, when the cooperativity parameter is positive, i.e.,  $\frac{1}{2}(W_{HH} + W_{LL}) > W_{HL}$ . In some cases a hysteresis can appear (dotted lines).

### Chemical Bimolecular Reactions Involving a Change of an Intramolecular Process

En route for miniaturization, let us consider now the attempts to switch “on” and “off” an intramolecular transfer process of electrons. In this section we wish to present some examples of switches operated by a bimolecular reaction where the switching unit requires a modification of its composition or electronic configuration (Fig. 5), usually by a *chemical* reaction.

All of the chemical approaches of the problem imply the synthesis of rather complicated molecules made of a pair of groups A, B, the energetic or electronic configuration of which will prove the transfer, and a switching unit able to respond to a chemical stimulation such as an ion complexation, a redox reaction, or even a more “classic” organic chemistry

**Fig. 5** Switch made of two outer sites and a central switching unit sensitive to a chemical agent.

reaction. Following natural phenomena, two types of transfer have also been explored: energy transfer and electron transfer.

Energy is a rather difficult communication vector to control, because, after light absorption by a molecule, creating an electronically excited state, the energy tends to relax as heat to other parts of the molecule or to the surrounding. This dissipation is unavoidable. However, smart molecules have been devised, allowing cascading the energy through an array of chromophores. The switching effect is then obtained either by uncoupling the chromophores, or most commonly by creating a temporary energy sink. Some examples<sup>[12,13]</sup> are given in Fig. 6.

Switching an electron transfer along a molecular wire may sound easier as the electron should not vanish. Among the best systems explored are mixed valence systems, basically composed of at least two almost identical redox centers: they are differing only by one excedentary electron. Hence such a molecule undergoes a permanent intramolecular redox reaction, reflecting the electron quantum exchange between the two sites. This redox process is simply described in terms of a double wellled energy landscape as a function of a reaction coordinate. Switching is now based on changing the coupling between the two redox states. This can be achieved for example by changing the set of molecular orbital of the bridge by an acid–base reaction<sup>[14]</sup> or even a Diels–Alder reaction<sup>[15]</sup> (Fig. 7).

Finally, for such chemically sensitive switches, although the molecules do not interact with themselves, the input requires a chemical reaction and the output is a population-averaged property. Consequently, these switches will be hardly downsized to a single molecule.

### MONOMOLECULAR SWITCHES (I): INTRINSIC MOLECULAR SWITCHES

#### Model Molecules Studied in Solution

Here we consider molecules for which the barrier is large enough (Fig. 1), defining two states, “on” and “off,” that we assume of nearby energies. This

**Fig. 6** Switches based on the control of an intramolecular energy flow by a redox group. Up: association of porphyrins. From Ref.<sup>[13]</sup>. Bottom: use of an azo group. Source: From Ref.<sup>[13]</sup>.

**Fig. 7** Switches based on the control of an intramolecular electron transfer by a chemical agent. Up: protonation/deprotonation. From Ref.<sup>[14]</sup>. Bottom: adduct formation. Source: From Ref.<sup>[15]</sup>.

corresponds to an intrinsic bistability, which persists even when the molecules are isolated. The transformation is actually an isomerization reaction, i.e., a unimolecular process that does not require the reactant molecules, but can be activated by a physical process. The description is based on a simple double-well energetic landscape.

Certain compounds undergo a light-induced one. This usually leads to a deep change in the light absorption properties and is therefore called photochromism. In such a process, a molecule is brought in its Franck-Condon excited state upon absorbing a suitable photon  $h\nu_1$  and then starts to relax back to its ground state (Fig. 8). However, for this type of compound two isomeric ground states are available. A careful choice of the system can lead to a quantitative isomerization of the starting compound. An identical process but with another light of energy  $h\nu_2$ , or if the activation barrier is low, simply heating can be used as a way to reverse the populations.

Photochromism has been widely used to demonstrate the basic principle of switching, because the photochemical transformation is an elegant way to transform, at the macroscopic scale, one form into another, and these forms remain usually unchanged

**Fig. 8** Potential energy curves involved in photochromic switches. The switching action drives the system from one potential well to the other, via high energy excited states.

after the irradiation. Following the approach mentioned in the previous section, several teams have presented molecules able to switch “on” and “off” an intramolecular “interaction” parameter.

Regarding the switching unit, any photochromic moiety could be used in principle, but the recent work has focused on diarylethene-based molecules, in which a photocyclization/ring reopening process occurs. They present indeed distinct advantages: they show excellent photochromic characteristics (stability, reversibility, quantum yield, etc.), but above all, the two states correspond to very different states of conjugation of an extended framework, thus heralding very different electronic properties, and finally, the geometry does not change very much during the photocyclization process, thus facilitating their incorporation in large supermolecules or assemblies.

The first members of the series were described independently by Irie,<sup>[16]</sup> and Gilat, Kawai, and Lehn<sup>[17]</sup> and this initiated a bunch of studies where photochromism has been associated to other properties. The change in absorption properties between the two photoisomers is already a signature of the large change in delocalization along the molecular skeleton. But, upon connection of redox sites of the pyridinium family, it is possible in addition to modifying the electrochemical properties.<sup>[17]</sup> Other variants have been described. For instance, the introduction of a fluorescent unit allows the change in the emission response.<sup>[18]</sup> The association with a hyperpolarizable group led to a modification of the non-linear optical properties.<sup>[19]</sup> Chiro-optical switching effects have also been described.<sup>[20]</sup> Grafting paramagnetic sites on each side of the central unit allowed the demonstration of switching an intramolecular exchange interaction parameter.<sup>[21]</sup> Finally, with redox sites of the Ruthenium(cyclometallated) family, it has been possible to switch “on” and “off” an intramolecular intervalence electron transfer,<sup>[22]</sup> i.e., a process which constitutes for mixed-valence molecules the equivalent of the conductance for a nanojunction (Fig. 9).

Thanks to the versatility of diarylethene chemistry, it is even possible to realize more complex functions than just switching. Playing with electrochemical and photophysical properties can lead to elaborate responses such as write/read/erase, which could be useful for the realization of molecular-based memories.<sup>[23]</sup>

As photochromic compounds are addressed by light, the response is typically the one of an ensemble of molecules, usually without interactions. But it is possible in principle to record signals corresponding to a unique isolated molecule. This has been achieved quite recently by Irie et al. who observed by confocal microscopy the signal of single molecules of a dithienylethene-bis(phenylethynylanthracene) dyad embedded in a polymer film.<sup>[24]</sup>

**Fig. 9** Photochromic switches based on diarylethenes. (A) Control of an exchange interaction between magnetic centers; From Ref.<sup>[21]</sup>. (B) control of an intramolecular electron transfer between redox sites. *Source:* From Ref.<sup>[22]</sup>.

## Electrical Studies on an Ensemble of Molecules

In this section, more recent molecules with an intrinsic “bistable” design are presented. They are destined to be supported by a surface, following the recent evolution of the technology to manipulate molecules at the surface of a solid. Therefore they can be triggered from the “on” to the “off” states by the application of an electric field when sandwiched between two metallic electrodes. As they are chemically designed to be adsorbed on a surface, the ultimate goal here is to electronically connect one molecule at a time. This field was opened by Aviram who synthesized in the 1980s a hemiquinone molecule well adapted to be attached to a surface. The switch was intrinsic and triggered by an electric field with double-well-potential-like characteristics. The first STM measurements were attempted in 1987 in IBM laboratories.<sup>[5]</sup> But at that time, the available equipment did not permit to reach a firm conclusion about the switching effect.<sup>[25]</sup>

This first experiment was nevertheless a prelude to studies aiming at the demonstration of electronic functions of molecules when disposed as thin monomolecular layers, in particular rectification. This latter goal was finally achieved by Metzger in 1997.<sup>[26]</sup> Since then and in relation to the switching problem, a large number of fascinating families of molecules equipped with different groups have been synthesized for this purpose. For example, the catenanes and rotaxanes molecular switches are based on the concept of “threading,” i.e., they contain two parts which cannot separate without breaking a bond.<sup>[27,28]</sup> The active parts used to control a motion are donor and acceptor moieties which can be associated through weak interactions, but because these moieties are kept in proximity by the special topology of the molecule and cannot fully separate, the association reaction is actually a monomolecular reaction analogous to an isomerization. Despite the flexibility inherent to large molecules presenting a large number of possible torsions, the number of pertinent conformations they can adopt is relatively limited, typically two, because of the unique topology of the system. They correspond to the location of a mobile part (the “shuttle”) in front of two possible “stations” (Fig. 10). Such molecules can be studied first in solution, where the acceptor/donor character of a moiety can be reversed by electrochemistry, and then can be transferred and used in solid-state devices.

Many examples have been described by Luo et al. The active molecules were deposited as Langmuir-Blodgett (LB) monolayers on an *n*-polycrystalline silicon substrate and covered by a Ti/Al top electrode, thus giving a two-terminal device of monomolecular thickness. The response was then probed by a method analogous to the remnant polarization method used

**Fig. 10** Molecular shuttle with two stations, A and B. The motion is controlled by the electrochemical oxidation of the TTF unit (station A). *Source:* From Ref.<sup>[29]</sup>.

for ferroelectric devices, i.e., scanning a voltage range while measuring the current at a low perturbing voltage, to avoid capacitance effects.<sup>[29]</sup> The basic signature of a switching effect is then the appearance of a hysteresis curve, associated with the existence of two possible conformations with different electron transport properties. Note that the perturbation here is an oxidation/reduction of a moiety, transforming, for instance, a donor tetrathiafulvalene (TTF) Scheme 1 into an acceptor (TTF<sup>+</sup>). This is basically an electrochemical process, requiring in solution the intervention of a counter ion. It is not clear how such a process occurs in the solid-state device based on a monolayer.

Although several control experiments show that a two-station structure is necessary to obtain a switching

**Scheme 1**

effect, the exact interpretation remains obscure, because the molecules contain several other flexible parts, and their exact orientation in the LB layer, as well as the geometry of the contacts with the interfaces, is not readily accessible to experiment.

Another series of molecules was designed and studied by Tour, Reed, et al.<sup>[30,31]</sup> They are made of several (phenylene ethynylene) groups with thiol end groups for attachments on electrodes (“alligator clips”). These molecules are then used either in a nanopore cell (Fig. 11), allowing the contacting of an ensemble of molecules (ca.  $10^3$ ) between a substrate and an evaporated upper electrode. The molecules form a self-assembled monolayer (SAM) and, because of the small size of the pore (30–50 nm), a defect-free ensemble can be expected. The interesting behavior resides in the appearance of a negative differential resistance effect (NDR), an effect tentatively assigned to the rotation of a phenylene group and/or charge injection under the influence of the applied voltage.

Looking further, although these devices are two-terminal ones, they can be of some use in electronics circuitry. The construction of a 2-D crossbar arrangement, with such layers of molecules at the nodes, would give an electronic circuit with a little amount of molecular material at the node in a defect-tolerant architecture similar to what was proposed in the 1960s.

## MONOMOLECULAR SWITCHES (II): SURFACE MOLECULAR SWITCHES

The end of the miniaturization roadmap for molecular switches is a single molecule connected between two, or if possible three, electrodes. This requires an underneath surface that will support the molecule and the nanoelectrodes. The surface can be active or passive in the definition of the molecular switch. The switching ability of the molecule can be intrinsic to the molecule, as mentioned in the previous section, or it can be created by the interaction of the molecule with the surface.

As an example of the first possibility, we can mention the recent experiment by Dulic et al.<sup>[32]</sup> who succeeded in contacting a photochromic switch of the diarylethene family with two electrodes, by the “break-junction” technique. The switching of the nanojunction conductance was observed, but in one direction only (from “on” toward “off”), due to the quenching effect of the metal surface.

We now consider the second possibility, i.e., systems strongly dependent on the interaction with a surface. The first real demonstration that an object of the size of a single atom can switch “on” and “off” a current was experimentally observed by Eigler et al. using a Xe atom switching back and forth under the tip of an STM at very low temperature.<sup>[33]</sup> This is a surface atomic switch whose double-well potential is created

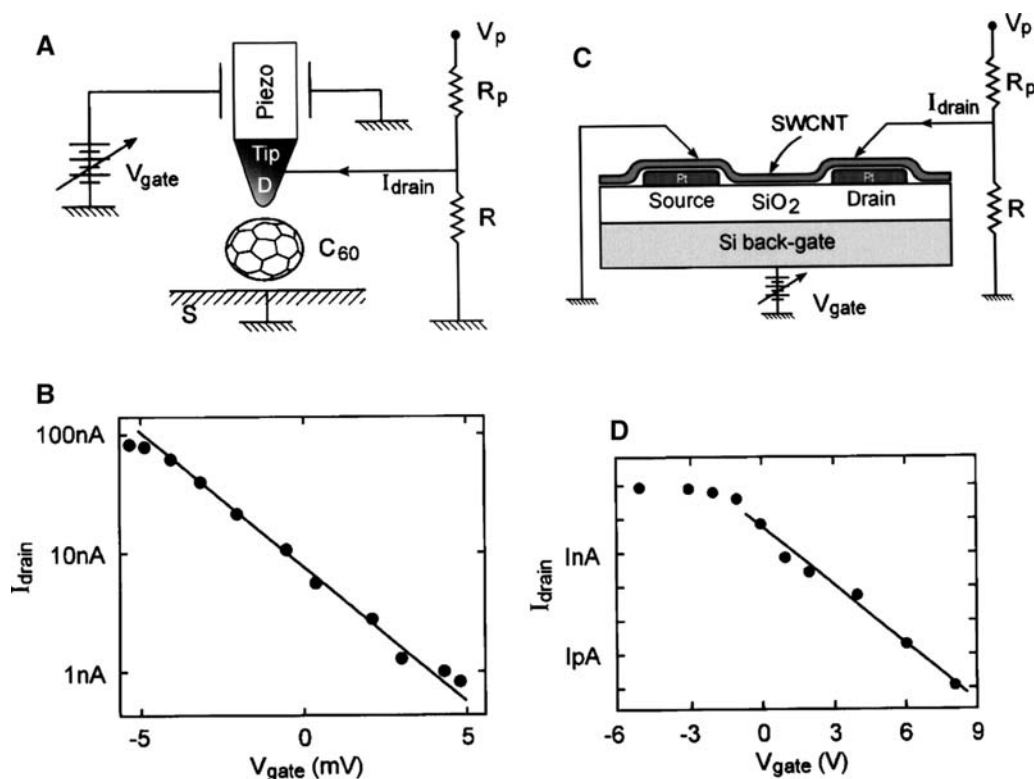

**Fig. 11** The “nanopore” setup. Each nanopore is filled by several thousands of active molecules. *Source:* From Ref.<sup>[30]</sup>.

**Fig. 12** Atomic and molecular switch on a surface. Up: Eigler's atomic switch using the positioning of a Xe atom. From Ref.<sup>[33]</sup>. Bottom: molecular switch based on the rotation of a porphyrin "leg" out of the molecular plane. Source: From Ref.<sup>[34]</sup>.

on the surface by the van der Waals trap created by the tip apex for the "on" state and by a nearby monoatomic step edge for the "off" state. The tip-apex-to-surface applied electric field is used to pass the atom from one well to the other (Fig. 12).

The first double-well, truly single-molecular switch was experimentally observed in 2001.<sup>[34]</sup> It results from a peculiar property of the adsorption of a leg porphyrin molecule on metal surface. On a Cu(100) surface, the four legs of this molecule are almost perpendicular to the surface. On a Cu(111) surface, the four legs are flat on the surface, the central porphyrin being attracted by the 111 surface state of copper. The fabrication procedure was to adsorb the molecule on a Cu(211) surface which presents 111 facets separated by monoatomic steps. Some molecules adsorb on the edge of a step with three legs on the 111 facet and one at the step edge. The three legs are flat but the fourth one is found in a metastable state. Its most stable position is, of course, flat on the lower terrace. But this leg is now a bit too far to the down facet compared to the three others legs. Therefore it prefers to stay perpendicular to the surface (Fig. 12, bottom part). This creates a double-well potential for the

**Fig. 13** The variation of the drain-source current intensity as a function of the gate voltage for the original  $C_{60}$  single-molecule amplifier and the original single-carbon nanotube transistor. This variation corresponds to the slope of the passage from an "off" to an "on" state in a mono-stable switch (Fig. 1). Source: Reproduced with permission from Nature, 2000, 408, p. 541. © 2000, McMillan Magazines Limited.

configuration energy of this leg. The barrier can be overcome by pushing on the leg by the tip apex of the STM. The “on” and “off” states are defined for the same altitude of the tip apex on the switching leg. The “on” and “off” electrical resistance of this single intramolecular switch has been measured together with the energy required to switch on/off the leg. The on/off current difference in this molecular switch is due to a control of the electronic coupling between the tip and the surface through the molecular legs. It is large when the leg is perpendicular to the surface and low when parallel.

Another way to change the electronic coupling between the tip and the surface using a single molecule is to change the homo–lumo gap of the molecule. A simple experimental way is to deform the molecule by pressing on it with the tip apex. The  $C_{60}$  single-molecule amplifier is an example of such a device<sup>[35,36]</sup> as shown in Fig. 13. Used in its blocked-saturated mode, this is a monostable molecular switch. The  $C_{60}$  device beneficiaries from the high degeneracy of its homo and lumo orbitals, a degeneracy yielding to a low transparency toward electrons because of destructive interference effects through the molecule. By compressing the  $C_{60}$ , this degeneracy is raised, giving rise to a very fast increase of the tunnel current through the  $C_{60}$  molecule in this compressed state. A  $C_{60}$  molecular device can be used as a switch but also as a transistor. This had opened the way to simulate very complex hybrid molecular circuits made of more than 600  $C_{60}$  transistors interconnected together by a standard metallic circuit to test how high impedance and low gain transistors may still be used to design simple processors.<sup>[37]</sup>

A macromolecular version of the  $C_{60}$  single molecule switch was proposed in 2003 using a single-wall carbon nanotube positioned on a mesoscopic junction.<sup>[38]</sup> To create a monostable switch, the tip of an AFM is brought from the top of the device to deform the tube in the center of the device (Fig. 12). Depending on the chirality of the tube, its band gap can be closed or opened, modifying the resistance of the junction. With a good trans-conductance, carbon nanotube electronic transistors have also been fabricated using a third top metallic electrode like the grid of a field effect transistor.<sup>[39]</sup> Those mesoscopic devices are at the down limit of microelectronics where the source–drain distance of the transistor is of the dimension of a macromolecule.

## CONCLUSION

The different approaches of “molecular switches” are displayed in Fig. 14, according to the type of switching action and the type of measured response. In addition,

		Response (R)			
		electrical	mechanical	optical	magnetic
Switching action (X)	electrical	○ a ○ b		● k ● l	
	mechanical	☺ c ☺ e ☺ d			
optical	☺ f ● g	☺ j	● m ● n ☺ o	● q	
chemical	● h ● i		● p		

**Fig. 14** Chart of the different types of molecular switches, according to the type of switching action, and the type of response. ●: Experiments performed on a statistical ensemble, leading to a relatively large device; ○: on a few molecules (ca. 1000); on one molecule. *Source:* From the following teams: a: Pease, Luo;<sup>[27,29]</sup> b: Tour, Donhauser;<sup>[30,31]</sup> c: Joachim and Gimzewski;<sup>[35,36]</sup> d: Moresco;<sup>[34]</sup> e: Tans;<sup>[39]</sup> f: Dulic;<sup>[32]</sup> g: Fraysse;<sup>[22]</sup> h: Gonzalo;<sup>[15]</sup> i: Haga;<sup>[14]</sup> j: Hugel;<sup>[40]</sup> k: Akasaka;<sup>[13]</sup> l: Holten;<sup>[12]</sup> m: Irie;<sup>[16]</sup> n: Gilat;<sup>[17]</sup> o: Irie;<sup>[24]</sup> p: Daffy, de Silva;<sup>[7,8]</sup> q: Matsuda.<sup>[21]</sup>

a third characteristic is important, i.e., the scale at which the system works: a large statistical ensemble, a few molecules, or ultimately one. Only in this last case can we expect to take the full benefit of miniaturization and really reach the domain of molecular electronics, where the major question is about the fundamental limits.

Like any devices, a molecular switch is characterized by its performance such as its switching time and the energy required to change the status of the switch. For a single molecular switch interconnected between two electrodes, it has not yet been possible to measure the switching time. This is due to the large resistance of a metal–molecule–metal tunnel junction of the order of  $1\text{ G}\Omega$  for a single organic molecule, down to a few megaohms for macromolecule molecular switches such as a single-wall carbon nanotube (SWCNT). The RC constant of the switch is mainly controlled by the product of this resistance by the line capacitance, the latter of the order of a few picofarads. This leads to a minimum observable switching time of a few microsecond. Of course, the isomerization of a single molecule takes less than a few picoseconds. Here it is the way the device is built which sets up the limit, not the intrinsic limitation of the molecule itself.

Measuring the energy associated with a single-molecule geometrical change is a technological challenge but has been realized, for instance, with azobenzene molecules by monitoring their mechanical properties.<sup>[40]</sup> In the case of a surface electrical molecular switch, the energy required to switch “on” and “off” has been recently measured using a new

Fig. 15 Switching energy as a function of time. The approach of fundamental limits. Source: From Ref.<sup>[42]</sup>.

near-field microscope: the non-contact UHV AFM microscope.<sup>[41]</sup> The tip apex of the AFM oscillates on the surface and the tip apex altitude is decreased progressively toward the surface. This permits in a dynamic way to record the interaction force between the tip apex and the surface, giving access to the interaction energy. This instrument was used on the leg porphyrin switch to record the energy required to switch “off” the switch. The tip apex is located on the chosen switchable leg of the molecule and the force–distance curve recorded. The switching energy found is about  $5 \times 10^{-20}$  J (7 kcal/mol), which is four orders of magnitude lower than the state-of-the-art semiconductor technology transistor. It is interesting to report this value on the diagram proposed some years ago by Keyes,<sup>[42]</sup> in which the energy dissipated per logic operation is displayed (in logarithmic units) as a function of date (Fig. 15). One sees that the trend toward smaller and smaller energy consumption continues and raises the question of the absolute limit.

Thus aside from its technological applications, a molecular switch is becoming a very interesting nano-device to study the thermodynamic limits of switching. With a value as low as 7 kcal/mol, one is very close to the  $kT \log 2$  limit, considered as the minimum energy necessary to drive any switching device interacting with a thermal bath at a temperature  $T$ .<sup>[43]</sup>

University of Groningen, Groningen, The Netherlands

## INTRODUCTION

The fascinating principles exploited by nature to control organization, switching, and motion are a major source of inspiration for the design and synthesis of artificial molecular systems with such functions. The highly efficient retinal *cis-trans* photoisomerization in the process of vision is a superior example of a molecular switch,<sup>[1,2]</sup> and the intriguing biomolecular motors<sup>[3]</sup> set an extremely high standard for the development of synthetic counterparts. The bottom-up construction of switches and motors, with the realization of machines and robotics of nanosize dimensions as the ultimate goal, offers a formidable challenge to scientists. Synthetic approaches toward artificial machinery have already resulted in several molecular systems whereby switching and/or motion is controlled by means of chemical, electrochemical, photochemical, or thermal input.<sup>[4–6]</sup> For instance, molecular propellers,<sup>[7]</sup> brakes,<sup>[8]</sup> switches,<sup>[9]</sup> turnstiles,<sup>[10]</sup> ratchets,<sup>[11]</sup> and shuttles<sup>[12,13]</sup> have been constructed. Catenanes and rotaxanes have shown to be particularly promising systems in the development of molecular machines.<sup>[14–17]</sup> Jimenez, Dietrich-Buchecker, and Sauvage,<sup>[18]</sup> for example, reported the contraction and stretching of a linear rotaxane dimer resembling a natural muscle at work,<sup>[19]</sup> and Chia et al.<sup>[20]</sup> demonstrated the threading and dethreading of rotaxanes assembled on a surface. Recently, Hugel et al.<sup>[21]</sup> reported the first single molecule machine based on photoactive azo dyes.

In this entry, we do not attempt to give a complete and detailed overview of all molecular switches and motors developed thus far and the reader is referred to various reviews. Molecular switches, based on a large variety of principles, have been reviewed extensively.<sup>[9]</sup> Molecular motors found in nature as well as synthetic counterparts are reviewed elsewhere.<sup>[22]</sup> We will focus on systems based on sterically overcrowded alkenes, in which light is used to induce switching or motion, to illustrate several of the key principles involved.

## STERICALLY OVERCROWDED ALKENES AS CHIROPTICAL MOLECULAR SWITCHES

In a chiral approach toward molecular switches, the unique properties associated with stereoisomers of chiral photoresponsive molecules are exploited. The two stereoisomers of such photochromic compounds represent the distinct states of a light-switchable digital molecular system (Fig. 1).

Chiroptical techniques offer the attractive feature that the change in chirality of the photochromic system<sup>[23]</sup> can be detected. A major advantage of chiroptical switches is that nondestructive readout is feasible by monitoring the change in optical rotation at wavelengths remote from the wavelengths used for switching. Another important advantage of using chiral photochromic compounds is that they can be employed to control other (chiral) properties, e.g., the organization of a liquid crystalline phase.

### Chiral Switches Based on Enantiomers

A direct way of controlling chirality in a molecular switching system is by using the interconversion between two enantiomers by chiral light (Fig. 2). Schuster et al.<sup>[24,25]</sup> have published switchable systems which function under the influence of circularly polarized light. The switching process we envisioned involves the interconversion of the (*P*)- and (*M*)-enantiomers of helically shaped, inherently dissymmetric alkenes.

The possible photoisomerization steps are the following: 1) irradiation with circularly polarized light (CPL) will lead to a small excess of one of the two enantiomers starting from a racemate; 2) alternating irradiation with (*l*)- and (*r*)-CPL at a certain wavelength will result in a modulation between both enantiomers; and 3) irradiation with linear polarized or unpolarized light results again in a racemic (*P,M*)-mixture.

**Fig. 1** Chiroptical molecular switch based upon stereoisomers A and B with different chirality.

Decisive factors for a successful molecular switch based on enantiomers are as follows: 1) irradiation with CPL should not cause any photodestruction; 2) the enantiomers should have sufficiently high  $g$ -values ( $g$  = anisotropy factor); and 3) the quantum efficiency for photoracemization should be high, as the rate of photoresolution is exponentially related to this quantity. Out of a large number of sterically overcrowded chiral alkenes that were synthesized and resolved, helically shaped alkene **1** meets these requirements (Scheme 1).<sup>[26]</sup> The enantiomers of **1** are stable at ambient temperatures and are fatigue-resistant. This overcrowded alkene shows structural resemblance to helicenes, and large CD absorptions and optical rotations are found. A stereospecific photoisomerization takes place that reverses the helicity of the molecules.

Starting from racemic **1**, switching between photostationary states with small enantiomeric excesses (0.07%) of (*P*)- and (*M*)-**1** was accomplished by irradiation with (*l*)- and (*r*)-CPL, respectively. This demonstrates that chiral light can be used to switch a molecular system from one handedness to the other. Such a switching behavior on the molecular level might have potential in developments toward molecular integrated systems or optical data storage units, for example, by employing liquid crystalline matrices (vide infra). The selectivity of switching is, however, severely limited by the theoretical limitations of the concept.<sup>[27]</sup>

### Chiral Switches Based on Pseudoenantiomers

A way of circumventing the major limitations predicted and encountered in enantiomeric switches is by the use of pseudoenantiomeric photochromic molecules. Inspired by the efficient switching of retinal in the human eye,<sup>[28]</sup> the design of pseudoenantiomeric chiroptical switches is again based on sterically overcrowded alkenes (Scheme 2).<sup>[29,30]</sup> As for **1**, the intrinsic (helical) chirality originates from a distortion of the molecular framework leading to (*M*)- and (*P*)-helices.

**Fig. 2** Schematic representation of a molecular switch based on enantiomers.

**Scheme 1** Circularly polarized light switch based on sterically overcrowded alkene **1**.

Both forms of the overcrowded alkene feature a *cis*- and a *trans*-stilbene chromophore in the same molecule. A photochemically induced *cis*–*trans* isomerization results in reversal of the helicity. Because of the near mirror-image relation of the two pseudoenantiomers, such a system offers a way to control molecular chirality merely by changing the wavelength of the light employed.

The first chiroptical switching process was realized with thioxanthene-based alkenes (*M*)-*cis*-**2** and (*P*)-*trans*-**2** (Scheme 3).<sup>[31]</sup> Irradiation of enantiomerically pure (*M*)-*cis*-**2** in *n*-hexane solution at 300 nm resulted in a photostationary state consisting of 64% (*M*)-*cis*-**2** and 36% (*P*)-*trans*-**2** because of different UV absorptions of the (*M*)-*cis* and (*P*)-*trans*-isomers (vide infra). Using 250-nm wavelength light, a photostationary state of 68% (*M*)-*cis*-**2** and 32% (*P*)-*trans*-**2** was reached. Alternated irradiation at 250 and 300 nm resulted in a photomodulation between these two photostationary states. It should be noted that after 20 switching cycles, 10% racemization was observed because of a relatively low racemization barrier. A second drawback is the relatively low switching efficiency of this prototype system. Both drawbacks can be overcome by synthetic modification.

It was found that the racemization barriers could be tuned over a range of approximately 50 to above 125 kJ mol<sup>-1</sup> by modification of the bridging atoms X and Y in the upper and lower half of the inherently dissymmetric alkenes (Scheme 2).<sup>[32]</sup> The effect of increasing the size of X and Y is that the naphthalene

**Scheme 2** General scheme of a chiroptical molecular switch based on pseudoenantiomers of a sterically overcrowded alkene.

**Scheme 3** The first chiroptical molecular switch based on a sterically overcrowded alkene **2**.

unit of the upper half is pushed toward the lower half, and as a consequence, the steric hindrance at the so-called *fjord region* and the barrier for racemization are increased. For instance, going from  $Y = O$  to  $S$ , the Gibbs energy of activation for the racemization process increases from 91.2 to 120.9 kJ mol<sup>-1</sup>.

In a switching process, which is based on the difference in UV/Vis absorption of two states of a photochromic molecular system, the switching efficiency is linearly related to the ratio of the UV/Vis absorptions of the isomers [following Eq. (1)]. The ratio of the two extinction coefficients at a certain wavelength, together with the ratio of the quantum yields ( $\Phi$ ) for interconversion of the two forms, determines the photostationary state ratios. The ratio of the two extinction coefficients of a photochromic switch is wavelength-dependent, and this is a decisive factor for the selectivity of the switch.

$$\frac{[cis]}{[trans]} = \frac{\epsilon_{trans}}{\epsilon_{cis}} \frac{\Phi_{trans \rightarrow cis}}{\Phi_{cis \rightarrow trans}} \quad (1)$$

To increase the stereoselectivity of the photochromic process, a dimethylamino electron-donating substituent and a nitro electron-withdrawing substituent were introduced in the lower half (Scheme 4).<sup>[33,34]</sup> This asymmetric substitution results in relatively large differences in the UV/Vis absorption characteristics of the two pseudoenantiomers (Fig. 3A). Maxima in the ratio of extinction coefficients of the two pseudoenantiomers are found at 365 and 435 nm. With this system, in *n*-hexane, switching between a photostationary state of 90% (*M*)-*cis*-**3** and 10% (*P*)-*trans*-**3** (435 nm) and

**Scheme 4** Donor-acceptor substituted chiroptical molecular switch **3** showing high stereoselectivity.

**Fig. 3** UV/Vis (top) and CD (bottom) absorption spectra of donor-acceptor switch **3** (inset: the ratio of the two extinction coefficients  $\epsilon_{cis}/\epsilon_{trans}$ ). The solid lines correspond to (*M*)-*cis*-**3** and the dashed graphs correspond to (*P*)-*trans*-**3**.

30% (*M*)-*cis*-**3** and 70% (*P*)-*trans*-**3** (365 nm) is achieved.<sup>[33]</sup> It was possible to perform 80 switching cycles without any deterioration or racemization.

Of utmost importance for further applications of chiroptical molecular switches is the pseudoenantiomeric relationship between the two isomers. This pseudoenantiomeric relation is evident from the circular dichroism (CD) spectra of the two forms (Fig. 3B). With this system, molecular chirality can effectively be controlled by changing only the wavelength of light used.

To obtain information on the necessity of both a donor and an acceptor moiety in the same molecule to induce efficient switching, the acceptor-only nitro-substituted and donor-only dimethylamine-substituted switches **4** and **5**, respectively, were synthesized

**Fig. 4** Simplified analogs of the donor–acceptor switches; acceptor-only compound **4** and donor-only compound **5**.

(Fig. 4). For both compounds, the wavelengths for the most selective switching process are considerably blue-shifted compared with the donor–acceptor switches because of the absence of a charge transfer absorption band, and switching selectivities for both **4** and **5** are lower than for the donor–acceptor substituted analog. Apparently, a combination of donor and acceptor substituents is a prerequisite for selective chiroptical switching in sterically overcrowded alkene systems. Therefore the concept of donor–acceptor substituted switches was further exploited.

The major drawback of **3**, which becomes of considerable importance especially when the molecule is incorporated in a liquid crystalline matrix, is low solubility and compatibility. Low compatibility leads to severe limitations with respect to the applicability of the system in an organized environment (vide infra). Donor–acceptor compound **6** was designed to increase the solubility without interfering with the switching efficiency (Scheme 5).<sup>[35]</sup> Although the UV/Vis spectra of **6** are comparable to those of its parent compound **3**, there are subtle differences resulting in slightly different photochemical behavior.

Irradiation of **6** in *n*-hexane solution at the most efficient wavelength of 380 nm resulted in the formation of a photostationary state consisting of 70% (*P*)-*trans*-**6** and 30% (*M*)-*cis*-**6**. Subsequent irradiation at 465 nm resulted in the formation of a photostationary state consisting of 98% (*M*)-*cis*-**6** and 2% (*P*)-*trans*-**6**. This system thus shows nearly quantitative switching to a *cis* photostationary state because of a slight bathochromic shift of the UV/Vis curve of the *trans*-isomer

relative to the *cis*-isomer. Although this is only a minor effect, it allows irradiation at the red edge of the spectrum to almost exclusively excite the *trans*-isomer resulting in a near quantitative switching to the *cis* photostationary state.

In another approach to change the photophysical properties of donor–acceptor switches, the relative position of the donor and acceptor substituents can be changed (Scheme 6).<sup>[36]</sup> By introducing a dimethylamino-substituent in the upper half of the switch as in **7**, the difference between the two isomers was expected to increase. In case of (*M*)-*cis*-**7**, where the donor and acceptor substituents are close together, a strong dipolar interaction between the donor and acceptor moieties is expected. The possibility for this direct interaction is absent in case of (*P*)-*trans*-**7**. Nevertheless, efficient photoisomerization was only observed in one direction strongly depending on solvent polarity. In toluene, for example, a remarkable *cis*/*trans* ratio of 99:1 was found upon irradiation at 435 nm. Switching to a state of excess, (*P*)-*trans*-**7**, however, was only possible in highly polar solvents such as, for example, dichloromethane, and even then, a maximum *trans*/*cis* ratio of only 55:45 was achieved. Although at certain wavelengths the extinction coefficient of the *cis*-isomer is higher than that of the *trans*-isomer, there is a preference for the *cis*-isomer throughout the entire spectrum and in almost any solvent. Because absorption characteristics are similar to those of **3**, in this case, apparently, the quantum yield ratio is the predominant factor for the switching selectivity. As a result of favorable donor–acceptor interaction in the excited state, a *cis*-like geometry will be preferred leading to a *cis*-ground state only slightly dependent on the wavelength used for excitation. This assumption is supported by the fact that in more polar solvents, where intramolecular dipole interactions become less important, the photostationary states are increasingly shifted to the *trans*-isomer. Compound **7** can, in principle, be used in a write-once type of molecular information storage system where, starting from the *trans*-state, information is written very efficiently with a diastereomeric ratio up to 99:1 (in toluene solution) in preference of the *cis*-state.

**Scheme 5** *n*-Hexyl modified donor–acceptor switch **6**.

## Special Molecular Switches

The above examples show that sterically overcrowded alkenes allow control of molecular chirality and offer a binary switch system on a molecular level. The next examples aim to further exploit this chiroptical switching concept toward control over other functions or toward more sophisticated photochromic systems.

### Controlled Molecular Rotation

An approach toward a functional switch involves the control of the rotation around a single bond in a photoswitchable molecule modified with a biaryl-type rotor.<sup>[37]</sup> Photoisomerization between the (*M*)-*cis*-**8** and the (*P*)-*trans*-**8** form should cause a distinct difference in rotation rate for the biaryl rotation because steric hindrance on the rotor is completely different for the two pseudoenantiomers (Scheme 7). Dynamic nmr studies revealed barriers for the biaryl rotation of  $\Delta G^\ddagger = 4.54$  and  $4.71 \text{ kJ mol}^{-1}$  for the *cis*- and *trans*-isomer, respectively. In contrast with expectation, but in agreement with semiempirical calculations, the barrier for the *trans*-compound was higher than for the *cis*-compound. The observed isomerizations were attributed to distinct differences in the chiral conformations and steric effects associated with folding in the molecules. Particularly, the methyl groups of the xylyl rotor meet severe steric hindrance of the  $\text{CH}_2$  groups of the upper half in *trans*-**8**, whereas the nearly planar naphthalene moiety in *cis*-**8** simply bends away during the rotary process. This system can be considered a molecular gear but suffers from

**Scheme 7** Controlled intramolecular rotation of a biaryl propeller unit in a chiroptical molecular switch **8**.

a small difference in energy barriers and inefficient photoswitching.

### Gated Response and Dual-Mode Photoswitching of Luminescence

Locking of written information is absolutely essential for optical data storage based on molecular switches. Donor–acceptor switch **3**, as a result of the presence of a basic dimethylamino-substituent, allows gated photoswitching (Scheme 8).<sup>[34]</sup> The photochemical isomerization process of both (*M*)-*cis*-**3** and (*P*)-*trans*-**3** was effectively blocked by protonation of the dimethylamine moiety which changes the lower half of the molecule from a *push–pull* donor–acceptor system to a *pull–pull* acceptor–acceptor system. The photoisomerization behavior can be restored upon subsequent deprotonation.

This protonation–deprotonation protocol does not only lead to gated response, but also has an effect on the fluorescence of the molecule, leading to a dual-mode photoswitching of luminescence. For (*M*)-*cis*-**3** in *n*-hexane, a weak fluorescence is found around 528 nm, whereas for (*P*)-*trans*-**3b**, a relatively strong fluorescent emission is observed around 531 nm. The fluorescence was found to be highly solvent-dependent. Protonation of these photochromic compounds resulted in complete quenching of the emission for both forms, whereas after deprotonation, fluorescence intensities were fully recovered. Combined with the photochemical switching, this allows for switching between three fluorescent states *on* (*trans*), *dimmed* (*cis*), and *off* (both protonated forms) by simultaneous use of light and acid/base stimuli. In circularly polarized luminescence studies, it was found that the chirality of the fluorescent excited states strongly depends on the polarity of the solvent.<sup>[38]</sup> In *n*-hexane, both (*M*)-*cis*-**3** and (*P*)-*trans*-**3** show circularly polarized luminescence of the same handedness, while in benzene, circular polarization of luminescence is opposite for (*M*)-*cis*-**3** and (*P*)-*trans*-**3**. This remarkable behavior was explained by the existence of a mutual *trans*-like luminescent excited state in *n*-hexane, where in benzene, clearly, *cis*-like as well as *trans*-like excited states can be observed. In benzene solution, this system

**Scheme 8** Gated photoswitching and fluorescence based on reversible protonation.

can function as a molecular modulator of circularly polarized luminescence.

### Pyrrolidine-Functionalized Molecular Switch

En route toward further functionalization of the switch skeleton in compound **9**, a chiral (*S*)-2-methoxymethyl-

pyrrolidine group was introduced as the electron donor moiety (Scheme 9). The additional stereogenic center in this molecular switch results in four distinct diastereomeric forms. As a result, the two photoequilibria are now different, and a difference in energy for the two separate *cis*- [(*S*)-(*M*)-*cis*-**9**]/[(*S*)-(*P*)-*cis*-**9**] and *trans*- [(*S*)-(*M*)-*trans*-**9**]/[(*S*)-(*P*)-*trans*-**9**] isomers of **9**

**Scheme 9** Four diastereoisomers of pyrrolidine-based chiroptical switch **9** and the isomerization pathways.

can be anticipated. For both pseudoenantiomeric couples, the ideal switching wavelengths and photostationary state ratios are summarized in Scheme 9. Switching selectivities are similar for the two diastereomeric bistable switching pairs, and functionalization of the donor part of the molecular switch has only a minor influence on the switching selectivity. This offers attractive possibilities for the use of these switch molecules in multicomponent photoactive materials.

Another interesting feature of **9** when compared with donor–acceptor switch **3** (Scheme 4) is that because of the diastereomeric relation between the respective *cis*- and *trans*-isomers, the thermal helix inversion steps are no longer true racemizations. The steady-state ratios are not 50 : 50, indicating that there is a small but significant energy difference between the two *cis*- and the two *trans*-forms of **9** (Scheme 9). This effect can be used to induce directionality in molecular rotation which might lead to molecular motors.

### Chiroptical Switching in Polymeric Matrices

In order for any molecular switch to be useful in future nanotechnological applications, the system should retain its properties when incorporated in a processable matrix. Incorporation into a polymer matrix would, for example, offer a photoswitchable film for reversible data storage. For this purpose, a polymer-bound sterically overcrowded alkene **10** was designed (Fig. 5).<sup>[39]</sup> Irradiation of thin films of this chiral photochromic polymer results in distinct changes in the CD spectrum, but **10** suffers from low switching selectivity and long irradiation times.

Photochemical switching of polymers doped with sterically overcrowded alkenes revealed that photo-switching was possible in a polymer matrix. The isomerization processes, however, critically depend on the mobility in the matrix. The restrictive polymer matrix slows down this process to a large extent, and more effective applications of the sterically overcrowded alkenes as chiroptical molecular switches were found with more flexible liquid crystalline host materials.

**Fig. 5** Polymer-bound chiroptical molecular switch **10** ( $n = 1-5$ ;  $x/y \geq 95.3:4.7$ ).

### TOWARD APPLICATIONS: SWITCHING OF LIQUID CRYSTALLINE PHASES

Liquid crystals (LCs), which are already widely applied in, for example, display technology, form excellent host materials for chiral molecular switches. When doped with a suitable molecular switch as a guest, liquid crystals offer a processable photoswitchable material, with essential features for application of these systems. Nematic liquid crystals are especially appealing for use in combination with these chiral guest compounds because they are extremely sensitive toward chiral perturbations forming chiral nematic or cholesteric phases. In their cholesteric packing, the mesogenic host molecules amplify the molecular chirality of the guest material resulting in a macroscopic chiral helical packing. Cholesteric phases can be assigned by a helical packing of the mesogens with a certain sign and a certain pitch.<sup>[40–42]</sup> This pitch is a measure of the chirality of the system. An important property of cholesteric liquid crystals for potential technological application is that they show unique optical properties when the pitch is of the same magnitude as the wavelengths of visible light. When illuminated with white light, cholesteric phases reflect light of a certain wavelength (color) dependent on the pitch of the LC phase. The interest in colored doped cholesteric phases in the research on chiroptical molecular switches is twofold. When chiroptical molecular switches can induce pitch lengths resembling the dimensions of the wavelength of visible light, a direct color readout of written information is possible. On the other hand, direct tuning of the color of the cholesteric phase opens the opportunity to develop color liquid crystal display materials addressable by light, i.e., color pixel formation.

### Enantiomeric Switches in a Liquid Crystal Matrix

A main goal of the research on enantiomeric switches has been the development of a potential liquid crystal phototrigger based on CPL. Because nematic materials are extremely sensitive to chiral perturbations, changes in LC films can even reflect enantiomeric excesses as small as 0.07% as found for **1**.<sup>[26]</sup> Irradiation with (*l*)-CPL (313 nm) of racemic **1** doped in a nematic LC host M15 resulted in the formation of a negative cholesteric phase. The molecular chirality controlled by circularly polarized light is amplified by the liquid crystalline environment. Accordingly, irradiation with (*r*)-CPL (again 313 nm) resulted in a cholesteric phase of opposite positive screw sense. The amount of dopant needed to obtain a measurable cholesteric phase is relatively large (20 wt.%) because of the small enantiomeric excesses reached in the photostationary state. Irradiation of the cholesteric film with linear polarized

**Scheme 10** Schematic representation of CPL switching between different liquid crystalline phases.

light at 313 nm resulted in an achiral compensated nematic phase. The two chiral influences (*l*- and *r*-)CPL at the most efficient wavelength stimulate the two extreme photostationary states. Actually, this macroscopic switchable material represents a multistate switch in which the cholesteric phases with intermediate pitches can be addressed by changing, for example, the irradiation time or wavelength (Scheme 10).

### Pseudoenantiomeric Switches in a Liquid Crystal Matrix

The photochemical modulation of the helical screw sense and the pitch of a cholesteric phase was also realized with the combination of a nematic liquid crystalline host and donor–acceptor switch **3**.<sup>[43]</sup> Different liquid crystals can be used as a host and show comparable results. For example, doping of liquid crystalline compound M15 with (*P*)-*trans*-**3** (2.4 wt.%) converts the nematic phase into a cholesteric phase. Irradiation at 365 or 435 nm of a thin film of this cholesteric phase led to photostationary states with an excess of (*M*)-*cis*-**3** or an excess of (*P*)-*trans*-**3**, comparable to the system in *n*-hexane solution. These two cholesteric phases show different pitches and opposite screw sense (+8.5 and –12.2 μm), as expected from the pseudoenantiomeric relationship of the two forms of the photoswitchable dopant. Switching efficiencies in a liquid crystalline environment and in solution are more or less equal, but irradiation times have increased. Doping concentrations are, however, limited for this particular system. For this reason, compound **6** with

a solubilizing *n*-hexyl tail was synthesized (*vide supra*) and an increase in compatibility was observed in all tested nematic host materials.

For compound **6**, a cholesteric phase was readily induced by doping with either one of the enantiomerically pure forms of **6** in all tested nematic liquid crystalline hosts. The molecular chirality of the dopant was amplified to provide a macroscopic chirality of the liquid crystalline phase comparable to compound **3**. Using a 2.6-wt.% sample of **6** in M15, for example, switching between cholesteric phases with pitches of +10.1 and –12.0 μm was achieved using 380- and 435-nm light, respectively. A material of choice for further improvement of the system is E7, a commercially applied LC mixture which is liquid crystalline at room temperature. Ideal switching wavelengths in this LC host were determined to be 380 and 470 nm. Using again a 2.6-wt.% sample, switching between cholesteric phases with pitches of +5.1 and –5.5 μm was possible. These values represent the minimum pitches that can be reached for a 2.6-wt.% sample. By changing the irradiation time or the irradiation wavelength, cholesteric phases with intermediate pitches, including a compensated nematic phase, are addressable (Scheme 11).

### Controlling the Color of Cholesteric Phases

As indicated above, to obtain colored LC phases, pitches in the range of nanometers are required. Although the dopant concentration for **6** in E7 can be further increased, for LC color application, a different host system has to be used. For two important reasons, the system of choice was a chiral polymerizable cholesteric acrylate mixture (**11** and **12**) developed by Philips Research (Fig. 6).<sup>[44–47]</sup> First of all, because of the presence of a chiral diacrylate, the LC host already shows a colored cholesteric phase. Upon doping with a chiroptical switch, the color of the LC phase only has to be influenced rather than fully induced. A second important property of this system is that because of the presence of an achiral monoacrylate and a chiral diacrylate, this system can undergo photopolymerization when a suitable photoinitiator is present. This photopolymerization process locks the cholesteric phase to generate a stable polymeric matrix reflecting the optical properties of the initial liquid crystal matrix. This could allow stable storage of information. The principle was demonstrated using a mixture of 40% chiral (*S,S*)-diacrylate **11** with 60% achiral monoacrylate **12** (forthwith denoted as **11/12**). This mixture forms a green cholesteric phase with a maximum reflection wavelength of about 440 nm.

Switching properties of **6** were retained in this acrylate mixture.<sup>[35]</sup> Upon 435-nm irradiation, a photostationary

**Scheme 11** Schematic representation of the switching of the chirality of a doped cholesteric liquid crystal.

state was reached with a ratio *cis*-**6**/*trans*-**6** of 67:33. Irradiation at 380 nm resulted in a photostationary state of 31% *cis*-**6** and 69% *trans*-**6**. In all doped cases, the reflection wavelength was red-shifted compared with the undoped mixture.

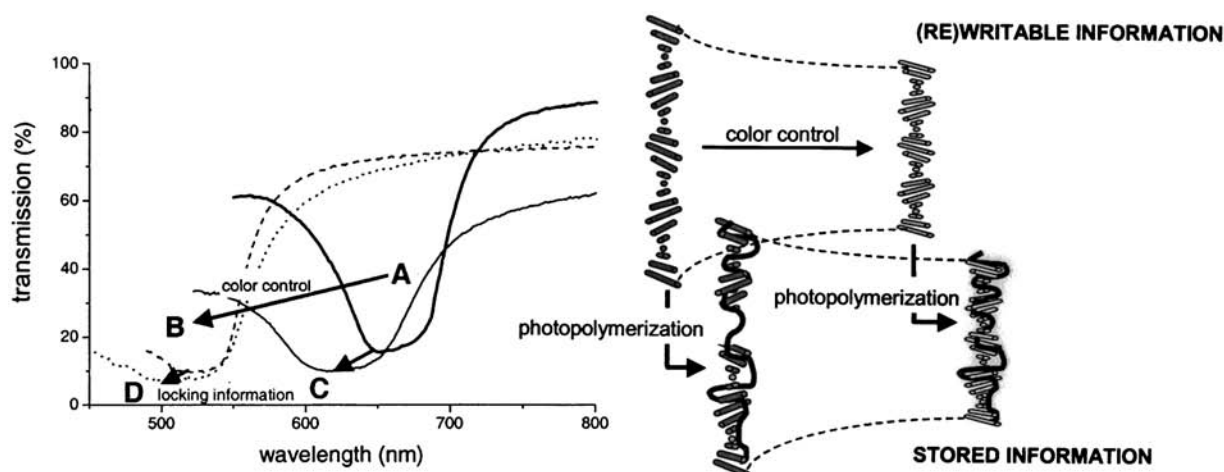

Switching experiments were performed on an aligned sample with 12.5 wt.% of enantiomerically pure (*M*)-*trans*-**6** in the presence of 1 wt.% of photoinitiator (Irgacure 651) and 1 wt.% of inhibitor (*p*-methoxyphenol) at 435-nm irradiation. At this wavelength, no polymerization is initiated and a *trans* to *cis* isomerization of the chiral dopant is the only process observed. Upon photoisomerization, the reflection band of the LC film was gradually shifted to shorter wavelength. Starting at a reflection wavelength of 666 nm (red), a blue shift of the reflection wavelength to 541 nm (green) was observed at the photostationary state after about 150 sec of irradiation (Fig. 7). When increasing the irradiation wavelength using a 450-nm cutoff filter, the wavelength of reflection could further be decreased to a value of 526 nm. This blue shift of 140 nm can also be induced directly by >450 nm irradiation of the initial pure (*M*)-*trans*-**6** doped film.

Photopolymerization of the LC film was effected by 5-min irradiation at 365 nm in vacuo. At this wavelength, photoisomerization of the dopant is expected to some extent. After the irradiation, the liquid crystalline phase was polymerized and a rigid polymer matrix was obtained. For the 12.5-wt.% sample of pure (*M*)-*trans*-**6** in **11/12**, photopolymerization resulted in a blue shift of the reflection from 666 nm in the monomeric state to 632 nm for the polymerized state. The photostationary mixture obtained after 450-nm irradiation, which showed a reflection of 526 nm in the monomeric state, gave a polymerized matrix with a 518-nm reflection. The obtained polymeric phases in all cases reflect the photostationary state of the chiral dopant. Furthermore, the polymerized phases are completely inert to prolonged irradiation and the photochemically written color information is effectively locked.

This system constitutes a “write and lock” mechanism for color information (Fig. 7). Writing is performed by light, and cholesteric phases with pitches between 666 and 526 nm can be induced by varying the irradiation time. Color inspection (red to green)

**Fig. 6** Photopolymerizable cholesteric mixture of monomeric acrylates **11** and **12**.

**Fig. 7** Color control of LC film: writing and locking information for a 12.5-wt.% sample of (*M*)-*trans*-6 in 11/12. Wavelength of reflection at different stages of the process: (A) initial sample; (B) photostationary state after 450-nm irradiation; (C) polymerized sample after 365-nm irradiation of the initial sample (A); (D) polymerized sample after 365-nm irradiation of the photostationary state (B) and a schematic representation of color control and storage of information by photopolymerization of a cholesteric liquid crystal.

offers an easy readout procedure. Further irradiation of this LC phase results in a change in the (*M*)-*trans*-6 to (*P*)-*cis*-6 ratio and, as a consequence, a change in the wavelength of reflection (the color) of the LC film, as long as the 450-nm photostationary state is not reached. This monomeric state can be considered a rewritable state. Upon photopolymerization, the LC matrix will harden and the written information is locked. Again, color inspection (orange to green) offers an easy readout procedure which is now absolutely non-destructive. The information is locked and there is no change in cholesteric pitch observed upon further irradiation.

### STERICALLY OVERCROWDED ALKENES AS UNIDIRECTIONAL ROTARY MOTORS

The design and synthesis of molecular motors are among the major endeavors in nanoscience. Inevitable motor functions will be needed to power nanomachines, although the design and functioning might be completely different from any known macroscopic or biological motor. We formulated three basic requirements for a molecular motor system: 1) repetitive 360° rotary motion; 2) consumption of energy; and 3) unidirectional rotation. The first chemically driven<sup>[48–50]</sup> and photochemically driven unidirectional rotary motors<sup>[51]</sup> were reported simultaneously.<sup>[52]</sup> Until these accomplishments, no synthetic system could be classified as a molecular motor according to the prerequisites formulated above.

The chiroptical molecular switches already show a unidirectional rotation of about 105° where the

direction of the movement is solely governed by the helicity in the initial state, and this process is driven by light. In the design of molecular motors, using sterically overcrowded alkenes as the basic structure, an extension of the rotary movement is necessary and the light-induced motion during the switching event should continue in the same direction. Realizing that these sterically overcrowded alkenes consist of four stereoisomers, i.e., the pseudoenantiomeric forms that constitute the two switching stages and their enantiomers, the possibility of full 360° rotation arises as illustrated briefly for compound 9 (vide supra).

### The First Light-Driven Unidirectional Molecular Motor

Following extensive study on the thermal and photochemical isomerization processes of biphenanthrylidene,<sup>[53–56]</sup> it was demonstrated that the intrinsic chirality associated with sterically overcrowded alkenes can be used to accomplish unidirectional rotary motion.<sup>[57–59]</sup> In compound (*3R*, *3'R*)-13 (Scheme 12), the sterically overcrowded alkene skeleton bears two additional stereogenic centers besides the (*P,P*)-helical structure. In its most stable conformation (*P,P*)-*trans*-13, the two methyl substituents adopt an energetically favored axial orientation because of steric hindrance (Scheme 12). Irradiation with light ( $\lambda \geq 280$  nm) results in an isomerization process (step 1) to form (*M,M*)-*cis*-13. Inherent to the nature of such an isomerization, the methyl substituents are forced to adopt an energetically unfavorable equatorial orientation. At room temperature, a fast helix inversion

**Scheme 12** Light-driven unidirectional molecular motor **13**.

(step 2) takes place resulting in *(P,P)-cis-13* where the methyl substituents again adopt an axial orientation. A second photoisomerization step (step 3) results in the formation of *(M,M)-trans-13* with the methyl substituents again in their energetically unfavorable equatorial position. A second helix inversion (step 4) is induced by heating at  $60^\circ\text{C}$  and results in the formation of the initial *(P,P)-trans-13* isomer.

These four discrete steps add up to a full  $360^\circ$  unidirectional rotation of one (rotor) half of the molecule relative to the other (stator) half. Two photochemical energetically uphill isomerizations driving the rotary movement (steps 1 and 3) are each followed by two irreversible energetically downhill thermal helix inversions (steps 2 and 4). The release of internal energy of the system that takes place during helix inversion, to place the methyl substituents again in the more favorable axial orientation, ensures the unidirectionality of the process. The direction of rotation is solely governed by the configuration of the stereogenic centers because this determines the axial or equatorial orientation of the methyl groups. Essential features of the rotating system are the central olefinic bond, the helicity of the overcrowded alkene, the absolute configuration of the stereogenic centers, and the conformational flexibility of the cyclohexenyl rings. Because of the same wavelength used for both photoisomerization steps, a repetitive unidirectional rotation can be induced by continuous irradiation at elevated

temperature. This is the first example of a light-driven unidirectional molecular motor as illustrated in Fig. 8.

### Second-Generation Molecular Motor

One drawback of the first-generation motor is the thermal requirement of the system, and although photon energy is the driving force, heating to about  $60^\circ\text{C}$  is necessary to continue the rotary motion. A second drawback is that this system has little opportunities for structural variation. To overcome these drawbacks, a so-called second-generation motor concept was

**Fig. 8** Continuous unidirectionally rotating molecular motor **13**.

developed combining the design versatility of our chiroptical molecular switches with the unique rotary behavior of the first-generation molecular motor (Fig. 9). In this concept, one-half of the molecule (a chiral 2-methyl-2,3-dihydrothiopyran upper part) would function as the rotor part, while the other could be used for adjusting the molecular properties by synthetic modifications. The main question was whether the presence of a single stereogenic center would suffice to induce unidirectional rotation.

The prototype system that was synthesized is compound (*2'R*)-**14**.<sup>[60]</sup> Analogous to the first-generation molecular motor, for **14**, a strong preference for an axial conformation of the methyl group at the stereogenic center was established. This stereochemical feature is essential to achieve unidirectional rotation. Starting from the energetically favored (*2'R*)-(*M*)-*trans*-**14** isomer, by irradiation with 365-nm light, a *trans* to *cis* isomerization was induced. This resulted in the corresponding less stable isomer (*P*)-*cis*-**14**, completely analogous to the first-generation molecular motor. Upon heating to 60°C, the unstable *cis*-isomer (*P*)-*cis*-**14** is converted to the stable (*2'R*)-(*M*)-*cis*-form. A second energetically uphill photoisomerization step yields the unstable (*2'R*)-(*P*)-*trans*-form which, upon heating, reverts again to stable (*2'R*)-(*M*)-*trans*-**14**, completing a full unidirectional 360° rotation of the rotor upper half relative to the stator lower half of the molecule (Scheme 13).

The direction of rotation in this second-generation motor is again dictated by the orientation of the methyl substituent at the stereogenic center. The process is solely driven by two light-induced energetically uphill photoisomerization processes, forcing the methyl substituent in the upper half of the molecule

**Scheme 13** First example of unidirectional rotation controlled by a single stereogenic center; the prototype of the second-generation motor **14**.

in an energetically unfavorable equatorial conformation. The release of internal energy is accomplished by a helix inversion step where the methyl substituent adopts the favorable axial conformation. These two energetically downhill processes ensure the unidirectionality of the entire rotary motion.

Following this proof of principle, an important objective was to decrease the barrier for the thermal helix inversion steps to allow rotation at room temperature. The approach focused on modification of the bridging groups X and Y (Fig. 9) to tune the steric

**Fig. 9** Design of second-generation motors.

**Fig. 10** Second-generation motor: unidirectional rotation controlled by a single stereogenic center and structural modifications that allow control of rotary behavior.

hindrance at the fjord region of the molecules. Based on the experience with the molecular switches, compounds **15**, **16**, and **17** were synthesized in which, because of decreased dimensions of the (hetero-)atoms X and Y (O and CH<sub>2</sub> compared with S), helix inversion was expected to be facilitated (Fig. 10).<sup>[61]</sup> Changing the sulfur atom (in **15**) for an oxygen atom in the lower half (in **16**) resulted in a decrease in the half-life (in *n*-hexane) at room temperature by a factor of about 8. Replacing a sulfur by a carbon atom in the upper half decreased the half-life by a factor of about 320. This resulted in a motor **17** with a half-life for thermal helix inversion of about 2400 sec at room temperature allowing unidirectional rotation under ambient conditions.

In an attempt to further reduce these energy barriers, a new motor **18** with a tetrahydronaphthalene instead of a tetrahydrophenanthrene upper part used in the other second-generation motors including parent compound **19** was synthesized (Fig. 11).<sup>[62]</sup> Counterintuitively, for motor system **18**, the rotary motion is severely slowed down. This remarkable effect was attributed to a higher ground state energy of motor **19** compared with **18**. It is evident that there is a delicate balance between ground-state distortion and steric and electronic effects on the photochemical and thermal isomerization processes in these sterically overcrowded alkenes.

Another objective is the design of a system that can function under the influence of visible light. For this purpose, the absorption of the molecules has to be shifted from the UV region to the visible region.

**Fig. 11** Tetrahydronaphthalene (**18**) and tetrahydrophenanthrene-based (**19**) motor.

Asymmetric donor–acceptor substitution in **20** was expected to induce a red shift in UV/Vis absorption (Scheme 14).<sup>[63]</sup> Fig. 12 clearly shows that the UV/Vis absorption of both isomers of **20** extends to about 500 nm implying the possibility of excitation of these photoisomerizable compounds in the visible region of the spectrum.

Completely analogous to other second-generation motors, irradiation of enantiomerically pure (2'*R*)-(M)-*cis*-**20** with visible light of 435 nm resulted in the formation of less stable (2'*R*)-(P)-*trans*-**20** (Scheme 14). In this compound, the methyl substituent is forced to adopt an equatorial orientation. Subsequent heating at 50°C resulted in the formation of the stable (2'*R*)-(M)-*trans*-**20**. Irradiation of (M)-*trans*-**20** with visible (435 nm) light induced a second isomerization and the formation of energetically unfavorable (P)-*cis*-**24**. Heating the system to 50°C resulted in a helix inversion to form (M)-*cis*-**20** again. The combined four-step rotary cycle ensures that compound **20** functions as a molecular motor that can be driven by visible light.

## UNIDIRECTIONAL ROTARY MOTION IN A LIQUID CRYSTALLINE ENVIRONMENT

In the first-generation molecular motor, the energy of the irradiation light is used to exert mechanical motion. The next step toward any nanotechnological application of such a motor would be to actually drive other functions or perform work. In addition, for future application of these molecular motors, conservation of the molecular properties in an organized medium is essential. Combining the properties of our first molecular motor **13** with those of liquid crystalline materials is a first step in the direction of a nanotechnological application. The essence of the research is to examine whether the control of molecular rotation that can be exerted by light irradiation can be amplified to control the motion of a large ensemble of molecules and, as a consequence, the macroscopic (chiral) properties in a liquid crystalline phase, thereby allowing indirect macroscopic visualization of rotary motion.

Compound **13** (Scheme 12) efficiently induces cholesteric phases for different mesogenic host compounds. A helical twisting power of +69 μm<sup>-1</sup>, for example, was found for (P,P)-*trans*-**13** in E7.<sup>[64]</sup> The rotary process in the liquid crystalline matrix was tested using a drop-casted sample of E7 doped with 2.4 wt.% of (P,P)-*trans*-**13** and was shown to be analogous to solution experiments (Scheme 12). Unidirectional rotation was proven to be possible in a liquid crystalline matrix. It should be noted, however, that during the heating step, the LC material was in an isotropic stage, and as a consequence, the orientation is

**Scheme 14** Visible light-driven unidirectional rotation of donor-acceptor motor **20**.

temporarily lost. The whole light-driven process is less efficient in a liquid crystal than in solution for two important reasons: 1) the absorption of the LC material reduces the amount of photons that will actually reach the photoisomerizable material, which is evident from the strong dependence of isomerization efficiency on substrate thickness; and 2) because of the absorption of the LC material, the wavelength range that actually reaches the compound is  $>340$  nm which causes a shift in the two photoequilibria.

The high helical twisting powers for (*P,P*)-**trans-13** open up the possibility to generate cholesteric phases with pitch lengths in the range of the wavelength of visible light. Doping of E7 with only 6.16 wt.% of (*P,P*)-**trans-13** resulted in a violet cholesteric phase with a pitch of 234 nm and a reflection wavelength (at an angle of  $45^\circ$ ) of 357 nm. From the ratio and the pitches

of the 2.4-wt.% sample discussed above, the helical twisting powers of (*P,P*)-**cis-13** and (*M,M*)-**trans-13** could be calculated to be  $+12$  and  $-5 \mu\text{m}^{-1}$ , respectively. The dramatic decrease in the helical twisting power going from (*P,P*)-**trans-13** to the other isomers is essential for generating light-induced macroscopic changes by unidirectional rotation. Upon irradiation ( $\lambda \geq 280$  nm) of the violet film of 6.16 wt.% of (*P,P*)-**trans-13** in E7, a fast bathochromic shift of the reflection wavelength was induced. In only 80 sec, the color of the film changed from violet via blue, green, yellow, and orange to red as can be readily detected by visual inspection. The time-dependent quantitative change in reflection wavelength measured at a  $45^\circ$  angle is presented in Fig. 13.

**Fig. 12** UV/Vis absorption of *cis*-**20** (solid) and *trans*-**20** (dashed) in chloroform.

**Fig. 13** Wavelength of reflection at a  $45^\circ$  angle of a molecular motor doped LC phase (6.16 wt.% in E7) as a function of time starting from (*P,P*)-**trans-13** upon irradiation with  $>280$  nm.

**Fig. 14** Schematic representation of unidirectional rotation of the guest molecular motor **13**, the induced elongation of the pitch of the LC host matrix, and the change in reflection wavelength of the light.

After heating the sample to 60°C at any time of irradiation, the *(M,M)*-*trans*-**13** isomer is converted to *(P,P)*-*trans*-**13** with a concomitant hypsochromic shift of the reflection wavelength. Again, during the heating process, the LC material was in an isotropic stage, and as a consequence, the orientation is temporarily lost.

These results show that unidirectional rotary motion could be performed in a LC matrix, as is schematically illustrated in Fig. 14. The light-driven motion in the dopant induces the motion of a large ensemble of rod-like molecules during the reorganization in the LC film. This indirectly allows visual observation of the rotary motion, but, more importantly, shows that rotation on a molecular level can be used to drive a reorganization of a macroscopic liquid crystalline film. Furthermore, it demonstrates that the molecular motor can perform actual work.

## CONCLUSION

It has been shown that chiral sterically overcrowded alkenes are extremely suitable for functioning as molecular switches and motors. Chiroptical switches based on sterically overcrowded alkenes were constructed that could function both in solution as well as in a liquid crystalline matrix. These switches might be used as molecular trigger elements or as reversible data storage units at the molecular level. The first light-driven molecular motors were also based on an overcrowded alkene. By combining two chiral elements (helical structure and stereogenic center) in the same photoactive molecule, the fundamental properties of

a molecular motor, energy consumption resulting in unidirectional rotary motion, were demonstrated. This prototype system led to the development of a second-generation of molecular motors for which tuning of the rotation speed and irradiation wavelength was proven to be possible. All the systems developed are still far from actual application, but they offer a solid basis for the development of future generations of switches and motors to meet the numerous challenges ahead on the road toward nanomechanical machinery.

# Molecular Wires

Dustin K. James

James M. Tour

Chemistry Department, Rice University, Houston, Texas, U.S.A.

## INTRODUCTION

Electrical wiring is used all around us in today's world. Metallic wiring 1 cm in diameter facilitates the flow of electrons that power our household lighting, radios, televisions, and other appliances such as computers. Within those appliances and computers, wires 1 mm wide on printed circuit boards connect electronic devices such as resistors, rheostats, and logic chips. Inside those logic chips, wires tenths of a micrometer wide connect solid-state transistors, carved out of silicon, and allow them to act in concert with thousands of similar transistors to carry out computations. This last size reduction nearly reaches what is thought to be the limit of present semiconductor manufacturing technology. To enable further miniaturization, recent research has produced molecular-scale wires, ranging in length from 1 to 100 nm. In this entry, we will review the state of the art in the synthesis and characterization of molecular wires and examine theoretical work concerning how they are thought to conduct electricity.

## Molecular Electronics

The rapidly developing field of molecular electronics is one of the driving forces behind the interest in molecular wires.<sup>[1–8]</sup> The limitations of the present “top-down” method of producing semiconductor-based devices have been the subject of debate and conjecture since the prediction of Moore<sup>[9]</sup> that the number of components per integrated circuit would double every 18 months. It is thought that the inherent limitations of the present technology will lead to a dead end in the next few years. For instance, silicon's band structure disappears when silicon layers are just a few atoms thick. Lithographic techniques that are used to produce the circuitry on the silicon wafers are limited by the wavelengths at which they work. However, leaders in the semiconductor manufacturing world are still making advances that appear to be

pushing “Moore's law” beyond its prior perceived limits. In the commercial technology of 2001, the copper wires in Intel's Pentium® 4 logic chip are 0.13 μm wide.<sup>[10]</sup> Intel is developing technology to create logic chips with wires 90 nm wide to be commercialized in 2003.<sup>[11]</sup>

For comparison's sake, a typical molecular wire synthesized in our laboratory is calculated to be 0.3 nm wide and 2.5 nm long (Fig. 1).<sup>[4]</sup> It would take 300 of these molecules, side by side, to span the 90-nm metal line in the most advanced logic chip in development. The small size of these molecules is emphasized when one considers that 500 g (about 1 mol) of this wire would contain  $6 \times 10^{23}$  molecules, or more molecules than the number of transistors ever made in the history of the world. This amount of material could be produced using relatively small 22-L laboratory reaction flasks. Changing the physical characteristics of this wire is as easy as changing the raw materials used to make it. The small size, the potential of synthesizing huge numbers in small reactors, and the ease of modification of the physical characteristics of the molecules are good reasons for pursuing molecular wire research. As an example of how far the technology has come, molecular electronics is discussed in the “Emerging Research Devices” section of the most recent International Technology Roadmap for Semiconductors<sup>[12,13]</sup> and new molecular wires are a large part of the emerging technology. Molecular electronics was named the “breakthrough of the year” by Science<sup>[14]</sup> for 2001.

## Optoelectronics

Because of their chemical structure, some highly conjugated molecular wires have applications in optoelectronics.<sup>[15–17]</sup> Poly(phenylene vinylene)s are being used as components in organic light-emitting diodes (OLEDs) in displays such as those used in cellular phones and other electronic devices. Various other polymeric materials and small molecules are also being used or are in development.

**Fig. 1** The dimensions of a typical molecular wire are calculated to be 0.3 nm in width and 2.5 nm in length using molecular mechanics (Spartan) to determine the energy-minimized structure. *Source:* From Ref.<sup>[4]</sup>.

These materials are applied in very thin layers about 100 nm thick, with the organic small molecules forming crystalline phases. This is quite different from the molecular electronics field, where it is envisioned that single molecules will eventually be used in circuits. However, much of the literature we will review addresses the optoelectronics applications of the molecular wires, and so we have included leading references for that area of research.

## MOLECULAR WIRES

In this work, when we say “molecular wires,” we mean discrete molecules, not crystals or films. We accept the statement of Cotton et al.<sup>[18]</sup> that linear chains of metal atoms that exist only in the solid state via the stacking of flat molecules, or through the formation of  $\mu$ -bridged chains of octahedral molecules (such as  $\text{NbCl}_4$ ) should not be called molecular wires. The extremely interesting inorganic crystalline nanowires being developed by Hu, Odom, and Lieber<sup>[19]</sup> Chung, Yu, and Heath<sup>[20]</sup> Cui and Lieber,<sup>[21]</sup> and Gudiksen, Wang, and Lieber<sup>[22]</sup> may eventually be used as wiring

in molecular electronics-based circuitry, but the fact that they comprise crystalline phases and not discrete molecules precludes their inclusion in this review.

In our survey of the literature, we find two general types of molecular wires. The largest portion of the literature, including most of our work, covers organic molecular wires. A smaller portion of the literature covers organometallic molecular wires. We include what some may call inorganic molecular wires in the organometallic class because of the ease of classification and the small number of inorganic molecular wires in the literature.

Molecular wires are meant to conduct electricity between two points of a circuit. However, a majority of the molecular wires intended for molecular electronics have never been tested in an actual circuit. One reason for this is that it is difficult to do so because of their small size. Another reason is that there is not one generally accepted test-bed that is readily available to all researchers. Rather, there are several different test-beds in the literature,<sup>[23–26]</sup> and the results from those molecular wires that have been tested are, in many cases, not comparable. These devices are difficult to make, yields are low, and obtaining reproducible results requires care and patience. Drawing conclusions about the activity of the classes of compounds, or building structure–activity relationships among several classes using the data generated can be a difficult exercise. However, because it has been shown that aromatic thiols are much higher conducting than alkane thiols<sup>[27]</sup> when bonded to Au surfaces, much attention has focused on conjugated aromatic molecular wires (*vide infra*).

## Organic Molecular Wires

### Oligo(2,5-thiophene ethynylene)s

Our group has focused on the synthesis of organic molecular wires. One class of compounds synthesized are the oligo(2,5-thiophene ethynylene)s (OTEs), several examples of which are compounds **1–5**, as shown in Fig. 2.<sup>[28–31]</sup> This class of rigid-rod oligomeric molecular wires was made through an iterative divergent–convergent synthesis method that allowed the quick assembly of the products, doubling their length at each step. The longest molecular wire synthesized was 12.8 nm in length. Note that these wires have thioester groups at one or both ends. When deprotected *in situ*, the thiol groups enable the molecular wires to adhere to Au (or other metal) surfaces,<sup>[27]</sup> thus serving as “alligator clips.” When large numbers of molecular wires bond to Au in a regular packed array, through this self-assembly process, the group of molecules is called a self-assembled monolayer (SAM). The bonding of

**Fig. 2** Oligo(2,5-thiophene ethynylene) molecular wires **1–5** synthesized by the authors. *Source:* From Ref.<sup>[28]</sup>. Note that **1–4** have thioester termini on one end only, whereas molecular wire **5** has thioester termini on both ends. The length of **5** is 12.8 nm for its energy-minimized conformation.

the S atom to Au enables the flow of electricity from the Au metal Fermi levels through the S molecular orbitals to the molecular orbitals formed by the conjugated portion of the molecule (see “[Theory and Measurement of Conduction](#)” and references cited therein for a discussion of this phenomena). The ethynyl units in between the aromatic molecules are used to maintain a maximum overlap of the orbitals and to keep the molecules in a rodlike shape. The various side chains appended to the thiophene cores were intended to increase the organic solvent solubility of the wires. Unfunctionalized rigid rod oligomers of this length suffer from severe solubility problems.

#### Oligo(1,4-phenylene ethynylene)s

A second class of molecules that has been studied extensively in our laboratory<sup>[32]</sup> and by others<sup>[33,34]</sup> are the oligo(1,4-phenylene ethynylene)s (OPEs). The molecule shown in [Fig. 1](#) is of this class, as are the molecules shown in [Fig. 3](#). As with the OTEs, the OPEs can be rapidly synthesized using transition metal-catalyzed coupling reactions. In this case, the compounds were synthesized in both solution phase and on a polymer-based solid resin. Compounds **6–9**

of [Fig. 3](#) are intermediates that were produced by cleaving the products from the resin using iodomethane and by coupling the resulting aryl iodides to the alligator clip acetyl(4-ethynylthiophenol) using typical transition metal-catalyzed coupling reactions.<sup>[32]</sup> The removal of the trimethylsilyl-protecting groups from the alkynes produced compounds **10–12** (from **6**, **7**, and **9**, respectively), and the coupling of the terminal alkyne in each case to acetyl(4-iodothiophenol) produced compounds **13** and **14** (from **10** and **12**, respectively). As in the OTEs, the C<sub>12</sub> side chains were used to impart organic solubility to the products. The use of longer side chains such as C<sub>16</sub> can result in side-chain interdigitation, leading to insolubility problems rather than increasing solubility.

In a series of syntheses of molecules in OPE subclasses, we have made products with more than two terminals and derivatives that are meant to test the necessity for a completely conjugated system.<sup>[35]</sup> [Fig. 4](#) shows a three-terminal molecular wire **15**. Note that all three terminals are functionalized with a protected thiol alligator clip, and that three of the aromatic nuclei have ethyl side chains to provide additional organic solvent solubility to the molecule. [Fig. 5](#) shows a three-terminal molecular wire **16** that contains an

**Fig. 3** A series of oligo(phenylene ethynylene)s (OPEs) was synthesized using a polymer support to increase the yields and to facilitate purification. *Source:* From Ref.<sup>[32]</sup>.

interior methylene group as a possible barrier to current. **Fig. 6** shows two four-terminal molecular wires **17** and **18**, each with one methylene group interior current barrier. **Fig. 7** shows two four-terminal molecular wires **19** and **20**, each with two methylene group interior current barriers. The unfortunate circumstance is that, presently, no reliable system exists for testing these three-terminal and four-terminal molecular wires, so it is unknown whether or not the interior methylene group barriers are indeed resistant to current. However, the conductance of alkanethiolates (containing no aromatic conjugation whatsoever) on Au surfaces has been determined and has been shown to be less than that of conjugated systems (vida infra).

To further explore the organic functionality necessary for molecular wires to carry current, we have synthesized a group of two-terminal molecular wires **21–26**, shown in **Fig. 8**, which contains interior methylene or ethylene group barriers to electrical conduction, and which could be tested using presently known testbeds.<sup>[35]</sup> Each of these was synthesized using relatively straightforward chemistry, a fact that illustrates our earlier claim that it is easy to explore molecular wire

**Fig. 4** A three-terminal molecular wire that is functionalized with an alligator clip at each terminus and contains side-chain ethyl groups for solubility. *Source:* From Ref.<sup>[35]</sup>.

space by changing just one or two aspects of the synthesis. We also synthesized a series of OPEs with different alligator clips to see what effect that variation would have on the conductance of the molecular wire,<sup>[36]</sup> and we have developed combinatorial chemistry routes that will be capable of the synthesis of tens to hundreds of new molecular wires at one time.<sup>[37]</sup>

When members of the OPE family were functionalized with groups other than aliphatic ones (see **Fig. 9**),

**Fig. 5** A three-terminal molecular wire containing an interior methylene group meant to serve as a possible small gate-like barrier to electrical current. *Source:* From Ref.<sup>[35]</sup>.

**Fig. 6** Two four-terminal molecular wires **17** and **18**, each containing an interior methylene group intended to be a gate-like barrier to current. *Source:* From Ref.<sup>[35]</sup>.

we began to see switching behavior,<sup>[24,38,39]</sup> although there is some question about whether the switching behavior results from molecular tilting modulations in the metal/molecule contact,<sup>[38]</sup> or from molecularly inherent features.<sup>[24]</sup> In the nanopore,<sup>[24]</sup> molecular wire **27** and amine-functionalized **29** had no activity,

whereas nitro-functionalized **28** and **30** were both active switches; conversely, analysis by scanning tunneling microscopy (STM)<sup>[38]</sup> indicated that all three of **27**, **28**, and **30** underwent conformational-based switching (**29** was not tested in the STM experiment) (see Refs.<sup>[1,2]</sup> for more information on switching). This

**Fig. 7** Two four-terminal molecular wires **19** and **20**, with each terminal having a protected alligator clip and each molecular wire having two interior methylene group current barriers. *Source:* From Ref.<sup>[35]</sup>.

**Fig. 8** Molecular wires **21–26**, each containing an interior methylene or ethylene group barrier to conduction. *Source:* From Ref.<sup>[35]</sup>.

underscores that fact that varying test-beds can afford widely different results.

### Oligo(phenylene vinylene)s

A third class of compounds that has been studied in our laboratories as well as in others' are the oligo-

**Fig. 9** Unfunctionalized OPE **27** and functionalized OPEs **28–30**. *Source:* From Refs.<sup>[24]</sup> and <sup>[38]</sup>.

(phenylene vinylene)s (OPVs).<sup>[40–46]</sup> As mentioned earlier, the majority of others' works on OPVs have been geared toward applications in the optical and OLED field.<sup>[41–44,46]</sup> Our work produced molecular wires targeted for molecular electronics applications, and involved the synthesis of the three OPVs **31–33**, shown in Fig. 10. Note that **31** is unfunctionalized, containing only a protected thiol alligator clip for later SAM formation. After formation of the SAM, Au or other metals would be deposited, under vacuum, for the formation of the top contact to complete the circuit through the  $\pi$ -framework. We functionalized **32** with a nitro group on the interior aromatic core to determine if **32** would then act as a switch. Compound **32** is undergoing testing in a collaborator's laboratory. Finally, **33** was synthesized with both a nitro functional group and protected thiol groups at both ends so that it could span two Au contacts and form a circuit via a self-assembly process. This type of self-assembly process is important in our nanocell research program,<sup>[1]</sup> and is quite different from the approaches of others, who have not necessarily designed OPVs that are meant to connect two proximal probes, an interface to the present solid state-based technology.

Detert and Sugiono<sup>[46]</sup> synthesized a series of readily soluble OPVs shown in Fig. 11 to study their electronic spectra. They found that appending various

**Fig. 10** Three OPVs **31–33** synthesized by the authors. Source: From Ref.<sup>[40]</sup>.

electron-withdrawing groups to the terminal aromatic rings allowed the tuning of the electron affinity of the chromophore without significant changes in the spectra. When those same substituents were placed on the vinylene segments of the OPV molecules, strong bathochromic shifts were observed. Wong et al.<sup>[42]</sup> investigated similar substituent effects. Syamakumari, Schenning, and Meijer<sup>[41]</sup> and Gu et al.<sup>[43]</sup> synthesized large assemblies of OPVs attached to other molecules and measured their optical, electronic, and aggregation behaviors.

Sikes et al.<sup>[45]</sup> and Davis, Ratner, and Wasielewski<sup>[44]</sup> have used OPVs as core components of molecules (Fig. 12) synthesized to test electron tunneling and long distance electron transfer, respectively. Of the

compounds Sikes et al. synthesized, **35** spanned the most distance, 3.3 nm. The OPVs were assembled on a Au electrode and the tethered ferrocene redox species at the other end of the OPV bridge was exposed to an aqueous electrolyte. They used laser-induced temperature jump techniques to measure the rate constants of thermal interfacial electron transfer through the system and observed transfer through the OPV. They found that OPVs up to 2.8 nm in length were good conductors, with the transfer limited by structural reorganization.

In their study of a series of compounds including **36** (Fig. 12), the longest molecule tested, Davis, Ratner, and Wasielewski<sup>[44]</sup> found that electron transfer over long distances depends critically on the low-frequency torsional motions of the molecular wires (i.e., when the molecules twist and turn, their molecular orbitals do not line up in a fashion that favors fast electron transfer). But their tests were in solution rather than the more device-realistic molecule-surface attached patterns.

### Aromatic ladder oligomers

Our group has synthesized a vast array of aromatic ladder polymers<sup>[47,48]</sup> for use in conducting polymer and optoelectronic applications. However, we realized that for molecular electronic applications, the molecules we synthesized needed to have defined length and composition to be commercially useful as molecular wires.

As shown in Fig. 13, Gourdon<sup>[49]</sup> have synthesized two classes of conjugated ladder oligomers that maintain similar guidelines for molecular wires, including a defined length, rigidity, extended  $\pi$ -conjugation for good electron transfer, and good electronic coupling with metallic contacts. The oligo(quinoxaline) derivative **37** and oligo(benzoanthracene) molecular wire **38** were synthesized using standard condensation and coupling reactions. The oligo(quinoxaline) **37** has

**Fig. 11** A series of OPVs **34** synthesized by Detert and Sugiono<sup>[46]</sup> to study the effect that variation of substituents  $R_1$ ,  $R_2$ ,  $R_3$ , and  $R_4$  had on the electronic spectra.

**Fig. 12** Sikes et al.<sup>[45]</sup> synthesized a series of OPVs including **35** to test electron tunneling whereas Davis et al.<sup>[44]</sup> synthesized a series of OPVs including **36** to measure long distance electron transfer.

built-in alligator clips in the terminal 1,10-phenanthroline moieties. We have also synthesized molecular wires containing terminal pyridine and other nitrogen-containing functional groups.<sup>[36]</sup> Calculations have supported their use as alligator clips.<sup>[50]</sup> An iterative crossed divergent–convergent process that leads to rapid growth of the oligomers was developed to synthesize the oligo(benzoanthracene) **38**.

**Fig. 13** Gourdon<sup>[49]</sup> synthesized the aromatic ladder oligomers oligo(quinoxaline) **37** and the oligo(benzoanthracene) **38**.

### Oligophenylenes and polyphenylenes

The oligophenylene and polyphenylene classes of molecules, possessing a continuous overlap of molecular orbitals through extended conjugation without intervening groups such as alkynes or olefins, has been an active area of research for our group.<sup>[51–53]</sup> Grimsdale and Müllen<sup>[54]</sup> have synthesized a series of one-dimensional polyphenylenes including polyindeno-fluorene **39** and poly(9,9-diarylfuorene) **40**, shown in Fig. 14. The photoluminescence (PL) spectra of the series of polyindeno-fluorenes **39** all have maxima around 430 nm, making them possible candidates for OLED materials as well as molecular wires, although for applications in molecular electronics, one would normally want to be able to synthesize molecular wires with known lengths and constitutions because of concerns about homogeneity and materials handling. We have synthesized many oligophenylene derivatives<sup>[35,36]</sup> and generally find that the torsional twisting caused by the steric hindrance between the hydrogen atoms at the *ortho* positions of adjacent phenyl rings leads to decreased orbital overlap, and possibly lower conductance.

### Acetylene oligomers

Schenning et al.<sup>[55]</sup> and Livingston et al.<sup>[56]</sup> have synthesized the acetylene oligomer class of organic molecular wires. Their work included producing acetylene oligomers that are insulated via dendritic encapsulation (see Fig. 15). They found that the insulated

**Fig. 14** One-dimensional polyphenylene polymers **39** and **40** that have been synthesized by Grimsdale and Müllen.<sup>[54]</sup>

product **41** underwent ready isomerization around the double bond, producing a mixture of *E* and *Z* isomers that made purification of the materials difficult. Oligomeric acetylenic molecular wires that have been encapsulated within zeolites and other mesoporous materials show high electrochemical charge uptake.<sup>[57]</sup>

**Fig. 15** Encapsulated oligo(pentaacetylene) molecular wire **41** synthesized by Schenning et al.<sup>[55]</sup>

Taylor et al.<sup>[58]</sup> have published an approach to insulated molecular wires of the oligo(phenylene) class.

### Carbon nanotubes

Carbon nanotubes have been attractive candidates for use as molecular wires.<sup>[59,60]</sup> The so-called “cross-bar” approach to the development of a molecular electronics-based computer has, as one approach, the use of carbon nanotubes for the wiring between the molecular switches<sup>[5,8]</sup> of the circuitry. It is unfortunately difficult to work with carbon nanotubes because of their insolubility in most organic solvents,<sup>[61]</sup> and their tendency to form bundles of tubes that are difficult to separate. Several methods for the functionalization of the carbon nanotubes that may make it easier to handle the carbon nanotubes have been developed.<sup>[62,63]</sup> However, the same functionalization techniques can also destroy the electrical properties of the molecules.<sup>[2]</sup> Calculations by Seifert, Köhler, and Fravenheim<sup>[64]</sup> indicate that sidewall fluorination of carbon nanotubes could produce products with a wide range of characteristics from insulating to metallic-like behavior. It is possible that nanowires<sup>[19]</sup> will be used in the cross-bar computing devices instead of carbon nanotubes because of the easier synthesis and handling of the nanowires.

**Fig. 16** Porphyrins **42–45** synthesized by the authors. *Source:* From Ref.<sup>[35]</sup>. Zn, Cu, and Co metal atoms were inserted into **42**. Subsequent deprotection of the thiol acetates resulted in no metal ion loss.

### Organometallic Molecular Wires

We have synthesized molecules in the porphyrin class of molecular wires<sup>[35]</sup> and have recently returned to this work.<sup>[65]</sup> Fig. 16 shows four porphyrin derivatives made in our laboratories. Zn, Cu, and Co were all inserted into **42** using the corresponding hydrated metal acetates. Deprotection of the thiol acetates by NH<sub>4</sub>OH resulted in no loss of metal, as indicated

by subsequent nuclear magnetic resonance (NMR) analysis. Although being interesting compounds in and of themselves, **44** and **45** could also be intermediates in the synthesis of more complex molecular wires. A four-terminal porphyrin shown in Fig. 17 was also synthesized.

Ambroise et al.<sup>[66]</sup> have published a large body of work concerning the synthesis and testing of molecular “photonic” wires based on porphyrin molecules linked

**Fig. 17** A four terminal porphyrin-based molecular wire **46** synthesized by the authors. *Source:* From Ref.<sup>[35]</sup>.

**Fig. 18** The porphyrin hexamer **47** synthesized by Anderson,<sup>[67]</sup> with six porphyrin units linked through dialkynes.

by diaryl ethyne units to light-absorbing dyes. The energy absorbed by the dyes is transmitted through the porphyrin-diaryl-ethyne wires to a free-base porphyrin transmission unit. The quantum efficiency was determined to be very high, from 81 to >99%.

Anderson<sup>[67]</sup> has reviewed the synthesis and optoelectronic properties of conjugated porphyrin molecular wires. As with the OPTs, OPEs, and oligomeric acetylenes, alkyne moieties have been used to link porphyrin units to make longer molecular wires, such as **47** in Fig. 18. The estimated length of **47** is 8.3 nm from Si atom to Si atom. Anderson's work has shown that the electronic behavior of these types of systems can be attributed to strong interporphyrin conjugation in the ground state. This strong interaction is amplified in the excited states, and also in the oxidized and reduced forms of the porphyrin core.

Iengo et al.<sup>[68]</sup> have used self-assembly techniques to synthesize large metallacycles of porphyrins. By synthesizing porphyrins having two peripheral pyridine appendages at either 90° or 180° to each other, and by adding the requisite ionic metallic component such as the RuCl<sub>2</sub> complex of dimethylsulfoxide (DMSO), supramolecular structures are produced. This self-assembly process proceeds with two porphyrin and two RuCl<sub>2</sub> complexes forming (as one example) the molecule **48** shown in Fig. 19. The substitution of CO for DMSO in the RuCl<sub>2</sub> raw material forms a similar metallacycle with CO instead of DMSO as Ru ligands. By inserting Zn into the resulting porphyrin core and by exposing the mixture to 4,4'-bipyridine (which acts as a ligand for the Zn atoms at the porphyrin cores), a stacked complex was formed. The authors envisioned that such complexes, with their extended conjugation and metal centers, could harvest light energy and act as molecular wires.

The self-assembly of inorganic molecular wires in solution has been described by Kimizuku.<sup>[69]</sup> However, it is unknown whether this process would produce products usable in constructing devices.

**Fig. 19** The porphyrin metallacycle **48** synthesized by Iengo et al.<sup>[68]</sup>

Pyridine ligands are common in organometallic molecular wires,<sup>[70–72]</sup> with a review recently appearing.<sup>[73]</sup> For instance, Constable et al.<sup>[70]</sup> synthesized the molecular wire **49** shown in Fig. 20. The [Ru(terpy)<sub>2</sub>]<sup>2+</sup> salts by themselves are nonluminescent, whereas adding the 2,5-thiophenediyl spacers produces a molecular wire that is luminescent. Shiotsuka et al.<sup>[71]</sup> made a Ru–Au–Ru triad by using a bis-σ-Au-acetylide to connect two Ru complexes. The resulting molecular wire showed an intense emission at 620 nm upon excitation at 360 nm, suggesting some energy transfer from the Au to the Ru site via the π-conjugation offered by the ethynyl units. Berry et al.<sup>[72]</sup> synthesized a trinickel complex of the ligand di-2,2'-pyridylamide that had a deep blue color and showed metal–metal bonding interaction in the crystal structure.

An interesting mixed-valence molecular wire pair **50** and **51** synthesized by Stang, Paul, and Lapinte<sup>[74]</sup> is shown in Fig. 21. As we have seen in many of the molecular wires, both the thiophenyl and the alkynyl units are present in this molecular wire.

## THEORY AND MEASUREMENT OF CONDUCTION

### Theory of Conduction in Molecular Wires

The difficulties in obtaining direct measurements of current in molecular wires have not deterred theoretical chemists from developing models of the conductive

**Fig. 20** The molecular wire **49** synthesized by Constable et al.<sup>[70]</sup> that showed luminescence because of the presence of 2,5-thiophenediyl spacers.

process. This has been a very fruitful area of research. The editors of *Chemical Physics* recently devoted an entire issue to “Transport in Molecular Wires.”<sup>[75]</sup> We will briefly review the relevant literature here.

**Fig. 21** A mixed-valence complex pair of molecular wires **50** and **51** as synthesized by Stang et al.<sup>[74]</sup>

### The molecular wire–electrode interface

One of the most important aspects of the application of molecular wires is developing a method for contacting the molecular wire with the electrode that will be carrying the current to the molecular wire. Several researchers have examined the theoretical aspects of this connection.<sup>[76–79]</sup> Yaliraki, Kemp, and Ratner<sup>[76]</sup> examined the bonding of 1,4-bis(thiomethyl)benzene (**52** in Fig. 22) to metal surfaces using Green’s function and the extended Hückel Hamiltonian, and found that, except for the length of the surface bond, conductance through the molecule was not affected by the angle of the S-metal bond to the surface. They found that if Se substituted for S in the molecular wire, the conductance through the wire was larger (O substitution produced conductance of the same magnitude as S). They also found that Au made a better electrode than Ag. Note that a methylene node was between the terminal S atom and the aromatic benzene molecule, unlike other models where the S atom is directly bonded to the aromatic nucleus.

Using ab initio Hartree–Fock calculations, Johansson and Stafström<sup>[77]</sup> found that for a benzenethiol bonded to Au, the conducting states of the organic molecular wire interacted directly with the electronic system of the Au substrate, forming an ohmic contact. Onipko, Klymenko, and Malysheva<sup>[78]</sup> presented a detailed analytical approach to modeling the connection of the contacts to molecular wires that is applicable to a variety of functionalized systems. Seminario, De La Cruz, and Derosa<sup>[79]</sup> used the Green function coupled with the B3PW91/LANL2DZ level of theory to calculate the behavior of S and isonitrile (–NC) alligator clip bonds to Ni, Cu, Pd, Ag, Pt, and Au. They found that

**Fig. 22** The structure of 1,4-bis(thiomethyl)benzene **52**, the molecule studied by Yaliraki et al.<sup>[76]</sup>

the best metal for the metal–molecule interface was Pd, followed by Ni and Pt. Cu was intermediate whereas Au and Ag were worst. The S-based alligator clip was slightly better than the isonitrile alligator clip. The bond angle of the metal–alligator clip bond did make a difference in the calculated conductance of the molecular wire, apparently because of various levels of overlap with the extended  $\pi$  system of the aromatic nucleus.

The theoretical use of molecular wires to transport spin-dependent information in an area of molecular electronics called “spintronics” has been studied by Emberly and Kirczenow.<sup>[80]</sup> Spintronics utilizes the electron’s spin degree of freedom as well the charge of the electron to store, transmit, and process data. Based on their calculations, spin valve behavior should be observable in SAMs formed from 1,4-benzenedithiol between two Ni wires (a “break-junction” test-bed).

Recall that in Figs.<sup>[5–8]</sup> were several examples of synthesized molecules that contained methylene or ethylene group spacers to break up the extended conjugation of the OPEs. Karzazi, Cornil, Brédas<sup>[81,82]</sup> have published quantum-chemical calculations that were used to describe qualitatively the mechanism leading to resonant tunneling diodes (RTDs) with negative differential resistance (NDR; a switching phenomena) in molecular wires with such spacers as part of their molecular structures. It was theorized that having an ethylene spacer versus a methylene spacer led to better NDR characteristics, with larger on–off ratios.

### Conductance theory of molecular wires

A large body of work has been published regarding the theoretical aspects of conductance of molecular wires.<sup>[83–96]</sup> We will highlight several aspects of the work here, and invite the reader to explore the cited literature for more information.

Seminario et al.<sup>[83,85,88]</sup> and Derosa and Seminario<sup>[87]</sup> have used density function theory and Green

function theory to model the molecular orbitals of simple 1,4-benzenedithiol and more complex conjugated OPE systems. Calculations show that the highest occupied molecular orbitals (HOMOs) and the lowest unoccupied molecular orbitals (LUMOs) of a system can be localized (i.e., confined to certain atoms of the molecule) or delocalized (i.e., distributed over the entire molecular system depending on the charge). The localization of molecular orbitals will tend to prevent conductance through the molecule, whereas delocalization will tend to favor conductance. The addition of substituents and/or addition or subtraction of electrons from the system can change not only the shape (localization or delocalization) of the LUMOs and HOMOs but their energy levels. Changes in energy levels will affect whether the LUMOs and/or HOMOs overlap with the Fermi levels of the metal contact, also affecting the conduction through the molecules. The values of conductance for these systems with various charges determined by calculation agreed with experimentally derived data. The change in the LUMOs and HOMOs brought about by the injection of electrons into the molecular system was the reason that they could act as switches, turning on or off to current.

Mujica, Ratner, and Nitzan<sup>[89]</sup> have examined the theoretical aspects of molecular rectification.<sup>[97]</sup> Rectification occurs when the shape of the forward  $I(V)$  curve is not the inverse of the reverse bias  $I(V)$  curve when determining the conductance of a molecular wire as related to the applied voltage. The work of Mujica et al. suggested that the rectification is difficult to achieve because the finite voltages in the system cause the deformation of the structure, leading to effectively symmetrical voltage profiles for the forward and reverse biases. Interestingly, many have observed rectification because the two contacts between the ends of the molecular wires are different.

Avouris and Lang<sup>[98]</sup> have done an interesting theoretical study on the effect of coadsorption of contaminants on the conductance of molecular wires. Avouris and Lang had observed experimentally that the conductance of semiconducting carbon nanotubes changed when metal/semiconducting nanotube/metal devices were exposed to oxygen. Density function theory was used to determine that adsorption of electropositive Li atoms or electronegative O atoms perturbed the molecular orbitals of biphenyl. This work has wide-ranging implications, as it has been thought that the development of molecular electronics-based computers might not require the ultra pure water (UPW) and expensive clean rooms that the semiconductor manufacturing industry needs to produce the high yields of working devices of the present commercial technology. However, purity of the chemicals and cleanliness of the tools and reaction chambers could be of paramount importance to the commercialization of

the molecular wire technology. This calculation also has implications for experimental work, as contamination could easily introduce artifacts and false positives or negatives into laboratory testing.

Granger et al.<sup>[99]</sup> have recently predicted that carbon nanotubes and other linear molecular conductors can support electronic states that are localized far from their surface. Hill and McLean<sup>[100]</sup> have published experimental evidence for such states around an In nanowire. This work could have implications in answering the question: "Just how close does a molecular wire have to be to a connection to conduct electricity?" Carbon nanotubes or inorganic nanowires placed in near proximity may have electronic effects on circuitry and devices.

### Measurement of Conductance in Molecular Wires

A large body of work has also been published concerning the measurement of conductance in molecular wires.<sup>[101–112]</sup> We will touch on the highlights in this review.

Reed et al.<sup>[23]</sup> and Chen and Reed<sup>[103]</sup> have studied the conductance of both single molecules and of SAMs of molecules formed in a nanopore device. Stable and reproducible switching and memory effects were seen in the nanopore devices, with demonstrated NDR and charge storage with bit retention times of greater than 15 min at room temperature.

Patrone et al.<sup>[105]</sup> compared the electronic coupling efficiency of S and Se alligator clips on Au surfaces and found Se to be the better coupling link. Rampi and Whitesides<sup>[107]</sup> have developed a test-bed for measuring conductance in molecular wires using two metal electrodes sandwiching two SAMs, with the top metal electrode being Hg for convenience of formation. There are three different forms of this test-bed; the first comprises two Hg drops, each covered with the same SAM; the second test-bed comprises a Hg drop covered with a SAM interacting with a SAM formed on Ag; the third test-bed is similar to the first, only with redox-active molecules trapped between the two SAMs to do electrochemical measurements on them.

Avouris<sup>[108]</sup> has carried out extensive conductance measurements on carbon nanotubes and has constructed electronic devices containing them, including carbon nanotube field effect transistors (CNTFETs). Nanotubes are known to have either metallic or semiconducting properties. One problem with single-walled nanotube (SWNT) bundles is separating the metallic tubes from the semiconducting tubes. Avouris has developed a process that removes the metallic nanotubes, leaving the semiconducting behind.

Kushmerick et al.<sup>[110]</sup> have developed a test-bed device in which a SAM of the molecule of interest is formed on one of two 10- $\mu\text{m}$  Au wires that are crossed, and brought into contact by the Lorentz force (i.e., DC current in one wire deflects it in a magnetic field). Using this device,  $I(V)$  characteristics were measured for three molecules **53–55** shown in Fig. 23. Normalizing the conductance of the  $\text{C}_{12}$  alkanethiol **53** to 1, the conductance of the OPE molecular wire **54** was measured at 15 and the conductance of the OPV molecular wire **55** was measured at 46. Note that **55** has benzylic thioester moieties with methylene barrier groups to disrupt the molecular orbital overlap of the rest of the conjugated system. The researchers attribute the increased conductivity of the OPV molecule to both the increased coplanarity of the molecule (the alkynes in the OPEs allow the phenyl rings to be more freely rotating when compared to the vinylene group-linked OPVs), thus the population of OPE molecules existing in fully conjugated form is lower than the population of OPV molecules existing in fully conjugated form at the same temperature), and to the more regular periodicity of the conjugated molecular backbone of the OPV molecular wire. Compare the short 0.1218-nm alkyne linkage in the OPE molecular wire to the 0.1352-nm vinylene linkage of the OPV molecular wire and the  $0.141 \pm 0.001$  nm periodicity of the  $\pi$ -conjugated molecular backbone.

Rawlett et al.<sup>[111]</sup> used conducting atomic force microscopy (cAFM) to measure the conductance of

**Fig. 23** The molecular wires **53–55** tested by Kushmerick et al.<sup>[110]</sup> using a crossed-wire tunnel junction test-bed.

**Fig. 24** The molecular wire **56**, the conductance of which was tested by Rawlett et al.<sup>[11]</sup> using cAFM.

two different molecules that had been inserted into the naturally occurring defect sites of a dodecanethiol SAM on Au. The molecular wires **54** (Fig. 23) and **56** were (Fig. 24) constrained to be standing upright, parallel to the surface of the Au, because of the tight packing of the dodecanethiol SAM. Au nanoparticles were attached to the projecting deprotected thiol groups, and the nanoparticle was contacted by a Au-coated AFM tip to measure the conductance through what are thought to be individual molecules based on evidence not discussed here. Reproducible NDR effects were seen only for molecular wire **56**, not for **54**, indicating that the functionalization of the wire with the  $-\text{NO}_2$  group leads to the NDR effect.

Wang, Lee, and Reed<sup>[12]</sup> have completed a systematic temperature-dependent study of the conductance of alkanethiolates in SAMs and have shown conclusively that direct tunneling is the dominant transport mechanism.

## CONCLUSION

Based on the wealth of literature cited, fully conjugated completely organic aromatic molecular wires are the best candidates for introduction into new electronic devices as replacements for the Al or Cu wiring presently used in logic and memory devices. The OPE and OPV classes of molecular wires with S alligator clips have the highest conductances, both theoretical

and measured. Recent data indicate that OPV molecular wires are better than OPE molecular wires. Many more questions remain to be answered, the most important of which is how these molecular wires will be integrated into processes to build the molecular electronic and optoelectronic devices of the future. Problems raised by such integration efforts will likely require several iterations in molecular wire research. As we have pointed out, the beauty of organic chemistry is that simple changes to the raw materials used in synthesizing the molecular wires can yield products with vastly different physical properties. The molecular wire(s) that eventually appears in commercial devices may bear no resemblance to those we have discussed. Thus research in this area can still yield much fruit.

## ACKNOWLEDGMENT

We thank DARPA administered by the Office of Naval Research (ONR); the ONR Polymer Program; the U.S. Department of Commerce, National Institute of Standards and Technology; the Army Research Office; NASA; and the Air Force Office of Sponsored Research (AFOSR F49620-01-1-0364) for financial support of this work.

## INTRODUCTION

Nanoparticles and nanoparticle-based materials are of considerable interest for their unique properties and their potential for use in a variety of applications. Metal nanoparticles, in which each particle's surface is coated with a protective organic monolayer, are of particular interest because the surface monolayer stabilizes them relative to aggregation and they can be taken up into solutions.<sup>[1-4]</sup> As a result, they can be processed into thin films for device applications. We will refer to these materials as monolayer-protected nanoparticles (MPNs). Typically, the metal is gold and the organic layer is a self-assembled thiol layer, and this composition will be assumed throughout the remainder of this chapter. A diversity of materials and properties is readily accessible by straightforward synthetic procedures, either by the structures of the monolayer-forming thiols used in the synthesis, or by postsynthetic modifications of the monolayers. A particularly promising application for these materials is as selective layers on chemical vapor sensors. In this role, the thin film of MPNs on the device surface serves to collect and concentrate gas molecules at the sensor's surface. Their sorptive properties also lend them to use as new nanostructured gas chromatographic stationary phases. This chapter will focus on the sorptive properties of MPNs as they relate to chemical sensors and gas chromatography (GC).

## BACKGROUND

The use of a sorptive layer to collect and concentrate vapor molecules at a sensor's surface is shown schematically in Fig. 1. The presence of these sorbed vapor molecules can then be detected in a variety of ways, depending on the transduction mechanism of the

sensor device. Acoustic wave devices, such as the thickness shear mode (TSM) device or the surface acoustic wave (SAW) device, transduce the presence of the vapor as an increase in mass detected by a change in the acoustic wave velocity.<sup>[5-8]</sup> Typically, the acoustic wave velocity change is measured as a change in oscillator frequency.

A schematic diagram of an MPN as an individual particle, its component parts, and a film is shown in Fig. 2. The film represents a cross section where gold cores are separated by the organic monolayers, with areas of lower density suggested between the MPNs. As a sorptive layer, molecules could sorb into the thiol material and/or the free volume associated with areas of lower density.

Chemiresistor devices measure a change in the resistance of the applied thin films as a function of the sorbed gas or vapor.<sup>[9-12]</sup> Because an MPN film on such a device carries the current, it participates directly in the transduction mechanism.<sup>[12]</sup> These films consist of metal particles separated from one another, insulating monolayers on their surfaces (Fig. 2). The current observed as electrons travel through a film from particle core to particle core can be modulated by the sorption of vapor molecules in the insulating regions. These insulating regions are of molecular dimensions, hence the sorption of molecules can represent a significant perturbation. Wohltjen and Snow<sup>[12]</sup> described MPN-sensing films as metal-insulator-metal ensembles (MIMEs) in recognition of the nanostructure of the films.

Regardless of the transduction mechanism chosen, the sorption of a vapor into the MPN film represents a significant aspect of the sensor response. The amount of vapor uptake and the rate of vapor uptake by these film materials provide useful information for understanding and interpreting sensor response behavior. Differences in the sorption of various vapors (i.e.,

**Fig. 1** Schematic diagram of the mechanism for a chemical vapor sensor where the sorption of a vapor from the gas phase into a sorptive layer on the transducer surface results in an analytical signal.

selectivity) provide the basis for discriminating among vapors using arrays of such sensors, and for separating vapors using GC.

## SYNTHESIS AND PROPERTIES

The typical synthesis procedure for MPNs involves the reduction of gold salts in the presence of a monolayer-forming thiol. A two-phase water/toluene process with a phase transfer salt was first reported by Brust et al.<sup>[2]</sup> and has been used by many others as well.<sup>[12–15]</sup> For example, alkanethiol-protected gold nanoparticles are typically prepared starting with solutions of  $\text{HAuCl}_4 \cdot \text{H}_2\text{O}$  in water, alkanethiol in toluene, sodium borohydride as the reducing agent in water, and tetraoctylammonium bromide as the phase transfer salt in toluene. The aqueous  $\text{HAuCl}_4$  solution is added to the toluene solution containing tetraoctylammonium bromide. After thorough stirring to transfer  $\text{AuCl}_4^-$  anions into the toluene, the dodecanethiol/toluene solution is added followed by the aqueous  $\text{NaBH}_4$  solution. The product MPNs are recovered from the toluene phase.

MPNs can also be prepared in one-phase procedures that have been used, for example, for a variety

**Fig. 2** Schematic diagram of a gold nanoparticle protected with organic thiol monolayer, along with a hypothetical film where the gold cores are black, the monolayer material is gray, and there are areas of potentially lower density between the particles that may facilitate vapor diffusion and sorption.

**Fig. 3** A selection of thiol structures that have been used as monolayers on gold nanoparticles. The alkanethiols indicated on the left typically range from octanethiol to dodecanethiol ( $n = 1-5$ ).

of arene thiol-protected gold nanoparticles. The single-phase methanol/water synthesis was developed by Brust et al.<sup>[1]</sup> and used by others.<sup>[15,16]</sup> A synthesis method from solvated metal atoms has also been described, where vaporized metal atoms and solvent vapors are codeposited as a frozen mixture, followed by reaction with the thiol.<sup>[17]</sup> This method is effective at generating gram quantities of MPNs that are unambiguously free of ionic impurities from reducing agents or phase transfer reagents.

A great variety of thiol ligands have been used in the synthesis of MPNs, some of which are shown in Fig. 3. Alkanethiols have been particularly popular, whereas the substituted arene thiols provide a facile method to incorporate varying functionality in the structure. In addition, the ligand shell can be synthetically modified by organic reactions with organic ligands. Additional examples of thiols used and postsynthetic modifications can be found in Ref.<sup>[3]</sup>.

Preparations are typically polydisperse in particle size. The metal cores can be observed and measured by high-resolution transmission electron microscopy (TEM). An example of a TEM of a monolayer of MPNs is shown in Fig. 4. Particle core sizes in most studies average between 1.5 and 5 nm in diameter. It is believed that the cores prefer to reach discrete sizes with closed-shell structures (i.e., completed outermost layers of gold on the particle or crystal), although non-equilibrium structures may be produced under kinetically controlled growth conditions.<sup>[3]</sup> A number of studies have described the ripening of nanoparticle

**Fig. 4** TEM image of a polydisperse sample of bromobenzenethiol-protected gold nanoparticles.

sizes after synthesis.<sup>[17–22]</sup> Particle sizes may increase with time and heating under appropriate conditions; however, reduction in gold core size has also been described by heating in neat thiol. Ripening of nanoparticles appears to lead to a more uniform size distribution than that obtained during synthesis.

A variety of additional characterization methods are also frequently applied. Thermogravimetric analysis (TGA) provides a measure of the mass percentages of gold and organic material in the prepared sample. Ideally, the organic material is all gold-bound thiol; however, impure samples may also contain excess free thiol, the corresponding disulfide, or phase transfer salt. Infrared spectra are sometimes used to look for the presence of phase transfer salt. Free thiol or disulfide can be observed by chromatographic methods including thin layer chromatography and liquid chromatography.

Additional techniques that have been applied to the study of MPNs include small-angle X-ray scattering (SAXS), conventional and synchrotron X-ray diffraction, mass spectrometry, scanning tunneling microscopy (STM), atomic force microscopy (AFM), differential scanning calorimetry, and nuclear magnetic resonance (NMR), to name a few. Detailed structural studies of carefully crystallized samples of alkanethiol-protected gold nanoparticles have been described.<sup>[4]</sup>

Of particular interest with regard to sorption are the relative proportions of the organic thiol material serving as a sorptive medium and the gold cores whose volume excludes sorbed molecules. The mass ratios of gold and thiol can be determined from TGA, where the organic material burns off, leaving gold. From our own data<sup>[15]</sup> as well as data in the literature,<sup>[13,14,23]</sup> it is found that MPN materials are typically 75–90% metal by mass and only 10–25% organic by mass. Nevertheless, these proportions are reversed when

volume fractions are considered. We have estimated that typical volume fractions are 70–90% organic material by volume and only 10–30% metal by volume, using the densities of bulk gold and condensed phase thiols to convert mass fractions to volume fractions.<sup>[15]</sup> Thus despite the low mass percentage of sorptive organic material, these materials are actually primarily sorptive organic material by volume.

Low-volume fractions of gold—and hence high-volume fractions of thiol—are also indicated by structural studies.<sup>[4]</sup> In studies of crystalline samples of MPNs with alkanethiol ligands, the gold cores have been assumed to have the density of bulk gold metal, and the volume not occupied by gold has been found to have a density very close to that of the bulk thiol.<sup>[24]</sup>

## SORPTIVE PROPERTIES AS MEASURED USING ACOUSTIC WAVE SENSORS

### Sorption, the Partition Coefficient, and Chemical Sensor Response

The analytical signal of a coated microsensors entails the sorption of the vapor and transduction of the presence of the vapor in the film.<sup>[25,26]</sup> The vapor sensor's response  $R$  is empirically expressed as a function of the gas-phase concentration of the test vapor  $C_v$  as in Eq. (1), and this is the basis of the calibration curve:

$$R = f(C_v) \quad (1)$$

Nevertheless, the sensor's response is more directly a function of the concentration of the vapor in the sorptive coating  $C_s$  as indicated in Eq. (2):

$$R = f(C_s) \quad (2)$$

The ratio of the concentrations  $C_v$  and  $C_s$  is given by the thermodynamic partition coefficient  $K$  [Eq. (3)]:

$$K = C_s/C_v \quad (3)$$

Consequently, the response function to the vapor concentration in the film [Eq. (2)] can be expressed as a function of the product of the gas-phase vapor concentration and the partition coefficient [Eq. (4)]:

$$R = f(KC_v) \quad (4)$$

Hence knowledge of the partitioning of vapors into sensor films (i.e., absorption) is fundamental to understanding sensor performance and mechanism.<sup>[25,26]</sup> We are particularly interested on how this knowledge can help to elucidate the relative roles of sorption and transduction in observed sensitivities and detection

limits. Partition coefficients are also fundamental to the separation of vapors by GC.

### Vapor Sorption by Nanoparticle Films

Four MPN materials were selected for detailed studies on sorptive behavior.<sup>[15]</sup> These four were satisfactorily characterized and all gave rapid and reversible sorption of the test vapors considered. They were MPNs with dodecanethiol, benzenethiol, chlorobenzenethiol, and trifluoromethylbenzenethiol ligands.

Vapor sorption measurements were made on TSM devices spray-coated with an amount of MPN material, yielding approximately 10 kHz frequency shifts (an indication of film thickness).<sup>[15]</sup> Impedance measurements were made to assure that the MPN layers on the TSM devices yield gravimetric sensors and valid vapor uptake measurements can be made. The test sensors were evaluated against four vapors: *n*-hexane, toluene, 2-butanone, and 1-butanol. These vapors represent a diverse set of properties to probe differences in behavior and chemical selectivity among the nanoparticle materials. Sensor responses to the test vapors were generally rapid and reversible, with exposures leading to steady-state or near-steady-state responses within the 6-min exposure period. Examples of such responses are shown in Fig. 5.

Calibration curves for vapor on four MPN a selected coatings are shown in Fig. 6. This figure includes calibration curves for two polymers selected for comparison. Polymers are widely used in chemical sensing

**Fig. 5** Response of a dodecanethiol-protected gold nanoparticle film on a TSM device to increasing concentrations of hexane. Data points are shown 2 sec apart.

**Fig. 6** Calibration curves for toluene on a series of mono-layer-protected gold nanoparticles with data for two polymers, PIB and PECH, included for comparison.

and their sorptive properties have been examined in detail. The selected polymers—poly(isobutylene), PIB, and poly(epichlorohydrin), PECH—have been used in a variety of vapor-sensing studies, including sorption measurements on 10-MHz TSM devices.<sup>[27]</sup> They represent simple prototypical sorptive polymers whose structures and sorptive properties have been described in detail elsewhere.<sup>[26–29]</sup> The data for the polymers were normalized to 10-kHz films to match the film amounts applied to the MPN-coated sensors.

The calibration curves show two main points. First, the curves are linear or nearly linear in the vapor concentration range considered. We found that TSM sensors with dodecanethiol, chlorobenzenethiol, and trifluoromethylbenzenethiol yielded calibration curves with small intercepts (typically 1 Hz or less) and high correlation coefficients (typically 0.998 or higher for  $R^2$  as evidence for linearity).<sup>[15]</sup> For gravimetric sensors at a fixed temperature, linear calibration curves indicate linear sorption isotherms over the test concentration ranges.

Second, from the results in Fig. 6 and others we have published,<sup>[15]</sup> it is apparent that the sorption of the test vapors by the MPN films is typically less than the sorption of vapors by the selected polymers. The most sorptive nanoparticle films for any test were less sorptive on a per-mass basis than the best sorptive polymer considered within the concentration range studies, the polymer being better by a factor of 2–2.5. This analysis compares the sorptive properties on a mass of vapor sorbed per mass of sorbent material.

Nevertheless, vapor sorption is often quantified based on the partition coefficient defined in Eq. (3), where the concentration of vapor in the sorbent phase is in grams per liter; thus quantification of sorption is measured on a mass-per-volume basis. The partition coefficient is related to gravimetric sensor responses according to Eq. (5):<sup>[30]</sup>

$$\Delta f_v = \Delta f_s C_v K / \rho \quad (5)$$

The frequency shifts indicated by  $\Delta f_s$  and  $\Delta f_v$  refer to the shift obtained on coating the bare sensor with the sorptive coating, and the shift observed when the sorptive coating absorbs a vapor. This relationship assumes that the observed frequency shifts are caused by the bulk absorption of vapor in the film. The  $\rho$  parameter is the sorptive material density. Densities of the applied films are required to convert observed frequency shifts to partition coefficients for vapor sorption. Based on the mass fractions of gold and thiol in the film materials as determined by TGA, and the bulk densities of the condensed-phase gold and thiol materials, estimates of the required densities were determined for the calculation of partition coefficients according to Eq. (5).<sup>[15]</sup> On a per-volume basis, the sorption of organic vapors by these MPN materials is of the same order of magnitude as the polymers at this concentration. Thus it appears unlikely that the nanoparticle-based materials considered are more sorptive than the conventional polymers. If the actual densities of the film materials were lower than the estimated values used in the calculations (i.e., because of inefficient packing and/or large free volumes), then the actual partition coefficients would be proportionately lower, and it would still be true that these nanoparticle-based materials are not more sorptive than the polymers used for comparison.

The sorptive properties of these nanoparticle films prepared by monothiols can also be compared with networked nanoparticle films containing bridging dithiols. Quantitative data on vapor uptake of the latter films as measured on TSM devices by Han et al.<sup>[31]</sup> were compared with our quantitative data on vapor uptake by the monothiol-based MPNs.<sup>[15]</sup> After converting the reported data to similar units, it appears that the networked films sorb organic vapors with gravimetric sensitivity of the same order of magnitude as the monothiol-based materials, with the sorption by the particular alkanethiol-based film in our study being somewhat greater than the particular alkanedithiol-based film in their study.<sup>[32]</sup>

## NANOPARTICLE FILMS AS GAS CHROMATOGRAPHIC PHASES

Our interest in the sorptive behavior of these nanoparticle materials prompted us to investigate them as gas

**Fig. 7** Scanning electron microscope image of a cross section of the open tubular GC column coated with the dodecanethiol-protected gold nanoparticles, shown as the light band between the silica column material and the column lumen. The band is 60 nm thick.

chromatographic phases. Dodecanethiol-protected gold nanoparticles were examined using an open tubular column configuration.<sup>[33]</sup> The nanoparticles were deposited on the inner walls of a deactivated silica capillary (0.530 mm i.d.) by deposition from a dichloromethane solution passed as a plug through the length of the column. This process was repeated until a layer yielding a uniform brown color was obtained. Scanning electron microscopy was used to characterize the thickness and consistency of the nanoparticle film. A film of 60 nm thickness in a 2-m column was used for subsequent chromatographic experiments. A cross-sectional image of the MPN film in the capillary is shown in Fig. 7.

Several test mixtures were separated on the open tubular GC column using both isothermal and temperature-ramped protocols. Rapid separations with good peak shapes and resolution were obtained.<sup>[33]</sup> Figs. 8 and 9 illustrate the separation of an eight-component mixture under isothermal and temperature-ramped conditions. Determination of reduced plate height as function of linear flow velocity indicated an efficient open tubular system. The performance of the MPN-coated column was compared with a commercial polymer stationary phase AT-1 in the same column length and inside diameter, and comparable phase thickness (100 vs. 60  $\mu\text{m}$  for the MPN phase). These two columns were found to have comparable separation efficiencies. These experiments demonstrate that MPN materials can be successfully coated as chromatographic phases for open tubular GC, yielding chromatographically efficient columns.<sup>[33]</sup>

**Fig. 8** Separation of an eight-component mixture on the nanoparticle-coated GC column under isothermal conditions at 50°C. The eight vapors were ethanol, benzene, 1-butanol, 3-heptanone, chlorobenzene, 3-octanone, anisole, and decane.

We have further demonstrated that MPNs can be coated in  $100 \times 100 \mu\text{m}^2$  square-bore capillaries.<sup>[34]</sup> Polymeric stationary phases present problems in the columns with noncircular channels because the material tends to be thicker in the corners than on the other sides. Using the MPN materials, this effect was greatly

**Fig. 9** Separation of the same eight-component mixture as in Fig. 8 under temperature-ramped conditions from 40°C to 80°C at 70°C/min.

**Fig. 10** High-speed separation of seven components using the dodecanethiol MPN stationary phase within the  $100\text{-}\mu\text{m}^2$  square-bore capillary. The retention order is: methyl ethyl ketone, benzene, octane, chlorobenzene, anisole, 3-octanone, and decane. The separations were obtained by using a 1.3-m column at 75°C operated under constant pressure conditions at 25 psi ( $\sim 200$  cm/sec hydrogen gas).

reduced and an efficient chromatographic system was obtained. The phase thickness on the column sidewalls was 15 nm. A seven-component mixture representing four compound classes was separated in 2 sec on a 1.3-m column. These results are shown in Fig. 10.

Columns with noncircular channels are of interest because microfabricated GC columns (i.e., microGC or GC-on-a-chip) typically have angular channels as a result of the etching and capping process. Thus the square bore capillary GC columns just described serve as a model for microGC angular channels, while focusing on the performance of the stationary phase and not on the rest of a microGC system. Our result demonstrated that the MPN materials have advantageous coating properties for microGC systems.

#### NANOPARTICLE FILMS AS CONDUCTIVE SENSING LAYERS ON CHEMIREซิสТОР SENSORS

As noted in the background material, MPN films can be used as the selective layer on chemiresistor sensors, which measure changes in the electrical conductivity of the films as a function of changing vapor concentration. Initial investigations by a number of groups have demonstrated the potential of MPN-based films for chemical vapor sensing by this mechanism.

Wohltjen and Snow<sup>[12]</sup> reported the first use of MPN-coated chemiresistors as vapor sensors, demonstrating large decreases in the conductance of an octanethiol-based MPN film in response to toluene and trichloroethene.<sup>[35]</sup> Snow and Wohltjen have observed that MPN-coated chemiresistors can offer detection limits that are significantly better than those of polymer-coated SAW devices (A. W. Snow, Naval Research Laboratory, 2000, personal communication).<sup>a</sup> Subsequently, Evans et al.<sup>[16]</sup> demonstrated that chemiresistor devices with four different arenethiol-based MPN films yielded different patterns for each of the eight vapors, although it was observed that reproducibility was a concern for some vapors on some sensors. Additional work by this group attributed MPN-coated chemiresistor responses to film permittivity changes at low vapor concentrations and to film swelling that increases core–core distance at high vapor concentrations.<sup>[38]</sup>

Han et al.<sup>[31]</sup> investigated novel networked nanoparticle film materials containing bridging dithiols between gold cores as layers on both chemiresistor and TSM devices. Vapor uptake as measured on the TSM device was correlated with film resistance changes as measured by the chemiresistor. Zamborini et al.<sup>[39]</sup> also described both chemiresistor and TSM sensor measurements on networked nanoparticle materials; these authors concluded that film swelling as a result of vapor uptake leads to reduced electron-hopping rates. Gold nanoparticle/dendrimer composites have also been used as layers on chemiresistor vapor sensors.<sup>[40–43]</sup> Joseph et al.<sup>[44]</sup> have also examined gold nanoparticle alkanedithiol films prepared by a layer-by-layer assembly process directly on sensor surfaces. These films showed linear current–voltage characteristics and reversible responses to toluene and tetrachloroethene. Responses were consistent with a film swelling mechanism. In experiments with alkylene chains of varying lengths, it was found that the normalized vapor responses increased exponentially with increasing alkanedithiol length.

Cai and Zellers<sup>[45]</sup> described the vapor-sensing performance of MPN-coated chemiresistors with either octanethiol-protected gold nanoparticle or 2-phenylethanedithiol-protected gold nanoparticles. Rapid and reversible responses to most of the 11 test vapors were observed in direct exposures. Detection limits were reported to be 10- to 90-fold (with 20 as a typical value) better than those of selected polymer-coated SAW sensors. The sensors were also used as detectors for GC.

<sup>a</sup>Comparisons between chemiresistor vapor sensors coated with monolayer-protected nanoparticles and surface acoustic wave vapor sensors coated with polymers have been presented by Refs.<sup>[36,37]</sup>

## CONCLUSION

Vapor sorption by a sensing film on a chemical microsensor is a fundamental influence on sensor response and performance. Our studies have examined the sorption of vapors by gold nanoparticle materials protected with organic thiols, where the organic thiol represents the largest volume fraction of the material and its structure influences vapor sorption and selectivity. The nanoparticle-based films considered here were less sorptive than the selected polymers on a per-mass basis. Partition coefficients, which measure the mass of vapor sorbed per volume of the sorptive phase, were estimated for these MPN materials and were found to be comparable with, or less than, those of the polymer layers. Strictly from the standpoint of sorption, these materials do not appear to have advantages over polymers as sensing layers.

Nevertheless, others have reported that chemiresistor sensors coated with MPN films can offer better detection limits than polymer-coated vapor sensors,<sup>[36,37,45]</sup> such as those based on SAW devices or those based on chemiresistors coated with carbon black-containing polymers. If this is the case, and the MPN layers and polymer layers absorb similar amounts of vapor, then it follows that the lower detection limits for MPN-coated chemiresistors must be because of more signal-to-noise ratio per sorbed vapor molecule. Apparently, the electron transfer from one nanoparticle to another is very sensitive to the sorption of vapors into the spaces between the conducting gold nanoparticle cores. These spaces are of molecular dimensions. The implications are that nanostructure materials and can be used in the design of new chemical sensors with superior properties.

As sorptive materials, MPN films may also be used in other microanalytical applications. We have demonstrated that these materials can be advantageously used as sorptive stationary phases in GC. In addition, they appear to offer advantages over conventional polymers with respect to angular chromatographic channels; thus they may be useful in microfabricated channels and structures.

## ACKNOWLEDGMENTS

The authors thank Dr. Scott Elder for initial syntheses of some of the nanoparticle materials and Alice Dohnalkova for TEM images. J. W. G. thanks Dr. Arthur Snow for informative and motivating discussion of the work on nanoparticle-coated sensors at the Naval Research Laboratory in March 2000 as well as helpful discussions subsequently, and Dr. Laura Hughes for a review of the manuscript. This work was funded by the U.S. Department of Energy via the Laboratory Directed Research and Development funds administered

by the Pacific Northwest National Laboratory. A portion of the research was performed at the W. R. Wiley Environmental Molecular Sciences Laboratory, a national scientific user facility sponsored by the U.S. Department of Energy's Office of Biological and Environmental Research and located at the Pacific Northwest National Laboratory. The Pacific Northwest National Laboratory is operated for the U.S. DOE by the Battelle Memorial Institute.

# Monolayer-Protected Metal Nanoparticles: Synthesis

Young-Seok Shon

Department of Chemistry, Western Kentucky University, Bowling Green, Kentucky, U.S.A.

## INTRODUCTION

The basic synthetic methods of monolayer-protected metal nanoparticles including Au, Ag, Cu, Pt, and Pd particles are presented. (There is also an article on “Metal Nanoparticles Protected with Monolayers: Applications for Chemical Vapor Sensing and Gas Chromatography,” which explores the sorptive properties in depth.) This entry introduces the fundamentals about protective monolayers from various organic compounds containing reactive functional groups such as thiol, disulfide, sulfide, thiosulfate, xanthate, ammonium, amine, phosphine, phosphine oxide, carboxylate, selenide, isocyanide, etc.

## BACKGROUND

Nanoparticles (particles of 1–100 nm in diameter) have generated intense interest over the past decades because of their unique electronic, optical, photoreponsive, and catalytic properties. However, nanoparticles are subject to the irreversible particle aggregation and the oxidation reactions. Thus the stabilization of nanoparticles against these problems is a requirement for further advancement in nanoparticle science and technology. In 1981, Schmid et al.<sup>[1]</sup> synthesized the first example of the ligand-stabilized gold nanoparticles,  $\text{Au}_{55}(\text{PPh}_3)_{12}\text{Cl}_6$ . However, the dependable and practical formation of more stable and isolable monolayer-protected gold nanoparticles was achieved about a decade ago by Brust et al.<sup>[2]</sup> The organic monolayers, which bind to the surface of metal nanoparticles, not only prevent aggregation of the metal nanoparticles, but also stabilize them from harsh reaction conditions and enhance the solubility in various solvents.<sup>[3–5]</sup> Subsequent investigations were extended to different metal particles including Au,<sup>[1–53]</sup> Ag,<sup>[31,38,54–68]</sup> Cu,<sup>[38,59,69–71]</sup> Pt,<sup>[72–79]</sup> Pd,<sup>[76,80–86]</sup> Ni,<sup>[85,87]</sup> and alloy particles.<sup>[88,89]</sup> Other organic compounds with different reactive head groups, such as thiol,<sup>[8–29]</sup> disulfide,<sup>[30,31]</sup> sulfide,<sup>[32–35]</sup> thiosulfate,<sup>[36,37]</sup> xanthate,<sup>[38]</sup> phosphine,<sup>[1,39–41]</sup> phosphine oxide,<sup>[42]</sup> ammonium,<sup>[43,44]</sup> amine,<sup>[45–47]</sup> carboxylate,<sup>[48–50]</sup> selenide,<sup>[51,52]</sup> and isocyanide,<sup>[53]</sup> can protect metal nanoparticles by self-assembly. Monolayers with different

functional groups and moieties can also be incorporated onto the surface of metal nanoparticles.<sup>[3–5]</sup> The modification of nanoparticles by the incorporation of a functional group is of potential significance for the expansion of chemical and biological applications of these nanomaterials. This entry focuses on the synthesis of various metal nanoparticles protected with monolayers containing different reactive head groups and functional tail groups.

## GOLD NANOPARTICLES

Gold nanoparticles have drawn remarkable interest in the last few years because of their high stability to oxidation and their optical and well-defined size-related electronic (e.g., quantized charging) properties.<sup>[6,7]</sup> Biological applications of hybrid Au nanoparticles have also shown a great promise for the use of these nanomaterials in biotechnology.<sup>[4]</sup> The synthesis of monolayer-protected gold nanoparticles will be described based on the reactive head groups, which provide self-assembly of organic monolayers onto the nanoparticle surface.

### Gold Nanoparticles Protected with Thiols

The stabilization of gold nanoparticles with alkanethiols was a direct result of advancement in the passivation of two-dimensional gold surfaces using alkanethiols in the late 1980s and early 1990s, which results in the formation of self-assembled monolayers on gold substrates.<sup>[90]</sup> The first report regarding the capping of Au nanoparticles with alkanethiols was made by Giersig and Mulvaney<sup>[8]</sup> in 1993. Brust et al.<sup>[2]</sup> reported a convenient two-phase synthesis of isolable and soluble alkanethiolate-protected gold nanoparticles in 1994, which had a huge impact on the nanoparticle research. In this reaction (Fig. 1),  $\text{AuCl}_4^-$  was transferred to toluene using tetraoctylammonium bromide as the phase-transfer reagent. Addition of dodecanethiol to organic-phase  $\text{AuCl}_4^-$  followed by the reduction with  $\text{NaBH}_4$  generated dodecanethiolate-protected gold nanoparticles. The research was extended to the alkanethiols with different chain lengths (C3–C24).<sup>[3]</sup>

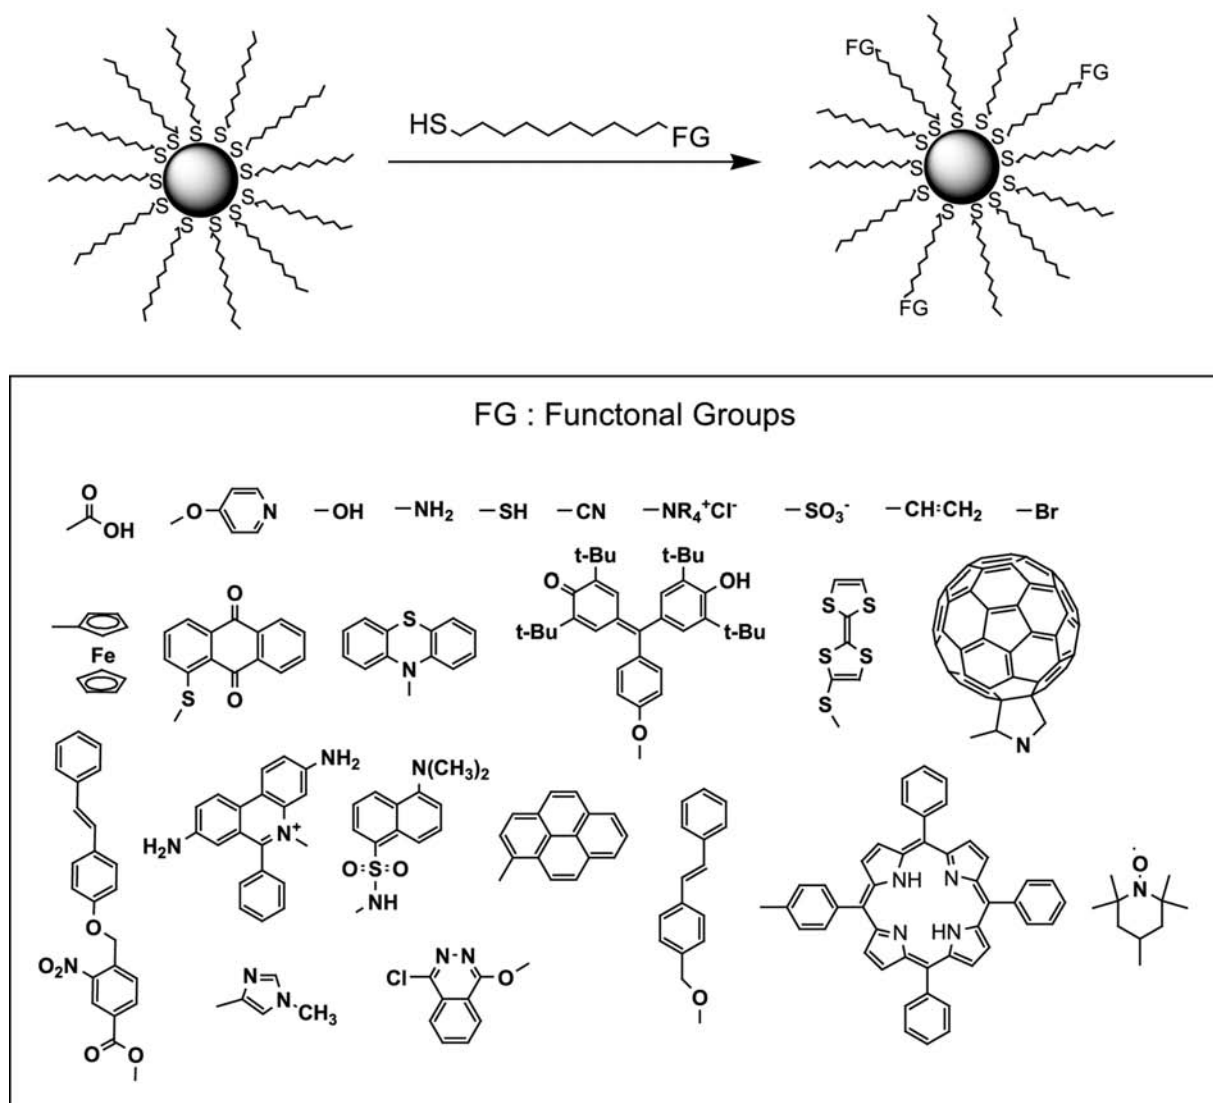

Fig. 3 General scheme and examples of functionalized thiols for the ligand-exchange reactions.

Templeton et al.<sup>[3]</sup> reported the “ligand-exchange” method to modify the composition of the monolayer-protected nanoparticles. This research enabled incorporation of many different functional groups and moieties onto the surface of gold nanoparticles (Fig. 3). In the exchange reaction, the incoming ligands replace the thiolate ligands on nanoparticles by an associative reaction, and the displaced thiolate becomes a thiol. The rate of ligand exchange depends on the chain length and/or steric bulk of the initial monolayers and electronic charge on nanoparticles. Various functional groups ranging from simple organic functional groups to functional complexes (electroactive or photochemical groups) were incorporated into the nanoparticles using ligand-exchange reactions.<sup>[3–5]</sup>

Reactions of functionalized gold nanoparticles were also frequently used for the incorporation of more specific organic groups and moieties having electroactive, photoresponsive, catalytic, mechanical, and biological properties (Fig. 4).<sup>[3–5]</sup>

### Gold Nanoparticles Protected with Other Sulfur-Containing Species

Other sulfur-containing species such as disulfides,<sup>[30,31]</sup> sulfides,<sup>[32–34]</sup> episulfides,<sup>[35]</sup> thiosulfates,<sup>[36,37]</sup> and xanthates<sup>[38]</sup> have been used for the synthesis of monolayer-protected gold nanoparticles (Fig. 5). The formation of alkanethiolate-protected gold nanoparticles generated by the adsorption of dialkyl disulfides

Fig. 4 General scheme and examples of organic reactions of functionalized metal nanoparticles.

showed that the characteristics (monolayer crystalline structure, core size, stability, and solubility) of these particles were identical to the nanoparticles generated by the adsorption of alkanethiols.<sup>[30,31]</sup>

Dialkyl sulfide-protected gold nanoparticles exhibited lower aggregation stability than alkanethiolate-protected gold nanoparticles because of the non-covalent bonding interactions between the gold surface and sulfur atoms. Because of low reactivity of sulfide groups, the average core size of dialkyl sulfide-protected gold nanoparticles was larger than that of alkanethiolate-protected nanoparticles prepared under the same conditions.<sup>[32]</sup> Alkyl sulfide-protected gold nanoparticles underwent ligand exchange by both thiols and disulfides.<sup>[33]</sup> In the case of thiol exchange of weakly adsorbed sulfides, it was found that intact thiols (RSH) rather than thiolates (RS<sup>-</sup>) were present on the surface of the nanoparticles. Tetradentate thioether was used for the spherical assembly of gold

nanoparticles that could be readily assembled and disassembled.<sup>[34]</sup>

The synthesis of alkanethiolate-protected gold nanoparticles using sodium *S*-dodecylthiosulfate resulted in the production of particles with larger average core dimensions (caused by low reactivity of thiosulfates) but indistinguishable Au-S bond compared with those prepared using dodecanethiol.<sup>[36]</sup> Xanthate-protected gold nanoparticles were found to be much less hydrophobic and temperature sensitive.<sup>[38]</sup>

#### Gold Nanoparticles Protected with Phosphorus-Containing Species (Phosphine and Phosphine Oxide)

The ligand-stabilized gold nanoparticles, Au<sub>55</sub>(PPh<sub>3</sub>)<sub>12</sub>Cl<sub>6</sub>, synthesized by Schmid et al.<sup>[1]</sup> were

Fig. 5 Various organic compounds used for the protection of metal nanoparticles.

the first example of phosphine-stabilized quantum-dot particles. Weare et al.<sup>[39]</sup> improved the initial cumbersome procedure (anaerobic conditions and diborane gas as a reducing agent) with a more convenient and safer method using a two-phase system similar to the Schiffrin reaction to produce Au<sub>101</sub>(PPh<sub>3</sub>)<sub>21</sub>Cl<sub>5</sub> particles. This improved synthetic method allows size control and is tolerant of a variety of functionalized phosphine ligands. These phosphine-stabilized gold nanoparticles underwent ligand-exchange with  $\omega$ -functionalized alkanethiols producing alkanethiolate-protected gold nanoparticles.<sup>[40]</sup> Subnanometer phosphine-stabilized undecagold nanoparticles were synthesized by the NaBH<sub>4</sub> reduction of AuCl(PPh<sub>3</sub>). Ligand-exchange reactions of these Au<sub>11</sub> nanoparticles with alkanethiols and  $\omega$ -functionalized alkanethiols resulted in the formation of thiol-protected Au<sub>11</sub> nanoparticles.<sup>[41]</sup>

The reduction of gold (IV) chloride by sodium borohydride in hot tri-*n*-octylphosphine oxide (TOPO) at ca. 190°C resulted in gold nanoparticles with core sizes of 10–100 nm.<sup>[42]</sup> TOPO acts as both a reaction medium and passivating ligand. Particle synthesis in a mixture of TOPO and octadecylamine at ca. 190°C produced smaller and stable gold nanoparticles (ca. 8.5 nm).

### Gold Nanoparticles Protected with Nitrogen-Containing Species (Amines and Ammonium Salts)

Au nanoparticles capped with tetraoctylammonium bromide were prepared by the NaBH<sub>4</sub> reduction using the modified two-phase protocol (without the presence of thiols).<sup>[43]</sup> Binding of these gold nanoparticles with organic molecules containing functional groups such as -SCN or -NH<sub>2</sub> was found to dampen the surface plasmon bands of gold. Cetyltrimethylammonium bromide (CTAB)-capped gold nanoparticles were also synthesized using CTAB as both a phase-transfer reagent and stabilizer in a two-phase system.<sup>[44]</sup>

Alkylamine-stabilized gold nanoparticles were synthesized and used for the formation of ordered superlattices.<sup>[45]</sup> Thermal decomposition of organometallic gold (I) amine complexes produced gold nanoparticles protected with a monolayer of alkylamines.<sup>[46]</sup> The antibacterial drug ciprofloxacin (cfH) has been used to protect gold nanoparticles synthesized by citrate reduction in water.<sup>[47]</sup> The release of the drug (cfH) molecule from the nanoparticles showed the possible drug delivery application of gold nanoparticles.

## Gold Nanoparticles Protected with Other Organic Compounds

Citrate reduction of  $\text{HAuCl}_4$  in water led to less stable citrate-capped gold nanoparticles with core sizes ranging from 15 to 150 nm. The core size of gold nanoparticles was based on the ratio of trisodium citrate to gold.<sup>[48]</sup> This method is typically useful when a rather loose shell of ligands is required around the gold core.<sup>[49]</sup> Thermal decomposition of  $\text{Au(I)(C}_{13}\text{H}_{27}\text{COO)PPH}_3$  at 180°C resulted in the formation of myristate-capped gold nanoparticles.<sup>[50]</sup> The core size (10–45 nm) of these particles increased with reaction time and increasing reaction temperature.

Gold nanoparticles stabilized by alkyl selenides and alkyl tellurides could be prepared by using a two-phase Schiffrin reaction.<sup>[51,52]</sup> Passivation by alkyl selenide was characterized by greater chain density and stronger Au–Se bond strength. Particle size was, however, uniform in the cases when different ligand/substrate ratios were employed.<sup>[52]</sup>

The adsorption behavior of 4-biphenylisocyanide on gold nanoparticles has been studied using surface-enhanced Raman scattering (SERS).<sup>[53]</sup> The result showed that the isocyanides adsorbed on gold via the carbon lone pair electrons.

## SILVER NANOPARTICLES

Recently, research efforts have been intensified for the synthesis of Ag nanoparticles because of important roles played by Ag particles in antimicrobial applications, catalysis, and as a substrate for SERS. Thiols<sup>[54–58]</sup> have been the most popular choice of capping reagents for Ag nanoparticles because of a higher stability over other capping reagents, such as amines<sup>[59,60]</sup> and carboxylates,<sup>[61–63]</sup> which are weakly anchored to Ag particle cores. Other organic compounds, such as dialkyl disulfides,<sup>[31,64]</sup> dialkyl sulfides,<sup>[65]</sup> thiosulfates,<sup>[66]</sup> thiosalicylic acids,<sup>[67]</sup> and xanthates,<sup>[38]</sup> have been used to generate monolayer-protected Ag nanoparticles.

### Silver Nanoparticles Protected with Sulfur-Containing Species

Alkanethiolate-protected Ag nanoparticles were synthesized using the modified two-phase Schiffrin reaction.<sup>[54,55]</sup> Two-dimensional ordered superlattices of the Ag nanoparticles could be formed by evaporating a drop of the particle solutions on carbon films.<sup>[55]</sup> The fluorinated thiol-capped Ag nanoparticles could be prepared using the  $\text{NaBH}_4$  reduction of  $\text{AgNO}_3$  in the presence of perfluorodecanethiol in acetone/water. These particles could be redispersed in acetone and

liquid and supercritical  $\text{CO}_2$ .<sup>[56]</sup> Thiolated  $\beta$ -cyclodextrin-protected Ag nanoparticles were also synthesized from  $\text{AgNO}_3$ .<sup>[57]</sup> *N,N*-Dimethylformamide (DMF) was used as both the solvent and the reducing agent in this reaction. Synthesis of water-soluble tiopronin-protected Ag nanoparticles was also reported.<sup>[58]</sup>

Unlike Au nanoparticles functionalized by the adsorption of dialkyl disulfides, the monolayers of alkanethiolate-protected Ag nanoparticles derived from dialkyl disulfides were somewhat less crystalline than those prepared similarly from alkanethiols.<sup>[31]</sup> Positively charged Ag nanoparticles were synthesized by the  $\text{NaBH}_4$  reduction of  $\text{AgNO}_3$  in the presence of quaternary ammonium dialkyl disulfides.<sup>[64]</sup> Adsorption of benzyl phenyl sulfide on silver nanoparticles in water has been studied.<sup>[65]</sup> Alkanethiolate-protected Ag nanoparticles were synthesized from sodium *S*-dodecylthiosulfate in aqueous solution.<sup>[66]</sup> Silver nanoparticles, produced by the borohydride reduction of  $\text{AgNO}_3$  in  $\text{H}_2\text{O}$ , were stabilized by the adsorption of *S*-dodecylthiosulfate followed by the removal of the  $\text{SO}_3^-$  moiety.

Alkyl xanthates were also used for the capping of Ag nanoparticles.<sup>[38]</sup> Xanthate-capped Ag particles are less hydrophobic than alkanethiol-protected Ag nanoparticles and less stable than the oleate-capped particles (but still stable in aqueous solutions for over a month). Thiosalicylic acid (TSA)-functionalized silver nanoparticles were synthesized from  $\text{NaBH}_4$  reduction of TSA- $\text{AgNO}_3$  in aqueous ethanol solution.<sup>[67]</sup>

### Silver Nanoparticles Protected with Other Organic Species

A synthesis of alkylamine-capped silver nanoparticles was developed using thermal decomposition of  $[\text{Ag}(\mu\text{-mesityl})_4]$  (mesityl = 2,4,7- $\text{Me}_3\text{C}_6\text{H}_2$ ) derivatives in alkylamine solution.<sup>[59]</sup> Two-phase (*n*-heptane/water)  $\text{NaBH}_4$  reduction of *N*-hexadecylethylenediamine silver nitrate complex produced *N*-hexadecylethylenediamine-protected silver nanoparticles.<sup>[60]</sup> The colloidal solution of diamine-protected silver nanoparticles was free from flocculation and aggregation for several months.

Long-chain carboxylates (or fatty acids) have been one of the most commonly used ligands for silver particles.<sup>[61–63]</sup> The simple dissolution of silver 2-ethylhexanoate in DMSO (as both a solvent and reducing agent) produced silver nanoparticles.<sup>[61]</sup> Addition of stabilizing agent, sodium citrate, produced stable yet catalytic monolayer-protected silver nanoparticles. Thermal reduction of silver trifluoroacetate in isoamyl ether in the presence of oleic acid generated Ag nanoparticles with diameters in the range of 7–11 nm with narrow size distribution.<sup>[62]</sup>

Surface-enhanced Raman scattering studies of 4-biphenylisocyanide of silver nanoparticles proved the adsorption of isocyanide on silver surfaces.<sup>[53]</sup> Dye-protected silver nanoparticles were prepared through the reduction of metallic Ag ions by NaBH<sub>4</sub> in aqueous media.<sup>[68]</sup> The dye used was a cyanine derivative, 5,5'-dichloro-3,3-disulfopropylthiacyanine sodium salt.

## COPPER NANOPARTICLES

Because of the inexpensive nature of copper precursors and the expected optical, electronic, and catalytic properties of copper nanoparticles, there has been an increased interest in the synthesis of stable monolayer-protected copper nanoparticles. Monolayer-protected copper nanoparticles have been synthesized using alkanethiols,<sup>[69,70]</sup> alkylamines,<sup>[59]</sup> tetra-alkyl ammonium complexes,<sup>[71]</sup> and alkyl xanthates<sup>[38]</sup> as their stabilizing ligands. However, progress has been limited because of the instability (oxidation) of these copper nanoparticles.

### Copper Nanoparticles Protected with Sulfur-Containing Species

Alkanethiolate-protected copper nanoparticles with the size of 1–2 nm in diameter were prepared in a one-phase tetrahydrofuran (THF) system using lithium triethylborohydride (superhydride) as the reducing agent.<sup>[69]</sup> The aged particles typically failed to maintain their electronic and optical properties because of the oxidation of the copper core. Thermal annealing of copper nanoparticles in solid state produced large (>10 nm) nanoparticles with distinct shape evolutions. Thermolysis of copper complexes in the presence of alkanethiols in supercritical water produced small monodisperse Cu nanoparticles.<sup>[70]</sup> Alkyl xanthate stabilization also enabled the preparation of copper nanoparticles in aqueous solution.<sup>[38]</sup>

### Copper Nanoparticles Protected with Other Organic Species

Alkylamine-protected copper nanoparticles (8–9 nm) were synthesized by thermolysis of [Cu(*μ*-mesityl)<sub>5</sub>] (mesityl = 2,4,7-Me<sub>3</sub>C<sub>6</sub>H<sub>2</sub>) derivatives in octylamine followed by injection into a hot hexadecylamine solution.<sup>[59]</sup> A sonochemical approach was used for the preparation of elongated copper nanoparticles coated with cetyltrimethylammonium *p*-toluene sulfonate.<sup>[71]</sup>

## PLATINUM NANOPARTICLES

Platinum nanoparticles have drawn quite an interest because of their catalytic properties and promising fuel

cell application. Ligand-stabilized platinum nanoparticles with alkanethiols,<sup>[72–75]</sup> thiolated  $\beta$ -cyclodextrins,<sup>[76]</sup> alkyl xanthates,<sup>[77]</sup> alkylamines,<sup>[78]</sup> and alkyl isocyanides<sup>[79]</sup> have been reported.

### Platinum Nanoparticles Protected with Sulfur-Containing Species

Alkanethiols have been the choice of protecting ligands for Pt particles. The reduction of H<sub>2</sub>PtCl<sub>6</sub> by a small (10%) stoichiometric excess of sodium borohydride in the presence of a toluene solution containing 1-dodecanethiol produced dodecanethiolate-protected platinum nanoparticles, which were transferred to the toluene layer.<sup>[72]</sup> Transmission electron microscopy (TEM) results showed that these Pt nanoparticles have a mean diameter of 2.6 nm and a nearly monodispersed particle size distribution. Concentrated HCl was sometimes added to transfer Pt hydrosol, prepared by the NaBH<sub>4</sub> reduction in water, to the organic phase for thiolation.<sup>[73]</sup> The platinum nanoparticles synthesized in this manner have an average diameter of 4.4 nm. One-phase synthesis of alkanethiol-protected platinum nanoparticles using tetrahydrofuran as the solvent and superhydride as the reducing agent generated Pt nanoparticles with an average size of ~3 nm.<sup>[74]</sup> Water-dispersible mercaptosuccinic acid-protected platinum nanoparticles were prepared by one-phase reduction of chloroplatinic acid with sodium borohydride in either water or methanol.<sup>[75]</sup> The average particle diameter changes from 2.5 to 4.7 nm depending on the thiol/Pt ratio from 0.7 to 0.1, respectively.

Thiolated  $\beta$ -cyclodextrin-protected platinum nanoparticles were synthesized by NaBH<sub>4</sub> reduction of PtCl<sub>4</sub><sup>2-</sup> in DMSO–H<sub>2</sub>O in the presence of per-6-thio- $\beta$ -cyclodextrin.<sup>[76]</sup> These water-soluble platinum nanoparticles exhibit catalytic activity for the hydrogenation of allylamines. Alkyl xanthate-capped platinum nanoparticles were produced by the addition of alkyl xanthates in an aqueous solution containing uncapped platinum particles (4.0 nm).<sup>[77]</sup> Xanthate-capped platinum nanoparticles were found to be more stable than alkanethiol-protected platinum nanoparticles toward chemical corrosion and heating.

### Platinum Nanoparticles Protected with Other Organic Species

The use of hexylamine as an intermediate labile capping reagent for 4-mercaptoaniline-protected platinum nanoparticles has been reported.<sup>[78]</sup> *tert*-Butylammonium-stabilized platinum nanoparticles were prepared by a two-phase chemical reduction method. The addition of dodecyl isocyanide to this solution produced alkyl isocyanide-protected platinum nanoparticles.<sup>[79]</sup>

## PALLADIUM NANOPARTICLES

Research efforts to synthesize palladium nanoparticles have been increased because of the important roles played by palladium in catalysis. The catalytic activity of palladium nanoparticles is very sensitive to the particle size, shape, and ligand structure and density. Palladium nanoparticles were protected with alkanethiols,<sup>[80–82]</sup> thiolated  $\beta$ -cyclodextrins,<sup>[76,83]</sup> tetra-alkylammonium salts,<sup>[84,85]</sup> and alkyl phosphines.<sup>[86]</sup>

### Palladium Nanoparticles Protected with Sulfur-Containing Species

Alkanethiol-protected palladium nanoparticles can be synthesized using either the two-phase Schiffrin reaction<sup>[80]</sup> or one-phase superhydride reduction.<sup>[81,82]</sup> The size and morphology of palladium nanoparticles are sensitive to the thiol/Pd precursor ratio used in the reaction mixture.  $\omega$ -Functionalized monolayer-protected Pd nanoparticles can be synthesized by the ligand-place exchange reaction. Further organic reactions of functionalized Pd nanoparticles allow for the preparation of ferrocene-functionalized Pd nanoparticles.<sup>[80]</sup> Pd nanoparticles can be modified with thiolated  $\beta$ -cyclodextrin receptors by the reduction of  $\text{PdCl}_4^{2-}$  in DMF, yielding water-soluble Pd nanoparticles with good catalytic activity for the hydrogenation of various alkenes in aqueous media.<sup>[76,83]</sup>

### Palladium Nanoparticles Protected with Other Organic Species

Palladium nanoparticles stabilized by tetra-alkylammonium salts are prepared by the electrochemical reduction of Pd complex in the presence of tetra-alkylammonium surfactants.<sup>[84]</sup> Glycolate-stabilized Pd and Ni nanoparticles were synthesized by hydrogen reduction of  $\text{Pd}(\text{NO}_3)_2$  in the presence of tetraoctylammonium glycolates.<sup>[85]</sup> Monodisperse Pd nanoparticles with core dimensions of 3.5, 5, and 7 nm were synthesized by the thermal decomposition of Pd-trioctylphosphine (TOP) complex in an argon atmosphere.<sup>[86]</sup> The core size of Pd nanoparticles was controlled by varying the concentration of TOP.

## APPLICATIONS

Because the precise control over the chemical and structural composition of a monolayer surrounding a metal nanoparticle can dramatically affect its macroscopic properties and functions, monolayer-protected metal nanoparticles have found increased use in many recent applications including electronics, optics, catalysis, and

chemical recognition. Quantized double-layer charging has been one of the more interesting properties of alkanethiolate-protected metal nanoparticles. Optical properties of metal nanoparticles could be tuned by the incorporation of photoactive ligands. Optoelectronic properties of metal nanoparticles related to the surface plasmon absorption have also drawn increased interests. Catalytic properties of monolayer-protected metal nanoparticles are now being investigated in the broad field of catalysis including simple organic reactions, polymerization, and electrocatalysis. Functionalized monolayer-protected metal nanoparticles recognize molecules, bioconjugates, supramolecules, and metals based on various interactions (e.g., hydrogen-bonding, van der Waals, and electrostatic interactions). The combination of electronic and/or optical properties of metal nanoparticles with sensing capability results in the development of excellent sensory devices. The article on “Metal Nanoparticles Protected with Monolayers: Applications for Chemical Vapor Sensing and Gas Chromatography” touches on some of these particular applications.

## CONCLUSION

The synthesis of monolayer-protected metal nanoparticles has undoubtedly expanded the available diversity of the nanomaterials as functionalized chemical reagents. Various monolayer-protected metal nanoparticles including Au, Ag, Cu, Pt, and Pd particles have been prepared in different reaction conditions. However, there is still a great demand for new and convenient techniques that allow environmentally benign and cost-effective preparation of monolayer-protected metal nanoparticles and other hybrid nanoparticles. More extensive and systematic studies are essential for further advancement in the nanoparticle-related research field.

# Moore's Law: Performance and Power Dissipation

Laszlo B. Kish

Department of Electrical Engineering, Texas A&M University,  
College Station, Texas, U.S.A.

## INTRODUCTION

Moore's law predicts that the number of transistors in a chip will grow exponentially in time. Exponents giving the best fit of various chip families suggest an 18-month transistor number doubling time. If Moore's law of miniaturization will be followed below the size of 40 nm, physics will impose fundamental and practical limits of performance because of shrinking noise margin, increasing and quickening noise, and increasing power dissipation. It is important to locate the fundamental aspects of the problem, to explore relevant practical problems and possible solutions, and to investigate this situation not only in microelectronics, such as complementary metal oxide semiconductor (CMOS), but also in single-electron transistor (SET)-based nanoelectronics and even in quantum informatics applications. Recent studies show that quantum computers are not satisfactory tools to solve these problems of *general-purpose* data handling, and that the fundamental limits governing classical (CMOS) computers allow a much better performance than possible quantum computers.

## FUTURE OUTLOOK

We all have been enjoying the fast growth of speed and memory size of computers during the last decades. Recently, the emerging fields of quantum computing and nanoelectronics have suggested that the future will be even more brilliant.

However, as soon as we confront physical laws and reality with expectations, the future becomes more realistic. In this entry, we briefly outline some of the key issues.

## GENERAL CONSIDERATIONS

Thermal noise is an omnipresent small-voltage fluctuation on resistors. It has been thought that thermal noise will never be an issue in digital electronics. This view has been reevaluated and changed recently by

Kish.<sup>[1]</sup> On a parallel resistor–capacitor (RC) unit, the effective thermal noise voltage  $U_n$  is given as:

$$U_n = \sqrt{kT/C} \quad (1)$$

and the bandwidth  $f_c$  of this noise is:

$$f_c = \frac{1}{2\pi RC} \quad (2)$$

Gaussian noise processes, such as thermal noise, can cross large amplitude levels, provided that sufficiently long time is available. In a logic circuitry, noise amplitudes reaching beyond the noise margin  $U_{th}$  cause false bit flips that can result in bit errors. For a single band-limited noise process, the mean frequency  $\nu(U_{th})$  of bit errors can be obtained from the Rice formula:<sup>[1]</sup>

$$\nu(U_{th}) = \frac{2}{\sqrt{3}} \exp\left(\frac{-U_{th}^2}{2U_n^2}\right) f_c \quad (3)$$

where  $U_n$  is the effective noise voltage and  $f_c$  is the bandwidth.

So, what happens during miniaturization? In CMOS technology, the resistors are two-dimensional conductors; thus the resistance stays (roughly) constant. Therefore the supply voltage has to be decreased to keep the electrical field and dissipation at acceptable levels. The capacitances decrease. Together, these effects yield the following trends:

1. Shrinking noise margin (because  $U_{th}$  is only a fraction of the supply voltage)
2. Growing noise [because of Eq. (1)]
3. Growing bandwidth [quickening of the noise; Eq. (2)].

All these phenomena (1, 2, and 3) act toward radically increasing the frequency of bit errors via Eq. (3). To have a feeling of the nature of this problem, on Fig. 1, the bit error frequency vs. the noise margin normalized to the noise voltage is shown for different bandwidths (clock frequency) and different numbers of transistor. The practical limit of usability is a certain

**Fig. 1** Bit errors vs. the ratio of noise margin and effective noise voltage. *Source:* From Ref.<sup>[1]</sup>.

$U_{th}/U_n$  ratio when the bit error rate is around 1 error/year. Even a 10% decrease of the  $U_{th}/U_n$  ratio compared with its critical value yields an error rate increase to  $10^5$  when we consider all transistors in a modern PC ( $3 \times 10^9$ – $10^{10}$  transistors).

Utilizing these results and a prediction of the evolution of capacitance and noise margin using present trends, recently, a prediction of the end of Moore's law was reported by Kish<sup>[1]</sup> (Fig. 2).

**Fig. 2** Prediction of the end of Moore's law. *Source:* From Ref.<sup>[1]</sup>. The technology faces a difficult problem when the upper limit of noise margin set by the dissipation/field constraint and the lower limit of noise margin required by the noise/error constraint cross each other (between points A or B, depending on the evolution of gate oxide thickness).

The shrinking noise margin (logic threshold voltage) and the increasing noise margin required by the increasing and quickening noise pose conflicting requirements, which would stop miniaturization in 6–8 years if the trends of the last year continue.

In the rest of this article, we outline the objectives that need further analysis and give some initiatives for extended research in the future.

### REFINEMENTS OF PREDICTIONS FOR CMOS TECHNOLOGY

It has been pointed out in Ref.<sup>[1]</sup> that the prediction was based on strong approximations to keep generality and because of lack of information about certain device parameters. Since Ref.<sup>[1]</sup> was published, new information from microprocessor makers about some previously unknown parameters has emerged and some new efforts have been made to reduce the supply voltage with a rate less than previously supposed. However, these efforts are controversial because many large-scale users (e.g., in aviation electronics)<sup>[2]</sup> would like to increase the rate of supply voltage reduction to improve device failure rate, which has been steadily growing because of high electric fields in chips.

Therefore theoretical efforts have been made on refining the prediction for the bit error problem because of thermal noise. The refined model takes into the account the following aspects:

- Further noise margin decrease because of the opening threshold voltages of the P-type and N-type MOSFET transistors
- Somewhat reduced noise because of parallel gate circuits
- Various supply voltage reduction strategies (predictions are controversial)
- The fact that the internal supply voltage and noise margin of microprocessors in 2002 were already less than supposed in Ref.<sup>[1]</sup>.

Interestingly, preliminary investigations indicate that the size range, where the problems begin, remains the same because the different corrections act in different directions and the effects compensate for each other. Thus the conclusions obtained in the context of Fig. 2 remain the same.

### THE CASE OF SINGLE-ELECTRON TRANSISTORS

The next question is the bit error situation of microprocessors based on SETs.<sup>[3]</sup> SETs work with tunneling, which is not dissipative, but the processes

coupled to it are dissipative. The electrons at the tunnel junction of a closed SET can be excited by thermal energy fluctuations to the energy level where tunneling can occur and a single electron can cause a single bit error in a SET. Similarly, an open SET can be temporarily shut down by thermal fluctuations. Thus the tentative expectation is that SETs will have a similar nature of bit error characteristics as CMOS. However, the picture is more complex.<sup>[3]</sup>

- Instead of a single capacitance, three different capacitances influence bit errors: the two tunnel junction capacitances and the quantum dot capacitance (gate capacitance).
- The noise margin cannot be increased arbitrarily by increasing supply voltage. It has a practical maximum that is equal to the voltage difference between the totally closed and totally open transistors. Higher voltages cause multiple-electron operation mode, and large noise and dissipation.
- There are two different working ranges vs. the quantum dot size: larger sizes (Coulomb blockade controls the current transport) and smaller sizes (<10 nm; quantum confinement effects dominate).

Preliminary studies<sup>[3]</sup> show that the requirement for small quantum dot size becomes much harder to satisfy when not only the d.c. characteristics but also the bit errors matter in a microprocessor with  $10^8$  or more SETs. To have SET-based microprocessors, the characteristic quantum dot size has to be less than 1 nm.

### ULTIMATE LIMITS OF ENERGY DISSIPATION VS. PERFORMANCE IN CLASSICAL AND QUANTUM COMPUTING

Heat problems with today's microprocessors have made it very clear that the ultimate and most fundamental questions of viability of the technology are related to power requirement information processing. This is the ultimate question for general-purpose classical or quantum computers. If CMOS and SET fail, it is a natural question if quantum computing and quantum information can help us out and—if yes—how. Because, so far, the existing quantum computing architectures have been neither practical nor general purpose, the only question we may be able to answer is the ultimate limits of performance. Performance includes error rate (accuracy), speed (bandwidth), and power dissipation. It is very important to take temperature into account, and to compare the ultimate performance limits of classical and quantum computers at the same temperature.<sup>[4]</sup> If it is room temperature, both the classical and quantum computers

**Fig. 3** Minimal power dissipation of a single logical gate, classical (CMOS) and quantum, vs. the error ratio of the gate. *Source:* From Ref.<sup>[4]</sup>.

should be tested at room temperature; if it is the microkelvin temperature range, than the same conditions are required for both.

Recent studies<sup>[5]</sup> show that quantum computers have energy requirement problems at high accuracy because of arguments similar to Heisenberg's uncertainty principle. Classical computers perform much better when accuracy is concerned; however, quantum computers can balance this deficiency by a greater speed.<sup>[4]</sup> (For a comparison of the energy requirements of a classical and a quantum gate when they run at the same clock frequency, see Fig. 3.<sup>[4]</sup>)

Realistic estimations<sup>[6]</sup> based on existing quantum error correction methods indicate that a general-purpose quantum computer, which would use the best known quantum error correcting methods, would dissipate at least 100 times more energy than its classical counterpart.

Concerning future research aspects, we think that the ultimate focus of this study will not be the accuracy (error rate) of classical and quantum computers, but the energy requirements of processing Shannon information (bit). This aspect induces many new questions, including the problem of computer architectures that are not sensitive to noise. An important question is the energy and complexity requirement of error-correcting coding, and the ultimate measure should be energy requirement vs. Shannon information.

## INTRODUCTION

After billions of years of evolution, biological nanomotors and, in particular, motor proteins have achieved a level of performance unmatched by current synthetic nanomotors. Motor proteins in hundreds of specific designs perform a wide range of functions in biology, while achieving more than 50% efficiency in the conversion of chemical energy to mechanical work.<sup>[1,2]</sup>

The research discussed in this entry aims at utilizing motor proteins in hybrid “bio/nano” devices to explore the potential of nanomotors in technological applications. Challenges for this approach include the design of suitable synthetic environments, the interfacing of biological components with synthetic structures, the controlled modification of biological motors using recombinant techniques, and in general, the difficulty of engineering at a size scale where random fluctuations due to Brownian motion are an integral part of the system.

At this point, an international group of research teams has utilized a variety of rotational and linear motor proteins to demonstrate the first devices integrating motor proteins. These devices illustrate the important role that motor proteins can play in nanotechnology.

## MOTORS IN NANOTECHNOLOGY

Technological revolutions often involve access to new materials, and the mastery of a new material is so fundamental to mankind that historic ages are defined by the state-of-the-art material, hence the “stone age” or “bronze age.” However, some technological revolutions are characterized by the newfound ability of

man to convert energy into mechanical work, based, for example, on the invention of the steam engine, which powered the industrial revolution. Can nanotechnology become a revolution of energy conversion in addition to a materials revolution, driven by a nanomotor, which will power the “Nanofactory” and the “Nanoautomobile” of tomorrow?

Currently, no man-made nanomotor exists that can impact nanotechnology in the way that the steam engine defined the industrial revolution. However, while the first prototypes of synthetic nanomotors are studied,<sup>[3,4]</sup> nature provides us with a wide range of biological nanomotors, which have evolved to perform a wide range of functions with an amazing efficiency.<sup>[5]</sup> While the center stage is occupied by motor proteins such as myosin, which is, for example, responsible for muscle contraction, biological motor designs include motors based on ribonucleic acid (RNA) pulling on double-stranded deoxyribonucleic acid (DNA) to package it into the protein shell of a virus,<sup>[6]</sup> ribosomes moving along RNA while synthesizing a new protein, or even an electrostrictive membrane protein aiding the process of hearing.<sup>[7]</sup> The mechanism by which biological motors, in particular motor proteins, generate force is a very active field of research, and significant progress has been made.<sup>[8]</sup> Nowadays, motor proteins can be readily isolated and are even commercially available.

Biomolecular motors, in particular motor proteins, are a gift of nature to the nanotechnologist. They can be used in hybrid “bionano” devices to explore the potential of nanomotors. At this point, a small number of prototypical nanodevices based on motor proteins has been assembled, and in the following, we will introduce the biological motors used, and discuss the progress in the design of hybrid devices.

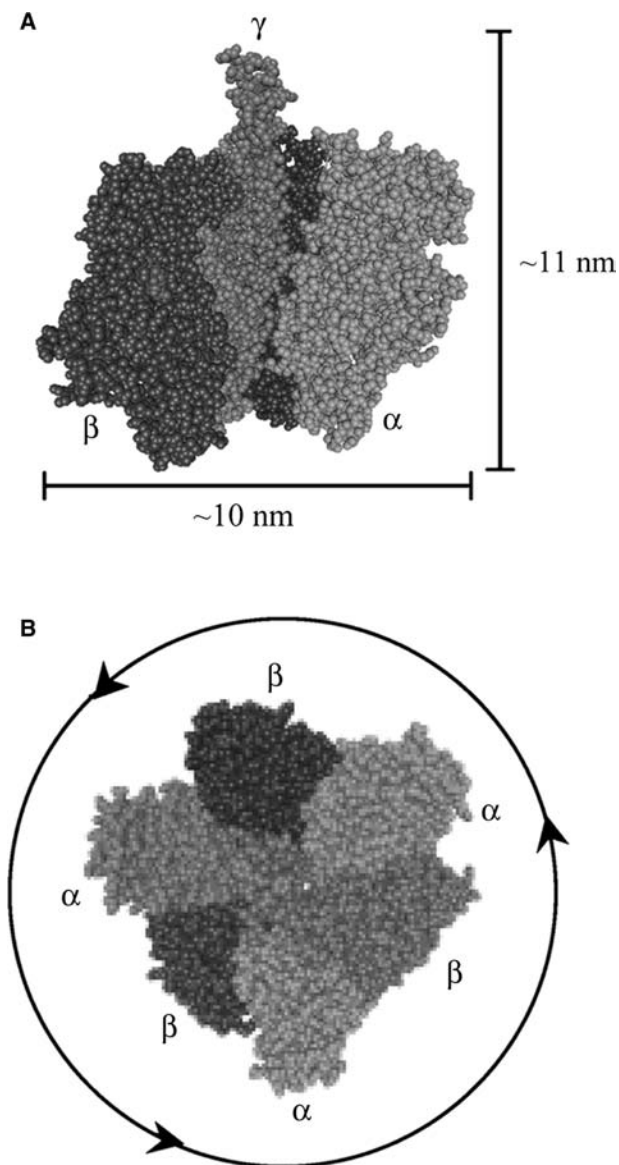

## BIOLOGICAL FUNCTIONS OF MOTOR PROTEINS

Motor proteins represent a unique class of enzymes and enzyme complexes that convert chemical energy into mechanical work with relatively high efficiency. In these proteins, energy associated with catalysis (or an electrochemical gradient) is linked to conformational changes in the structure. As with man-made motors, these molecular machines can be categorized as either rotary or linear motors, depending on their mode of translation.

Two true rotary molecular motors were identified, and extensively studied in terms of the biochemical and biophysical properties of these protein complexes. The bacterial flagellar motor is a classic example of a rotary motor used by certain bacteria to move in a fluid environment. The complex uses a proton gradient to propel a large flagellum at speeds of up to 300 rps, and produces a rotary torque in excess of 550 pN nm.<sup>[9]</sup> A second rotary motor, ATP synthase ( $F_0F_1$ -ATPase), is a ubiquitous enzyme complex responsible for proton-powered production of adenosine 5'-triphosphate (ATP) in living system.<sup>[10]</sup> Translocation of  $H^+$  across a membrane results in the rotation of a central shared subunit, and synthesis of three molecules of ATP per revolution. Moreover, the cytoplasmic  $F_1$ -ATPase domain may independently function as an ATP-fueled rotary motor;<sup>[11]</sup> construction of integrated devices with this motor protein will be discussed later (Fig. 1).

A number of linear motors were extensively studied in terms of their biomechanical characteristics,<sup>[8,13,14]</sup> as well as their potential use in hybrid nanodevices.<sup>[15]</sup> Linear motors can be chosen from three principal families: myosins—moving along actin filaments toward the barbed end; kinesins—moving along microtubules toward the plus end; and dyneins—moving along microtubules toward the minus end<sup>[16]</sup> (Fig. 2).

Actin filaments, which are double-stranded twisted ropes polymerized from 5.5-nm-long actin monomers, are highly flexible and can branch into a dense mesh. Microtubules are stiff, unbranched, proteinaceous tubes with an outer diameter of  $\sim 30$  nm, consisting of 8–18 parallel protofilaments assembled from 8-nm-long tubulin dimers. While motors of the myosin family are the molecular actuators responsible for the contraction of muscles, specialized motors of all families participate in the intracellular transport of membrane organelles and protein complexes. The morphology and biochemistry of the different types of motors is closely coupled to their function. For example, myosin II has evolved to act in a large array of motors in fast skeletal muscle. Consequently, the biochemical cycle of binding ATP, hydrolyzing ATP, and releasing the products adenosine 5'-diphosphate (ADP) and phosphate is tuned toward a short time

**Fig. 1** (A) Side view of the crystal structure of the bovine  $F_1$ -ATPase reported by Braig et al.<sup>[12]</sup> Adjacent  $\alpha$  and  $\beta$  subunits were removed to show the  $\gamma$  subunit and bound ADP (red). (B) Top of the  $F_1$ -ATPase motor showing the alternating  $\alpha/\beta$  hexamer (stator) and central  $\gamma$  subunit (rotor). The  $\gamma$  subunit rotates counterclockwise in a three-step process during ATP hydrolysis. The  $F_0$  portion of ATP synthase, which inserts into a membrane and converts a proton flow into a rotary motion, is not shown.

of attachment to the actin filament (non-processive motion). In contrast, the step size of a conventional kinesin motor (transporting as a single motor, e.g., synaptic vesicles) matches exactly the 8-nm spacing between adjacent tubulin binding sites on a protofilament of a microtubule, which, together with a coordinated hydrolysis cycle of the two heads of the motor, facilitates a large number of consecutive steps without detaching from the microtubule (processive motion).<sup>[5]</sup>

**Fig. 2** (A) Myosin II, the myosin type present, e.g., in skeletal muscle, assembles into a thick filament. The collective, unsynchronized motion of the myosin motors along the actin filament causes the contraction of muscle cells. Each myosin motor attaches only intermittently to the actin filament (non-processive motion), “running” along with a velocity of up to  $8 \mu\text{m}/\text{sec}$ . Actin filaments consist of two helical strands polymerized from actin monomers with a full period of  $72 \text{ nm}$ . (B) Conventional kinesin is a two-headed motor moving toward the “plus” end of a microtubule. The two heads move in coordinated fashion, covering a distance of  $8 \text{ nm}$  with each step, hydrolyzing one ATP molecule per step, and generating a maximum force of  $7 \text{ pN}$ . In vitro, kinesin takes up to 100 steps/sec. At least one of the kinesin heads is attached at any point in time (processive motion). Cytoplasmic dynein is a processive, two-headed motor moving toward the “minus” end of the microtubule. It is a particularly large protein complex, consisting of more than eight subunits with a combined mass of more than  $1000 \text{ kDa}$ . Microtubules are tubular structures with an outer diameter of  $30 \text{ nm}$ , which are polymerized from individual tubulin monomers with a length of  $8 \text{ nm}$ . Microtubules assembled in vitro can reach a length of up to  $100 \mu\text{m}$ . In vivo, microtubules constantly assemble and disassemble; however, the use of drugs like taxol can stabilize microtubules for weeks by slowing the depolymerization.

The large number of natural designs of linear motors for functions ranging from muscle contraction to vesicle transport can serve as a tool chest for hybrid devices. It is also an inspiration for artificial modifications to existing motors, for example, by integrating chemical switches or by changing their processivity.<sup>[17,18,61]</sup> Currently, conventional kinesins and microtubules are a motor/filament combination, which is often utilized for reasons related to the robustness of the proteins, the successful expression of kinesin in *Escherichia coli*,<sup>[19]</sup> and the easy modification of tubulin.<sup>[20]</sup>

## MOTOR PROTEINS IN A SYNTHETIC ENVIRONMENT

Controlling the interaction between the motor proteins and the synthetic materials is a major challenge in the

design of hybrid devices.<sup>[21]</sup> While regions of the surface intended as motor protein-coated tracks or islands have to have a high affinity for protein adsorption, denaturation and concomitant loss of function of the protein after adsorption to the surface has to be avoided as well. It is equally important for the defined positioning of motors in a device to prevent the adsorption of motors to regions surrounding the intended motor protein-rich regions, a challenging task because of the general tendency of proteins to stick to many synthetic surfaces.

A variety of approaches to reduce denaturation were developed, ranging from precoating surfaces with a generic protein (albumin, casein),<sup>[22]</sup> which restricts the surface–motor contact to small patches in-between the preadsorbed proteins, to coating the surface with polymer brushes with functionalized ends,<sup>[23]</sup> which prevents motor adsorption directly to the surface while providing a designated binding site on the polymer. The most sophisticated approach toward attaching a motor (discussed in more detail in the subsection “Rotational Systems”) relied on genetically engineering specific anchor sites into the protein, which connect to a patterned nickel film on the surface.<sup>[11,24]</sup> The adsorption of motors has been selectively prevented by either empirically identifying materials, which together with added detergents in the solution reduce protein adsorption,<sup>[25]</sup> or by using surface modification strategies originally developed for non-fouling surfaces.<sup>[26]</sup>

The lifetime of hybrid bionanodevices is a frequent concern. To maintain motor proteins in a functional state, the temperature, ionic strength, pH, and salt concentration of the surrounding solution have to be controlled.<sup>[27]</sup> Microtubules and actin filaments depolymerize over time,<sup>[28]</sup> a process which can be slowed but not entirely prevented. In addition, proteins are subject to degradation by proteases, and they sustain photodamage during observation under the fluorescence microscope. In combination, these factors currently limit the lifetime of actively operating devices to hours or a few days at room temperature. However, for a large number of applications, this lifetime, together with adequate storage at low temperatures before operation, is sufficient.

## REGULATING BIOMOLECULAR MOTOR ACTIVITY

A fundamental element in the engineering of biomolecular motor-powered devices and materials is the ability to modulate the activity of the motors. To date, two strategies have been used to regulate the functionality of biomolecular motors in synthetic systems. The first strategy involved the controlled release of caged ATP

into solution to modulate the linear translation of conventional kinesin.<sup>[29]</sup> Because the density of tethered kinesin was relatively low, an ATP-consuming enzyme, hexokinase, was used to rapidly reduce the liberated ATP in solution, and produce discrete spikes of available ATP. In this manner, the magnitude of velocity and distance could be regulated based on the intensity of light exposure.<sup>[29]</sup> This strategy has direct application for controlling any molecular motor that utilizes ATP as a fuel source. A primary advantage in this system is the ability to produce discrete spikes in ATP that, in turn, may be used to regulate the velocity/distance traveled by linear motors, or the speed/number of cycles for rotary motors.

The second strategy for controlling motor functionality involved genetically engineering an allosteric effector site into the catalytic domain of the F<sub>1</sub>-ATPase molecular motor.<sup>[30]</sup> This site was engineered to bind Zn<sup>2+</sup> such that the conformation changes necessary for ATP hydrolysis and  $\gamma$  subunit rotation would be reversibly inhibited when the site was occupied; chelation of the Zn<sup>2+</sup> would subsequently restore activity. In single molecule assays, rotation of all (i.e., 100%) mutated F<sub>1</sub>-ATPase was observed in the presence of 800  $\mu$ m ZnSO<sub>4</sub>, whereas bulk activity assays indicated a 60% inhibition in catalytic activity at saturating levels of Zn<sup>2+</sup>. This suggests that the complete inhibition of hydrolytic activity is not requisite for tight control of motor rotation in ATPase. Repeated cycles of Zn<sup>2+</sup> inhibition, followed by chelation with 1,10-phenanthroline, demonstrated the ability to reversibly control the functionality of the F<sub>1</sub>-ATPase motor.<sup>[30]</sup> A unique advantage in this strategy is the ability to tailor the allosteric binding site, which may serve as a recognition element in sensor-type applications.

## NANODEVICES

### Rotational Systems

The F<sub>0</sub>F<sub>1</sub>-ATPase enzyme complex consists of eight subunits ( $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\epsilon$ , and  $\delta$ ) that are arranged in two distinct domains, the cytoplasmic F<sub>1</sub> and hydrophobic F<sub>0</sub> domains. The F<sub>1</sub>-ATPase domain can function independently as an ATP-powered rotary motor,<sup>[11,31]</sup> and offers a potential source of actuation in nanoscale device architectures.<sup>[24,32]</sup> During ATP hydrolysis, the central rotor (i.e.,  $\gamma$  subunit) of F<sub>1</sub>-ATPase rotates in response to the conversion of ATP to ADP + P<sub>i</sub> at each of the three catalytic sites. This three-step process that results in rotation of the  $\gamma$  subunit was confirmed by a number of methods.<sup>[32–34]</sup> The precise mechanism of mechanical coupling of ATP hydrolysis and rotation of the  $\gamma$  subunit has yet to be determined.

In general, a prerequisite technology for utilizing molecular motors as functional components of nanoscale devices is the ability to interface biological and non-biological components. To this end, the F<sub>1</sub>-ATPase from thermophilic bacterium *Bacillus* PS3 was genetically engineered to express a 10x histidine (His) tag on the N-terminus of the  $\beta$  subunits.<sup>[24,32]</sup> The His-tagged motors were subsequently used to precisely position individual F<sub>1</sub>-ATPase motors on arrays of nanoscale nickel dots.<sup>[35]</sup> Because the His-tags were located on the N-terminal of the  $\beta$  subunit, the motors were positioned such that the base of the stator was adjacent to the surface, and the rotor was positioned perpendicular to the surface and fully accessible for attachment of additional components. A single cysteine (Cys) was also engineered at position 107 in the  $\gamma$  subunit to provide a unique chemical “handle” for attaching synthetic cargo.<sup>[24,32]</sup> The ability to genetically engineer the motors for specified interactions with synthetic components represents a powerful tool for tailoring the interaction of various components.

As a basic proof-of-principle, a simple device was designed and constructed, in which the F<sub>1</sub>-ATPase motors provided a source of actuation to nanoscale metallic components.<sup>[36]</sup> This device has three primary components: 1) a lithographically defined surface of Ni posts, 2) F<sub>1</sub>-ATPase motors, and 3) functionalized nanoscale “propellers” (Fig. 3). The device was assembled by sequential addition of individual components; however, yield was relatively poor (i.e., 1%, defined as the number of rotating propellers divided by the number of propellers distributed on the surface). Rotation was initiated with the addition of ATP, and stopped with sodium azide, an inhibitor of ATPase activity. The mean frequency of rotation was 4.8 Hz and directly correlated with the length of the propeller,

**Fig. 3** Schematic representation of the integrated nanoscale device that provided a proof-of-principle with regard to actuating nanomechanical devices with a biomolecular motor.<sup>[36]</sup> In the presence of ATP, the rotary motor F<sub>1</sub>-ATPase spins the nickel nanorod (10 × 150 × 1000 nm) with an angular velocity of 4 Hz while providing a torque of 20 pN nm. Elevating the motor on a post reduces the viscous drag on the moving nanorod, which increases near a surface.

suggesting that the torque was constant. The work performed by the  $F_1$ -ATPase motor to rotate a propeller through one complete revolution was calculated to be  $\sim 120$  pN nm, with an efficiency of 50%.<sup>[36]</sup> The device functioned for over 2 hr, at which point the propeller broke free from the motor. Overall, this experiment demonstrated the ability of this biomolecular motor to function as an actuator in a nanoscale mechanical device.

The force tolerances of these devices were characterized by using dynamic force spectroscopy to understand and potentially design integrated nanodevices with an increased assembly yield and lifetime.<sup>[37]</sup> In these experiments, the relative order of bond strengths (strongest to weakest) based on the magnitudes of their lifetimes were: biotin-streptavidin,  $(\text{His})_6$ -Ni-NTA,  $(\text{His})_6$ -Ni, and  $(\text{His})_6$ -gold. Based on these findings, the weakest bond in the  $F_1$ -ATPase-powered devices resides in the interaction between histidine and Ni, and likely represents a critical factor resulting in device failure. Improvements in device assembly and longevity may be engineered through further analysis and redesign of the interaction used to adhere the  $F_1$ -ATPase motors to the substrate, as well as to the propellers (or other components).

Overall, the  $F_1$ -ATPase biomolecular motor represents a highly efficient rotary actuator in integrated, nanomechanical devices. A number of enabling technologies were developed and used to construct a simple nanodevice powered by  $F_1$ -ATPase motors. Further characterization of this device by force measurements of binding strengths has determined the key linkages that likely result in poor assembly yields as well as device failure. As a whole, these data provide a foundation for the continued engineering and analysis of biomolecular motor-powered nanodevices.

## Transport Systems

One of the first ideas for a hybrid bionanodevice was a nanoscale transport system, a “molecular shuttle,” with the ability to move single molecules along tracks under user control.<sup>[15]</sup> The close analogy to the biological motor protein-based transport mechanisms<sup>[38]</sup> provided a clear vision of the feasibility and utility of such a system. Conceptually, a transport system requires solutions to the questions of how to direct the movement, how to load and unload cargo, and how to control the speed of the system.<sup>[29]</sup> The guiding issue was addressed with two different approaches (Fig. 4): either the actin filaments or microtubules are selectively immobilized on the surface and support the movement of motors attached to the cargo (bead assay),<sup>[39]</sup> or the motors are selectively adsorbed to the surface and move the corresponding filament, which in turn connects to the cargo (gliding assay).<sup>[40]</sup>

While the initial experiments by Turner et al.<sup>[41]</sup> yielded unpolarized patterns of aligned and immobilized microtubules capable of supporting kinesin motility, later experiments demonstrated polarized alignment of microtubules on surfaces using a variety of methods based on fluid flow.<sup>[42–44]</sup> Kinesin motors nonspecifically bound to the cargo surface then supported the directed transport of micrometer-sized objects across the array of microtubules.

The inverse arrangement, using microtubules as shuttle modules that move across a surface coated with motors and link specifically to the cargo, requires the structuring of the surface in order to create tracks. A variety of strategies including chemical modification,<sup>[45,46]</sup> guiding channels,<sup>[29,47]</sup> and combinations of surface chemistry and topography<sup>[25,48,49]</sup> has been employed to direct the shuttles along predetermined

**Fig. 4** Nanoscale transport systems based on motor proteins face three principal challenges: guiding the movement, loading the cargo, and controlling the speed.<sup>[15]</sup> Two approaches toward guiding the movement have emerged: (A) motor proteins are selectively adsorbed to a structured surface and guide the movement of microtubules or actin filaments serving as shuttle modules, or (B) an oriented array of microtubules is assembled on a surface by adsorption or polymerization and support the directed movement of motor proteins connected to the cargo. Selective loading of cargo and control of movement has been demonstrated for approach (A) by using biotin/streptavidin links for cargo attachment and controlled release of ATP from an inactive, “caged” precursor using UV light. *Source:* From Ref.<sup>[29]</sup>. © 2001 Am. Chem. Soc.

paths. In addition, flow fields<sup>[50]</sup> and electric fields<sup>[51]</sup> can influence the path of the shuttle. The choice between these guiding strategies is, in large part, determined by the physical properties of the filaments used as shuttles. For example, the large stiffness of microtubules<sup>[52]</sup> precludes effective guiding by motors adsorbed in tracks on a chemically modified surface.<sup>[53]</sup> Unidirectional motion of the shuttles propelled by surface adsorbed motors can be achieved by suitable track geometries.<sup>[25,53]</sup> Conveniently, the orientation of the surface adsorbed motors does not have to be controlled, because the flexible tail region of the kinesin motor allows the motor heads to find a suitable position for microtubule binding independent of the original orientation.<sup>[54,55]</sup> Microtubules can be readily functionalized with fluorescent dyes or biotin linkers,<sup>[54]</sup> which facilitates the observation of their movement as well as the attachment of cargo if the microtubules are employed as shuttles.

In summary, the basic challenges of guiding, loading, and controlling can be addressed by using a variety of approaches to achieve directed transport, by linking cargo to microtubules or motors, and by controlling motor activity as described in the section on controlling motor functionality. By integrating these approaches, a nanoscale transport system can be assembled and, in the future, combined with other modular systems such as assembly and packaging stations.

### Surface Imaging

The self-propelled movement of microtubules with a diameter of 30 nm on a kinesin-coated surface provides us with a novel nanoscale probe, which can explore a surface in a radically different fashion compared to the tip of a scanning probe microscope. While scanning probe microscopes use a single tip, which scans the surface in a controlled, linear movement, the microtubule movement per se is random. Therefore it is necessary to synthesize an image of the surface based on the random paths of a large number of microtubules exploring the unknown surface at the same time. A basic implementation of this new approach to surface imaging (Fig. 5) was demonstrated for a surface with a structured topography,<sup>[56]</sup> but the research into guiding mechanisms for nanoscale transport systems indicates that the microtubule path is influenced by surface chemistry or fluid flow as well. Despite its limitations due to the sensitivity of the proteins and the optical detection of the microtubule position, the described technique is an example of how the availability of self-propelled nanoprobe enables the implementation of a new scanning method with similarities to mathematical Monte Carlo methods. Nanotechnology is

**Fig. 5** Fluorescently labeled microtubules transported by surface-adsorbed kinesins can serve as nanoscale probes exploring the surface. The sensitivity of the microtubule path to the topography allows us to image an unknown surface.<sup>[56]</sup> This is illustrated in (A), where a microfabricated pattern of 1- $\mu\text{m}$ -high posts divides the surface into an accessible and an inaccessible region, because microtubules move on the bottom surface and are unable to climb a steep incline. Repeated observation of microtubule positions under the fluorescence microscope as shown in (B) yields information about the path of several hundred microtubules. The superposition of 500 images taken every 5 sec reveals the surface topography (C). *Source:* From Ref.<sup>[56]</sup>. © 2002 Am. Chem. Soc.

not always “the same but smaller.” Instead, sometimes “small is different” (Uzi Landman) applies, which creates opportunities to utilize nanosystems for innovative technologies.

## Actuators

While nanoscale transport systems are the technological equivalent to the biological tasks of kinesin in intracellular transport, nanoactuators are inspired by the biological application of myosin motors in muscles. Evidently, molecular motors can be assembled into large arrays and exert many Newtons of force, and it is an interesting question if highly efficient engines built from macroscopic arrays of molecular motors may replace electric motors or heat engines in the future. However, for the purposes of nanotechnology, even single biomolecular motors generate forces, which are sufficient to overcome typical loads.<sup>[57,58]</sup>

Recently, a miniaturized forcemeter for the measurement of intermolecular bond strengths was demonstrated.<sup>[59]</sup> In this forcemeter, several kinesin motors provide the force to strain the bond between a receptor–ligand pair, while the magnitude of the strain is reflected in the bending of a microtubule attached to the ligand, which serves as a nanoscale cantilevered beam of known stiffness (Fig. 6). The forcemeter with lateral dimensions of less than 10  $\mu\text{m}$  can generate and detect forces on the order of several piconewtons, which is sufficient to rupture most single molecule receptor/ligand bonds within seconds. The strain generated by the action of motor proteins

**Fig. 6** A microscopic forcemeter for the measurement of intermolecular forces on the order of a few piconewtons can be assembled from microtubules functionalized with ligands, beads coated with receptors, and kinesins (0 and 10 sec). It consists of a cantilevered microtubule that binds to a streptavidin-coated bead loaded onto a microtubule moved by kinesins.<sup>[59]</sup> The kinesins push the moving microtubule (30 sec), straining the bond between streptavidin and biotin until it ruptures (40 sec). Observation of the concurrent bending of the cantilevered microtubule allows the determination of the strain forces based on the known stiffness of microtubules. *Source:* From Ref.<sup>[59]</sup>. © 2001 Am. Chem. Soc.

inherently matches the low rate of force application characteristic for in vivo conditions, a situation that is difficult to duplicate with other approaches to molecular force measurements.<sup>[60]</sup> In addition, the small size of the instrument suggests the assembly of an array of forcemeters, capable of drastically reducing the time required for a statistically significant number of force measurements.

This forcemeter points the way to more sophisticated nanodevices, which aid in the measurement of properties of nanoscale objects, and can play an active role in the assembly and disassembly of nanoscale structures.

## CONCLUSION

Motor proteins are fast and versatile nanomotors with high energy efficiency and interface in a very specific manner with “road”-like filaments and various objects serving as “cargo.” At this point, this makes them superior to any man-made nanomotor, and allows us to explore the technological applications of nanomotors in hybrid nanodevices. Inspired by the biological applications of motor proteins in intracellular transport and as actuators, a number of devices have been designed. Challenges regarding the interface between biological and synthetic elements in the hybrid devices are addressed, and artificial elements, such as “anchors” or a “throttle,” are directly integrated into the motor protein. Nature has mastered not only the design of nanoscale functional units but also the integration of these units into the sophisticated multipurpose subcellular or cellular systems. This research attempts to learn nature’s lessons and translate them into valuable engineering.

# Nano–Mesoscopic Interface: Hybrid Devices

Gianfranco Cerofolini

Post-Silicon Technology, STMicroelectronics, Agrate Brianza, Italy, and Department of Materials Science, University of Milano–Bicocca, Milan, Italy

## INTRODUCTION

The continuous size reduction associated with the development of microelectronics will, sooner or later, face the need of manipulating single molecules, addressing and contacting them to wanted regions of the device. Although the manipulation of individual molecules is already possible using the scanning tunneling microscope and their functional characterization is usually achieved for thiol-terminated molecules grafted to gold electrodes, both the process (individual management by scanning tunnel microscopy) and material (gold) are, however, incompatible with the integrated-circuit (IC) technology. Batch processing requires that the molecules are addressed to (photolithographically predefined) regions by a difference of chemical potentials. In turn, that requires a control of the chemical terminations of the surfaces of the most important IC films. Among them, the unique single crystalline surface is that of the silicon substrate, which makes it the most serious candidate for the growth of ordered functional films. Of the several producible orientations of silicon, the (100) surface is that with the largest applications. In usual technological cases, the (100) surface of silicon is hydrogen-terminated (immediately after aqueous HF etching) or covered by oxo terminations (after the formation of the native oxide). Although neither one nor the other has the necessary chemical and crystalline order required to be a seed for the deposition of molecular devices, they can, however, be used to prepare clean silicon surfaces with  $2 \times 1$  reconstruction or hydrogen-terminated silicon surfaces with  $2 \times 1$  or  $1 \times 1$  reconstruction. Alkenes or alkynes can be used to functionalize the silicon via cycloaddition to the clean  $2 \times 1$ -reconstructed surface or via hydrosilylation on the hydrogen-terminated surfaces.

## THE CONCEPTUAL POSSIBILITY OF MOLECULAR ELECTRONICS

With the synthesis of rotaxanes, catenanes, Möbius strips, etc., topological chemistry has changed from a visionary view<sup>[1,2]</sup> (one of the founding papers, Ref.<sup>[1]</sup>, circulating as a preprint at the Reaction Mechanisms Conference held in Princeton, NJ, at the

end of summer 1960, was summarily rejected as not being chemistry<sup>[3]</sup>) to a consolidated discipline for the synthesis of molecules able to mimic, on a molecular scale, the behavior of macroscopic machines.<sup>[4,5]</sup> In a way, those molecules may be considered as molecular machines.

Although the first molecular machines mimicked mechanical machines, a number of molecules able to perform even sophisticated electrical functions have been also synthesized.

Fig. 1 shows an example of molecule<sup>[6]</sup> with interesting electrical properties. The molecule is formed by a bipyridinium core, two alkane chains, and two thiol terminations. The bipyridinium core works as a Schmitt trigger, the alkane chains behave as wires, and the thiol terminations provide alligator clips to external electrodes. Once grafted to gold electrodes (through its thiol terminations), the molecule displays or not resonant electronic conduction, according to the charge state on one nitrogen atom in the bipyridinium core: if both nitrogen atoms are positively charged, the molecule does not display conduction; if one nitrogen is reduced (by injection, controlled by an external electrode, of one electron), the molecule displays conduction. In a way, the molecule performs as an electronic device (a Schmitt trigger), but has a size of the order of  $3 \text{ nm}^3$ .

The molecule in Fig. 1 is certainly not unique in possessing interesting electronic properties: the review of Ref.<sup>[7]</sup> reports wires, rectifiers, memories, etc. listing 106 references. The availability of such a molecular scaffold has kindled the interest toward an application of molecular devices for a new electronics—*molecular electronics*.

Molecular electronics has, however, a chance to become interesting for large-volume applications (and thus a potential competitor of microelectronics) only if it goes beyond the current and expected future limits of the IC technology.

## MICROELECTRONICS AND THE EVOLUTION OF THE INTEGRATED CIRCUIT

At present (end of 2002 A.D.), ICs have bit density of the order of  $10^8 \text{ bit cm}^{-2}$  (for microprocessors). This density has been achieved by an increase by a factor

certain ICs may operate as measuring devices is demonstrated by the detection of single photons through p–i–n diodes supplied at a voltage just above the breakdown<sup>[14]</sup> and of alpha particles through the soft errors of dynamic random access memories.<sup>[15]</sup> The first example is particularly interesting because it applies to a situation in which the event to be detected (the presence of a photon) has an energy (say, 1 eV) not exceedingly higher than the thermal unit (say, 25 meV). This occurrence thus suggests the possibility of using suitable microelectronic devices for the detection of the state (e.g., the oxidation number) of microscopic systems (e.g., molecules) hosted on the IC.

Actually, scanned probe techniques [such as the scanning tunneling microscope (STM)] have already been proven to have the necessary sensitivity to image single electrons in nanostructures<sup>[16]</sup> (although “they almost invariably alter the properties of the system they are measuring”<sup>[17]</sup>). Even assuming the ability to reduce the STM size in the micrometer length scale (to be compatible with the IC circuitry), its use for the detection and modification of the electronic state of an ordered array of molecules (considered as a molecular memory) will require dramatic changes in circuit architecture. In present ICs, all bits are matrix-ordered and are singularly accessible by specifying row and column; the use of STM as sensing-writing element suggests the need of organizing the memory as a shift register.

The STM is not the unique apparatus able to detect the electronic state of single molecules; in recent years, the single electron transistor has been proven to work. Such a transistor, based on the concept of Coulomb blockade<sup>[18,19]</sup> has the advantage over STM to be producible with the methods of the IC technology and not to require dramatic changes in circuit architecture.

This state of affairs suggests that molecular electronics will necessarily involve a combination of microtechnologies and nanotechnologies<sup>[20]</sup> and identifies in *self-assembly* (i.e., the deposition of functional molecules in wanted regions of the microelectronic device) and in *grafting* (i.e., the selective bonding of certain groups of the molecules to electrodes in the microelectronic regions) the key problems of molecular electronics. Actually, the few examples of logic devices prepared exploiting the electronic properties of molecules are hybrid devices with photolithographically defined electrodes.<sup>[21–23]</sup>

Determining the conductance of individual molecules is a difficult task. The case of DNA is emblematic of this difficulty—depending on the study, DNA is indeed said to be an insulator, semiconductor, conductor, or proximity-induced superconductor.<sup>[24]</sup> The usual approach to allow electrical testing of organic molecules is to terminate them with thiol (–SH) groups, which behave as alligator clips to gold. Gold electrodes with parallel-plate geometry are now

currently prepared down to separations of 4 nm. While useful for the determination of the electrical characteristics of the molecules (allowing the assessment of their conduction mechanism), this arrangement is, however, largely incompatible with silicon-based ICs, for which gold should be avoided.

Although it may seem difficult to insert functional molecules between two electrodes with a controlled separation in the nanometer length scale (say, 3 nm), a solution to this problem, fully compatible with the IC technology, has recently been proposed.<sup>[25]</sup> The MOS transistor provides indeed a parallel-plane geometry with silicon plates separated by just the gate-oxide thickness—3 nm in the current technology. To allow the insertion of functional molecules therein, it is sufficient to define the gate geometry with an etch sequence formed by a plasma etch of the unmasked polysilicon followed by a wet (aqueous HF) etch of the underlying SiO<sub>2</sub>. This process, initiated with a “vertical” attack, does not complete with the total dissolution of the unmasked SiO<sub>2</sub> but rather proceeds laterally overetching a portion of the SiO<sub>2</sub> covered by the polysilicon. The width of the overetched region (the “recessed region”) is controlled by the exposure of the structure to the etching solution. Of course, this is only one of the several possibilities offered by microelectronics, and it is expected that the region hosting the molecular electronics will be obtained exploiting features (such as overetches) hitherto ignored (or even demolished) in IC processing.

Accepting this view, the development of any nanotechnology for data processing does necessarily require the ability to control a number of IC surfaces to allow self-assembly, while still providing the functions of power supply, addressing, sensing, etc. To a large extent, the materials of microelectronics are limited to Si, SiO<sub>2</sub>, Si<sub>3</sub>N<sub>4</sub>, Al, and Ti; of them, only silicon is single crystalline and is thus the most natural candidate as the seed for ordered organic layers.

## THE (100) SURFACE OF SILICON AND ITS USUAL CHEMICAL STATES

Silicon surfaces are producible in various orientations: (111), (100), (110), (113), etc. Of them, the (100) surface is the most used in IC processing. In practical conditions, the (100) silicon surface is mainly oxygen-terminated or hydrogen-terminated.

### The Surface Resulting After Aqueous HF Etching of Sacrificially Grown SiO<sub>2</sub>

Silicon and fluorine combine to form one of the most stable bonds, the Si–F bond energy  $E_b[\text{Si–F}]$  being

6.9 eV.<sup>[26]</sup> It does not surprise, therefore the astonishment when etching by HF-concentrated aqueous solutions of thermally grown SiO<sub>2</sub> was discovered to leave hydrogen-terminated silicon surfaces.<sup>[27]</sup>

The first explanation of this fact was given by Ubara, Imura, and Hiraki<sup>[27]</sup> in terms of polarization of Si-Si backbonds to Si-F bonds. Assuming that the strength of the Si-F bond derives from an electrostatic reinforcement because of electron transfer from silicon to fluorine, the ionicity of the Si-F bond polarizes the Si-Si backbonds, which allows an easy insertion of HF into the weakened Si-SiF bond. If this bond is cleaved with the addition of fluorine to the SiF site and of hydrogen to the other silicon atom, the ionicity is increased and so is the polarization of the residual backbonds. Reiterating this argument, one obtains that the formation of a SiF<sub>n</sub> moiety becomes easier the higher is *n*, and that the process is concluded with the formation of a volatile molecule, SiF<sub>4</sub>, and of hydrogen terminations at the silicon surface.<sup>[27]</sup>

This scheme was investigated quantum mechanically on model molecules (such as H<sub>3</sub>Si-SiH<sub>2</sub>F or H<sub>3</sub>SiF) by Trucks et al.<sup>[28]</sup> They showed that the activation energy, 1.0 eV, of the process leading to two fluorine atoms attached to the same silicon atom is lower than the activation energy, 1.4 eV, of the process transferring the fluorine to the adjacent silicon atom. Although the Si-H bond is spontaneously destroyed by reaction with HF (the reaction being exothermic by 1.3 eV), an activation energy of 1.2 eV was calculated for this process. Although small, the difference of 0.2 eV, between the activation energies for the destruction of the Si-H bond and that for the attachment of another fluorine atom to fluorinated silicon, is so high as to make the time constant of the former reaction 4 orders of magnitude higher than that of latter reaction. These calculations support therefore the opinion, first formulated by Ubara, Imura, and Hiraki<sup>[27]</sup> that the formation of hydrogen-terminated surfaces is kinetically, rather than thermodynamically, controlled.

The assumption that undissociated HF is the etching agent is, however, contradicted by the following facts:

1. In diluted aqueous solution, HF is completely dissociated,

its behavior as a weak acid is a result of the reduction of the H<sub>3</sub>O<sup>+</sup> activity resulting from tight ion pairing H<sub>3</sub>O<sup>+</sup>⋯F<sup>-</sup> between the oxonium and fluoride ions (Ref.<sup>[29]</sup>, Chapter 3).

2. In concentrated aqueous solution, the H<sub>3</sub>O<sup>+</sup> activity is increased because of the formation of the hydrogen-bonded adduct F<sup>-</sup>⋯HF

via the equilibrium

the concentrated aqueous solution does therefore contain undissociated HF, but its binding energy to F<sup>-</sup> is so high (Eb[F<sup>-</sup>⋯HF] = 2.2 eV; Ref.<sup>[30]</sup>, p. 76) that the adduct F<sup>-</sup>⋯HF is considered a well-defined ion HF<sub>2</sub><sup>-</sup> (Ref.<sup>[29]</sup>, Chapter 3).

3. In gas phase (where the etching species is undissociated HF), the attack results mainly in fluorine-terminated silicon surfaces.<sup>[31]</sup>

Following the criticism of Ref.<sup>[32]</sup> and using the results of high-level quantum mechanical calculation of the stability of the Si-Si bond in relation to its terminations,<sup>[33]</sup> Cerofolini thus proposed an ionic route able to account for the observed hydrogen termination resulting after attack by HF-concentrated aqueous solution to thermally oxidized silicon. The route is constituted by three cycles each composed by four consecutive steps, the rate-determining one being F<sup>-</sup> transfer from the etching solution to the coma of SiF<sub>n</sub> termination.<sup>[34]</sup> Even the gas-phase attack, leading to fluorine-terminated silicon, seems to be controlled by the presence of adsorbed water.<sup>[31]</sup>

## The “Native Oxide” and Its Growth Kinetics

An ideally hydrogen-terminated surface is presumed to be indefinitely stable (in the laboratory timescale) in air.

Although the (100) surface resulting after aqueous HF etching of the overlying oxide is expected to be terminated with silicon dihydride, the hydrogen terminations actually form, however, a heterogeneous family of monohydride, dihydride, and trihydride species,<sup>[35,36]</sup> and the surface still contains an appreciable amount of silicon-oxygen centers, roughly corresponding to 0.2–0.5 monolayers, depending on the preparation.<sup>[37]</sup> Such oxygen-containing centers are responsible for the environmental instability of these surfaces via the oxidation of the backbonds to Si-O bonds; this process, initiated at oxygen defects and mediated by adsorbed water, proceeds with an island growth and is eventually responsible for surface roughening.<sup>[38]</sup>

Once the first layer has grown (at a characteristic time τ<sub>1</sub>), further oxidation occurs in a layer-by-layer fashion; the characteristic time τ<sub>n</sub> required for the formation of the *n*th layer increasing exponentially with *n* is given by:

$$\tau_n = \tau_1 a^{n-1}$$

where  $a$  is a suitable constant.<sup>[37]</sup> The native oxide so formed is the final result of a complex oxidation process, in which  $H_2O$  and  $O_2$  both play a crucial role.<sup>[37]</sup>

Understanding such a behavior is not a trivial task. A microscopic model for it was proposed by Cerofolini et al. in a series of papers in terms of tunneling either of a proton from adsorbed water<sup>[39,40]</sup> or of an electron to adsorbed oxygen.<sup>[41,42]</sup> The development of the kinetic description of layer-by-layer growth does not require the detailed knowledge of the tunneling species (for that it suffices to assume that the process is limited by a tunneling-assisted step); rather, the kinetic model provides a practical example for a self-similar process, in which the rates of growth from layer to layer are scaled by a subunitary positive Grossmann factor.<sup>[43]</sup>

Grafting of organic molecules to  $SiO_2$  is a relatively simple task.<sup>[44]</sup> For that it suffices first to cleave (by immersion in water or in water solutions of ammonia) the surface siloxanic bridges  $Si-O-Si$ , thus forming an array of silanols  $Si-OH$ , and then to expose the surface to alcohols; grafting occurs via condensation:

Because  $R$  can contain practically any functional group, this route seems to offer an interesting possibility for the functionalization of silicon.<sup>[45]</sup> However, two factors play against it:

1. No process is known for the preparation of a complete ordered layer of silanols, either at the  $SiO_2$  or silicon surface.
2. The oxo bridge between silicon and carbon undergoes readily hydrolysis, so that the condensation reaction above is somewhat reversible, that renders the grafted species environmentally weak.

It is generally believed that the production of environmentally robust, ordered organic layers requires a preparation of the surface somewhat different from the current ones and a grafting through  $Si-C$  bonds.

### TRYING TO CONTROL THE CHEMICAL AND CRYSTALLINE ORDER OF THE (100) SURFACE OF SILICON

The “technological” surfaces discussed in the previous section do not preserve either the crystalline order of the underlying substrate or its chemical homogeneity; they are not useful as seed for ordered organic layers.

### The Clean, $2 \times 1$ -Reconstructed, (100) Silicon Surface

Clean (100) silicon surfaces with  $2 \times 1$  reconstruction [referred to as  $2 \times 1$  (100) Si, in which neighboring pairs of surface atoms form double-bonded dimers, and the dimers are organized in a two-dimensional lattice] can be prepared by suitable heat treatment in an ultrahigh vacuum (UHV) of technological surfaces. If the surface is covered by a native oxide, the oxo groups can be destroyed by heating at high temperature  $T$  (above  $1000^\circ C$ ); in the absence of oxygen, interfacial silicon reacts with  $SiO_2$  forming volatile  $SiO$ :

If the surface is mainly hydrogen-terminated (because it is prepared via aqueous HF etching of a sacrificial  $SiO_2$  film), the hydrogen terminations may be demolished at somewhat lower temperature (say,  $T < 800^\circ C$ ) with the formation of  $H_2$ .

Experimental evidence for the presence of the double-bonded dimers at the (100) silicon surface can be obtained from the presence of a satellite peak shifted by  $0.2\text{ eV}$  toward lower binding energies in the  $Si\ 2p$  spectrum obtained by X-ray photoemission spectroscopy (XPS).<sup>[46]</sup>

### The Hydrogen-Terminated, $2 \times 1$ - or $1 \times 1$ -Reconstructed, (100) Silicon Surfaces

Hydrogen-terminated,  $2 \times 1$ -reconstructed, (100)-oriented silicon surfaces [referred to as  $2 \times 1$  (100)H Si, in which the  $\pi$  bond of the surface dimer is broken and the two radicals are saturated by bonding to hydrogen] can be obtained by exposing, without breaking the vacuum, the clean  $2 \times 1$  (100) surface kept at ca.  $400^\circ C$  to a few langmuirs of atomic hydrogen, in turn obtained by the dissociation of  $H_2$  after contact with a hot tungsten filament.

The overall process (requiring a treatment in an UHV and an exposure to atomic hydrogen) is, however, complicated and may be simplified as follows. The surfaces prepared by aqueous HF etching can indeed be used for the preparation of highly ordered hydrogen-terminated surfaces via exposure to an  $H_2$  atmosphere at relatively high temperature. In fact, the oxygen terminations remaining after the HF attack are totally demolished after heating at  $T > 750^\circ C$ ; this treatment destroys the preexisting heterogeneous distribution of trihydride, dihydride, and monohydride terminations and eventually results in monohydride terminations and  $2 \times 1$  reconstruction<sup>[36]</sup> or in dihydride terminations and  $1 \times 1$  reconstruction<sup>[47]</sup> (for which even the residual  $\sigma$  bond of the surface dimer

**Fig. 2** Addition of an alkene ([2 + 2] cycloaddition, bottom) or a conjugated diene ([4 + 2] cycloaddition or Diels–Alder reaction, top) to the clean,  $2 \times 1$ -reconstructed, (100) silicon surface.

is broken and the radicals are saturated with hydrogen atoms), according to the process. The surfaces so prepared are flat down to the atomic level.

## USING CONTROLLED SURFACES TO FUNCTIONALIZE SILICON

### Functionalization of Clean (100) Silicon via Cycloaddition

The clean,  $2 \times 1$ -reconstructed, (100) silicon surface can be used to functionalize the silicon via [2 + 2] or [4 + 2] cycloaddition.<sup>[48,49]</sup> Fig. 2 sketches both these reactions for the simplest alkene and diene.

Dienes are particularly interesting because, irrespective of whether they undergo [4 + 2] cycloaddition (as sketched in Fig. 2) or [2 + 2] cycloaddition (as performed in Ref.<sup>[50]</sup> using 1,4-cyclohexadiene), they may be used to insert a second functional group (the C=C double bond) on  $2 \times 1$  (100) Si. An ordered layer of intact functional groups allows the possibility of preparing hybrid organosilicon devices. Cycloaddition reactions must, however, be carried out in an UHV because the  $2 \times 1$  (100) Si surface is very reactive

**Fig. 3** Silicon–oxygen moieties at the silicon surface.

**Fig. 4** Expected reactions of water (bottom) and oxygen (top) at the  $2 \times 1$  (100) Si surface, showing how silanols, peroxy, and oxo centers may be formed after exposure to air of the clean,  $2 \times 1$ -reconstructed, (100) surface of silicon.

and, when exposed to air, forms quickly a disordered native oxide, characterized by the copresence of silanic and silanolic terminations in addition to oxo, peroxy, and perhaps epoxo bridges (Figs. 3 and 4).

### Functionalization of Hydrogen-Terminated (100) Silicon via Hydrosilation

In view of its relative inertness, it is not easy to graft organic molecules to hydrogen-terminated silicon. The preferred way for that is the *hydrosilation* reaction (Ref.<sup>[29]</sup>, p. 1255). This reaction occurs between 1-alkenes and hydrogen-terminated silicon.

Hydrosilation is a reaction involving hydrogen shift from silicon to a carbon atom involved in the  $\pi$  bond and bond formation between the silicon atom and the other carbon atom (Fig. 5). If the number  $n$  of carbon atoms in the alkane chain is small (say,  $n < 8$ ), the alkene hydrosilation occurs only in the presence of a catalyst ( $\text{H}_2\text{PtCl}_6$ )<sup>[44]</sup> or after activation (radical formation);<sup>[51]</sup> for long chains (say,  $n > 10$ ), the reaction occurs spontaneously at a temperature of about  $200^\circ\text{C}$ .<sup>[44,52]</sup>

Because hydrosilation involves only one silicon atom, it was mainly studied on the hydrogen-terminated,  $1 \times 1$ -reconstructed, (111) silicon surface [denoted as  $1 \times 1$  (111)H Si], and only few works have been devoted to study alkene hydrosilation on  $1 \times 1$  (100)H Si.<sup>[52,53]</sup> The hydrosilation of 1-alkenes at  $1 \times 1$  (100)H Si is expected to occur according to pathways (I') or (I'') in Fig. 6.

**Fig. 5** Hydrosilylation of 1-alkenes as a concerted reaction. One between  $R^1$  and  $R^2$  denotes hydrogen; the other may be either hydrogen or an alkane chain.

The C=C bond is not unique in undergoing hydrosilylation. This reaction is indeed known to occur for the C=N, C=O, and C≡C bonds also (Ref.<sup>[29]</sup>, p. 1256).

Although the reactivity of 1-alkynes is similar to that of 1-alkenes, there is, however, an important difference: after the first addition (II), the formed species,  $2'$  and  $2''$  in Fig. 6, contain a double bond in the vicinity of another hydrogen termination of silicon, so that the reaction can, in principle, proceed, via (III) or (IV), with the formation of the species 3 or 4. Understanding the nature of the interfacial species is not without interest: for instance, if the reaction stopped after (II), the silicon surface would be equipped with a

**Fig. 6** Hydrosilylation of 1-alkene [pathway (I)] and 1-alkyne [pathway (II)] at the hydrogen-terminated,  $1 \times 1$ -reconstructed, (100)-oriented, silicon surface; R denotes a suitably terminated alkane chain.

second reactive group (the C=C group) in addition to the one, if any, carried by R.

The only characterizations we know of the hydrogen-terminated,  $1 \times 1$ -reconstructed, (100) silicon surface derivatized with 1-alkyne are the ones due to Sieval et al.<sup>[54]</sup> and Cerofolini et al.<sup>[55]</sup> The first collaboration, basing their conclusions on infrared spectroscopy and quantum mechanical calculations, arrived to the conclusion that the grafting of 1-hexadecyne at 200°C on the technological hydrogen-terminated surface occurs mainly with the formation of the adducts 3 and 4. The second collaboration, basing their conclusions on XPS, arrived to the conclusion that the grafting of 1-octyne at 170°C on  $2 \times 1$  (100)H Si occurs with the formation of the adducts 2. At the present level of investigation, it is not clear if the different reported behaviors are a result of the nature of the surface, length of the alkyne, or reaction temperature or simply to an inadequate interpretation of the experimental data.

## CONCLUSION

The evolution of molecular electronics via the hybrid route requires the functionalization of the (100) surface of silicon. Two states of the (100) silicon surface seem to have the necessary characteristics of crystalline and chemical order required for the deposition of molecular devices with size in the nanometer length scale: the clean  $2 \times 1$ -reconstructed surface and the hydrogen-terminated  $1 \times 1$ - or  $2 \times 1$ -reconstructed surfaces. Alkenes or alkynes may be used for their functionalization: via cycloaddition to the clean surface or via hydrosilylation at the hydrogen-terminated surfaces.

# Nanoarrays: Electrochemically Self-Assembled

S. Bandyopadhyay

Department of Electrical Engineering, Virginia Commonwealth University,  
Richmond, Virginia, U.S.A.

## INTRODUCTION

Nanotechnology is currently a major scientific and engineering undertaking. It has been described with such plaudits as the “third industrial revolution,” the “final frontier,” and so on. Only a few research laboratories in the world will not have a focus on this field. On a global scale, investment in nanotechnology dwarfs those in many other important fields of scientific enterprise.

Nanotechnology is the science and engineering of few nanometer-sized objects endowed with unique properties not commonly encountered in larger “bulk” objects. To study these objects and exploit their special properties, one must first be able to produce them using techniques that are relatively inexpensive, reliable, and have a rapid throughput. This entry is concerned with electrochemically “self-assembled” nanostructures that are made cheaply, rapidly, and with high yield using a technique based on simple beaker electrochemistry.

## NANOFABRICATION

Traditionally, nanostructures have been made by fine-line lithography. Lithography is the workhorse of microfabrication. Computer chips, or other microelectronic circuits such as those found in supermarket laser scanners, are all made with standard lithography. In this approach, a circuit pattern with micron-sized features is transferred to a silicon chip by a series of processes that involves masking selected regions of the surface of a wafer and exposing the rest to light to make them either more amenable or less amenable to etching. In the case of nanometer-sized features, one would need X-ray light for this purpose. An alternate technique is to directly write the patterns on the surface of a wafer using an electron or ion beam. The problem with this approach is twofold. First, direct writing is a slow process. It is also *serial* in nature, whereby each wafer is patterned one at a time, resulting in an exceedingly slow throughput. Second, the patterning beams (electron beam or ion beam) can cause radiation damage to the nanostructures. In the

case of semiconductor structures, these damages cause the structures to become depleted of electrical carriers, so that they cannot function properly. Hence there is a great interest in non-lithographic techniques for nanosynthesis.

Among the non-lithographic techniques, one technique of interest is “nanostamping.” Here one makes a “stamp pad” using standard electron beam lithography. This stamp pad is then used to “stamp” the pattern on the surface of a wafer using pressure just like an ordinary rubber stamp. This technique does not cause radiation damage and has a fast throughput. As long as a single level of pattern definition is required (so that there is no requirement to align two patterns), it is an excellent technique for nanosynthesis. Its only drawback is that it cannot produce very small features because it is, after all, a stamping technique.

An even gentler technique, causing even less damage and capable of producing very small nanostructures is the process of “self-assembly.” Roughly speaking, self-assembly is the process in which the natural evolution of a physical or chemical system to its thermodynamic ground state results in the spontaneous formation of nanostructures on a surface. Normally, the nanostructures would nucleate with random size and at random locations on the surface. However, there are some processes where the size can be made uniform and even the locations can be controlled to the point where the structures that are spontaneously formed have some degree of spatial ordering. In our laboratory, we work with an electrochemical process that produces nanostructures with less than 1% standard deviation in surface area, and the structures form a nearly periodic two-dimensional array (hexagonal close packed structure). This entry is concerned with a description of this process and two specific applications of the structures. The applications we have chosen are 1) infrared (IR) photodetection and 2) neural networks for image processing.

## ELECTROCHEMICAL SELF-ASSEMBLY

We self-assemble regimented arrays of quasi one-dimensional nanostructures (so-called “quantum wires”)

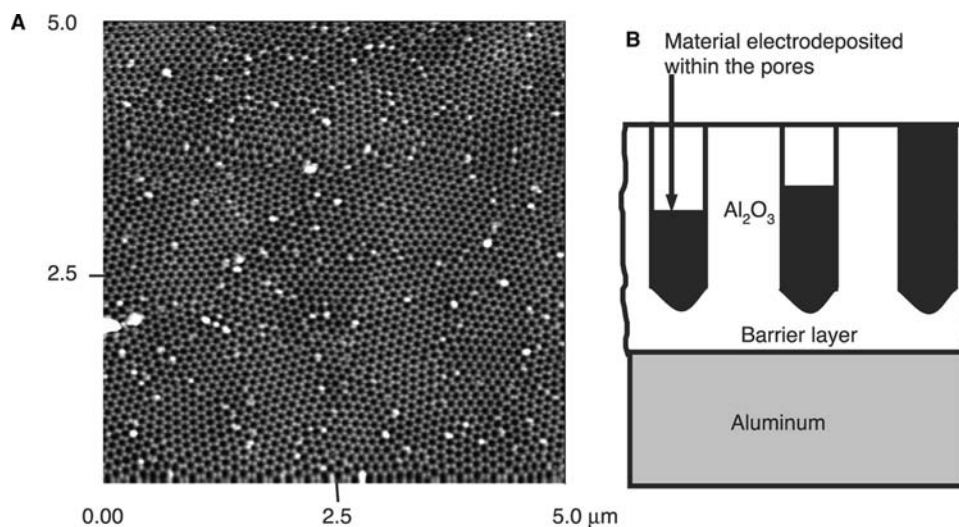

and quasi zero-dimensional nanostructures (known as “quantum dots”) via a simple electrochemical technique. It consists of first self-assembling a thin (typically  $\sim 1 \mu\text{m}$  thick) nanoporous alumina film by anodization of aluminum. This film has a nearly periodic two-dimensional array of pores with hexagonal close packed arrangement. The next step is to electrodeposit the materials of interest within the pores to create a quasi-periodic, two-dimensional array of quantum dots or wires in an alumina matrix. It is now possible to synthesize *device-quality nanostructures* with this simple and inexpensive electrochemical technique. The advantages of this method are low cost, high throughput, and sometimes even improved quality.

This technique is now widely used for self-assembling semiconducting or metallic quantum dots and wires of uniform diameter (see, e.g., Refs.<sup>[1–3]</sup>). The structures that are formed are automatically (electrically) isolated from each other by the intervening alumina layer so that no etching or diffusion steps are needed to isolate neighboring structures. Furthermore, the boundaries of the structures are well-defined, sharp, and comparatively free of interface defects. Fig. 1 shows the top and side views of the alumina films (templates) used in this process. Note the excellent degree of ordering within domains that are about  $1 \mu\text{m}^2$  in size. Also note that the diameter of the pores is extremely uniform. Detailed microscopy and image analysis have shown that the standard deviation in the pore diameter is less than 1% of the average diameter.

For most optical applications, one does not need to make electrical contacts to the individual nanostructures, so that the structures in Fig. 1 are already adequate for many optical devices. For electronic devices, it is necessary to establish electrical contacts to the nanostructures. Electrical access to the dots or wires can be established by removing the alumina from the bottom of the dots/wires (the so-called “barrier layer” in Fig. 1) following a sequence of steps described later, and then contacting both top and bottom of the structures with metal (usually gold) contacts. It is obvious that this process of nanosynthesis is “parallel” in nature, whereby several wafers can be simultaneously processed resulting in fast throughput. It is also very inexpensive and easily accessible for academic laboratories with rather modest resources. The only disadvantage of this method, common to all self-assembly techniques, is the inability to create arbitrary patterns. For some device applications (including the ones discussed in this entry), this is not a serious drawback. Ultimately, the ideal nanosynthesis technique will be an optimum blend of lithography and self-assembly exploiting the merits of both approaches.

### Anodization

As mentioned before, the first step in electrochemical self-assembly of quantum dots or wires is the formation of the nanoporous alumina film. This is produced by controlled anodization of aluminum.

**Fig. 1** (A) Atomic force micrograph of a porous alumina film produced by anodizing aluminum in oxalic acid. The pore diameter for oxalic acid anodization is  $\sim 50 \text{ nm}$ , whereas for sulfuric acid anodization, it is  $\sim 10 \text{ nm}$ . A bright field TEM micrograph of the pores for sulfuric acid anodization can be viewed in Fig. 7 of Ref.<sup>[9]</sup>. The dark areas are the pores and the surrounding light areas are alumina. (B) The side view of the porous structure is sketched showing the barrier layer. Note that when the pores are filled with electrodeposition, they are filled to various heights.

A 99.999% pure 100- $\mu\text{m}$  aluminum foil is first degreased in trichloro-ethylene, washed in distilled water, and electropolished at 30 V for 60 sec in LECO-1 solution consisting of perchloric acid, ethanol, butyl cellulose, and water. The foil is then d.c.-anodized in either sulfuric, oxalic, or phosphoric acid at room temperature using a dc current density of  $\sim 25 \text{ mA}/\text{cm}^2$ . This results in the formation of a porous alumina film on the surface of the aluminum. The film is stripped off by soaking in phosphoric acid, and the anodization is repeated a few times. With the first few anodizations, the ordering of the pores in the film dramatically improves.<sup>[4,5]</sup> Finally, after the third or fourth iteration, the pores form a nearly perfect periodic (hexagonal close packed) array within domains that are 1–10  $\mu\text{m}$  in diameter. This self-ordering is usually best for oxalic acid anodization, and worst for sulfuric acid anodization. For anodization in sulfuric acid, the average pore diameter is about 8 nm<sup>[6]</sup> (with  $\sim 10\%$  standard deviation), resulting in an areal pore density of  $\sim 10^{11}/\text{cm}^2$ . For oxalic acid anodization, the pore diameter is  $50 \pm 1 \text{ nm}$  and the pore density is  $\sim 10^{10}/\text{cm}^2$ . For phosphoric acid anodization, the pore diameter is  $\sim 100 \pm 2 \text{ nm}$  and the pore density is less than  $10^9/\text{cm}^2$ . An atomic force micrograph (top view) of a porous film produced by anodization in oxalic acid is shown in Fig. 1A.

In Fig. 1B, we show the side view of a pore. If the pore is filled up with a material to a depth that is about equal to the diameter of the pore, we would have created a “quantum-dot.” On the other hand, if the pore is filled up to a depth that is much larger than the diameter, we would have created a short “quantum wire.” Thus, whether a dot or a wire is produced can be simply determined by the duration of the pore-filling action—electrodeposition. Care must be taken not to overfill the pores or allow the material to spill over the brim, which creates electrical shorts between neighboring wires. If this happens, the surface can be etched in phosphoric acid to reestablish electrical isolation between neighboring wires.

### Electrodepositing a Metal

The technique to electrodeposit a metal within the pores is well known and has been practiced for many years.<sup>[2,3,7–9]</sup> To electrodeposit a metal  $M$  in the pores, the porous anodic alumina film (along with the aluminum substrate) is immersed in a suitable non-cyanide aqueous electrolyte containing a dissolvable salt of  $M$ , such as  $\text{MSO}_4$  (we assume  $M$  is a divalent element). An alternating signal of 20–50 V rms amplitude and 100–1000 Hz frequency is imposed between the aluminum foil (substrate) and a platinum counterelectrode. Because the alumina structure preferentially conducts

in only one direction (the cathodic direction), it is called a “valve metal oxide”.<sup>[2,3]</sup> Metal ions ( $M^{2+}$ ) are reduced to zero-valent metal during the cathodic half-cycles of the imposed a.c. signal, and are selectively deposited within the pores because the pores offer the least impedance path (largest capacitance path) for the a.c. (displacement) current to flow. These ions are not reoxidized during the anodic half cycles to  $M^{2+}$  because alumina is a valve metal oxide. Once the metal is electrodeposited to the desired depth (controlled by the duration of the electrodeposition step), the pores are sealed by a 10-min immersion in boiling water, which covers the surface with a layer of  $\text{Al}(\text{OH})_3$ . This prevents or retards surface oxidation of the metal particles.

The presence of electrodeposited material in the pores were verified numerous times in the past by energy-dispersive analysis of X-ray,<sup>[10]</sup> cross-section TEM,<sup>[10]</sup> and variable-angle spectroscopic ellipsometry.<sup>[11]</sup> The last two techniques also yield information about the shapes of the metal nanostructures. They appear to resemble rotational ellipsoids (the shape of a football).

### Electrodepositing a Compound Semiconductor

There are different approaches to electrodepositing compound semiconductors within the pores.<sup>[10,12]</sup> Here we outline one of our approaches.

In our laboratory, we typically electrodeposit two different compound semiconductors within the pores: CdS and ZnSe. CdS is electrodeposited by immersing the alumina film (along with the aluminum substrate) in an electrolyte consisting of a non-aqueous solution of dimethylsulfoxide comprising 50 mM cadmium perchlorate, 10 mM lithium perchlorate, and 10 mM sulphur powder, whereas in the case of ZnSe deposition, cadmium perchlorate is replaced by zinc perchlorate and sulfur powder with selenium powder. Electrodeposition is carried out at 100°C with an a.c. signal of 20 V at 250 Hz. During the negative half of the a.c. cycle, the  $\text{Cd}^{2+}$  or  $\text{Zn}^{2+}$  ions in the solution are reduced to zero-valent Cd or Zn and are selectively deposited in pores offering the least impedance path for the electric current to flow. During the positive cycle, the zero-valent metals are not reoxidized into the ions. The high temperature of the solution then allows Cd or Zn in the pores to react with S or Se in the solution to produce CdS or ZnSe nanowires within the pores.

### Contacting Nanowires

The nanowires produced by the above method are not directly suitable for current–voltage measurements because they cannot be contacted easily. Particularly

bothersome is the presence of an alumina “barrier layer” in contact with the aluminum substrate (see Fig. 1), which presents a large potential barrier to current flow along the wire axis (perpendicular to the surface of the porous alumina film). Therefore, we carry out a series of steps to remove the barrier layer and make the wires electrically accessible. These steps are shown in Fig. 2. First, the top surface of the sample is etched for a few minutes in 0.2 M  $\text{H}_2\text{CrO}_4$ /0.4 M  $\text{H}_3\text{PO}_4$  solution. This dissolves the alumina and exposes the top of some of the semiconductor wires. Not all wires are exposed as the wires have varying length. A thin coating of Au (10–20 nm) is then applied on the surface, followed by a thick organic layer which provides mechanical strength to the film during later processing steps. The aluminum substrate is then dissolved in  $\text{HgCl}_2$  to expose the barrier layer of alumina, which is subsequently removed in 5%  $\text{H}_3\text{PO}_4$  (several minutes of soaking), thereby exposing some of the semiconductor nanowires from the bottom. The sample is flipped over and the bottom layer is coated with 10–20 nm of Au. The final structures are arrays of parallel nanowires with Au ohmic contacts at both ends.

**Fig. 2** (A) Anodized aluminum foil with the porous alumina film on top, showing the “barrier layer” between the aluminum substrate and the bottom of the pore, (B) after filling the pores with semiconductor to create buried nanostructures, (C) etching away the top layer of alumina in phosphoric acid to expose the tips of a few nanostructures, followed by deposition of 50-nm gold electrode by e-beam evaporation, (D) coating with an organic binder to provide mechanical stability during later processing steps, (E) after dissolving the aluminum substrate in  $\text{HgCl}_2$  to expose the barrier layer, (F) after etching the alumina bottom barrier layer in phosphoric/chromic acid to expose the other end of the nanostructures, (G) after evaporating gold on the bottom for the second electrode, and (H) after dissolving away the organic binder in a solvent and attaching wires for current measurement. *Source:* From Ref.<sup>[13]</sup>. Gold wires and silver paint are used to connect the Au contacts with the measuring equipment.

## QUANTUM WIRE BASED ROOM TEMPERATURE INFRARED PHOTODETECTORS

There are many device applications of electrochemically self-assembled nanostructures. They span such diverse areas as optics, electronics, magnetism, and superconductivity. In this section, we will discuss an application in sensors—infrared photodetectors.

Infrared photodetectors have widespread applications in remote sensing, terrain mapping, night vision, missile defense, automobile collision avoidance systems, etc. There are a large number of devices that detect infrared radiation. However, solid-state detectors such as  $\text{HgCdTe}$  (the workhorse of infrared photodetectors),  $\text{InSb}$  photodiodes, quantum well photodetectors, and Stranski–Krastanow-grown quantum dot photodetectors all suffer from one common shortcoming. They do not work at room temperature, but require cooling down to about 77 K. In contrast, we have produced self-assembled quantum wire photodetectors that work well at room temperature with a very high signal-to-noise ratio of 45 dB. Moreover, their conductance is so low that the noise-equivalent power is also very low (it is less than  $10^{-18}$  W at room temperature). That translates to an extraordinarily high detectivity  $D^*$  approaching  $10^{14}$   $\text{cm} \sqrt{\text{Hz}}/\text{W}$ .

There is one peculiarity in our infrared photodetectors—they are “inverse” photodetectors. Normal photodetectors are those whose conductance *increases* when illuminated with infrared radiation. Ours exhibit the opposite effect; the conductance *decreases* when illuminated with infrared radiation. This has to do with the origin of infrared photoreponse in our structures, which is quite different from that of other photodetectors. However, they are just as effective in photodetection because they successfully transduce an infrared signal into an electrical signal. They are ideally suited for focal plane arrays.

We prepared 10- and 50-nm diameter nanowires of  $\text{CdS}$  and  $\text{ZnSe}$  by the electrodeposition of the compounds in porous alumina templates produced by anodization in sulfuric and oxalic acid, respectively. The d.c. current–voltage characteristics of both 10- and 50-nm diameter wires are measured using an HP 4140B electrometer in the dark and in the presence of infrared radiation. The infrared (IR) source is the glowbar of a BOMEM Fourier-transform IR (FTIR) spectrometer, which produces radiation in the wavelength range of 1.8–50  $\mu\text{m}$  covering the photon energy range of 0.025–0.686 eV. The radiation is always normally incident on the sample surface (direction of

wave propagation is along the length of the wires to maximize absorption). The intensity of the radiation is not enough to produce any significant sample heating. Results of these measurements are shown in Fig. 3A. The resistance of all samples increase significantly, by up to a factor of 160, when exposed to IR radiation. This is not a sample heating effect, which can only produce a few percent change in resistance. In any case, the radiation intensity is low enough to avoid measurable sample heating. In Fig. 3B, we show the characteristics for a “blank” alumina film (with no

semiconductor in it) to ascertain that the photoresponse is indeed attributable to the semiconductor and not to the alumina. Note that the alumina shows a weak increase in the conductance, i.e., the behavior is opposite to that of semiconductors; the conductance is slightly larger, rather than smaller, when the IR radiation is on. The ratio of dark to illuminated current ( $I_{\text{dark}}/I_{\text{IR}}$ ) for 10- and 50-nm diameter CdS and ZnSe nanowires is shown in Fig. 3C as a function of applied voltage. This ratio is essentially the signal-to-noise ratio which approaches 45 dB at the highest biases used in this experiment.

**Fig. 3** (A) The current–voltage characteristics of 10-nm diameter wires, (B) the current–voltage characteristics of blank alumina templates, and (C) the ratio of dark-to-illuminated current as a function of applied bias. Source: From Ref.<sup>[13]</sup>. American Institute of Physics.

## Origin of Photoresponse

The photoresistive behavior described here most likely accrues from photoassisted real-space transfer of electrons from the semiconductor nanowires into traps in the surrounding alumina. The majority carriers in the semiconductor nanowires are electrons as has been verified in the past by capacitance–voltage spectroscopy.<sup>[14]</sup> Many of these electrons absorb infrared photons and are excited to trap levels in the alumina where they become trapped and can no longer contribute to conduction. As a result, the resistance rises. This process is depicted in Fig. 4A. It is an indirect process in real-space, but the wavefunctions of electrons in the semiconductors penetrate a short distance into the alumina, thereby making the matrix element for this process significant at the interface between the semiconductor and alumina.

An interesting feature is that the larger-diameter (50 nm) wires show a stronger photoresistive effect (larger ratio of dark-to-illuminated conductance) than the smaller-diameter (10 nm) wires. This can be explained within a simple band picture (see Fig. 4B). When the wire is narrower, the subband level in the wire is higher up in energy so that fewer trap levels in the insulator are now *above* the subband level and accessible. Thus, fewer carriers can transfer out of the wire into the traps, and the photoresistive effect is weaker. This picture is substantiated by the IR absorption spectra for 10- and 50-nm diameter wires shown in Fig. 5A and B. The integrated absorption is always much larger for the wider-diameter wires showing that more trap levels are participating in their case.

Note that if there is a “dominant trap level” causing a dominant absorption peak, then it will be *red-shifted* in the narrower wire because the energy separation between the subband level and the trap states *decreases* as the wire becomes narrower. The red-shift is clearly observed in the CdS wires (Fig. 5A), where there is a dominant peak. On the other hand, the spectrum for ZnSe is much more complex (obviously because of a more complex distribution of traps in

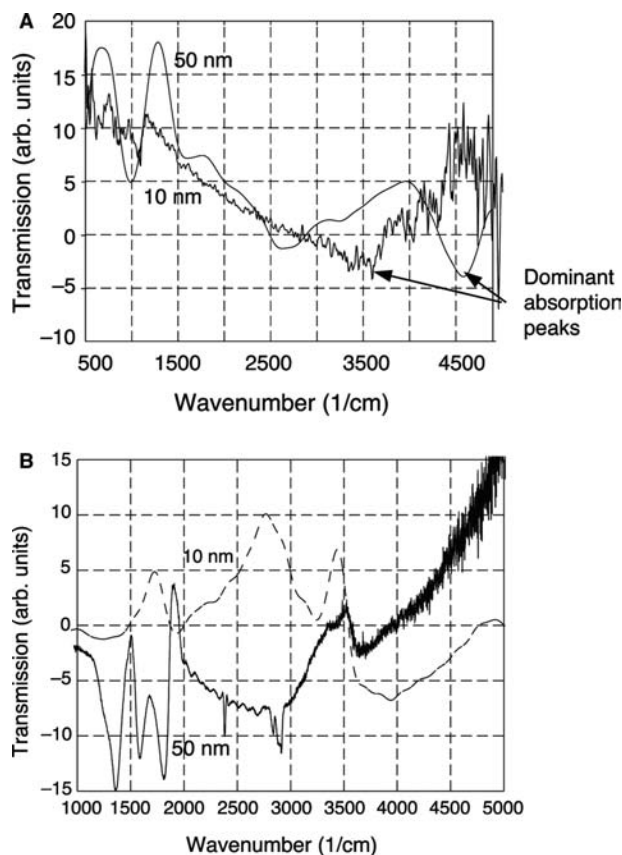

**Fig. 4** (A) Energy band diagram explaining photoabsorption of electrons from the semiconductor conduction band states into traps in the bandgap of alumina. (B) Fewer traps states are available as final states in narrower wires. Traps below the lowest subband level in the semiconductor wire (and therefore not accessible as final states) are shown with broken lines. *Source:* From Ref.<sup>[13]</sup>. American Institute of Physics.

energy space) and does not show a dominant peak, indicating that there is no single dominant trap level at the ZnSe/Al<sub>2</sub>O<sub>3</sub> interface. Little, if anything, is known about trap levels at the interface of electrodeposited semiconductors and anodic alumina. They are probably sensitive to electrodeposition and anodization conditions. There are trap states at the Au–semiconductor interface as well, but this interface is much smaller in area than the interface between

the semiconductor and alumina, so that these traps are unlikely to have a dominant effect.

In the past, a weak photoresistive effect, where the conductance dropped by a mere  $\sim 10\%$  (as opposed to the 160-fold drop reported here), was observed in *bulk* CdS and ZnSe samples,<sup>[15,16]</sup> but was attributed to an entirely different mechanism. There, electrons were photoexcited by the IR radiation from the valence band into intentionally created empty traps in the bandgap. The resulting holes in the valence band recombined with electrons in the conduction band to reduce the conductance by 10%. We do not have any intentionally created traps. Furthermore, capacitance voltage spectroscopy has shown<sup>[14]</sup> that the trap concentration is small enough in our samples that the Fermi level is completely unpinned. In any case, all traps in the bandgap must be filled because we have significant electron concentration in the conduction band, meaning that the Fermi level must be close to the conduction band edge. Thus, our effect cannot be explained by the same mechanism as that of Refs.<sup>[15,16]</sup> That mechanism is a two-step process: photoexcitation of electrons into traps (or, equivalently, photoemission of holes from traps), followed by recombination of those holes with electrons in the conduction band. Ours is a one-step process that only involves trapping and no recombination.

More recently, we have measured the current–voltage characteristics of a sample using an HP 4145B semiconductor parameter analyzer. A SiO filter was used to cut off any visible light from the infrared source. The results are shown in Fig. 6. In this particular sample, the signal-to-noise ratio is over 45 dB before breakdown occurs. There is some variability in the signal-to-noise ratio from sample to sample (in some samples, it is as low as 5 dB) and a concerted research effort will be required to standardize this nascent technology. The variability most likely accrues from the variability of the traps in the alumina, which are acquired during the processing steps. Traps are difficult to control, but a correct sequence of annealing

**Fig. 5** Infrared absorption spectra in (A) CdS nanowires and (B) ZnSe nanowires. In some cases, the spectrum was smoothed to eliminate spurious interference effects. *Source:* From Ref.<sup>[13]</sup>. American Institute of Physics.

**Fig. 6** The current–voltage characteristic of a 50-nm diameter CdS wires in the dark and under infrared illumination. A filter was used to cut off all visible light.

steps may mitigate this problem somewhat. This is a topic of current research.

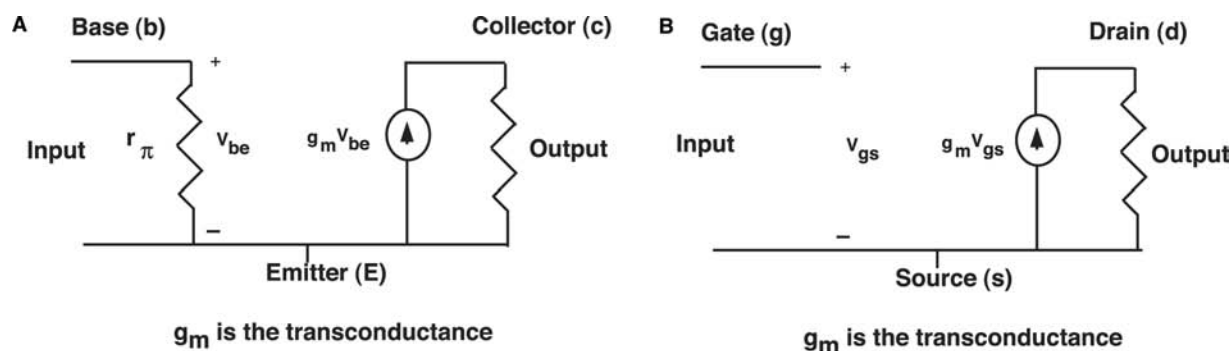

Another shortcoming of these photodetectors is the response time. Because the response time is associated with the response of traps, it is slow. Based on our measurements, we know that the photoresponse cannot be modulated any faster than 1 kHz (the lowest limit of our equipment); hence the response time is slower than 1 msec. Whether this becomes a serious limitation depends on the application. For most commercial applications, this is probably not a limitation at all.

## QUANTUM DOT IMAGE PROCESSORS

A holy grail of nanoelectronics is to find suitable paradigms where structures such as quantum dots and wires can perform signal processing tasks, particularly Boolean logic operations, such as transistors. However, this is a very tall order because transistors are a

unique find; they have properties that are not easy to duplicate. Two very important properties of transistors that are well appreciated in the electrical engineering community but seldom appreciated elsewhere are: 1) a transistor has a “gain” between its output and input terminals, i.e., the output can be a magnified (or amplified) version of the input. This property, which can be attained with three-terminal active devices such as transistors, is important for logic applications because it is necessary to restore logic signals that are corrupted by noise and other imperfections to their correct values. 2) Gain alone is not sufficient. Transformers have voltage gain, but nobody has successfully produced logic circuits with transformers alone. An additional property that is needed is “isolation” between the input and output terminals of the device, so that the input signal determines the output signal and not the other way around. Electrical engineers often call this property “unidirectionality,” that is, logic signal flows unidirectionally from the input terminal to the output terminal. Transistors have this property. Any undergraduate student of electrical engineering is familiar with the small signal equivalent model of a transistor, which is shown in Fig. 7. There is a dependent source at the output end, which depends on the input signal. However, the input does not depend on the output. This model follows from Ebers–Moll equations describing a transistor, and if one traces back the origin of this unidirectionality, one will ultimately find that this unidirectionality comes about because of the Fermi distribution of carriers (electrons and holes) in a transistor’s emitter (or source) that is driven not too far from equilibrium. Thus, the unidirectionality has its origin in thermodynamics (Fermi–Dirac statistics). Thermodynamics has a character trait to cause unidirectionality. It is somewhat responsible for the unidirectionality of time and it is also responsible for the unidirectionality of signal propagation in a transistor!

Many proposals have been forwarded (and published in major journals) to replace the transistor with quantum dots and other exotic devices, in hopes that

**Fig. 7** The simplest small signal equivalent models of a transistor: (A) bipolar junction transistor, (B) field effect transistor.

they will perform logic operations. There are widely publicized but flawed proposals for logic gates realized with quantum dots. Unfortunately, most of these proposals are wrong because these exotic devices do not have the properties of transistor, namely gain and unidirectionality.<sup>a</sup> As of now, nobody has made logic gates with quantum dots in spite of all the initial tall claims. Nonetheless, it is still attractive to look for ways to replace transistors with quantum dots because there can be tremendous savings in device density on a chip (quantum dots are much smaller than transistors), power dissipation (quantum dots typically dissipate much less power than a transistor), and cost (quantum dots are much easier to fabricate than a transistor).

### Quantum Dot–Based Neuromorphic Architectures

In 1995, Roychowdhury and coworkers proposed a revolutionary new idea for utilizing quantum dots for signal processing and computation.<sup>[17,18]</sup> Their scheme was not based on logic circuits, so that they did not need the properties necessary to build logic circuits. Instead, they proposed to build a neural network architecture. They also realized that making connections to quantum dots will be a nearly insurmountable challenge because quantum dots are so small that aligning multiple (or for that matter *any*) contact to them is very difficult. They overcame this problem by proposing a locally interconnected architecture, where every device is connected only to its nearest neighbors. Thus, in a rectangular lattice structure, every device will be connected to at most four nearest neighbors. The connections did not have to be metallic lines (wires) either. They could simply be the resistive and capacitive couplings between neighboring quantum dots that exist whenever the dots are embedded in a semiinsulating medium. For certain applications, the exact values of the resistances and capacitances of these couplings also did not matter so much as long as they were relatively uniform. Therefore, this architecture did not present much of a fabrication challenge at all to self-assembly (in fact, it was partly inspired by advances in self-assembly). We now describe this architecture.

Consider the system shown in Fig. 8. It consists of a two-dimensional periodic array of nanometer-sized metallic islands (or clusters), with nearest neighbor electrical interconnections, self-assembled (and self-aligned) on mesas whose current–voltage characteristics (for vertical transport) have a *non-monotonic* non-linearity.

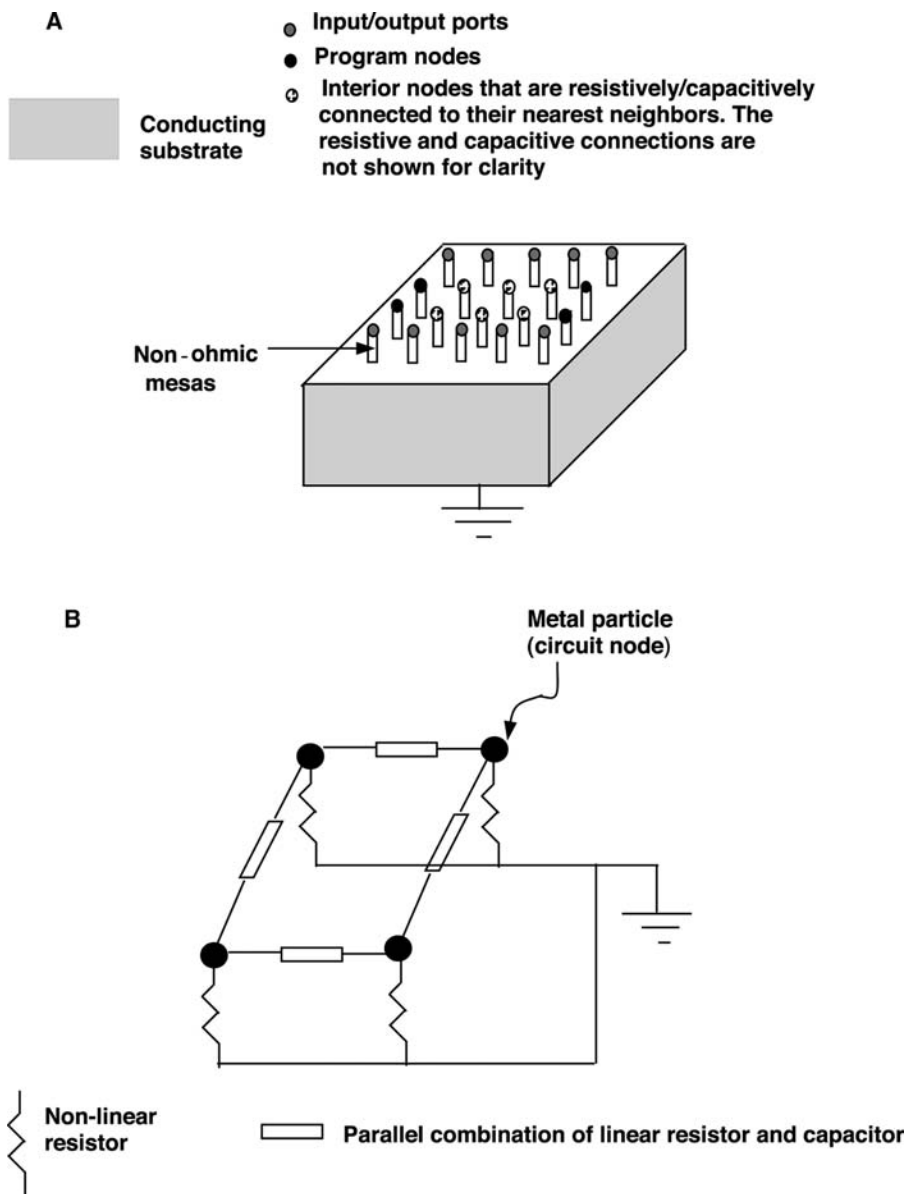

<sup>a</sup>There are five basic requirements for a logic device. They are listed in the textbook: David A. Hodges and Horace G. Jackson, *Analysis and Design of Digital Integrated Circuits*, 2nd edition, McGraw-Hill, New York, 1988, Chapter 1, p. 2.

The above system displays a fundamental kind of computational effect based on non-linear cooperative charge interactions between the dots and the underlying non-ohmic substrate. A number of publications<sup>[17–20]</sup> have shown that this system realizes the content addressable models of associative memory, can exhibit image-processing capability, and can solve combinatorial optimization problems. It is a *neuromorphic network* inspired by the simple realization that, in any large-scale system, comprising tens of billions of nanoscale devices, there will be inherent randomness. It is easier to exploit that in realizing computational activity through collective computational models, than to strive against it to realize logic. Moreover, this network is massively parallel and fault-tolerant. Even a 100% variation in the size of an individual device is quite tolerable. The relative insensitivity to size variation stems from the fact that the size determines the capacitance of an individual device. A 100% variation in the size of an individual device will result in a similar variation in the capacitance and this does not affect the performance of the circuit very much as a whole because of the “collective” nature of the computation. Here the collective activities of all devices acting cooperatively matter, rather than the characteristic of a single device. Similar ideas were later proposed by Wu, Shibata, and Amemiya.<sup>[21]</sup>

We will not discuss the detailed theory of this architecture because that has already been described in Refs.<sup>[17–20]</sup>. Instead, we will focus on the realization of this system based on our technique of electrochemical self-assembly.

### Self-Assembling a Neural Network

Basically, the quantum dot network of Fig. 8A has two main components: 1) a 2-D periodic array of metallic islands, each interfaced with a mesa (resistor) displaying a negative differential resistance, and 2) a resistive/capacitive coupling between nearest neighbor islands. This network can be self-assembled electrochemically. We start with a  $n^+$  silicon substrate, evaporate a thin titanium layer, and evaporate or sputter a 1- $\mu\text{m}$ -thick layer of aluminum on it. The titanium layer allows the aluminum layer to adhere to the surface. Then, we anodize the aluminum in sulfuric or oxalic acid to convert it to a porous alumina film containing a *nearly periodic* regimented array of nanopores. When all of the aluminum is anodized into a porous alumina layer, the anodizing current begins to change rapidly, at which point the anodization is terminated. Then, we remove the alumina “barrier layer” by soaking in phosphoric acid. Next, we sequentially electrodeposit a semiconductor (e.g., CdS) and a metal (e.g., Cu) selectively within the pores. The metal dots are then

**Fig. 8** (A) A generic array of metallic islands deposited on a non-ohmic layer, which has been grown on a conducting substrate. It is assumed that all islands have direct resistive and capacitive links to nearest neighbors. A subset of the islands serves as program nodes, which are driven by external current sources. Another subset of islands serves as input/output ports, and the remaining islands introduce complexity to the system through non-linear conductive links to the substrate. The substrate non-linearity could arise, e.g., from resonant tunneling, which causes the substrate current-voltage characteristic to have a *non-monotonicity*. (B) A non-planar circuit representation of the network.

partially exposed by controlled etching of the alumina in phosphoric acid. Neighboring dots are electrically isolated by the intervening alumina layer, which is a semiinsulator. In the case of sulfuric acid anodization, the thickness of the semiinsulating layer is about 10 nm and in the case of oxalic acid anodization, the thickness is about 20 nm. Once complete, the structure is a self-assembled experimental realization of the system shown in Fig. 8A.

### Measurements of Circuit Parameters

#### Interdot resistance

To obtain an estimate for the interdot resistances, we need to measure the resistance of the alumina layer

separating neighboring pores. Two contact pads, spaced  $100\ \mu\text{m}$  apart, were delineated on the surface of a  $1\text{-}\mu\text{m}$ -thick porous alumina film produced by anodization of aluminum in sulfuric acid. The pores were filled with a semiconductor. The resistance measured between the pads, which were  $1\ \text{mm}$  wide, was about  $80\ \text{M}\Omega$ .<sup>[22]</sup> In this experiment, the effective width of the alumina between the pads was approximately one-half of the distance between the pads, namely  $50\ \mu\text{m}$ . Therefore, the resistivity of the alumina is  $80\ \text{M}\Omega \times 1\ \text{mm} \times 1\ \mu\text{m}/50\ \mu\text{m} = 160\ \text{K}\Omega\text{cm}$ . Conduction through the alumina was found to be ohmic<sup>[22]</sup> (probably conduction takes place through impurity bands in the alumina), so that the alumina resistivity can be assumed to be a constant. Therefore, when the alumina layer thickness between neighboring pores is 10 nm and the pore diameter is 10 nm (sulfuric acid

anodization), the interdot resistance will be of the order of  $1.6\text{ G}\Omega$ . If the anodization is carried out in oxalic acid instead of sulfuric acid, the alumina barrier between neighboring pores is  $20\text{ nm}$  wide and the pore diameter is  $50\text{ nm}$ . In that case, the interdot resistance is  $640\text{ M}\Omega$ . These parameters can change somewhat, depending on anodization conditions.

### Negative Differential Resistance

When metals or semiconductors are electrodeposited within pores, they tend to break up in small crystalline grains. Each grain is a few nanometers in diameter.<sup>[23]</sup> Neighboring grains are separated by amorphous regions, which are also a few nanometers thick. The amorphous regions are much more resistive than the crystalline regions, so that an amorphous–crystalline–amorphous combination acts like an effective double-barrier resonant tunneling diode. A series of these diodes will result in a “pass-bands” of energies separated by “stop-bands.” As a result, we expect the current–voltage characteristic to exhibit a weak negative differential resistance. In fact, we have observed negative differential resistance in vertical conduction through CdS nanowires electrodeposited within  $50\text{-nm}$  pores produced by anodization in oxalic acid. Two current–voltage characteristics showing negative differential resistance are given in Fig. 9. They were measured at room temperature. In the first sample, we probed about 100 mesas in parallel.<sup>[24]</sup> The peak-to-valley ratio is 1.5:1 and the peak current is  $1.5\text{ nA}$  for the 100-mesa ensemble. Therefore, the peak current per dot is  $15\text{ pA}$ . In the second sample shown in Fig. 9, we probed about 10 wires and observed *multiple* negative differential resistance peaks at room temperature.

### Dot Capacitance

In the past, we have observed room-temperature single electron charging (Coulomb blockade) effects in these systems.<sup>[24]</sup> From those measurements, we estimate that the dot-to-substrate capacitance (i.e., the capacitance of the CdS nanowire) is of the order of  $0.5\text{ aF}$  in sulfuric acid anodized templates. This value agrees nicely with what we would have calculated if we viewed the CdS wire as a parallel-plate capacitor. The wire has the shape of a cylinder with a diameter of  $10\text{ nm}$  and height of  $1\text{ }\mu\text{m}$ . The relative dielectric constant of bulk CdS is 5.4. Therefore, the “parallel-plate” capacitance of the mesa is  $0.1\text{ aF}$ , which is of the same order as what we measured. We have also observed Coulomb blockade in the oxalic acid anodized structures. There, the Coulomb blockade picture is somewhat more complicated because the semiconductor within the pores breaks up into small crystalline grains separated by

**Fig. 9** The current–voltage characteristics of two arrays of  $0.5\text{-}\mu\text{m}$ -long cylindrical CdS quantum wire samples of diameter  $50\text{ nm}$  showing negative differential resistance at room temperature. In the top figure, about 100 wires in parallel are probed, and in the bottom figure, roughly 10 wires in parallel are probed. The non-zero current at zero voltage in the bottom figure is an artifact of the measurement process. The non-zero current is purely a displacement current that flows through sample at zero voltage when the voltage source is scanned at a finite rate. The capacitance of the sample causes a displacement current  $C(dV/dt)$  to flow through the sample at zero voltage. In the top figure, this current is not visible because the current magnitude is more than 20 times larger. The positions and heights of the peaks change with repeated electrical cycling and finally after many cycles may tend towards stabilizing. The data shown here is after 3 cycling. Ref.<sup>[25]</sup> shows the data after many cycles when the I–V characteristics tend towards stabilizing. However, the peak-to-valley ratio surprisingly does not change perceptibly from one run to another.

amorphous regions. Consequently, they form a series of capacitors (or tunnel junctions). In fact, we have observed Coulomb staircase in oxalic acid anodized systems<sup>[24]</sup> because they comprise multiple capacitors in series. Based on the observed Coulomb staircase, we found that the effective dot-to-substrate capacitance in

oxalic acid anodized templates is actually 5 times smaller than what it is in sulfuric acid anodized templates, even though the pore area in oxalic anodized templates is 25 times larger. This apparently unexpected result can be explained by the fact that, in the case of oxalic acid templates, the dot-to-substrate capacitance is a series combination of many capacitors, which reduces the effective capacitance between the dot and the substrate.

### The Concept of “Superdot” for Image-Processing Applications

The pitch of the 2-D quantum dot array (dot diameter plus interdot separation) in oxalic acid anodized templates is about 70–80 nm. Considering that the edge of a pixel in an image should be perhaps 10 times the wavelength of light (we will assume light of wavelength 550 nm which is in the middle of the visible range), therefore the edge of a pixel is  $5500/70 = 80$  times larger than the pitch of the quantum dot array. Therefore, approximately  $80 \times 80 = 6400$  dots will represent a pixel. Thus, we will assume that a dot cluster of about 6400 dots can be approximated as an equivalent “superdot,” which will act as a single node interacting with the light wave in image-processing applications. Hence, its dynamical behavior can be modeled by treating it as a single dot if the circuit parameter values are modified accordingly. This means that the superdot-to-substrate capacitance is 6400 times the single dot capacitance, i.e.,  $6400 \times 0.5 = 3.2$  fF, the intersuperdot resistance is 80 times smaller than the interdot resistance (because the edge of the superdot contains 80 single dots), i.e.,  $640/80 = 8$  M $\Omega$ , and the peak current for a superdot is  $6400 \times 15$  pA = 0.1  $\mu$ A. The peak-to-valley ratio can be improved by annealing the structures at some optimum temperature to promote uniform grain growth. This requires a systematic study, which is reserved for future work. It stands to reason that the peak to valley ratio can be improved to at least 10:1. One parameter that we have not been able to measure is the interdot capacitance. Therefore, we will estimate it assuming a parallel-plate geometry for simplicity. The relative dielectric constant of alumina is roughly 4; therefore, the interdot capacitance is 5 aF if the anodization is carried out in oxalic acid. Here we have assumed that the quantum dot is 50 nm wide for oxalic acid anodization and 50 nm thick (to electrodeposit 50 nm of metals within the pores takes only a few seconds of electrodeposition). Based on this, the inter-superdot capacitance is 4 fF for oxalic acid anodization. The circuit parameters for the superdot are given in Table 1.

Circuit theorists have simulated the system architecture described here for image-processing applications

**Table 1**

Circuit parameter	Value
Superdot-to-substrate capacitance	3.2 fF
Intersuperdot capacitance	4 fF
Intersuperdot resistance	8 M $\Omega$
Peak current in a superdot	0.1 $\mu$ A
Valley current in a superdot	0.01 $\mu$ A

using the circuit parameter values of Table 1.<sup>[25]</sup> They found that the simple self-assembled architecture, in its most primitive form, can perform image-processing tasks. The natural dynamics of the system result in a response similar to edge detection. A preprocessing of input images may be necessary to handle more specific tasks. The response time of the circuits is few tens of nanoseconds. Together with the immense processing density, this makes the quantum dot array a fast and high-resolution image processor candidate for several applications.

### CONCLUSION

In this entry, we have provided a glimpse of how electrochemically self-assembled templates and nanostructures can be used for various device and circuit applications. This is a rapidly maturing field and can soon emerge as a competitive technology for high-throughput nanosynthesis.

### ACKNOWLEDGMENTS

Many sections of this review entry have been excerpted from work published by the author and coworkers. I am indebted to our Russian collaborators Drs. S. Tereshin, A. Varfolomeev, and D. Zaretsky, who measured the interdot resistances; Drs. Latika Menon and Nikolai Kouklin, who self-assembled many of the structures and made current–voltage, photoresponse, and capacitance–voltage measurements; Dr. Koray Karahaliloglu and Prof. Sina Balkir for circuit simulations; and Prof. Vwani Roychowdhury for stimulating discussions on the image-processing architecture. The atomic force micrograph in this entry was provided by Dr. Feng Yun and the current–voltage characteristics showing negative differential resistance, as well as some photoresponse data, were provided by Mr. Sandipan Pramanik.

Various facets of this work were supported by the Army Research Office, National Science Foundation, Office of Naval Research, and the State of Nebraska under the Nebraska Research Initiative.

## Abstract

Nanobiological sensors are playing an increasingly important role in diagnosing disease, monitoring biological and chemical processes, and elucidating important biological and physical mechanisms. Nanotechnology has advanced our ability to create biosensors that interrogate, interact with, and examine biological targets at the molecular scale. This entry discusses the basic principles of biological sensing and illustrates how nanotechnology and nanoscale material and process technologies have helped shape a new class of “nanobiosensors.” Similar to larger-scale biosensors, nanobiosensors rely on two basic components, a recognition element and a signal transduction element. To illustrate the role of nanotechnology in these elements, specific biological targets and mechanisms of signal transduction are presented and discussed. A strong emphasis is placed on how nanomaterials can enhance both specificity and sensitivity in these systems.

## INTRODUCTION

Nanotechnology is defined as the ability to manage and control individual atoms and molecules at the nanoscale, leading to the design and fabrication of real-life functional physical, chemical, and biological systems at the macroscale. Nanotechnology offers a host of new materials and novel functionalities that can be exploited for biological and chemical sensors. In many cases, materials at the nanoscale have unusual optical, magnetic, catalytic, and mechanical properties, which differ greatly from their bulk material counterparts.<sup>[1]</sup> These unique properties are beginning to be harnessed for the development of novel sensors and transduction systems with improved spatial resolution, reduced detection volumes, higher sensitivity levels, and faster response times. Since a majority of biological processes occur at the nanoscale, these characteristics are highly desirable for biological sensing applications. In a typical cell, most of the major building blocks are nanoscale molecules that interact at nanometer length scales. Cell membranes and DNA are only a few nanometers wide, while the largest cellular proteins can be tens of nanometers in diameter. Such small dimensions require nanoscale sensors to accurately and sensitively probe highly complex biological systems.

Nanoscale biological sensors, or nanobiosensors, are biological sensing systems that have at least one feature size of 100 nm or smaller or perform measurements over nanometer length scales. Like most sensors, nanobiosensors are composed of both a recognition element and a transduction element, which define their mode of operation. The recognition element, which is often a biological molecule or biologically (chemically)

reactive compound, specifies the interaction between the sensor and the biological target. The transduction element converts the recognition event into a measurable signal through electrical, optical, or mechanical processes. To date, nanobiosensors have utilized each of these signal transduction mechanisms, although a majority has been based on optical and electrical mechanisms. In what follows, this description of nanobiosensors will first cover the range of biological targets that can be detected and will then outline specific transduction mechanisms that have been used. Examples of current nanobiosensor technologies will be covered for each transduction mechanism.

## BIOLOGICAL TARGETS

In its simplest form, a biosensor is a biological sensing element coupled to a transducer that generates a signal proportional to the concentration of its target.<sup>[2]</sup> Biosensors can be used to detect specific biological molecules, the products of biological reactions, or even whole cells. Nanobiosensors operate at a smaller length scale than conventional biosensors, giving them distinct advantages in precision, accuracy, sensitivity, and response time. Recently described nanobiosensors have been used to detect a wide range of biological targets including nucleic acids, proteins, lipids, and carbohydrates. To this end, each of these potential targets is described briefly.

Nucleic acids, which include DNA and RNA, are the information storage molecules of all biological organisms. Using four different nucleotide building blocks, adenine, guanine, cytosine, and thymine

(replaced by uracil in RNA), nucleic acids have the ability to encode a vast number of sequences that are responsible for the construction of individual proteins and entire organisms. A typical double-stranded DNA strand has a width of 2 nm (a nanometer is a billionth of a meter) and a length, which is dependent on the number of nucleotides in its sequence. In the past two decades, understanding of DNA structure and function has grown and the amount of sequence information has increased exponentially.

This understanding is useful for a variety of reasons, including identification of harmful mutations and detection of potentially dangerous microorganisms. For sensor applications, nucleic acids can be specifically captured through sequence-specific hybridization between a target strand and an immobilized capture strand. Nucleic acids are compatible with various amplification strategies, including the polymerase chain reaction (PCR), which can be used to generate multiple copies of the target. Such amplification can be particularly useful for nanobiosensors that have limited interaction volumes with limited numbers of target molecules for detection.

Proteins, which are composed of long chains of amino acids, can also be detected using nanobiosensing strategies. Proteins can serve a variety of functions within living organisms, including structural, catalytic, and regulatory roles. Other proteins mediate biological interactions and can bind or attach to specific molecular targets. Small proteins can be as small as a few nanometers in diameter while larger proteins can approach tens of nanometers in size. This size makes proteins amenable for both attachment to nanobiosensors, and detection by these systems. Antibodies, which are of particular interest for many biosensors, are proteins with unique specificity to a nearly infinite number of potential targets. They can be used as specific recognition elements for the detection of chemical compounds, biological molecules, or even inorganic materials. Enzymes, which are catalytic proteins, are also useful for biosensing since they can mediate biochemical reactions that produce detectable reaction products. Multiple biosensor technologies utilize immobilized enzymes as high specificity biological recognition elements and catalysts for the detection of biochemical reaction substrates. Structural and regulatory proteins are also good biosensing targets since they can be used as unique biological indicators. Cellular production of certain proteins can indicate the status and viability of a biological system, while the presence of particular proteins on the surface of a cell or virus can be used for identification.

Lipids and carbohydrates are essential components of many biological systems and can be used for identification and as biological indicators. Cell membranes and viral envelopes are constructed from lipid bilayers

that form an amphiphilic, water impermeable barrier. These lipid bilayers can be studded with membrane-soluble proteins that serve as receptors, pores, or regulatory elements and are excellent biosensing targets. Typical lipid bilayers in cells have a thickness of approximately 2 nm and can span large areas as continuous films. Carbohydrates, on the other hand, are typically small organic molecules (6 carbon rings such as glucose) but can be polymerized into linear and branching chains known as polysaccharides.

In addition to being energy storage molecules, carbohydrates can often be found in the form of polysaccharides, which are linked to both proteins and lipids for a variety of purposes. In Gram-negative bacteria, lipopolysaccharides (LPS) are commonly found on the external face of the outer membrane. These LPS molecules contain complex polysaccharide chains that are often strain-specific and can be used for identification purposes. Eukaryotic cells (including animals, plants, and some fungi) commonly attach carbohydrates to proteins in a process called glycosylation. These uniquely attached carbohydrates can also be used for identifying specific proteins and to differentiate different cell types or whole organisms. Carbohydrates can also be used as indicators of metabolic activity for living systems. For instance, glucose, which is used by many cells for energy production, can be detected and quantified with enzymatic biosensors.

Nanobiosensors have also been used to probe and analyze whole cells. Owing to their small size, these whole cell analytical sensors can be used without harming cells and without disrupting normal cellular functions. Whole cells can be attractive targets for high-sensitivity applications since they can contain large concentrations of target biomolecules and their larger size can affect more substantial transduction events than smaller biomolecular targets. Bacterial (prokaryotic) cells are typically within the 0.5–5  $\mu\text{m}$  size range, while plant, animal, and fungal (eukaryotic) cells can range from 1  $\mu\text{m}$  to 100  $\mu\text{m}$  in size. At this size scale, cellular analyses with nanobiosensors typically involve the manipulation of a single cell, or interrogation of individual components of the cell. This can yield important information about cellular structure and function, which would not be possible with macro-scale and microscale analysis (see Fig. 1).

## ELECTRICAL NANOBIOSENSORS

The use of nanoscale materials (nanomaterials) for electrochemical biosensing has seen an explosive growth in the past 5 years and there are several comprehensive reviews available that cover the use of nanomaterials for amperometric or voltammetric electrochemical detection.<sup>[3–7]</sup> Most developmental efforts

**Fig. 1** An example of a generic eukaryotic cell structure and key biological targets for nanobiosensors. Physical nanoprobe, such as optical and electrical fibers, can be used to make intracellular and extracellular measurements, while diffusible probes, such as fluorescent quantum dots, can be used for protein, carbohydrate, and nucleic acid labeling.

for electrochemical nanobiosensors have focused on the use of nanomaterials for electrode fabrication and for direct wiring of biological molecules to the sensor. This use of nanomaterials is aimed at promoting electrochemical reactions and amplifying the signal of biorecognition events. These systems can integrate protein machinery for sensitivity and specificity, peptide, or nucleic acid chemistry for aligning the various electron-transducing elements, and nanoelectrodes for enhancing sensitivity of electrical detection. The fundamental basis of electrochemical biosensing is to electrically monitor biochemical processes, including biochemical reactions, and the detection of electrically charged biomolecules. Many enzymatic biochemical reactions result in the oxidation or reduction of chemical compounds.

When coupled to an electrode surface, electrons can be transferred from the compound to the electrode (or vice versa), resulting in a measurable change in electrical current. Electrically charged biomolecules can also be detected using potentiometric methods. If the proper recognition elements (such as proteins or nucleic acids) are linked to an electrode, binding events with charged biomolecular targets could result in a measurable change in electrical potential. Incorporating nanoscale components into these types of electrochemical sensors enables active components of the sensor to approach the size and scale of biological molecules. This section focuses on electrochemical

nanobiosensors developed for detecting biologically relevant compounds.

Sensors based on carbon nanotubes are an excellent example of how nanotechnology can be used for electrochemical sensing applications. The advantages of using carbon nanotubes include high surface area, favorable electronic properties and electrocatalytic effects. These properties make nanotubes attractive for the construction of electrochemical enzyme-based biosensors. Carbon nanotube biosensors for glucose detection have utilized immobilized enzymes, such as glucose oxidase, to catalyze glucose oxidation in proximity to the nanotube.<sup>[8]</sup> When glucose is oxidized, electrons are transferred to the nanotube, generating a measurable electrical current.

Electrochemical nanobiosensors have also been based on conductive nanoparticles that are heavily functionalized with DNA molecules that could be used for the detection of specific target DNA sequences.<sup>[9]</sup> Hybridization events between target DNA and immobilized DNA can result in nanoparticle condensation. If condensation occurs between two electrodes, the conductivity of the condensate can be measured, yielding information about the original concentration of target DNA. Alternative nanomaterials, such as nanowire arrays can also be used for nanobiosensing applications. Nanowires can be formed by template synthesis methods involving electro- and electroless depositions that can be used to develop electrochemical

**Fig. 2** (A) Scanning electron micrograph (SEM) of Chitosan + PEO nanofibers without gold nanoparticles, (B) SEM of Chitosan + PEO nanofibers with gold nanoparticles, (C) transmission electron micrograph (TEM) of Chitosan + PEO nanofibers with gold nanoparticles.

nanobiosensors for the detection of hydrogen and *E. coli* bacteria.<sup>[10]</sup>

Another class of electrochemical nanobiosensors includes sensors based on electrospun polymeric nanofibers. Electrospun nanofibers are high surface area filaments that range from 35 nm to few hundreds of microns in diameter and can be formed from both conducting and non-conducting polymers. Electrospun nanofibers can be functionalized with capture molecules (including nucleic acid probes, antibodies, proteins) for electrical detection of various biomolecules. Such sensors can report real-time electrical signals indicative of electrically charged biological targets using conductive-insulating polymeric nanofibrous composites. Furthermore, the conductivity of such nanofibers can be enhanced by incorporating either gold or silver nanoparticles during the electrospinning process. Figure 2 shows the incorporation of gold nanoparticles (15–20 nm in diameter) into the Polyethylene Oxide (PEO) + Chitosan composite nanofibers.

Figure 2A shows a scanning electron microscope (SEM) image of PEO + chitosan nanofibers without any gold nanoparticles, while Fig. 2B shows the SEM image of nanofibers with gold nanoparticles, and Fig. 2C shows a transmission electron microscope (TEM) image of nanoparticles dispersed in the nanofiber matrix.

Investigations concerning the sensing performance as a function of surface modifying groups, polymer chemistry, nanofiber diameter, degree of alignment, pore size, and surface functionalization is currently being undertaken to achieve high levels of sensitivity, selectivity, and reliability. These fiber-based sensors have the potential to be intrinsically more rapid and sensitive sensors than thicker (> 100 nm) films of the same polymer matrix because of i) low steric hindrance of the attached biomolecules by the polymer matrix, ii) reduced need for target molecule diffusion through a microporous polymer matrix, and iii) the high surface to volume ratio that exponentially increases the

electrical and optical response of the polymer for the binding of the biomolecules.

## OPTICAL NANOBIOSENSORS

Optical nanobiosensing techniques include a wide range of nanoscale materials and devices. Similar to larger-scale optical detection systems, optical nanobiosensors rely on signal generation through fluorescence, absorbance, luminescence, or optical scattering. Many nanomaterials have unique optical properties that are the result of their size, and are not observed in the bulk material. For instance, compound semiconductor quantum dots have become popular tags for biological imaging and detection. These nanoscale particles exhibit enhanced fluorescence properties that are far superior to conventional organic dyes<sup>[11]</sup> and are dependent on the elemental composition and discrete particle size.

Other types of nanoparticles, including those made from gold and silver, can be used for simple colorimetric assays with extremely high sensitivity.<sup>[12]</sup> These particles can be linked to biological molecules, including nucleic acids and proteins, which can then bind specifically to biological targets. A simple color change can be observed when the biological molecules form molecular complexes, creating aggregates of the nanoparticles. This relatively simplistic detection method can be further enhanced by precipitation of other materials onto these aggregates, which can further modify optical and electrical properties for detection.<sup>[12]</sup>

Gold and silver nanoparticles are also useful for enhancing the sensitivity of spectroscopic techniques, including signal enhancement for Raman spectroscopy. Surface Enhanced Raman Spectroscopy (SERS) is a relatively new technique that utilizes nanoparticle-based spectral signal enhancement for high-sensitivity detection.<sup>[11]</sup> To perform SERS-based analyses, Raman-active compounds are placed in proximity to nanoscale metallic particles or nano-textured metallic surfaces where surface-generated plasmons can greatly enhance the Raman spectral signal.<sup>[13]</sup> For each of these techniques, detectable signal generation depends on the unique properties of nanoscale materials. While some nanomaterials simply enhance existing signals, such as the case for SERS, other nanomaterials such as quantum dots have optical properties that are dependent on their nanometer size scale and that are not present in the bulk material.

In addition to utilizing nanoscale materials for signal generation or signal enhancement, nanobiosensors can also use nanoscale tools for obtaining optical signals. For many colorimetric and spectroscopic detection assays, nanoscale lipid vesicles, known as liposomes,

have been used to contain high concentrations of dye molecules or optically active reagents.<sup>[14]</sup> In their simplest form, liposomes are small spheres that are composed of monolayers or bilayers of amphiphilic lipids and can range from a few nanometers to many microns in diameter. Similar to a cell membrane, liposomes can contain small volumes of materials, such as fluorescent dyes, and can have proteins or other biological molecules embedded in the lipid layer.

These embedded molecules can be used to link liposomes to specific targets or mediate biological recognition events. Because the liposomes can be filled with high concentrations of dyes and other reagents, they provide superior signal over targets labeled with individual molecules. Although many liposome-based detection assays utilize fluorophores or chromophores, liposomes can also be filled with enzymes or other catalytic species that can mediate fluorescence-generating or colorimetric reactions. Biological interactions between liposomes and their targets can cause release of catalysts into the solution or entry of substrates into the interior of the liposome. Through either mechanism, catalysts can be exposed to their substrates to generate an optical signal. This type of biosensing reaction can greatly amplify the signal due to the catalytic nature of the process.

Optical tools have also been developed for probing nanoscale features of biological systems. Nanometer-sized optical fibers are currently used for Near-field Scanning Optical Microscopy (NSOM) applications and for direct insertion into living cells.<sup>[15]</sup> To create these nanometer sized probes, optical fibers are stretched or etched to reduce their diameter to 50 nm or less. This dimension is typically smaller than the wavelength of light used for sample interrogation, which can greatly increase resolution. The sharpened optical probe can be used to collect light from an illuminated sample or can be used for localized, nanoscale illumination.

In either method, raster scanning of the probe across the sample can be used to create a high-resolution image that greatly exceeds the limits of traditional light microscopy. Spatial resolution on the order of 12 nm has been achieved with this type of optical probe system, making a true nanoscale technique.<sup>[15]</sup> Another use for these nanoscale optical probes is to insert them into living cells for observation of intracellular processes. Unlike larger probes, nanoscale probes can penetrate a living cell without causing cellular damage or cell death. This creates a unique opportunity to observe the cellular interior without the need for destructive preparation techniques. By coupling biomolecules or capture agents to the tip of these optical fibers, these nanoprobe can also be used as sensitive detectors. Biomolecular interactions with the tip can mediate a change in optical signal, which

**Fig. 3** Quantum dot molecular beacons for sequence-specific DNA detection. In their native state, quantum dot molecular beacons form a stable hairpin complex that brings the quencher molecule in proximity with the fluorescent quantum dot. When exposed to target DNA, the DNA hairpin can open, hybridizing with the target and spatially distancing the quantum dot from the quencher. This significantly decreases FRET efficiency, resulting in reduced quenching and a significant increase in fluorescence. The upper image shows quenched (1) and un-quenched (2) quantum dots, demonstrating the large difference in fluorescence. The lower image schematically depicts a quantum dot molecular beacon target interacting with its complementary target DNA.

can be correlated to the presence or absence of a particular target or target concentration.

In most optical systems, the sensitivity of target detection is a function of the intensity of the signal and the background noise of the system. One method of increasing signal-to-noise ratios involves the use of fluorescence resonance energy transfer (FRET). Fluorescence resonance energy transfer is a distance-dependent phenomenon that occurs when a donor fluorophore and an acceptor chromophore (quencher) are in proximity.<sup>[16]</sup> When the fluorophore and quencher are within a certain distance from each other, excitation energy can be transferred from the fluorophore to the quencher, preventing fluorescence emission.

Multiple biological detection strategies have been devised to harness this effect, and often include the use of nucleic acid and proteins. Molecular beacons<sup>[17–20]</sup> are one of the most well-known nucleic acid-based biosensing elements that utilize FRET. Molecular beacons are composed of a fluorophore and a quencher moiety attached to opposite ends of a single-stranded DNA oligonucleotide. The sequence of the oligonucleotide is designed such that it preferentially base pairs with itself, forming a stem-loop structure. Included inside the loop region is a probe sequence that can bind to a complementary target DNA sequence. This hybridization event causes the stem-loop structure to open and spatially distance the fluorophore from the quencher. This decreases the FRET efficiency and results in increased emission from the fluorophore. To increase the fluorescence signal of molecular beacons, semiconductor quantum

dots have been used, replacing traditional organic fluorophores<sup>[11]</sup> (Fig. 3), creating novel, molecular-level nanobiosensors.

## MECHANICAL NANOBIOSENSORS

Mechanical observation and detection of biological targets has been used for many years at the macro- and micro-scale. Quartz crystal microbalances and other oscillatory platforms can be used to detect picogram and lower quantities of biological targets. These systems, however, do not measure nanoscale mechanical forces and do not have the resolution to measure nanometer length-scale events. Current cantilever-based technologies, such as atomic force microscopy (AFM), do perform measurements at the nanoscale and are capable of measuring both nanoscale topographical features and nanoscale forces. These nanomechanical biosensors are typically designed as a single-sensing element, biomechanical devices targeted for a specific measurement.

Recent efforts have focused on the development of cantilever-based sensors for the detection of biomolecular recognition events.<sup>[21]</sup> The high mechanical quality factors associated with resonant micro- and nanomechanical cantilever systems<sup>[22–25]</sup> have proven useful in a number of application areas ranging from signal processing,<sup>[26]</sup> to nanobiotechnology.<sup>[27]</sup> Such biosensors can be label-free systems and can also be applied to the detection of viruses,<sup>[28,29]</sup> single cells, and individual strands of DNA. In these “dynamic mode” systems, the amount of attached mass is

**Fig. 4** Detection of biomolecular interactions using microcantilevers. Cantilevers can be modified with biorecognition elements that are specific to certain biological targets. In this example, cantilever “A” is modified with a recognition element that can bind to the spherical molecular targets. This binding event causes a measurable deflection of the cantilever, which can be measured by the change in position of a laser beam focused on its surface. Cantilever “B” is coated with a recognition element that does not interact with the target and is not deflected.

typically determined by observing changes in the resonant frequency of the oscillator. Cantilever readout is often performed optically, in which case spatial multiplexing is relatively easy.

Piezoelectric technology, which is responsible for generating mechanical oscillation in most nanomechanical sensors, can also be employed for the development of a novel class of smart nanodevices that mimic biological design. In piezoelectric materials, an electro-mechanical transduction process takes place within a given material. It is worth noting that some biological molecules, including certain proteins, are naturally piezoelectric. Systems that incorporate these biomimetic, piezoresistive structures can perform localized, high-resolution molecular recognition measurements.<sup>[30]</sup> The microcantilevers translate the molecular recognition of biomolecules into nanomechanical motion ranging from a few to hundreds of nanometers (see Fig. 4).<sup>[21]</sup> This mechanical response by the cantilever is commonly coupled to an optical or piezoresistive read-out system.<sup>[31,32]</sup>

## CONCLUSIONS

Nanobiosensors are increasingly becoming a powerful new class of sensors that can probe biological systems at the molecular scale and enhance sensitivity through the use of novel nanomaterials. The measurement of biological processes with such devices can provide new insights into biomolecular structure, function, and interactions. The novel properties of integrated nanomaterials can also improve our ability to interface

physical sensors with biological systems. A large number of electrical and optical nanobiosensors have been described and active research continues for the integration of nanomaterials into these transduction mechanisms. Although there are fewer reports of nanobiosensors based on nanomechanical signal transduction, it is expected that future efforts will expand our abilities to mechanically probe biological systems at the nanoscale.

## INTRODUCTION

As the scale of electronic devices continues to shrink, fundamental interest has focused on the nature of the mechanical, optical, and electrical behavior of one-dimensional nanometer-scale channels such as quantum wires<sup>[1]</sup> and carbon nanotubes.<sup>[2,3]</sup> The development of new experimental techniques such as mechanically controllable break junctions (MCBJs) and scanning tunneling microscopy (STM) has made it possible to form and to study atomic-sized junctions or contacts between macroscopical metals. The mechanical and electrical properties of nanocontacts between metallic bodies have been a subject of intensive research.<sup>[4–13]</sup> Quantum point contacts are structures in which a ‘neck’ of atoms, of just a few atomic diameters, bridges two electrical contacts. The results prepared by contacting a metal surface with an STM<sup>[7–14]</sup> and by other methods<sup>[15–19]</sup> have typically displayed a conductance quantized in steps of  $2e^2/h$ , where  $e$  is the electron charge and  $h$  is Planck’s constant. The mechanical properties of nanocontacts have shown that before the first yielding, nanowires preserve the elastic stage and, after that, the elongation deformation proceeds in alternating quasi-elastic and yielding stages.<sup>[12,13,20,21]</sup>

The thermal properties of infinite nanowires with periodical boundary conditions (PBCs) along the nanowire axis have been investigated using molecular dynamics (MD) simulations. For example, the MD methods were used to investigate the premelting of infinite Pb nanowires with the axis along a (110) direction<sup>[22]</sup> and the melting of infinite Au nanowires with a multishelled structure.<sup>[23]</sup> However, previous works<sup>[22,23]</sup> have not been enough to provide the thermal properties of nanocontacts and nanobridges, such as the melting and the breaking of nanobridges. Nanobridges can be sustained by supporting layers in contact with both ends of the nanobridges. This condition is considered as a similar situation to that in which a string, such as a guitar string, is connected between two clamps separated by a fixed distance. Therefore the nanobridge can also make an oscillation at a

resonant frequency to set up a standing wave pattern. Copper is an important engineering material, so in this investigation, we use MD simulations to investigate ultrathin Cu nanobridges. In this entry, we show the thermal properties of nanobridges in Sections ‘‘Oscillations of Nanobridges’’ and ‘‘Melting and Breaking of Nanobridges,’’ using a classical MD simulation.

## METHODS

In our MD simulations, we have used the same MD methods that we employed previously in studies on the cluster deposition and the structural motifs of Cu nanowires.<sup>[20,21,24–27]</sup> The MD time step is 0.5 fsec. The MD code uses the velocity Verlet algorithm, a Gunstern–Berendsen thermostat to keep temperature constant, a PBC along the wire axis, and neighbor lists to improve computing performance.<sup>[28]</sup> For Cu, we have used a many-body potential function of the second-moment approximation of the tight-binding (SMA-TB) scheme,<sup>[29]</sup> which has already been tested in nanoclusters and nanowires,<sup>[20,21,24–27,30]</sup> etc. The potential reproduces many basic properties of crystalline and non-crystalline bulk phases and surfaces,<sup>[31]</sup> and gives a good insight into the structures and thermodynamics of metal clusters.<sup>[32,33]</sup> The total potential energy of the system  $E_{\text{tot}}$  can be expressed as a sum of the potential energies of each atom  $i$ . The energy of each atom  $E_i$  is expressed as the sum of the attractive band energy determined by the occupied local density of states  $E_i^{\text{band}}$  and the repulsive term determined by the ion core–core interaction  $E_i^{\text{rep}}$ . The total energy of system  $E_{\text{tot}}$  can be written as:

$$E_{\text{tot}} = \sum_i E_i = \sum_i (E_i^{\text{rep}} + E_i^{\text{band}}) \quad (1)$$

$$E_i^{\text{rep}} = \sum_j A \exp[-p(r_{ij}/r_0 - 1)] \quad (2)$$

$$E_i^{\text{band}} = \left[ \sum_j \zeta_0^2 \exp[-2q(r_{ij}/r_0 - 1)] \right] \quad (3)$$

where  $r_0$  and  $r_{ij}$  are the nearest-neighbor bond length in a perfect crystal and the distance between  $i$  and  $j$  atoms, respectively.  $A$ ,  $\xi$ ,  $p$ , and  $q$  are adjustable parameters, which are determined by fitting the calculated values of cohesive energy, lattice constant, and elastic constants to the experimental values. The parameters are the same as those in Ref.<sup>[29]</sup>. The cutoff distance is set to the value between the fourth and fifth nearest neighbors of a perfect crystal.

## INITIAL STRUCTURES

The nanostructures we studied have two supporting layers that are connected with both ends of the nanobridges. The last layers at both supporting ends are rigid; all the atoms in these layers are kept fixed during the MD simulations. These fixed layers at both ends are assumed to be connected to the external agent. Atoms in the following two layers adjacent to the fixed atoms and those of the nanobridges are identified as dynamic atoms and are fully relaxed during the MD steps. We considered eight different structures, which are described in Table 1.  $D$  and  $L$  in Table 1 and Fig. 1 denote the diameter and the length of the nanobridges, respectively. The nanowires with a face-centered cubic (fcc) structure have been observed in a previous work<sup>[23]</sup> and the ultrathin nanowires also have a type of cylindrical multishell (CMS) structure.<sup>[24,30]</sup> Therefore we have selected nanobridges with fcc or CMS-type structures. The supporting layers have the same structures as those of the nanobridges. To describe CMS-type nanowires, we use the notation  $n - n' - n'' - n'''$  introduced by Ohnishi, Kondo, and Takayanagi<sup>[11]</sup> when the nanowire consists of coaxial tubes with  $n$ ,  $n'$ ,  $n''$ ,  $n'''$  helical atom rows ( $n > n' > n'' > n'''$ ). Because the structures of the CMS-type nanobridges are closely related to the  $\{111\}$  plane,<sup>[24]</sup> they are connected to the supporting layers with  $\{111\}$  planes. Nanobridges with different diameters were simulated under conditions of the same structure and the same length.

Fig. 1 Oscillation of the D1 nanobridge.

## OSCILLATIONS OF NANOBRIDGES

The MD simulations of all nanobridges in Table 1 have been performed during 1 nsec at room temperature. Fig. 1 shows four cuts representing the oscillations of the D1 nanobridge. The momentum of supercells for bulk systems is almost zero. However, the supercells for one-dimensional systems can have nonzero momentum in a specific condition and, in this situation, if tension is exerted on the one-dimensional system, the one-dimensional system will oscillate. Nanobridges can exist in this state. The mean kinetic temperature  $k_B T$  is calculated as follows:

$$k_B T = [2/(3N - 6)] \left\langle \sum_{i=1}^N (mv_i^2/2) \right\rangle \quad (4)$$

where the angular brackets denote averaging over time and  $k_B$  is the Boltzmann constant. It supplies the energy to atoms in the nanobridges, and the collective

Table 1 Structures of ultrathin Cu nanobridges

	Supporting layer	Nanobridge	$D$ (Å)	$L$ (Å)	Number of atoms in nanobridge
A1	{100}	{100}	10.2	61.449	425
A2	{100}	{100}	15.0	61.449	969

D1	{111}	CMS 6-1	4.9	64.294	209
D2	{111}	CMS 11-6-1	10.2	64.294	534

Fig. 2 Vibrations of the center of the nanobridge during the initial 200 psec for all cases in Table 1.

motion of the atoms in the nanobridges is discovered by the oscillation of the nanobridge.

Figure 2 shows the vibrations of the center of the nanobridges during the initial 200 psec for all cases. The thermal energy can make the nanobridges oscillate at a certain frequency. In the cases of A1, A2, B1, B2, and C2, the vibrations of the nanobridges show sinusoidal waves, such as resonance. In the A1 case, the resonance is stabilized after 100 psec. However, in the cases of C1, D1, and D2, the sinusoidal vibrations of the nanobridges disappear as the MD time increases. In classical oscillation systems, for certain frequencies, the interference produces a standing wave pattern or oscillation mode, and then the string resonates at a certain frequency, called resonant frequency. If the string oscillates at some frequencies other than a resonant frequency, a standing wave is not set up. In our simulations of nanobridges, if the nanobridges are in the mode of the certain resonant frequency at the beginning of the MD simulation, the standing waves of nanobridges are maintained. However, during the MD simulations, when the structures of the nanobridges are changed, the standing waves are not set up in our simulations, and atoms in the contact region between the supporting layer and the nanobridge are rearranged. The standing waves have been damped by structural rearrangements taking place. As the diameter of the nanobridge increases, because the tension in the nanobridge increases, the displacements

of its center decrease and, at the same time, the amplitude of the wave decreases.

Figure 3 shows the structures after the MD simulations of 1 nsec. In the A1 case, the neck of the nanobridge connected by the bottom supporting layer became narrow, as pointed out by the arrow. Therefore the rearrangements of the A1 nanobridge before 100 psec led to the damping of the sinusoidal wave, as shown in Fig. 2. However, because its final structure was the same as the original structure, the resonance was maintained in the nanobridge. In the C1 case, the nanobridge that originally had a {111} structure has been transformed into a complex nanobridge with

Fig. 3 Structures after MD simulations of 1 nsec.

diverse structures. Especially, the region pointed to by the arrow is a multishell-type 10-5-1 structure. Considering the 10-5-1 multishell nanoparticle, the pentagonal small particles, such as decahedron and icosahedron particles, have been extensively investigated and reviewed in Ref.<sup>[34]</sup>. The decahedron and icosahedron nanoclusters, called multiple twinned particles, are different from single crystalline particles and are composed of tetrahedrons, which consist of only triangular {111} faces.

In the D1 and D2 cases, at the early stage of the MD simulations, structural rearrangements were achieved in the contact regions between the supporting layer and the CMS-type nanobridge. As results of the structural rearrangements, the deviations of the center of the nanobridges are shown in the waves of Fig. 2. Most of all, the CMS-type nanobridges maintained their structures between the supporting layers with {111} planes. However, one or two layers of the nanobridge contacting the supporting layers were transformed into the {111} structure and the other regions of the nanobridges preserved the CMS-type structure.

We also performed MD simulations of 100 psec using the nanobridges, which have been obtained from simulations as explained in Fig. 2. The waves on the nanobridge can have two modes, such as longitudinal and transverse modes, because of their structural property. The waves shown in Fig. 2 are closely related to the transverse waves on the nanobridges. Because the transverse wave on the nanobridge makes a resonance, as shown in Fig. 2, the lowest resonant frequency of the nanobridge is calculated by the following method. Atoms in the center regions of the nanobridges were initially applied to the external force, 0.01 nN, during 1 psec at room temperature. Then we monitored the displacements of the center region of the nanobridge. Table 2 shows the lowest resonant frequency of the nanobridges at room temperature. In the C1 case, the

resonance did not appear. Therefore it is assumed that the nanobridges, which are not well-defined structures, cannot resonate at a certain frequency.

From the theory of the classical oscillation system, the relation between the wave length  $\lambda$  and  $L$  for a standing wave on a string can be summarized as:

$$\lambda = \frac{2L}{n}, \quad n = 1, 2, 3, \dots \quad (5)$$

The resonant frequencies that correspond to these wavelengths follow from Eq. (5):

$$f = \frac{v}{\lambda} = n \frac{v}{2L}, \quad n = 1, 2, 3, \dots \quad (6)$$

where  $v$  is the speed of the travelling waves on the string. The lowest resonant frequency is  $f = v/2L$ , which corresponds to  $n = 1$ .

The speed of the waves on the string is also expressed as follows:

$$v = \sqrt{\frac{\tau}{\mu}} \quad (7)$$

where  $\tau$  is the tension in the string and  $\mu$  is the linear density of the string. In the case of the first harmonic, the tension is calculated by Eqs. (6) and (7):

$$\tau = v^2 \mu \quad (8)$$

In Table 2, the larger the diameter of the nanobridge is, the larger is the lowest resonant frequency. When the wavelength is the same, the speed of the travelling wave on the nanobridge increases in linear proportion with the lowest resonant frequency. We can also calculate the linear density by using the mass of the nanobridge against the length of the nanobridge. From these

**Table 2** Lowest resonant frequency, speed of the traveling wave, linear density, and tension in the nanobridge of ultrathin Cu nanobridges

Nanobridge	Lowest resonant frequency (GHz)	Speed of the traveling wave (m/sec)	Linear density ( $\mu$ ) ( $10^{-16}$ kg/m)	Tension in the nanobridge ( $10^{-11}$ kg m/sec <sup>2</sup> )	
				Eq. (8)	MD simulation
A1	5.6	68.9	73.0	3.46546	6.95621
A2	7.2	89.2	166.5	13.24780	18.18869
B1	15.6	131.0	80.3	13.78028	10.03054
B2	18.5	155.4	118.8	28.68920	26.23471
C2	8.3	117.8	163.9	22.75958	17.25665
D1	4.7	60.2	34.3	1.24304	1.50018
D2	7.8	99.8	87.7	8.73495	10.44815

values, the tensions in the nanobridges were calculated by Eq. (8) and were compared with those obtained from the MD simulations. As the diameter of the nanobridge increases, the tension in the nanobridge increases. The tensions obtained directly from the MD simulations are the forces acting on the supporting layers and are in agreement, within the limits, with those calculated using the continuum theory [Eq. (8)]. For all cases, the tensions obtained from the MD simulations are slightly higher or lower than those obtained from the continuum theory. Because the tensions calculated by Eq. (8) reflect only upon the transverse waves, this difference could be derived from the interference of the longitudinal waves on the nanobridges. As the diameter of the nanobridge increases, the tension in the nanobridge increases. In spite of this difference, our simulations have shown an aspect of nanobridges in the state of the art. The oscillation of nanobridges can be understood by the classical oscillation theory.

### THE MELTING AND BREAKING OF NANOBRIDGES

We have also investigated the properties of nanobridges as the temperature is raised. The initial structures of the nanobridges were the structures obtained from Oscillations of Nanobridges and were equilibrated at 300 K. Each system was heated by uniformly scaling the atomic velocities. The MD runs of 20,000 time steps were performed with each temperature step from 300 K. Therefore the average temperature ascent rate is 0.1 K/psec. We monitored the internal energy as a function of temperature.

The caloric curves for some of the ultrathin Cu nanobridges in Table 1 are shown in Fig. 4. To compare nanobridges with semi-infinite nanowires, Fig. 4 includes the caloric curve of the CMS 16-11-6-1 applied to the PBC from Ref.<sup>[35]</sup>. The caloric curve of the CMS 16-11-6-1 nanowire close to the one-dimensional system is in the regime of the pseudo-first-order transitions and the jump in the caloric curve is apparent. The slope of the caloric curve of the CMS 16-11-6-1 corresponds to the Dulong–Petit specific heat.<sup>[35]</sup> The  $M_{\text{point}}$  and  $B_{\text{point}}$  indicate the temperatures of pronounced upward and downward points in the caloric curve, which are related to the melting and the breaking of the nanowire. The downward curvature in the caloric curve has not been observed until now. The caloric curve of the CMS 16-11-6-1 nanowires is divided into five regions. The first region ranges below the  $M_{\text{point}}$ , where the ultrathin nanowire is solid. The second region is the  $M_{\text{point}}$  at which the caloric curve exhibits an upward curvature, where the specific heat markedly increases at the beginning of

Fig. 4 Caloric curves of some of nanobridges and the CMS 16-11-6-1 nanowire.  $M_{\text{point}}$  and  $B_{\text{point}}$  indicate temperatures of upward and downward points in the caloric curve, respectively.

the surface melting. This upward curvature is associated with the loss of the solid rigidity of the nanowire. The third region is between the  $M_{\text{point}}$  and the  $B_{\text{point}}$ , where the ultrathin nanowire is in the melting state, and the slope is the same as that in the first region. The fourth region is the  $B_{\text{point}}$  at which the ultrathin nanowire is broken and then the spherical cluster is formed. In the last region, a spherical cluster has been maintained in the MD simulation applied to the PBC. The slope in the caloric curve of the CMS 16-11-6-1 nanowire is always the same as those in the first, third, and fifth regions. Thus properties of the caloric curve of nanowires are in excellent agreement with previous works on nanowires<sup>[22,23,35]</sup> and nanoclusters.<sup>[36]</sup> The melting temperatures of the ultrathin Cu nanowires and nanobridges are much lower than the bulk melting temperature.

The properties of the caloric curves of nanobridges are generally similar to those of nanowires or nanoclusters.<sup>[22,23,35,36]</sup> However, the caloric curves of nanobridges are different from those of nanowires for the slopes of the caloric curves. The caloric curves of nanobridges make it difficult to define both the  $M_{\text{point}}$  and the  $B_{\text{point}}$ . The difference of the slopes in the caloric curves is because of the supporting layers. As investigated in Oscillations of Nanobridges, the attractive force between the supporting layer and the nanobridge could maintain the nanobridges. Therefore the caloric curves of the nanobridges include effects of structure dependence related to the tension on the nanobridge as well as temperature dependence. In the

**Table 3** The  $M_{\text{point}}$  and  $B_{\text{point}}$  of Nanobridges

	$M_{\text{point}}$ (K)	$B_{\text{point}}$ (K)
A1	–	$350 \pm 7$
A2	$530 \pm 10$	$650 \pm 10$
B1	–	$420 \pm 7$
B2	$645 \pm 15$	$745 \pm 10$
C1	–	$410 \pm 8$
C2	$535 \pm 15$	$730 \pm 25$
D1	–	$330 \pm 5$
D2	$475 \pm 10$	$600 \pm 10$

The graph in the table shows the curve fitted with Eq. (8).

case of the CMS 16-11-6-1 semi-infinite nanowire, because its caloric curve is dependent only on temperature, the slopes of the solid and melting states in the caloric curve are fixed. However, in the cases of the nanobridges, because their caloric curves are dependent on both the structure and the temperature, their caloric curves before the breaking of the nanobridges are different from the caloric curves of semi-infinite nanowires. The slopes of caloric curves in the melting states of nanobridges are closer to the slopes of caloric curves in nanowires than to the slopes in the solid state of nanobridges. When the kinetic temperature of the nanobridge reaches its  $M_{\text{point}}$ , the nanobridge enters a quasi-melting state and then the tension in the nanobridge gradually decreases. The slopes of the caloric curves after the breaking of nanobridges come to have the same value as those of nanowires.

The  $M_{\text{point}}$  and the  $B_{\text{point}}$  of nanobridges are shown in Table 3. In the cases of A1, B1, C1, and D1, the  $M_{\text{point}}$  was not observed in our simulations but the  $B_{\text{point}}$  was observed. We can see that the  $M_{\text{point}}$  of nanobridges is closely related to the linear density and diameter of nanobridges in Fig. 5. In cluster science, the melting temperature depends on the cluster size and is expressed in the following form:<sup>[23]</sup>

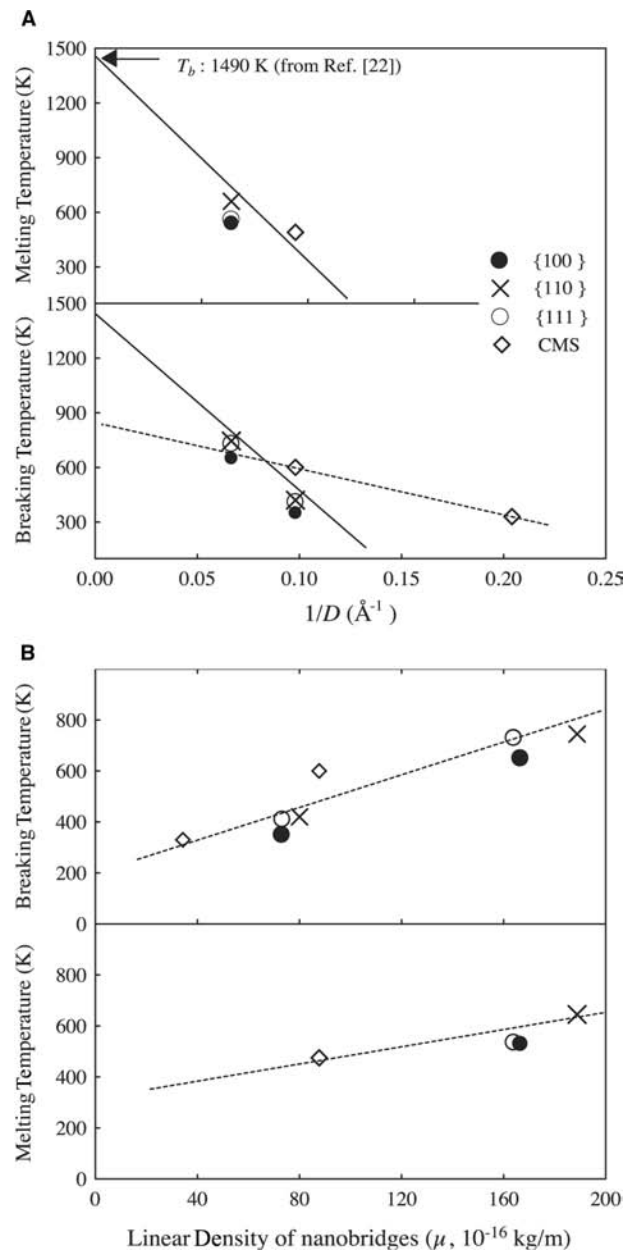

$$T_{\text{mc}} = T_b - c/D_c \tag{9}$$

where  $T_{\text{mc}}$  is the melting temperature of the spherical nanoparticle of radius  $D_c$ ,  $T_b$  is the bulk melting temperature, and  $c$  is a constant. From our results, the melting temperature of nanobridges is expressed approximately as follows:

$$T_{\text{mn}} = T_b - n/D_n \tag{10}$$

where  $T_{\text{mn}}$  is the melting temperature of the nanobridge with linear density  $D_n$ , and  $n$  is a constant. The upper graph of Fig. 5A shows the  $T_{\text{mn}}$  with the line fitted by Eq. (10) originating at the  $T_b$  obtained from the SMA-TB potential (1490 K).<sup>[22]</sup>

Because the breaking temperature of nanobridge can be dependent on the diameter of nanobridges, linear density of nanobridges, crystallographical orientation, shapes in different directions, etc., our simulation results in this paper are not enough to provide some physical properties of the breaking of nanobridges because of thermal energies. However, in our simulation results, if we assume that the  $B_{\text{point}}$  of nanobridges depends on the diameters of nanobridges, the form of Eq. (9) could express those. Therefore the bottom graph of Fig. 5A shows the  $B_{\text{point}}$  with the solid

**Fig. 5** (A) The  $M_{\text{point}}$  and  $B_{\text{point}}$  of nanobridges with curves fitted by Eq. (10). (B) The  $M_{\text{point}}$  and  $B_{\text{point}}$  of nanobridges as a function of the linear density of nanobridges.

Fig. 6 Structures of A2 nanobridge for temperature.

line fitted by Eq. (10) originating at the  $T_b$  obtained from the SMA-TB potential. For ultrathin nanobridges, because it has been well known that the CMS-type structures are more stable than the other structures, the  $M_{\text{point}}$  and  $B_{\text{point}}$  of the CMS-type nanobridges are higher than those of the other nanobridges. However, for larger nanowires, because the nanobridges with fcc structure are more stable than the CMS-type nanobridges, the dashed line of Fig. 5A, the line fitted for the CMS-type nanobridges, originates near 900 K. Fig. 5B shows  $M_{\text{point}}$  and  $B_{\text{point}}$  as a function of the linear densities of nanobridges. The  $M_{\text{point}}$  and  $B_{\text{point}}$  of nanobridges are linearly proportional with the linear density of nanobridges.

Figure 6 shows the structures of the A2 nanobridge for various temperatures. As the temperature increases, the diameter of the neck of the nanobridge and the tension in the nanobridge decrease because atoms in the nanobridge migrate to the supporting layers. When the temperature reaches the  $B_{\text{point}}$ , the nanobridge is broken and, at the same time, atoms are swiftly accumulated on the supporting layers because of tension just before breaking. Therefore the breaking point  $B_{\text{point}}$  can also be defined by the variation of atomistic mobility as a function of temperature. The corresponding diffusion coefficient is evaluated for each temperature as:

$$(1/6t) \left\langle \left\langle \sum_{i=1}^N |r_i(t) - r_i(0)|^2 \right\rangle \right\rangle \quad (11)$$

where  $r_i(0)$  and  $r_i(t)$  are the vector positions of the  $i$ th atom at time=0 and  $t$ , respectively.

Figure 7 shows the atomistic diffusivity of nanobridges in Arrhenius form. The maximum points of the diffusivity of A1 and C1 are their  $B_{\text{point}}$ . Figure 7B compares the diffusivities of nanobridges and nanowires with that of bulk, which are the experimental values for liquid Cu, the melting point more or less.<sup>[37]</sup> At low temperature, the diffusivities of atoms in nanobridges and nanowires are higher than those of atoms in bulk. The reason is that in a one-dimensional

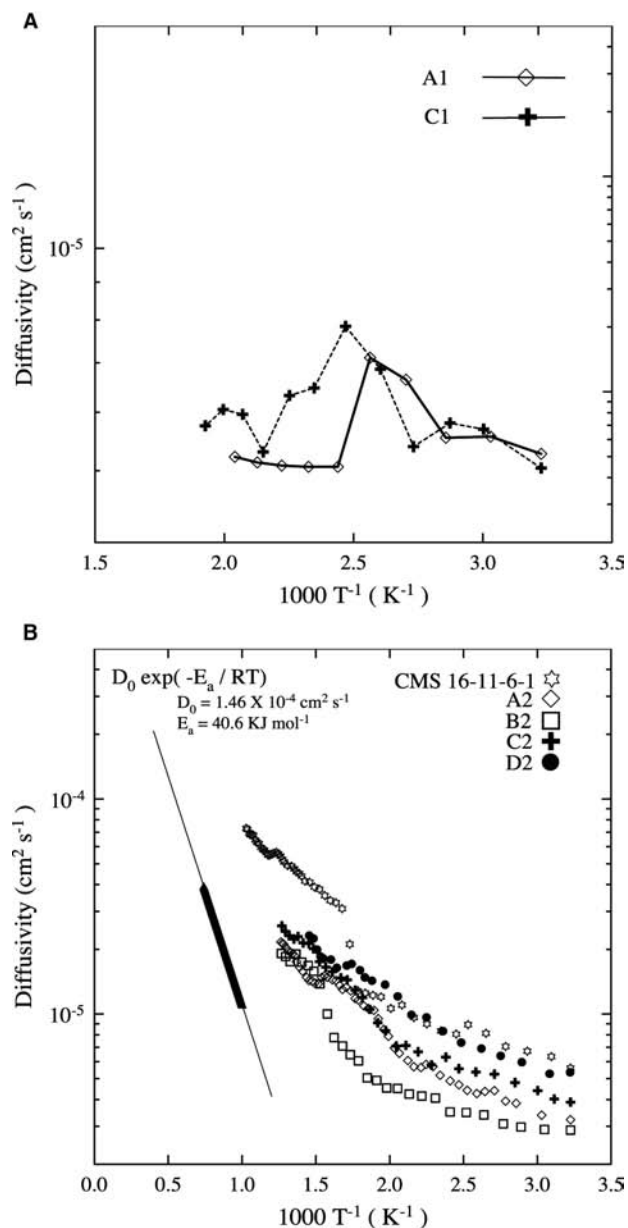

Fig. 7 Diffusivity of nanobridges. (A) A1 and C1. (B) A2, B2, C2, D2, and the CMS 16-11-6-1 nanowires. The diffusivities of nanobridges and nanowires are compared with that of the bulk for melting temperature more or less.

system, the surface area is the main region contrary to the bulk system. The variations of diffusivity before the breaking of nanobridges and nanowires are in good agreement with those of clusters<sup>[36]</sup> and nanowires.<sup>[23]</sup> Although the diffusivities of the CMS 16-11-6-1 nanowire slowly increase until the  $M_{\text{point}}$ , the diffusivities at the  $M_{\text{point}}$  show pronounced upward curvature. The diffusivities after the  $M_{\text{point}}$  show a more rapid increase than those before the  $M_{\text{point}}$  as the temperature is raised. This is because atoms in the CMS 16-11-6-1 nanowire, due to the surface melting at the  $M_{\text{point}}$ ,

rapidly migrate along the wire axis. However, the upward curvatures in the diffusivity curves of nanobridges at their  $M_{\text{point}}$  are less obvious than those of the CMS 16-11-6-1. As investigated in the caloric curves of nanobridges, atoms on the surfaces of nanobridges are gradually accumulated on the supporting layers, as shown in Fig. 5. Therefore, after their  $M_{\text{point}}$ , atoms in nanobridges begin to migrate to the supporting layers. This migration is a major factor in diffusivity ascension. Although the atoms of the CMS 16-11-6-1 nanowire applied to the PBC freely move in both directions along the wire axis, the atoms of the nanobridges lay thick on the supporting layers. The diffusivities of the nanobridges after their  $M_{\text{point}}$  are in good agreement with the experimental values of the diffusivity of liquid Cu, which is indicated by the thick line in Fig. 7B.

When the temperature reaches the  $B_{\text{point}}$  of the nanobridges, the nanobridge is broken and, at the same time, atoms are swiftly piled up on the supporting layers because of the tension just before breaking. Therefore the diffusivities of nanobridges just after their  $B_{\text{point}}$  decrease. However, as the temperatures of the nanobridge system increase above the  $B_{\text{point}}$ , diffusivities again increase. In the case of the CMS 16-11-6-1 nanowires, the nanocluster is formed from the nanowire just after the  $B_{\text{point}}$ , and then the diffusivities of the system also decrease. As the temperatures of the CMS 16-11-6-1 nanowire increase above the  $B_{\text{point}}$ , the diffusivities again increase. Previous studies on nanoclusters<sup>[36]</sup> and semi-infinite nanowires<sup>[22,23,35]</sup> have shown the physical phenomena related to only the melting point  $M_{\text{point}}$  of nanoclusters and nanowires. However, in this entry, we have shown various physical phenomena of ultrathin nanobridges, such as melting, breaking, variance of the diffusion constant, and the role of the supporting layers of ultrathin nanobridges.

## CONCLUSION

Nanobridges have attracted much interest for several reasons. One of the main reasons is that the nanobridge is the fundamental element used to fabricate nanometer-scale electronic devices. Another is the issue of their mechanical, optical, electrical, and thermal properties. This study has disclosed some interesting features of nanobridges using classical MD simulations. We have shown the resonance of nanobridges at room temperature and the physical phenomena of nanobridges because of the thermal energy. When nanobridges have a well-defined structure, the resonance frequency is defined and the resonance phenomenon is in common with classical oscillation systems. The caloric curves and diffusivities of nanobridges

have shown information on the melting and breaking points of nanobridges. The supporting layers of nanobridges have played important roles in the dynamics and thermal properties of nanobridges. Although our study has disclosed some interesting features of nanobridges, because this study was confined within eight systems of nanobridges, further study should be done and will give a more complete understanding of nanobridges.

# Nanoceramics

Abbas Khaleel

Department of Chemistry, United Arab Emirates University, Al-Ain, United Arab Emirates

## INTRODUCTION

Ceramics is one of the fields where nanoscience and nanotechnology have shown remarkable progress, producing a variety of advanced materials with unique properties and performance. Nanoceramics is a term used to refer to ceramic materials fabricated from ultrafine particles, i.e., less than 100 nm in diameter. In this field, a great deal of research has been accomplished in the last 20 years and has resulted in significant outcomes that are of great impact academically as well as industrially.

## OVERVIEW

Advanced ceramics include inorganic and non-metallic solid materials composed of polycrystalline sintered bodies, fine powders, single crystals, non-crystalline materials, thin or thick films, and fibers with various morphologies. Systems of metal oxides, carbides, borides and nitrides compose most of the important ceramic materials. Traditional ceramics, or old ceramics, such as tile pottery, are made from minerals such as clay; however, industrial ceramics, or advanced ceramics, are made of highly pure well-chosen materials such as silicon carbide and alumina. Many people think that ceramic materials are used for artistic objects and tableware only. In fact ceramic products are now very important in a wide range of industrial and advanced technical applications in several fields including electronics, medicine, nuclear industry, magnetic applications, and several others.

It has been well proven that the bulk behavior of materials can be dramatically altered when constituted of nanoscale building blocks. Mechanical, magnetic, optical, and other properties of materials have been found to be favorably affected. Hardness and strength, as an example, can be greatly enhanced by consolidating ceramic materials from nanoscale particles. Ductility and superplastic-forming capabilities of nanophase ceramics have now become possible, leading to new processing routes that will be more cost-effective than traditional methods.

In this entry, our focus will be on advanced ceramics fabricated from nanometer-sized powders.

Preparation, properties, and applications will be the main directions of focus and a special attention will be given to the effect of the particle size in these materials.

## PREPARATION

Remarkable progress in synthetic chemistry has led to significant advances in material science, making possible the synthesis of various substances and materials. The manufacture of ceramics involves heat treatment of tightly squeezed powders. The size of the building block of these powders has been found to affect the properties of the final product. The method of preparation is very often a determining factor in shaping the material and its properties. For example, burning Mg in O<sub>2</sub> (MgO smoke) yields 40–80-nm cubes and hexagonal plates, whereas thermal decomposition of commercial Mg(OH)<sub>2</sub>, MgCO<sub>3</sub>, and especially Mg(NO<sub>3</sub>)<sub>2</sub> yields irregular shapes often exhibiting hexagonal platelets. Surface areas can range from 10 m<sup>2</sup>/g (MgO smoke) to 150 m<sup>2</sup>/g for Mg(OH)<sub>2</sub> thermal decomposition. On the other hand, aerogel-prepared Mg(OH)<sub>2</sub> can lead to MgO with surface areas as high as 500 m<sup>2</sup>/g.

Because the main focus of this article is ceramics fabricated from nanometer-sized building blocks, different methods for preparing ultrafine ceramic powders will be discussed. The steps in manufacturing ceramics from powders, which include molding, extrusion, and densification, will not be discussed here.

## Physical Methods

### Vapor condensation methods

Gas-condensation techniques to produce nanoparticles directly from a supersaturated vapor of metals are among the earliest methods for producing nanoparticles. They generally involve two steps: First, a metallic nanophase powder is condensed under inert convection gas after a supersaturated vapor of the metal is obtained inside a chamber. Second, the powder is oxidized by allowing oxygen into the chamber (to produce metal oxide powder). A subsequent annealing process at high temperatures is often required to complete the oxidation. The system consists of a vapor source inside a

vacuum chamber containing a mixture of an inert gas, usually argon or helium, mixed with another gas, which is selected based on the material to be prepared. Oxygen is mixed with the inert gas to produce metal oxides.  $\text{NH}_3$  is usually used to prepare metal nitrides and an appropriate alkane or alkene, as a source of carbon, is usually used to prepare metal carbides. Nanoparticles are formed when supersaturation is achieved above the vapor source. A collection surface, usually cooled by liquid nitrogen, is placed above the source. The particles are transported to the surface by a convection current or by a combination of a forced gas flow and a convection current, which is set up by the difference in the temperature between the source and the cold surface. Some improved systems involve a way to scrap the nanoparticles from the cold collection surface so that the particles would fall into a die and a unit where they can be consolidated into pellets. Supersaturated vapor can be achieved by many different vaporization methods. The most common techniques include thermal evaporation, sputtering, and laser methods. A variety of nanoscale metal oxides and metal carbides have been prepared using laser-vaporization techniques.

The advantages of vapor condensation methods include versatility, ease in performance and analysis, and high-purity products. On the other hand, they can be employed to produce films and coatings. Furthermore, laser-vaporization techniques allow for the production of high-density, directional, and high-speed vapor of any metal within an extremely short time. Despite the success of these methods, they have the disadvantage that the production cost is still high because of low yields. Heating techniques have other disadvantages that include the possibility of reactions between the metal vapors and the heating source materials.

### Spray pyrolysis

This technique is known by several other names including solution aerosol thermolysis, evaporative decomposition of solutions, plasma vaporization of solutions, and aerosol decomposition. The starting materials in this process are chemical precursors, usually appropriate salts, in solution, sol, or suspension. The process involves the generation of aerosol droplets by nebulizing or “atomization” of the starting solution, sol, or suspension. The generated droplets undergo evaporation and solute condensation within the droplet, drying, thermolysis of the precipitate particle at higher temperature to form a microporous particle, and, finally, sintering to form a dense particle.

Different techniques for atomization are employed including pressure, two-fluid, electrostatic, and ultrasonic atomizers. These atomizers differ in droplet size (2–15  $\mu\text{m}$ ), rate of atomization, and droplet velocity (1–20 m/sec). These factors affect the heating rate and

residence time of the droplet during spray pyrolysis which, in turn, affect some of the particle characteristics including particle size. For a specific atomizer, particle characteristics, including particle size distribution, homogeneity, and phase composition depend on the type of precursor, solution concentration, pH, viscosity, and the surface tension.

Aqueous solutions are usually used because of their low cost, safety, and the availability of a wide range of water-soluble salts. Metal chloride and nitrate salts are commonly used as precursors because of their high solubility. Precursors that have low solubility or those that may induce impurities, such as acetates that lead to carbon in the products, are not preferred.

The advantages of this method include the production of high-purity nanosized particles, homogeneity of the particles as a result of the homogeneity of the original solution, and the fact that each droplet/particle goes through the same reaction conditions. The disadvantages of spray pyrolysis include the need for large amounts of solvents and the difficulty to scale-up the production. The use of large amounts of non-aqueous solvents increases the production expenses because of the high cost of pure solvents and the need for proper disposal.

### Thermochemical/flame decomposition of metalorganic precursors

Flame processes have been widely used to synthesize nanometer-sized particles of ceramic materials. This is another type of gas-condensation technique with the starting material being a liquid chemical precursor. The process is referred to as chemical vapor condensation (CVC). In this process, chemical precursors are vaporized and then oxidized in a combustion process using a fuel-oxidant mixture such as propane-oxygen or methane-air. It combines the rapid thermal decomposition of a precursor-carrier gas stream in a reduced pressure environment with thermophoretically driven deposition of the rapidly condensed product particles on a cold substrate. The flame usually provides a high temperature (1200–3000 K), which promotes rapid gas-phase chemical reactions.

A variety of chemical precursors can be used including metal chlorides, such as  $\text{TiCl}_4$  to prepare  $\text{TiO}_2$  and  $\text{SiCl}_4$  to prepare  $\text{SiO}_2$ , metal-alkyl precursors, metal alkoxides, and gaseous metal hydrides, such as silane as a source of silicon to prepare silica. Chlorides have been the most widely used precursors in the industry and the process is sometimes referred to as the “chloride process.” The high vapor pressure of chlorides and the fact that they can be safely stored and handled make them excellent potential precursors. The disadvantages of using chloride precursors are the formation of acidic gases and contamination of the products with halide residues. Flame processes

are used industrially to produce commercial quantities of ceramic particulates, such as silica and titania. This is because of the low cost of production as compared to all other methods. The disadvantage of flame synthesis is that the control of particle size (both primary particle and aggregates size), morphology, and phase composition is difficult and limited.

## Chemical Methods

### Sol–gel technique

The sol–gel process is typically used to prepare nanometer-sized particles of metal oxides. This process is based on the hydrolysis of metal reactive precursors, usually alkoxides in an alcoholic solution, resulting in the corresponding hydroxide. Condensation of the hydroxide by giving off water leads to the formation of a network-like structure. When all hydroxide species are linked, gelation is achieved and a dense porous gel is obtained. The gel is a polymer of a three-dimensional skeleton surrounding interconnected pores. Removal of the solvents and appropriate drying of the gel result in an ultrafine powder of the metal hydroxide. Further heat treatment of the hydroxide leads to the corresponding powder of the metal oxide. As the process starts with a nanosized unit and undergoes reactions on the nanometer scale, it results in nanometer-sized powders. For alkoxides that have low rates of hydrolysis, acid or base catalysts can be used to enhance the process.

When drying is achieved by evaporation under normal conditions, the gel network shrinks as a result of capillary pressure that occurs and the hydroxide product obtained is referred to as xerogel. However, if supercritical drying is applied using a high-pressure autoclave reactor at temperatures higher than the critical temperatures of solvents, less shrinkage of the gel network occurs as there is no capillary pressure and no liquid–vapor interface, which better protects the porous structure. The hydroxide product obtained is referred to as an aerogel. Aerogel powders usually demonstrate higher porosities and larger specific surface areas than analogous xerogel powders.

Sol–gel processes have several advantages over other techniques to synthesize nanopowders of metal oxide ceramics. These include the production of ultrafine porous powders and the homogeneity of the product as a result of homogeneous mixing of the starting materials on the molecular level.

### Reverse microemulsions/micelles method

The reverse micelle approach is one of the recent promising routes to nanocrystalline materials including ceramics. Surfactants dissolved in organic solvents

form spheroidal aggregates called reverse (or inverse) micelles. In the presence of water, the polar head groups of the surfactant molecules organize themselves around small water pools ( $\sim 100 \text{ \AA}$ ), leading to dispersion of the aqueous phase in the continuous oil phase.

Reverse micelles are used to prepare nanoparticles by using a water solution of reactive precursors that can be converted to insoluble nanoparticles. Nanoparticle synthesis inside the micelles can be achieved by different methods including hydrolysis of reactive precursors, such as alkoxides, and precipitation reactions of metal salts. Solvent removal and subsequent calcination lead to the final product. Several parameters, such as the concentration of the reactive precursor in the micelle and the weight percentage of the aqueous phase in the microemulsion, affect the properties, including particle size, particle-size distribution, agglomerate size, and the phases of the final ceramic powders. There are several advantages to using this method including the ability to prepare very small particles and the ability to control the particle size. Disadvantages include low production yields and the need to use large amounts of liquids.

### Precipitation from solutions

Precipitation is one of the conventional methods to prepare nanoparticles of metal oxide ceramics. This process involves dissolving a salt precursor, usually chloride, oxychloride or nitrate, such as  $\text{AlCl}_3$  to make  $\text{Al}_2\text{O}_3$ ,  $\text{Y}(\text{NO}_3)_3$  to make  $\text{Y}_2\text{O}_3$ , and  $\text{ZrCl}_4$  to make  $\text{ZrO}_2$ , in water. The corresponding metal hydroxides are usually obtained as precipitates in water by adding a base solution such as sodium hydroxide or ammonium hydroxide solution. The remaining counter-ions are then washed away and the hydroxide is calcined after filtration and washing to obtain the final oxide powder. This method is useful in preparing ceramic composites of different oxides by coprecipitation of the corresponding hydroxides in the same solution. Solution chemistry is also used to prepare non-oxide ceramics or pre-ceramic precursors that can be converted to ceramics upon pyrolysis.

One of the disadvantages of this method is the difficulty in controlling the particle size and size distribution. Very often, fast and uncontrolled precipitation takes place resulting in large particles.

### Chemical synthesis of pre-ceramic polymers coupled with physical processing techniques

This method is based on the use of molecular precursors, which facilitates the synthesis of nanomaterials containing phases of desired compositions. It involves a chemical reaction to prepare an appropriate polymer, which is then converted into ceramic material upon

**Fig. 1** General structural formulas of polycarbosilanes and polysilazanes.

pyrolysis. Using chemical reactions to prepare the pre-ceramic polymer not only allows for control of phase compositions but also overcomes the limitation of low production yields of the physical methods. This method has been very useful in preparing non-oxide ceramics such as silicon carbide and silicon nitride. The conversion of an organometallic precursor into a ceramic depends on different parameters such as the molecular structure of the precursor and the pyrolysis conditions (temperature, duration, and atmosphere). Metal carbides and metal nitrides have been obtained by pyrolysis of polymers containing the appropriate elements such as Si or Al and C or N. These polymers are called pre-ceramic polymers and are prepared from simpler chemical precursors. A considerable amount of free carbon from the thermolysis process is very often a problem. Silicon carbide (SiC) and silicon nitride (Si<sub>3</sub>N<sub>4</sub>) are the most studied ceramic materials prepared via this route. They are usually synthesized by the pyrolysis of polycarbosilanes and polysilazanes, for which general structural formulas are shown in Fig. 1, at temperatures between 1000°C and 1200°C.

### Mechanochemical synthesis

Mechanochemical synthesis involves mechanical activation of solid-state displacement reactions. This process has been successfully used recently to make nanoceramic powders such as Al<sub>2</sub>O<sub>3</sub> and ZrO<sub>2</sub>. It involves the milling of precursor powders (usually a salt and a metal oxide) to form a nanoscale composite of the starting materials, which react during milling, and subsequent heating, if necessary, to form a mixture of dispersed nanoparticles of the desired oxide within a soluble salt matrix. Nanoparticles of Al<sub>2</sub>O<sub>3</sub> (10–20 nm), for example, can be prepared by milling AlCl<sub>3</sub> with CaO.

## BONDING CONSIDERATIONS

Understanding chemical bonding and structures in ceramic materials is necessary in order to understand their chemical and physical behavior. When materials are composed of nanometer-sized building blocks, they deviate considerably from structural perfection and stoichiometry. As a result, the number of defects due to edges, corners, f-centers, and other surface imperfections is greatly enhanced, which, in turn, affects several physical and chemical properties as will be discussed below.

A range of cohesive forces contribute to the nature of bonding in ceramic materials including ionic (MgO, Fe<sub>1-x</sub>O), covalent, metallic, van der Waals, and hydrogen bonding. Ionic compounds are formed when highly electronegative and highly electropositive elements are combined in a lattice. Pure ionic model is a reasonable approximation for some systems while it is a poor approximation for crystals containing large anions and small cations. In such systems, covalent contribution to bonding becomes significant. van der Waals interactions play a crucial role in many ceramic systems, especially those with layered structures. In many oxide hydrates or hydroxy oxides, hydrogen bonding also contributes to the cohesive energy. For further reading on structure and bonding, the reader is referred to structural inorganic chemistry books.

## SELECTED PROPERTIES

Ceramics possess their own chemical, physical, mechanical, and magnetic properties that are different from those of other materials such as metals and plastics. The properties of ceramics depend mainly on the type and the amounts of materials in their composition. However, the size of the building blocks of a ceramic material has been found to play an important role in its properties (see Ref.<sup>[1]</sup> and references therein).

When materials are prepared from nanometer-sized particles, a significant portion of the atoms become exposed on the surface. As a result, such materials exhibit unique properties that are remarkably different from those of the corresponding bulk. The physical and chemical properties of nanoparticles show the gradual transition from atomic or molecular to condensed matter systems.

### Chemical Properties

Ceramic materials are relatively inert, especially crystalline materials that tend to have perfect structures with minimum amount of defects. Most of the reactivity of these materials involves the surfaces where coordinatively unsaturated as well as defect sites exist.

The behavior of the surface toward other species and the nature of interaction depend on the composition and the morphology, which determine the nature and the degree of surface interactions with other substances. Most of the time, interactions are limited to adsorption on the surface, which does not affect the bulk making these materials good corrosion-resistant.

The possibility of preparing ceramic powders in high surface areas with high porosity makes them well desired in some advanced applications. One example is the use of ceramic materials as supports for heterogeneous catalysts. Another example is the use of such materials in biomedical applications, where the surface of nanophase ceramics exhibits a remarkably improved biomedical compatibility compared to conventional ceramics, as discussed below.

### Mechanical Properties

Ceramics are very strong materials showing considerable resistance against compression and bending. Some ceramic materials are similar to steel in strength. Most ceramics retain their strength at high temperatures. Silicon carbides and silicon nitrides, as an example, retain their strength at temperatures as high as 1400°C. As a result, such materials are used in high-temperature applications. Many of the physical and mechanical properties are particle-size dependent. As a result, several systems of nanophase ceramics have exhibited quite interesting and favorably enhanced mechanical properties.

#### Improved sintering and hardness properties

Nanoceramics are processed from nanophase powders by compacting first powders composed of individual ceramic particles (usually less than 50 nm in size) into a raw shape (often called a green body). This compacted powder is then heated at elevated temperatures. Densification occurs as a result of diffusion of vacancies out of pores (to grain boundaries), which lead to shrinkage of the sample. This process is referred to as pressure-less sintering. Fortunately, nanophase powders were found to compact as easily as their analogous submicron particles. To avoid particle size growth, samples have to be sintered at the lowest temperature possible for a time sufficient to remove the residual porosity and establish coherent grain boundaries. Successful sintering enhances the hardness of the final material.

Experimental evidence shows that nanophase powders densify at faster rates as compared to commercial (submicron) particles.<sup>[1]</sup> Faster densification rates allow achieving a given density at smaller grain sizes, before serious growth takes place. As a result of their

small particle and pore sizes, nanocrystalline powders sinter to much greater densities than their conventional analogs at the same temperature. This also establishes that nanocrystalline powders, as compared to conventional powders, reach the same density at much lower temperatures. This, of course, eliminates the need for very high temperatures.

One disadvantage that can accompany fast densification though is inhomogeneous heating where the outside layers of the particles densify into a hard impervious shell which constrains the inside of the sample from normal shrinking, leading to some cracking as a result of strain incompatibility. This problem can be avoided by several ways. The most efficient way is to heat the samples slowly to reduce the shrinkage in the outer shell while heat is transported to the inner regions. On the other hand, high-density nanostructured ceramic systems including  $Y_2O_3$ ,  $TiO_2$ , and  $ZrO_2$  have been achieved by means of pressure-assisted sintering. Applying some pressure during sintering can increase the densification rate and suppress the particle growth.

Nanoscale powders of non-oxide ceramics such as metal carbides and nitrides show similar behavior. Conventional SiC, as an example, is difficult to sinter. Addition of some additives such as boron or carbon is very often necessary to densify SiC. Ultrafine powder of SiC sinters at lower temperatures and densifies without additives. On the other hand, mechanical properties can be fairly improved by the introduction of metallic nanoparticles dispersed within the matrix grains. Such systems are referred to as nanocomposites. Tungsten, nickel, or molybdenum nanoparticles dispersed within  $Al_2O_3$  matrix grains, as an example, can enhance the mechanical properties of alumina, including the fracture strength and hardness.

#### Reduced brittleness and enhanced ductility and superplasticity

Superplasticity and ductility refer to the capability of some polycrystalline materials to undergo extensive tensile deformation without necking or fracture. Ceramic brittleness is the biggest technical barrier in practical applications, especially in load-bearing applications. Theoretical and experimental results provide evidence for the possibility that traditional brittle materials can be ductilized by reducing their grain sizes.<sup>[1]</sup> When made from nanoparticles, brittle ceramics can be superplastically deformed at modest temperatures and then heat treated at higher temperatures for high-temperature strengthening.

The capability to synthesize superplastic ceramic materials is now established. Nanocrystalline ceramics deform at faster rates, lower stresses, and lower temperatures. One important use of superplasticity in

ceramics is diffusion bonding, where two ceramic parts are pressed together at moderate temperatures and pressures to form a seamless bond through diffusion and grain growth across the interface. Diffusion bonds form more easily in nanocrystalline ceramics than in larger grained ceramics as a result of both the enhanced plastic flow of nanocrystalline ceramics and the larger number of grain boundaries they provide for diffusional flux across the interface.

### Electrical Properties

Ceramics include electrical conducting, insulating, and semiconducting materials. Chromium oxide is an electrical conductor, aluminum oxide is an insulator, while silicon carbide behaves as a semiconductor. As a result, ceramic materials have been used in a variety of electronic applications based on their electrical behavior.

Several electrical properties are particle-size and composition dependent. Electrical resistance and dielectric constant, as an example, for some systems increased as a result of small particle size. Conductivity of some mixed oxide ceramics, such as lithium aluminosilicate, is higher than that of their constituent oxides.

### Magnetic Properties

Some ceramic materials possess magnetic properties. These include iron oxide-based ceramics and oxides of chromium, nickel, manganese, and barium. Ceramic magnets are known to exhibit high resistance to demagnetization. As a result, several ceramic powders have been employed in a wide range of electronic and magnetic applications as discussed below.

The fabrication of such materials from ultrafine particles can significantly enhance their magnetic behavior. The fact that in nanometer-sized particles a large portion of the atoms are on the surface, where the coordination numbers are less than that for bulk atoms, affects several parameters including unique surface/interface behavior and different band structure, which both lead to magnetism enhancement. It is now well established that one of the requirements to achieve appropriate coercivity and high magnetization saturation is to fabricate such materials in highly divided particles, preferably in the nanometer-sized range, with homogeneity and narrow size distribution. For further reading on nanoscale magnetism, the reader is referred to Sorensen's chapter "Magnetism" in Ref.<sup>[1]</sup>.

Many other properties are also particle-size dependent. The optical properties, as an example, of some ceramic materials have been found to depend on particle sizes. Nanoparticles of  $\text{TiO}_2$ , as an example, are more efficient UV absorber than powders of large particles.

## APPLICATIONS

Ceramic materials are of great value in a variety of applications as a result of their unique properties compared to other materials. Because of their electrical and magnetic properties, ceramics are important in several electronic applications, where they are used as insulators, semiconductors, conductors, and magnets. Ceramic materials also have important uses in the aerospace, biomedical, construction, and nuclear industries. In many of these applications, ceramic materials have shown significantly better performance when fabricated from nanometer-sized particles.

### Mechanical Applications

Industrial ceramics are widely employed in applications that require strong, hard, and abrasion-resistant materials. Metal-cutting tools, tipped with alumina, and tools made from silicon nitrides for cutting, shaping, grinding, and sanding iron, nickel-based alloys, and other metals are very commonly used. Other ceramics such as silicon nitrides and carbides are used to make components for high-temperature use such as valves and turbocharger rotors. Ceramic materials and metal-based ceramics (cermets) are used to make components for space vehicles, including heat-shield tiles for the space shuttle and nosecones for rocket payloads.

### Electrical Applications

Ceramics are used as insulators, semiconductors, and conductors. Aluminum oxide ( $\text{Al}_2\text{O}_3$ ), for example, does not conduct electricity at all and is used to make insulators. Other ceramics, such as barium titanate ( $\text{BaTiO}_3$ ), are used as semiconductors in electronic devices. Some copper oxide-based ceramics are superconductive at temperatures higher than those at which metals become superconductive. Superconductivity refers to the ability of a cooled material to conduct an electric current with no resistance. This phenomenon can occur only at extremely low temperatures, which are difficult to maintain. Transition metal nitrides, carbides, and borides are of interest as cathodes in electrochemical applications. This interest stems from the favorable properties of these materials including electronic conductivity and good thermal conductivity, which when coupled with their mechanical strength and high melting points suggest that such materials can be stable in a range of environments.

Some ceramics such as strontium titanate ( $\text{SrTiO}_3$ ) are employed in the form of thin films as capacitors in several electronic devices because of their capability to store large amounts of electricity in extremely small

**Table 1** Examples of electronic ceramics

Functions	Examples of materials	Applications
Insulation	Al <sub>2</sub> O <sub>3</sub> , SiC + BeO	IC substrate
Dielectricity	BaTiO <sub>3</sub>	Capacitor
Semiconducting	SiC, LaCrO <sub>3</sub> , SnO <sub>2</sub> , ZnO + Bi <sub>2</sub> O <sub>3</sub>	Gas defector, thermistor, varistor
Piezoelectricity	ZnO, SiO <sub>2</sub>	Piezolighter, piezofilter, surfacewave transducer, piezovibrator, flexible piezodetector
Pyroelectricity	PZT	IR detectors
Ferroelectricity	PLZT	Optical shutter, optical memory
Ionic conduction	$\beta$ -Al <sub>2</sub> O <sub>3</sub> , ZrO <sub>2</sub>	Na-S battery, O <sub>2</sub> sensor
Luminescence	Y <sub>2</sub> O <sub>3</sub> :S:Eu, ThO <sub>2</sub> :Nd, Al <sub>2</sub> O <sub>3</sub> :Cr	Cathode luminescence, IR laser
Light guide	SiO <sub>2</sub>	Optical communication fiber
Polarization	PLZT	Optical shutter
Soft magnetism	$\gamma$ -Fe <sub>2</sub> O <sub>3</sub> , Zn <sub>1-x</sub> Mn <sub>x</sub> Fe <sub>2</sub> O <sub>4</sub>	Magnetic tape
Hard magnetism	SrO·6Fe <sub>2</sub> O <sub>3</sub>	Magnet seal

PZT: lead zirconate–titanate ceramics. PLZT: lanthanum-modified lead zirconate–titanate ceramics.

volumes. Lithium aluminosilicate ceramics have potential applications as solid electrolytes for utilization in solid high-energy density lithium battery systems. Piezoelectric ceramics are now key electronic components for television, FM radio, and the like. Very recently, piezoelectric ceramic displays have been developed in Japan, where microceramic actuators for activating the pixels are used. Piezoelectric effect refers to the appearance of an electric potential across certain faces of a crystal when it is subjected to mechanical pressure.

Other examples of functions and applications of advanced ceramics in the field of electronics are shown in Table 1.<sup>[2]</sup>

### Magnetic Applications

Iron oxide-based ceramics (ferrites) are widely employed as low-cost magnets in electric motors. Such magnets help in converting electric energy into mechanical energy. Unlike metal magnets, ferrites conduct high-frequency currents, and as a result, they do not lose as much power as metal conductors do. Manganese zinc ferrites are used in magnetic recording heads, and ferric oxides are the active component in several magnetic recording media, such as recording tapes and computer diskettes.

### Biomedical Applications and Bioceramics

Some advanced materials are used in the biomedical field to make implants for use within the body. The main requirement of biomaterials for this application

is the ability of their surfaces to support new bone growth. Ceramic materials are known to possess exceptional biocompatibility properties with bone cells and tissues. Specially made porous ceramic materials such as alumina, titania, zirconia, and others bind with bone and other natural tissues. Such ceramics are used to make hip joints, dental caps, and bridges. Other advanced ceramics such as hydroxyapatite, Ca<sub>10</sub>(PO<sub>4</sub>)<sub>6</sub>(OH)<sub>2</sub>, which is the principal component of bones and teeth, have excellent biocompatibility and bone in-growth capabilities and are used in reconstructing fractured bones and as replacement materials.

Recent research on long-term functions of osteoblasts on nanophase ceramics has shown evidence for unique and significant behavior.<sup>[3]</sup> Compared to conventional ceramics, nanophase ceramics has shown enhanced osteoblast adhesion and proliferation, alkaline phosphatase synthesis, and concentration of extracellular matrix calcium.

### Coatings

Because of its unique hardness and corrosion resistance, ceramic enamel is often used in coating metals. Thin hard wear-resistant coatings of ceramics include materials such as titanium nitride and titanium carbonitride. An emerging class of new hard protecting coatings beyond homogeneous layers of a ceramic nitride material is layered coating structures such as superlattices or multilayers of different nitrides. Such multilayer coating has been successfully applied in several applications such as bearings, pumps, and

compressors. Non-nitride coatings, such tungsten carbide/carbon, are also of interest because of their high elasticity and chemical inertness.

Several techniques are being employed for protective ceramic coating. These include thermal spraying, chemical vapor deposition (known as CVD), and plasma spraying.

### Nuclear Industry

Lithium-based ceramics are now considered as potential solid tritium breeders in nuclear fusion reactors. Potential breeder materials include  $\text{LiAlO}_2$ ,  $\text{Li}_2\text{O}$ ,  $\text{Li}_2\text{ZrO}_3$ , and  $\text{Li}_4\text{SiO}_4$ . Solid breeders are safer during operation than liquid lithium systems, which are highly reactive.

### CONCLUSION

Nanoceramics is one of the great outcomes of the evolutionary research in the field of nanoscience and nanotechnology, where fabrication of materials from nanometer-sized building blocks has resulted in a wide range of industrially useful materials. Recent research has proven that ceramic materials fabricated from ultrafine powders can be obtained through several physical as well as chemical methods that can be scaled up to produce commercial amounts. These unique materials have exhibited very remarkable behavior as compared with their bulk counterparts. Significant characteristics include chemical, mechanical, magnetic, electrical, and optical properties. As a result, improved performance of ceramic materials has been observed in a variety of applications including chemical, mechanical, magnetic, electrical, and biomedical. The new properties and improved performance of nanoceramics that are being discovered stimulate the development and improvement of ceramic processing, which, in turn, open the doors wide for the use of ceramics in a wide range of new technologies.

Directions of current interests include the preparation and processing of ultrafine (nanometer-sized) powders, the development of new synthetic routes to materials of homogeneous sintered bodies, and the preparation of ceramics made of several composites.

# Nanoceramics: Thermal Conductivity

Paul G. Klemens

Department of Physics, University of Connecticut, Storrs, Connecticut, U.S.A.

## INTRODUCTION

The heat carriers in ceramic insulators are lattice waves. The thermal conductivity is governed by their attenuation length or mean free path. Scattering of these waves by grain boundaries can reduce the mean free path and thus decrease the thermal conductivity. The lattice waves, which carry heat range over a wide frequency spectrum, and only waves of the lower part of that spectrum are scattered by grain boundaries. This will be discussed with emphasis on thermal barrier coatings, where nanoscale grains and point defects, acting on different parts of the spectrum, each cause an independent thermal conductivity reduction. In coatings protecting against wear one can use nanoscale inclusions to enhance mechanical properties without reducing the thermal conductivity. Finally, there are applications where the thermal conductivity of ceramics is to be enhanced by appropriate high-conductivity inclusions, such as carbon nanotubes.

## LATTICE THERMAL CONDUCTIVITY

The thermal vibrations of solids can be described by a superposition of plane progressive displacement waves, which transport heat energy.<sup>[1,2]</sup> The frequency of these waves extends over a wide spectrum. Each wave of frequency  $f$  has energy  $E$  and energy flow  $Ev$ , where  $v$  is its group velocity. In the limit of low frequencies, and wavelengths large compared to interatomic distances, these waves are identical to elastic waves in the corresponding continuum. For higher frequencies or shorter waves, the dependence of  $f$  on direction and wavelength is modified.

In a solid of perfectly periodic structure and with perfectly harmonic interatomic forces, these waves would be normal modes of vibration; that is, the energy content of each wave would remain constant with time. In real solids there are structural lattice imperfections, which also include external and internal boundaries. In addition, all solids are somewhat anharmonic: the interatomic forces as function of relative displacements between atoms are not strictly a linear function of these displacements but contain

higher-order terms. The corresponding potential energy of displacement contains not only quadratic or harmonic terms, but higher-order or anharmonic terms. All these departures from perfection cause slow energy transfer among the waves. The multiplicity of these possible interactions in macroscopic solids tends to establish thermal equilibrium. In thermal equilibrium each wave in a group of frequency  $f$  has an average energy  $E(f)$ , a function of frequency but the same for all directions, and there is no net energy transport: for every wave  $f$  and  $v$  there is a wave  $f$  and  $-v$ . It is sufficient to know that interactions occur so that thermal equilibrium can be attained. For non-equilibrium properties such as the thermal conductivity one must also know at what rate equilibrium is restored, once equilibrium is disturbed. This requires knowledge of the interaction processes.

Whereas  $E(f)$  depends on both  $f$  and absolute temperature  $T$ , the equipartition value  $E = k_B T$  independent of frequency  $f$  is attained if  $T/f$  is sufficiently high. Here  $k_B$  is the Boltzmann constant. This limit applies for all waves that transport heat at ordinary and high temperatures, and will be used in the present discussion.

Each wave makes a contribution  $k_B$  to the specific heat. The number of waves in a given frequency interval varies as  $f^2 df$ . Therefore, the major contribution to the specific heat, of the waves with high group velocity and thus carry heat, come from the highest frequencies  $f_m$  of those waves, the acoustic branch.<sup>[3]</sup> This part of the specific heat, for a solid of unit volume and containing  $N$  molecular units, is

$$C = \int C(f) df = \int_0^{f_m} 9Nk_B \frac{f^2}{f_m^3} df = 3Nk_B \quad (1)$$

A temperature gradient slightly enhances the energy of waves propagating toward the colder side, and vice versa. The thermal conductivity is composed of contributions from each frequency interval. If  $l(f)$  is the attenuation length of waves of frequency  $f$ , the thermal conductivity  $\kappa$  has the form

$$\kappa = \frac{1}{3} \int C(f) v l(f) df = \frac{3Nk_B}{f_m^3} \int_0^{f_m} v f^2 l(f) df \quad (2)$$

The attenuation length plays here the same role as a mean free path in the corresponding expression in the kinetic theory of gases. It is important that in general  $l(f)$  increases with decreasing frequency, so that low frequencies play a larger role in the lattice thermal conductivity than they do in the specific heat or thermal energy of vibrations. This will enhance the effect of grain boundary scattering on the thermal conductivity.

## INTERACTION PROCESSES

In all real solids there is an interchange of energy among the waves because of the anharmonic terms (cubic or higher in the potential energy as function of strain), in addition to the harmonic terms, quadratic in strain and defining the elastic moduli. The corresponding intrinsic attenuation length is  $l_i(f, T)$ . Waves can also be attenuated by scattering from the various structural imperfections. These include extended obstacles, such as external and internal boundaries, and defects of atomic dimensions (point defects such as solute atoms, vacancies, interstitials, and small aggregates thereof). Platelets, tubes, and dislocations may also be significant. Each obstacle or defect, labeled  $\alpha$ , has its characteristic magnitude and frequency dependence, and some are listed in Table 1. All these processes contribute to the overall attenuation per unit path length for waves of a given frequency  $f$ :

$$\frac{1}{l(f)} = \frac{1}{l_i(f, T)} + \sum_{\alpha} \frac{1}{l_{\alpha}(f)} \quad (3)$$

The intrinsic thermal conductivity  $\kappa_i$  can be obtained from Eq. (2) by substituting  $l_i = (Bf^2T)^{-1}$  for  $l(f)$ . The integrand is independent of  $f$ , so that equal frequency intervals make equal contributions to the intrinsic conductivity. The coefficient  $B$  can be calculated from theory in terms of density, elastic moduli, and anharmonicity parameters.<sup>[1,2]</sup> Alternatively, it can be derived from measured conductivities, since

$$\kappa_i(T) = \frac{3Nk_B v}{Bf_m^2 T} \quad (4)$$

**Table 1** Inverse attenuation lengths

Processes	$1/l(f)$	$f$ dependence
Cubic anharmonic	$1/l_i(f, T)$	$Bf^2T$
Point defects	$1/l_p(f)$	$Af^4$
Line defects	$1/l_{\text{cyl}}(f)$	$Af^3$
Thin sheets, thickness $t$	$1/l_{\text{sh}}(f)$	$t^2 f^2$
Boundaries	$1/l_B$	$1/L$

## THERMAL CONDUCTIVITY REDUCTIONS

Of the imperfections that lower the thermal conductivity, two are important and are discussed here: point defects and large obstacles, including internal boundaries. The first reduces  $l(f)$  mainly at high frequencies, the second mainly at low frequencies. These reductions are practically independent of each other, so that

$$\kappa = \kappa_i(T) - \delta\kappa_p - \delta\kappa_B \quad (5)$$

Here  $\delta\kappa_p$  is the reduction in thermal conductivity due to point defects, and  $\delta\kappa_B$  is that due to internal boundaries and large obstacles. For grain boundary scattering it is provisionally assumed that it is frequency independent, although this assumption will have to be modified later. It is convenient to define a frequency  $f_o$  such that  $l_p(f_o) = l_i(T, f_o)$ , making  $f_o \propto T^{1/2}$ , and define a frequency  $f_B$  such that  $L = l_i(T, f_B)$ , hence  $f_B \propto (LT)^{-1/2}$ . Substituting each scattering mechanism in turn into  $l(f)$  of Eq. (3), and this into Eq. (2), one finds for the usual case when  $f_B \ll f_o$

$$\kappa - \delta\kappa_p = \kappa_i(f_o/f_m) \arctan(f_m/f_o) \quad (6a)$$

$$\begin{aligned} \delta\kappa_B &= \kappa_i(f_B/f_m) \arctan(f_m/f_B) \\ &\approx \frac{\pi}{2} \kappa_i(f_B/f_m) \end{aligned} \quad (6b)$$

The reductions due to these two scattering processes are additive. This differs from the frequently used approximation of adding their corresponding thermal resistances to give the total thermal resistance  $1/\kappa$ . Using Eq. (5) yields a larger reduction in conductivity than one obtains from adding resistances.

From this theory, two conclusions emerge: 1) The fractional reduction  $\delta\kappa_i/\delta\kappa_B$  is significant, even when the average intrinsic mean free path  $\langle l_i \rangle$  is very small compared to  $L$ . One would have expected, at first sight, a fractional reduction of the order  $\langle l_i \rangle/L$  or  $(f_B/f_m)^2$ , but the reduction from Eq. (6b) is of the order  $f_B/f_m$ . Because  $f_B < f_m$ , this reduction is much larger. 2) The fractional decrease due to small grain size  $\delta\kappa_B/\kappa$  is enhanced if  $\kappa$  is already significantly reduced by point defects. This was first seen in measurements on polycrystalline silicon of micron-sized grains.<sup>[4]</sup>

In the case of stabilized zirconia there is a large concentration of oxygen vacancies, which are responsible for the low thermal conductivity. It was suggested that a further reduction could be obtained if the grain size could be reduced below the micrometer into the nanometer regime. This assumes, of course, that the grain boundaries scatter the relevant phonons of frequencies  $f < f_B$  strongly, so that their mean free path is indeed limited by the grain size  $L$ . Using Eqs. (5) and 6(b), the thermal conductivities were calculated;<sup>[5]</sup> similar

calculations were made for other materials. The crucial assumption was of course that in calculating  $f_B$  in terms of  $L$ , the magnitude of  $L$  was given by the grain size, even for nanometer-sized grains. Unfortunately, this turned out not to be the case for nanometer-grained zirconia stabilized by 7 wt.% of yttria, a widely used composition for thermal barrier coatings<sup>[6]</sup> (Figs. 1 and 2). Therefore, it is necessary to look more closely at the scattering of lattice waves by grain boundaries.

## SCATTERING BY GRAIN BOUNDARIES

Because scattering by grain boundaries affects mainly the lattice waves at low frequencies, measurements of thermal conductivity at low temperatures provides much relevant information, because at low temperatures only the low frequencies contribute to the specific heat and the thermal conductivity. The important frequencies are then  $f < nk_B T/\hbar$ , where  $\hbar$  is the Planck constant and  $n$  ranges between 3 and 4. At very low temperatures, typically below 20 K, the thermal conductivity of single crystals is limited by the scattering of lattice waves at external boundaries. The corresponding mean free path  $L$  is comparable to the shortest linear dimension of the crystal.<sup>[7]</sup> Because the specific heat  $C$  is then proportional to  $T^3$ , the thermal conductivity  $\kappa = CvL/3$  also varies as  $T^3$ . If the crystal contains some imperfections, in some cases even a mixture of isotopes, this variation can be reduced somewhat; however, an average mean free path of

**Fig. 1** Theoretical reductions in the thermal conductivity of  $ZrO_2$  containing 7 wt.%  $Y_2O_3$  due to point defects and grain boundary scattering for various grain sizes. *Source:* From Klemens, P.G., Gell, M. *Mater. Sci. Eng., A* 245, 143 (1998).

**Fig. 2** Thermal conductivity as a function of temperature in nanocrystalline tetragonal zirconia (5.8 wt.% yttria). Densities (% of theoretical) and grain diameters (in nanometers) are also indicated. *Source:* From Ref.<sup>[6]</sup>.

the order of the shortest linear dimension is frequently clearly observed.

This conductivity is substantially reduced when there are grain boundaries, as observed, e.g., by Berman,<sup>[8]</sup> who first compared a single crystal of  $Al_2O_3$  (sapphire) with polycrystalline alumina at low temperatures. The thermal conductivity varied more slowly than  $T^3$ , suggesting that the mean free path increased with decreasing phonon frequency. This, and similar results, need to be reconciled with calculations of phonon scattering by grain boundaries. The back reflection coefficient of a boundary between two materials is of the order  $(v_1 - v_2)^2/v^2$ , where  $v_1$  and  $v_2$  are the wave velocities on either side, and  $v$  is their average. For tilt boundaries this factor is generally no more than about 0.03, except for some very anisotropic materials. Thus the difference in orientation is not the major source of grain boundary scattering.<sup>[9,10]</sup>

This suggests that grain boundary scattering is due to a thin region between the grains of thickness  $t$  (believed to be around 2 nm), where the material is less compact than inside the grains, and where the local wave velocity is decreased by an amount  $\Delta v$ . This phonon-scattering problem, originally done for nitrogen platelets in diamond,<sup>[11]</sup> leads to a reflection probability for an infinite sheet of thickness  $t$  well below the wavelength  $\lambda$ ,

$$R \approx \frac{2}{3} (2\pi)^2 \left(\frac{t}{\lambda}\right)^2 \left(\frac{\Delta v}{v}\right)^2 \quad (7)$$

For short wavelengths  $\lambda < 2\pi t$  or frequencies greater than  $2\pi v/t$ ,  $R$  reaches a saturation value

$$R \approx \frac{2}{3}(\Delta v/v)^2 \quad (8)$$

These equations give an order-of-magnitude agreement with grain boundary scattering at both low and ordinary temperatures.<sup>[10]</sup> They are based on the assumption that a grain boundary acts as a set of thin plates, each plate having a diameter that is large compared to the wavelength of the lattice wave to be scattered, i.e., waves of frequencies around  $f_B$ . This holds approximately for grains that have a diameter  $D$  above 100 nm, but not smaller. For smaller grains, even if the intergrain regions remained 2 nm thick, they could no longer be regarded as thin plates of diameter large compared to the thickness. The theory of Ref.<sup>[11]</sup> also deals with plates of small  $D$ : the scattering is reduced in such cases. In the extreme case the plates become small obstacles or pores. This accounts for the observation in Ref.<sup>[6]</sup> that for very small grains the conductivity depends not on grain size but on overall porosity.

## WAVE SCATTERING BY OBSTACLES

Obstacles can be pores or inclusions of foreign material, but in contrast to thin plates, their linear dimensions are similar in all directions. For very long waves, scattering varies as the square of the volume, and does not depend on shape. The obstacles are thus approximated by spheres of diameter  $D'$ . If  $D'$  is small compared to the important wavelength  $\lambda$ , scattering is in the Rayleigh regime, and the scattering cross section area,  $\Sigma$ , is proportional to  $f^4$  or to

$$\Sigma \propto (\Delta v/v)^2 (D')^6 / \lambda^4 \quad (9)$$

Here  $\Delta v$  is the difference between the wave velocities in the matrix and in the material of the obstacle,  $v$  is that of the matrix. The extreme case of an obstacle of atomic size is the point defect, treated earlier. In the opposite case, when  $\lambda < D$ , it is the geometric cross section

$$\Sigma \approx \pi(D')^2/4 \quad (10)$$

Scattering in the intermediate region, Mie scattering, depends on the details of the obstacle, as it does in the corresponding case of light scattering. Because the lattice thermal conductivity involves an integration over a wide-frequency spectrum, it is not too bad an approximation to disregard this complication and to take scattering to vary as  $f^4$  at low frequencies, and be independent of frequency and given by the

geometric cross section at high frequencies, with a sharp transition at  $f_c$ , the frequency where both expressions are equal. Thus, one uses Eq. (10) for  $f > f_c$ , whereas for  $f < f_c$  one uses

$$\Sigma \approx \pi/4(D')^2(f/f_c)^4 \quad (11)$$

where

$$f_c \approx \frac{v}{D'} \left( \frac{\Delta v}{v} \right)^{-1/2} \quad (12)$$

for pores  $\Delta v = -v$ , so that  $f_c \approx v/D$ . For solid obstacles,  $\Delta v$  is smaller and  $f_c$  is larger.

It is the volume fraction  $\phi$  of the obstacles or pores that is usually known. Still assuming them to be spheres of diameter  $D'$ , the phonon mean free path for  $f > f_c$  becomes

$$L = \frac{2}{3} \frac{D'}{\phi} \quad (13)$$

This follows from expressing  $L$  and  $\phi$  in terms of the number of obstacles per unit volume, then eliminating that number. The obstacles reduce the thermal conductivity provided  $f_B > f_c$ . Since  $f_B \propto (LT)^{-1/2} \propto (D'T/\phi)^{-1/2}$  while  $f_c \propto (D'/\phi)^{-1/2}$ , obstacles will reduce the thermal conductivity the more, the lower the temperature and the higher their fractional volume.

## RADIATIVE COMPONENT

At very high temperatures, infrared radiation makes an additional contribution to thermal conduction. This component depends on layer thickness and can be reduced by pores, by internal absorption and by scattering. The effective thermal conductivity between two parallel slabs, acting as black bodies, separated by a distance  $L$  (in meter) and filled with a non-absorbing medium of refractive index  $n$ , is given by the Stefan–Boltzmann constant and the average temperature  $T$  (in Kelvin) as

$$\lambda_{\text{rad}} = 2.27 \times 10^{-7} n^2 L T^3 \text{ W m}^{-1} \text{ K}^{-1} \quad (14)$$

For dense yttria-stabilized zirconia,  $n = 2.7$ . At 1300 K and for a thickness  $L = 1$  mm, this yields a conductivity of about  $3 \text{ W m}^{-1} \text{ K}^{-1}$ . In flash-diffusivity measurements, this value is substantially reduced by a coating on the front that absorbs the heat of the radiative flash, and that has a reduced but unknown emissivity into the ceramic, so that the radiative component may be only about  $1 \text{ W m}^{-1} \text{ K}^{-1}$ .<sup>[12]</sup> Scattering of infrared radiation by submicron pores

is small, but all pores, irrespective of size, reduce the average value of  $n^2$  and thus the radiative component. The fractional reduction is comparable to the corresponding reduction in the lattice thermal conductivity.<sup>[13]</sup> In thermal barrier coatings, where  $L$  is substantially less than in the specimens used in flash-diffusivity measurements, the radiative component of the conductivity is correspondingly reduced.

## REDUCTIONS BY INCLUSIONS AND THIN LAYERS

Whereas nanometer-scale grains do not meet the original expectations of reducing the thermal conductivity of ceramics because grain boundaries do not scatter lattice waves when grains are small, this does not apply to small obstacles composed of a foreign material. Of course, these obstacles should not just reside at the boundaries between larger grains, although this would result in some reductions, but should be distributed uniformly throughout the ceramic. This implies that the ceramic must have been composed of very fine grains at some stage, when preexisting obstacles were incorporated, or that the obstacles were formed by some precipitation process, perhaps at some centers formed by irradiation. If the desired distribution of very small obstacles could be achieved, the reductions are given in terms of Eqs. (12) and (13), with the factor  $(\Delta v/v)$  appropriately reduced.

Greater reductions can be obtained if the foreign material is deposited as very thin sheets, preferably oriented across the direction of heat flow, interleaved with thin sheets of the ceramic. Sheets present a larger scattering cross section than spheres for the same volume. It was found that an array of alternating thin layers of tungsten and alumina, each 1 to 2 nm thick, have a thermal conductivity in the normal direction as low as  $0.4 \text{ W m}^{-1} \text{ K}^{-1}$  at room temperature, if the temperature at which the layers were deposited was low enough.<sup>[14]</sup>

For thermoelectric power conversion and refrigeration, one needs a low thermal conductivity combined with sufficient electrical conductivity and large thermoelectric power. Because these properties are interdependent, the coefficient of performance of these materials, intermediate between semiconductors and semimetals, requires not only careful control of the carrier concentration, but also a reduction of the parasitic lattice thermal conductivity, to be less than the electronic component of the thermal conductivity. It was pointed out earlier here that the lattice thermal conductivity is made up of contributions from a wide spectrum of lattice waves. It is necessary to reduce the mean free path of phonons over the entire spectrum. The reduction of the mean free path of waves

at high frequencies is achieved by solute atoms of the same valence (e.g., Ge in Si). The waves of low frequency interact with the carriers: their mean free path is also short. There remains a wide range of intermediate frequencies with a mean free path as large as in a perfect crystal. Their mean free path could be reduced when scattered by electrically inert obstacles of nanometer dimension.<sup>[15]</sup> Early attempts to realize this improvement were only marginally successful.<sup>[16]</sup> At that time the obstacles that were inserted into the material were not small enough and their diameter was not well controlled. The optimum diameter would be around 1–2 nm. Obstacles of larger size would reduce the electrical conductivity and the thermopower and be counterproductive.<sup>[17]</sup> Modern techniques may allow better control of obstacle size and may give better results.

## INCREASING THE THERMAL CONDUCTIVITY

It has been suggested to increase the thermal conductivity of an electrically insulating matrix by dielectric inclusions of high thermal conductivity. In packaging applications the matrix material is small, so that the inclusions should be even smaller, of submicron size. Unfortunately the thermal conductivity of these inclusions is then reduced well below the bulk value. Thus, the overall thermal conductivity is not enhanced, even if the inclusions occupy a significant volume fraction. This difficulty can be overcome by using small inclusions having a phonon gas of low dimensionality, such as graphite, graphene, or carbon nanotubes.

In three dimensions, the spectral specific heat varies as  $C(f) \propto f^2$  and the intrinsic mean free path  $l_i \propto f^{-2}$ , so that in Eq. (2) equal frequency intervals make equal contributions to the intrinsic thermal conductivity  $\kappa_i$ . However, for a two-dimensional phonon gas  $C(f) \propto f$ , but  $l_i$  still has the same dependence on  $f$  and on temperature  $T$ .<sup>[18]</sup> Thus

$$\kappa_i \propto \frac{1}{2} \int C(f) v \frac{B}{T f^2} df \propto \int_{f_{\min}}^{f_D} \frac{df}{T f} \quad (15)$$

Here  $f_{\min}$  is the lowest frequency for which the phonon gas is two-dimensional, either because there are lattice waves in a third direction or because the waves of lower frequency are scattered by another interaction, e.g., by boundaries. In graphite the phonon spectrum becomes three-dimensional below  $4 \times 10^{12}$  Hz, while  $f_D \approx 46 \times 10^{12}$  Hz. Thus,  $\ln(f_D/f_{\min}) = 2.44$  and the intrinsic thermal conductivity is

$$\kappa_i = \frac{5.71 \times 10^5}{T} \times 2.44 \text{ W m}^{-1} \text{ K}^{-1} \quad (16)$$

This agrees with measurements on pyrolytic graphite and single crystals.<sup>[18]</sup> Small graphite flakes of limited size in the  $a$  plane would have a lower  $f_{\min}$  and their conductivity would be reduced, as would graphite containing a large point defect concentration that reduces the effective value of  $f_D$ .

A graphene sheet, consisting of a single atomic layer of graphite or a small number of such layers, has a phonon gas that is two-dimensional down to zero frequencies. Here the logarithmic low-frequency divergence is removed by the condition that at very low frequencies the mean free path is limited by the shortest linear dimension  $L$  in the plane of the sheet, and  $f_{\min}$  is the frequency at which  $l_i = L$ . If  $L$  is given in meters, and for a free-standing graphene sheet

$$f_{\min} = \left[ \frac{8.5 \times 10^{21}}{LT} \right]^{1/2} \text{ Hz and}$$

$$\lambda(\text{graphene}) = \frac{1.17}{T} \ln((f_D^2 + f_{\min}^2)/f_{\min}^2)$$

For  $L = 1 \mu\text{m}$  and  $T = 300 \text{ K}$ ,  $f_{\min} = 5.3 \times 10^{12} \text{ Hz}$ , and  $\lambda(\text{graphene}) = 1.7 \times 10^3 \text{ W m}^{-1} \text{ K}^{-1}$ . However, for a graphene sheet or thin stack lying on a substrate, phonon energy can leak into the substrate, reducing the thermal conductivity.<sup>[19]</sup>

Similar considerations apply to carbon nanotubes, where a long graphene sheet but only  $N$  atomic units wide is rolled into a cylinder. The longitudinal modes are continuous, but the circumferential modes have discrete frequencies, multiples of  $f_D/N$ . Unless  $N$  is very small, this discreteness does not significantly change the value of  $l_i$ . Thus, the thermal conductivity of a free-standing nanotube is very similar to that of a free graphene sheet.<sup>[19]</sup> Again,  $f_{\min}$  is given by the length of the tube and is increased if the nanotubes are enclosed in a matrix, allowing wave energy to slowly leak into the matrix. Note that we have discussed the

conductivity of a single tube; the conductance is proportional to the cross-sectional area of the tube. A significant enhancement of the overall conductivity requires a large filling factor of the tubes in the matrix.

## INTRODUCTION

The unique and new optical, electrical, and magnetic properties of colloidal superstructures as opposed to the bulk characteristics of the constituent materials is attracting the attention of an increasing number of both fundamental scientists and technology-oriented industry. The colloid size used in the assembled structures varies over approximately 3 orders of magnitude and is closely related to the specific application. For photonic band gap materials, the particle size is of the same order of magnitude as the wavelength of light, while for magnetic applications, such as ultrahigh density storage devices, the particle radius is in the low-nanometer range. A combination of the aforementioned physical properties of colloidal matter introduces even more exciting fields of research. Electron transport through monolayers of magnetic nanocrystals or tunable photonic band gap materials, both controlled by applying a magnetic field, are only two examples of the many possibilities.

Nanotechnology is characterized by a continuous decrease of feature sizes, e.g., in electronic devices. Top-down fabrication methods, such as the well-established photolithography techniques, are being pushed toward their physical limits. Increasingly more research effort is presently being devoted to bottom-up fabrication methods. Instead of reducing the size of much larger, bulk materials, as is done with photolithography in combination with etching techniques, the focus is turning toward building up superstructures of much smaller building blocks. Self-assembly of single molecules or nanocolloidal particles into larger arrangements, employing intrinsic, extrinsic, or even externally induced

interactions, seems to be a most promising method, which is not hampered by problems related to scaling the processes to production scale. Much of the research activities in the field are focused on gold nanoparticles, as these systems are stable in a large number of environmental conditions and are relatively easy to prepare and control. In the first part of this contribution, we will summarize the different self-assembly methods with which nanocolloidal gold particles are composed into monolayers or multilayered superstructures.

In the second part of this contribution, we show how non-imaging, single wavelength reflectometry measurements can be applied to in situ study the formation of nanocolloidal gold monolayers at derivatized silicon surfaces. The kinetics of particles with dimensions in the low-nanometer range are investigated using a radial impinging jet setup, also referred to as a stagnation point flow geometry. We compare our results to similar adsorption experiments using micrometer-sized silica particles. For these large particles, the random sequential adsorption (RSA) model adequately describes the overall deposition kinetics. However, for considerably smaller particles in the 10–100 nm range, this relatively simple model fails. Here we show that a generalized adsorption model is in perfect agreement with deposition transients of particles in the low-nanometer range over the entire coverage range.

## SELF-ASSEMBLY METHODS TO GROW NANOCOLLOIDAL GOLD FILMS

Many different ways have been employed to assemble colloidal particles into disordered structures or highly

ordered superlattices. Most of these methods have also been applied to nanometer-sized gold particles, but because their size is orders of magnitude smaller than, for example, the particles used in photonic band gap applications, the results are often different.

One of the most frequently used methods, and without doubt the most often described<sup>[1–20]</sup> assembly technique, involves the chemical modification of the substrate onto which the nanocolloidal gold particles are adsorbed. Amino ( $\text{NH}_2$ )- and thiol ( $\text{SH}_2$ )-terminated surfaces lead to a high affinity for irreversible deposition of gold entities from solution. Additionally, the adsorption is self-limiting, as only submonolayer coverage can be achieved. Amino- or thiol-functionalized surface can be produced either by attaching aminosilane or thiolsilane molecules to oxidic surfaces, such as silicon and aluminum oxide, or by adsorbing bifunctional amino–thiol or dithiol molecules onto gold substrates. In the latter case, short-chain molecules are used because long-chain molecules with a sufficient degree of freedom will attach to the gold surface with both ends. In most cases, immersion of the substrate into a solution of the functionalizing substance is adequate, but also evaporation/sublimation of the amino or thiol compounds is employed.

The interaction between the functional groups on the surface and the gold nanocrystals in solution is generally considered to be electrostatic, which enables relatively simple tuning of the surface potential by varying the pH of the solution. Once the gold particles are adsorbed on the substrate, the strong bonding, which is of a covalent character, prevents desorption. Also, the lateral mobility is negligible and the deposition is governed by a random sequential adsorption (RSA) process. For this reason, ordering does not take place and the spatial arrangement of the nanocrystals is random. The maximum surface coverage corresponding to an RSA event is approximately 55%.

To increase the coverage, e.g., to grown conducting gold layers, several routes can be taken. One of these involves the specific enlargement of the adsorbed gold nanoparticles by electroless deposition of gold or any other desired method. This seeded growth has been described in several publications.<sup>[9,10]</sup> In Fig. 1, we show scanning electron microscopy images of a monolayer of gold nanoparticles before and after seeded growth for 5 min in a  $\text{AuCl}_4^-/\text{NH}_2\text{OH}$  aqueous solution. It is clear that the particles are enlarged to form a nearly percolating network. Additional growth leads to closed, conductive layers of gold.

Closely related to the aforementioned chemical functionalization of the substrates to enhance the specific affinity for gold nanoparticles is the use of DNA.<sup>[21,22]</sup> A major advantage of using DNA is that

**Fig. 1** Scanning electron microscopy images of colloidal gold particles irreversibly adsorbed at silicon/silicon oxide substrates, derivatized with APTES. The image size amounts to  $1200 \text{ nm} \times 800 \text{ nm}$ . Prior to seeded growth (A), the average spacing between the isolated nanocrystals is tunable via the ionic strength. Seeded growth for 5 min in a  $\text{AuCl}_4^-/\text{NH}_2\text{OH}$  aqueous solution (B) gives rise to homogeneous particle enlargement.

a specific network can be generated using specific DNA molecules. Thiol-terminated DNA molecules can be built into the structure; the location and the density can be determined by the ratio of various DNA types in solution.

As mentioned above, specific functionalization of the surface onto which the gold entities are adsorbed limits the coverage to submonolayer values. To overcome this restriction, the layer-by-layer (LBL) technique can be employed.<sup>[3,5,6,9,11–13,17,18,23–25]</sup> For example, adsorbed gold nanoparticles can be covered with a layer of cross-linker molecules, such as amino–thiols or dithiols. One end of these molecules attaches to the gold nanocrystal surface, while the other end generates new functionalized adsorption sites for additional colloidal particles. Not only the aforementioned chemical interaction can be used in LBL deposition, but also electrostatic interactions are employed to form multilayers of gold nanoparticles.

In this case, the cross-linker entities are polyelectrolyte molecules, or oppositely charged nanoparticles. In principle, the number of deposition cycles, and therewith the thickness of the superstructure, is not restricted. However, the roughness of the structure substantially increases, which limits the application in many cases.

The aforementioned derivatization, either chemical or electrostatic, of the substrate enables patterning of the substrate and thus also of the superstructure of nanocolloidal gold particles.<sup>[12,19,26,27]</sup> Examples of ways to locally functionalize substrates include microcontact printing and scanning probe microscopy (SPM)-based methods. In the former case, a polydimethylsiloxane (PDMS) stamp is generally used to apply the amino-thiol molecules or polyelectrolytes to predefined areas on the substrate surface. After rinsing, the gold nanocolloidal particles adsorb only onto the derivatized patterned regions. With SPM, the approach is somewhat different. A surface is completely functionalized with, for example, amino endgroups. Subsequently, specific regions on the surface are defunctionalized by oxidizing or removing the molecules, therewith destroying the local affinity of the surface for gold adsorption. Although it allows complicated patterns to be made, the latter method is intrinsically slow as all structures have to be “written” onto the surface.

A completely different method used to form dense monolayers of gold nanoparticles is by electrophoretic deposition.<sup>[27–30]</sup> An external electric field is applied to drive the particles toward the surface. Although very impressive results have been obtained for micrometer-sized colloidal systems, the work on nanocolloidal gold particles is limited to a few reports of experimental results. In principle, highly ordered monolayers, and possible also multilayers, can be formed as the lateral mobility of the gold nanocrystals is not hindered.

Finally, hydrodynamic interactions can also be employed to form superstructures of gold nanoparticles.<sup>[4,16,31–33]</sup> The simplest approach is to simply dry the colloidal suspension on a substrate. This already generates a short-range order in the deposited layers. Control over the spatial extent of the ordering can be achieved by lowering the evaporation rate of the solvent, therewith giving the particles the opportunity to find a suitable spot in the superstructure while it is forming. The volume fraction also plays an important role. Modifications of this method, specifically for gold nanoparticles, have been described. The nanocrystals are first adsorbed onto amino- or thiol-derivatized surface, after which they are “liberated” by a ligand-exchange reaction. This is considered to increase the lateral mobility of the particles on the surface, which then allows them to “dry” in an ordered monolayer.

## KINETICS OF IRREVERSIBLE GOLD NANOCRYSTAL DEPOSITION

A prerequisite for studying any system in general, but nanocolloidal systems in particular, is the ability to unambiguously characterize them under relevant conditions. Among the large number of methods available for characterizing colloids and their superstructures, electron microscopy [scanning electron microscopy (SEM)/transmission electron microscopy (TEM)] is by far the most popular. Both for very small as well as relatively large particles, this encompasses the most employed *ex situ* technique. Among colloid scientists, the use of scanning probe microscopy [atomic force microscopy (AFM), scanning tunneling microscopy (STM), magnetic force microscopy (MFM)] is increasing, but also in this case experiments are typically performed *ex situ*. In fact, the only techniques that have been used *in situ* to study colloidal systems are optical methods. Imaging techniques such as conventional or confocal microscopy are used for large colloids. For particles with dimensions well below the diffraction limit of (visible) light, such as with gold nanoparticles, only non-imaging (lateral averaging) *in situ* experiments are available. These include primarily UV/*vis* absorption spectroscopy, but also optical waveguide lightmode spectroscopy, and reflection techniques as reflectometry and ellipsometry.

### Single Wavelength Reflectometry Results

We employed single wavelength reflectometry to characterize the adsorption of nanocolloidal gold particles onto substrates derivatized with aminopropyltriethoxysilane (APTES).<sup>[20]</sup> Gold colloids are prepared by standard citrate reduction of  $\text{HAuCl}_4$  in aqueous solution at  $100^\circ\text{C}$ , which yields colloidal particles with an average radius of  $a = 6.7\text{ nm}$ .<sup>[1,5]</sup> In all our reflectometry measurements, the as-prepared nanocolloidal gold suspension is diluted by a factor of 4, which leads to a particle concentration of approximately  $c_0 = 1.85 \times 10^{18}\text{ m}^{-3}$  and an ionic strength of  $3.6\text{ mM}$ .

The homebuilt reflectometer setup consists of a He-Ne laser, the stagnation point flow cell, a beamsplitter, and two photodiodes for detecting the intensities  $I_p$  and  $I_s$  of the parallel and perpendicular components of the reflected light. A more extensive description of our specific setup is given by Dijt et al.<sup>[34]</sup> The intensity ratio  $S = I_p/I_s = (I_{0p}/I_{0s})(R_p/R_s)$  is measured, where  $I_{0p}$  and  $I_{0s}$  are the initial intensities and  $R_p$  and  $R_s$  are the intensity reflection coefficients. The angle of the incident beam can be adjusted and is set to  $71^\circ$  with respect to the normal of the sample surface. The volume flow during the experiments was approximately  $1.0\text{ mL min}^{-1}$ .

**Fig. 2** Three-dimensional representation of the ionic-strength-dependent adsorption kinetics of gold nanocolloidal particles in stagnation point flow geometry. The coverage is obtained by polarized reflectometry. The data on the back panel indicate the evolution of the saturation coverage with increasing ionic strength for a number of reflectometry experiments; the solid line is a guide to the eye.

For the reflectometry experiments, we used substrates cut from *p*-type silicon (100) wafers with a deposited oxide layer of 45 nm. When the oxide layer is too thin,  $R_p$  is very small and the initial sensitivity of the setup is low. With too thick oxide layers, the reflectometer signal flattens and even decreases above a certain surface concentration. The reflectometer signal has been calculated as a function of the gold nanocrystal coverage using the thin island film theory,<sup>[35,36]</sup> the relation between signal and coverage is used as a calibration to obtain an absolute surface coverage from the optical response.

In Fig. 2, we show typical reflectometry transients, obtained during colloidal gold deposition in the aforementioned stagnation point flow cell at various ionic strengths. For  $t < 0$ , only water flows through the cell, and a constant baseline is measured. At  $t = 0$ , the gold suspension is injected into the cell. When the flow is switched back to water at  $t = 38$  min, no significant decrease of the surface coverage is observed, indicating the absence of particle detachment. Two distinct regimes are observed in the measured curves in Fig. 2, which will be discussed in the next section.

### Two Limiting Regimes in the Deposition Transients

At longer deposition times, the deposition process leads to saturation at coverage values, which show a

clear dependence on the ionic strength.<sup>[15]</sup> This will be discussed at the end of this section. For short times, the deposition rate is similar for all ionic strengths, which implies that the deposition process is initially limited by the supply of colloidal particles to the surface. The hydrodynamics of colloid deposition in a stagnation point flow cell have been extensively described.<sup>[37,38]</sup> The initial particle flux toward the surface is in good approximation given by

$$j_0 = 0.776c_0 \left( \frac{D^2 \alpha V_m}{R^2} \right)^{\frac{1}{3}} = k_c c_0 \quad (1)$$

where  $c_0$  is the bulk particle concentration,  $D$  is the diffusion coefficient of the nanocolloidal particles,  $R = 0.64$  mm is the radius of the inlet tube and  $V_m = \nu Re/R$  is the average flow velocity, with  $Re$  the Reynolds number and  $\nu$  the kinematic viscosity of the fluid. The dimensionless flow parameter  $\alpha$  depends on the Reynolds number and the cell geometry parameter  $h/R$ . In our case, a value  $\alpha = 4.2$  is obtained from the work of Dabros and Van de Ven<sup>[37]</sup> using  $Re = 8.3$  and  $h/R = 1.7$ . The mass transfer coefficient  $k_c$  will be discussed in a later section.

Assuming pure random sequential adsorption (RSA), with a sticking probability of 1, the above considerations imply a constant deposition rate  $d\theta/dt$  from the moment the colloidal suspension is inserted. After a short transition time, this linear regime is indeed observed. The adsorption rate  $d\theta/dt = \pi a^2 j_0 = 0.0225 \text{ min}^{-1}$  in Fig. 2 is used to calculate the particle diffusion coefficient  $D$  from Eq. (1). For lower ionic strengths, the value of  $D$  is less accurate but within an experimental error of 5%, the aforementioned value  $d\theta/dt = 0.0225 \text{ min}^{-1}$  does not vary with ionic strength. Inserting the known values for particle density and cell geometry parameters, we find  $D = 6.9 \times 10^{-12} \text{ m}^2 \text{ sec}^{-1}$ . We now compare this result to the diffusion coefficient obtained using the Stokes–Einstein relation

$$D = \frac{kT}{6\pi\eta a} \quad (2)$$

where  $kT$  is the thermal energy and  $\eta$  is the dynamic viscosity of the fluid (for water,  $\eta = 1.00 \times 10^{-3} \text{ kg m}^{-1} \text{ sec}^{-1}$ ). With a particle radius  $a = 6.7$  nm, the Stokes–Einstein relation yields a diffusion coefficient  $D = 3.2 \times 10^{-11} \text{ m}^2 \text{ sec}^{-1}$ . Our experimentally determined value is about 4–5 times lower than this value. The apparent discrepancy is reasonable, considering the following arguments. One reason is that Eq. (2) represents an approximation<sup>[38]</sup> that is only valid in the infinitely small stagnation point in the center of the cell, whereas an elliptical area of

about  $1 \times 2 \text{ mm}^2$  is probed in the experiments. From SEM data, Böhmer, van der Zeeuw, Kopel<sup>[39]</sup> estimated that in the initial stage of nanocolloidal film growth, the adsorption rate is underestimated by a factor of 1.5. Numerical calculations based on the flow field in the cell<sup>[38]</sup> confirm that indeed the average flux on a probe area of  $1 \times 2 \text{ mm}^2$  is approximately  $0.7j_0$ . This implies an underestimation of the diffusion coefficient  $D$  in our experiments by approximately a factor of 2. Furthermore, the gold nanocolloids have a relatively large surface charge, which leads to an increased hydrodynamic radius, and thus a lower diffusion constant [Eq. (2)]. The particle concentration has been determined to have a small error, so we do not believe this interferes with our determination of the diffusion coefficient.

Let us now turn to the saturation regime of the deposition curves in Fig. 2. For higher ionic strengths, the maximum attainable coverage increases, in agreement with the Derjaguin-Landau-Verwey-Overbeek (DLVO) theory. This theory describes the accumulation of ions near charged interfaces, in this case the colloid-solvent interface, which results in a double layer around every particle. When the double layers of two particles overlap, the ions around the particles are confined to a smaller volume, which results in an entropic repulsion. This repulsion prevents coagulation of the particles, and also defines the distance of closest approach of two particles. When particles adsorb on a surface, this distance determines the maximum attainable coverage.<sup>[15]</sup>

More quantitatively, the double-layer interaction potential  $U_{pp}(r/a)$  in units  $kT$  is described by,<sup>[40,41]</sup>

$$\frac{U_{pp}\left(\frac{r}{a}\right)}{kT} = B_{pp} \frac{a}{r} e^{-\kappa(r-2a)} \quad (3)$$

where  $r$  is the particle-particle distance and  $\kappa$  is the Debye screening parameter, given by

$$\kappa^2 = \frac{e^2 \sum_i n_i z_i^2}{\epsilon \epsilon_0 kT} \quad (4)$$

with  $n_i$  and  $z_i$  being the number density and valence of ions  $i$ , respectively,  $e$  the elementary charge, and  $\epsilon \epsilon_0$  the dielectric permittivity of the electrolyte. The particle-particle interaction coefficient is defined as

$$B_{pp} = \left( \frac{4\pi\epsilon\epsilon_0 kT a}{e^2} \right) \left( \frac{y_p + 4\gamma\Omega\kappa a}{1 + \Omega\kappa a} \right)^2 \quad (5)$$

with  $\gamma = \tanh(y_p/4)$ ,  $\Omega = [(y_p - 4\gamma)/2\gamma^3]$ , and  $y_p = \psi_p(e/kT)$  the dimensionless surface potential. This yields an interaction potential that is valid over a large range of  $\kappa a$  provided  $r$  is larger than about

**Fig. 3** Saturation coverage  $\theta_{\text{calc}}$  calculated from the ionic strength using the DLVO theory as a function of the experimentally determined maximum coverage  $\theta_{\text{meas}}$  from the reflectometry measurements. The line has a slope of 1.

$a + (3/2)\kappa^{-1}$ . Assuming a constant surface potential, the distance  $r_{kT}$  between particles when their interaction energy drops below  $(3/2)kT$  can be numerically determined as a function of  $\kappa a$ , i.e., as a function of the ionic strength. The choice for the interaction energy is justified by the fact that particles have an average thermal energy of  $(3/2)kT$ , which competes with their electrostatic repulsion upon approaching each other.

In Fig. 3, the saturation coverage  $\theta_{\text{calc}}$ , calculated using Eqs. (3)–(5) with a particle surface potential  $y_p, kT/e = -85 \text{ mV}$ .<sup>[42,43]</sup> is plotted as a function of the surface concentration  $\theta_{\text{meas}}$  obtained from Fig. 2. The calculated coverage is obtained from the double-layer thickness defined as  $\Delta a = r/2 - a$ . Using the thus determined effective double-layer thickness  $\Delta a$ , the saturation coverage  $\theta_{\text{calc}}$  is obtained from

$$\theta_{\text{sat}} = \theta_{\text{jam}} \left( \frac{a}{a + \Delta a} \right)^2 \quad (6)$$

in which  $\theta_{\text{jam}} = 54.7\%$  represents the jamming limit for irreversible random deposition of hard spheres.<sup>[41,44,45]</sup>

The data in Fig. 3 exhibit a good one-to-one relation between experiment and the DLVO theory. However, at large values of the ionic strengths and thus high surface concentrations, the measured coverages are higher. One cause is that the linear approximation of the Poisson-Boltzmann equation underestimates the potential drop near the particles. When a far-field potential is used, as it is here, the potential at short distances is overestimated. This results in an overestimation of the distance where the particle-particle

interaction drops below  $(3/2)kT$ , and consequently leads to an underestimation of the surface concentration. The effect will become important when  $r < a + (3/2)\kappa^{-1}$ , which is approximately 10 nm for the highest ionic strengths. This value corresponds to a surface coverage of 25%, which is approximately the value at which the data in Fig. 3 start to deviate from the one-to-one relation (the solid line). Another possible explanation for the deviation at higher ionic strengths may be the formation of clusters on the sample surface. A cluster has a larger volume on a relatively small area, thereby accounting for a larger optically determined surface concentration.

### Modeling the Deposition Transients

The deposition kinetics of colloidal particles can be described in terms of the adsorption rate  $d\theta/dt$  by

$$\frac{d\theta}{dt} = \pi a^2 j_0 B(\theta) \quad (7)$$

where  $\pi a^2$  is the geometrical particle surface area and  $j_0$  represents the limiting deposition flux for uncovered surfaces. The quantity  $B(\theta) = j(\theta)/j_0$ , with  $j(\theta)$  being the actual deposition flux for a given coverage, is usually referred to as the overall kinetic blocking function. This designation is somewhat misleading as  $B(\theta) = 1$  for low coverages, while in the limit of saturating coverages  $B(\theta) \rightarrow 0$ ; so in fact  $B(\theta)$  represents an effective, coverage-dependent available surface. More correctly, it is also referred to as the “available surface function.”<sup>[46]</sup> The function  $B(\theta)$  not only depends on the coverage, but also on many additional factors such as particle–particle interactions, the mechanism of particle transport, and the reversibility of particle adsorption.

In principle, the overall kinetic blocking function can only be determined empirically from the particle deposition rate as a function of time, i.e., curves similar to those presented in Fig. 2. If we assume that all deposition transients for our system (nanocolloidal gold particles irreversibly deposited on APTES-derivatized silicon oxide surfaces) are characterized by a single, coverage-dependent overall kinetic blocking function  $B(\theta/\theta_{\text{sat}})$ , where  $\theta_{\text{sat}}$  is the saturation coverage defined in Eq. (6), the general adsorption Eq. (7) can be rewritten in terms of the dimensionless variables

$$\bar{\theta} = \theta/\theta_{\text{sat}} \quad (8a)$$

$$\bar{t} = \frac{\pi a^2 j_0}{\theta_{\text{sat}}} t \quad (8b)$$

Fig. 4 Deposition transients of Fig. 2, scaled according to Eq. (9), using the dimensionless variables  $\bar{\theta}$  and  $\bar{t}$  as given by Eqs. (8a) and (8b).

to yield

$$\frac{d\bar{\theta}}{d\bar{t}} = B(\bar{\theta}) \quad (9)$$

The result of this scaling, applied to the deposition curves in Fig. 2, is shown in Fig. 4 where we have plotted the data according to Eq. (9). Apart from the initial first minutes (not shown in Fig. 4), it is clear that all curves collapse to a single curve, verifying that indeed a single overall kinetic blocking function governs the deposition process, irrespective of the ionic strength.

### A Generalized Adsorption Model

A theory, which is more specifically applicable to our system of colloidal particles, irreversibly deposited under forced convection conditions (stagnation point flow geometry), has been extensively described by Adamczyk.<sup>[47,48]</sup> A similar model was also described by Faraudo and Bafaluy.<sup>[49]</sup> In this generalized adsorption model, the deposition is considered to consist of two processes, i.e., 1) the actual adsorption, and 2) the convective supply of nanocrystals to the surface. The convective supply of colloidal particles to the outer edge of the adsorption layer, at a distance  $\delta_a$  from the surface, is described by the rate constant  $k_c = j_0/c_0$ , where  $j_0$  is equal to the particle flux. For the well-defined flow conditions in our stagnation point flow setup,  $k_c$  is given by Eq. (1).

The adsorption process is described by

$$\frac{d\theta}{dt} = \pi a^2 k_a c(\delta_a) B'(\theta) \quad (10)$$

and is governed by a rate constant  $k_a$  and a particle concentration  $c(\delta_a)$  at distance  $\delta_a$  from the surface.<sup>[50]</sup>

The available surface function  $B'(\theta)$ , also often referred to as the generalized blocking function, describes the transport resistance of the adsorbed layer to adsorbing particles; effectively, it is equal to the overall sticking probability. In fact, Eq. (10) is similar to Eq. (7), in which the actual adsorption process is taken into account by the overall kinetic blocking function  $B(\theta)$  considering a constant supply of colloidal particles. In Eq. (10), the adsorption process is considered and the supply of colloidal particles is described by the time dependence of  $c(\delta_a)$ . Within the adsorption layer of thickness  $\delta_a$ , convection effects can be neglected. The thickness  $\delta_a$  is comparable to the range of specific interactions, in principle electrostatic interactions, the extent of which is governed by the double-layer thickness. For our nanocolloidal particles, this implies that  $\delta_a$  is of the same order of magnitude as the particle radius.

For the irreversible adsorption of particles at uniformly accessible surfaces, Adamczyk<sup>[47]</sup> derived an expression for the kinetic overall blocking function, given by

$$B(\theta) = \frac{KB'(\theta)}{1 + (K - 1)B'(\theta)} \quad (11)$$

where  $K = k_a/k_c$  represents the coupling between adsorption and convection processes. In the case of strong particle–particle interactions,  $B'(\theta)$  can be approximated by the RSA available surface function  $B_0(\theta)$ . It is not possible to analytically evaluate  $B_0(\theta)$ , but a good approximation is given by<sup>[47,51]</sup>

$$B'(\theta) = \left[ 1 + 0.812 \frac{\theta}{\theta_{\text{sat}}} + 0.426 \left( \frac{\theta}{\theta_{\text{sat}}} \right)^2 + 0.0716 \left( \frac{\theta}{\theta_{\text{sat}}} \right)^3 \right] \left( 1 - \frac{\theta}{\theta_{\text{sat}}} \right)^3 \quad (12)$$

With this expression, the overall kinetic blocking function  $B(\theta)$  can be calculated, using Eq. (11), which now only depends on the maximum coverage  $\theta_{\text{sat}}$  obtained after saturation and the coupling constant  $K$ .

In practice,  $K \sim 1$  for micrometer-sized particles.<sup>[47]</sup> However, our colloidal particles are markedly smaller, which leads to a significant increase of the value of  $K$ . This can be understood by considering that from Eq. (2),  $D$  is inversely proportional to the particle radius  $a$ . Therewith the convective flux, expressed by the rate constant  $k_c$  in Eq. (1), varies as  $a^{-2/3}$ . An analytical expression for the adsorption constant  $k_a$  is given by Adamczyk and Szyk<sup>[52]</sup>

$$k_a = \frac{D}{2a} \frac{1}{1 + \frac{1}{2} \ln(1 + \frac{\Delta a}{a})} \quad (13)$$

where  $\Delta a$  represents the extent of the repulsive interactions, i.e., the effective thickness of the double layer. With Eq. (2), we obtain for the coupling constant  $K = k_a/k_c \sim a^{-4/3}$ ; that is, for smaller particles,  $K$  is expected to become considerably larger than 1.

In Fig. 5A, the coverage dependence of the overall kinetic blocking function is plotted for different values of  $K$ . A large value of  $K$  ( $\gg 1$ ) implies that the adsorption rate is considerably larger than the convective supply of particles. Thus up to relatively large coverages, the deposition is transport-limited, which is expressed by the considerable coverage range over which  $B(\theta/\theta_{\text{sat}}) \approx 1$ . Only near the saturation coverage,  $B(\theta/\theta_{\text{sat}})$  rapidly drops to 0. In the opposite case when  $K = 1$ , corresponding the pure RSA, the adsorption itself becomes

**Fig. 5** (A) The overall kinetic blocking function  $B(\theta/\theta_{\text{sat}})$  for different values of the coupling constant  $K$ , as a function of the normalized coverage  $\theta/\theta_{\text{sat}}$ . The solid line represents the RSA limit ( $K = 1$ ). The broken lines correspond to calculations using the generalized adsorption model with values for  $K$  as indicated. In (B), the data in Fig. 4 are replotted (symbols) and compared to the calculation for  $K = 55$ .

rate-limiting. Accordingly, for low  $K$  values,  $B(\theta/\theta_{\text{sat}})$  exhibits a sharp decrease already at low coverages.

From the deposition curves in Fig. 2, it is obvious that for a large coverage range, the deposition is dominated by mass transport of particles to the adsorption layer. The deposition rate  $d\theta/dt$  only decreases upon approaching the saturation coverage. This indicates that for our system of nanocolloidal gold particles, irreversibly deposited in a stagnation point flow geometry,  $K$  is considerably larger than 1. To obtain more quantitative information, we fitted the generalized adsorption model, expressed by Eqs. (7), (11), and (12), to the deposition transients in Fig. 2. As fitting parameters, a single value for both the coupling constant  $K$  and the initial, limiting deposition flux  $j_0$  is used for all ionic strengths. Only the saturation coverage  $\theta_{\text{sat}}$  is allowed to vary with ionic strength. Over the entire coverage range, there is a perfect correspondence between the measured and calculated deposition curves. This is also shown in Fig. 5B where the data obtained from the deposition transients are compared to the overall kinetic blocking function obtained from the fits. In agreement with results presented in the previous section, the initial deposition rate  $d\theta/dt = \pi a^2 j_0$  amounts to  $0.0225 \text{ min}^{-1}$ , while the saturation coverages  $\theta_{\text{sat}}$  are identical to the values given in Figs. 2 and 3. The fits yield a value  $K = 55 \pm 5$  for the coupling constant. Using the value  $k_c = 1.44 \times 10^{-6} \text{ m sec}^{-1}$  for our specific system, determined from Eq. (1), we obtain a value for the adsorption rate constant  $k_a = 7.91 \times 10^{-5} \text{ m sec}^{-1}$ . Using Eq. (13) with  $\Delta a = 2 \text{ nm}$ , we obtain a value of  $k_a = 2.9 \times 10^{-4} \text{ m sec}^{-1}$ , somewhat higher than our experimentally determined value but of the same order of magnitude.

### Comparison to Similar Nanoparticle Adsorption Experiment

Using the aforementioned generalized adsorption model, Adamczyk<sup>[48]</sup> collected adsorption rate constants for typical proteins [bovine serum albumin (BSA), fibrinogen, and IgG], which are of the same order of magnitude as our colloidal particles. Comparison with the  $k_a$  values for these proteins indicates that our aforementioned value for the irreversible deposition of nanocolloidal gold is in line with other systems of similar dimensions but of very different nature. As far as we are aware, the absolute value of the adsorption rate constant  $k_a$  has not been determined for colloidal systems with particle sizes in the low-nanometer range. In two papers,<sup>[39,53]</sup> Böhmer et al. describe similar measurements of silica particles with diameters between 32 and 200 nm. Their transients are very similar to our results for nanocolloidal gold, as presented in Fig. 2. In the analysis, the authors conclude that they are able to

**Fig. 6** Deposition transients for 32-nm-diameter silica particles, scaled according to Eq. (9), using the dimensionless variables  $\bar{\theta}$  and  $\bar{t}$  as given by [Eqs. (8a) and (8b)] Source: From Ref.<sup>[39]</sup>.

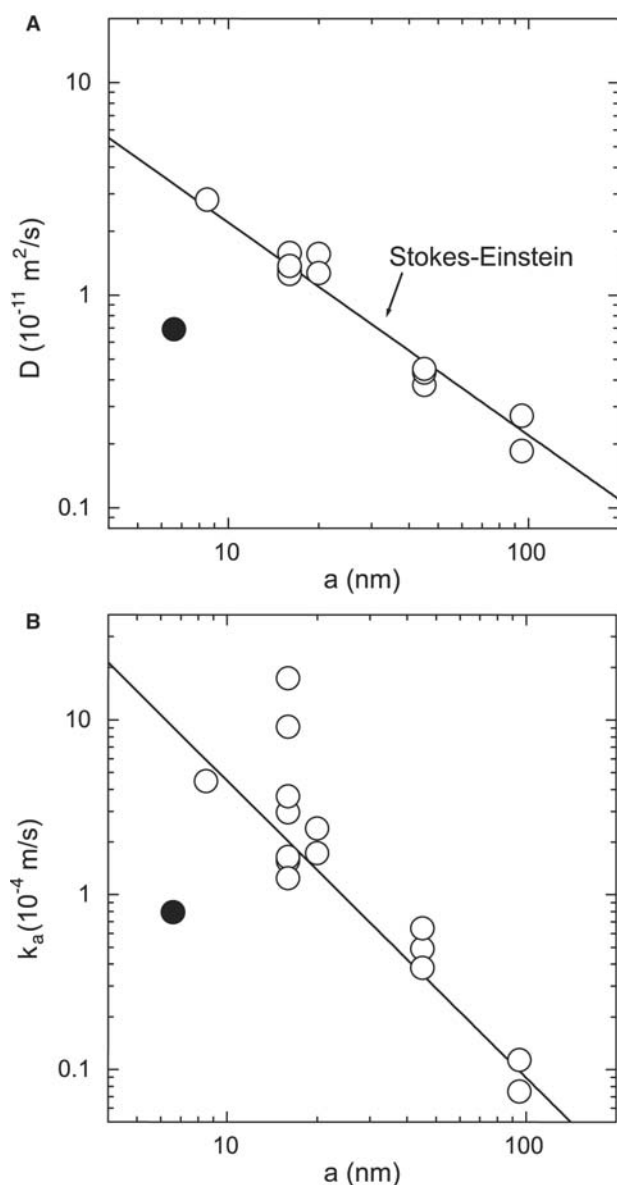

quantitatively analyze the limiting regimes in their deposition transients. However, the overall transients could not be adequately described.

We have taken the data from the aforementioned work and analyzed them as we have described above for gold nanocrystal adsorption. The curves all scale onto a single, universal transient, similar to our results. This is shown in Fig. 6 for a deposition experiment using silica particles with a radius  $a = 16 \text{ nm}$ . Using Eqs. (1), (7), (11), (12), and (13), we obtain the size-dependent diffusion coefficient  $D$  and the adsorption rate constant  $k_a$ . The results are shown in Fig. 7, and compared to our results for nanocolloidal gold particles. Both the diffusion coefficient and the adsorption rate constant are lower than the trends observed for silica particles. Also, it is clear from Fig. 6 that the diffusion coefficients determined for the silica particles are in perfect agreement with the Stokes–Einstein relation [Eq. (2)], represented by the solid line. The origin of the discrepancy between the deposition parameters of gold nanocrystals and nanocolloidal silica particles is unclear and needs further investigation.

### CONCLUSION

The formation of nanocolloidal thin films consisting of assembled gold nanocrystals with diameters in the low-nanometer range has been reviewed. The different methods to produce monolayers as well as multi-layered superstructures are briefly summarized.

Also, a more detailed study of the kinetics of irreversible deposition of gold nanocrystals from colloidal suspensions onto silicon/silicon oxide substrates is presented. Using a stagnation point flow geometry, the

**Fig. 7** Size-dependent (A) diffusion coefficient  $D$  and (B) adsorption constant  $k_a$  for silica particles, obtained from analysis of results from Refs.<sup>[39,53]</sup>. For comparison, the values for nanocolloidal gold from our work (solid symbol) are compared to the silica results (open symbols). The solid line in (A) represents the Stokes–Einstein relation in Eq. (2); the line in (B) is a guide to the eye.

convective supply of colloidal particles is controlled. The deposition process is simultaneously monitored by in situ single wavelength reflectometry, as imaging optical methods cannot be used for such small particles. The absolute coverage is measured as a function of time for different ionic strengths. Two regimes are distinguished, related to two different processes in the adsorption process. Initially, the deposition is merely governed by mass transport limited supply of colloidal particles. The ionic strength of the suspension only

affects the deposition process in the saturation regime at higher coverages.

The coupling between the convection and adsorption processes, i.e., the transition from mass transport limitation to the regime where surface blocking effects dominate, is analyzed using a generalized adsorption theory. In this theory, the deposition rate is expressed in terms of an overall kinetic blocking function. For the irreversible deposition of particles, the adsorption is treated on the basis of the random sequential adsorption model. Using the generalized adsorption model, the measured deposition curves can be adequately described, and the rate constant for particle adsorption is determined. The experimental results are compared to those for proteins and also silica particles of similar dimensions as our nanocrystals. Although there is qualitative agreement, there is a discrepancy between the results for nanocolloidal gold and the other systems. The origin of the difference is unclear.

## ACKNOWLEDGMENTS

We thank Z. Adamczyk for valuable discussions regarding the quantitative analysis of the reflectometry experiments. This work is part of the research program of the Stichting voor Fundamenteel Onderzoek der Materie (FOM), financially supported by the Nederlandse Organisatie voor Wetenschappelijk Onderzoek (NWO) and Philips Research.

## INTRODUCTION

Dynamic compaction utilizing high-pressure shock waves offers the possibility of fabricating bulk nanocrystalline materials via consolidation of amorphous or nanocrystalline alloy powders, while retaining the metastable structure and/or the nanoscale grain-size of the starting powders. Shock compression also has the potential of confining the movement of magnetic domain walls to the inside of grain boundaries in nanocrystalline magnetic materials, thereby providing an alternate method for design and fabrication of magnetic materials. With the anticipation of the next generation of high-performance permanent magnets produced at lower costs, in recent years, nanocomposite magnetic materials based on exchange-coupled nanoscale hard and soft magnetic phases have attracted the most attention owing to the combination of high magnetocrystalline anisotropy of magnetically hard phase, e.g.,  $R_2Fe_{14}B$  ( $R = \text{rare earth}$ ) and large saturation polarization of magnetically soft phase, e.g.,  $\alpha\text{-Fe}$ . Exchange-coupled magnets have usually been synthesized as thin films or as powders made by melt spinning and mechanically alloying off-stoichiometric alloys, which are then subjected to controlled crystallization to produce a mixture of the desired phases. Samples crystallized from amorphous precursors and those sintered to obtain bulk magnets usually result in non-uniform phase-separated structures with coarse grain size that limits exchange coupling, and, thus, significantly degrades magnetic properties. In fact, *fabrication of bulk nanocrystalline materials* has been the main obstacle that has limited the commercialization of such otherwise unique materials for a variety of applications.

In this entry, the shock consolidation approach employed for fabrication of high-performance magnetic nanocomposite  $R_2Fe_{14}B/\alpha\text{-Fe}$  ( $R = \text{Nd, Pr}$ )

hard-/soft-phase powders, using gas-gun impact and explosive shock-loading methods, will be described. The structure-property characteristics of highly dense compacts (up to 97–99% of full density) of  $R_2Fe_{14}B/\alpha\text{-Fe}$  ( $R = \text{Nd, Pr}$ ) nanocomposite magnets with a laminar particle morphology, solid-state interparticle bonding, and complete retention of nanoscale grain size and concomitant magnetic properties will be discussed. Effects of subsequent heat treatment on the improvement of coercive field and energy product will also be described. It will be illustrated that the control of starting powder characteristics, shock consolidation conditions, and postshock annealing treatments are necessary for fabrication of exchange-coupled nanocomposite bulk magnets with optimized magnetic properties.

## EXCHANGE-COUPLED NANOCOMPOSITE PERMANENT MAGNETS

One of the most important properties of permanent magnets is the maximum energy product,  $(BH)_{\text{max}}$ , which is a measure of the maximum stored energy. In the last 50 years,<sup>[1,2]</sup> remarkable evolutionary and revolutionary progress made in permanent magnet materials has resulted in the development of AlNiCo's with  $(BH)_{\text{max}} \sim 8 \text{ MGOe}$ , strong rare earth  $\text{SmCo}_5$  (1:5) and  $\text{Sm}(\text{Co, Fe, Cu, and Zr})_z$  (2:17) with  $(BH)_{\text{max}} \sim 30 \text{ MGOe}$ , and the new R-Fe-B supermagnets, which have large values of magnetization and magnetocrystalline anisotropy because of the highly *anisotropic* tetragonal  $R_2Fe_{14}B$  phase ( $a = 0.8792 \text{ nm}$  and  $c = 1.2177 \text{ nm}$  for  $\text{Nd}_2\text{Fe}_{14}\text{B}$ ). These single-phase Nd-Fe-B magnets have the highest energy product  $[(BH)_{\text{max}} \sim 54 \text{ MGOe}]$  of all existing magnets.<sup>[3]</sup>

The revolutionary progress has allowed dramatic miniaturization of devices in which the magnet was

previously a major part of the device volume and weight. High-energy permanent magnets are crucial for devices/components used in civilian and military systems and subsystems that require large and stable magnetic fields over a wide variety of environmental conditions. Examples of some of these applications include generators, actuators, electric drives (in tanks and automobiles), quieter and more efficient motors [unmanned undersea vehicles (UUV) propulsion], permanent magnet-based bearings for lubeless motors, holding and coupling devices, magnetic amplifiers, open magnetic resonance imaging (MRI), and faster spindle motors for hard drives (in which hard drive capacity increases by 60% a year).

Nanostructured magnetic materials show unique and interesting properties<sup>[4]</sup> that have been found to be scientifically and technologically very challenging to fully realize. Most of the endeavor in the development of magnetic materials in recent years has been placed in the exploration of nanocomposite magnets,<sup>[5]</sup> as this category of materials provides significant potential in obtaining a much higher remanence magnetization  $M_r$  and a large value of the theoretical maximum energy product  $(BH)_{\max}$  as compared to that in current commercial magnets. The unique properties of nanocomposite magnets originate from the exchange coupling between neighboring magnetic nanosize hard and soft phases, where the former provides high magnetocrystalline anisotropy and the latter contributes to the large saturation polarization. However, the grain size of soft and hard phases in these materials should be below a critical dimension of  $\sim 10$  nm to ensure effective exchange coupling and maximum fraction of the soft magnetic phases. It is anticipated that if the theoretical expectation of  $(BH)_{\max}$  for achieving  $1 \text{ MJ/m}^3$  is realized practically based on optimal exchange coupling,<sup>[6]</sup> then the overall volume and cost of magnets would be significantly reduced. Hence, the biggest challenge is to come up with an appropriate approach for fabricating bulk nanocomposites with sufficiently small and uniform grain size distribution to ensure the exchange interactions between neighboring grains.<sup>[7]</sup>

Magnetic nanocomposites such as  $\text{R}_2\text{Fe}_{14}\text{B}/(\alpha\text{-Fe, Fe}_3\text{B})$  ( $\text{R} = \text{rare earth}$ ) and  $\text{FePt}/\text{Fe}_3\text{Pt}$ <sup>[8]</sup> have to date been generally prepared in the form of powder particles, thin films, or rapidly quenched flakes via processes involving mechanical alloying/milling, sputtering, or melt spinning, chemical approaches, and subsequent heat treatment.<sup>[9–12]</sup> Bulk magnets are generally produced by resin bonding, sintering, extrusion, and hot isostatic pressing, etc. However, these approaches are not the preferred methods for fabricating bulk nanocomposite magnets, owing to the practical difficulty of attaining high density while also controlling the structure of the material at the nanoscale; hence the  $(BH)_{\max}$  values obtained are still far below the theoretical predictions.

## DYNAMIC SHOCK CONSOLIDATION OF POWDERS

Dynamic consolidation of powders using high-pressure shock waves is a potentially important method for the fabrication of bulk nanocrystalline or metastable materials.<sup>[13–17]</sup> The one-stage densification/bonding process occurring in the microsecond duration of the shock pulse involves the intense heterogeneous deposition of energy into particles, resulting in annihilation of the voids via plastic flow, and interparticle bonding. With this approach, it is possible to fabricate nanocomposite bulk magnets without introducing grain growth, as the localized heat generated at interparticle regions is dissipated into particle interiors in extremely short-time duration ( $\sim$  tens of microseconds). Shock waves can be generated through the impact of a projectile on to a powder-containing target, with the projectile being accelerated using a gas-gun or explosive devices, or by detonating explosive charges in contact with the powder container.<sup>[18]</sup> While the shock-densification conditions can be controlled by the initial packing density and by changing the impact velocity in the case of gas-gun compaction or explosive type in the case of explosive compaction, proper design of the shock-loading geometry (powder containment fixture) is essential to minimize variations in pressure distribution, and, therefore, ensure recovery of well-densified and crack-free powder compacts.

Recent work has illustrated that with typical shock pressures in the order of a few to tens of GPa, magnetic nanocrystalline powders can be successfully shock consolidated (with  $\sim 95\%$  of theoretical density) without significant grain growth.<sup>[19–23]</sup> However, these studies have employed shock compression under more excessive conditions, leading to the decomposition of the hard phase and even formation of undesired phases, causing significant deterioration of the hard-phase magnetic properties.

We have investigated shock consolidation of magnetic nanocomposite  $\text{R}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  ( $\text{R} = \text{Pr, Nd}$ ) powders,<sup>[24–26]</sup> using a three-capsule plate-impact gas-gun compaction recovery fixture and a double-tube cylindrical-implosion explosive loading geometry, designed based on appropriate models for powder densification and optimizing shock-wave interactions across materials of dissimilar impedance. The gas-gun method involves planar-wave propagation through the powders, while in the explosive geometry, radial shock-wave implosion leads to powder densification. Fully dense, bulk nanostructured magnets have been successfully fabricated by optimization of compaction parameters (shock pressure and initial packing density), proper design of fixtures, and use of appropriate starting powder morphology. Amorphization and ultrafine-scale recrystallization along localized shear bands forming under

coupled high strain rate and high-pressure conditions have been observed to lead to grain-size refinement, which provides insight into the process of deformation of nanocrystalline materials and possibly its control for design of structures for optimized properties.

### Shock Consolidation of Hard-/Soft-Phase Nanocomposites

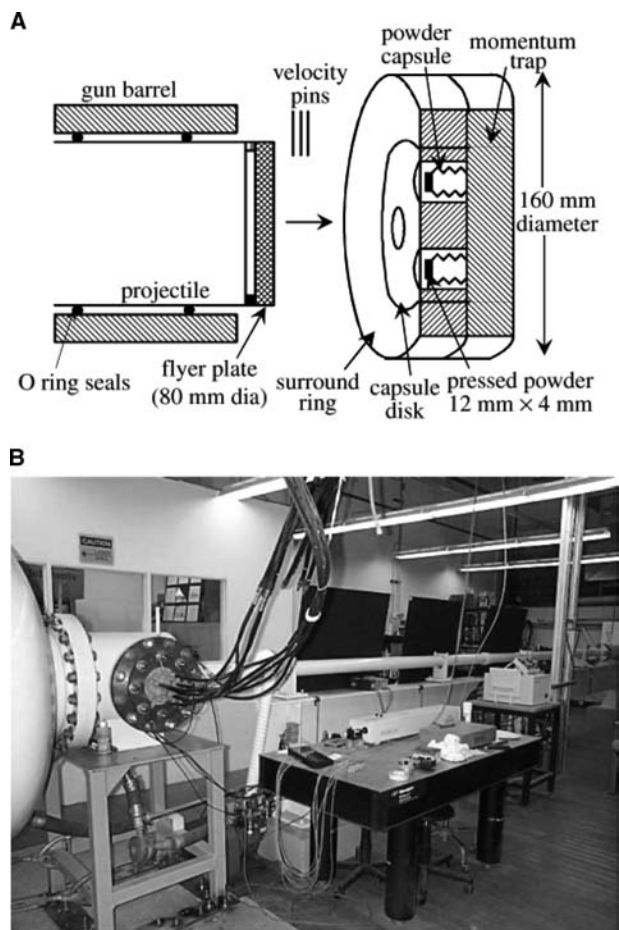

Nanocomposite ribbons with hard-phase  $\text{Pr}_2\text{Fe}_{14}\text{B}$  and 20 wt% soft-phase  $\alpha\text{-Fe}$  were prepared by melt spinning and subsequent heat treatment under conditions that ensured nanoscale phase retention. The ribbons were then pulverized to 10–200  $\mu\text{m}$  powder flakes, prior to packing (at predetermined green densities) in the powder containers for shock consolidation. Figure 1A and B are scanning electron microscopy (SEM) images

illustrating the morphology of the starting  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  particles, and Fig. 1C and D are bright-field (BF) and dark-field (DF) transmission electron microscope (TEM) images showing the nanocrystalline (25–30 nm) grain size.

For gas-gun impact experiments, the nanocomposite powders were statically pressed in capsules at various packing densities. Impact experiments were conducted using an 80 mm diameter single-stage gas-gun facility where a stainless steel flyer-plate mounted on an aluminum sabot was accelerated at various velocities (500–1000 m/sec) to impact the target containing the three-capsule fixture. A schematic illustration of the three-capsule fixture and a photograph of the 80-mm diameter Georgia Tech gas-gun are shown in Fig. 2A and B, respectively. To minimize radial wave-focusing effects (and buildup of extreme pressure), originating because of differences in

**Fig. 1** (A) and (B) SEM images illustrating the morphology of melt-spun and ground  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  particles, and (C) and (D) BF and DF TEM images showing the nanocrystalline (25–30 nm) grain size of the starting powders.

**Fig. 2** (A) Schematic illustration of three-capsule plate-impact fixture used for shock-consolidation of powders. (B) Photograph of 80-mm diameter Georgia Tech gas-gun.

the impedance between powder and steel container, the powder-containing capsules were designed with a surrounding void (air gap).

For explosive compaction, a cylindrical geometry consisting of two concentric tubes was used, as illustrated in Fig. 3. The internal steel tube contained the powder and the external steel tube acted as the flyer tube, which accelerated inwards upon detonation of the surrounding explosive ammonium nitrate and fuel oil mixed with low-density perlite diluent (ANFOIL). Upon ignition, the detonation wave sweeps along the flyer tube and accelerates it inwards resulting in a convergent shock wave propagating through the length of the cylinder.

With both geometries, corresponding maximum peak shock pressures generated upon impact were calculated, using AUTODYN-2D<sup>[27]</sup> and the  $P$ - $\alpha$  model of powder densification.<sup>[28]</sup>

Following shock compression, the compacts were recovered as 12-mm diameter by 3-mm thick discs (in the case of gas-gun experiments) and 25-mm diameter

**Fig. 3** Schematic illustration showing the geometry of the explosive-loading fixture used for making rod-shaped bulk nanocomposite magnets.

by 120-mm long cylinders (in the case of explosive-loading configuration). The compact densities were determined using the Archimedeian method, and microhardness measurements were performed using the Leco DM-400F microhardness tester. The compacted magnets were analyzed by X-ray diffraction (XRD) using  $\text{Cu K}\alpha$  radiation, SEM, and TEM. The magnetic properties were measured using a superconducting quantum interference device (SQUID) magnetometer with a maximum applied field of 70 kOe. The measured magnetic properties were corrected by using effective demagnetization factor (estimated according to the sample morphology) of 0.33 and 0.14 for starting powders and shock-compacted samples, respectively.

### Physical and Structural Characteristics of Shock-Consolidated Bulk Magnets

Figure 4 shows a plot illustrating the shock compaction conditions and resulting characteristics of the  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  nanocomposite compacts. The shock

**Fig. 4** Plot of shock pressure and final density of compacts of  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  nanocomposites shown as a function of compaction conditions (initial packing density and gas-gun impact velocity or explosive-detonation velocity). The rectangular bars correspond to the shock pressure range for the corresponding gas-gun impact and explosive-loading experiments. The initial packing densities of starting powders are marked as hollow circles. The solid circles denote the compact density of the final recovered shock-consolidated magnets. Note: The bracket indicates three samples of different initial packing densities compacted at same velocity of 880 m/sec.

pressure is a function of the compaction geometry (gas-gun impact or explosive loading), impact/detonation velocity, and initial powder packing “green” density. The degree of densification of  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  powders depends on the shock pressure and the green density, with the final compact density approaching up to  $\sim 99\%$  of theoretical maximum density (T.M.D.), particularly in the case of the powders pressed at an initial green density of  $\sim 76\%$  T.M.D with the gas-gun geometry. The shock-consolidated compacts also had high hardness values (9–12 GPa), revealing the nature of strong interparticle bonding between the powders. While gas-gun experiments yielded disc-shaped compacts, the explosive compaction experiments provided compacts in the form of cylinders with uniform density of 97–98% T.M.D throughout the compact length. Compaction at very high shock pressures ( $\sim 12$  GPa) led to formation of an axial cavity owing to Mach stem effects.<sup>[29]</sup>

Figure 5 illustrates typical SEM images of the fracture surfaces of the  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  compacts shock-consolidated using the gas-gun at the same impact velocity (880 m/sec), but starting with three different initial packing densities (64%, 76%, and 78% T.M.D). It can be seen from the images that the individual flaky powders are substantially compressed and deformed to fill the interstitial spaces. Because the starting ribbon

**Fig. 5** SEM images of fracture surfaces of  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  compacts shock-consolidated using the gas-gun at the same impact velocity (880 m/sec), but starting with three different initial packing densities (64%, 76%, and 78% TMD). The 64% initial density compact shows incomplete bonding between particles, and the 78% initial density compact shows intraparticle cracking. The 76% initial density compact shows the highest degree of densification with solidstate intimate bonding.

powders have flat flake morphology, the initial uniaxial pressing causes the flakes to become aligned with the flat surfaces perpendicular to the pressing direction. The flat flakes retain their alignment even after shock compression. Archimedean-density measurements revealed that each of the 64%, 76%, and 78% initial density compacts had final densities of 94%, 99%, and 98%, respectively. As shown in Fig. 5, the 64% initial density compact indeed has incomplete bonding between particles, and the 78% initial density

**Fig. 6** SEM images of planar surface of compacts made at two different impact velocities (660 and 950 m/sec for left and right images). The micrograph of the 950-m/sec impact velocity sample shows the presence of melted and resolidified interparticle regions, evidenced by the presence of microcrystalline and solidification shrinkage voids.

compact while being almost fully dense shows intraparticle cracking. The 76% initial density compact, in fact, shows the highest degree of densification with intimate solid-state bonding of particle interfaces.

In general, the SEM images of the fracture surfaces reveal partitioning of shock energy, with a significant amount of energy being localized at particle surfaces leading to interparticle bonding in the process of collapsing the voids. Excessive deposition of energy at interparticle regions, owing to low initial packing density or extreme shock-loading conditions (e.g., owing to high gas-gun impact velocity) can lead to interparticle bonding via surface melting and resolidification. Figure 6 shows SEM images of planar surfaces of compacts made at two different impact velocities (660 and 950 m/sec). The micrograph of the higher impact velocity sample clearly shows the presence of melted and resolidified interparticle regions, which is detrimental to the retention of nanoscale structure and optimum magnetic properties.

Figure 7 shows XRD patterns comparing the structure of the starting material and the recovered shock-compacted samples. The diffraction patterns of the starting specimen match the peaks corresponding to those of the 2:14:1 hard phase and the  $\alpha$ -Fe soft phase. Upon shock compression, the respective peak intensity ratios for both hard and soft phases do not change much, indicating no grain rotation and no preferred texture formation under the shock conditions employed. However, the recovered samples show broadening of peaks for both magnetic phases, more so for soft  $\alpha$ -Fe phase grains. The XRD peak broadening for as-compressed samples is associated with either lattice deformation/microstrain or a decrease in the grain size as a result of the uniaxial strain compression

during the rapid shock-energy dissipation. Calculations based on Williamson-Hall diffraction peak-width analysis showed microstrain of  $3\text{--}5 \times 10^{-3}$ , which is of same order of magnitude as heavily cold-worked materials. It is important to note that the crystallite size (15–20 nm) measured in the gas-gun compacts was found to be slightly lower than that of the starting powders ( $\sim 24$  nm in grain size). The retention of fine

**Fig. 7** XRD patterns comparing the structure of (A) starting material and recovered shock-compacted samples prepared by (B) gas-gun compaction and (C) double-tube explosive compaction. The diffraction pattern of starting specimen matches the peaks corresponding to those of the 2:14:1 hard phase and the  $\alpha$ -Fe soft phase. Upon shock compression, respective peak intensity ratios for both hard and soft phases do not change much, indicating no grain rotation and no preferred texture formation under the shock compaction conditions employed.

grain size in the compacts is attributed to the rapid deposition of energy in time durations of fractions of a microsecond. When the powders are packed at a lower initial density; however, a higher temperature rise associated with the annihilation of a larger volume fraction of voids can result in grain growth.

BF and DF TEM observations shown in Figs. 8 and 9 confirm the retention of nanoscale structure in the recovered  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  samples, obtained both in the gas-gun and in the explosive compaction experiments, respectively. It can be seen from Fig. 8 that the starting  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  powder has a mean grain size of  $\sim 25$  nm; however, some coarse  $\alpha\text{-Fe}$  grains are also visible. Following shock compaction with the gas-gun at 880 m/sec, the grains have a size distribution of 20–25 nm, and even more fine grains of 10–15 nm are evident, consistent with XRD

line-broadening analysis. The explosively consolidated compacts also showed similar retention and refinement of grain size. As illustrated by the TEM images shown in Fig. 9, both the top and the bottom parts of the rod-shaped compact have the same uniform bimodal 20–25 and 15–20 nm grain size distribution. In fact the nanocrystalline grain size of the compacts is quite stable and even upon annealing at 750°C for 2 hr, the same grain size is retained as illustrated by the TEM images of the annealed explosively shock-consolidated compact.

The retention, and, most significantly, the refinement of nanometric grain size appear to be because of fragmentation of the larger grains by shear bands generated during dynamic compaction,<sup>[19]</sup> which is an important attribute of this technique. Figure 10 shows a TEM micrograph illustrating parallel nanoscale

**Fig. 8** TEM DF and BF images illustrate that the starting  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  powder has a mean grain size of  $\sim 25$  nm along with some coarse  $\alpha\text{-Fe}$  grains. Following shock compaction with the gas-gun at 880 m/sec, the grains have a bimodal size distribution of 20–25 nm (same as that of starting powder), in addition to finer grains of 10–15 nm size believed to have been formed during shock compaction.

**Fig. 9** TEM images showing retention of similar 20–25 and 15–20 nm grain size distribution in the top and bottom parts of the 12 cm long by 2 cm diameter rod-shaped as shock-consolidated (explosively) compact. TEM images of the same annealed explosively shock-consolidated compact illustrate that the nanocrystalline grain size is quite stable (with no grain growth) even upon annealing at 750°C for 2 hr.

shear bands that span through multiple grain lengths but are confined within particle interiors. The very narrow “nanometer” scale of the shear bands is an indication that these are formed under an extremely high strain rate.<sup>[30]</sup> The shear bands have a shiny appearance quite different from the surrounding matrix because of its different structure where plastic deformation becomes highly concentrated often producing a precursor or a path to fracture. High-resolution transmission electron microscope (HRTEM) images shown in Fig. 10 reveal that the shear bands consist of a mixture of very fine  $\alpha$ -Fe nanocrystallites and amorphous  $\text{Pr}_2\text{Fe}_{14}\text{B}$  phase. The even higher magnification image also reveals the presence of amorphous phase inside the shear band. The strain rate estimated within the shear band is  $\sim 10^9$ /sec, which is close to the critical value of the strain rate determined by MD simulations for amorphization of metallic monocrystal nanowire.<sup>[31]</sup> Formation of other defects, including dislocations and twinning, is also commonly observed during shock compression of powders.<sup>[8,9,12]</sup> In the case of the shock-consolidated hard/soft phase nanocrystalline powder compacts, these structural defects were

indeed observed as revealed in the TEM images of the explosively compacted samples, shown in Fig. 11.

### Magnetic Properties of Shock-Consolidated Bulk Nanocomposite Magnets

Figure 12 shows typical hysteresis loops for the gas-gun compacted  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  nanocomposite samples of different compact densities. Although all the samples consist of magnetically hard and soft phases, the smooth hysteresis loops reveal a single-phase-like behavior and a high remanence ratio of over 50% in these shock-consolidated compacts, indicating an effective exchange coupling between hard-magnetic  $\text{Pr}_2\text{Fe}_{14}\text{B}$  and soft-magnetic  $\alpha\text{-Fe}$  phases. The values of saturation magnetization for the various compacts are very close to that of starting materials, indicating that shock compaction does not affect the phase constitution of the material, as was also confirmed by XRD analysis, which showed the same phase structures before and after compaction. In addition, it can be seen that the difference in coercivity is minor

**Fig. 10** TEM micrograph illustrating parallel, nanoscale, shiny, shear bands spanning through multiple grain lengths, but confined within particle interiors. HRTEM images reveal that the shear bands consist of a mixture of very fine  $\alpha$ -Fe nanocrystallites and amorphous  $\text{Pr}_2\text{Fe}_{14}\text{B}$  phase. The even higher magnification image also reveals presence of amorphous phase inside the shear band.

and independent of the initial green density, although it is slightly lower than the value (550 kA/m) of the preshock samples. However, it appears that the remanent magnetization scales with the final compact density, with the 99% dense compact having the highest remanence value ( $M_r = 0.96 \text{ T}$ ) and the largest energy product  $(\text{BH})_{\text{max}} = 111 \text{ kJ/m}^3$ . After considering the effect of demagnetization factor, an energy product of  $\sim 128 \text{ kJ/m}^3$  was obtained, which is comparable to that of the starting materials.

An even higher energy product of  $142 \text{ kJ/m}^3$  was obtained in the explosive-compacted samples (made at a shock pressure of  $\sim 1 \text{ GPa}$ ). However, in the case of the explosively compacted rods, it was found that too high a shock pressure results in demagnetization of the hard magnetic phase and loss of coercivity, possibility owing to amorphization of crystallites caused by the intense shock compaction conditions.

**Fig. 11** HRTEM image of shock-compacted nanocomposite  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  compact showing the presence of (A) twinning and (B) edge dislocation in a hard-phase crystal.

Hence, the effect of subsequent heat treatment on the magnetic properties of the shock-compressed bulk magnets was investigated. As shown in Fig. 13, the coercivity and energy product are observed to increase with subsequent annealing at  $750^\circ\text{C}$ , which is slightly higher than the crystallization temperature. The increase of coercivity may be attributed to the crystallization of preexisting amorphous phase and formation and retention of nanostructure. Annealing at temperatures above  $750^\circ\text{C}$  lowers the coercivity, possibly because of grain growth and existence of free zones within the soft-phase grains where the exchange coupling is quite weak. The free zones act as reversal nucleation center, and magnetization reversal nucleates at relatively lower fields over the soft phase, resulting in the reduction of the coercivity. These observations suggest that the magnetic properties of shock-consolidated nanocomposite compacts can actually

**Fig. 12** Hysteresis loops obtained for recovered  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  samples shock consolidated at 880 m/sec starting with different initial densities  $\rho_c$  and attaining varying final compact densities  $\rho_c$ . The smooth hysteresis loops indicate exchange coupling between hard and soft phases. Varying density does not seem to significantly influence the coercivity, but the remnance and energy product are significantly influenced.

be optimized by proper control of subsequent annealing treatment conditions.

It is well established that in the case of nanocomposite magnets, polarization reverses by a mechanism of nucleation and further expansion of inverse domains. These inverse domains nucleate at sites exhibiting a non-uniform magnetization distribution, such as grain boundaries, internal pores, and high stress concentrations. Shock compression results in large amounts of highly strained and defected regions, which can be energetically preferred locations for nucleation and growth of inverse domain nuclei, and thus result in a lowered reversal field and the reduction of coercivity. However, the coercivity is easily recovered with

**Fig. 13** Annealing temperature dependence of the magnetic properties for the explosive-compacted  $\text{Pr}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$  samples.

subsequent annealing treatment. The refinement of grain size, owing to shock compression, plays an important role in the increase of coercivity and the enhancement of exchange coupling. Therefore, appropriate control of shock conditions and postcompaction annealing treatments can allow further improvements in magnetic properties. It should be noted that the magnetic properties of the shock-consolidated nanocomposite bulk compacts reported in this entry are higher than those of commercially available resin-bonded nanocomposite magnets ( $\rho < 80\%$  TMD,  $(\text{BH})_{\text{max}} < 100 \text{ kJ/m}^3$ ) because non-magnetic resins in these bonded magnets lower the bulk density, and, hence, reduce the energy product. The optimal magnetic properties are also closely associated with the retention of nanostructure and strong exchange coupling between hard- and soft-magnetic phases at nanoscale. Further refinement in grain size can be expected to provide more significant improvement in magnetic properties.

## CONCLUSIONS

Shock compression processing via gas-gun impact and explosive-loading geometries is shown to be an effective method for producing fully dense, bulk nanocomposite magnets while retaining nanocrystalline grain

size, and without grain growth. The investigation of the structural and magnetic properties as a function of shock-loading conditions (initial powder-packing density and impact velocity) shows that proper control can result in complete densification and retention (or even refinement) of nanostructure of both the soft and the hard phases. The grain refinement occurs because of the formation of shear bands during shock compression. The magnetic properties of compacts are also found to be sensitive to shock pressure, packing density, and shock compaction geometry. The understanding of amorphization and recrystallization in shear bands provides insight into the deformation response of nanocrystalline materials under coupled high strain rate and high-pressure conditions.

## ACKNOWLEDGMENTS

The results reported in this entry have been obtained from work supported by US DoD/DARPA through ARO under grant DAAD-19-01-1-0546. We are thankful to all collaborators with whom we have had the opportunity to interact with in this program. We are particularly grateful to Prof. J. P. Liu at the University of Texas at Arlington and Prof. Z. L. Wang at Georgia Institute of Technology for their collaborations and discussions during the course of this work.

## INTRODUCTION

Over the last few years, research in the area of nanoscience has blossomed into an independent and highly interdisciplinary area.<sup>[1]</sup> Materials in the nanometer scale (size range 10 Å to 1 μm) are typically referred to as nanoparticles, nanocrystals, nanorods, or nanowires, depending on their crystallinity and shape. Here we refer to them simply all as nanocrystals, without distinguishing the differences. The unique material properties in this size range come from several sources: 1) quantum size effects,<sup>[2]</sup> where confinement of charge carriers in a small space leads to discrete energy levels; 2) classical charging effects,<sup>[3]</sup> which originate from the discrete nature of the electrical charge; and 3) surface/interface effects,<sup>[4]</sup> where the properties of surface or interface atoms become much more significant, as the surface-to-volume ratio increases with decreasing of particle size. Many novel properties of single, isolated nanocrystal have been investigated during the past two decades, such as size-dependent optical absorption and luminescence in semiconductors,<sup>[5,6]</sup> coulomb blockade phenomena in charge transfer,<sup>[7]</sup> or enhanced surface magnetic moments in magnetic nanocrystals.<sup>[8]</sup>

By comparison, assemblies of nanocrystals have only begun to be studied in a systematic fashion in recent years. The exciting aspect of nanocrystal arrays is that they form a truly new class of materials, where the basic building blocks are nanocrystals instead of atoms.<sup>[9]</sup> The properties of these materials not only depend on which chemical elements are used to form the building blocks, but also depend on how many atoms are in each building block and how strongly coupled these building blocks are. Traditional materials can be either crystalline or amorphous, depending on the arrangement of the constituent atoms. Similarly, nanocrystal arrays

can also be ordered or disordered. In the former case, they are referred to as nanocrystal superlattices (NCSs).

The purpose of this entry is to introduce several recent developments in the field, focusing on the experimental point of view. In “Formation of Nanocrystal Arrays,” experimental issues regarding the formation of nanocrystal arrays will be discussed and, in particular, the conditions for controlled formation by self-assembly. In “Electronic Transport” and “Optical Properties,” we consider electronic and optical transport properties of nanocrystal arrays, with the main theme being the collective phenomena in these systems, rather than behavior related to the individual nanocrystal. “Conclusion” contains a brief discussion of outstanding issues and concluding remarks. Because of the limited space, we will focus our entry on arrays formed by chemically synthesized nanocrystals only. Therefore lithographically patterned quantum dot arrays will not be discussed. For aspect not covered here and for additional, in depth information on nanocrystal arrays, we refer the reader to Refs.<sup>[9–12]</sup>

## FORMATION OF NANOCRYSTAL ARRAYS

The ultimate goal of nanocrystal self-assembly is the fabrication of highly ordered two-dimensional (2-D) or three-dimensional (3-D) superlattices or other well-defined structures.<sup>[12,13]</sup> One of the earliest research efforts in this direction can be found in the work of Bentzon et al.<sup>[14]</sup> who observed uniformly sized Fe<sub>2</sub>O<sub>3</sub> particles to spontaneously form hexagonal arrays. The discovery of high-temperature routes for high-quality semiconductor nanocrystals synthesis further stimulated the development of this field.<sup>[15]</sup> By now, nanocrystals made of metals,<sup>[16–20]</sup> semiconductors,<sup>[21,22]</sup> and

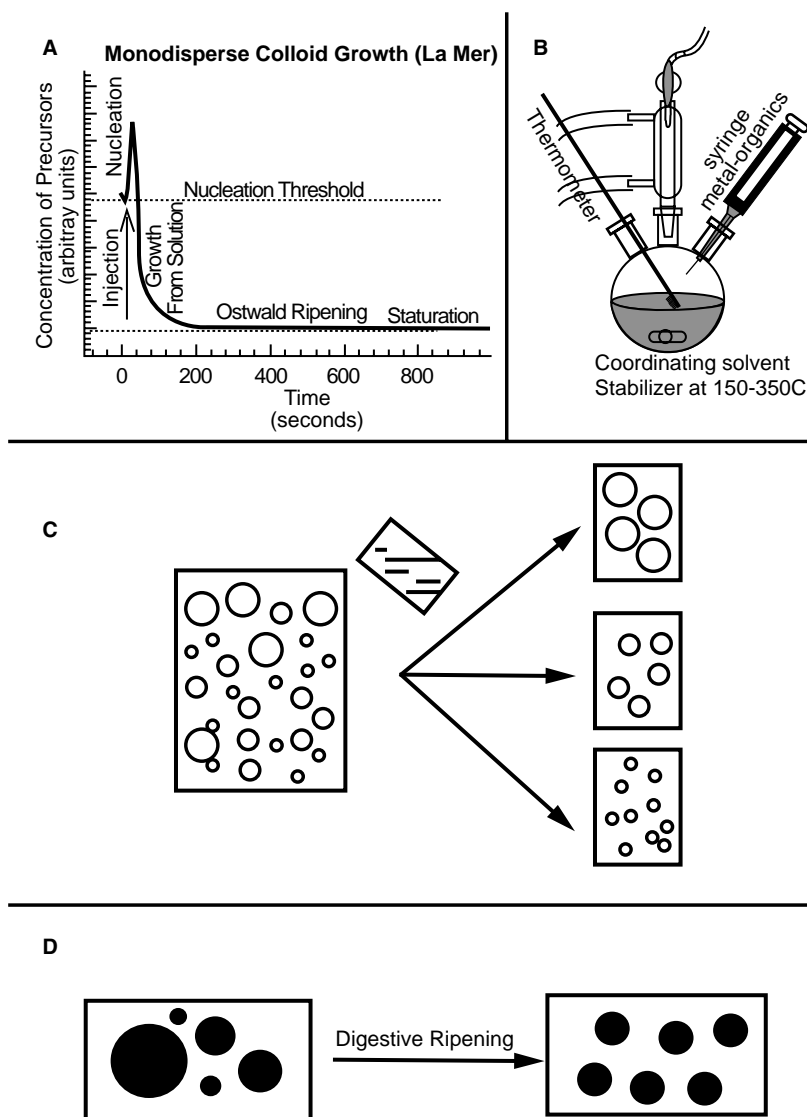

oxides<sup>[14,23,24]</sup> have been shown to form ordered NCS under proper experimental conditions, although the degree of ordering can still vary rather significantly.

In general, the spontaneous formation of nanocrystal superlattices via self-assembly requires the following: 1) a high degree of monodispersity in nanocrystal diameter (typically a relative size deviation in nanocrystal core diameters of less than 5%); 2) a complete coating of core surface with ligand molecules; and 3) suitable physical mechanisms to promote ordered packing. In the following, we discuss the relevant issues associated with the nanocrystal cores, the ligand shells surrounding the cores, and the self-assembly mechanisms.

### Nanocrystal Core

There are several different techniques to obtain monodisperse nanocrystals. High-temperature synthesis is the

most widely used since Murray, Norris, and Bawendi<sup>[15]</sup> in 1993 obtained high-quality semiconductor nanocrystals by this method. The basic principle behind this kinetically controlled process was actually proposed quite some time earlier.<sup>[25]</sup> The idea is to oversaturate the nucleating species in a very short period of time, so that there is a burst of nucleation sites at the beginning of the chemical reaction (Fig. 1A). If the concentration of the nucleating species is kept below the saturation level afterward, there will be no new nucleation sites. Subsequently, only the existing nucleation sites can grow. By monitoring the growth of particles, different sizes of nanocrystals can be synthesized with high monodispersity. Sugimoto<sup>[26]</sup> used this idea to synthesize uniform micron-sized spheres. Murray et al. extended this technique to semiconductor nanocrystals by using a high boiling point solvent (mixture of long chain alkylphosphines, alkylphosphine oxides, and alkylamines). High reaction temperature, necessary to decompose the organometallic precursor,

**Fig. 1** Schematic diagrams of various approaches to synthesize monodisperse colloidal nanocrystals. (A) Nucleation rate diagram of high-temperature synthesis.<sup>[9]</sup> (B) Experimental setup of high-temperature synthesis.<sup>[9]</sup> (C) Size-selective precipitation technique through solvent replacement.<sup>[20]</sup> (D) Digestive ripening process.<sup>[30]</sup> Source: Parts A and B are reprinted with permission from Ref.<sup>[9]</sup>. © 2000, Annual Review of Materials Science.

also results in high crystallinity of the final product (Fig. 1B). The relative size distribution of nanocrystals can, furthermore, be “focused” in situ by adjusting the concentration of reaction species during the growth.<sup>[27]</sup>

The second technique that is frequently used is the size-selective precipitation method (Fig. 1C).<sup>[28,29]</sup> This method exploits the fact that the solubility of nanocrystals in a solvent–non-solvent mixture is highly size-dependent. By slowly adding a nonsolvent into a polydisperse colloid, large particles typically become destabilized and are the first to precipitate out from the solution, which can be separated and redissolved into the original solvent. Increasing the concentration of non-solvent gradually causes smaller particles to precipitate. By repeating this process, different fractions become increasingly more monodisperse. Whetten et al.<sup>[20,29]</sup> have coupled this process with mass spectroscopy to obtain nanocrystals of highly precise mass.

Different from the above two methods is a recently developed process called digestive ripening which can transform a polydisperse colloid directly into a more monodisperse colloid through a thermodynamic pathway (Fig. 1D). Lin, Sorensen, and Klabunde<sup>[30]</sup> first demonstrated this process by heating a polydisperse gold colloid in an environment of excess dodecanethiol molecules. The large particles break up into smaller ones upon heating, and the initially polydisperse colloid evolves into a much more uniform system. This is in sharp contrast to the Ostwald ripening process, which favors large particles because of their lower surface energy. Stoeva, Klabunde, and Sorensen<sup>[31]</sup> recently showed that this process is not limited to the gold colloid synthesized by the inverse micelle technique, but works as well for gold colloid prepared by the solvate metal atom dispersion (SMAD) method. This ripening process explains why thiolated gold colloid typically gives particle sizes in the range of 4–6 nm. Although it has been reported that different thiol–gold ratios can be used to adjust the particle sizes,<sup>[32]</sup> they may be formed in kinetically trapped metastable sizes at room temperature. Reflux heating would eventually drive these particles into thermodynamically favored size ranges.<sup>[33]</sup> Although the detailed mechanism behind digestive ripening is still under investigation, it has been speculated that intermolecular interaction and molecular surface interaction might induce a specific ligand packing curvature on the nanocrystal surface, which, in turn, determines the particle size.<sup>[31]</sup>

## Ligand Shell

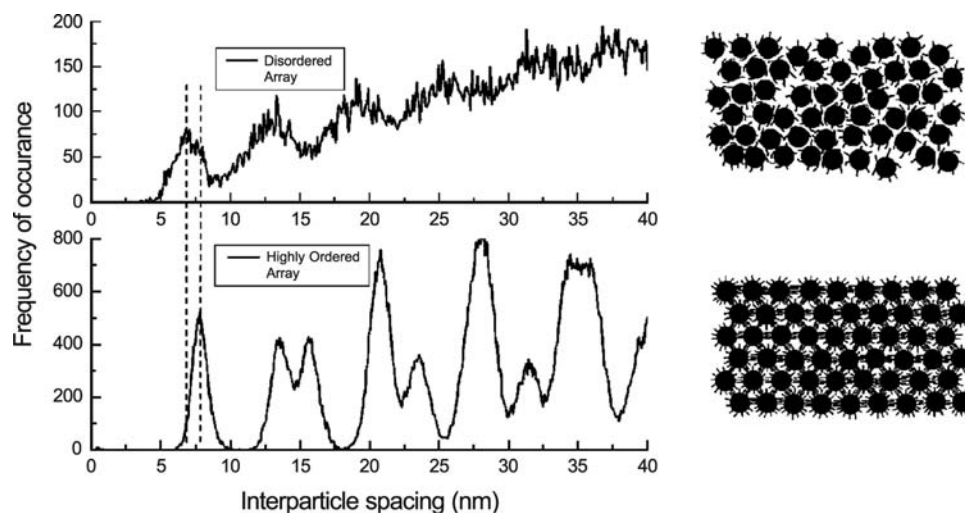

In aqueous solution, nanocrystals are typically stabilized by double layers of ions adsorbed on the surface.<sup>[34]</sup> Nanocrystals in the organic solvent generally require coating with an organic ligand shell.

There has been quite a variety of ligand molecules used in the literature, such as alkanethiol,<sup>[35,36]</sup> amine,<sup>[37]</sup> and carboxylic acid.<sup>[38]</sup> Ligand shells have several functions. First, and most importantly, they prevent nanocrystals from sintering upon colliding in the solution or on the substrate. The resulting steric repulsive force between ligand molecules is essential to the ordered packing of nanocrystals into arrays.<sup>[34]</sup> Molecular dynamics simulation by Luedtke and Landman<sup>[39]</sup> showed that ligand molecules interdigitate and even bundle together to form a robust structure that separates nanocrystals in the array. Subsequent high-resolution transmission electron microscopy experiments supported this claim.<sup>[40]</sup>

An important point is that the array packing order will depend not only on the particle size dispersion, but also on the integrity of the ligand shells. Adsorption of ligand molecules in the solution is a reversible process, and there is frequent exchange between molecules adsorbed on the nanocrystal surface and molecules in the solution. Therefore repeated precipitation and washing can remove some ligand molecules from nanocrystal surface, which causes incomplete coating of ligand molecules on the surface. Depending on the number of attached ligands and their interactions with those of neighboring nanocrystals, the interparticle spacings will vary when nanocrystals self-assemble on the surface. As a result, for incomplete ligand coating, the average interparticle spacing is typically smaller and has a wider distribution. As shown in Fig. 2, arrays formed by nanocrystals surrounded by an incomplete ligand shell exhibit a much reduced long-range ordering as compared with arrays formed by nanocrystals that have their surface saturated with ligands.<sup>[41]</sup>

Ligand molecules can also affect the nanocrystal solubility and induce specific interaction with complementary molecules adsorbed on other nanocrystals or surface. Alkanethiol with carboxylic acid group on one end can replace straight alkanethiol molecules, therefore allowing nanocrystals synthesized in the organic phase be transferred to aqueous solution.<sup>[38]</sup> DNA-labeled nanocrystals can form aggregates when complementary strands of DNA are added and result in a color change that is easy to detect.<sup>[42]</sup> Streptavidin-labeled nanocrystals can form a large array through biotin–streptavidin linkage.<sup>[43]</sup>

The physical properties of nanocrystals can also be changed by the ligand molecules. For example, electron-donating ligand such as pyridine or CO can change the unpaired electron density of a magnetic nanocrystal, quenching the magnetic moment of surface atoms attached.<sup>[44]</sup> On the other hand, enhanced surface moments were observed for nanocrystals formed in the gas phase without electron-donating ligands on the surface.<sup>[45]</sup>

**Fig. 2** Interparticle spacings for a highly ordered array formed by monodisperse 5-nm Au nanocrystals with complete ligand shell and for a disordered array formed by the same nanocrystals but with incomplete ligand shells. *Source:* Image analysis based on transmission electron micrographs was done by N. Mueggenburg.

### Self-Assembly Mechanism

The driving forces for self-assembly of nanocrystals in solution and on surfaces have been extensively studied in a variety of systems.<sup>[46–51]</sup> The mechanisms are, however, quite complicated, depending on the specific materials, the size and shape of the particles, the charges on their surfaces, and on the physical environment during the self-assembly process. They can be roughly categorized into the following types.

1. Entropy-driven systems. Colloidal particles with strong repulsive interaction can crystallize when the concentration of particles exceeds a critical limit.<sup>[46–48]</sup> This is because the entropy gain associated with local motions around the regular lattice point compared with motion around random sites is sufficient to compensate the entropy loss arising from long-range ordering. In some cases, the structure of colloidal crystals grown from the surface can also be controlled by prefabricated patterns on the surface.<sup>[49]</sup>
2. Attraction-driven systems. For neutral, uncharged particles of sufficiently large size, van der Waals interaction can be strong enough to induce aggregation. At large distance, the attraction force varies as  $-AR^6/D^6$ , where  $A$  is the Hamaker constant,  $R$  is the particle radius, and  $D$  is the interparticle distance. At small distance, the functional form changes into  $-AR/D$ .<sup>[50–52]</sup> If the attraction force is the only force that acts upon the particles or it is significantly stronger than any other interaction that is present, it will cause irreversible, diffusion-limited aggregation. Ligand coating on nanocrystal

surfaces can act as a “bumper” or buffer layer to prevent such irreversibility. Diffusion of nanocrystals under the influence of the attractive force can lead to formation of large ordered arrays.<sup>[16]</sup> Care must be taken to minimize the disruptive effect of solvent dewetting to obtain high-quality arrays (Fig. 3).<sup>[16]</sup> Temperature also plays an important role to anneal out some defect sites during the self-assembly process. For a pair of 6-nm gold particles separated by a gap of 1.7 nm (dodecanethiol chain length), a simple calculation shows that the interparticle van der Waals force is roughly 46 meV, which is comparable to the thermal energy at room temperature. Fig. 4 shows the edge of a self-assembled gold nanocrystal array. Particle sizes are more polydisperse at the edge than in the interior of the domain, presumably because of the thermal annealing effect during the assembly process.

3. Other physically driven systems. Assembly of micron spheres and nanocrystals can also be accomplished by electrophoretic deposition.<sup>[53,54]</sup> The assembly of particles on the electrode surface is a result of electrohydrodynamic fluid flow arising from an ionic current flowing through the solution. By adjusting the electric field strength or frequency, the lateral attraction force between particles can be modulated. This facilitates the reversible formation of two-dimensional fluid and crystalline states on the surface.

### ELECTRONIC TRANSPORT

Charge transfer through nanocrystal arrays is of great importance not only because of the fundamental new

**Fig. 3** Long-range-ordered gold nanocrystal superlattices formed on silicon nitride substrate by controlling solvent dewetting. Each individual nanocrystal is about 5 nm in diameter.<sup>[16]</sup> Inset shows the Fourier transformation of a small portion of the image.

physics involved in such highly correlated system, but also because the modern electronic components are approaching the size limit of standard photolithography techniques.<sup>[55]</sup> Self-assembled structures based on chemically synthesized nanocrystals have the potential to circumvent such limitations and thus be used as alternative future electronic components.<sup>[56]</sup>

The transport through individual nanocrystals has been well-studied both theoretically and experimentally (by both scanning tunneling microscopy<sup>[57,58]</sup>

and two-terminal measurements).<sup>[59]</sup> For metal nanocrystal, its main feature is the Coulomb blockade effect, in which transfer of a single electron on or off a nanocrystal is strongly affected by electrostatic interaction with the nanocrystal's charge. Because of the large number of free electrons in metal nanocrystals, the discrete level spacing as a result of quantum confinement effects is small and becomes significant only at very low temperatures, typically  $\ll 1$  K. For semiconductor nanocrystals, the number of free carriers is much

**Fig. 4** (A) The edge of self-assembled gold nanocrystal superlattices shows a sharp boundary, indicating that diffusion under the influence of interparticle van der Waals forces is responsible for the assembly process. (B–C) The edge of the domain exhibits a large-size polydispersity in size than the interior of the domain, indicating thermal annealing effect during the assembly process.

smaller and quantum confinement effects, together with the Coulomb blockade, determine transport properties.<sup>[59]</sup>

Many-particle systems, on the other hand, are not as well understood and are more complex because of the intricacies of coupling between constituent nanocrystals, effects of structural order and disorder, and charge transfer between nanocrystal cores and ligands. A variety of phenomena have been reported in different systems, including spin-dependent tunneling in magnetic particle assemblies,<sup>[18]</sup> hopping-type transport in dithiol linked arrays,<sup>[60]</sup> and metal-insulator-like transitions in silver nanocrystal monolayers.<sup>[61–63]</sup> Arrays of semiconductor particles exhibit interesting time- and illumination-dependent transport which, furthermore, shows striking slow relaxation behavior, reminiscent of glasses.<sup>[64]</sup>

Our own work has focused on weakly coupled metallic nanocrystal system—monolayers of 5 nm diameter 1-dodecanethiol-ligated gold nanocrystals, self-assembled on silicon nitride substrates—and we will begin our discussion with these arrays as our focus.<sup>[65,66]</sup> By “weakly coupled” we mean that the Coulomb blockade energy, associated with the transfer of individual electrons between individual nanocrystals, dominates transport—the Coulomb or single electron charging energies are large compared with  $k_B T$ , and the electron wavefunctions, consequently, are localized on the scale of single nanocrystals. A typical current–voltage ( $I$ – $V$ ) curve at 12 K, from an array of length  $N \approx 50$  particles separating the electrodes and width  $M \approx 270$  particles, is shown in Fig. 5. There is a significant voltage threshold ( $V_T = 4.2$  V) below

**Fig. 5** Current–voltage ( $I$ – $V$ ) characteristic for a weakly coupled gold nanocrystal superlattice array at low temperature (12 K). The distance between the in-plane electrodes was 330 nm and the array width was 2  $\mu$ m. The lower inset shows a schematic  $I$ – $V$  curve for a single nanocrystal. Source: From Ref.<sup>[65]</sup>.

which no current flows. The voltage threshold is the direct consequence of the Coulomb blockade. For each particle, an energetic cost  $V_0 \sim e/\epsilon r = e/C_0$ , where  $r$  is the particle radius,  $\epsilon$  is the dielectric constant of the medium surrounding the metal core, and  $C_0$  is the self-capacitance of the metal sphere, must be paid to transport a single electron onto the charged nanocrystal. For the particles in Fig. 5,  $V_0$  is around 100 mV, and  $V_T$  arises as the sum of this single electron charging energy over all nanocrystals traversed in crossing from one electrode to the other.  $V_T$  grows linearly with array length:  $V_T = \alpha N(e/C_0)$ , where the parameter  $\alpha$  ( $\alpha < 1$ ) accounts for interparticle capacitive coupling and the randomness of the offset charges in the underlying substrate that give rise to the Coulomb blockade repulsion.<sup>[65–68]</sup>

Current can flow when the voltage threshold is exceeded—but how, microscopically, do electrons move from nanocrystal to nanocrystal? This can be answered by detailed measurements of the non-linear current–voltage characteristics as a function of temperature. In the following, we start with a discussion of the low-temperature limit, in which thermal energies can effectively be neglected, and then consider the influence of finite temperatures.

### Low-Temperature Limit

There is a distinctive threshold voltage in this temperature range. Beyond the array’s threshold, current rises as a power law in voltage:

$$I \sim M \frac{V_0}{R} \left[ \frac{(V - V_T)}{V_T} \right]^\zeta$$

where  $R$  is the interparticle resistance,  $M$  is the array width,  $V_0$  is the charging voltage ( $e/C_0$ ), and  $V_T$  is the threshold voltage. This power-law form was predicted independently nearly a decade ago by Middleton and Wingreen (MW)<sup>[67]</sup> and by Roux and Herrmann (RH).<sup>[68]</sup> Middleton and Wingreen pointed out that local charge disorder (i.e., random offset charges) gives each nanocrystal a different single-electron charging energy, uniformly distributed in the interval  $(0, V_0)$ . The path between the electrodes with the lowest total Coulomb blockade cost determines the voltage threshold. Beyond threshold, the applied voltage allows an increasing number of paths to conduct current. As the current–voltage relation in each one-dimensional path is linear, the resulting array  $I$ – $V$  curve (beyond threshold) is superlinear. In fact, MW provided an analogy between the branched, meandering flow of current in this sort of arrays to Kardar–Parisi–Zhang (KPZ) models.<sup>[69]</sup> This deterministic growth model was originally used to describe

interface growth in disordered media, such as cluster formation, liquid front in fluid flow, and surface roughness of growing crystal. From this analogy, MW's theory gives a value of the scaling exponent:  $\zeta = 5/3$ .

Experiments on highly ordered superlattices show robust power-law scaling (Fig. 6A), in accord with the MW model. However, the measured scaling exponent,  $\zeta = 2.2$ , differs from the theoretical prediction,  $\zeta = 5/3$ . The cause for the discrepancy between theory and experiment remains an open question, although it may arise from dispersity in the interparticle resistances or from inadequacies in the analogy to KPZ-type models.

Structurally disordered arrays display different behavior beyond threshold. Fig. 6 compares ordered

**Fig. 6** Log-log plots of  $I$ - $V$  curves above the voltage threshold for both highly ordered nanocrystals arrays (A) and disordered nanocrystals array caused by solvent dewetting (B). A single power law with an exponent of 2.25 fits all the highly ordered arrays, while structural disorder causes significant deviations from power-law behavior. Inset to (B) shows simulated  $I$ - $V$  curves for parallel one-dimensional chains of nanocrystals with randomly distributed thresholds. Source: From Ref.<sup>[65]</sup>.

arrays with disordered arrays in which voids were caused by solvent dewetting, thereby breaking up the monolayer. Rather than exhibiting robust scaling with a single exponent  $\zeta$  over several orders of magnitude, the current-voltage data for the disordered samples are not well fit by a single power law and display significant sample-to-sample variations. The lack of scaling behavior can be understood by considering disordered arrays as two-dimensional patches connected by one-dimensional “bottlenecks” which disturb the branching and growth of current-carrying paths. Accurate determination of array scaling exponents thus can only be performed in structurally ordered arrays.

### Finite Temperatures

Fig. 7 shows a set of  $I$ - $V$  curves measured at different temperatures. A careful examination of this data reveals that, at low temperatures ( $<100$  K), there is a very weak temperature dependence. In this temperature region, the  $I$ - $V$  characteristics above  $V_T$  appear simply shifted along the voltage axis with increasing temperature, while the current scale is untouched.<sup>[70,71]</sup> Based on the experimental results, we can write  $V_T(T) = V_T(0) \left(1 - b \frac{k_B T}{e^2/C_0}\right)$ , where  $V_T(T)$  is the threshold voltage at temperature  $T$  and  $b$  is a numerical factor. In other words, temperature contributes energy of order  $k_B T$  per nanocrystal, which assists the electrons in “paying” the coulomb blockade cost for transport. Quantitatively,  $b = 13.9$ , both from experiments and from a model of thermally assisted

**Fig. 7**  $I$ - $V$  curves for a gold nanocrystal array as a function of temperature. In the low-temperature limit (below 100 K), a clear threshold exists, with a weak, linear temperature dependence. At high temperatures (above 100 K), there is a finite zero-biased conductance. Source: From Ref.<sup>[70]</sup>.

**Fig. 8** Schematic diagram of thermally-assisted tunneling at finite temperatures. The offset between energy levels involved in tunneling is caused by the single-electron charging energy. Source: From Ref.<sup>[70]</sup>.

tunneling.<sup>[69]</sup> Fig. 8 is a schematic picture of thermally assisted tunneling in metal nanocrystals. This correspondence, combined also with the absence of exponentially activated conduction in this region, implicates as the transport mechanism tunneling from metal core to metal core through large barriers (eV) provided by the ligands.<sup>[69]</sup>

At high temperatures, in our array around 100 K,  $V_T$  is lowered to zero, and the zero-bias conductance ( $g_0 = dI/dV$  at  $V = 0$ ) is found to obey an Arrhenius form:  $g_0 = \exp(-U/T)$ . In certain other nanocrystal systems, only this exponential form is seen at the temperatures examined.<sup>[60]</sup> One must be wary of equating Arrhenius-like conductance with, for example, activated hopping over a barrier, as it also follows from a direct tunneling scenario at temperatures which overwhelm the Coulomb blockade energy.

We have referred to the arrays above as “weakly coupled,” meaning several things: First, the tunneling amplitudes between particles are low, leading to only picoamperes of current flow at biases of several volts. Second, the interparticle capacitances (determined by both the interparticle spacings and the nanocrystal sizes) are less than or equal to the single-particle capacitance  $C_0$ . Third, transport is dominated by coulomb blockade effects, as shown by a finite

voltage threshold at low temperatures. Experiments on strongly coupled nanocrystal arrays have also been performed, as we will now discuss.

Interparticle coupling can be increased by the use of more complex conjugated or aromatic ligands<sup>[60]</sup> or by compressing arrays in Langmuir–Blodgett troughs. The latter technique has been used extensively by Heath et al.<sup>[61,62]</sup> Characteristic of transport data from these systems is the lack of a voltage threshold, i.e., a finite zero-bias conductance, down to the lowest temperatures examined.

The most dramatic feature of compressed nanocrystal monolayers, discovered by Heath’s group, is the appearance of shiny, metallic optical reflectivity beyond a certain critical compression.<sup>[61,62]</sup> This has been referred to as a metal-insulator transition; we will discuss it also in the next section in the context of plasmon coupling. At present, simultaneous optical and electronic transport data do not exist. However, a wide range of transport data from these films (transferred from Langmuir troughs onto solid substrates), from compressions at both sides of the optical transition, show resistivity which increases exponentially with decreasing temperature, indicating insulating behavior. Although not technically metallic, the arrays show a rich variety of transport characteristics, with conductivity ( $\sigma$ ) following activated hopping forms [ $\sigma \sim \exp(-U/T)$ ],<sup>[72]</sup> variable-range hopping of interacting electron forms [ $\sigma \sim \exp(-U/T^{1/2})$ ],<sup>[73]</sup> and other forms depending on variables such as compression and disorder.<sup>[73]</sup> We will return to some of the issues raised by these experiments in the final section of this entry.

## OPTICAL PROPERTIES

The optical properties of small particles have received considerable attention during the past decade because of potential applications in optical sensors<sup>[74]</sup> and lasing devices.<sup>[75]</sup> Research has mainly focused on semiconductor nanocrystals and their assemblies. Size-dependent optical absorption and photoluminescence as a result of the creation and recombination of excitons have been studied extensively.<sup>[5,6]</sup> In nanocrystal arrays, it has been found that interactions between nanocrystals can lead to long-range resonance transfer (LRRT).<sup>[22,76]</sup> This process is schematically sketched in Fig. 9. When two different sizes of CdSe nanocrystals, for example, are combined in a mixed nanocrystal array, excitation in the small particles (donors) can resonantly excite large particles (acceptors). If the transferred excitation can be trapped in a low energy state of the large particle, then the reverse process cannot occur and a unilateral energy transfer process has taken place. Photoluminescence (PL) quantum yield (QY) of both the donor and acceptor

**Fig. 9** Schematic diagram of electronic energy transfer between two different size nanocrystals in a close-packed nanocrystal array. The smaller particles that have large bandgaps are donors of excitation, while large particles with smaller bandgaps are acceptors of excitation. Different pathways of both radiative (R) relaxation and non-radiative (NR) relaxation are also indicated. *Source:* From Ref.<sup>[9]</sup>. Copyright 2000, Annual Review of Materials Science.

in a mixed nanocrystal array showed a quenching of QY for the small particles and an enhancement for the large particles and thus confirm that the energy transfer process indeed takes place.<sup>[76]</sup> Even in a highly uniform nanocrystal array with size deviation less than 5%, the intrinsic inhomogeneity can lead to energy transfer among particles with different sizes. As a result, the PL spectrum of nanocrystals in solid form red-shifts compared with the same nanocrystals in colloidal form (Fig. 10).

Optical properties of metallic nanocrystals are dominated by surface plasmon phenomena, where spatially confined electrons oscillated in resonance with incident electromagnetic waves. For specific metals, such as silver and gold, the plasmon absorption occurs in the visible wavelength range, giving rise to the visible colors for these colloids. For example, 5-nm gold nanocrystals are deep maroon in color. The frequency-dependent polarizability of a single nanocrystal is given by the Clausius–Mossotti equation:<sup>[77]</sup>

$$\alpha_A(\omega) = R^3 \frac{\varepsilon(\omega) - \varepsilon_m}{\varepsilon(\omega) + 2\varepsilon_m}$$

where  $R$  is the radius of the particle,  $\varepsilon(\omega)$  is the dielectric function of the particle, and  $\varepsilon_m$  is the dielectric function of the medium. Using the dielectric function of metals, the polarizability of a single nanocrystal is

$$\alpha_A(\omega) = \frac{R^3}{1 - \omega(\omega + i/\tau)/\Omega^2}$$

where  $\Omega = \omega_p/\sqrt{3}$  and  $\omega_p$  is bulk plasmon frequency. The single particle therefore behaves like a harmonic

**Fig. 10** Absorption and photoluminescence spectra (PLs) for different sizes of CdSe nanocrystals (A) 30.3, (B) 39.4, (C) 48.0, and (D) 62.1 Å diameters. PL spectra for nanocrystals in a close-packed array are red-shifted compared to spectra obtained from particles in solution. oscillator of frequency  $\Omega$  and damping constant  $\tau$ . The dipolar oscillation produces a strong electrical field near the surface, which is responsible for the surface-enhanced Raman scattering (SERS) of small molecules adsorbed on surfaces.<sup>[78]</sup> When nanocrystals are brought into close vicinity, interparticle coupling can lead to additional resonances.<sup>[79]</sup> Fig. 11 shows, in a schematic diagram, how light at normal incidence can induce a coupled mode where neighboring particles are oscillating in phase. This coupling causes addition absorption peaks in the long wavelength region. This coupling resonance depends not only on the particle size and interparticle spacing, but also on the polarization of the incident light and the structure of the nanocrystals lattices.<sup>[80]</sup> Persson and Liebsch<sup>[81]</sup> performed a theoretical calculation of a  $p$ -polarized

**Fig. 11** Schematic diagram of surface plasmons induced by a polarized plane wave incident upon two adjacent nanocrystals from different directions. (A) The external electric field is parallel to the line joining the nanocrystals. (B) The external field is perpendicular to the line joining the nanocrystals.

light incident on a two-dimensional square lattice (Fig. 12). Two resonant peaks in the imaginary part of the polarizability correspond to coupled plasmon oscillations, either parallel or perpendicular to the array. The frequencies of these resonances are given by:

$$\Omega_{//} = \Omega^2 \left( 1 - \frac{1}{2} R^3 U_0 \right)$$

$$\Omega_{\perp} = \Omega^2 (1 + R^3 U_0)$$

where  $U_0$  is a geometric factor that depends on the structure of the array. In the case of disordered particle arrangements, the same calculation based on a coherent potential approximation shows that both of these

**Fig. 12** Calculated imaginary part of the polarizability of nanocrystals arranged on a square lattice. Resonance frequencies  $\Omega_{\perp}$  and  $\Omega_{//}$  correspond to surface plasmon oscillations perpendicular and parallel to the plane of nanocrystals. *Source:* From Ref.<sup>[81]</sup>. © 1983, American Physical Society.

absorption peaks are broadened. Experiments on disordered nanocrystal arrays confirmed that prediction.<sup>[82]</sup>

A promising scheme of utilizing surface plasmons of coupled nanocrystals for optical applications was proposed by Quinten et al.<sup>[83]</sup> In their model, a linear chain of metal nanocrystals was used to transmit electromagnetic waves through interparticle dipolar coupling. The field intensity of the transmitted electromagnetic wave depends strongly on the polarization of the incident light. Traditional dielectric optical waveguides have a fundamental wavelength limitation. In comparison, small particle arrays have the potential to become functional units for guiding, modulation, and amplification of light signals on a length scale that is much smaller than the wavelength of light.

In the case of strongly coupled nanocrystal arrays, such as Ag nanocrystal arrays compressed on the Langmuir trough, the optical properties also undergo dramatic changes when metal-insulator-like transitions occur.<sup>[61,62]</sup> The real part of the dielectric constant turns negative, indicating more metallic features. However, the derived value of the dielectric constant is about 10 times larger than typical values for an ordinary Ag film. This indicates that the “metallic” state caused by the strong coupling of neighboring nanocrystals is still quite different from the bulk metallic states that we are familiar with.

## CONCLUSION

The controlled assembly of nanocrystals into large arrays and superlattices opens the door to a new class of artificial materials whose properties can be tuned by choosing different core materials, by varying the core sizes and shapes, and by tuning the interparticle coupling strength. In particular, the ability to vary independently the properties of the individual nanocrystal building blocks and the type and strength of the interactions between them allows for new and unprecedented control. As a result, materials with electronic or optical properties not obtainable from bulk can be designed “bottom up” by nanocrystal assembly.

At present, the main challenge still lies in our ability to tune all of the key physical parameters of a nanocrystal array at will. As far as electronic transport is concerned, weakly coupled arrays are dominated by single electron Coulomb blockade effects. Strongly coupled arrays, on the other hand, are considerably different. Understanding the strongly coupled state and the transitions between strong and weak coupling are two pressing issues in this field. Experimentally, it is difficult to controllably adjust interparticle couplings. Compression in Langmuir troughs has yielded the

fascinating data described above, but it suffers from the disadvantage of simultaneously altering both the voltage and current scales of transport. As nanocrystals are brought closer together, their capacitive coupling increases, lowering the Coulomb blockade cost for electron transport.<sup>[67]</sup> Also, the tunneling barrier separating the metal cores narrows, increasing the interparticle tunneling amplitudes. Techniques to independently manipulate these two effects would do much to further our understanding. One possible route is a better grasp of the role of ligands in nanocrystal systems, perhaps designing metal core/ligand particles with specific tunneling rates. (Such feats have been accomplished in the context of electron tunneling through proteins.)<sup>[84]</sup> voltage scaling relations. For strongly coupled arrays, the paucity of studies is even more pronounced. It is not yet clear to what extent such well-known concepts such as variable-range hopping, metal-insulator transitions, localization, etc. developed for microscopic disorder in semiconductors or disordered thin metal films carry over directly to nanocrystal arrays. For example, it is not obvious that anything besides fixed-range, nearest-neighbor hopping should even occur in metal nanocrystal arrays because of the large, mesoscopic distances involved and because, in contrast to hopping between sharp impurity levels in semiconductors, in metals, at any finite temperatures, the spectrum of available states is broad. Furthermore, the interplay of several types of disorder (random offset charges and variations in the particle size modulating the local charging energy and variations in the particle spacings giving rise to coupling strength disorder) as well as the potentially complex roles played by any electronic states inside the ligands make application of these established, but more microscopic concepts nontrivial.

Controlling the optical response on a nanometer scale is another emerging direction of much promise. With strong coupling between nanocrystals, theoretical models have predicted that coherent transfer of electromagnetic energy along nanocrystal arrays should be possible, despite significant radiative loss. Experiments have not unambiguously demonstrated this phenomenon so far largely because of the difficulty of creating the desired array structures on a very small length scale and also because of current limitations with near-field optical detection schemes.

Several of the recently developed approaches discussed in this article provide new pieces to the expanding toolkit for nanocrystal array assembly: The digestive ripening method can produce size dispersions significantly below 5%; fully ligand-saturated Au nanocrystals can assemble into extended monolayer superlattices with unprecedented degree of long-range order; nanocrystal arrays can be patterned into arbitrary 2-D shapes by electron beam exposure or can

be interfaced with lithographically defined electrodes; and the use of membrane substrates allows for transport measurements and, with the same samples, for characterization of the local structural order by transmission electron microscopy.

## ACKNOWLEDGMENTS

We would like to thank fruitful discussion with Prof. David Grier about the manuscript. This work has been supported by the U.S. Department of Energy, BES-Materials Sciences, under Contract W-31-109-ENG-38, University of Chicago-Argonne National Laboratory Consortium for Nanoscience Research (CNR), and by the MRSEC program of National Science Foundation under Award Number DMR-0213745.

## INTRODUCTION

During this last decade, because of the emergence of a new generation of high-technology materials, the number of groups studying nanomaterials has increased exponentially.<sup>[1,2]</sup> The electrical, optical, and magnetic properties of inorganic nanomaterials vary widely with their sizes and shapes. Nanomaterials are used in several domains such as chemistry, electronics, high-density magnetic recording media, sensors, and biotechnology. This is, in part, because of their novel material properties, which differ from both the isolated atoms and the bulk phase. An ultimate challenge in materials research is the creation of perfect nanometer-scale crystallites identically replicated in unlimited quantities in a state than can be readily handled and can behave as pure macromolecular substances. Thus the ability to systematically manipulate these is an important goal in modern materials chemistry. Optimizing this ability requires an understanding of nanocrystal growth, which turns out to be a complex process. The essential first step in the study of their physical properties and the use of nanomaterials in various technologies is their production. Several approaches to manipulate inorganic nanocrystals have been undertaken. The major contribution was to produce spherical nanocrystals with a very low size distribution. Deposition processes include use of microwave plasma,<sup>[3]</sup> low-energy cluster beam deposition,<sup>[4]</sup> inorganic chemistry,<sup>[5]</sup> ball milling,<sup>[6]</sup> sonochemical reactions,<sup>[7]</sup> sol-gel,<sup>[8]</sup> and flame by vapor phase reaction and condensation.<sup>[9]</sup> In 1986, we developed a method based on reverse micelles (water-in-oil droplets) to prepare nanocrystals.<sup>[1,2]</sup> Normal micelles make it possible to produce ferrite magnetic fluids.<sup>[10]</sup>

To control the shapes of nanocrystals, several procedures are now being studied. Hard templates are employed to direct 1-D nanostructure growth. The nanometer-sized pores in membranes and zeolites are utilized to confine the growth of wires.<sup>[11–14]</sup> Alternatively, lithography and deposition are combined to create quantum wires on single-crystal surfaces.<sup>[15–17]</sup> Electrochemical synthesis is used to produce well-defined nanorods.<sup>[18–20]</sup> In 1993 and again in 1995,

we were able to partially control the shape of nanocrystals by using colloidal solutions as templates.<sup>[21,22]</sup>

In the following, we will concentrate mainly on nanocrystal growth in colloidal self-assemblies and describe discrepancies in the control of size and shape.

## COLLOIDAL SELF-ASSEMBLIES OF SURFACTANTS

### Direct Micelles

Surfactants are molecules with a polar hydrophilic head (attracted to water) and a hydrophobic hydrocarbon chain (attracted to oil). If a surfactant is solubilized in water, the chains tend to self-associate to form various aggregates.<sup>[23,24]</sup> Of course, if the solvent is able to solubilize simultaneously the polar head and the alkyl chains, no aggregates are formed. The shape of the surfactant plays an important role in forming the assembly. If the surfactant molecules have a very large polar head and a small chain, the chains tend to self-associate and form a spherical aggregate that is called a direct micelle. When the direct (or normal) micelle is formed at low concentrations, it is spherical and the length of the hydrocarbon chain and the size of the polar head fix its diameter. On increasing the surfactant concentration, various aggregate shapes are formed. The most commonly used surfactants are sodium dodecyl sulfate [Na(DS)], cetyl trimethyl ammonium chloride (CTAC), or cetyl trimethyl ammonium bromide (CTAB).

### Reverse Micelles

If the surfactant has the shape of a champagne cork (small polar head and branched hydrocarbon chains), spherical water-in-oil droplets are formed. These are usually called reverse micelles.<sup>[25]</sup> They are a thermodynamically stable mixture of water, oil, and surfactant, where water and oil regions are separated by a surfactant monolayer. Because of the amphiphilic nature of

the surfactant, numerous disordered or partially ordered phases are formed, depending on temperature and concentration.<sup>[26]</sup> The surfactant most frequently used is sodium di(2-ethylhexyl) sulfosuccinate, usually called Na(AOT). The water/isooctane/Na(AOT) ternary-phase diagram shows a large zone where the reverse micellar phase is found. In this liquid-like phase, the ratio of water to surfactant concentration  $w = [\text{H}_2\text{O}]/[\text{Na}(\text{AOT})]$  determines the reverse micelle size. At  $w$  values lower than 15, water mobility is greatly reduced (bound water). Above  $w = 15$ , the linear increase of the water pool radius  $r_w$  with  $w$  (from 4 to 18 nm) is explained by a geometrical model,<sup>[27]</sup> which assumes a constant area per surfactant molecule and that all surfactant molecules participate in the reverse micelle interface. They are able to exchange their water content during collision between two droplets. The volume of water added to the solution is the only parameter controlling the droplet diameter. Hence, the droplet size remains unchanged in various bulk oil solvents. The intermicellar potential, modeled by an adhesive sphere potential, depends on the particle diameter ( $d$ ), the attractive range ( $\Delta$ ), and the sticky parameter ( $\tau^{-1}$ ) describing the attractive strength between two droplets.<sup>[28]</sup> The latter increases with the length of the bulk oil alkyl chain. It is related to the decrease in percolation threshold with oil chain length, and is explained in terms of an increase in intermicellar droplet interactions. This is caused by penetration of solvent molecules into the interface screening the AOT-alkyl chain interactions. In the case of long-chain oil solvents, steric hindrance does not allow solvent molecules to penetrate the interface, inducing an increase in attractive interactions.<sup>[29–32]</sup> The kinetic exchange process<sup>[33]</sup> is directly related to the sticky parameter and to the modulus binding of the film at the water-oil interface. Hence, the solvent used tunes the kinetic exchange process: for short-chain solvents, the surfactant alkyl chain is well solvated and the micellar interactions are weak, inducing a low kinetic exchange rate constant. Conversely, large molecules are poor solvents for alkyl chains inducing strong interactions between micelles (i.e., high kinetic rate constants). Hence, by replacing cyclohexane by isooctane as the bulk oil solvent, the kinetic rate constant, at fixed droplet size, increases by a factor of 10.<sup>[34]</sup> These two properties (size and exchange process) make it possible by mixing two micellar solutions containing the reactants to produce nanomaterials.

### Colloidal Self-Assemblies Made of Divalent Surfactant

Following our paper<sup>[35]</sup> in 1991, a great deal of work has been performed with divalent bis(2-ethylhexyl)

sulfosuccinate  $[\text{X}(\text{AOT})_2]$ . We demonstrated that, at low water content, spherical reverse micelles are formed. It was found that, with  $\text{Cu}(\text{AOT})_2$ ,  $\text{Co}(\text{AOT})_2$ , and  $\text{Cd}(\text{AOT})_2$ , on increasing the water content, spherical water-in-oil droplets turn into cylinders. This study has been extended by other groups; Eastoe et al.<sup>[36–39]</sup> confirm these data and show this for other surfactants such as  $\text{Zn}(\text{AOT})_2$ ,  $\text{Ni}(\text{AOT})_2$ , and  $(\text{C}_7\text{H}_{14})_4\text{N}(\text{AOT})_2$ . In the oil-rich region, the phase behavior of copper(II) bis(2-ethylhexyl)sulfosuccinate  $[\text{Cu}(\text{AOT})_2]$ -isooctane-water is known over a wide domain.<sup>[40–43]</sup> When the surfactant is not totally solvated, the various structures are governed by the hydration of the head polar group with a progressive increase in the surfactant parameter  $s = v_s/a_s l_s$ , where  $v_s$ ,  $a_s$ , and  $l_s$  are the volume of the surfactant, the surface area, and the length of the alkyl chain, respectively. All these divalent surfactants behave similarly: At low water content, reverse micelles are formed. On increasing the water content, the system evolves to interconnected cylinders, to an equilibrium between lamellae and interconnected cylinders, to an onion-phase region, and, finally, to reverse micelles.<sup>[40–43]</sup> Hence, these structures are made with the same surfactant and differ by their shapes. In the region where the head polar group is totally hydrated, spontaneously formed thermodynamically stable emulsions in equilibrium with other microstructure phases are observed. These spontaneous emulsions are comprised of supra-aggregates,<sup>[43]</sup> lamellar spherulites in which the interior and exterior are phases of interconnected cylindrical nanostructures. In another part of the phase diagram, clumps of interdigitated micelles are surrounded by an interconnected cylinder phase. The phase boundaries emerge qualitatively from elementary considerations that require only notions of local and global packing constraints.

### SYNTHESES OF NANOCRYSTALS IN SELF-ASSEMBLIES DIFFERING BY THEIR SIZES AND SHAPES

In the oil-rich region, the reactants are confined in the water pool. Because of this, the chemical reaction (i.e., production of nanocrystals) takes place in the supersaturation regime, thus allowing the formation of particles having a very high crystallinity. Such self-assemblies are either droplets (reverse micelles), or bicontinuous phases such as interconnected cylinders or lamellar phases. In aqueous solutions, a functionalized surfactant is used to make normal micelles that are the chemical media for nanocrystal growth. In this case, the reactants are localized at the water-oil interface of the micelles, creating a supersaturation regime.

**Fig. 1** Change of the copper nanocrystal sizes with the reverse micelle diameter. Reverse micelles are made with 0.1 M Na(AOT) surfactant solubilized in isoctane. One solution contains  $10^{-2}$  M  $\text{Cu}(\text{AOT})_2$ , whereas the second one contains  $2 \times 10^{-2}$  M hydrazine. The water content is fixed by the amount of water added to the solution and controls the droplet size. By mixing the two reverse micelles, copper nanocrystals are formed. A drop of solution is deposited on grid and the transmission electron microscopy (TEM) patterns are presented for various water droplet sizes.

### Syntheses in Reverse Micelles with Formation of Spherical Nanocrystals

Fifteen years ago,<sup>[44]</sup> we discovered that reverse micelles are good candidates for templates. Coprecipitation reactions and chemical reduction occur in reverse micelles by using the two properties described above (change in the droplet size with the water content and micellar exchange process). Let us consider A and B solubilized in two micellar solutions. On mixing them and because of the exchange process, A and B are in contact and react. Thus it is possible to fabricate a very wide range of spherical nanomaterials<sup>[1]</sup> such as semiconductors, metals, oxides, and various metal and semiconductor alloys. The control of the template size, by changing the water content, enables control of the spherical nanocrystal size.<sup>[21,44]</sup> Fig. 1 shows the control of copper nanocrystal size with the water content. It is of interest to note that this nanoreactor makes it possible to produce metal nanocrystals without any detectable oxide. The nanocrystals are characterized by a very high crystallinity when one of the reactants used is a functionalized surfactant (the surfactant has one of the reactants as the counterion). Otherwise, when the two highly hydrated reactants are solubilized in the two droplets, amorphous nanomaterials are formed and metals are produced in their oxide form. The size of the produced material, under the same experimental conditions, is not that of the droplet used as a template.<sup>[1,2]</sup> In fact, for II–VI semiconductors<sup>[45]</sup> (CdS, CdTe, and CdMnS), the particle size varies from 2 to 4 nm, whereas for metals, it increases from 2 to 6 nm for silver<sup>[46]</sup> and from 2 to 10 nm for copper<sup>[21]</sup> and silver sulfide.<sup>[47]</sup> This control of the particle size is obtained for the smallest water-in-oil droplets (varying from 0.6 to 6 nm), whereas for larger template sizes (from 6 to 12 nm), no changes in the particle size are observed (Fig. 2). This is well demonstrated for large numbers of nanocrystals and is explained in terms of

water structure.<sup>[48]</sup> An exception is found for silver sulfide nanocrystals with a linear increase in the particle size with that of the template and similar sizes of the droplets and the material.<sup>[47]</sup> By changing the length of the solvent alkyl chain, we know that the droplet size remains the same, whereas the intermicellar interactions change. Syntheses at constant droplet size and in various bulk oil solvents induce a change in the produced nanocrystal size. This is observed for a large variety of nanocrystals and is well demonstrated with copper nanocrystals made in reverse micelles having isoctane and cyclohexane as the bulk phase (Fig. 2). This change in the particle size, keeping the same droplet radius, is explained in terms of efficiency in the exchange control process: Because cyclohexane is a

**Fig. 2** Variation of the copper nanocrystal size with the droplet diameters by using either isoctane or cyclohexane as the bulk oil solvent. The same procedure as described in Fig. 1 is used. Isooctane is replaced by cyclohexane. From the TEM pattern, the average diameter of nanocrystal sizes is measured.

good solvent for surfactant chains, intermicellar interactions between droplets and then the kinetic exchange rate constant are smaller with cyclohexane than isooctane.

### Discrepancies in the Use of Reverse Micelles as Templates

The method described above makes it possible to obtain a very large number of spherical nanomaterials, indicating that reverse micelles are efficient templates. However, note that some of them do not exist in the bulk phase and others can never be produced. Hence, in equilibrium states, the solid solubility between Fe and Cu is negligibly small. Their mixing enthalpy is positive and they form no intermetallic compounds even though their atomic radii are quite similar. On the nanoscale, reverse micelles produce Fe/Cu alloys.<sup>[49]</sup> With semimagnetic semiconductors<sup>[45]</sup> such as  $\text{Cd}_y\text{Mn}_{1-y}$ , it is possible to include, as in the bulk phase, 50% of  $\text{Mn}^{2+}$  ions in the CdS matrix, whereas with CdTe, there are no detectable manganese ions in the nanocrystals<sup>[50]</sup> and telluride nanorods are formed. No obvious explanations can be given. However, this indicates that physical chemistry in colloidal and homogeneous solutions differs.

The experimental mode used to prepare the nanocrystals is one of the key parameters. This is also described below for controlling nanocrystal shape. Let us consider spherical reverse micelles made of functionalized surfactants such as cadmium bis(2-ethylhexyl) sulfosuccinate [ $\text{Cd}(\text{AOT})_2$ ]. By adding a given amount of water, the water pool diameter reaches 10 nm. By replacing pure water with a solution containing sodium sulfide, spherical CdS nanocrystals are produced. Conversely, bubbling  $\text{H}_2\text{S}$  diluted with nitrogen gas results in formation of flat triangles of CdS nanocrystals<sup>[51]</sup> (Fig. 3). High-resolution electron microscopy shows formation of well-defined

monocrystals. The formation of flat triangles could be explained by the fact that the nucleation process is slower in using diluted  $\text{H}_2\text{S}$  gas. This enables selective adsorption of hydronium ( $\text{H}^+$ ) on specific faces. Such nanocrystal growth cannot be explained by surfactant impurity: The same reverse micelles produce spheres and triangles. This shape control by the presence of  $\text{H}^+$  in the solution can be related to the formation of cubic platinum nanocrystals<sup>[52]</sup> from aqueous solutions containing  $\text{PtCl}_4^{2-}$  and bubbled with hydrogen ( $\text{H}_2$ ). With time, hydrogen and chloride ions are formed in the solution and a precipitate of cubic platinum nanoparticles appears. It must be noted that the particles are well defined and faceted. Coalescence is prevented by selective adsorption of  $\text{H}^+$  or  $\text{Cl}^-$  on the facets. Other examples in the literature show formation of non-spherical nanoparticles: hence, spherical reverse micelles made of CTAB/butanol/octane produce cubic  $\text{KMnF}_3$  nanocrystals.<sup>[53]</sup> Details of the synthesis are not given and it is rather difficult to explain which parameter plays the determinant role. However, we have to keep in mind that bromide derivatives of CTAB are present during the synthesis. This will be discussed below. Similarly, elongated and rod-shaped  $\text{BaCrO}_4$  and  $\text{CaCO}_3$  nanocrystals are produced by using reverse micelles.<sup>[54-57]</sup> This could be caused by selective adsorption on various faces during the nanocrystal growth of either reactive products or impurities coming from the preparation of functionalized surfactants used to form reverse micelles. From this, it is reasonable to conclude that reverse micelles can be used as nanoreactors to produce nanoparticles. In most cases, a spherical template produces nanospheres. Hydration of the water pool, procedure mode, and size of the template control the nanocrystal growth. However, production of various species during the chemical reaction and the presence of some impurities prevent the control of spherical particles and induce the formation of nanoparticles having various shapes.

### Colloidal Solutions Used as Template to Produce Nanocrystals

Instead of using reverse micelles, let us consider a phase diagram made of a functionalized surfactant such as  $\text{Cu}(\text{AOT})_2$ -water-isooctane. The confinement of the reactant is still one of the major parameters. As (already) described above, the phase diagram markedly differs with the water content: At low water content, reverse micelles are formed. On increasing the water content, the system evolves to interconnected cylinders, then to an equilibrium between lamellae and interconnected cylinders, to an onion-phase region, and, finally, to reverse micelles.<sup>[41,42]</sup> Hence, the polar volume fraction controls the shape of

**Fig. 3** Triangles of CdS nanocrystals at various enhancements. Reverse spherical micelles of 0.1 M  $\text{Cd}(\text{AOT})_2$  solubilized in isooctane at water content equal to 31 are submitted to a slow bubbling of  $\text{H}_2\text{S}$ . CdS nanocrystals are formed.

**Fig. 4** Change in the shape of copper nanocrystals in various colloidal solutions differing by their structures. The colloidal solution is made of 0.1 M  $\text{Cu}(\text{AOT})_2$  in isoctane and hydrazine is injected in the colloidal solution. At low water content (below 3), spherical reverse micelles are formed, inducing formation of spheres. On increasing the water content to  $w = 5$ , interconnected cylinders are produced with the formation of a mixture of spherical and cylindrical copper nanocrystals. In lamellar phase obtained at  $w = 11$ , a mixture of spheres and cylinders is produced, whereas at  $w = 30$ , supra-aggregates are formed and a large variety of copper nanocrystals differing by their shapes are produced.

colloids. To make nanocrystals and to determine if the shape of the template controls that of the nanocrystals, water is replaced by hydrazine in the aqueous solution, keeping the same polar volume fraction colloidal shapes described above. Fig. 4 shows that the shape of the template partially controls that of copper nanocrystals.<sup>[57]</sup> The crystallinity of these nanomaterials is very high. In the interconnected cylinder region, spheres and cylinders are formed: The cylinder structure is characterized by a fivefold symmetry.<sup>[58]</sup> In the

region of the phase diagram consisting of an onion phase containing internal and external interconnected cylinders, a large variety of shapes are observed.<sup>[59]</sup> This control of the nanocrystal shape by that of the template has been recently confirmed by Simmons et al.<sup>[60]</sup> Syntheses of CdS nanoparticles in such colloidal assemblies characterized by various structures make it possible to vary the morphology of the nanocrystals from spheres to nanorods with a switch in the crystal structure from cubic to hexagonal. However,

**Fig. 5** TEM patterns at various enhancements of copper nanorods. Hydrazine is added to 0.1 M  $\text{Cu}(\text{AOT})_2$  solubilized in isoctane in the presence of  $10^{-3}$  M NaCl and copper nanorods are produced at the end of the chemical reduction of  $\text{Cu}^{2+}$  by hydrazine.

**Fig. 6** Change in the copper nanocrystal shape in the presence of various anions, keeping  $\text{Na}^+$  as the cation,  $[\text{Salt}] = 10^{-3}$  M. The same procedure as described in Fig. 5 is used. NaCl is replaced by  $\text{Na}_2\text{SO}_4$ ,  $\text{Na}_2\text{CO}_3$ ,  $\text{NaHSO}_3$ ,  $\text{Na}_2\text{HPO}_4$ , NaCl, NaBr,  $\text{NaNO}_3$ , and  $\text{NaClO}_4$ .

the role of templates is not as obvious as described above. Adsorption of ions, salts, and molecules has to be taken into account.

#### Influence of adsorption of ions on nanocrystal growth

Let us consider the system described above  $[\text{Cu}(\text{AOT})_2\text{-isooctane-water}]$ . In the region of interconnected cylinders that are in equilibrium with a lamellar phase, small cylinders are obtained. Addition of a small amount of salt to the colloidal solution gives long copper nanorods with a high crystallinity in fivefold symmetry (Fig. 5)<sup>[61]</sup> and an aspect ratio controlled by the concentration of chloride ions in the microphase.<sup>[62,63]</sup> It has been demonstrated that this effect is mainly caused by the chloride ions. This is attributed to selective adsorption of these ions on (001) faces and to the fact that the growth is faster on the (111) faces. Formation of these nanorods is not observed, except with bromide, on replacing chloride by other anions<sup>[64]</sup> (Fig. 6). Note that with bromide anions, a rather large amount of cubic nanocrystals is formed, whereas with most other anions, mainly spherical objects are produced. From this, it is obvious that adsorption of a given anion enables control of the copper nanocrystal shape. These data have to be related to those obtained by Esumi, Matsuhisa, and Torigoe,<sup>[65]</sup> who produced gold nanorods by UV-visible irradiation of a gold salt solubilized in the bulk phase of normal micelles made of CTAC. The authors claim that direct micelles play the role of the template. It is difficult to understand this role: Gold

ions do not interact with the micellar solution and are reduced photochemically. The chloride ions coming from the counterion of the surfactant could play this role, as observed above for copper nanorods produced in the presence of  $\text{Cl}^-$ , and allow the gold crystal growth along the 111 direction. These data can also be related to those published by Jana, Gearheart, and Murphy,<sup>[66,67]</sup> who produced silver and gold nanorods with an aspect ratio controlled by the ratio of seeds and base concentrations in the presence of the CTAC surfactant. As mentioned, cubic  $\text{KMnF}_3$  nanocrystals are formed<sup>[53]</sup> from reverse micelles made from the CTAB surfactant and  $\text{Cu}(\text{AOT})_2\text{-H}_2\text{O-isooctane}$  solution<sup>[63]</sup> in the presence of  $\text{Br}^-$ . Similarly, self-assembled monolayers (SAMs) used as templates and immersed in a solution containing bromide ions produce cubic cadmium sulfide nanoparticles.<sup>[68]</sup> The environments of these various systems totally differ. The only common factor is the presence of bromide ions during the nanocrystal growth. However, it cannot be claimed that the general principle for growing cubes is that bromide ions have to be present during the process. As mentioned, bubbling hydrogen through an aqueous solution containing  $\text{PtCl}_4^{2-}$  produces cubic platinum nanocrystals.<sup>[52]</sup> From this, it can be concluded that cubic nanocrystal growth is more related to the presence of ions that adsorb selectively than the template.

#### Influence of molecule adsorption on the nanocrystal growth

Molecules added to the solution can also play a role in the control of particle shape. Nanodisks<sup>[69]</sup> are

produced in the presence of surfactants that no longer form well-defined templates (aggregates), whereas nanospheres are produced in reverse micelles.<sup>[70]</sup> Nanodisk size depends on the amount of hydrazine present in the solution. Note that this is the first example where it is possible to control nanodisk size, and the color of the colloidal solution containing nanodisks evolves from red to gray<sup>[71]</sup> (Fig. 7). Because the concentration of the surfactant remains unchanged, to explain the disk formation, we have to take into account the adsorption of hydrazine or/and hydrogen, and hydroxyl ions on the faces. Association of molecules used as additives and salts (together) can also play a role in the control of particle shapes. Polymers and salts are needed to produce PbS nanorods<sup>[72]</sup> from functionalized surfactants solubilized in chloroform, whereas spheres are produced in their absence. In the latter case, the surfactants do not self-assemble in chloroform because the head polar group and the alkyl chains are both soluble in this solvent and act as reactants.

From the literature, a general agreement seems to emerge that control of the nanoparticle shape, via inorganic syntheses, needs to involve a mixture of two surfactants.<sup>[73,74]</sup> This has been well demonstrated with various materials such as CdSe, cobalt, and Fe nanorods. The relative ratio of surfactants controls

**Fig. 7** Silver nanodisks characterized by various absorption spectra caused by change in the nanodisk size while keeping the same aspect ratio. A large volume of hydrazine added to 0.1 M Ag(AOT) is hexane. The relative amount of hydrazine controls the size of nanocrystals.

their aspect ratio. However, such claims are not always valid. In fact, the presence of a single surfactant is enough to control the dimensions of silver, gold, and copper nanorods. A convincing experiment showing that the selective adsorption of molecules is one of the major parameters in controlling the particle shape is the production of ZnTe and CdTe nanowires<sup>[75,76]</sup> by the solvothermal process. Metals are solubilized in hydrated hydrazine, which is not only an electron transfer medium but also a strong electron donor. These authors claim that in this medium, which is, from my knowledge, a homogeneous solution, hydrazine plays the role of a template.

### NORMAL MICELLES USED TO PRODUCE FERRITE NANOCRYSTALS

Fine magnetic particles, dispersed in a suitable liquid carrier (such as water, kerosene, diester, etc.), form a magnetic fluid. Their magnetic properties<sup>[77,78]</sup> cannot be analyzed without the inclusion of the effects of size, shape, surface, polydispersity, and interactions between particles. For this reason, a method for synthesizing the particles with good control of these parameters is necessary. Recently, we developed a new procedure to make ferrite nanocrystals that allows changing of the nanocrystal size while keeping the same surface area.<sup>[10,79,80]</sup>

Divalent dodecyl sulfate  $[X(DS)_2]$  ( $X = \text{Fe}, \text{Co}, \text{Zn}$ ) is solubilized in aqueous solution and forms mixed oil-in-water micelles. A base is added to the micellar solution, is stirred for 2 hr, and, after centrifugation, the precipitate is washed several times with a solution of 50% water and 50% ethanol to remove the surfactant. Thus the powder obtained consists of ferrite nanocrystals. Depending on the type of ions, X, associated with  $\text{Fe}(DS)_2$  stoichiometric solid solutions of ferrite, is obtained. Hence, various materials such as  $\text{Fe}_3\text{O}_4$ ,<sup>[10,79,80]</sup>  $\gamma\text{-Fe}_2\text{O}_3$ ,<sup>[10,79,80]</sup>  $\text{Co}_x\text{Fe}_y\text{O}_4$ ,<sup>[81]</sup> and  $\text{Co}_x\text{-Zn}_y\text{Fe}_z\text{O}_4$ <sup>[82,83]</sup> were produced and the obtained material depends on the relative concentration of the reactants. Note that  $\text{Fe}_3\text{O}_4$  is the reduced form of  $\gamma\text{-Fe}_2\text{O}_3$ . Immediately after synthesis,  $\text{Fe}_3\text{O}_4$  is produced. After a few hours, the  $\text{Fe}^{2+}$  ions are oxidized to  $\text{Fe}^{3+}$  and  $\gamma\text{-Fe}_2\text{O}_3$  is formed. With this procedure, a large variety of ferrite nanocrystals can be prepared. To obtain an alkaline magnetic fluid, the nanocrystals are dispersed in aqueous solution, whereas for a neutral fluid, the nanocrystals are coated with citrate ions and dispersed in water.<sup>[81,84]</sup> The nanocrystal size distribution is around 20–30%. Changing the surfactant concentration controls the particle size by a factor of 2 or 4. Whatever the fabricated material is, the nanocrystals structure is an inverted spinel. This procedure

drastically differs from syntheses in homogeneous solution.<sup>[85–93]</sup> The major differences are:

1. The reactant concentration is two orders of magnitude lower than that in homogeneous solution.
2. A spinel structure can be obtained in the absence of Fe(III) at the starting point of the reaction, whereas the ratio Fe(II)/Fe(III) must be higher than 0.4 in homogeneous solution. In the latter case, with a high Fe(II) salt concentration and without Fe(III) derivatives,<sup>[94–96]</sup> the formation of Fe<sub>3</sub>O<sub>4</sub> micrometer particles is observed. Their morphology depends critically on parameters similar to those described above (reactant concentrations, pH, ionic strength, etc.). Furthermore, it has been impossible to produce particles in the nanosize range when Fe(II) salt is used for the synthesis.
3. Changing the micellar concentration controls the particle size. In homogeneous solution, it is controlled by changing the type of salt (chlorides, nitrates, perchlorates, etc.), Fe(II)/Fe(III) ratio, pH, and ionic strength of the media. Such drastic changes in experimental conditions induce a large modification in the particle interface (hydroxide formations, etc.) and magnetic properties<sup>[92,93]</sup> of the nanocrystals. Conversely, using colloidal solutions makes it possible to produce nanocrystals with magnetic properties that do not depend on their coating.<sup>[81]</sup>

## CONCLUSION

In the last decade, colloidal solutions were assumed to be very efficient templates for controlling particle size and shape. A large number of groups used reverse micelles to control spherical nanoparticles.<sup>[1,2]</sup> This makes possible determining the various parameters involved in such processes and demonstrates that they can still be considered as efficient nanoreactors with some discrepancies. There are fewer reports concerning the control of the particle shape and it is still rather difficult to determine the key parameters. They depend on the adsorption of salts, molecules, and procedure. Crystal growth on the nanoscale seems to follow behavior similar to that of the bulk phase with a marked dependence on pH. The latter is particularly important when some impurities are present in the growth medium because it influences, for example, the formation either of zwitter-ions or complex ions, the efficiency of which is greater than that of the initial impurity. These elements lead to a decrease in the growth rates of certain crystal faces. Most of the changes are based on the existence of a more or less

epitaxial adsorption layer on the crystal. This layer is composed of solvents, impurities, or salts. Their precise roles are as yet uncertain. The changes are because of the differences between the growth rates of the various crystallographic faces. From this, it can be concluded that the template is not the key parameter in the shape control.

From these comments, we can ask why templates made of surfactants are quite effective in controlling the formation of nanospheres whereas rather large exceptions are observed for anisotropic shapes. This is probably because of the fact that colloidal templates are highly dynamic. The energy needed to produce spherical nanocrystals is less than that for producing anisotropic nanocrystals. A general method for controlling nanocrystal shapes through soft chemistry has not yet been found, but this does not mean that such a method cannot be discovered. To reach a final conclusion, we need more data and we need to compare the fabrication of anisotropic nanocrystals with various types of materials. Probably other approaches, which have yet to be found, are required. This is suggested by the fact that the fabrications of elongated ferrite nanocrystals in biological media and in vitro are completely different. In biological media, the mechanism of crystal growth is not well known. However, to produce similar nanomaterials in vitro, a very high base concentration is needed and the corresponding pH would induce the destruction of the biological media. This means that other ways exist and have to be discovered.

# Nanocrystalline Magnesia and Alumina: Surface Chemistry

Richard M. Narske

Department of Chemistry, Augustana College, Rock Island, Illinois, U.S.A.

## INTRODUCTION

In recent years the study of the nanocrystalline MgO and Al<sub>2</sub>O<sub>3</sub> has increased because of the potential importance of these methods as catalysts and adsorbents. This research has ranged from preparation of these ultrafine powders with surface areas on the order of 500 to 600 m<sup>2</sup>/g for MgO and 600 to 700 m<sup>2</sup>/g for Al<sub>2</sub>O<sub>3</sub> to the chemistry occurring on the surface of these unique particles. Most of the work on nanocrystalline MgO and Al<sub>2</sub>O<sub>3</sub> has centered on the adsorption and reactions of gases or easily vaporized liquids at elevated temperatures or under high vacuum with very little focusing on the reactions at room temperature with neat liquids or solutions. Very little has been reported on the surface reactions of these particles in slurries with the organic substrate dissolved in the solvent. The purpose of this paper is to introduce recent developments of solvent effects on the surface chemistry of nanoparticle MgO and Al<sub>2</sub>O<sub>3</sub> with organic substrates.

The adsorption and reactions of some organic substrates on aerogel prepared (AP)-MgO and nanocrystalline (NC)-Al<sub>2</sub>O<sub>3</sub> have been reported as vapor reactions, reactions of the neat liquid substrate, and reactions in solvents ranging from pentane to methanol.<sup>[1-6]</sup> These reactions yielded elimination and substitution products. Reactions in pentane showed a greater degree of reactivity on both the AP-MgO and NC-Al<sub>2</sub>O<sub>3</sub> surfaces than reactions involving neat organic substrates. More polar solvents, such as tetrahydrofuran (THF) and methanol, gave results quite different than the hydrocarbon solvent. These studies have also shown that reactivity of AP-MgO and NC-Al<sub>2</sub>O<sub>3</sub> is greater than the reactivity of the bulk materials and is due to more than the surface areas of these nanocrystalline materials.

## SURFACE CHEMISTRY OF MgO NANOPARTICLES

The preparation of nanocrystalline MgO can be accomplished through different methods. Each method produces nanocrystalline MgO. For example, two

methods reported by Ito et al.<sup>[7]</sup> and Stark et al.<sup>[8]</sup> give different size particles of MgO. One method gives particles that have an average size range of 7–15 nm and an average surface area of 250 m<sup>2</sup>/g. These particles, prepared by the conventional preparation (CP), are called CP-MgO particles. In the second method reported by Stark et al.,<sup>[8]</sup> the particles are aerogel prepared, and these particles are 4–7 nm in size and have an average surface area of 500–600 m<sup>2</sup>/g. These nanocrystals of MgO are called CP-MgO or AP-MgO, respectively.

The surface morphology and surface chemistry of these different nanocrystals vary greatly from that of the bulk MgO. Figures 1 and 2<sup>[7-10]</sup> show these differences in the nanocrystal surfaces.

The irregularity of the AP-MgO nanocrystalline surface exposes more edges and corners for reactions to occur than for the CP-MgO nanocrystals. It is believed that many of the –OHs, which make up approximately 30% of the surface of AP-MgO, are exposed on these edges and readily available for reactions. The importance of these –OH groups will be discussed later.

Wagner et al.<sup>[1,2]</sup> reported in 1999 that nanocrystalline metal oxides, such as MgO and CaO, were very effective in decontaminating chemical warfare agents (CWA), such as VX, GD, and HD as well as a CWA mimic, 2-chloroethyl ethyl sulfide (2-CEES). This study was at room temperature using the pure liquid substrate introduced on a column of nanocrystalline oxide. Wagner et al. found that products formed in these reactions over a period of several days. The *t*<sub>1/2</sub> for the reaction of HD on AP-MgO, for example, was 17.8 hr and the kinetic data were still being taken after 1 week into the reaction. 2-Chloroethyl ethyl sulfide was not studied on AP-MgO but was studied on AP-CaO<sup>[2]</sup> (Scheme 1).<sup>[1]</sup>

These reactions were limited by the physical distribution of the agent passing through the column of oxide similar to a mobile phase moving through a column of adsorbent in column chromatography.<sup>[1]</sup> As these compounds studied were very viscous with viscosities of 3.098 cs or greater and surface tensions of 24.5 dynes/cm or greater, the process of moving

Scheme 2

Narske, Klabunde, and Fultz<sup>[4]</sup> also showed the importance of surface  $-\text{OH}$  groups on these reactive sites. These  $-\text{OH}$  groups make up about 30% of the surface of the reactive surface on these particles.<sup>[7]</sup> They showed that the reaction was occurring at the non-H-bonded  $-\text{OH}$  groups on the surface of the AP-MgO by studying what happens to the rate of the reaction when these  $-\text{OH}$  groups are enhanced or hindered. Enhancement was seen by the addition of small amounts of water to the reaction mixture. Small amounts of water were found to increase the reaction rate (Fig. 5).<sup>[4]</sup> To determine what was occurring on these  $-\text{OH}$  groups on the surface, diffuse reflectance FT-IR was utilized to study the surface changes of the AP-MgO. Diffuse reflectance FTIR spectroscopy indicated small amounts of water (below  $10\ \mu\text{L}$ ). This water addition changed the surface of AP-MgO by increasing the non-H-bonded  $-\text{OH}$  groups. Thus the reaction rate increased. As water addition increased (above  $10\ \mu\text{L}$ ), the  $-\text{OH}$  groups became increasingly H-bonded and the rate of decomposition of 2-CEES decreased. Eventually, a monolayer of water covers the surface of the particles and the reaction rate was

slowed to almost zero (see Figs. 6 and 7 for diffuse reflectance FT-IR spectra of the surface of AP-MgO).<sup>[4]</sup> These results indicated that the probable mechanisms needed to explain the reaction products were Sn2 (ethoxyethylsulfide)- and E2 (ethylvinyl sulfide)-type mechanisms involving the  $-\text{OH}$  groups (Scheme 3).

To further indicate the importance of the  $-\text{OH}$  groups in these reactions, capping studies with methoxy trimethylsilane were used. By reacting as many available  $-\text{OH}$  sites with methoxy trimethylsilane, the  $-\text{OH}$  groups would not be available for the reaction. The results of these studies indicated the reaction rate slowed significantly. Rates of 60% of the substrate reacted over 4 hr were observed when the  $-\text{OH}$  groups were available. These rates were reduced to 3–5% of the substrate reacted over the same period of time when the  $-\text{OH}$  groups were not available for the reaction. Thus indicating the importance of free, non-H-bonded  $-\text{OH}$  groups in order for these surface reactions to occur with the 2-CEES substrate in solvents such as pentane<sup>[4]</sup> (see Scheme 4 for the capped  $-\text{OH}$  groups on AP-MgO).

It was also noted in reactions when water was added that the rate of formation of the ethylvinyl sulfide occurred at a slower rate and had lower yield than the alkoxy compound. Scheme 3 shows that there are

**Table 1** Surface area of different AP-MgO preparation batches

Batch <sup>a</sup>	Surface area (m <sup>2</sup> /g)
2	380
3	487
4	581
5	417
6	188
7	336
9	457

<sup>a</sup>B4, 581 refers to batch 4, surface area = 581 m<sup>2</sup>/g.

<sup>b</sup>Commercially available MgO, surface area = 77 m<sup>2</sup>/g.

<sup>c</sup>Conventionally available MgO, surface area = 220 m<sup>2</sup>/g.

two reaction mechanisms competing on the surface of the AP-MgO, Sn2 and E2. The vinyl compound is being formed by an E2-type mechanism and the alkoxy compound is being formed by a Sn2-type mechanism. The addition of water may make the -OH groups less basic and more nucleophilic, thus slowing the E2-type mechanism.

The alkoxy compound, however, was not able to be isolated during the reaction studies. This compound was found bonded tightly to the surface oxygen on the AP-MgO similar to the results reported by Wagner et al.<sup>[1]</sup> in their work with HD (mustard gas). Diffuse reflectance FT-IR spectroscopy was used to determine that it was present on the surface, as Mawhinney et al. reported in their work with Al<sub>2</sub>O<sub>3</sub><sup>[5]</sup> (Fig. 8).<sup>[4]</sup>

Reactions in more polar solvents, such as THF and methanol, gave much different results than reactions in pentane. The only product observed in the surface reactions of AP-MgO in THF was the vinyl compound. These reaction results indicated that the THF complexes with the surface of the AP-MgO (Scheme 5) and blocks the magnesium sites where the complexation

of the -S- from the 2-CEES substrate occurs. The complexing of THF on the surface of the AP-MgO would not allow the 2-CEES to physi-adsorb on the surface of the AP-MgO and therefore hinders the Sn2 mechanism. Tetrahydrofuran complexation such as this is similar to ethers and thioethers complexing with magnesium in other organomagnesium reactions.<sup>[11]</sup> The THF blocking these sites hinders the Sn2 reaction which forms the alkoxy compound as the mechanism in Scheme 5 shows. The basic -OH groups are now only available for the E2 reaction, which gives the vinyl compound.

Reactions in methanol also gave only one product, the methoxy compound (Structure 1).

**2-methoxyethylethylsulfide**

The methanol is believed to be complexed with the oxygens on the surface of the AP-MgO, thus allowing the methanol groups to act as nucleophiles. A substitution reaction occurs as shown in Scheme 6. Once the methoxy compound is formed it moves from the surface of the MgO and does not bond to the surface of the MgO as the alkoxy product in pentane. This

**Fig. 4** Comparison of initial reaction rates for different batches of MgO (rate = molecules/nm<sup>2</sup> min).

**Fig. 5** Reactions in pentane with water added.

Fig. 6 Diffuse reflectance FT-IR of surface of AP-MgO before and after water was added.

made the product easily analyzed and identified by GC and GC/MS.<sup>[4]</sup>

For surface reactions of AP-MgO, the presence of non-H-bonded –OH groups, the shape or morphology of the crystallite, the surface area and the presence of sites where the molecules become adsorbed on the surface of the crystallite, as well as the distribution of the substrate over the surface are all important for these reactions to occur at a reasonable rate.

## SURFACE CHEMISTRY OF ALUMINUM OXIDE NANOPARTICLES

Because of its importance as a catalyst, the surface chemistry of aluminum oxide,  $\text{Al}_2\text{O}_3$ , has been extensively studied over the years.<sup>[5,6,13–16]</sup> In many of these studies, bulk (non-nanocrystalline)  $\text{Al}_2\text{O}_3$  has been studied.<sup>[13–16]</sup> More recent work has been done on the surface chemistry of nanocrystalline (NC)- $\text{Al}_2\text{O}_3$ .<sup>[5,6,11–17]</sup> Carnes<sup>[17]</sup> has reported a method similar to the preparation of AP-MgO for the preparation of NC- $\text{Al}_2\text{O}_3$ . This again involves aerogel preparation as it did with AP-MgO.<sup>[17]</sup> These nanocrystals typically have surface areas in the range of 700–800  $\text{m}^2/\text{g}$ . The crystallites are on the order of 2–4 nm in size, making them slightly smaller than the AP-MgO crystallites.

The morphology of the surface of NC- $\text{Al}_2\text{O}_3$  is not as well defined as that of AP-MgO. The surface of the NC- $\text{Al}_2\text{O}_3$  seems to be somewhat more amorphous. The crystallites do not seem to form the types of polyhedrons found in AP-MgO, and high resolution TEM studies have not given us much in the way of crystallite structure or surface morphology as it has for AP-MgO. The reactive surfaces, however, are still there, and it has been found that the surface chemistry is slightly

Fig. 7 Diffuse reflectance FT-IR of AP-MgO surface before water was added and before degassing.

different than that of AP-MgO.<sup>[5,6]</sup> AP-MgO has a basic surface during the initial stages for reactions and changes to an acidic surface as the reaction proceeds toward completion. Fennelonov et al.<sup>[18]</sup> noted this in their work with reactions involving AP-MgO and chlorobutane to form butenes. It was found that the surface changed to  $\text{MgCl}_2$  and thus became acidic. The surface of NC- $\text{Al}_2\text{O}_3$  has –OH groups as well as Lewis acid sites and Lewis base sites. Mawhinney et al.<sup>[5]</sup> found that both were important in the reaction of NC- $\text{Al}_2\text{O}_3$  with 2-CEES in vapor phase surface reactions. They proposed two possible mechanisms for the removal of the chlorogroup in these reactions (Schemes 7 and 8).

Yates found that the optimum reaction conditions were observed when the NC- $\text{Al}_2\text{O}_3$  samples were formed at temperatures of 400–500°C (673–773 K) under vacuum. This activation gave the optimum ratio of unassociated –OH groups on the surface of the oxide. Samples that were activated at these temperatures gave optimum conversion of 2-CEES at reaction temperatures of 70°C to 200°C (303 to 473 K). Samples activated at lower or higher temperatures did not react as well as these. According to Mawhinney et al.,<sup>[5]</sup> the reaction in Scheme 7 is dominant when there are more –OH groups on the surface (activated at lower temperatures), whereas the reaction in Scheme 8 is dominant when the surface has been highly dehydroxylated (activated at higher temperatures). The reactions of Scheme 7 were referred to as hydrolysis reactions and the reactions in Scheme 8 as nucleophilic substitution reactions. To determine the importance of the acid–base pairs of Al–O and the unassociated –OH groups, the surface was reacted with pyridine. The pyridine bonded to the acid–base pairs and not to the –OH groups, therefore hindering the “substitution reaction” of Scheme 8.

Scheme 3

Scheme 4

The reactions at these sites were found to be reduced by 40% while the reaction at the  $-OH$  groups dropped only by 10%. This study showed that both the acid-base pairs and the  $-OH$  were important in this reaction.

Reactions conducted and reported by Martin, Narske, and Klabunde<sup>[19]</sup> in various solvents found results similar to those observed with AP-MgO that were reported by Narske, Klabunde, and Fultz<sup>[4]</sup> and by Mawhinney et al.<sup>[5]</sup> These reactions of NC- $Al_2O_3$  with 2-CEES were studied in pentane, THF, and 3 M HFE-7100<sup>[19]</sup> (methyl perfluorobutyl ether; Structure 2). They found that reactions run in pentane gave the best results. This is similar to what was reported earlier in a previous work done on AP-MgO.<sup>[4]</sup> It was also found that NC- $Al_2O_3$  reacted at a faster rate than did AP-MgO under similar conditions. All reactions studied were with NC- $Al_2O_3$  made in their laboratories and 2-CEES was decomposed completely within 24 hr (Fig. 9).<sup>[19]</sup> Samples from other sources and commercial  $Al_2O_3$  were found not to react as well as

their NC- $Al_2O_3$ . These other samples had smaller surface areas.

HFE-7100

(A methyl perfluorobutyl ether)

Reactions run in HFE-7100, methyl perfluorobutyl ether (Structure 2), preceded as well as reactions run in pentane (Fig. 10).<sup>[19]</sup> Reactions studied in THF showed the same problem that was observed with the MgO reactions reports by Narske, Klabunde, and Fultz<sup>[4]</sup> (Fig. 11).<sup>[19]</sup>

An interesting aspect of this study was the reactions reported with mixed oxide nanocrystals.<sup>[19]</sup> It was found that mixed NC- $Al_2O_3$ /MgO in ratios of 2:1, 1:1, and 1:2 showed reactivities similar to those reported for AP-MgO and NC- $Al_2O_3$  (Fig. 12).<sup>[19]</sup> They also found that the mixed oxides were more influenced by atmospheric water than the pure NC- $Al_2O_3$  samples. The mixed oxide samples were found to lose reactivity when allowed to set on the shelf in sample bottles for a period of time. This is similar to what was found with pure AP-MgO.<sup>[4]</sup> After these samples were heated to 200°C under high vacuum, the reactivity returned. Again these results were similar to what was observed for AP-MgO.

Like the reactions of AP-MgO and the results reported by Mawhinney et al.<sup>[5]</sup> for  $Al_2O_3$ , no ethyl hydroxyethyl sulfide was observed during the reactions. Study of the residual oxides after the reaction with diffuse reflectance FT-IR indicated that the alcohol was bonded to the surface of the  $Al_2O_3$  as the alkoxide (Fig. 13).<sup>[19]</sup> Unlike the reaction of AP-MgO, however, no ethylvinyl sulfide was observed in any of the reactions involving pure NC- $Al_2O_3$ . Some of this compound was observed in reactions involving the

Fig. 8 Diffuse reflectance FT-IR before and after reaction showing the Mg-O- $CH_2$  bonding.

Scheme 5

Scheme 6

mixed oxides of aluminum/magnesium, but the amounts were barely detectable by GC analysis. Only about 3% of the total conversion product was observed as the vinyl product. This is an indication of a different type of surface on the NC- $\text{Al}_2\text{O}_3$ . The surface of the AP-MgO is a basic surface, thus leading to Sn2/E2-type mechanisms. The surface of the NC- $\text{Al}_2\text{O}_3$  is not as basic as AP-MgO, but it is slightly acidic in nature. The surface of NC- $\text{Al}_2\text{O}_3$  is therefore not conducive to basic attack on the hydrogens of 2-CEES carbons. This type of attack is needed in the E2-type mechanism. Although Mawhinney et al.<sup>[5]</sup> discuss the possibility

of nucleophilic attack by the  $-\text{O}-$  of the Al-O-Al surface, the  $-\text{O}-$  is not basic enough to abstract hydrogen from the carbon to produce the elimination product via an E2-type mechanism. It is, however, nucleophilic enough to substitute for the chloride through a Sn2-type mechanism.

Martin et al.<sup>[19]</sup> agree with the conclusion reported by Mawhinney et al.<sup>[5]</sup> that the probable mechanism on the surface of NC- $\text{Al}_2\text{O}_3$  is twofold. Studies of reactions using only NC- $\text{Al}(\text{OH})_3$  have shown that the decomposition reaction with 2-CEES proceeded at a slightly slower initial rate than the reactions with the

Scheme 7

Scheme 8

Fig. 9 Comparison of NC-Al<sub>2</sub>O<sub>3</sub> batches 1, 2, and 3 with 2-CEES in pentane.

Fig. 11 Comparison of NC-Al<sub>2</sub>O<sub>3</sub> batch 1 in THF and pentane.

NC-Al<sub>2</sub>O<sub>3</sub> (Fig. 14)<sup>[19]</sup> but had decomposed 100% of the 2-CEES within 24 hr. This would seem to indicate that the surface reaction at the -OH is as effective as the reaction at the Al-O-Al surface. Further work is in progress to help confirm this phenomenon and to study this reaction with no available -OH groups. These studies will either confirm or not confirm the presence of two mechanistic pathways on the samples during this reaction.

**CONCLUSION**

The surface chemistry of nanocrystalline AP-MgO and NC-Al<sub>2</sub>O<sub>3</sub> appears similar in nature. Both surfaces

react very rapidly under very mild conditions over similar periods of time in these reactions with 2-CEES. Although NC-Al<sub>2</sub>O<sub>3</sub> does appear to be more reactive than AP-MgO as these reactions are complete within 24 hr, which is not the case for AP-MgO. The differences in reactivity between these two compounds are probably due to differences in crystal size, shape, surface area, and morphology as well as differences in surface acid/base properties. AP-MgO is a basic surface, and NC-Al<sub>2</sub>O<sub>3</sub> is more amphoteric in nature but definitely not basic. As the reaction proceeds on AP-MgO the -OH groups react and the surface changes from basic to acidic<sup>[18]</sup> as the -OH groups are replaced by -Cl groups, thus changing the surface chemistry of the AP-MgO. For NC-Al<sub>2</sub>O<sub>3</sub>, there are two reactive

sites, the  $-\text{OH}$  and the  $-\text{O}-$ , on the surface rather than one for AP-MgO, and also the surface does not change as much during the reaction. These are perhaps the reasons why the reactions proceed more rapidly to completion than the AP-MgO. More work is in progress and has to be accomplished in this area in order to further understand these reactions.

## INTRODUCTION

The processes of damage accumulation and the resulting fracture of materials under cyclic loading at stress levels below the tensile strength are collectively referred to as *fatigue*. These phenomena are quite sensitive to materials structure, including crystal structure grain size, character and distribution of grain boundaries, dislocation density and arrangement, internal stress, texture, surface quality, etc. Additional complexity is introduced by a wide variability of testing and service conditions, including environments. Various factors can be of greater or lesser importance for different aspects of fatigue. However, grain size can be regarded as a key structural factor affecting nearly all aspects of fatigue. This is not surprising because the grain is the elementary structural unit of polycrystalline solids. Furthermore, grain size is known to strongly affect all known mechanisms of inelastic deformation, particularly dislocation slip and deformation twinning. Notably, without plastic deformation mechanisms leading to damage accumulation, there would be no fatigue.

The advent of nanocrystalline materials after the early work by Gleiter<sup>[1]</sup> opened new horizons for the discovery and design of new materials with unusual properties, as well as opportunities for scientific investigation of potentially novel mechanisms heretofore unobserved in classical materials systems. The purpose of the present entry is to review the state-of-the-art within both of these contexts, as investigations of the fatigue behavior of nanocrystalline (NC) materials have been motivated by the possibility that NC materials will have enhanced fatigue resistance, as compared to their coarse-grained counterparts, as well as basic a desire to understand the fundamental mechanisms of deformation and fracture in nanoscale.

Before discussing the fatigue behavior of NC materials, it is useful to briefly outline why the properties, in general, and fatigue response, in particular, of NC materials are considered unique.

1. Nanomaterials are at the “interface” between amorphous and ordinary crystalline solids. Some authors (such as Gleiter)<sup>[1]</sup> have entertained the notion that their structure might be considered a two-phase composite consisting of small perfect crystalline regions of nano-dimensions surrounded by relatively thick glassy-like grain boundaries (Fig. 1). Hence NC materials may inherit some properties from both crystals and glasses, while potentially remaining distinct from both of these extremes.
2. The number of atoms associated with grain boundaries can approach the number of atoms within the grain interior. Another way of stating this is that the volume fraction of grain boundaries can become as large as 50%. Thus the grain boundaries and their specific structure and properties will play a very important role in most, if not all, properties of NC materials.
3. Finally, a grain size of the order 100 nm corresponds to the structural level obtained within severely deformed metals. Specifically, the defects accommodating plastic deformation (dislocations) self-assemble into the collective structures with a characteristic length-scale in tens of nanometers.

A variety of techniques have been developed in the past decade for manufacturing nanomaterials (see Ref.<sup>[2]</sup> for a review). Among these, some of the more important are inert gas condensation, electrodeposition, devitrification from an amorphous precursor obtained by rapid solidification or ball milling, and severe plastic deformation (SPD) (see entry on “Nanocrystalline Substances: Synthesis and Properties”). The present entry emphasizes the latter approach because severe plastic deformation for grain reduction has the advantage of producing of fully dense, bulk ultra-fine grain (UFG) and NC materials with desired purity or target composition. In other words, SPD allows one to produce material suitable for investigation of fatigue behavior using classical testing methods and possessing

**Fig. 1** Schematic presentation of the atomic structure of nano-materials: two-phase composite structure of crystalline grains and disordered glassy-like grain boundaries. *Source:* From Ref.<sup>[1]</sup>.

dimensions large enough for structural applications, where fatigue properties are of interest. Among SPD techniques, the equal channel-angular pressing (ECAP) technology introduced by Segal<sup>[3]</sup> as a cold (or warm) working technique allows extremely large strains to be imposed on bulk samples without fracture. The technique has proven to be capable of fabricating massive samples with a variety of UFG and nanostructures. As the majority of experimental results concerning fatigue of nanocrystals have been obtained on ECAP materials so far, the present review will primarily be concerned with these materials.

ECAP is performed by passing a billet through two intersecting channels of the same cross section. Severe plastic deformation occurs by simple shear on the plane of intersection between the channels. Because the cross-section geometry does not change during processing, ECA pressing can be repeatedly performed through various routes determined by possible rotations of the billet between subsequent passes. With repeated pressing, the material hardens dramatically so that unusually high strengths can be achieved. Ideally, the resultant strain imposed per ECA pass is controlled by the included angle between channels  $2\theta$  solely (given sharp die channel corners), and the cumulative shear strain  $\Gamma$  after  $N$  passes is  $\Gamma = 2N \cot \theta$ . The effective strain is given by  $\varepsilon_i = 2N \cot \theta / \sqrt{3}$ .<sup>[3]</sup> Thus when the tool angle  $2\theta = 90^\circ$ ,  $\Gamma = 2N$  and the amount of the imposed strain can be substantially higher than is usually attained in standard cold-working procedures, such as rolling.<sup>[3]</sup>

## BACKGROUND

### Fatigue Life Characterization

Total fatigue life of smooth bodies has been conventionally divided into two regions corresponding to

the time required for crack nucleation and propagation.<sup>[4,5]</sup> The resistance to crack initiation naturally requires strength, while the tolerance to the crack advance requires ductility. The most promising feature of SPD materials, which suggests the possibility of obtaining significantly enhanced fatigue properties, is associated with a combination of high strength and good ductility in the nanostructured state.<sup>[2,6,7]</sup> Low-cycle fatigue (LCF) and high-cycle fatigue (HCF) regimes are conventionally distinguished in accord with applied strain amplitude. HCF testing corresponds to probing a material's resistance to crack initiation, whereas LCF testing corresponds to assessing the material's defect tolerance. Combining these two regimes, it is convenient to consider the total strain range  $\Delta\varepsilon_t$  consisting of two components—elastic  $\Delta\varepsilon_{el}$  and plastic  $\Delta\varepsilon_{pl}$ . The empiric Coffin–Manson relationship relates the total fatigue life (number of cycles to failure  $N_f$ ) to  $\Delta\varepsilon_{pl}/2$  as

$$\frac{\Delta\varepsilon_{pl}}{2} = \varepsilon_f'(2N_f)^c \quad (1)$$

where  $\varepsilon_f'$  is the fatigue ductility coefficient (which is often found to be approximately equal to the true fracture ductility  $\varepsilon_f$  in monotonic testing<sup>[4,5]</sup>) and  $c$  is the fatigue ductility exponent. Similarly,  $\Delta\varepsilon_{el}/2$  is related to the number of reversals to failure according to the Basquin law as

$$\frac{\Delta\varepsilon_{el}}{2} = \frac{\sigma_f'}{E}(2N_f)^b \quad (2)$$

where  $E$  is the Young's modulus,  $\sigma_f'$  is the fatigue strength (which is supposed to be related to the yield stress or the ultimate tensile strength of the material), and  $b$  is the Basquin exponent. Hence the fatigue life under a given total strain is expressed in terms of materials constants  $\varepsilon_f'$ ,  $\sigma_f'$ ,  $c$ , and  $b$

$$\frac{\Delta\varepsilon_t}{2} = \frac{\sigma_f'}{E}(2N_f)^b + \varepsilon_f'(2N_f)^c \quad (3)$$

Although a simple equivalence of the pair  $\varepsilon_f'$  and  $\sigma_f'$  to the tensile ductility and  $\sigma_{UTS}$ , respectively, is rarely observed in experiments, the correlation between these pairs of qualities often exists. Eq. (3) is schematically illustrated in Fig. 2 for the fine-grain ECAP AlMgSc alloy. At high strains corresponding to short lives, the plastic strain component is dominant in the total applied strain and the fatigue life is primarily determined by ductility. At long fatigue lives, the elastic strain amplitude is more significant than plastic and fatigue life is dictated by the fracture strength so that the endurance limit increases with strength.<sup>[3,4,8]</sup> Unfortunately, in most cases, ductility is sacrificed as the highest strength levels are achieved. This rule holds

**Fig. 2** Strain-life diagram. Solid line corresponds to Eq. (3) with experimentally obtained parameters of Coffin–Manson and Basquin law for the ECAP Al–4.5Mg–0.2Sc–0.2Zr alloy. Experimental points for this alloy are also plotted.

for most high-strength nanomaterials as well, and those fabricated by inert gas condensation, devitrification from the glassy state, powder compaction, etc. are usually so brittle that their potential is limited. Similarly, the simultaneous enhancement of both HCF and LCF lives is challenging, and inevitably requires a balance between strength and ductility.<sup>[4,8]</sup> It has been shown<sup>[5,6,9]</sup> that nanomaterials manufactured by severe plastic deformation can, in principle, significantly benefit from spectacular improvement of both the strength and ductility.

For a comprehensive assessment of fatigue response, one also needs to evaluate the crack growth rate under a given stress intensity range  $\Delta K$  and loading cycle asymmetry  $R = \sigma_{\max}/\sigma_{\min}$ , where  $\sigma_{\max}$  and  $\sigma_{\min}$  are the maximum and minimum applied stress, respectively. This information is of primary concern for engineering. Furthermore, an in-depth analysis involves characterization of the stress–strain hysteresis loop. In the present review, we briefly address all these issues as they apply to NC materials.

### Effect of Grain Size on Fatigue

To describe the effect of grain size  $d$  on fatigue, it is necessary to specify how the grain size relates to the material's resistance to crack initiation and propagation, i.e., to quantify the effect of  $d$  on fatigue life parameters such as  $\epsilon'_f$ ,  $\sigma'_f$ ,  $c$ ,  $b$ , and the fatigue limit  $\sigma_f$ , defined as the peak cyclic stress below which no fatigue failure occurs prior to  $10^7$  or  $10^8$  cycles. The influence of grain size on the fatigue of conventional polycrystalline materials has been investigated and reviewed on many occasions (see, for example, Refs.<sup>[4,5,10–14]</sup>). Most observations can be summarized in two sentences.

1. The fatigue limit of pure face-centered cubic (f.c.c.) metals is not affected by the grain size.
2. The fatigue strength of materials exhibiting planar slip increases with decreasing grain size and follows the Hall–Petch relationship, shown below, in the same way as the yield stress in conventional polycrystals.

$$\sigma_f = \sigma_{of} + K_f d^{-1/2} \quad (4)$$

where  $\sigma_{of}$  and  $K_f$  empiric materials properties.

It has been concluded that one of the most important fundamental material characteristics governing fatigue is the slip character. During LCF, the wavy-slip materials form a well-defined cell structure, with the cell size being dependent upon the saturation stress and independent of the preliminary strain history.<sup>[4,5,10–12]</sup> Materials with a planar slip do not form a cell structure, and the dislocations are arranged in planar arrays extending across a grain. That grain size has a more pronounced effect on the fatigue behavior of planar slip materials has been convincingly demonstrated by Tomson and Backofen<sup>[11]</sup> by using pure copper (wavy slip) and  $\alpha$ -brass (planar slip). Mughrabi<sup>[14]</sup> suggested extending this standpoint to UFG metals as well.

Indeed, the fatigue limit  $\sigma_f$  of UFG wavy slip aluminum alloys is not improved after multiple ECA pressing despite a remarkable enhancement of their monotonic strength, as will be discussed in more detail below. Results on commercial purity copper vary notably from modest to high  $\sigma_f$  improvement, depending, possibly, on fabrication (number of ECA passes, strain path, etc.). However, the independence of the grain size in coarse-grain wavy slip f.c.c. metals appears to be related to a specific cell structure formed during cycling. Because the typical grain/cell size in the SPD metals of 100–300 nm is smaller than the typical fatigue cell size in coarse-grained metals ( $\sim 500$  nm), exceptions to the classical rules may be anticipated.

A small grain size can result in more homogeneous deformation, which can retard crack nucleation by reducing stress concentrations and ultimately raise the fatigue limit of the material. It has been reported<sup>[15]</sup> that the fatigue limit follows the Hall–Petch relationship with decreasing grain size in the same way as the ultimate tensile strength  $\sigma_{UTS}$  until critical grain size is attained, below which the slope of the  $\sigma - d^{-1/2}$  curve is decreased. Consider NC copper with a grain size  $d = 20$  nm,  $\mu = 45$  GPa, and  $b = 2.5 \times 10^{-10}$  m. An estimate of the stress required for dislocation multiplication (where the source length is assumed to be one-half the grain size,  $d$ )  $\tau \geq 2\mu b/d = 12$  GPa, which is approximately equal to the theoretical strength  $\sigma_{\text{theor}} = E/10$ , where  $E$  is the

**Fig. 3** Bright-field TEM images illustrating the equiaxed (A) and elongated (B) UFG structures after ECAP (Fe–36Ni Invar alloy after 8 and 12 ECA passes, respectively). Arrows indicate the extrusion direction.

Young's modulus of the material ( $E = 120$  GPa for copper). In other words, dislocation activity within nanocrystalline grains is expected to be extremely difficult, which explains their frequently observed brittleness. On the other hand, there have been suggestions that the plasticity of NC materials may be associated with mechanisms other than perfect dislocation motion. Hence there may be an optimum grain size in the nanoscale region, where the maximum monotonic and cyclic strength is reached. Because the volume fraction of grain boundaries is comparable with the volume of grains, for very small grain sizes, there have been numerous suggestions that the deformation might localize within an amorphous grain boundary region, depicted in Fig. 1. Youngdahl et al.<sup>[17]</sup> concluded that the deformation of nanocrystalline copper with a mean grain size between 30 and 100 nm produced by gas condensation and compaction occurs as a result of dislocation activity. No evidence for grain boundary sliding or rotation was found in their in situ transmission electron microscopy (TEM) experiments.

Experimental results concerning the cyclic behavior are currently available for various UFG SPD metals such as: 1) pure Cu<sup>[18–28]</sup> and Ni<sup>[29]</sup>—the most studied representative wavy-slip materials; 2) single-phase solid solutions—AA5056 Al–Mg alloy<sup>[30,31]</sup> and Fe–36Ni (Invar) alloy,<sup>[32,33]</sup> 3) Ti,<sup>[34,35]</sup> which is a typical example of hexagonal close-packed (h.c.p.) metals exhibiting planar-slip; 4) precipitation hardenable CuCrZr alloy,<sup>[36]</sup> 6061 Al–Mg alloy,<sup>[37]</sup> Al–Mg–Sc alloys,<sup>[38]</sup> and low-carbon steel.<sup>[39]</sup> Brief reviews of the fatigue life of ECAP metals have been reported.<sup>[16,33]</sup> Details of preparation and ECA processing are in the above-cited publications.

## STRUCTURE OF ECAP METALS

Before reviewing the cyclic behavior of UFG materials, it is useful to first observe the microstructure prior to

and after fatigue. A typical UFG structure after ECAP is shown in Fig. 3A. Let us briefly summarize the microstructural features of nanocrystalline materials fabricated by SPD, which are most relevant to fatigue. (See Ref.<sup>[2]</sup> for a comprehensive review.)

1. The average grain size ranges from 100 to 350 nm, depending on the particular metal or alloy. The grain size distribution is often broad, depending on the details of the processing. The largest grains in the grain size distribution can be as large as 1–5  $\mu\text{m}$  after SPD. It is emphasized that the grain boundaries are often hardly visible in TEM bright- or dark-field images.
2. Whether the grains are primarily separated by low- or high-angle boundaries remains an issue of some dispute. Some authors claim high-angle boundaries on the basis of qualitative indications of selected area electron diffraction patterns (SAEDP).<sup>[2]</sup> Others have performed more statistical studies using scanning electron microscopy (SEM)-based electron back scattering diffraction (EBSD), or a similar TEM-based Kikuchi pattern analysis.<sup>[40–42]</sup>
3. Two major structural types can be distinguished by the grain shape: a rather uniform structure with nearly equiaxed grains (Refs.<sup>[1,25]</sup> and references therein) (Fig. 3A), and a kind of fragmented structure with significantly elongated grains (Fig. 3B).
4. There is a great deal of stored energy in these systems associated with dislocations and their structures. Despite the very high average dislocation densities ( $10^{13}$ – $10^{15} \text{ m}^{-2}$ ) commonly observed in these materials by TEM,<sup>[2,43]</sup> it is noted that the interiors of the smaller grains appear to be free of dislocations. Thus it has been surmised that the dislocations may largely be incorporated within the boundaries themselves. These lattice strains associated with these defects are best characterized by using X-ray

**Fig. 4** Abnormal grain growth in cyclically deformed ECAP copper ( $\Delta\epsilon_{pl}/2 = 5 \times 10^{-3}$ ) (A) and ladder-like dislocation walls formed in the enlarged grains in the course of fatigue (B).

diffraction techniques associated with the broadening of Bragg peaks,<sup>[29]</sup> and frequently identified as root mean squared (rms) strains in that analysis.

5. Because of the large stored energy, microstructural instability is often a hallmark of NC materials. After cyclic deformation, a variety of structural changes have been observed in ECAP metals.
6. The most striking feature of the postfatigue structure pure wavy slip SPD metals is the grain coarsening and abnormal grain growth triggered by cyclic deformation (Fig. 4A). This phenomenon has been noticed in many publications dealing with pure Cu and Ni.<sup>[20–25,29,41]</sup> Recovery, recrystallization, and grain growth can be largely suppressed by limiting the mobility of grain boundaries as well as controlling the ease of relaxation by dislocation climb or cross-glide. Solid solutions and h.c.p. metals are rather stable and no substantial grain growth is observed in the Invar alloy<sup>[24]</sup> (Fig. 5), and Ti after fatigue.<sup>[23]</sup> Grain coarsening in

the 5056 Al–Mg alloy depends on the processing and can be negligible.<sup>[7]</sup>

7. For some materials, the average dislocation density in the central part of the grains may remain unaltered, being of the order of  $10^{12}$ – $10^{15} \text{ m}^{-2}$ . However, the grain boundaries themselves appear more distinct after cycling in all materials examined (e.g., Fig. 5). This seems to be the only noticeable structural change in fatigued Ti, Al–Mg, Cu–0.44Cr–0.2Zr, and Invar alloys, and it may be associated with a reduction in the dislocation density in the immediate vicinity of the grain boundaries.
8. A decrease in the internal stresses during the course of fatigue has been carefully demonstrated by Thiele, Holsten, and Klemm<sup>[29]</sup> for UFG Ni, and by Wang et al.<sup>[25]</sup> for UFG Cu using the X-ray technique. Some of the changes observed by X-ray diffraction may be associated with grain coarsening as well. The evolution of the grain size distribution calculated from the X-ray peak broadening is shown in Fig. 6 for different stages of fatigue of ECAP Cu.

**Fig. 5** TEM photos showing the structure of ECAP Invar alloy (8 ECA pressings, compare Fig. 3A) after fatigue at  $\Delta\epsilon_{pl}/2 = 5 \times 10^{-3}$ . Low dislocation density is observed in some grains (B). Arrows indicate the loading axis that is aligned with extrusion direction.

### HIGH CYCLE FATIGUE BEHAVIOR

Tensile and HCF properties of a variety of ECAP materials are summarized in Table 1. The enhancement

of HCF life in terms of fatigue limit is achieved for most NC materials, as has been expected merely from the improvement of monotonic strength after grain refinement (“Introduction”). The scatter in experimental data obtained by different researchers on UFG Cu is caused by a variety of manufacturing conditions in different laboratories, resulting in a variety of actually imposed strain and resulting microstructures. (Examples of the Wöller plots for two types of ECAP Cu having the equiaxed and elongated grain structure similar to those shown in Fig. 3 are given in Fig. 7A.) As suggested in the section “Background,” a very pronounced improvement of the fatigue limit is observed in a planar slip material, ECAP Ti, processed at elevated temperature (400°C) and then subjected to further strengthening by cold-rolling to 75% area reduction and annealed for structural stabilization at 300°C for 1–2 hr<sup>[35]</sup>. The fatigue limit of 500 MPa in pure SPD titanium is close to that of conventional Ti alloys (Fig. 7B). The impressive improvement of the fatigue strength in the peak-aged ECAP Cu–0.44Cr–0.2Zr alloy<sup>[36]</sup> (Fig. 7A) is also worth noting in comparison with other commercial Cu-based alloys

and tempers. The combination of affordable electric conductivity, thermal conductivity, and thermal stability with high tensile and fatigue strength make this multifunctional material attractive for a variety of electromechanical applications. The experimental data reveal that the ultimate tensile strength and the fatigue limit of NC SPD metals follow the Hall-Petch relationship<sup>[4]</sup> (Fig. 8). Hence it is concluded that NC materials fabricated by SPD generally demonstrate a great potential for enhancement of high cycle fatigue life, in full agreement with the analysis given in the sections “Introduction” and “Background,” Eq. (6), and Fig. 2.

Markushev and Murashkin<sup>[48]</sup> have reviewed the effect of grain refinement via SPD on the mechanical properties of commercial Al alloys, and concluded that SPD, in general, is not very effective for strength or fatigue improvement of Al alloys. The results of Chung et al.<sup>[37]</sup> on solution treated 6061 Al alloy typify the finding that multiple ECAP does not significantly improve the fatigue limit of Al alloys; however, they demonstrated notable improvement of fatigue limit just after the first pass through the die (note that they did not employ a standard heat treatment for

Fig. 8 Hall-Petch behavior of the ultimate tensile strength (for Fe-36Ni alloy) and fatigue limit (for Fe-36Ni and Ti) of ECAP metals.

precipitation hardening). Strengthening via grain refinement by SPD may be masked by other strengthening mechanisms on one hand and, on the other, the redistribution of phases and alloying elements can give rise to grain boundary brittleness and loss of ductility at room temperature. It is noted that grain refinement of Al alloys via SPD has proven extremely valuable for inducing superplasticity at elevated temperatures in a large number of alloy systems.<sup>[49,50]</sup>

## LOW CYCLE FATIGUE BEHAVIOR

At relatively large plastic strain ranges from 10<sup>-4</sup> to 10<sup>-2</sup> and short fatigue lives, the cyclic response of UFG materials is described by the Coffin-Manson law.<sup>[1]</sup> as illustrated in Fig. 9 for UFG Cu and 5056 Al-Mg alloy. Although the data in Fig. 9A are compiled from the results obtained by different researchers on differently processed samples, one can see a reasonable agreement between these results. Samples in the as-received state after ECAP demonstrate notable degradation in low cycle fatigue (LCF) life when compared to the ordinary coarse-grain samples. This is not surprising in view of their lower ductility and poor resistance to macroscopic and microscopic plastic instabilities such as necking, shear banding, cracking, etc. Such behavior is typical of metals with low levels of strain hardening (recall Considères criterion). As will be discussed in detail below, a postprocessing heat treatment can significantly improve the LCF properties. Remarkably, UFG Ti obtained by ECAP did not reveal a significant degradation in low-cyclic fatigue performance in the plastic strain controlled testing, and the Coffin-Manson lines were practically indistinguishable for the samples before and after ECAP<sup>[35]</sup> This result agrees with the general observation in the

**Fig. 9** Coffin–Manson plots for ultrafine grain Cu (A) and 5056 Al–Mg alloy (B) obtained by SPD (reprinted with permission). Arrows indicate the improvement of fatigue life after post-ECAP heat treatment. *Source:* From Ref.<sup>[30]</sup>.

sections “Introduction” and “Background,” that non-f.c.c. metals can exhibit greater improvement in their fatigue performance if both LCF and HCF regimes is of major concern.

**Cyclic Softening and Hardening**

The cyclic stress–strain curves (CSSC) of NC materials can be represented by a power law in the same way as for other polycrystalline metals (see Refs.<sup>[4,5]</sup> and references therein).

$$\sigma_a = K'_b (\Delta \epsilon_{pl}/2)^{n'_b} \tag{5}$$

This relation is essentially the same as that used to describe the monotonic stress–stress curve

$$\sigma = K \epsilon^n \tag{6}$$

where  $K'_b$ ,  $n'_b$ ,  $K$ , and  $n$  are materials constants, and the subscript index  $b$  stands for the basic CSSC. Fig. 10 summarizes some currently available cyclic stress strain data for ECAP metals. It has been observed in a former communication<sup>[32]</sup> that the slopes of the CSSC in logarithmic scale for the same material

**Fig. 10** Basic cyclic stress–strain curves for several UFG ECAP metals.

(Fe–36 Ni Invar alloy) subjected to different number of ECA pressings between 2 and 12 are approximately the same, i.e., the cyclic strain hardening exponent  $n'_b$  values are nearly equal for all samples regardless of the preimposed strain. Fig. 11 compares the monotonic and CSSC for ECAP Fe–36 Ni Invar alloy (only the initial part of the tensile stress–strain curve is shown). The relative position of the monotonic and cyclic stress–strain curves delivers information on the materials cyclic hardening/softening behavior under different strain amplitudes. In the region of strain amplitudes where the CSSC lies above the monotonic strain–stress curve, the material cyclically hardens.<sup>[5]</sup> On the other hand, in the regions where the CSSC is positioned below the monotonic stress–strain curve, the material cyclically softens. Hence it becomes obvious that the ECAP materials are prone to cyclic softening at any imposed plastic strain amplitude.

**Fig. 11** Fragments of tensile stress–strain curves and CSSC for ECAP Fe–36Ni Invar alloy after 2 and 12 ECA passes. *Source:* From Ref.<sup>[32]</sup>.

Nanocrystal – Nanocrystals

**Fig. 12** Cyclic hardening/softening curves of some selected SPD metals with UFG structures. *Source:* From Ref.<sup>[33]</sup>.

Softening is common for cyclic deformation of pre-strained f.c.c. metals.<sup>[4,5,51]</sup> It has been also clearly observed in many ECAP f.c.c. metals such as copper,<sup>[20–22,26]</sup> Ni,<sup>[29]</sup> single-phase Al–Mg 5056<sup>[30,31]</sup> and Fe–36Ni Invar alloys,<sup>[32]</sup> and precipitation-hardened Cu0.44Cr0.2Zr alloy.<sup>[36]</sup> However, the detailed characteristics of cyclic softening, its phenomenology, and microscopic mechanisms vary broadly depending on the material and processing. Fig. 12 shows the cyclic hardening–softening curves for various NC ECAP metals tested under plastic strain control. The very first investigations of LCF behavior of ECAP materials revealed that the cyclic response strongly depends on processing and the initial UFG structure. Vinogradov et al.<sup>[18]</sup> observed no cyclic softening in ECAP Cu under plastic strain amplitudes  $\Delta\epsilon_{pl}/2 = 5 \times 10^{-4}$  and  $10^{-3}$ . Furthermore, some light hardening was noticed on the early stage of straining (Fig. 12). However, Agnew and Weertman<sup>[20]</sup> observed pronounced cyclic softening in similar UFG Cu produced by ECAP. The degree of softening appears to depend on the temperature, time, and plastic strain amplitude, and can vary from material to material.<sup>[23]</sup> The mechanism of cyclic softening of UFG f.c.c. metal is largely associated with a complex effect of dislocation recovery, cyclically induced dynamic “recrystallization,” and grain coarsening, which is more pronounced at higher strain amplitudes.<sup>[17–21,23,25,27]</sup> Interestingly, cyclic softening and the associated coarsening facilitates the formation of dislocation structures typical for ordinary metals, i.e., cellular and ladder-like dislocation arrangements<sup>[20,23]</sup> (Fig. 4B). Thiele et al.<sup>[29]</sup> performed a detailed structural investigation of the fatigue-induced structures in UFG Ni and the dependence of the grain size. Using X-ray diffraction peak profile analysis, they detected a reduction of internal stresses in the course of cycling. It was demonstrated

that there is a lower threshold grain size  $d_{th}$  of 1  $\mu\text{m}$ , above which dislocation patterning takes place with a length scale ( $\sim 500$  nm) nearly independent of the initial grain size. For materials with  $d < d_{th}$ , the cyclic stress–strain curve obeys the Hall–Petch relation.

Not surprisingly, the SPD structure can be stabilized and the rate of cyclic softening can be reduced by: 1) annealing at an intermediate temperature, i.e., reducing the stored strain energy prior to cyclic loading;<sup>[19,22,26,30,33,44]</sup> 2) using solid solution alloys instead of pure metals;<sup>[31,32]</sup> and 3) precipitation.<sup>[36]</sup> The numerous large-scale shear bands, which are observed in the fatigued ECAP Fe–36Ni alloy, may contribute to the cyclic softening in that alloy. Höppel and Mughrabi,<sup>[55]</sup> using Vickers microhardness measurements, have convincingly shown that the material in the shear band of a cyclically deformed ECAP Cu sample is softer than its surroundings. The values are in line with the concept of cyclically induced dynamic recrystallization and grain growth.<sup>[22,23,26]</sup> Similar measurements have been performed by Vinogradov on the fatigued ECAP Fe–36Ni alloy. It has been demonstrated that the main reason for rapid cyclic softening of the UFG under- or peak-aged CuCrZr alloy (Fig. 12) is related to dislocation cutting of the fine strengthening precipitates.<sup>[36]</sup> The degree of softening is substantially lowered in overaged samples; however, the monotonic mechanical properties (strength and ductility) are degraded in this case.

## FATIGUE DAMAGE AND STRAIN LOCALIZATION

Internal stresses in metals increase during monotonic straining, finally leading to microvoid nucleation or crack initiation as the resources of plastic deformation exhaust in local volumes of the material. Thus it may come as a surprise to some readers that the cyclic deformation of UFG metals fabricated by SPD may reduce the level of internal stress (as indicated by X-ray diffraction measures of rms strains<sup>[29]</sup> and the general cyclic softening behavior referred to above), yet the end result is still a fatigue fracture. The answer, in its general form, is actually trivial: fracture occurs as a result of inhomogeneity in the plastic deformation manifesting itself as strain localization. The gradients of plastic deformation are often connected with grain boundaries, which may serve as barriers to dislocation motion as well as effective sources and sinks of lattice dislocations. These concepts are supported by atomic force microscopy (AFM) observations of fine traces of plastic deformation in UFG copper and nickel where: 1) dislocation activity is particularly visible at the grain boundaries,<sup>[16,33,52]</sup> and 2) dislocation slip is terminated at the grain boundary and is not transferred to an adjacent grain. TEM observations have

also demonstrated some reduction of the dislocation density near the grain boundary during fatigue (compare Fig. 5A and B, for example). Reducing the excess dislocation density around grain boundaries may explain the observed cyclic softening and the decrease of root mean square internal stress levels and, ironically, it may ultimately promote intergranular cracking. Fracture surface analysis and the surface crack morphology shows that failure in the SPD metals indeed occurs intergranularly.<sup>[16,32,35]</sup>

Strain localization in the ECA-processed materials is frequently observed during both monotonic and cyclic deformation.<sup>[10–15,44]</sup> Fig. 13 shows shear bands oriented at 45° to the loading axis in pure Cu after fatigue at  $\Delta\epsilon_{pl}/2 = 5 \times 10^{-3}$  and 5056 Al–Mg alloy after monotonic deformation. These bands commonly appear shortly after yielding in tensile deformation or at the end of saturation in cyclic testing. Fatigue cracks initiate and propagate along this kind of shear band (Fig. 13A).<sup>[25]</sup> Although shear banding is the major form of fatigue damage in wavy-slip UFG materials, these bands play a twofold role in fracture: on one hand, they promote crack nucleation due to strain localization and stress concentration; on the other hand, they reduce the overall elastic stresses, as evidenced by the reduction in stress at the end of saturation in strain controlled tests. Therefore it is unclear if suppression of the susceptibility to shear banding would delay or accelerate fatigue failure because cracking is a likely alternative mechanism for stress relaxation when other plastic mechanisms are exhausted. For instance, in UFG titanium or precipitation-hardened CuCrZr alloy, large-scale shear bands are not observed. However, a large population of surface microcracks is observed on the late stage of fatigue.

The microstructural nature of shear bands has been investigated in detail, at least for UFG Cu. Agnew et al.<sup>[21]</sup> observed that the shear bands in UFG copper appear like ordinary persistent slip bands (PSBs) in coarse-grain poly- and single crystals. For instance, the shear bands were removed by electropolishing, and then they reappeared on the same places during subsequent cyclic loading, indicating materials

softening associated with shear bands. Furthermore, careful structural observations have shown that the shear bands in UFG copper can have essentially the same ladder-like dislocation structure as the PSBs in ordinary crystals. The TEM image shown in Fig. 4B demonstrates the dislocation walls separated by dislocation-free channels in fatigued UFG copper. Höppel et al.<sup>[23]</sup> investigated the microstructural aspects of shear banding in UFG copper, including the dependence of strain amplitude and temperature, and have found that grain coarsening and shear banding are more pronounced at high strain amplitudes, which agrees with the observed faster cyclic softening. Thus pure f.c.c. UFG metals first exhibit relaxation and coarsening during cyclic softening, along with the formation of the low-energy configurations typical of conventional fatigued crystals, i.e., ordinary PSBs may occur. Finally, microcracks appear to initiate on intrusions and then behave similarly to those in conventional metals.

Although a similar scenario is applicable to those UFG metals exhibiting considerable grain coarsening during cycling,<sup>[16,21–23,29]</sup> conflicting observations have been reported by Vinogradov et al.<sup>[54]</sup> and Wu et al.,<sup>[27,28]</sup> who did not observe any gross structural coarsening in fatigued ECAP Cu. Furthermore, using TEM, SEM, and electron channeling contrast imaging (ECCI), it was shown that the dimensions of protrusions on the surface did not match the dimensions of the grains. In fact, numerous questions remain unanswered as to which elements govern the fatigue behavior in the complex UFG microstructure.

There are at least two kinds of plastic instabilities which manifest themselves in various NC metals under various testing conditions: 1) the PSB-like shear bands that appear during fatigue as a result of slow large-scale structural rearrangement involving grain coarsening as a prerequisite for ladder structure formation; and 2) the shear bands that arise both in monotonic and cyclic testing, and phenomenologically (if not structurally) resemble twinning events. Shear bands of the second kind are not crystallographic and are not microscopically straight (Fig. 14A). They emerge

**Fig. 13** SEM micrographs showing the shear bands in fatigued ECAP Cu (A) and in the tensile tested ECAP 5056 Al–Mg alloy (B). Final crack propagating along the shear band is shown in (A).

**Fig. 14** SEM image of the shear offset on the surface of fatigued Fe-36Ni ( $\Delta\epsilon_{pl}/2 = 3 \times 10^{-3}$ ) (A). AFM image illustrating the large-scale displacement of adjacent grains along the grain boundary in the shear direction (B). The dislocation slip in the grain interior is clearly visible.

very suddenly at free surfaces along grain boundaries in adiabatic fashion and are accompanied by significant acoustic emissions.<sup>[54,56]</sup> The possibility of grain boundary sliding at ambient temperature in UFG SPD materials has been speculated in the literature<sup>[2,43]</sup> in terms of enhanced diffusion and grain boundary mobility associated with heavily distorted grain boundaries. However, it is of particular importance to note the traces of dislocation slip of 1–10 nm height in the grain interior (Fig. 14B): that the slip lines are confined to a single grain, and the slip does not transfer through the boundary.<sup>[33]</sup> Thus the AFM observations<sup>[16,33,52]</sup> highlight the fact that conventional intragranular dislocation activity cannot be neglected as the most important mechanism of plastic deformation of UFG metals.

Shear bands in NCs may emerge to a free surface in a way similar to the shear bands commonly observed in metallic glasses during inhomogeneous plastic flow,<sup>[57]</sup> which is also accompanied by intensive acoustic emission,<sup>[58]</sup> and the morphology of shear bands in metallic glasses is very similar to that in NCs; however, this similarity may be completely coincidental because the concept of thick amorphous boundaries has not been justified by direct structural observations, particularly for metals fabricated by SPD. Wu et al.<sup>[25,27]</sup> and Vinogradov et al.<sup>[54]</sup> have found that the shear bands tend to align themselves with the plane of simple shear on the last ECA pressing, i.e., these bands are sensitive to the structure and its inhomogeneities formed during the last pass through the die. This leads to a conclusion that the careful control over processing (strain path, temperature, velocity, etc.) may allow control of the material's resistance to shear banding. Indeed, the nanostructure with equiaxed grains is less susceptible to rapid adiabatic shear banding than the structure with the grains (cells, fragments, etc.) elongated in the direction of last shear. Furthermore, UFG copper manufactured using different die sets (with round and rectangular corner) and different processing routes (but the same number of ECA passes and nearly the same grain size) exhibited different

shear banding susceptibility: the softer UFG copper, which saturated at 120 MPa and then cyclically softened at  $\Delta\epsilon_{pl}=1 \times 10^{-3}$ , did not reveal the shear bands during either cyclic or monotonic loading,<sup>[59]</sup> while the stronger copper saturated at 250 MPa and demonstrated many shear band on late stage of fatigue at the same plastic strain amplitude.<sup>[18,54]</sup>

Annealing of as-processed UFG copper at an intermediate temperature for a short time, which does not give rise to substantial grain growth, resulted in the disappearance of adiabatic shear bands and accompanying acoustic emission.<sup>[56]</sup> Despite the considerable difference in the microscopic mechanisms resulting in the two kinds of shear bands, they both appear as precursors of microcracks and serve as a preferred sites of crack nucleation.

## FATIGUE CRACK GROWTH

The fatigue life assessment of smooth bodies delivers only indirect information regarding resistance to flaws either pre-existing or forming in the course of cycling. Comprehensive understanding of fatigue properties requires evaluation of the fatigue crack growth. The attention to fatigue crack growth in NC materials is presently growing with the development of processing techniques capable of producing large enough samples from which to make the standard compact tension (CT) or center-cracked-tension (CCT) specimens. The kinetic diagram showing the crack growth rate  $da/dN$  vs. the stress intensity factor range  $\Delta K$  ( $\Delta K = Y\Delta\sigma\sqrt{\pi a}$ , where  $Y$  is the geometrical factor dependent upon the specimen and crack geometry,  $\Delta\sigma = \sigma_{max} - \sigma_{min}$  is the applied stress range, and  $a$  is the crack length) for a given stress ratio  $R$ , and environment is used commonly to quantify the fatigue crack growth behavior. We should underline that the  $da/dN$  vs.  $\Delta K$  plot for NC materials (Fig. 15) exhibits the same stages of a stable crack propagation as those well known for conventional polycrystals, i.e., a stage of slow crack advance in a near threshold region and

**Fig. 15** Crack growth rate diagram of the fine grain ECAP 5056 Al alloy in comparison with its coarse grain O-temper counterpart. *Source:* From Ref.<sup>[31]</sup>.

an intermediate stage, where the Paris relationship

$$\frac{da}{dN} = C(\Delta K)^m \quad (7)$$

(where  $C$  and  $m$  are materials properties) applies for most materials. Patlan et al.<sup>[30]</sup> found that the fatigue threshold  $\Delta K_{th}$  decreased after ECAP of a non-heat-treatable 5056 Al–Mg alloy (Fig. 15). Chung et al.<sup>[37]</sup> demonstrated very similar results for the UFG 6061 Al alloy and UFG ECAP low carbon steel.<sup>[39]</sup> It has been shown that the crack growth rate in the near threshold region is higher in the UFG state than in the ordinary polycrystalline state; however, the result is reversed at relatively high stress intensity factor increments  $\Delta K$ , i.e.,  $da/dN$  in UFG metals is smaller on the intermediate fatigue stage. Recently, Hanlon, Kwon, and Suresh<sup>[60]</sup> obtained similar results for electrodeposited NC Ni with grain size of 20–40 nm. The lower crack growth resistance in the near threshold regime was attributed to a less tortuous path of the intergranular crack in the UFG structure (Fig. 13A). One can see that the crack propagates nearly perfectly straight on stage I of fatigue and then, as the crack length and the related  $\Delta K$  value increase, the tortuosity of the crack path increases with numerous deflections and attempts to switch from mode II to mode I.

It has long been established in the fracture mechanics approach that the transition from the near-threshold slow crack growth regime to the intermediate fatigue stage is accompanied by a transition in the crack behavior from being strongly structure sensitive to structure insensitive. Such a transition is often observed when the crack tip cyclic plastic zone  $r_{cp}$ , which is estimated as

$$r_{cp} = \lambda \left( \frac{\Delta K}{2\sigma'_y} \right)^2 \quad (8)$$

(where  $\lambda$  is the numerical factor of the order of  $1/\pi$  and  $\sigma'_y$  is the cyclic yield stress determined from the CSSC) becomes of the same order as the grain size  $d$ .<sup>[4,61]</sup> If the stress intensity factor range corresponding to the transition point is denoted as  $\Delta K_T$ , the last equation yields a transition criterion  $r_{cp}(\Delta K_T) \approx d$ . However, estimations of a reverse plastic zone radius  $r_{cp}$  at the transition point return a  $r_{cp}$  value for the materials tested (Cu, 5056, and 6161 Al alloys), which is significantly greater than the average grain size  $d$ . For example, taking for A5056 Al–Mg alloy  $\sigma'_y = 280$  MPa and the threshold  $\Delta K = \Delta K_{th} = 4.3$  MPa  $m^{1/2}$ ,<sup>[31]</sup> one obtains  $r_{cp} = 7$ – $8$   $\mu\text{m}$ —which is considerably larger than  $d = 0.3$ – $0.4$   $\mu\text{m}$ . This suggests that a large number of neighboring grains may be involved into crack tip plasticity, even near threshold. Eq. (8) at the transition point can be simply rearranged as

$$\Delta K_T \sim \sigma'_y \sqrt{d^*} \quad (9)$$

[where  $d^*$  is a characteristic scale of a materials structural unit responsible for fracture (grain size, subgrain or cell size, particle size, etc.)], which predicts  $\Delta K_T$  to increase with  $d$ ; this effect is observed in low-carbon steels (for example, Refs.<sup>[4,61]</sup>). Assuming that threshold  $\Delta K_{th}$  approximately equals  $\Delta K_T$ , the last relationship is often written in a more general, but less-transparent and less-argued form as

$$\Delta K_{th} = A + B\sqrt{d^*} \quad (10)$$

where  $A$  and  $B$  denote materials constants. However, observations reported in Refs.<sup>[30,37,39,60]</sup> show the reduced  $\Delta K_{th}$  in UFG metals processed by SPD and NC metals, in general. If Eq. (9) were valid for these materials, a shift of  $\Delta K_{th}$  to lower magnitudes (1 MPa  $m^{1/2}$  in the 5065 Al alloy, for example) should be expected, which is far below the observed values (of 4–4.5 MPa  $m^{1/2}$  in the same Al alloy). These observations cast some doubt on the general applicability of a simplified plastic zone size concept to explain the fatigue transition behavior of materials. Higo, Pickand, and Knott<sup>[62]</sup> performed a systematic investigation of  $\Delta K_{th}$  and  $da/dN$  dependence on the grain size and the  $\sigma_{0.1}$  yield stress in Cu and Cu–Al alloy with different Al content, i.e., with different stacking fault energy ranged between 5 and 45  $\text{mJ m}^{-2}$  approximately. In contrast with the linear behavior of Eq. (9), they experimentally observed that the propagation rates were slower in the fine-grained materials and  $da/dN$  varied linearly with  $d^{-1/2}$  in the same manner as the  $\sigma_{0.1}$  yield stress, i.e., followed the Hall–Petch relationship, which is the reverse of Eqs. (9) and (10). These effects were pronounced in alloys with higher Al content, i.e., in planar slip metals where (we have stated) a stronger dependence of fatigue life on the grain size

is expected. Thus it is shown that although the fatigue crack growth behavior in NC metals reveals some similarity to that of conventional polycrystals, the quantitative explanation of the fatigue threshold reduction as well as the reduction of the crack growth rate at relatively high  $\Delta K$  is not straightforward. More experimental data are required in the following areas:

1. crack growth rate dependence on  $\Delta K$  at different  $R$  values for different materials (so far, data are only available for Al alloys);
2. precise investigations of fatigue crack closure; and
3. more precise experimental evaluation of the reverse plastic zone are required before the mechanism controlling the fatigue crack behavior will be identified. Despite a somewhat lower tolerance of the NC metals to small and sharp intergranular cracks (at least in Al alloys), these materials demonstrate a better resistance to large cracks, perhaps, because of a smaller plastic zone size, which in turn, according to Eq. (11), appears smaller because of a higher strength and cyclic yield stress.

## FATIGUE MECHANISMS IN UFG MATERIALS

The apparent similarity between the CSSCs in the coarse-grain and NC metals, which we have discussed above, suggests that the major deformation mechanisms are also alike for both kinds of materials. Thus before introducing any complication in the modeling of fatigue behavior of NC metals, one should first determine if it is possible to explain the mechanical properties of SPD metals via ordinary dislocation dynamics.

Many discussions have been put forward in the literature about the particular role of grain boundaries in the properties of UFG materials.<sup>[1,2]</sup> Obviously, the interfacial energy and higher diffusivity of grain boundaries cannot be disregarded for many phenomena (particularly in nanocrystalline materials). In fatigue of SPD metals, for instance, grain boundaries play a significant role. On one hand, the fine-grained structure usually possesses longer fatigue life—at least under stress controlled cycling—than the coarse-grain one. On the other hand, the grain boundaries appear to contribute to the relatively low stability of the UFG structure and the tendency toward recovery and grain coarsening during cycling. Furthermore, grain boundaries appear to play a role in the frequently observed shear banding as well as crack initiation and propagation. Therefore grain boundaries arguably represent the most critical structural element.

## Stress–Strain Response under Cyclic Loading

Despite the complexity of the nanocrystalline structures, the fatigue behavior of NC metals is, in many ways, more easily described than that of ordinary poly- and single crystals. The main reason for simplification is the lack of dislocation patterning in the UFG structures. Vinogradov et al.<sup>[30,35]</sup> have suggested that the shape of a stable hysteresis loop and the cyclic stress–strain curve can be described, at least semiquantitatively, by considering only the kinetics of the average dislocation density within the framework of a simplified one-parameter model first proposed by Essmann and Mughrabi<sup>[63]</sup> for dislocation annihilation. It was assumed that the mobile dislocations initiate at a grain boundary pass through the grain and disappear in the opposite grain boundary. Thus the grain boundaries act as effective sources and sinks for dislocations. Because TEM observations do not reveal any substantial difference between the initial and postfatigued structures, in some UFG metals, it is plausible to suggest that dislocations do not accumulate inside the fine grains during cycling in these cases. Following Essmann and Mughrabi<sup>[63]</sup> and Mughrabi,<sup>[64]</sup> a kinetic equation for dislocation density,  $\rho$ , can be written in its simplest form as

$$\frac{d\rho}{d\gamma} = \frac{2}{bL} - \frac{2}{b}y\rho \quad (11)$$

where  $L$  is the slip path of dislocations with the Burgers vector  $b$  and  $y$  is the so-called annihilation length. The first term on the right-hand side of Eq. (11) describes the rate of dislocation multiplication with the strain increase, while the second term accounts for the strain-induced decrease of dislocation density (dislocation dynamic recovery and annihilation of a general kind). At large enough strains, saturation is attained because of the equilibrium between the dislocation multiplication and annihilation,  $d\rho/d\varepsilon = 0$ .

To describe the stress–strain relationship, we assume that the shear flow stress,  $\tau$ , is controlled by the average total dislocation density as

$$\tau = \tau_0 + \alpha\mu b\sqrt{\rho} \quad (12)$$

where  $\tau_0$  is the friction stress,  $\alpha$  is a geometrical factor of the order of 0.5, and  $\mu$  is the shear modulus. For numerical estimations, one can take  $\tau_0$  as equivalent to the cyclic shear yield stress ( $\sigma_0 \approx 240$  MPa). Combining Eqs. (11) and (12) results in an elementary differential equation, which can be solved analytically assuming  $y$  and  $L$  do not vary with straining. While the assumption concerning the constancy of the annihilation distance seems reasonable, and has been experimentally justified (at least for Cu,<sup>[63]</sup>), the

assumption regarding  $L$  is considerably less obvious. Adopting  $L = \text{const}$  condition for the sake of simplicity one can, however, propose a few arguments in a favor of this suggestion. For the cell structure, which is typical of conventional polycrystals, the slip path has been related to the cell diameter. In UFG materials, the grain size is smaller than the typical cell size, and the grain boundaries form the main barriers for dislocation motion. Therefore it is plausible to relate the dislocation mean free path to the average grain size if the grain size is small enough. Integration of Eq. (14) together with Eq. (12) and  $\tau(0) = \tau_0$  as an initial condition yields

$$\tau = \tau_0 + \alpha\mu b \sqrt{\frac{1 - \exp(-2\gamma\gamma/b)}{Ly}} \quad (13)$$

The saturation stress  $\tau_s$  at sufficiently high strain  $\gamma \gg b/y$  takes the form

$$\tau_s = \tau_0 + \frac{\alpha\mu b}{\sqrt{Ly}} \quad (14)$$

As an example, a typical ascending part of the stable hysteresis loop of the 5056 Al alloy is plotted in Fig. 16 in the so-called relative coordinates<sup>[5]</sup>  $\sigma_r - \varepsilon_{pl,r}$ , where the loop is displaced in such a way that the tip of the compressive half-loop comes to the origin coordinates, and both half-loops are treated as identical. The non-linear curve fit of experimental points by function (13) with two fitting parameters— $L$  and  $y$ —provides a good agreement between the experimental and calculated loops with  $L$  and  $y$  of  $(1.2 \pm 0.6) \times 10^{-7}$  and  $(8.4 \pm 3.0) \times 10^{-9}$  m, respectively (Fig. 16). The ordinary relations between shear and nominal stress–strain characteristics— $\sigma = M\tau$  and  $\varepsilon = \gamma/M$  with  $M \approx 3$  as the geometrical Taylor factor—are adopted. It is worth noting that the mean free pass of dislocations  $L$  appears to be of the order of the half-grain (cell) diam-

**Fig. 16** Results of modeling of the hysteresis loop shape and CSSC of UFG 5056 Al-alloy within the frames of a single-parametric kinetic dislocation model. *Source:* From Ref.<sup>[30]</sup>.

eter  $d$ , which is in fair agreement with the assumptions made above.

Analogously, by using Eq. (14), one can calculate peak stresses,  $\sigma_s$ , at different plastic strain amplitudes examined, giving an approximation of the cyclic stress–strain curve (Fig. 8).<sup>[30,35]</sup> Because of the simplicity of this one-parameter model, the qualitative agreement between experimental results and calculations achieved is surprising. In the low strain limit, formula (14) can be rewritten as

$$\tau = \tau_0 + \alpha\mu b \sqrt{\frac{2\gamma}{bL}} = \tau_0 + 2\alpha\mu(\gamma b)^{1/2} d^{-1/2} \quad (15)$$

which corresponds to Ashby's expression of the Hall–Petch work-hardening stress  $\tau = \tau_0 + kd^{-1/2}$  [ $\tau_0$  and  $k = k(\gamma)$  are materials properties; compare with Eq. (7)], if  $L = d/2$ . In other words, from Eq. (11), the “ $d^{-1/2}$ ” dependence of the flow stress recovered theoretically agrees with the experimentally observed Hall–Petch behavior of the CSSC and the fatigue limit.

Thus despite oversimplification, this approach is capable of qualitative explaining such experimental results as

1. saturation of the cyclic stress amplitude,
2. high saturation stress,
3. rapid hardening/softening on the early stage of cycling,
4. shape of the cyclic stress–strain curve and
5. Hall–Petch behavior of the fatigue limit.

More precise modeling would require two (or three) kinds of dislocations to be distinguished—mobile and immobile (the former are responsible the intergranular slip and the latter are attracted to the grain boundaries) as has been suggested by Estrin, Braasch, and Brechet<sup>[65]</sup> for ordinary polycrystals.

## Fatigue Life Prediction

The first attempt to model the fatigue life of SPD metal was performed by Ding, Mughrabi, and Höppl<sup>[66]</sup> They considered the NC metal to be a two-phase composite consisting of a soft matrix representing grain interior and “hard” reinforcement representing the heavily distorted nonequilibrium grain boundaries (or the grain boundary affected zone having a characteristic thickness of 5 nm, which they suggested was experimentally supported by TEM and X-ray structural analysis). The authors suggested the dislocation accumulation to be the main strengthening mechanism in UFG metals; however, the grain boundaries also contribute to the resultant strength. The crack growth rate  $da/dN$  was calculated from the fracture mechanics concept assuming  $da/dN$  to be proportional to the

crack tip opening displacement ( $\Delta$ CTOD). The  $\Delta$ CTOD was related to the  $J$ -integral, and the latter was calculated in the cited work with an assumption that within the fatigue damage zone, the local cyclic stress was uniform and equal to the ultimate tensile strength of the UFG material. The empirical Coffin–Manson and Basquin laws were finally derived as

$$\frac{\Delta \varepsilon_{pl}}{2} = \left[ \frac{192C^2}{\lambda \pi^2 F^2} \left( \frac{n'}{n'+1} \right) \left( \frac{\sigma'_y}{K'} \right) \ln \left( \frac{a_f}{a_i} \right) \right]^{\frac{1}{3n'+1}} (2N_f)^{\frac{-1}{3n'+1}}$$

$$\frac{\Delta \sigma}{2} = K' \left[ \frac{192C^2}{\lambda \pi^2 F^2} \left( \frac{n'}{n'+1} \right) \left( \frac{\sigma'_y}{K'} \right) \ln \left( \frac{a_f}{a_i} \right) \right]^{\frac{n'}{3n'+1}} (2N_f)^{\frac{-n'}{3n'+1}} \quad (16)$$

where  $a_i$  and  $a_f$  are the initial and final critical crack length, respectively,  $\lambda$  is a fitting parameter having a sense of the cyclic plastic zone correction factor same as that in Eq. (8), and  $C$  and  $F$  are the so-called GB constraint and GB strengthening factors respectively, which are introduced as:

$$F \equiv \frac{\sigma_{yUFG}}{\sigma_{yO}}$$

$$C \equiv \frac{1}{2} \frac{\Delta \sigma / 2}{\Delta \sigma_{eff} / 2} \quad (17)$$

where  $\sigma_{yUFG}$  and  $\sigma_{yO}$  denote the yield stresses in the UFG and ordinary polycrystalline materials, respectively, and  $\Delta \sigma / 2$  and  $\Delta \sigma_{eff} / 2$  are the average steady-state cyclic flow stress amplitude in the bulk of the material and the effective stress amplitude that contributes to local deformation, respectively. A satisfactory agreement between the calculated from Eqs. (16) fatigue life and experimental data was obtained,<sup>[66]</sup> demonstrating a potential for fatigue life prediction in frames of the proposed phenomenological approach.

## EFFECT OF TEXTURE

It is now understood that crystallographic texture exerts a very strong influence on the cyclic response of polycrystalline metals. For instance, Lukáš and Kunz<sup>[13]</sup> first demonstrated that coarse-grain copper saturates at higher stresses than its small grain analog. Llanes and Laird<sup>[67]</sup> showed that this effect could be attributed to a strong  $\langle 111 \rangle$ – $\langle 100 \rangle$  fiber texture formed in coarse-grain copper during annealing. The SPD processing used to produce most of the materials discussed in this report inevitably results in the formation of at least moderate textures,<sup>[68–70]</sup> which can be important for fatigue because of its effect on dislocation mobility, as well as the relative sensitivity of the material to plastic instabilities. Other methods of producing NC

materials (e.g., film growth or inert gas condensation) may be more or less prone to these textural issues.

## EFFECT OF ENVIRONMENT

It has long been recognized that the environment plays a very important role in fatigue damage, affecting both the crack nucleation and propagation, and a survey of the experimental results concerning the cyclic response of NC materials would not be complete without a few words about environmentally assisted fatigue. Yamasaki et al.<sup>[59]</sup> investigated corrosion fatigue of ECAP copper immersed into 1 M NaNO<sub>2</sub> aqueous solution in terms of cyclic hardening/softening behavior and surface morphology. They found that UFG copper possesses a notably better resistance to environmental attack, including corrosion fatigue, when compared to its coarse-grain counterpart. In contrast with coarse-grain Cu, which shows a transgranular fatigue fracture, corrosion fatigue in UFG specimens occurs intergranularly. Because localized corrosion is the most deleterious, the use of NC materials (having boundaries nearly everywhere) is said to be beneficial in the case where mass loss is the same for both sample types. Further improvement of fatigue properties and corrosion fatigue resistance is possible if the instability problem of SPD materials is resolved.

## EFFECT OF PROCESSING ON FATIGUE AND OPTIMIZATION OF FATIGUE PERFORMANCE

The most influential SPD processing parameter is the amount of strain imposed. Increasing number of ECA pressings results in increasing monotonic strength and fatigue limit.<sup>[32–34,36]</sup> Furthermore, the fatigue properties of UFG metals can be improved by gaining some ductility and reducing constraints for dislocation motion, i.e., by decreasing the tendency for shear banding and strain localization, which is common in many hardened metals. Thus it can be advantageous for fatigue properties to employ materials with a partially recovered structure. The positive effect of heat treatment on LCF has been already revealed in the early fatigue studies of ECAP materials.<sup>[18]</sup> It has been shown, via the acoustic emission technique and microscopic surface observations, that susceptibility to shear banding in ECAP Cu decreases dramatically after a short-term (10 min) annealing at relatively low temperature of 250°C,<sup>[56]</sup> and LCF life can be improved by a factor of 5–10 after a heat treatment that does not result in any grain growth.<sup>[19,21,23]</sup> While ECAP results in considerable reduction of tensile and cyclic ductility, the same materials subjected to a post-ECAP annealing can potentially obtain a higher ductility than its conventional

coarse-grain counterpart,<sup>[23,45]</sup> and shifts the Coffin–Manson line toward higher fatigue lives (Fig. 9).

Because SPD metals retain some ductility after fabrication, their tensile and high cyclic strength can be additionally improved after postprocessing conventional cold rolling with or without intermediate annealing at moderate temperature. This has been shown for several Al–Mg alloys<sup>[31]</sup> and commercial purity Ti<sup>[23,25]</sup> as discussed in the section “High Cycle Fatigue Behavior.”

The effect of precipitation in SPD NC metals is complex. On one hand, it has already been mentioned that precipitates can dramatically increase the thermal stability of SPD metals and, on the other, grain boundaries may recover during aging thereby reducing their susceptibility to strain localization and premature cracking. As an example, it has been shown that optimal aging of ECAP UFG Cu–Cr–Zr alloy results in a high-strength structure with 200 nm grain size, which remains fine after subsequent annealing at temperatures as high as 500°C.<sup>[36]</sup> Kim et al.<sup>[71]</sup> have shown that the one-pass ECA pressing of the solid-solution treated 2024 Al alloy, followed by a low-temperature aging, can impressively enhance both strength and ductility: samples aged at 100°C for 20 hr had the strength  $\sigma_{UTS} = 715$  MPa, and the total elongation to failure  $\delta = 16\%$ . Chung et al.<sup>[37]</sup> have shown that the yield stress and tensile strength of 6061 Al alloy benefit from multiple ECA pressing (four passes) as compared to the one-time-pressed sample (the ECAP of solution treated billets was performed at 125°C and no subsequent heat treatment was applied.) Although the effect of the single ECA pressing of aluminum alloy 6061<sup>[37]</sup> is impressive, it is not clear whether it would be impossible to achieve the same strength and ductility in Al alloys after conventional treatment. Hence two principal competing approaches for enhancement of fatigue properties via SPD can be seen: 1) achievement of compromise between strength and ductility in a minimum number of ECA pressings—one wherever possible, i.e., a cost-effective procedure employing relatively small imposed strains; and 2) achievement of maximum possible strength and high cycle fatigue life. The results of Chung et al.<sup>[37]</sup> show a lack of correlation between the tensile strength and fatigue limit, i.e., the four-pass sample with higher  $\sigma_{UTS}$  has the fatigue limit lower than the one-time pressed sample. In conclusion, there are still great opportunities for the development of optimum processing scheme for desired fatigue properties of SPD materials.

## CONCLUSION

The presently available experimental results concerning the fatigue behavior of NC materials have been reviewed, and the following aspects are highlighted in

retrospect to the available knowledge about the grain size effect on fatigue of conventional materials:

1. The significant enhancement of high cyclic fatigue life has been demonstrated after grain refinement down to submicrocrystalline and nanoscopic size for most materials, depending on the slip mode.
2. Despite the high tensile strength and improved high cyclic fatigue properties on NC and UFG metals, the low cyclic fatigue life appears shorter than that of their coarse-grain counterparts because of some loss in ductility during SPD.
3. Fatigue damage occurs on different scale levels from the intragranular movement of individual dislocations to macroscopic strain localization in the shear bands. The nature of the shear bands on SPD metals has been discussed from the standpoint of the initial ultrafine grain structure and its evolution during cyclic deformation.
4. The susceptibility of the ECAP materials to strain localization and microcracking can be a main factor, which limits their tensile and fatigue ductility and, to a large extent, determines their fatigue performance.
5. Postprocessing annealing has proven to be capable of considerable improvement of LCF performance of SPD metals because of reduction of their susceptibility to strain localization.
6. NC and UFG materials possess lower resistance to crack propagation than their coarse-grain analogs near the threshold.
7. Both grain refinement and dislocation work hardening play an important role in the resultant properties of materials obtained by severe plastic deformation. As a consequence, most of the cyclic properties of NC materials can be rationalized, at least qualitatively, in terms of Hall–Petch and dislocation hardening within a framework of a simple approach involving one- or two-parametric dislocation generation–annihilation kinetics.

The effects of texture, processing, and environment on fatigue life, crack initiation, and propagation in NC materials have been just scarcely studied, and further investigations in this field should be of interest for both potential applications and fundamental issues of fatigue of these materials.

# Nanocrystalline Materials: Synthesis and Properties

Alexandr I. Gusev

*Institute of Solid State Chemistry, Ural Division, Russian Academy of Sciences,  
Yekaterinburg, Russia*

## INTRODUCTION

The synthesis of nanocrystalline bulk and powder materials is one of the problems facing the modern materials scientist. In recent decades, the interest paid to this problem has grown remarkably because it was found that the properties of nanocrystalline substances change considerably when the size of crystallites decreases below a threshold value.<sup>[1–8]</sup> Such changes arise when the average size of crystal grains does not exceed 100 nm and are most pronounced when grains are less than 10 nm in size. Ultrafine-grain substances should be studied considering not only their composition and structure, but also particle size distribution. Ultrafine-grain substances with grains 300 to 40 nm in size on the average are usually referred to as submicrocrystalline, while those with grains less than 40 nm in size on the average are called nanocrystalline. The classification of substances by the size  $D$  of their particles (grains) is shown in Fig. 1.

Nanosubstances and nanomaterials may be classified by geometrical shape and the dimensionality of their structural elements. The main types of nanomaterials with respect to the dimensionality include cluster materials, fibrous materials, films and multilayered materials, and also polycrystalline materials whose grains have dimensions comparable in all the three directions (Fig. 2).

The main objective of this entry is to give a general idea about diverse nanocrystalline substances and materials. The chemical composition, the microstructure, the grain size distribution, and, consequently, the properties of nanosubstances largely depend on their production method. It is for this reason that the paper first describes main methods for production of powders and bulk samples in the nanocrystalline state and then considers specific features of the microstructure of nanocrystalline substances. The influence of the nanocrystalline state on properties of various substances and determination of causes of this influence present the objective of the final part of this paper.

## BACKGROUND OF FINE MATERIALS

In December 1959, at his talk at the California Institute of Technology, Feynman<sup>[9]</sup> stressed the problem

of control over the substance in the interval of extremely small dimensions as an insufficiently explored, but very promising field of science. He noted in particular that "...when we have some control of the arrangement of things on a small scale we will get an enormously greater range of possible properties that substances can have, and of different things that we can do... The problems of chemistry... can be greatly helped if our ability to see what we are doing, and to do things on an atomic level, is ultimately developed."

In 1982–1985, Gleiter<sup>[1]</sup> proposed a concept of the nanostructure of solids and was the first to realize a method for production of bulk materials with nanometer-sized grains (crystallites). From that time on, bulk and powder substances, which contained nanometer-sized particles, have been called nanocrystalline. Gleiter's works spurred studies into the synthesis, the structure, and the properties of nanocrystalline substances.

Differences in the properties of fine particles from those of bulk materials have been known and used for a relatively long time. Examples are aerosols, dyeing pigments, and glasses colored with colloidal particles of metals. A very significant field of successful application of fine particles is catalysis of chemical reactions. Multilayered nanostructures are used in electronics. These structures represent a crystal, which has, in addition to the usual lattice of periodically arranged atoms, a superlattice comprising alternating layers of different compositions.

Semiconductor nanoheterostructures, which realize quantum-size effects, are of special interest to electronics. Nanoheterostructures, especially double ones, including quantum wells, wire, and dots, allow controlling basic parameters of semiconductors (the energy spectrum, the forbidden gap width, the effective mass, and the mobility of carriers).

## DISTINCTIVE PROPERTIES

The density of states  $N(E)$  is a continuous function in a three-dimensional (3-D) semiconductor. When the electron gas dimensionality decreases, the energy spectrum

**Fig. 1** Classification of substances and materials by their particle (grain) size  $D$ .

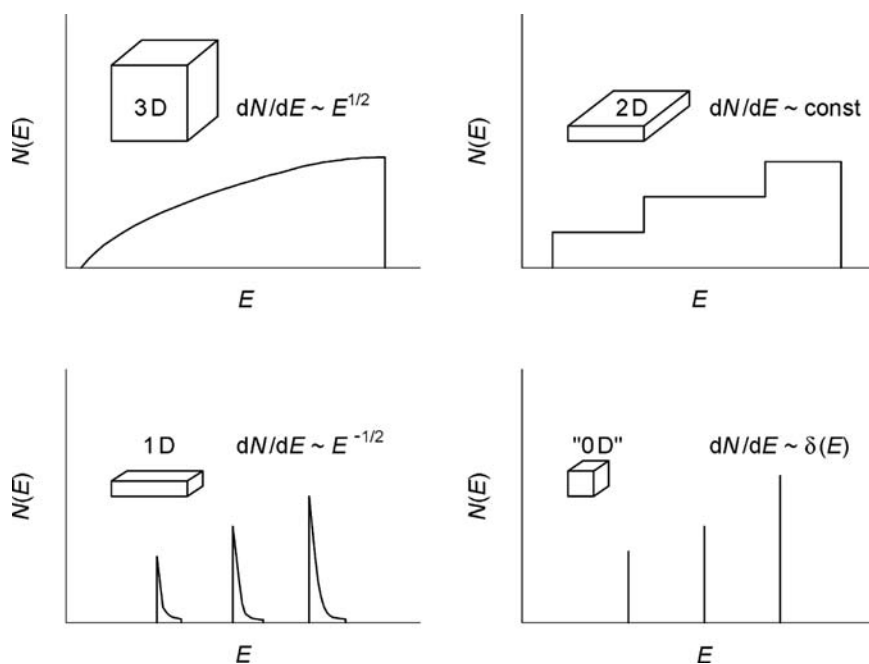

becomes split and discrete (Fig. 3). A quantum well is a two-dimensional structure, in which charge carriers are limited to the direction perpendicular to the layers and can move freely in the layer plane. Charge carriers are limited to two directions in a quantum wire and only move along the wire axis. A quantum dot is a quasi-zero-dimensional (“0”  $D$ ) structure, in which charge carriers are limited in three directions. The electron energy spectrum of an ideal quantum dot is fully discrete

(Fig. 3) and corresponds to the spectrum of a single atom, although a real quantum dot (a “superatom”) can include hundreds of thousands of atoms.

A small size of grains determines a large length of grain boundaries. Also, grains may have various atomic defects (vacancies or their complexes, disclinations, and dislocations), whose number and distribution differ from those in coarse grains 5 to 30  $\mu\text{m}$  in size. If dimensions of a solid in one, two, or three

**Fig. 2** Types of nanocrystalline materials: 0-D (zero-dimensional) clusters; 1-D (one-dimensional) nanotubes, filaments, and rods; 2-D (two-dimensional) films and layers; 3-D (three-dimensional) polycrystals.

**Fig. 3** Density of states of charge carriers of states  $N(E)$  as a function of the semiconductor dimensionality: (3-D) three-dimensional semiconductor; (2-D) quantum well; (1-D) quantum wire; (0-D) quantum dot.

directions are comparable with characteristic physical parameters having the length dimensionality (the size of magnetic domains, the electron free path, the size of excitons, the de Broglie wavelength, etc.), dimensional effects will be observed for the corresponding properties. Thus dimensional effects imply a set of phenomena connected with changes in properties of substances, which are caused by 1) a change in the particle size, 2) the contribution of interfaces to properties of the system, and 3) comparability of the particle size with physical parameters having the length dimensionality. Specific features of the structure of nanocrystalline substances make their properties differ considerably from those of usual polycrystals. Therefore the decrease in the grain size is viewed as an efficient method for adjustment of properties of solids.

Nanocrystalline substances represent a special state of condensed matter, namely, macroscopic ensembles of superfine particles up to several nanometers in size. Properties of nanosubstances are determined by both specific features of separate particles and their collective behavior, which depends on the interaction between nanoparticles.

## SYNTHESIS OF NANOCRYSTALLINE POWDERS

### Gas Phase Synthesis

Isolated nanoparticles are prepared by the evaporation of a metal, an alloy, or a semiconductor at a controlled temperature in the atmosphere of a low-pressure inert gas and the subsequent condensation of the vapor near

or on a cold surface. The gas phase synthesis provides particles between 2 and several hundreds of nanometers in size. Nanoparticles  $\leq 20$  nm in size have a spherical shape, while coarser particles are faceted.

The metal may be evaporated from a crucible or fed to the evaporation zone as a wire or a powder. A beam of argon ions serves for the metal evaporation. The energy may be injected via direct heating, passage of an electric current, an electric-arc plasma discharge, inductive heating with currents of high and superhigh frequencies, laser radiation, or electron beam heating. A vacuum, a motionless inert gas, a gas flow, or a plasma jet may serve as the working medium. The composition and the size of nanoparticles may be controlled by changing the atmosphere pressure and composition (an inert gas or a reagent gas) and the temperature gradient between the evaporated substance and the surface, on which the vapor condensates.

Properties of isolated nanoparticles largely depend on the contribution of the surface layer. In the case of a spherical particle with the diameter  $D$  and the surface layer thickness  $\delta$ , the fraction of the surface layer in the total volume of the particle is  $\sim 6\delta/D$ . When the surface layer thickness equals 3–4 atomic monolayers (0.5–1.5 nm) and the size of nanoparticles is 10–20 nm, the surface layer accounts for up to 50% of the whole substance.

### Plasmachemical Technique

Low-temperature (4000–8000 K) nitrogen, ammonium, hydrocarbon, or argon plasma of the arc, glow, high-frequency, or superhigh-frequency discharge is used

**Fig. 4** Structure of most significant fullerenes  $C_{60}$  and  $C_{70}$ . The  $C_{60}$  molecule is shaped like a soccer-ball and its cage is about 0.7 nm in diameter. All fullerenes exhibit hexagonal and pentagonal rings of carbon atoms.

in the plasmachemical synthesis. Elements, their halogenides, and other compounds serve as the starting material. Particles of plasmachemical powders represent single crystals 10 to 100–200 nm in size. Laser heating provides nanopowders with a narrow particle size distribution. The gas phase synthesis with laser radiation for generation and maintenance of the plasma, in which the chemical reaction takes place, proved to be an efficient method for production of molecular clusters.

Molecular clusters occupy a special place among nanostructured substances. The best known of these structures are the fullerenes,<sup>[10]</sup> representing a new allotropic modification of carbon in addition to graphite and diamond. The  $C_{60}$  and  $C_{70}$  fullerenes are produced by electric arc sputtering of graphite in the helium atmosphere at a pressure of  $\sim 10^4$  Pa. However, electron beam evaporation and laser heating are also used.

A  $C_{60}$  molecule has the structure of a truncated regular icosahedron (Fig. 4), where carbon atoms form a closed hollow spherical surface comprising 5- and 6-member rings. Each atom has its coordination number

equal to 3 and is located at vertices of two hexagons and one pentagon. Crystallization of  $C_{60}$  from a solution or a gas phase leads to appearance of fullerites, which are molecular crystals with a cubic lattice having the constant of 1.417 nm. The  $C_{70}$  fullerene is shaped like a closed spheroid (Fig. 4).

In 1992, a stable  $Ti_8C_{12}^+$  cluster was discovered<sup>[11]</sup> corresponding to a  $Ti_8C_{12}$  molecule in the form of a distorted pentagon dodecahedron (Fig. 5). The  $Ti_8C_{12}$  cluster has the linear dimension of about 0.5 nm.  $Ti_8C_{12}$  clusters were produced by the plasma-chemical gas phase synthesis in a helium atmosphere using hydrocarbons (methane, ethylene, acetylene, propylene, and benzene) and titanium vapors as reagents. Titanium was evaporated under irradiation from a Nd-laser with a 532-nm wavelength. The  $Ti_8C_{12}$  cluster is the first member in the new class of molecular clusters, that is,  $M_8C_{12}$  metallocarbohedrenes, where  $M = Zr, Hf, V, Cr, Mo, \text{ or } Fe$ .

### Precipitation from Colloid Solutions

A standard method for producing nanoparticles from colloid solutions consists of a chemical reaction between the solution components and interruption of this reaction at a certain moment of time. After this, the dispersed system changes from the liquid colloid state to the dispersed solid state. For example, nanocrystalline cadmium sulfide CdS is produced by precipitation from a mixture of  $Cd(ClO_4)_2$  and  $Na_2S$  solutions. The solution pH is increased abruptly to stop the growth of CdS particles.

Mixed-composition nanoparticles, i.e., nanocrystalline heterostructures, are synthesized by precipitation from colloid solutions. The core and the shell of a mixed nanoparticle are made of semiconductor

**Fig. 5** Dodecahedral structure of the molecular cluster  $Ti_8C_{12}$  with the symmetries  $T_h$  and  $T_d$  taking into account different length of Ti–C and C–C bonds.

substances having different structures of electronic levels. Heterostructures, such as CdSe/ZnS or ZnS/CdSe, HgS/CdS, ZnS/ZnO, and TiO<sub>2</sub>/SnO<sub>2</sub>, are formed through a controlled precipitation of one type of semiconductor molecules on presynthesized nanoparticles of a semiconductor of another type.

Precipitation from colloid solutions is highly selective and allows producing stabilized nanoclusters with a very narrow particle size distribution.

### Thermal Decomposition and Reduction

Subject to thermal decomposition are elemento- and metallo-organic compounds, carbonyls, formates, oxalates, amides, and imides of metals, which decompose at some temperature and form the synthesized substance. For example, metal powders with particles 100 to 300 nm in size on the average are prepared by pyrolysis of iron, cobalt, nickel, and copper formates in a vacuum or an inert gas at 470–530 K.

Superfine metal powders are also produced by hydrogen reduction of hydroxides, chlorides, nitrates, and carbonates of metals at <500 K. Advantages of this method include a low concentration of impurities and a narrow particle size distribution of powders (Fig. 6).

### Mechanical Synthesis

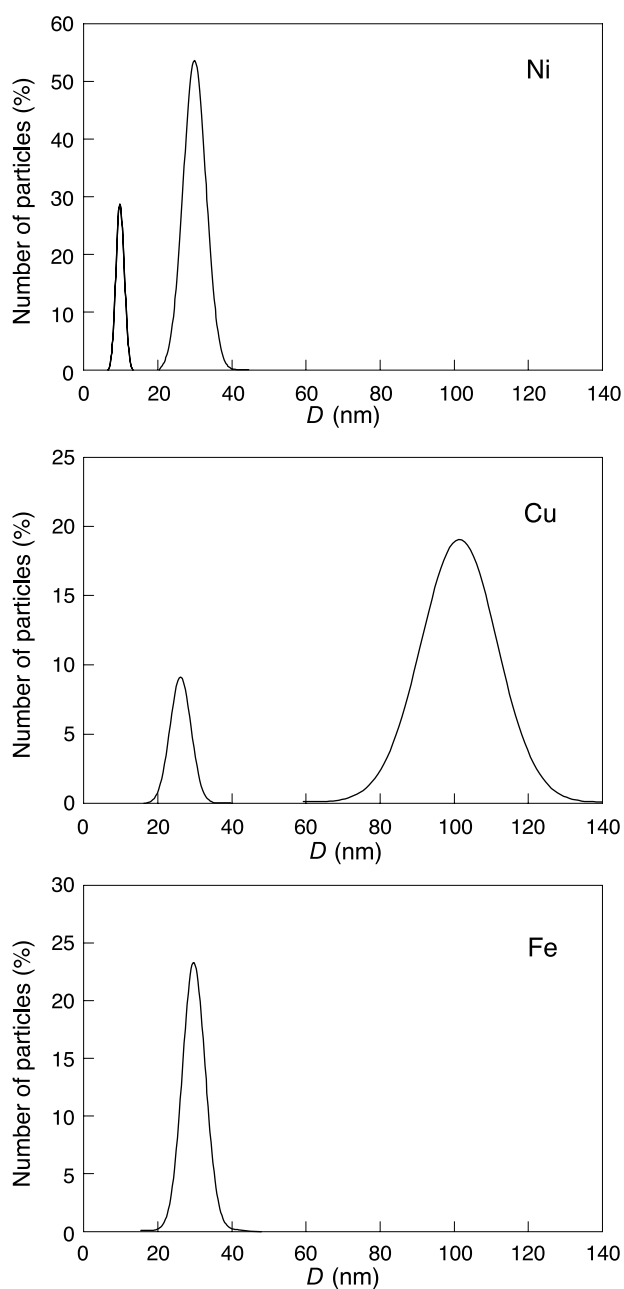

Mechanical synthesis as a method for producing nanopowders may be divided into two categories: mechanical milling and mechanical alloying. Mechanical milling is used both for grinding and amorphization of the starting material. Mechanical alloying requires grinding, mixing, mass transfer, and chemical interaction of powders of several pure elements, compounds, or alloys. Substances in the crystalline and amorphous states may be prepared by mechanical alloying.

Mechanical synthesis is the most efficient method for large-quantity production of nanopowders.

Grinding and mechanical synthesis are performed in high-energy planetary, ball, or vibrating mills. The average size of powder particles is 200 to 5–10 nm. For example, Fe–Ni and Fe–Al nanocrystalline alloys with grains 5 to 15 nm in size were synthesized by grinding of metal powders in a ball vibrating mill during 300 hr.<sup>[8]</sup>

### Synthesis by Detonation and Electric Explosion

One more type of the mechanical treatment, which provides conditions for synthesis and dispersion of the final product, is a shock wave. Nanocrystalline diamond powders are prepared from mixtures of graphite

**Fig. 6** Typical distributions of metal particles by their size  $D$ . The particles were synthesized via reduction of metals from compounds in a hydrogen flow.

and metals under the shock wave pressure of a few dozens of gigapascals. Diamond powders may be produced more conveniently by explosion of organic substances with a high concentration of carbon and a low percentage of oxygen.

Detonation of condensed explosives, which decompose with liberation of free carbon, is used for commercial production of diamond nanopowders. The volume of explosion chambers is not less than 2–3 m<sup>3</sup>. Synthesized diamond powders consist of cubic particles about 4 nm in size on the average.

Fine powders with particles up to 50 nm in size are produced by an electric explosion of wire when it passes a strong current pulse,  $10^{-5}$ – $10^{-7}$  sec long, having a density of  $10^4$ – $10^6$  A mm<sup>-2</sup>.<sup>[12]</sup> A wire of diameter 0.1 to 1.0 mm is used. A current pulse quickly heats the metal up to a temperature  $T > 10^4$  K (above the melting point) and the overheated metal is dispersed as in explosion. The average size of particles diminishes as the current density grows and the pulse length shortens. Electric explosion in an inert atmosphere provides powders of metals and alloys. Fine powders of oxides, nitrides, carbides, or their mixtures may be synthesized when reagents (O<sub>2</sub> + He, N<sub>2</sub>, H<sub>2</sub>O, and C<sub>10</sub>H<sub>22</sub>) are added into the reactor.

### Synthesis of Superfine Oxides in Liquid Metals

In this method, molten gallium, lead, or Pb–Bi alloy serve as the working medium. A metal M, whose chemical affinity for oxygen is larger than the oxygen affinity of the molten metal, is dissolved in the melt. Then the dissolved metal M is oxidized by bubbling water vapor or an oxidizing gas mixture (H<sub>2</sub>O + Ar) through the melt. Superfine amorphous oxides of metals are formed as a result of selective oxidation. For example, oxidation of aluminum in molten gallium leads to formation of flocks of amorphous Al<sub>2</sub>O<sub>3</sub> · H<sub>2</sub>O. It consists of fibers 5 to 100 nm in diameter, which are spaced 5 to 400 nm. The synthesized material has a porosity of 97–99 vol.% and a specific surface of 30 to 800 m<sup>2</sup> g<sup>-1</sup>.

Nanostructured oxides SbO<sub>2</sub>, TeO, NiO, GeO<sub>2</sub>, SnO<sub>2</sub>, In<sub>2</sub>O<sub>3</sub>, K<sub>2</sub>O, ZnO, Ga<sub>2</sub>O<sub>3</sub>, Na<sub>2</sub>O, MnO, Li<sub>2</sub>O, Al<sub>2</sub>O<sub>3</sub>, BaO, SrO, MgO, and CaO may be produced via selective oxidation. The method is also applicable to synthesis of superfine nitrides, sulfides, and halogenides. In this case, a mixture of an inert gas and nitrogen N<sub>2</sub>, hydrogen sulfide H<sub>2</sub>S, or gaseous gallium or lead chlorides is passed through the melt with a dissolved metal.

### Self-Propagating High-Temperature Synthesis

Self-propagating high-temperature synthesis (SHS) represents solid-state burning of reagents (metal and carbon for carbides or metal in nitrogen for nitrides) at a temperature of 2500 to 3000 K. Usually, the average size of grains in carbides produced by the SHS method is 5 to 20 μm.

A nanosized powder of titanium carbide was prepared by the SHS method using sodium chloride as an inert dilutant.<sup>[13]</sup> As titanium and carbon are burning, NaCl forms a melt, which insulates the formed carbide particles and prevents their growth. Also, NaCl dissolves well in water and can be easily separated from the synthesized carbide. The size of titanium

carbide particles decreases with growing percentage of NaCl in the initial mixture. The average size of particles is about 100 nm.

### Ordering in Non-stoichiometric Compounds as a Method of Producing a Nanostructure

A nanostructure in non-stoichiometric compounds such as MC<sub>y</sub> cubic carbides is produced through disorder–order transformations, which take place as phase transitions of the first kind with an abrupt change of the volume.<sup>[14]</sup> If a non-stoichiometric compound is cooled quickly from a high temperature, at which the disordered state is at equilibrium, ordering cannot be completed and the compound remains in a metastable disordered state. Because lattice constants of the disordered and ordered phases are different, stresses arise in the sample, leading to the cracking of crystallites at interfaces between the disordered and ordered phases and formation of a nanostructured powder.

The first ordering-induced nanostructure was realized in a non-stoichiometric vanadium carbide.<sup>[15]</sup> The initial powder of the VC<sub>0.875</sub> carbide with grains 1 to 2 μm in size was aged for a long time at 300 K. The aged powder contained agglomerates 5 to 30 μm in size, which were formed by particles measuring about 1 μm. The particles had a complicated structure (Fig. 7). Each entity ~1 μm in size looked like an open rosebud and contained a large number of nanocrystallites in the form of strongly bent plate disks 400 to 600 nm in diameter and 15 to 20 nm thick (Fig. 8). The bulk of the nanocrystallites consisted of the V<sub>8</sub>C<sub>7</sub>-ordered carbide, while the surface layer about 0.7 nm thick included a great number of vacancy agglomerates.

## PREPARATION OF BULK NANOCRYSTALLINE SUBSTANCES

### Disorder–Order Transformations

A nanostructure may be produced not only by ordering of powders, but also bulk non-stoichiometric compounds. Bulk samples of the VC<sub>0.875</sub> carbide were prepared using a hot pressing of a powder of disordered vanadium carbide at a temperature of 2000 K and a pressure of 20–25 MPa.<sup>[16]</sup> The size of grains in sintered samples was 10 to 60 μm. The sintered samples were annealed at 1370 K for 2 hr and then were cooled slowly (at a rate of 100 K hr<sup>-1</sup>) to 300 K or quenched from 1500 to 300 K. The maximum thermal treatment temperature approached the disorder–order transformation temperature  $T_{trans}$  and

**Fig. 7** Microstructure of a powder of the  $\text{VC}_{0.875}$  vanadium carbide after long-term aging at ambient temperature in an ambient atmosphere ( $\times 10000$  magnification). *Source:* From Ref.<sup>[15]</sup>.

was equal to  $T_{\text{trans}} \pm 100$  K. Along with structural reflections, additional weak reflections corresponding to the  $\text{V}_8\text{C}_7$ -ordered phase appeared in the X-ray diffraction spectrum after both annealing and quenching.

The  $\text{V}_8\text{C}_7$ -ordered phase was formed thanks to the disorder–order transformation. The grain size of the basic phase did not change upon ordering, but superstructural lines widened because of a small size of domains of the ordered phase. Superstructural reflections widened most for the sample, which was quenched from 1500 K. This means that domains of

the ordered phase were smallest in that sample. The size of domains was about 130 nm in annealed samples and  $\sim 20$  nm in samples quenched from 1500 K.

Thus the nanostructure in the bulk non-stoichiometric vanadium carbide represented a set of domains of an ordered phase and was formed thanks to the  $\text{VC}_{0.875} \rightarrow \text{V}_8\text{C}_7$  disorder–order phase transformation.

Ordering is an efficient method for creation of a nanostructure in bulk and powder non-stoichiometric compounds. Disorder–order transformations, which are accompanied by changes of the volume, can

**Fig. 8** Morphology of particles of an aged powder of the  $\text{VC}_{0.875}$  carbide ( $\times 50000$  magnification). *Source:* From Refs.<sup>[15,16]</sup>. Particles about 1  $\mu\text{m}$  in size represent a set of nanocrystallites having the shape of bent plate disks 400 to 600 nm in diameter and about 15–20 nm thick.

be used to produce a nanostructure not only in non-stoichiometric compounds, but also in substitutional solid solutions, including alloys.

### Compaction of Nanopowders

A method for production of bulk nanocrystalline substances, which was proposed by researchers<sup>[17]</sup> in 1981–1986, has been well known. This technology uses the method of evaporation and condensation for production of nanoparticles, which are deposited on the cold surface of a rotating cylinder. Evaporation and condensation are realized in a rarefied inert gas, mostly helium. Particles of the surface condensate are usually faceted. The deposited condensate is removed from the cylinder surface using a special scraper and is placed in a collector. The inert gas is pumped out and the nanocrystalline powder is compacted in a vacuum first at a pressure of  $\sim 1$  GPa and finally at a pressure up to 10 GPa. Bulk nanomaterials prepared by this method contain particles of an average size  $D$  from 1–2 to 80–100 nm and have a relative density of 85–97% depending on evaporation and condensation conditions. The absence of contact with the ambient atmosphere during synthesis and compaction of the nanopowder precludes contamination of the bulk samples. For production of bulk nanocrystalline oxides and nitrides, the metal is evaporated to an oxygen- or nitrogen-containing atmosphere.

Porosity of nanoceramics prepared by compaction of powders is connected with triple junctions of crystallites. It may be decreased and made more uniform by compaction of nanopowders and their sintering at relatively low temperatures  $T \leq 0.5T_m$  ( $T_m$  being the melting point).

The magnetic pulsed method<sup>[18]</sup> is reduced to intensive dry pressing of powders. Pulsed compression waves cause vigorous heating of the powder thanks to the quick release of energy during friction of particles. When the size of particles is small ( $D \leq 0.3 \mu\text{m}$ ), their heating time is shorter than the characteristic length of pulsed compression waves (1–10  $\mu\text{sec}$ ). If compression wave parameters are chosen properly, it is possible to realize dynamic hot pressing of nanopowders thanks to their high surface energy. The magnetic pulsed method provides denser samples than steady-state pressing at nearly equal pressures (Fig. 9). Short-time heating reduces recrystallization caused by high temperatures and helps preserving a small size of particles.

A promising method for compaction of ceramic nanopowders without plasticizers is dry cold ultrasonic pressing.<sup>[19]</sup> Ultrasound decreases interparticle friction, breaks agglomerates and coarse particles, and improves the volume distribution of particles. Therefore the

**Fig. 9** Pressure dependence of the density  $\rho$  of the nanocrystalline oxide  $n\text{-Al}_2\text{O}_3$  for steady-state and magnetic pulsed pressing: (1), (2), (3) represent steady-state pressing at temperatures of 300, 620, and 720 K, respectively; (4) represents magnetic pulsed pressing.

density of the compact is enhanced, the growth of grains during sintering is limited, and the nanostructure is preserved. Ultrasonic pressing of nanopowders is especially efficient in the production of intricate articles, such as bushes, gear wheels, and spirals (Fig. 10).

Ceramic nanomaterials are sintered using heating with millimeter-range superhigh frequency (SHF) radiation.<sup>[20]</sup> Volume absorption of the SHF energy ensures one-time uniform heating of the whole sample and provides sintered ceramics having a homogeneous microstructure. The sintering temperature is 1300 to 2300 K. Microwave sintering of compacts, which had a relative density of 70–80% and were made of a  $\text{TiO}_2$  nanopowder with an average size of particles equal to 20–30 nm, allowed producing sinters having a relative density of 97–99% and grains 200 to 220 nm in size on the average.

The existing methods for compaction of nanopowders and sintering of bulk nanomaterials already provide high-density intricate articles. However, it has been so far impossible to maintain the same small size of grains in sintered nanomaterials as in initial nanopowders. To keep the size of grains small, one has to decrease the temperature and duration of sintering and perform the sintering operation under a high pressure.

### Film and Coating Deposition

Deposition on a cold or heated surface of a substrate allows making films and coatings, i.e., continuous layers of a nanocrystalline substance not more than several micrometers thick. Films may have different

**Fig. 10** Ceramic articles synthesized by ultrasonic pressing of nanopowders. *Source:* From Ref.<sup>[19]</sup>.

compositions and the size of their crystallites may change over a wide interval including the amorphous state and multilayer structures (superlattices). Pressing is not necessary because a bulk layer of a nanomaterial is obtained.

Deposition on a substrate may be realized from vapors, plasma, or a colloid solution. In the case of vapor deposition, a metal is evaporated in a vacuum or an oxygen- or nitrogen-containing atmosphere and then vapors of the metal or its compound (an oxide or a nitride) are condensed on a substrate. The size of crystallites in the film may be adjusted by varying the evaporation rate and the substrate temperature. Nanostructured films may be produced by deposition from plasma.

Oxide and sulfide semiconductor films are obtained by deposition on a substrate from colloid solutions. Nanostructured films containing nanoparticles of different semiconductors are prepared by the codeposition method. The methods of chemical and physical deposition from a gaseous phase (CVD and PVD) are traditionally used for producing of films.

### Nanocrystallization of Amorphous Alloys

Non-porous nanostructured materials are produced by crystallization of amorphous metal alloys. Thin bands of amorphous alloys are made by melt spinning, i.e., quick (at a rate  $\geq 10^6 \text{ K sec}^{-1}$ ) cooling of the melt on the surface of a rotating disk. Then the amorphous band is annealed to create a nanostructure.

Considerable study currently devoted to crystallization of amorphous alloys in connection with development of soft magnetic materials in Fe–Cu–M–Si–B

(M = Nb, Ta, W, Mo, or Zr) systems.<sup>[21]</sup> Amorphous alloys of the Fe–Cu–Nb–Si–B system proved to be most successful. Their crystallization at 700–900 K resulted in formation of a uniform nanocrystalline structure. Grains of the  $\alpha$ -Fe(Si) phase  $\sim 10 \text{ nm}$  in size and copper clusters about 1 nm in size were uniformly distributed in the amorphous matrix of the alloy.

Crystallization of quickly solidifying amorphous alloys of the Al–Cr–Ce–M (M = Fe, Co, Ni, or Cu) system, which contained over 92 at.% Al, led to formation of a structure including an amorphous phase and Al-rich icosahedral nanoparticles ( $D \sim 5\text{--}12 \text{ nm}$ ) precipitated in the amorphous phase.<sup>[22]</sup> Alloys with this structure possess a high tensile strength (up to 1340 MPa), which approaches the strength of special steels.

### Severe Plastic Deformation

Severe plastic deformation applies mostly to plastically deformable materials. In addition to the decrease in the average size of grains to 100–200 nm, it allows producing bulk samples with a nearly pore-free structure, which cannot be prepared by compaction of superfine powders.

The main methods, which are used to considerably refine grains without breakage of samples, are high-pressure torsion and equal-channel angular (ECA) pressing (Fig. 11). The ECA pressing method was proposed in Ref.<sup>[23]</sup>. As compared with other methods of plastic deformation, this method provides the most uniform structure of substances. The structure and properties of submicrocrystalline materials, which were produced using severe plastic deformation, are described in Ref.<sup>[24]</sup>.

**Fig. 11** Schemes of main methods of severe plastic deformation: *Source:* From Ref.<sup>[24]</sup> (A) high-pressure torsion; (B) equal-channel angular pressing.

The main feature of the structure of submicrocrystalline materials prepared by deformation methods is non-equilibrium grain boundaries, which are a source of strong stresses. Triple junctions of grains represent one more source of stress. Annealing of submicrocrystalline materials causes changes in their microstructure. Initially, when the annealing temperature equals nearly one-third of the melting point, stresses are relaxed, grain boundaries acquire a more equilibrium state, and grains grow insignificantly. The further increase in the annealing temperature and time is followed by collective recrystallization, i.e., coarsening of grains.

The method of severe plastic deformation was used to produce a submicrocrystalline structure in such metals as Cu, Pd, Fe, Ni, and Co, aluminum, magnesium, and titanium alloys, and intermetallics. A bulk nanocrystalline sample with grains  $\sim 30\text{--}40$  nm in size was prepared from a coarse ( $D \sim 2\text{--}5\ \mu\text{m}$ ) powder of a non-stoichiometric  $\text{TiC}_{0.62}$  titanium carbide by the method of high-pressure torsion.<sup>[8]</sup>

## MICROSTRUCTURE OF BULK NANOCRYSTALLINE SUBSTANCES

In the simplest case, a nanocrystalline substance, which comprises atoms of one species, includes two components with different structures: grains (crystallites) 5 to 20 nm in size and intercrystalline boundaries up to 1.0 nm long. Crystallites have a similar structure and differ by their orientations and sizes only. The structure of interatomic interactions is determined by the type of interatomic interactions and the mutual orientation of adjacent crystallites. It was thought originally that the intercrystalline substance is characterized by a random location of atoms and the absence of the long- and short-range order.<sup>[17]</sup> This state

was called a gas-like structure, taking into account the location of atoms only.

Later studies showed that the atomic order on interfaces of nanosubstances approaches the atomic order in coarse-grain polycrystals. An example is a comparative study of the structures of coarse-grain palladium and nanocrystalline palladium n-Pd, which was prepared by evaporation and condensation. This study demonstrated that widening of diffraction reflections for n-Pd was a result of a small size of crystallites and stresses in grains or on interfaces rather than the gas-like structure of the grain-boundary phase or a large number of vacancies in grains.<sup>[25]</sup> Pores were detected only at triple junctions and not on the entire length of the interfaces.<sup>[26]</sup> The atomic density on intercrystalline boundaries proved to be nearly equal to its counterpart in crystallites.

According to Ref.<sup>[27]</sup> the coordination number of the first coordination sphere in an as-prepared n-Pd sample was 5–6% smaller than in coarse-grain palladium. However, almost all atoms were located at lattice sites in n-Pd samples, which were aged at room temperature for several months.<sup>[28]</sup> It was found<sup>[27,28]</sup> that grain boundaries in an as-prepared bulk n-Pd sample were in the equilibrium state with a small short-range order. This state was unstable even at room temperature and the sample acquired a more ordered state during 120–150 days, while the size of crystallites increased from 12 to 25–80 nm.<sup>[29]</sup>

Interfaces in compacted nanocrystalline substances may contain three types of defects:<sup>[2]</sup> separate vacancies, vacancy agglomerates or nanovoids at triple junctions, and large voids instead of missing crystallites (Fig. 12).

The annihilation of positrons<sup>[2,30]</sup> is the most reliable up-to-date method used for the study of free volumes in nanocrystalline substances. It is sensitive to extremely small concentrations of defects in solids, namely, from  $10^{-6}$  to  $10^{-3}$  defects per atom. The capture of positrons by defects allows using the electron-positron annihilation for analysis of interfaces in nanosubstances.

When a positron emitted from a radioactive source gets into a solid, it quickly loses its velocity and energy, which drops to the value corresponding to the crystal temperature. Then the positron diffuses in the substance in the free (delocalized) state and annihilates from this state in the characteristic lifetime  $\tau_f$  of about 100 psec. During the time  $\tau_f$ , the positron may move a distance of about 100 nm in defectless solids. Because the size of grains in a nanosubstance is smaller than the length of the positron diffusion in a defect-free grain, virtually all positrons may reach the grain surface and interfaces. If grains contain defects, which capture positrons, only part of positrons reach the grain boundary. Therefore it is possible to obtain

**Fig. 12** Two-dimensional schematic model of a nanocrystalline material with microscopic free volumes as detected by positron lifetime spectroscopy: *Source:* From Ref.<sup>[2]</sup> vacancy-like free volumes (with positron lifetime  $\tau_1$ ) in the interface, nanovoids (agglomerates of about 10 vacancies) at the triple junction of crystallites ( $\tau_2$ ), and a large void ( $\tau_3$ ) of the size of missing crystallites.

information about intragrain defects. After a positron has been captured by a defect, it annihilates from the localized state in a time exceeding  $\tau_f$ . The longer the lifetime of a positron in a defect is, the larger is the free volume.

Schaefer<sup>[2]</sup> and Würschum, Greiner, and Schaefer<sup>[30]</sup> have given considerable study to nanomaterials by the electron-positron annihilation method. Vacancies and nanovoids were detected in nanocrystalline metals Al, Cu, Mo, Pd, Fe, and Ni, nanocrystalline silicon Si and zirconium oxide  $ZrO_2$ , and many other materials. The investigations demonstrated that lifetime spectra of positrons usually contain two strong components and one weak component with intensities  $I_1$ ,  $I_2$ , and  $I_3 = 1 - I_1 - I_2$ , which correspond to the lifetime  $\tau_1$ ,  $\tau_2$ , and  $\tau_3$ , respectively (Fig. 12). In nanocrystalline metals, the lifetime  $\tau_1$  approaches the lifetime of positrons  $\tau_{1V}$  in lattice monovacancies of coarse-grain metals. Therefore  $\tau_1$  is viewed as the lifetime of positrons in vacancy-like free volumes in grain interfaces (interface vacancies). The size of these vacancies corresponds to one or two missing atoms. The positron lifetime  $\tau_2$  characterizes annihilation of positrons in three-dimensional vacancy agglomerates (nanovoids) of the size of about 10 missing atoms. A very long lifetime  $\tau_3$  corresponds to annihilation of positrons in large voids of the size of missing crystallites.

Generally, the positron annihilation revealed the following: 1) the lifetime of positrons in nanocrystalline metals is longer than the lifetime  $\tau_f$  of free

delocalized positrons; 2) positrons are captured by monovacancies, vacancy complexes, and voids, whose size approaches the size of crystallites; and 3) free vacancy volumes, which capture positrons at low temperatures, belong to interfaces and not to crystallites.

The microstructure of submicrocrystalline substances, which are synthesized using severe plastic deformation, differs from the microstructure of compacted nanocrystalline substances. The main feature of the structure of submicrocrystalline substances is the presence of randomly misoriented non-equilibrium grain boundaries. Unannealed submicrocrystalline metals and alloys are characterized by extinction contours along grain boundaries, which point to large elastic stresses. Annealing eliminates dislocations from grains, extinction contours vanish, and a stripe contrast, which is typical of the equilibrium state, appears. The relaxation of interfaces is accompanied by growth of grains during annealing.

## PROPERTIES OF ISOLATED NANOPARTICLES AND NANOCRYSTALLINE POWDERS

The transition from crystals to nanoparticles is followed by changes in the interatomic distances and lattice constants. For example, when the size of Ag and Au particles decreases from 40 to 10 nm, the lattice constant becomes  $\sim 0.1\%$  smaller. When the size of Si particles decreases from 10 to 3 nm, the lattice constant increases by 1.1%. The ambiguity of the dimensional effect may be a result of adsorption of impurities or different chemical compositions of particles. One more possible reason is the structural transformations, which are caused by the decrease in the particle size. Reliable experiments did not reveal shrinkage of the lattice constant as the particle size decreased to 10 nm, whereas shortening of interatomic distances for particles of smaller sizes is real enough as compared with bulk substances.

The most probable reason why the lattice constant of small particles changes as compared with its counterpart in a macroscopic substance consists in uncompensated interatomic bonds of surface atoms and hence the surface relaxation. In the case of nanoparticles, the surface relaxation is a maximum on the surface, decreases toward the center of the particle, and may prove to be oscillating under certain conditions. Thus the lattice constant may either increase or decrease as the size of nanoparticles diminishes.<sup>[7,8]</sup>

The melting temperature  $T_m$  drops non-linearly with decreasing size of small particles of Pb, Sn, Bi, In, Ga, Cu, Ag, Au, and Al. For example, the maximum decrease in the melting temperature of Sn, Ga, and Hg clusters  $\sim 1$  nm in size was 152, 106, and 95 K,

respectively.<sup>[4]</sup> When the radius of CdS colloid nanoparticles was reduced from 4 to 1 nm,  $T_m$  dropped nearly by 800 K.<sup>[31]</sup> According to Refs.<sup>[4]</sup> and <sup>[8]</sup>, melting temperatures of bulk crystals and small particles  $>10$  nm in size differ insignificantly. The melting temperature decreases when the size of nanoparticles becomes less than 10 nm.

Differences in thermodynamic properties of nanoparticles and a bulk substance are a result of changes in the phonon spectrum. The phonon spectrum of small particles contains low-frequency modes, which are absent in spectra of bulk crystals. The phonon spectrum of nanoparticles is limited by some minimum frequency on the side of low-frequency vibrations. No such limitation exists for bulk samples. Specific features of the vibration spectrum of nanoparticles affect the low-temperature heat capacity in the first place.

A theoretical analysis,<sup>[32]</sup> which took into account the quantum-size effect, showed that the low-temperature region ( $T \rightarrow 0$ ) has some temperature  $T_0$ , below which the nanoparticle heat capacity  $C_v(r)$  is smaller than the heat capacity  $C_v$  of a bulk crystal. At  $T > T_0$ , the difference  $\Delta C = C_v(r) - C_v$  becomes positive, reaches a maximum, and, as the temperature rises further, turns to zero. The difference of the heat capacities  $\Delta C = C_v(r) - C_v \rightarrow 0$  with increasing size  $r$  of the particle. These conclusions agree with experimental data.<sup>[33]</sup> The heat capacity of Ag nanoparticles 10 nm in size had the quantum-size effect in a magnetic field with  $B = 6$  T: at  $T < 1$  K and  $T > 1$  K, the heat capacity of Ag nanoparticles was lower and higher than the heat capacity of bulk silver, respectively. In the absence of the magnetic field, the heat capacity of colloid silver nanoparticles was higher than the heat capacity of bulk Ag over the whole temperature interval studied (Fig. 13).

An examination of phonon densities for coarse-grained Ni and a nanocrystalline nickel powder with particles  $\sim 10$  nm in size showed that the density of phonon states increased in n-Ni as compared with coarse-grained Ni at energies lower than 15 meV.<sup>[34]</sup>

Specific features of magnetic properties of nanoparticles are connected with discreteness of electron and phonon states. In particular, the Curie paramagnetism of a nanoparticle can overlap the Pauli paramagnetism at low temperatures. For example, magnetic susceptibility of lithium nanoparticles of diameter 3.2 nm corresponds to the Pauli paramagnetism at high temperatures and obeys the Curie law at low temperatures.<sup>[4]</sup>  $\text{Hg}_{13}$  clusters are weak paramagnetics in a magnetic field of up to 15 kOe independently of temperature. In a field with  $H > 20$  kOe, susceptibility of  $\text{Hg}_{13}$  clusters increases to large paramagnetic values at temperatures below 80 K, although mercury is a diamagnetic.<sup>[4]</sup>

**Fig. 13** Specific heat capacity  $C$  of colloidal Ag with  $D = 10$  nm at  $T \leq 10$  K. Measurements were made in the absence of a magnetic field and in a magnetic field  $B = 6$  T. The dashed line shows the specific heat capacity of bulk coarse-grained silver.

The phenomenon of superparamagnetism is connected with the small size of ferromagnetic particles. When some critical size  $D_c$  is reached, ferromagnetic particles turn to single-domain ones, and, simultaneously, the coercive force  $H_c$  becomes a maximum. As the particle size diminishes further, the coercive force drops abruptly to zero as a result of transition to the superparamagnetic state. Typical ferromagnetics acquire the superparamagnetic state when the particle size is less than 1–10 nm.

When the size of Fe nanoparticles decreases from 80 to 8–10 nm, the coercive force  $H_c$  increases almost three times. The dimension dependence of  $H_c$  for Ni nanoparticles exhibits a maximum corresponding to nanoparticles 15 to 35 nm in diameter. As the particle size diminishes from 15 to 12 nm,  $H_c$  decreases nearly 5 times.<sup>[35]</sup> An analysis of the saturation magnetization  $I_s$  for bulk Ni and a nanocrystalline Ni powder ( $D = 12, 22$  and  $100$  nm)<sup>[36]</sup> showed that refinement of particles to 12 nm caused an almost twofold decrease in the  $I_s$  value as compared with bulk Ni.

Optical dimensional effects show themselves for nanoparticles whose size is smaller than the radiation wavelength and does not exceed 10–15 nm.<sup>[37]</sup> When fine-grain metal films absorb light, the visible part of the spectrum contains peaks, which are absent in the spectra obtained for bulk metals. For example, granulated films of Au particles 4 nm in diameter have a maximum absorption at  $\lambda = 560\text{--}600$  nm. Absorption spectra of Ag, Cu, Mg, In, Li, Na, and K nanoparticles also contain maxima in the optical range.<sup>[4]</sup> Differences in absorption spectra of nanoparticles and bulk metals are explained by the fact that the imaginary part of dielectric permeability is inversely proportional to the particle size. The particle size determines the shape of the low-frequency edge and the absorption bandwidth.

The size of semiconductor nanoparticles is comparable with the Bohr radius of excitons in a macroscopic crystal: the exciton radius changes over broad limits from 0.7 nm for CuCl to 10 nm for GaAs. The decrease in the size of nanoparticles causes displacement of the exciton absorption band to the high-frequency region (“blue” shift). The blue shift is observed for CdS nanoparticles with  $D \leq 10\text{--}12$  nm. When the size of ZnO, ZnS, CdS, and CdSe nanoparticles decreases, their luminescence spectra are displaced to the short-wave region.

### EFFECT OF THE GRAIN SIZE AND INTERFACES ON PROPERTIES OF BULK NANOSUBSTANCES

Properties of bulk nanomaterials depending on the grain size and the state of grain boundaries have been analyzed in reviews.<sup>[6,38,39]</sup>

At 300 K, the microhardness of bulk nanocrystalline substances is usually several times larger than  $H_V$  of coarse-grained substances. The growth of  $H_V$  was observed with decreasing size of n-Fe and n-Ni grains.<sup>[40]</sup> The microhardness  $H_V$  of nanocrystalline n-Cu copper ( $D \sim 16$  nm) is  $\sim 2.5$  times larger than that of copper with grains 5  $\mu\text{m}$  in size. However, as the size of n-Cu grains diminishes from 16 to 8 nm,  $H_V$  decreases by  $\sim 25\%$ . The decrease in  $H_V$  is also observed when n-Pd grains are refined from 13 to 7 nm. The microhardness  $H_V$  of Ni-P, TiAlNb, TiAl, and NbAl<sub>3</sub> nanocrystalline alloys drops as the grain size decreases from 60–100 to 6–10 nm.

In a general case, the microhardness of nanosubstances grows as the grain size decreases to some  $D_c$  value and drops at  $D < D_c$ . Mechanical and elastic properties of nanocrystalline metals are determined not only by a small size of grains, but also by the state of interfaces. Therefore contradictory results on the dimension dependence of the microhardness may be due to different structures of interfaces.

Strength properties of nanosubstances are enhanced with decreasing size of grains. The yield stress of nanocrystalline Pd ( $D = 5\text{--}15$  nm) and Cu ( $D = 25\text{--}50$  nm) is 2–3 times higher than the yield stress of coarse-grained metals.<sup>[41]</sup> The tensile strength of nanocrystalline metals is 1.5–8 times larger than that of coarse-grained metals.<sup>[40,41]</sup>

At temperatures from 150 to 300 K, the heat capacity  $C_p$  of n-Pd ( $D = 6$  nm) and n-Cu ( $D = 8$  nm) is 30–50% and  $\sim 10\%$  higher than the heat capacity of coarse-grained bulk Pd and Cu, respectively. In the interval of 0.06 to 10.0 K, the low-temperature heat capacity of compacted nanocrystalline copper n-Cu with grains 6.0 and 8.5 nm in size proved to be 5–10 times larger than the heat capacity of coarse-grained copper. Measurements of the heat capacity of amorphous, nanocrystalline, and coarse-grained selenium Se over the temperature interval from 220 to 500 K<sup>[42]</sup> revealed a small increase in the heat capacity of bulk nanocrystalline n-Se as compared with coarse-grained Se at  $T < 375$  K. A comparison of the heat capacity of substances in nanocrystalline, amorphous, and coarse-grained states<sup>[43]</sup> showed that the heat capacity of samples prepared by compaction of nanopowders is largely different from the heat capacity of substances in the coarse-grain state (Table 1). Oppositely, this difference does not exceed 2% for samples prepared by crystallization from the amorphous state. One may think that most of the excess heat capacity of compacted nanomaterials is a result of a large surface area of interfaces, structural distortions, and impurities.

The thermal expansion coefficient  $\alpha$  is proportional to the heat capacity. Therefore the coefficient  $\alpha$  of bulk nanosubstances should be higher than  $\alpha$  of coarse-grained polycrystals. Indeed, the coefficient  $\alpha$  of nanocrystalline copper n-Cu with grains 8 nm in size on the average is twice as large as  $\alpha$  of coarse-grained copper.<sup>[44]</sup>

A large surface area of interfaces and a high concentration of defects determine an intensive scattering of charge carriers in nanomaterials. A considerable increase in electroresistivity  $\rho$  of nanocrystalline Cu, Pd, Fe, and Ni and various alloys with decreasing size of grains has been noted by many researchers. For example, at temperatures  $0 < T \leq 275$  K, electroresistivity of n-Cu ( $D = 7$  nm) is 7 to 20 times larger than  $\rho$  of common coarse-grained copper.

The effect of the nanostate on magnetic properties of paramagnetics is well pronounced, e.g., in palladium (Fig. 14).<sup>[8]</sup> At 300 K, susceptibilities of nanocrystalline n-Pd and the initial coarse-grained palladium differ by 8%. According to Ref.<sup>[8]</sup> such a considerable variation of the susceptibility is a result of the presence of intra-grain vacancy complexes in n-Pd, which change the density of electron states at the Fermi level.

**Table 1** Comparison of heat capacity  $C_p$  ( $\text{J mol}^{-1} \text{K}^{-1}$ ) for the nanocrystalline, amorphous, and coarse-grained polycrystalline states of different substances

Material	State					
	Nanocrystalline			Amorphous	Coarse-grained

Source: From Ref.<sup>[43]</sup>.

The majority of studies into magnetic properties of bulk nanosubstances have dealt with ferromagnetic metals and alloys. A study of submicrocrystalline Ni<sup>[45]</sup> has confirmed that the coercive force of plastically deformed ferromagnetics is several times larger than  $H_c$  of initial metals. However, annealing of submicrocrystalline Ni at  $T \leq 470$  K causes a decrease in the coercive force, while the grain size remains unchanged. Annealing at higher temperatures leads to a decrease in  $H_c$  and an increase in the grain size. Therefore a large

coercive force of submicrocrystalline metals and alloys is equally determined by a non-equilibrium state of interfaces on the one hand and a small size of grains on the other hand. Relaxation of interfaces during annealing and growth of grains cause a decrease in  $H_c$ .

## CONCLUSION

Studies performed in recent decades have considerably improved our understanding of the effects related to the size of grains (crystallites) in solids. For a long time, studies have been focused on small particles (nanoclusters) whose properties are intermediate between properties of isolated atoms and polycrystalline solids. The advent of methods for production of compact materials having an extremely fine-grain structure with nanometer-sized grains provided conditions for the study of the structure and properties of solids in the nanocrystalline state. Each of those methods has its virtues and drawbacks, and neither of them is universal because each is applicable to a certain range of substances. Because of their specific structure, properties of nanocrystalline substances differ considerably from those of usual polycrystals. An analysis of the available experimental data shows that not only the grain size (as in isolated nanoparticles), but also the structure and the state of interfaces (grain boundaries) play a significant role in a nanocrystalline solid. The separation of surface effects (connected with interfaces) and volume effects (related to the size of particles) is very important for the theoretical interpretation of the experimental results obtained for isolated nanoparticles and bulk nanocrystalline materials.

Extensive studies of nanocrystalline substances and materials have led to appearance of new sciences,

**Fig. 14** Magnetic susceptibility  $\chi$  of nanocrystalline n-Pd and coarse-grained palladium: Source: From Ref.<sup>[8]</sup> (1) annealing  $\chi(300, T)$  and (2) temperature  $\chi(T)$  dependences of the susceptibility for n-Pd; (3) annealing  $\chi(300, T)$  and (4) temperature  $\chi(T)$  dependences of the susceptibility for the initial coarse-grained Pd. namely, nanocrystalline solid-state physics and chemistry. Therefore it is possible to establish tight contacts between nanomaterials and nanotechnologies, which will present the main motive force of the scientific and technological progress in the 21st century.

## INTRODUCTION

Advances in nanoparticle synthesis stem from their fundamental technological importance; numerous research efforts have recently been devoted to the preparation of metal oxide nanostructures with tailored features, because of their unique electronic, optical, and mechanical properties and their widespread potential applications in fields including catalysis, nanoelectronics, optoelectronics, and biotechnology.<sup>[1–4]</sup>

The use of surfactants to control the features of tailored nanoparticles is widespread, and the number of synthetic routes reported in the literature to obtain oxides with controlled features is enormous. The adopted procedures can be complex and composite so that it is not always easy to individuate some common principle in the selection of the stages, conditions, and nature of surfactant molecules. In this article, results will be grouped with reference to three main categories that imply a different philosophy of operation: templated synthesis, microemulsion procedure, and hydrothermal growth.

## TEMPLATED SYNTHESIS

One of the first and main applications of surfactants in the synthesis of metal oxides is as templates or directing agents for the effective control of mesophase structures. In principle, in these syntheses, the morphology of the solid is imposed by the tridimensional mesostructure of a surfactant, which acts as a nucleating agent and which is finally removed after the growth of the inorganic material. By modulating the operation conditions and the surfactant features, the synthesis can be projected toward liquid crystal phases with different tridimensional organization and consequently toward materials having accurately controlled pore network.

Outstanding examples of surfactant templating technique are represented by the synthesis of mesostructured silicates, the M41S family,<sup>[5]</sup> which includes the hexagonal MCM-41, the cubic MCM-48, and the

lamellar MCM-50 phases, obtained in basic media using ionic surfactants as templates. Active debate is present in the literature concerning the actual mechanism of the process, either following the expected liquid crystal templating route or a transformation mechanism from lamellar to hexagonal phase. Vartuli et al.<sup>[6]</sup> found that in the case of MCM41, MCM48, the lamellar, and the cubic octamer, the three-dimensional (3-D) organization of the solid exactly reproduced the behavior of the surfactant in solution; on the other hand, Chen et al.<sup>[7]</sup> used x-ray diffraction (XRD), Si-nuclear magnetic resonance (NMR), and in situ N-NMR, and observed no hexagonal liquid crystalline mesophases either in the synthesis gel or in the surfactant solution used as a template. Stucky and coworkers<sup>[8]</sup> assert a transformation mechanism for the formation of the hexagonal phase where a preformed micellar assembly of a surfactant that is broken up and rearranged upon the addition of the inorganic species to form a new phase, converts to the hexagonal phase upon prolonged ageing. Possibly the formation of these mesophases follows a cooperative self-assembly mechanism, based on the electrostatic interactions between the oppositely charged micellar headgroups and polysilicate species.

Indeed Adachi, Harada, and Harada<sup>[9]</sup> recently proposed a surfactant/oxide interactive mechanism to be controlling the microstructure formation in the growth processes of silica nanotubes by a templating mechanism with cationic surfactants; the important factors leading to the desired morphology are found to be the geometric matching between the occupied area of surfactant and that of silicate molecules at the interface, and the packing parameter of the surfactant/silicate assemblies.

Since the MCM synthesis, the molecular templating technique has been used to synthesize a variety of mesoporous materials<sup>[10]</sup> both for pure oxides and for composites. For example, Chao and Ruckenstein<sup>[11]</sup> recently obtained mesostructured V-Mg oxides by ionic micellar templates by accurately controlling the conditions of charge development at the oxide/surfactant interface.

However, in the case of several oxides (e.g., alumina and titania) where ionic surfactants were used as a template, the nanostructured mesophases collapsed, at least in part, upon surfactant removal.<sup>[12]</sup> The electrostatic surfactant/oxide interactions combined with the fast grain growth of the oxide, which occurs upon calcination of the surfactant-rich precursor, may in fact provoke pore collapse with degradation of the mesostructure.<sup>[12]</sup> Also in our laboratory, the templated synthesis of titanium dioxide by gemini cationic surfactants<sup>[13]</sup> was not fully successful. Mesoporosity induced by the three-dimensional organization of the surfactant could be appreciated by the hysteresis loop of the nitrogen adsorption–desorption isotherm (Fig. 1, curve b), with respect to the reference material prepared without surfactant. However, the promotion of the sample surface area (around 12–13 m<sup>2</sup>/g vs. the reference sample without surfactant, 7–9 m<sup>2</sup>/g) was not relevant owing to sintering between the particles upon heating. The inset to Fig. 1 reports the experimental adsorption isotherms, at the TiO<sub>2</sub>/solution interface, of both the gemini-like and the monomeric pyridinic surfactants. The shape of the two curves, obtained at constant ionic strength and oxide surface potential (solution pH), is markedly different: The monomeric isotherm (curve 2) is S-shaped showing a low adsorbent–adsorbate affinity, in agreement with results by other authors on simple alkylpyridinium salts adsorbed at solid/liquid boundaries. Dodecylpyridinium monomers are reported to be

**Fig. 1** N<sub>2</sub> adsorption–desorption isotherms of TiO<sub>2</sub> samples, the reference and the surfactant-assisted one. Inset: linear plot of the surface excess ( $\Gamma$ ) vs. the surfactant equilibrium concentration: 1) dimeric surfactant, 1,10-didodecyl-4,40-bipyridinium chloride; 2) monomeric molecule, 1-dodecyl-4-methylpyridinium chloride. Adsorption of cationic “gemini” surfactants at the TiO<sub>2</sub>/solution interface. *Source:* From Ref.<sup>[13]</sup>.

weakly interacting with rutile.<sup>[14]</sup> The higher affinity of the gemini for the solid appears also from the strikingly larger adsorbed amounts apparent in inset of (Fig. 1, curve 1). Comparing the quasiplateau regions, the gemini adsorbed amounts are about four times larger than for the monomer; however just this high affinity leads to a subsequent collapse of the mesoporous structure during the calcinations step.

Success was achieved, instead, by using neutral surfactants or carboxylic acids as surfactants. In the case of titanium dioxide, for example, very recent results show that the use of tri- or di-block copolymers has led to the formation of stable mesoporous structures.<sup>[15–17,8]</sup> Serrano et al.<sup>[15]</sup> combined the neutral templating route with a crystallization treatment in acid–ethanol mixtures and succeeded in obtaining bimodal micromesoporous anatase TiO<sub>2</sub> (Fig. 2) with a large surface area; hollow titania particles were obtained by using a triblock copolymer (PEO<sub>n</sub>–PPO<sub>m</sub>–PEO<sub>n</sub>).<sup>[16]</sup> In Fig. 2, the nitrogen adsorption isotherm is apparently of type IV, typical of mesoporous materials, although with a remarkable adsorption at low relative pressures, suggesting the presence also of micropores.

By means of neutral templating, other features, besides porosity, could be successfully controlled. Monodisperse titania particles (Fig. 3) of variable sizes could be obtained in the presence of diblock Lutensol (RO(CH<sub>2</sub>CH<sub>2</sub>O)<sub>x</sub>H) and/or triblock-copolymers Pluronic (PEO<sub>n</sub>–PPO<sub>m</sub>–PEO<sub>n</sub>)<sup>[9]</sup> owing to cooperative mechanisms possibly implying steric stabilization. As shown in Fig. 3, highly monodispersed particles are obtained in the presence of Lutensol polymers. In addition, other researchers,<sup>[12]</sup> by simply adjusting the surfactant/solvent ratio, have successfully controlled the size of magnetic nanoparticles ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, Fe), all

**Fig. 2** N<sub>2</sub> adsorption–desorption isotherm and pore-size distribution of TiO<sub>2</sub> sample after treatment with 1% HCl/EtOH. *Source:* From Ref.<sup>[15]</sup>.

**Fig. 3** SEM pictures of the titania particles synthesized by addition of Lutensol ON 50. *Source:* From Ref.<sup>[16]</sup>.

having spherical shape and uniform size. The phase composition, especially in the case of the possible concomitant formation of different polymorphs, could also be controlled. Luo<sup>[17]</sup> using a triblock copolymer as a structure-directing agent (F-127 or Pluronic P-123) and  $\text{TiCl}_4$  as precursor, by simply varying the solvents, successfully controlled the phase composition and obtained either pure anatase, pure rutile, or bicrystalline compounds (anatase and rutile) or tricrystalline (anatase, rutile, and brookite) with controlled relative enrichment (Table 1). All the samples were calcined at  $380^\circ\text{C}$  for five hours.

## MICROEMULSION TECHNIQUE

A microemulsion is an isotropic and transparent mixture containing oil and water separated by a thin surfactant monolayer. From a particle preparation point of view, the microemulsion system, with an internal structure consisting of small droplets, is the most

interesting. The water-in-oil (w/o) microemulsion is of particular interest because it can be regarded as a collection of tiny compartments made up of the hydrophilic moiety of the surfactant, each filled with water, where the water droplets are in the size range of a few nanometers to 100 nm; they can be used as small microreactors for the product synthesis. The surfactant-stabilized microcavities provide a cage-like effect, which limits particle nucleation, growth, and agglomeration. The size of the final particle will depend much on the size of the droplets in the microemulsion. The droplet size will, in its turn, be influenced by the water-to-surfactant ratio. An increase of this ratio at constant concentration of the surfactant will increase the average diameter of the droplets. When the amount of water and oil is kept at fixed values, an increase in the amount of surfactant will increase the number of droplets. That means that the number of metal ions per droplet will decrease and consequently the size of the particles.<sup>[18]</sup> In the case of a microemulsion-mediated synthesis of acicular  $\gamma\text{-Fe}_2\text{O}_3$  with a spherical diameter of 7–8 nm, Chhabra et al.<sup>[19]</sup> showed that each microemulsion droplet gives birth to a single particle of  $\gamma\text{-Fe}_2\text{O}_3$ .

In the case of  $\text{SnO}_2$ , Chen and Gao<sup>[20]</sup> by combining a simple w/o microemulsion with a hydrothermal process, obtained small single-crystal particles with a narrow size distribution, which could be refined by modulating the ageing conditions. Fig. 4 illustrates the high-resolution transmission electron microscope image of the  $\text{SnO}_2$  nanoparticles. According to the distinct lattice fringes (inset of Fig. 4), the observed nanoparticles are equiaxial single crystals, whose diameters are less than 3.0 nm.

Nanoparticles of either anatase or rutile phases were obtained by the hydrothermal treatment of microemulsions and by only varying the acid (either HCl or  $\text{HNO}_3$ ) during the hydrothermal treatment of the microemulsion. Similarly Yan, Chen, and Zhang<sup>[21]</sup>

**Table 1** Synthetic conditions for mesoporous  $\text{TiO}_2$

Sample	Solvent	Aging time (days)	Phase content <sup>a</sup>	Crystalline size <sup>b</sup> (nm)
Ti-M (F-127)	Methanol	3	Pure A	12
Ti-MH (F-127)	Methanol + $\text{H}_2\text{O}$	3	A (75%) + R (25%)	12 (A)
Ti-E (F-127)	Ethanol	6	A (80%) + R (20%)	16 (A)
Ti-E (P123)	Ethanol	6	A (52%) + R (48%)	17 (A)
Ti-EH (F-127)	Ethanol + $\text{H}_2\text{O}$	6	A (48%) + R (32%) + B (20%)	13 (A)

have obtained either anatase or rutile by autoclaving microemulsions and by simply changing the proportion of Cl<sup>-</sup> and SO<sub>4</sub><sup>2-</sup> in the aqueous phase of the microemulsion.

## HYDROTHERMAL GROWTH

In the case of hydrothermal growth of oxides in the presence of surfactants, the nature and extent of the surfactant–oxide interaction are very important because they control the reactions of dissolution–reprecipitation of the solid and, consequently, they potentially impose both morphological and structural aspects. In the case of ionic surfactants, the presence of attractive electrostatic interactions is crucial.

In the preparation of ceria nanorods, Vantomme et al.<sup>[22]</sup> observed that only at pH values above the isoelectric point of the particle attractive interactions with the cationic surfactant cetyltrimethylammonium bromide (CTMA<sup>+</sup>Br<sup>-</sup>) occurred, leading to ion pairs. The ion pairs (Ce–O<sup>-</sup>⋯CTMA<sup>+</sup>) polymerize during micellization and under autoclaving, by interchain attraction, flocculation, or coalescence, which results in the formation of ceria/surfactant bilayers, which in turn drive the orientation growth of ceria nanorods. The positive adsorption of the surfactant at the growing ceria particles is directly observed in the Fourier transform infrared spectroscopy spectrum (Fig. 5A) of the as-synthesized sample, which exhibits absorption bands in the region 2800–2900/cm, attributed to the C–H stretching mode of hydrocarbons and the bands at 1450–1500 and 720/cm assigned to the bending vibration of the C–H band of methylene groups. The presence of the surfactant was appreciable also in the XRD patterns of the as-synthesized sample (Fig. 5B). The peak at the low angle is the result of the

**Fig. 5** Ceria nanorods before (1) and after calcinations (2): (A) FT-IR spectra; (B) x-ray diffraction patterns (\*, reflection of the participating CTMABr species; #, reflections of hexagonal Ce(OH)<sub>3</sub>; \*, reflections of cubic CeO<sub>2</sub>). *Source:* From Ref.<sup>[22]</sup>.

interactions between surfactant and ceria and is similar to an XRD pattern of the surfactant itself (CTMABr).

The analysis of the XPS spectra of carbon 1s of TiO<sub>2</sub>–sodium dodecyl sulfate (SDS) adsorbed samples may allow the obtaining of information concerning the mode of surfactant adsorption. Carbon spectra show the presence of a peak localized at 288.6 eV (Figs. 6A and B). This peak (peak D in the figure) is present in all adsorbates, although its intensity is decreasing with the concentration of the surfactant, while it is not appreciable in the pure salt spectra. In the literature carbon 1s peaks at comparable binding energy are attributed, in the absence of C–O bonds, to carbon species with neighboring electron-attracting species. In the present case it can be suggested that the

**Fig. 6** XPS C 1s region of  $\text{TiO}_2$  precursor samples hydrothermally grown at  $\text{pH} = 3$ , at increasing surfactant (SDS) concentration (A) monomer; (B) micelles. Components—*a*: 284.6 eV,  $\gamma$  carbons and adventitious; *b*: 285.4 eV,  $\beta$  carbons; *c*: 286.4 eV,  $\alpha$  carbons; and *d*: 288.6 eV. Insets: sketches of the possible surfactant orientations.

peaks at 288.6 eV are the result of local environments produced by the proximity of several sulfate groups on the carbon atoms of the alkyl chain. The observed decreasing intensity of the peak with the surfactant concentration can be related to different orientations assumed by the molecules at the surface. At low surface coverages (monomer adsorption), the molecules can be supposed to be mainly lying flat on the oxide surface (inset Fig. 6A); the carbons in the chain would therefore experience the electron-attractive effects produced by the adsorbed sulfate groups. At higher surfactant concentrations hemimicelles<sup>[13]</sup> start to form and, eventually, micelles also adsorb (inset in Fig. 6B). The alkyl chains in the micelles are shielded from the neighboring interactions with the sulfate groups and the intensity of the 288.6 eV peak decreases progressively.

Also in the case of the hydrothermal growth of  $\text{TiO}_2$  particles, the electrostatic interactions between the oxide surface and ionic surfactants play a central role. Specifically in the case of  $\text{TiO}_2$  crystals, obtained by sol-gel from titanium alkoxide<sup>[23–26]</sup> and subsequently grown in the presence of an anionic surfactant (SDS) the oxide phase composition (Fig. 7) appears to be imposed by the interplay between oxide/surfactant interactions and surfactant self-aggregation processes. At a positive oxide surface charge ( $\text{pH} 3$ ), in the

**Fig. 7** Quantitative anatase content by elaboration of x-ray diffractograms of samples calcined at  $600^\circ\text{C}$  as a function of  $\text{pH}$  of the hydrothermal growth. The third axis reports the sequence of the samples obtained for increasing surfactant (SDS) concentration.

absence of surfactant and for the surfactant monomers, anatase is by far the major component, while for surfactant concentrations at the CMC or larger, the anatase content drops dramatically. The situation is opposite in the conditions corresponding to the isoelectric point of the oxide ( $\text{pH} 6$ ). The amount of anatase in the powder increases markedly for the largest surfactant concentration in the hydrothermal treatment.

Conditions of particle-promoted aggregation are reported to favor the growth of rutile crystals and the relative enrichment of the sample in this polymorph, in contrast with the case of anatase. Let us examine now how the conditions adopted during the hydrothermal growth intervene in this process. The most evident case concerns the samples obtained in attractive electrostatic surfactant-oxide conditions ( $\text{pH} 3$ ). When the surface of the precursor particles is the locus of adsorption of surfactant monomers at low degree of coverage with, possibly, a prevailing flat orientation on the surface, the particles do not tend to aggregate, and the formation of anatase is slightly promoted with respect to the sample with no surfactant. At higher concentrations, the micelles are strongly adsorbed and the positively charged oxide acts, at least in part, as the counterion for the organic anion. The presence of strong electrostatic attraction between the micelles and the charged oxide may promote bridging phenomena between different particles. It is even possible that some deposition of soluble  $\text{Ti}(\text{OH})_4$  species may occur in the region with a negative curvature

radius (Fig. 8A) induced by the micelle bridge. For growth processes at the oxide isoelectric point (pH 6) again the monomer at low concentration provokes no important effects, while at higher surfactant concentrations, the micelles much less adsorbed and surrounded by a diffuse double layer of thickness larger than the micelle radius (Fig. 8B), may act as spacers imparting stability to the suspension and, consequently, promoting the growth of the anatase polymorph.

The importance of the effects induced by the presence of a surfactant during the growth of an oxide depends on intrinsic balance between the hydrophilic and hydrophobic surfactant molecule components. Fig. 9 shows the direct comparison between the effects of three ionic surfactants on the  $\text{TiO}_2$  growth, in the respective conditions of attractive electrostatic interactions. It is immediately apparent that the anionic surfactant induces larger effects with respect to the other two molecules in the same conditions, and further that for the same pyridinium head group the longer the alkyl chain the larger the effects. This occurrence is to be traced back to the larger affinity shown

**Fig. 8** Sketches of the possible role played by micelles on the particle attachment, during the growth: (A) in the presence of attractive electrostatic interactions with the  $\text{TiO}_2$  particles (pH 3) and (B) at the particles isoelectric point (pH 6).

**Fig. 9** Quantitative anatase content of samples calcined at  $600^\circ$  at different surfactant concentrations, in the conditions of attractive oxide–surfactant interactions (SDS, sodium dodecylsulfate; DPC, dodecylpyridinium chloride; CPC, cetylpyridinium chloride).

by SDS toward the  $\text{TiO}_2$  surface, with respect to pyridinium salts.<sup>[27,28]</sup>

In growth processes, surfactants may also act as “shape inducing reagents”,<sup>[29,30]</sup> i.e., as species that, by modulating the surface free energy of the crystal, promote growth along one direction. Numerous recent studies have been focused on the synthesis of one-dimensional (1-D) nanostructures including nanorods and nanowires with their advantages of exceptional anisotropic electronic properties as well as facile applicability for the construction of two-terminal circuit devices. In these cases a careful design of the reaction factors is indispensable for the morphological control of the products. The synthetic approach for 1-D nanocrystals must fulfill the following requirements: the development of a well-defined precursor system that can generate stable monomers, sufficiently high monomer concentration to maintain the kinetically controlled growth regime, and the proper choice of surfactants that can modulate the energy of specific crystal faces. This latter effect can occur either through direct adsorption of the surfactant at the surface of the growing crystallites or be mediated by the formation of complexes or even hydrogen bonding. In the case of the growth of  $\gamma$ -alumina nanofibers, Zhu, Riches, and Barry<sup>[30]</sup> believe that the anisotropic growth of the boehmite precursor is to be related to hydrogen bonding between the oxide groups in the nonionic surfactants and the boehmite surface which reduces the free energy of the crystallites with low dimensions. This will allow the boehmite crystals to grow along one direction.

Sun et al.<sup>[31]</sup> have obtained ZnO single-crystal nanorods by hydrothermal oxidation of a zinc metal

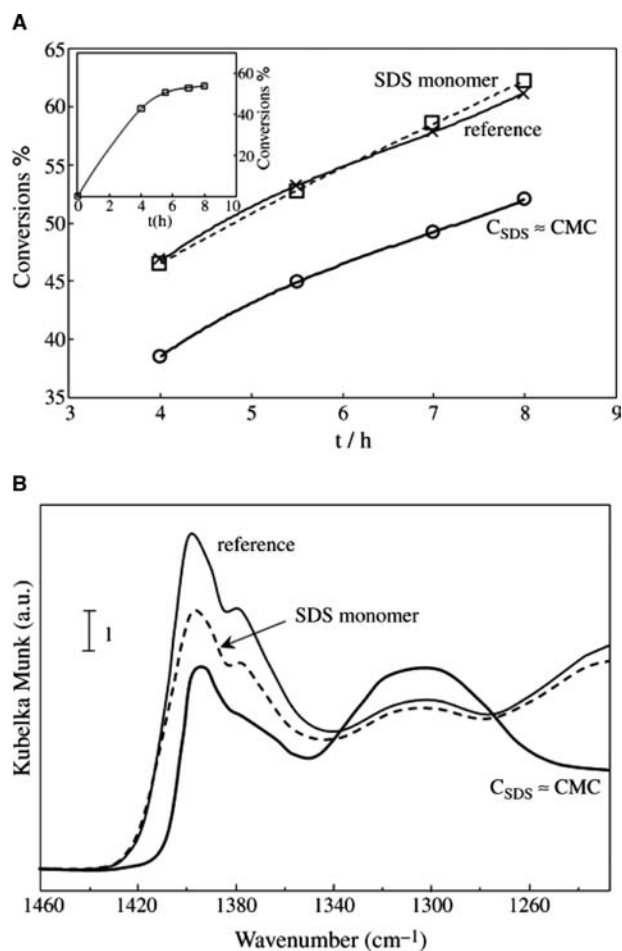

**Fig. 10** TEM micrograph of the ZnO sample obtained in the presence of CTAB with 20 hr of hydrothermal treatment at 180°C. *Source:* From Ref.<sup>[31]</sup>.

powder at 180°C in the presence of cetyltrimethylammonium bromide (CTAB). The typical morphology of the samples obtained in the presence of CTAB with 20 hr of hydrothermal treatment is shown in Fig. 10. The presence of CTAB intervenes in several ways in supporting the oxide growth. On one side the surfactant lowers the surface tension at the ZnO/solution interface so that a lower supersaturation is needed for the solid formation. Further the surfactant acts as a carrier for  $\text{CTA}^+ - \text{Zn}(\text{OH})_4^{2-}$  ion pairs and controls the landing of the growing units onto the (0001) crystal face promoting the preferential growth.

### SURFACTANT-ASSISTED PREPARATION OF NANOPARTICLES FOR APPLICATIONS IN HETEROGENEOUS CATALYSIS

The main advantages of using surfactant-assisted techniques in the preparation of catalytic materials are related to the possibility of controlling properties such as particle size, morphology, and size distribution. Nanosize particles with a narrow size distribution can often be achieved and, therefore, structure-sensitive catalytic reactions can benefit from the preparation procedure. A review by S. Eriksson shows several examples, relative to both metallic particles and oxides, of catalysts prepared by microemulsion technique; they prove to be, in some cases, superior to catalysts prepared by traditional methods, regarding both the catalytic activity and/or selectivity.<sup>[32]</sup> However there may be some drawbacks. For example, in the case of catalysts prepared by microemulsions the scaling-up of the catalyst preparation is still a challenge and in

**Fig. 11** (A) Reagents conversion for benzoic acid esterification as a function of the reaction time for  $\text{SO}_4\text{-ZrO}_2$  sample calcined at 620°C. Inset: total reaction profile (conversion vs. time) and (B) DRIFT spectra of the same samples.

some cases the presence of the surfactant in the catalysts preparation may affect the surface structure of the material and, therefore, its catalytic activity. For example the mesosilicates of the M41S family obtained by templating with ionic surfactants proved to be ineffective in several applications, particularly in catalysis, because of the absence of active sites in the siliceous framework. Sulfated zirconia is an excellent solid acid catalyst.<sup>[33–35]</sup> There is abundant catalysis literature in the area of strong zirconia-based solid acids,<sup>[36–38]</sup> such as the isomerization of butane at room temperature<sup>[39]</sup> and hydrocracking and hydroisomerization reactions of molecules in the liquid phase. Conventional preparations of sulfated zirconia lead to microporous material suitable for reactions of small molecules in the vapor phase. If conventional sulfated zirconia is calcined at high temperatures, the micropores collapse and larger pores are formed with wider pore-size distributions.<sup>[40]</sup> To form a catalyst that has shape selectivity for larger molecules, narrow pore-size

distributions need to be created.<sup>[41,42]</sup> However, the synthesis of sulfated zirconia by templating with anionic surfactants produces less active catalysts for the liquid-media reaction of esterification of benzoic acid with methanol. The catalytic conversion (Fig. 11) appreciably decreases in the case of the samples obtained by in situ sol-gel synthesis at the highest concentration of SDS. It is relevant to note that the samples were routinely calcined at 620°C and that no residual surfactant was present in the samples; further the reported decrease in the activity cannot be brought back to morphological effects. Apparently the presence of the surfactant at high concentrations modifies the adsorption of sulfates species at the oxide surface, which creates the acidity of the surface Zr species. The DRIFT spectra of the calcined samples support this hypothesis. The presence of the two intense peaks between 1250 and 1350/cm in the case of the samples obtained at the highest surfactant concentration suggest a different coordination of the sulfate groups bound to zirconia crystallites with respect to the “regular” coordination of sulfates in an active zirconia catalyst.

## CONCLUSIONS

The addition of an amphiphilic molecule in one of the synthetic steps leading to a nanocrystalline material may greatly contribute to controlling the manifold features bearing relevance to the reactivity of the material. The possible choices of operation are numerous and the effects provoked may concern control of the particle size and shape, the relative enrichment in different polymorphs, or the surface state.

The authors believe that the first goal to be reached, in the use of surfactants for the assisted growth of oxides, is the development of a better fundamental understanding concerning the features of the solid-surfactant interactions virtually encompassing all steps in the material evolution. This knowledge, based on general criteria, could be successively used to project a priori the specific conditions to be adopted to obtain the material tailored for the final application.

# Nanocrystalline Zeolites

Vicki H. Grassian

Sarah C. Larsen

Department of Chemistry, University of Iowa, Iowa City, Iowa, U.S.A.

## INTRODUCTION

Zeolites are aluminosilicate molecular sieves with pores of molecular dimensions.<sup>[1,2]</sup> Zeolites can be synthesized with a wide range of pore sizes and topologies and are used in applications such as catalysis, chemical separations, and as adsorbents and ion exchangers. The zeolite chemical composition, framework topology, and pore size can be varied to control reactivity and selectivity. Two common zeolites, ZSM-5, and Y, are shown in Fig. 1 with one molecule of adsorbed cyclohexane to show the relative sizes of the pores in these materials. It can be seen that these materials, by their very nature, have dimensions in the nanometer-size regime.

Although the pore dimensions of these materials are in the nanometer-size range, the zeolite crystals prepared through conventional syntheses are typically on the order of micrometers in diameter. Recently, however, there has been a great deal of interest in the synthesis of nanocrystalline zeolites, i.e., zeolites with discrete, uniform crystals with dimensions of less than 100 nm, and their unique properties relative to conventional micrometer-sized zeolite crystals.<sup>[3–16]</sup> For some applications, it would be advantageous to employ much smaller nanometer-sized zeolite crystals in the range 10–100 nm. New synthetic methods have been developed that enable the selective and quantitative formation of small crystallites.

The impact of crystal size on zeolite properties can be profound. For example, Bein<sup>[17]</sup> has studied thin films formed using nanometer-sized zeolites (10–100 nm crystallite size) and has found that “thin films can adsorb and desorb most vapors within a few seconds to minutes, often at room temperature, while the bulk materials usually require substantial heating (ca. 200–300°C) to remove adsorbed vapors.” The facile desorption of products would be a distinct advantage in many gas phase heterogeneous processes involving zeolites, so nanotechnology has the potential to be utilized in many zeolite-based applications. The increased surface area of the small particles also provides these materials with a distinct advantage in heterogeneous catalysis. In addition, these nanometer-sized zeolites can then be assembled into nanostructures, such as thin films, fibers, or

membranes.<sup>[17]</sup> These zeolite nanostructures can potentially be used to control chemical reactivity on molecular length scales. The objectives of this paper are twofold. First, the synthesis of nanocrystalline zeolite particles and the self-assembly of these particles into thin films, fibers, and coatings are discussed. Second, potential applications of nanocrystalline zeolite materials in environmental catalysis are described.

## NANOCRYSTALLINE ZEOLITES MATERIALS: SYNTHESIS AND SELF ASSEMBLY

The synthesis of nanometer-sized zeolites, such as ZSM-5,<sup>[18]</sup> silicalite,<sup>[19]</sup> A,<sup>[20]</sup> Y,<sup>[4,15,21]</sup> Beta,<sup>[3]</sup> L,<sup>[13]</sup> and TS-1<sup>[8]</sup> (the titanium containing analog of ZSM-5), has been reported in the literature. Typically, the particle size distribution is controlled by varying the gel composition or the synthesis temperature and time. Recently, other methods of controlling particle size distribution, such as confined space<sup>[12]</sup> or templating methods,<sup>[16]</sup> have been introduced. In the confined synthesis method, an inert mesoporous support material, such as carbon black, is used to control the particle size in zeolite synthesis. In the templating method, pitch imprinted with colloidal silica<sup>[22]</sup> is used as the crystal template for preparing zeolites with crystal sizes ranging from 13 to 90 nm in size.<sup>[16]</sup> The advantage of these approaches is that a wide range of zeolites can be synthesized by the same general method. In addition, a variety of nanoarchitectures can be constructed using nanocrystalline zeolites as the building blocks. Nanoarchitectures have previously been discussed in the context of multifunctional materials.<sup>[23,24]</sup> A schematic of various possible zeolite nanoarchitectures is shown in Fig. 2. Some examples of specific syntheses and nanoarchitectures are described in more detail below.

## Hydrothermal Synthesis of Nanocrystalline Zeolites X, Y, and ZSM-5

Several methods for the preparation of zeolite Y with nanometer-sized crystals have been reported in the literature.<sup>[4,15,21]</sup> The synthesis of zeolite Y has been

**Fig. 1** Diagram of zeolites ZSM-5 and Y and their relative pore size dimensions.

described by Schoeman, Sterte, and Otterstedt<sup>[21]</sup> and Castagnola and Dutta.<sup>[4]</sup> Typically, this synthetic procedure produces zeolite Y crystals that range in size from 70 to 150 nm with a Si/Al = 1.6. The general features of this synthetic procedure for the synthesis of zeolite Y involve the preparation of a tetramethylammonium hydroxide (TMA)-aluminate solution that is subsequently added to a silica sol to form a homogeneous solution. The solution is then heated at 100°C in a polypropylene bottle with reflux in a poly(ethylene glycol) bath. Recently, Alwy et al.<sup>[25]</sup> reported the synthesis of nanocrystalline zeolite Y with a smaller average crystal size of  $46 \pm 8$  nm and have formed transparent films from this material (vide infra). Fig. 3 shows the scanning electron microscope (SEM) image of the nanocrystalline zeolite Y prepared by Alwy et al. Several other synthetic methods used to prepare zeolite Y and X nanocrystals have been described in the literature.<sup>[5,15,26–29]</sup>

Similar hydrothermal syntheses have been reported for the preparation of nanocrystalline ZSM-5 and silicalite-1 (the purely siliceous form of ZSM-5).<sup>[10,11,19,30–32]</sup> In these studies, ZSM-5 and silicalite were synthesized

with crystal sizes in the range of 10–100 nm. One method involves the hydrothermal crystallization from clear solutions under autogenous pressure,<sup>[32]</sup> and another approach involves using silicalite seed crystals at atmospheric pressure.<sup>[11]</sup> An SEM image of nanocrystalline silicalite synthesized in our laboratory with an average particle size of 39 nm is shown in Fig. 4.

### Templating Methods for the Syntheses of Nanocrystalline Zeolites

Several hydrothermal methods for the synthesis of zeolites Beta and ZSM-5 with nanometer-sized crystals are available in the literature.<sup>[3,14,19,30,33]</sup> In addition, templating methods have been recently reported that rely on the growth of zeolite crystals in a carbon-based template such as carbon black or colloid imprinted carbon (CIC). The advantages of these templating methods are that the zeolite crystal size is controlled by the size of the template and the carbon-based templates reported so far can be easily removed by calcination in air.

The confined space synthesis method described by Jacobsen et al.<sup>[7,12,18]</sup> for the synthesis of zeolites A, X, ZSM-5, and Beta has several distinct advantages over conventional hydrothermal syntheses. The confined space method involves crystallization of a zeolite in the mesopores of an inert porous matrix support. The crystal size distribution is controlled by the size of the mesopores of the inert support and results in a narrow distribution of pore sizes. Carbon black is typically used because it is available with different pore sizes and it can be easily removed by pyrolysis of the carbon.<sup>[7,12,18]</sup> In addition, in the confined space synthesis method, the gel composition and crystallization temperature and time are not as critical in determining the crystal size distributions. Jacobsen et al.<sup>[7,12,18]</sup> reported the synthesis of ZSM-5 with particle sizes ranging from 22 to 45 nm depending on the carbon matrix used in the synthesis. Similarly, they reported the confined space synthesis of zeolites

**Fig. 2** Examples of nanoarchitectures that can be formed from nanocrystalline zeolites. The patterned areas represent nanocrystalline zeolite, and the solid shaded areas indicate a support such as polystyrene beads (diameters of ~1–200 nm) or optical fiber.

**Fig. 3** Scanning electron microscopic image of the nanocrystalline zeolite Y film.

Beta, Linde Type A (LTA), and Linde Type X (LTX).<sup>[7,12,18]</sup> The disadvantage of the confined space synthesis method is that the size distribution of the resulting zeolites could be quite large because the carbon black template is disordered.

A templating method using colloid imprinted carbons (CIC)<sup>[22]</sup> was recently reported by Kim, Shah, and Pinnavaia<sup>[16]</sup> In this method, colloidal silica is used to imprint mesopores in carbon precursor particles (pitch). In this way, pores of different sizes can be tailored for specific applications.<sup>[22]</sup> Kim, Shah, and Pinnavaia<sup>[16]</sup> prepared CICs with pore diameters of 12, 22, 45, and 85 nm. These CICs were impregnated to incipient wetness with the zeolite precursor solutions for ZSM-5 and then were subjected to hydrothermal synthesis conditions of ~48 hr in an autoclave at 180°C. The CIC was subsequently removed by calcination in air at 570°C. ZSM-5 nanocrystals prepared by this method had average particle sizes of 13, 22, 42, and 90 nm as determined by transmission electron

**Fig. 4** Scanning electron microscopic image of silicalite with an average particle size of 39 nm.

microscopy (TEM). One note about the zeolites produced by this method is that the zeolite crystals are intergrown into aggregates because of the nature of the CIC template.

### Assembly of Nanocrystalline Zeolites

Nanometer-sized zeolites can be assembled into zeolite nanostructures, such as fibers or thin films, to optimize their potential for applications in heterogeneous environmental catalysis or perhaps sensor technology. For applications in thermal chemistry, a primary consideration is to increase the surface area of the zeolite and to reduce intracrystalline diffusion effects. For applications in photocatalysis,<sup>[34–36]</sup> the use of optically transparent zeolites would increase the efficiency of the process. The formation of a transparent film of nanocrystalline zeolite Y relative to commercial zeolite Y has been demonstrated by Alwy et al.<sup>[25]</sup> Films of the zeolite Y were prepared by sonication of an aqueous mixture of nanocrystalline zeolite Y for several hours. The resulting hydrosol was pipetted onto a Pyrex slide and dried in ambient air. Films of commercial zeolite Y (Aldrich) were prepared using the same method. Digital images of the zeolite Y films are shown in Fig. 5. In each case, the film was prepared using approximately the same mass of zeolite Y. The film prepared from the nanocrystalline zeolite Y hydrosol is much more uniform than the film prepared from the Aldrich zeolite Y hydrosol. The increased transparency of the films can be observed visually. The “Y” printed on the paper behind the film can be clearly seen through the nanocrystalline zeolite Y film (right) but is much more difficult to see through the Aldrich zeolite Y film (left). To obtain more quantitative information, the percent transmittance (%T) was measured using UV/Vis spectroscopy. The nanocrystalline zeolite Y film had a %T of 70–80 in the 300–700 nm range compared with a %T of 30–40 for the Aldrich Zeolite Y film in the same range.

In considering all the factors to be optimized, zeolite fibers (either coated or hollow)<sup>[37–40]</sup> are potentially very

**Fig. 5** Thin films prepared from hydrosols of Aldrich zeolite Y (left) and nanocrystalline zeolite Y (right).

promising materials. Reactant absorption and product desorption will be facilitated because of the fact that the zeolite layer is very thin.<sup>[17]</sup> For applications involving separations and catalytic reactions, zeolite fibers could be positioned within a tube and reactant gases, or liquids could be flowed over the zeolite fibers. For these applications, a large surface area is desirable and can be achieved using bundles of small-diameter zeolite fibers. A fiber bundle 10 cm in length and 1 cm in diameter containing individual fibers of 100- $\mu\text{m}$  diameter with a packing fraction of 50% has a surface area 1570  $\text{cm}^2$ , compared with a surface area of 31  $\text{cm}^2$  if the inside of a 10-cm-long, 1-cm diameter glass tube was coated directly. For zeolite systems in which optical access is needed for photoexcitation or detection, the zeolite fibers will enable the efficient propagation of light through a long path length of zeolite.

Several methods for the preparation of zeolite coated or hollow fibers have been reported in the literature. Pradhan, Macnaughtan, and Raytery<sup>[39]</sup> reported a method for coating optical fibers with pre-synthesized zeolites via a sol-gel process. Okada et al.<sup>[41]</sup> have reported the coating of zeolite Na-X on glass fibers by a soft solution process, and Deng and Balkus have used laser ablation to coat optical fibers.<sup>[40]</sup> Recently, Ke et al.<sup>[42]</sup> have reported an electrophoretic method for coating carbon fibers. The carbon fibers can then be removed by combustion leaving hollow zeolite fibers. Huang et al.<sup>[6]</sup> reported the self-assembly of zeolite nanocrystals (silicalite, ZSM-5, Beta, A, and faujasite) into films, membranes, and fibers. The self-assembled zeolite fibers that were produced in that study were transparent and approximately 27–33  $\mu\text{m}$  in diameter and  $\sim 1.5$  cm in length.

Nanocrystalline silicalite, a purely siliceous form of ZSM-5, was used to prepare zeolite fibers. An SEM image of the 35-nm particle size silicalite is shown in Fig. 4. From this image, it can be seen that the zeolite

**Fig. 6** Scanning electron microscopic image of free-standing fibers formed from nanocrystalline silicalite (100- $\mu\text{m}$  scale bar).

crystals are uniform in size and are closely packed. The nanocrystalline particles shown in the SEM image in Fig. 4 self-assemble into transparent, rectangular fibers as illustrated in Fig. 6. These films and fibers (Figs. 5 and 6) formed from nanocrystalline zeolites (Figs. 3 and 4) are both examples of zeolite nanoarchitectures.

## NANOCRYSTALLINE ZEOLITE MATERIALS: APPLICATIONS IN ENVIRONMENTAL CATALYSIS

Recently, zeolites have emerged as important materials for applications in environmental catalysis.<sup>[43–46]</sup> Environmental catalysis involves the use of catalysts to solve environmental problems in areas such as emission abatement and environmentally benign synthesis.<sup>[47]</sup> Many new catalysts and catalytic processes have been developed to meet the challenges posed by environmental concerns.<sup>[48]</sup> Besides emissions abatement, the emphasis of environmental catalysis has expanded to include the development of environmentally benign synthetic routes designed to decrease the amount of chemical waste produced.<sup>[46]</sup>

As already noted, nanocrystalline zeolites are promising catalytic materials which have higher external surface areas and reduced diffusion path lengths relative to conventional micrometer-sized zeolites that may be beneficial for catalytic activity and selectivity. For example, nanocrystalline ZSM-5 exhibits increased selectivity and toluene conversion into cresol and decreased coke formation relative to conventional ZSM-5 materials.<sup>[49]</sup> Potential uses of nanocrystalline zeolites as environmental catalysts are described below.

### Environmentally Benign Synthesis: Selective Partial Oxidation Reactions of Hydrocarbons

The partial oxidation of hydrocarbons is significant to chemical industry because the products are used to convert petroleum hydrocarbon feedstocks into chemicals important in the polymer and petrochemical industries. Liquid-phase air oxidations are generally preferred by chemical industry because of the mild reaction conditions. Notable examples<sup>[50]</sup> of liquid phase air oxidation reactions are listed in Table 1. As can be seen from Table 1, the conversions of the oxidation processes are typically very low to maintain high selectivity. This is necessary because the desired partial oxidation products can easily be further oxidized under typical reaction conditions. A major motivation for the development of new oxidation routes is the desire to achieve high selectivities at high conversions.

**Table 1** Examples of liquid-phase oxidation reactions

Reactant	Partial oxidation product	Conversion (selectivity)	Application
Cyclohexane (C <sub>6</sub> H <sub>12</sub> )	Cyclohexyl hydroperoxide, cyclohexanol, cyclohexanone C <sub>6</sub> H <sub>11</sub> OOH, C <sub>6</sub> H <sub>11</sub> OH, C <sub>6</sub> H <sub>10</sub> O	12–13% (>90%)	Nylon-6
Isobutane [CH(CH <sub>3</sub> ) <sub>3</sub> ]	<i>tert</i> -butyl hydroperoxide, <i>tert</i> -butyl alcohol (CH <sub>3</sub> ) <sub>3</sub> COOH, (CH <sub>3</sub> ) <sub>3</sub> COH	10–20%	Propylene oxide

One approach to the partial oxidation of hydrocarbons is to eliminate the use of organic solvents through the use of gas-phase reactants and products. A clean, inexpensive oxidant, molecular oxygen can be used in these reactions. Thus these reactions have the potential to be green processes that use no solvents and minimal energy with catalysts (i.e., zeolites) that have been used in industry for many years. However, several crucial issues related to the application of these processes have emerged. These issues involve improving the efficiency of the photooxidation process and improving the diffusion of product and reactant molecules in the zeolites.<sup>[34,35]</sup>

For the application of zeolites as environmentally benign photooxidation catalysts, a major problem is light scattering by the zeolite. The efficient use of light energy in zeolites requires that light be propagated through a long path length of the zeolite material. However, zeolite crystallites strongly scatter visible light because of their small dimension. Thus only a thin photoreactive zone is obtained regardless of the zeolite bed thickness. In previous photooxidation work, it was determined that yield of photooxidation reactions in zeolites strongly depended on the thickness of the zeolite layer. Using zeolite Y with a crystallite size of approximately 1 μm, product formation for the photooxidation reaction of *p*-xylene (holding irradiation time

and loading constant) was monitored as the sample thickness was varied. The results are shown in Fig. 7 and clearly demonstrate that the effective yield drops drastically as the thickness of the zeolite layer increases. This is because the light is not able to penetrate through more than approximately 100 μm of zeolite and, as stated above, is a problem for applications to photooxidation reactions. Therefore nanocrystalline materials should be better materials for these reactions as they can form optically transparent thin films.

### Environmental Remediation: NO<sub>x</sub> Emissions Abatement

The emission of NO<sub>x</sub> and N<sub>2</sub>O from stationary and automotive sources, such as power plants and lean-burn engines, is a major environmental pollution issue. NO<sub>x</sub> leads to the production of ground-level ozone and acid rain and N<sub>2</sub>O is a greenhouse gas. The catalytic reduction of nitrogen oxides to N<sub>2</sub> is an important environmental challenge for scientists and engineers. Recently, the selective catalytic reduction of NO<sub>x</sub> and N<sub>2</sub>O by hydrocarbons (SCR-HC) over transition-metal exchanged zeolites, particularly in the presence of oxygen, has attracted much interest for emission abatement applications in stationary sources, such as natural gas-fueled power plants.<sup>[43,51–53]</sup> SCR-HC of NO<sub>x</sub> and N<sub>2</sub>O shows promise for applications to lean-burn gasoline and diesel engines where noble-metal three-way catalysts are not effective at reducing NO<sub>x</sub> in the presence of excess oxygen.<sup>[54]</sup> Another aspect of these transition metal-exchanged zeolites that has been reported in the literature is the photocatalytic activity for the direct decomposition of NO<sub>x</sub> and N<sub>2</sub>O<sup>[55–57]</sup> and the SCR-HC of NO<sub>x</sub>.<sup>[58]</sup> The use of zeolite nanostructures would provide some of the same advantages as have been discussed for the oxidation reactions such as more efficient light absorption, reactant diffusion, and increased surface area. Applications for which these materials might be important include transparent objects, such as windows, that could be coated with transparent zeolite thin films. The zeolite thin film would then be activated for NO<sub>x</sub> decomposition by sunlight.

**Fig. 7** Conversion of paraxylene to paratolualdehyde as a function of BaY film thickness.

Another interesting question is whether the catalytic activity of transition-metal exchanged zeolites changes when nanometer-sized zeolites are used instead of conventional zeolites. For example, Zhang, Bao, and Wang<sup>[14]</sup> determined that nanometer-sized HZSM-5 has more Brønsted acid sites on the external surface than conventional HZSM-5. Iron-exchanged zeolites exhibit high activity for the SCR of NO<sub>x</sub> and N<sub>2</sub>O with ammonia or hydrocarbons as the reductant.<sup>[59–67]</sup> In addition, iron-exchanged zeolites are highly resistant to poisoning by water which is a crucial property for potential applications. The catalytic activity of iron-exchanged zeolites is very sensitive to the exchange procedure used to introduce the iron into the zeolite. Therefore it is conceivable that the properties of iron-exchanged nanozeolites could be dramatically affected by the use of nanometer-sized zeolites and have the potential to be more active catalysts.

### Environmental Remediation: Photocatalytic Decomposition of Organic Contaminants

Photocatalysts, such as TiO<sub>2</sub>, can be used to degrade a wide range of organic compounds found in polluted water and air.<sup>[68–70]</sup> Much of the research in the last decade has focused on aqueous solution photocatalysis for the decontamination and purification of water. However, gas phase heterogeneous photocatalysis can be an effective way to remove undesirable organic contaminants from air.<sup>[70–77]</sup> TiO<sub>2</sub> photocatalysts are active at ambient temperatures and pressures in the presence of UV irradiation and oxygen. Potential applications include purifying enclosed atmospheres, such as those found in spacecrafts, offices, industrial plants, and homes. The major pollutants in these applications are oxygenates and aromatics. TiO<sub>2</sub> photocatalysts have been shown to oxidize toluene, trichloroethylene (TCE), methanol/ethanol, and a number of other organic compounds.<sup>[70]</sup> Recently, several groups have considered the use of zeolite TiO<sub>2</sub> composites,<sup>[78–80]</sup> TS-1 (titanium-substituted ZSM-5),<sup>[81]</sup> and nanometer-sized TiO<sub>2</sub>.<sup>[82,83]</sup>

Similar to the problems discussed in the selective oxidation of hydrocarbons, light-scattering problems make these zeolite TiO<sub>2</sub> composite catalysts less than optimal. Zeolite TiO<sub>2</sub> composites prepared using nanometer-sized zeolites may be useful decomposition catalysts. Molecules such as toluene, benzene, and oxygenates, including aldehydes and ketones, are candidates to evaluate the effectiveness of nanometer zeolite TiO<sub>2</sub> composites for the removal of these undesirable organic contaminants from air and water.

### CONCLUSION

The development of nanometer-sized zeolites for applications in heterogeneous catalysis can potentially lead to solutions of several important environmental problems. These problems span from new methodologies in environmentally benign synthesis to new methodologies in environmental remediation of pollutants. The development of new green methodologies for the catalytic syntheses of industrially important compounds is necessary if the production of hazardous waste is to be reduced. The remediation of harmful pollutants using nanometer-sized zeolite catalysts has important implications in the area of emission abatement. NO<sub>x</sub> and volatile organic compounds (VOC) emissions are intimately linked to tropospheric ozone formation in a complex nonlinear way.<sup>[84]</sup>

Because zeolites are also used in sensors and as materials in separation processes, there are other environmental benefits to developing zeolite nanostructured materials that go beyond what has been discussed in this paper. For chemical sensor applications, photoactive molecules can be occluded within the structure of the zeolite.<sup>[17,85,86]</sup> As other molecules enter the pores of the zeolite, they can be expected to influence the electronic structure and therefore the optical spectrum of the occluded chromophores.<sup>[17,86]</sup> Detection of the change in the optical spectrum using a fiber optic would enable the construction of chemical sensors. Zeolites-based sensors could be developed for detection of specific pollutants or perhaps chemical warfare agents. Zeolite thin films could be used in applications to separate hazardous substances from environmentally benign species. These and other applications could result from the further development of the zeolite nanostructures. The studies described in this paper are just a first step in the synthesis and potential uses of nanocrystalline zeolite materials.

### ACKNOWLEDGMENTS

Dr. Russell Larsen, Dr. Weiguo Song, Hassan Alwy, and Gonghu Li are acknowledged for experimental assistance including the synthesis and characterization of nanocrystalline zeolites and zeolite nanoarchitectures. Although some of the research described in this entry has been funded by the EPA through grant R829600 to SCL and VHG, it has not been subjected to the agency's required peer and policy review and therefore does not necessarily reflect the views of the EPA and no official endorsement should be inferred.

## INTRODUCTION

This discussion focuses on the development of nanostructured materials through controlled primary crystallization reactions of amorphous alloys. The nanocrystalline state is at the forefront of study in a variety of disciplines involving condensed matter. In broad terms the main activities can be classified into material synthesis strategies, property measurement and evaluation, applications, and computer simulation and modeling. A key attribute of the nanocrystalline state that offers a broad attraction for many disciplines is derived from the nanometer length scale. At this length scale the chemical, biological, physical, mechanical, and structural properties and performance of materials are susceptible to significant changes during synthesis,<sup>[1]</sup> and the current computational capabilities allow for effective simulation and analysis of nanocrystalline assemblies.<sup>[2]</sup>

The principles that govern the kinetics of microstructural evolution apply directly to other devitrification reactions that yield nanostructured intermetallic phases and quasi-crystalline phases that are also promising in terms of their structural and functional performance. Some of the key issues concerning synthesis and stability are illustrated from the observed behavior in specific amorphous alloys, but the discussion also applies to other similar alloy systems.

## OVERVIEW

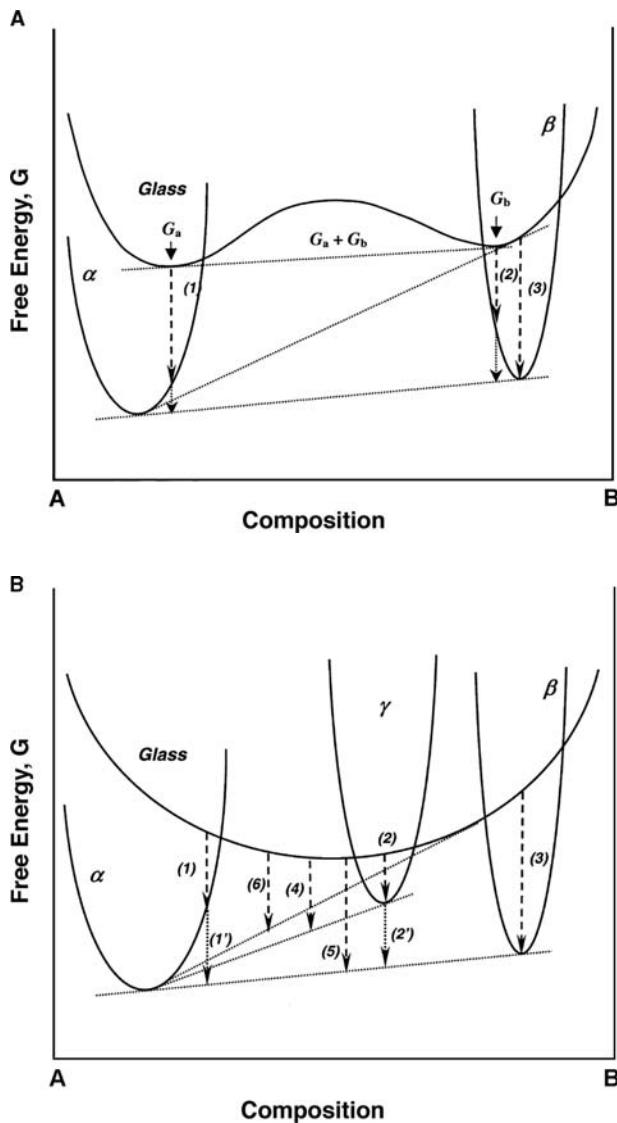

The nanocrystalline state, where the microstructural size scales are in the 1- to 100-nm range, can be synthesized by a variety of processing routes starting with the vapor, liquid, or solid state.<sup>[1]</sup> Although it may be expected that the final nanocrystalline state is independent of the processing route, in practice this is not the case. For example, for deposition from the vapor at the high rates that promote nanocrystalline grain sizes, residual impurities or entrapped gas can be present in the deposit. Similarly, from an initial solid, the nanocrystalline state is often achieved by the mechanical milling of powders. During subsequent consolidation of powders to a bulk form, it is common to incorporate impurities from the medium used for

milling and to retain a residual porosity.<sup>[3]</sup> The attainment of nanocrystalline structures from the liquid or vapor requires the attainment of a high crystal nucleation rate, which in turn is promoted by a large undercooling before the onset of crystallization. Actually, there are two pathways that may be followed to achieve the high crystal nucleation density.<sup>[4]</sup> If a liquid is rapidly quenched at a rate that happens to coincide with the conditions for a high nucleation rate a nanocrystalline structure is possible by direct quenching.<sup>[5]</sup> However, under most conditions of rapid quenching it is difficult to control the processing and the reproducibility. Instead, a direct cooling to an amorphous state and a subsequent low-temperature crystallization treatment is usually preferred as a method of achieving reproducible nanostructure synthesis including the fabrication of nanostructures in bulk sample volumes.<sup>[6-8]</sup>

The classes of metallic glasses that provide the most effective routes to nanocrystallization are closely related to two important aspects of solidification that involve kinetic competition: 1) avoidance of crystallization upon cooling of the liquid and 2) the control of crystallization upon heating of the glass. Although there are connections between these aspects, including the common underlying important role of melt undercooling as a measure of liquid metastability, in each case the controlling reactions occur under regimes of different kinetic constraints.<sup>[9]</sup> In addition to the closed-system methods involving liquid or vapor quenching, it is recognized that open systems involving continuous deformation<sup>[10]</sup> or irradiation<sup>[11]</sup> can drive a material toward nanocrystallinity and in some cases to an amorphous structure. In this case, the stored energy due to defects, grain refinement, and solute supersaturation is a measure of the level of metastability that is crucial to consider in the analysis of amorphization and the development of nanostructured microstructures.<sup>[12]</sup>

## NANOCRYSTALLIZATION REACTIONS

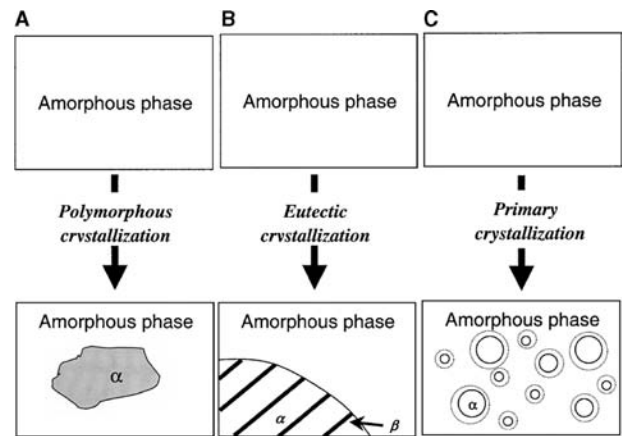

The crystallization behavior of amorphous materials is of central importance in the synthesis of nanostructured materials. The reaction pathways that are operative

**Fig. 1** Schematic free energy vs. composition diagrams illustrating some of the possible nanocrystallization reactions of an amorphous phase. (A) reaction pathways for an alloy with a negative heat of mixing and a metastable  $\gamma$  phase. (B) reaction pathways for an alloy with a positive heat of mixing.

during crystallization must be identified and controlled to develop successful strategies for the consolidation of amorphous powders or ribbons that can be processed into bulk nanostructured solids. Moreover, the control of the reaction path during crystallization provides for the option to develop nanoscale structures with different phase selection.

The different reaction paths and product selection options are identified in Fig. 1, which illustrates schematically the free energy relationships between an initial amorphous phase that is considered as an undercooled liquid solution and several crystalline product phases that include stable  $\alpha$  and  $\beta$  phases and a metastable  $\gamma$  phase.<sup>[13,14]</sup> Within the alloy composition ranges that

**Fig. 2** Schematic illustration of the characteristic microstructural morphologies that develop during nanocrystallization by (A) polymorphic, (B) eutectic, and (C) primary phase reactions. In (C) the dotted curve around primary phase nanocrystals denotes the extent of the solute diffusion field.

are usually favored for glass formation there are several types of crystallization reactions that can be used to develop nanocrystalline structures during controlled heating or isothermal reaction. One of the simplest reactions is the direct transformation from the glass to a single-phase crystal without composition change as illustrated in Fig. 1A and B by pathways (1) and (2) for either stable or metastable initial product phases. The composition invariant or polymorphic reaction can yield metastable structures such as supersaturated solid solution phases or metastable intermediate phases that can undergo further transformation that is indicated by pathways (1') and (2') in Fig. 1A and B. With primary crystallization, a single phase is the initial product, but the reaction proceeds with a partitioning of solute to yield a solute lean primary crystal and a residual amorphous phase matrix that is enriched in solute.<sup>[6,15–18]</sup> The kinetics of primary crystallization is evidently related to the rate of solute diffusion in the amorphous matrix that is necessary to dissipate the solute that is rejected during primary crystal growth.<sup>[19]</sup> It is also apparent that primary crystallization does not result in a stable equilibrium product structure that is indicated by the compositions  $\alpha_e$  and  $\beta_e$  in Fig. 1A and B. To complete the primary crystallization, a subsequent multiphase crystallization develops either from the nucleation site provided by the primary crystal or directly from the amorphous phase. For example, with eutectic crystallization that is indicated by pathway (3) in Fig. 1A, the product phases (i.e.,  $\alpha$  and  $\beta$ ) often develop by a coupled growth and appear with a lamellar or rod type of regular morphology in a spherulitic pattern.<sup>[8,19]</sup> In this case the synthesis of a nanoscale microstructure requires a high density of  $\alpha$  and  $\beta$  colonies with an ultrafine lamellar spacing. A schematic illustration of the characteristic microstructural morphologies

associated with each of the nanocrystallization reactions is provided in Fig. 2. Often, under high-undercooling conditions metastable phase reactions can develop as a precursor to the formation of stable crystallization products. For example, as indicated in Fig. 1B, the undercooled liquid or amorphous phase can undergo a phase separation reaction leading to the formation of two liquids with different compositions that are indicated by  $G_a$  and  $G_b$  in Fig. 1B. At low temperature or high undercooling, limited atomic mobility will result in a fine scale of phase separation that can extend into the nanoscale regime.<sup>[20]</sup> Moreover, in some cases the interfaces between the different liquid regions can serve as heterogeneous nucleation sites for subsequent crystallization reactions and establish high nucleation product number densities. In addition, there is evidence that in some systems minor impurity levels can promote the development of phase separation reactions.<sup>[14]</sup> Another example of a precursor reaction is the formation of an intermediate phase as a metastable product as illustrated in Fig. 1A for the  $\gamma$  phase.

## KINETICS OF NANOCRYSTALLIZATION

One of the key requirements that must be satisfied for the development of a nanoscale microstructure by a crystallization reaction is the attainment of a very high nucleation product number density. The main features of the steady-state nucleation rate kinetics can be described by

$$J_i^s = \Omega_i \exp\left[-\frac{\Delta G^* f(\theta)}{kT}\right] \quad (1)$$

where  $J_i^s$  is the steady state nucleation rate on a volume ( $i = v$ ) or surface basis ( $i = a$ ).<sup>[12]</sup> Respective values for the prefactor,  $\Omega_i$ , activation barrier,  $\Delta G^*$ , and the contact angle function,  $f(\theta)$ , are used in Eq. (1), and  $kT$  is the thermal energy. The expressions for  $\Omega_i$  involve a product of a nucleation site density on a catalytic surface or volume basis, the number of atoms on a nucleus surface and a jump frequency. For most cases,  $\Omega_v = 10^{30}/\eta \text{ cm}^{-3} \text{ sec}^{-1}$  and  $\Omega_a = 0.10^{22}/\eta \text{ cm}^{-2} \text{ sec}^{-1}$ , with  $\eta$  the liquid shear viscosity (in poise) given by Ref.<sup>[6]</sup> as

$$\eta = 10^{-3.33} \exp\left[\frac{3.34T_L}{T - T_g}\right] \quad (2)$$

in terms of the liquidus temperature,  $T_L$ , and the glass transition,  $T_g$ , and  $\phi$ , the fraction of active catalytic sites. The activation barrier for nucleation is given by

$$\Delta G^* = \frac{b\sigma^3}{\Delta G_v^2} \quad (3)$$

where  $\sigma$  is the liquid–solid interfacial energy,<sup>[21]</sup>  $\Delta G_v$  is the driving free energy for nucleation of a unit volume of product phase, and  $b = 16\pi/3$  for spherical nuclei. With a planar catalytic surface site and spherical nuclei  $f(\theta) = [2 - 3 \cos \theta + \cos^3 \theta]/4$ . Following the establishment of a supersaturation or undercooling, there is an initial time period during which the nucleation cluster population evolves toward the steady-state distribution.<sup>[22]</sup> During this transient period the time-dependent nucleation rate,  $J_i(t)$ , is given by

$$J_i(t) = J_i^s \left[ 1 + 2\Sigma(-1)^n \exp\left(-\frac{n^2 t}{\tau}\right) \right] \quad (4)$$

where  $\tau$  is the time lag or delay time that is estimated by  $(n^{*2}/\pi^2\beta)$ . The critical nucleus size,  $n^*$ , in atoms is obtained from  $n^* = 4\pi r^{*3}/(3V_a)$  where  $V_a$  is the volume per atom and  $r^* = -2\sigma/\Delta G_v$  is the critical nucleus radius. The atomic jump frequency,  $\beta$ , can be estimated by  $D/\lambda^2$ , where  $D$  is the diffusion coefficient in the undercooled phase and  $\lambda$  is the jump distance.<sup>[23,24]</sup>

To achieve a nanocrystalline microstructure (i.e., with a size scale  $\leq 100$  nm) in a fully crystallized volume, the nucleation number density should be at least of the order of  $10^{21} \text{ m}^{-3}$ . Of course, nanocrystallization can be achieved only if there are also restrictions on the kinetics of nanocrystal growth following nucleation.

The kinetic analysis of growth follows different forms that depend on the nature of the solute partitioning associated with phase growth. For example, during polymorphous transformation without solute redistribution, the growth rate,  $V$ , is controlled by interface attachment limited kinetics as represented by

$$V = V_0 \exp\left[-\frac{Q_D}{RT}\right] \left( 1 - \exp\left[-\frac{\Delta G_v}{RT}\right] \right) \quad (5)$$

where  $V_0$  is a prefactor of the order of  $5 \times 10^3 \text{ m/sec}$  and  $Q_D$  is the activation energy for interface jumps.<sup>[19,25]</sup> At low temperature where  $\Delta G_v \gg RT$  growth is diffusion controlled as expressed by

$$V = V_0 \exp\left[-\frac{Q_D}{RT}\right] \quad (6)$$

For the case of eutectic reaction where the solute redistribution is limited to the reaction interface

$$V \cong 4D_1 \frac{\delta}{\lambda^2} \quad (7)$$

where  $D_1$  is the interface diffusivity,  $\delta$  is the thickness of the reaction front, and  $\lambda$  is the lamellar spacing.<sup>[25,26]</sup> With these kinetic modes, the reaction is relatively rapid and a metastable microstructure based on nanocrystals and an amorphous phase with the original

**Fig. 3** TEM bright-field images from an  $\text{Al}_{88}\text{Y}_7\text{Fe}_5$  melt-spun ribbon that was isothermally annealed at  $245^\circ\text{C}$  for (A) 10 min, (B) 30 min, (C) 100 min, and (D) continuous heating differential scanning calorimetry (DSC) trace at 40 K/Min showing a primary crystallization onset at  $276^\circ\text{C}$ .

composition is possible if the kinetics of subsequent decomposition reactions to a more stable phase constitution is sluggish.

When growth requires a redistribution of solute as in primary crystallization, the kinetics are limited by the rate of diffusion of the rejected solute into the amorphous matrix. For evolving nanocrystals that are isolated from each other the growth rate has the following form

$$V = \frac{\alpha}{2} \sqrt{\frac{D}{t}} \quad (8)$$

where  $\alpha$  is a dimensionless factor that is evaluated from the compositions at the particle/matrix interface and the average composition and  $D$  will be controlled by the slowest diffusing solute in a multicomponent alloy.<sup>[26]</sup> However, at high nucleation densities the isolation can be lost as the diffusion fields from neighboring nanocrystals begin to overlap (i.e., soft impingement).<sup>[25]</sup> Under this condition there is a kinetic inhibition to further growth. Concurrent with the growth of nanocrystals, the highly refined sizes indicate that capillarity effects such as Ostwald ripening due to curvature-driven transport (i.e., Gibbs–Thomson effect) can be important.<sup>[25,27]</sup>

## AMORPHIZATION KINETICS AND TRANSITIONS

The kinetic transition between nanocrystalline products and an amorphous phase is a common structural change that occurs during solidification with increasing cooling rate as the liquid undercooling approaches  $T_g$ .

Often, the initiation of the transition is represented by a critical cooling rate and interpreted as a sharp structural change.<sup>[28]</sup> However, there are also many reports of mixed crystal/glass phase structures indicating that the transition occurs over a range of cooling rates reflecting the kinetic competition and the probabilistic nature of nucleation.<sup>[29,30]</sup> It is useful to note that the glass transition is not a phase transformation in a thermodynamic sense, but it is a kinetic manifestation of the slowing of atomic transport in the liquid with cooling. In fact, the calorimetric glass transition signal is due to the large change in heat capacity that occurs when a liquid becomes configurationally frozen. The slowing of atomic transport is also reflected by an increase in liquid viscosity. The time for the liquid structure to relax during cooling is related to the viscosity, and for typical laboratory measurement conditions  $T_g$  corresponds to a viscosity in the range of  $10^{12}$ – $10^{13}$  P ( $10^{11}$ – $10^{12}$  Pa sec).<sup>[31]</sup>

Indeed, following amorphization by rapid melt quenching, many metallic glasses do not exhibit a clear glass transition signal,  $T_g$ , upon reheating. Instead, initial exothermic maxima are observed to develop that indicate a multiple-stage crystallization<sup>[5,32,33]</sup> as shown in Fig. 3 for an amorphous  $\text{Al}_{88}\text{Y}_7\text{Fe}_5$  ribbon after melt spinning and after initial crystallization. The microstructural analysis has established that for many amorphous Al-base alloys that contain transition metal (TM) and rare earth (RE) solutes, the initial crystallization corresponds to primary phase formation (i.e., Al) yielding a sample that contains a high density of nanocrystals within an amorphous matrix.<sup>[5]</sup> This behavior is of importance in understanding the kinetic control of glass formation. The two basic strategies to synthesize amorphous alloys

**Fig. 4** The principal forms of kinetic control for metallic glass formation.

are illustrated schematically in Fig. 4. With nucleation control, the undercooling that is achieved during cooling bypasses the nucleation reaction and the nucleation size distribution,<sup>[9]</sup> $C(n)$  that may be retained by the cooling does not overlap with the critical nucleation size,  $n^*$ , at the crystallization temperature,  $T_x$ . As a result, there is no precursor reaction to influence the evolution of crystalline clusters during subsequent thermal treatment. In this way, a clear separation in temperature between the  $T_g$  and  $T_x$  signals can be observed during reheating of a glass. These kinetic conditions are the basis for bulk glass formation during slow cooling. During isothermal annealing at  $T_x$ , the heat evolution rate  $\dot{Q}$  exhibits a clear delay before the onset of the nucleation reaction and a peak maximum associated with the completion of nucleation and continued growth. On the other hand, under growth-controlled conditions the cooling rate is insufficient to bypass the nucleation onset completely so that some small fraction of crystallites may form initially, but the rapidly rising viscosity and falling growth rate with continued cooling near  $T_g$  prevents rapid cluster growth. In addition, the cluster size distribution that is retained overlaps in size with the critical nucleation size at  $T_x$ . In this case, as indicated in Fig. 4, upon reheating a sample with preexisting crystallites (i.e., quenched-in nuclei), rapid crystallization because of the development of quenched-in clusters as well as additional nucleation ensues at  $T_x$ , which will essentially coincide with  $T_g$ .<sup>[34]</sup> Whereas many of the early metallic glass alloys were synthesized under growth-controlled conditions (i.e., marginal glass formers)<sup>[35]</sup> the primary crystallization particle densities in these alloys are of the order of  $10^{18} \text{ m}^{-3}$ . For the class of amorphous Al- and Fe-base glasses, the primary crystallization number densities range from  $10^{21}$  up to almost  $10^{23} \text{ m}^{-3}$ . Both of the

basic mechanisms for glass formation that are outlined in Fig. 3 can yield a high number density of nanocrystals upon devitrification. With nucleation control, nanostructure development can be achieved by controlled reheating, because the maximum in the growth rate typically occurs at a higher temperature than the maximum in the nucleation rate.<sup>[25]</sup> In addition to the two basic synthesis routes outlined in Fig. 4, there is another important distinction between alloys that form bulk glasses and the marginal glass-forming alloys based on the temperature dependence of the liquid viscosity.<sup>[31]</sup> The main features of the viscosity behavior are shown in Fig. 5 where “strong” liquids display an Arrhenius type of temperature dependence. A good example of a strong liquid is  $\text{SiO}_2$ , but the bulk glass-forming alloys also display strong liquid characteristics.<sup>[31]</sup> For the “fragile” liquid behavior shown in

**Fig. 5** A schematic illustration of the liquid viscosity behavior vs.  $T_g/T$  for strong and fragile glasses.

Fig. 5 the viscosity is low even in the undercooled regime, but increases sharply upon approaching the glass transition. It appears that the marginal glass-forming alloys exhibit a fragile type of viscosity behavior. It is evident that the transport behavior will impact both the ease of glass formation and the kinetics of nanocrystal development. The different synthesis routes that are shown in Fig. 4 originate from the relative time scales for the onset of nucleation and melt cooling. The transition from growth control to nucleation control can be achieved either by an increase in the cooling rate or by lengthening the time for onset of nucleation,  $t_n$ . Because  $t_n$  is related to atomic transport in the liquid, strong liquids with high viscosity are favored for bulk glass formation. It is also apparent that  $t_n$  can be lengthened by removing active nucleation sites from the melt. In fact, this is the basis for the effectiveness of melt fluxing, which has been shown to promote bulk glass formation.<sup>[36,37]</sup> The actual mechanism for the development of the ultrahigh number densities of nanocrystals is under active study, and proposals based on homogeneous<sup>[38,39]</sup> and heterogeneous<sup>[35,40]</sup> nucleation and precursor phase separation reactions<sup>[41]</sup> are under examination.

The attainment of nanocrystal dispersions of essentially pure Al with ultrahigh number densities is a critical component of the attractive structural performance, but an equally important characteristic is the high thermal stability. One indication of this stability is the wide temperature range between the primary crystallization and final crystallization of between 75° and 100°C in Fig. 3. Within this range, there is a metastable two-phase coexistence involving the Al nanocrystals and the surrounding amorphous matrix with limited coarsening of the microstructure. The sluggish kinetics is related at least in part to the large differences in component atom sizes and diffusivities<sup>[42–44]</sup> as well as the onset of impingement of the diffusion fields from neighboring nanocrystals.<sup>[40]</sup> Indeed, even at a particle density of  $10^{21} \text{ m}^{-3}$  the average nanocrystal separation is only about 100 nm. It is also evident that for the Al nanocrystals to grow there is a rejection of solute (i.e., TM and RE) as is typical for primary crystallization reactions. The low solute diffusivities, especially for the large RE atom, act to limit the growth,<sup>[45]</sup> and the transport is limited further by the reduced concentration gradient due to impingement as indicated by the asymmetric primary crystallization exotherm in Fig. 3. In fact, because the amorphous matrix composition will also be enriched in TM and RE components, it is possible to use the solute redistribution during primary crystallization to enhance the stability of the amorphous matrix (i.e., raise  $T_g$ ).<sup>[15,46]</sup> This kinetic restriction inhibits further nanocrystal growth and accounts for the asymmetric crystallization peak and the remarkable thermal stability.

Fig. 6 Phase diagram for the Nb–Si system showing the metastable extension of the  $\text{Nb}_3\text{Si}$  (i.e.,  $\gamma$ ) liquidus to form a metastable eutectic  $L \rightarrow \alpha\text{-Nb} + \text{Nb}_3\text{Si}$ . This extension is relevant when the  $\text{Nb}_3\text{Si}$  phase is absent. Also shown are approximate  $T_0$  curves for the transformation of liquid to  $\alpha\text{-Nb}$  and to  $\gamma$ .

## NANOCRYSTALLIZATION DURING MELT QUENCHING

As noted in Fig. 4, it is possible to encounter conditions that represent the maximum nucleation rate (i.e., the minimum time for the onset of nucleation or the nose of the  $C$  curve) during continuous cooling. One important requirement to achieve a maximum nucleation density is the removal of potent heterogeneous nucleation sites so that the alloy melt may be cooled to the temperature yielding the maximum nucleation rate without prior crystal formation. For homogeneous nucleation the temperature for a maximum nucleation rate is about  $2/3 T_m$ .<sup>[12]</sup> The schematic illustration in Fig. 4 does not provide a perspective on the sensitivity of the microstructural scale to cooling rate at temperatures near the maximum nucleation rate temperature, but this important feature of nanocrystallization can be developed by considering a melt-quenched nanostructure.

**Fig. 7** (A) Microstructure of a Nb–25 at.% Si melt-spun ribbon near the TEM foil edge (the left-hand side of the micrograph) for a specimen polished from one side; (B) SADPs positioned under the areas from which they were taken; (C) a schematic drawing showing the microstructure across the ribbon (EB, electron beam).

For Nb-rich alloys in the Nb–Si system the main solidification reaction is a eutectic yielding Nb + Nb<sub>3</sub>Si as indicated in the phase diagram in Fig. 6.<sup>[47]</sup> The microstructure that is developed following melt spinning is revealed in Fig. 7 for a wedge-shaped sample that was produced by thinning the ribbon of a Nb–25 at.% Si alloy from one side (opposite from the wheel side) the most rapidly cooled region adjacent to the wheel is amorphous. With increasing distance from the chill surface the onset of crystallization is characterized by nanoscale grains with a size of about 15 nm. The fine-grain structure is a mixture of Nb and Nb<sub>5</sub>Si<sub>3</sub>, but the size scale increases to about 100 nm over short distance within the 20- $\mu$ m-thick ribbon before the equiaxed structure evolves into a dendritic morphology.

A common occurrence in the synthesis of nanostructures during rapid solidification is the absence of a phase that according to the equilibrium phase diagram should be present. This occurs when the missing phase is subjected to kinetic limitations in nucleation and/or growth. In the absence of a stable phase, solidification is then governed by a metastable phase diagram. This diagram is constructed from the equilibrium diagram in Fig. 6 where the Nb<sub>3</sub>Si phase is suppressed and where the Nb<sub>5</sub>Si<sub>3</sub> (designated  $\gamma$ ) liquidus extends below the L + Nb<sub>5</sub>Si<sub>3</sub>  $\rightarrow$  Nb<sub>3</sub>Si peritectic isotherm and intersects the Nb liquidus to yield a metastable L  $\rightarrow$  Nb + Nb<sub>5</sub>Si<sub>3</sub> eutectic. For alloys near a peritectic reaction, solidification of the high-temperature phase (in this case, Nb<sub>5</sub>Si<sub>3</sub>) can continue below

the peritectic temperature while the remaining liquid develops only slight undercooling with respect to the low-temperature phase (in this case, Nb<sub>3</sub>Si). Hence, phases that are ordinarily formed by peritectic reactions may often be absent in nanocrystallization reactions.

A useful method for examining the thermodynamic options available to an alloy undergoing nanocrystallization is to examine the  $T_0$  curves for the various liquid-to-crystal transformations in a system. Schematic  $T_0$  curves are included for the Nb and Nb<sub>5</sub>Si<sub>3</sub> ( $\gamma$ ) phases in Fig. 6. The  $T_0$  curves place a bound on temperatures and compositions where partitionless solidification is possible.<sup>[13]</sup> Regardless of the level of undercooling that is achieved during rapid quenching, a range of compositions may exist between adjacent  $T_0$  curves where partitionless solidification is impossible and crystal growth must involve the more difficult process of diffusional solute redistribution into a mixture of solid phases.<sup>[48]</sup> Because of this difficulty, glass formation or nanocrystallization is most likely in this range, which was observed to be centered near Nb<sub>3</sub>Si as indicated in Fig. 6.

The synthesis of a two-phase nanostructure clearly involves copious nucleation. One factor that can increase the opportunity for high nucleation rates is the relatively slow growth for crystals that require solute redistribution. Furthermore, during continuous cooling, the rate of recalescence after the initial nucleation event depends on the crystal growth rate. If it is slow, the melt may be undercooled further, permitting a rapid rise in the nucleation rate.<sup>[12]</sup> Moreover, the two-phase nanostructures that are developed during melt spinning identify an important class of metastable microstructure that is available in the form of very high grain densities of the equilibrium phases that were observed to range from 10<sup>18</sup> to 10<sup>21</sup> m<sup>-3</sup>. A high density of grains for a two-phase mixture is metastable because of a high incoherent interphase boundary area. For example, with a grain size of 0.12  $\mu$ m and an interphase boundary energy in the range of 500–1000 mJ m<sup>-2</sup> that is typical for incoherent interfaces, the excess free energy due to the polycrystalline grain structure is 120–150 J mol<sup>-1</sup>. However, for nanoscale grains with a size of 15 nm the free energy increment increases to the range of 800–1600 J mol<sup>-1</sup>. Thus, with nanostructured grains the level of metastability is comparable with that associated with non-equilibrium crystal structures.<sup>[14]</sup>

The devitrification of an amorphous phase is a fairly well recognized approach to the synthesis of a nanocrystalline grain structure. The attainment of an equiaxed grain structure resulting from an isotropic growth is characteristic of a polymorphic type of crystallization reaction. In this sense the evolution of an equiaxed two-phase nanocrystalline grain structure represents a distinct pattern of non-cooperative growth that does not appear to be readily achieved by continuous heating

or isothermal annealing devitrification treatment. However, the production of a high nucleation density for each phase appears to require a high rate of heat extraction as well as diffusional growth limitations so that the two-phase nanocrystalline structure is limited in spatial extent because of a relatively narrow range of favorable processing conditions.

## NANOCRYSTAL CATALYSIS

The limited experimental information available indicates that the nucleation process during primary crystallization of amorphous alloys is usually heterogeneous in nature, but the origin of the active catalytic sites has not been identified in all cases.<sup>[49]</sup> For example, it has been established that, with several amorphous Fe alloys, the development of a high density of Fe nanocrystals is strongly promoted by the addition of small amounts of certain solutes such as Cu.<sup>[50]</sup> In fact, high-resolution transmission electron microscopy (TEM) and atom probe field ion microscopy (APFIM) observations indicate that Cu solute allows for reactions that act to catalyze Fe nucleation.<sup>[51,52]</sup> In amorphous Al-base alloys it appears that a comparable nucleation catalysis behavior can be observed with both soluble and insoluble additions. For example, the addition of 1 at.% Cu to amorphous Al–Ni–Sm has been reported to yield an Al nanocrystal density approaching  $10^{23} \text{ m}^{-3}$  with diameters of 5–7 nm.<sup>[53]</sup> Similarly, the incorporation of insoluble nanosized Pb crystalline particles in an amorphous matrix is effective in catalyzing the crystallization of Al nanocrystals and yields a significant increase in the total number density of nanocrystals.<sup>[54]</sup> The catalysis behavior highlights the opportunity for the controlled synthesis of bulk alloys with an ultra-high number density of nanoscale dispersoids.

## MECHANICALLY INDUCED CRYSTALLIZATION OF AMORPHOUS PHASES

One consequence of the metastability of nanocrystalline and amorphous phases is that the structure and properties of the materials can depend on the processing pathway. This pathway dependence offers the chance to obtain phases with novel characteristics that cannot be achieved by melt quenching. For example, nanocrystallization reactions during cold rolling occur after continued folding and rolling of initially crystalline or amorphous multilayer samples, as illustrated schematically in Fig. 8. The repeated folding and rolling process can yield a true strain in the multilayer sample of the order of 100.<sup>[55]</sup> The kinetics of this crystallization process appears to be linked to the initial size

**Fig. 8** A schematic illustration of the cold-roll and fold process. A multilayer of elemental foils with foil thicknesses between 7 and 25  $\mu\text{m}$  is reduced by 50% with each rolling pass.

distribution and density of the quenched-in nuclei in the amorphous matrix. In some cases, for example in melt-spun  $\text{Al}_{92}\text{Sm}_8$ , the sample fully crystallizes during rolling.<sup>[56]</sup> Amorphous alloys that follow the nucleation-controlled solidification pathway and therefore have no significant cluster concentration are considerably more stable against a rolling-induced crystallization reaction.<sup>[57]</sup> The observed primary crystallization of marginal glass formers during initial rolling implies an atomic transport of the constituents through the amorphous matrix. Nanocrystals can also be induced by deformation in bulk glass-forming alloys without any thermal annealing.<sup>[58]</sup> The redistribution of solute atoms during crystallization appears to be characteristic of a driven system where an athermal mechanical process during shear deformation controls the transport.<sup>[59–61]</sup> A more complete understanding of deformation-catalyzed nanocrystallization should also consider the non-equilibrium nature of the rolling process as well as the structural metastability of the amorphous phase. Understanding the nature of shear-induced crystallization is thus not solely a matter of focusing on the processing conditions and their influence on the structural modifications, but necessitates a refined knowledge of the amorphous structure before deformation.

## CONCLUSION

The development of nanostructured materials can be achieved in bulk form by the use of amorphous phases as effective precursors. Indeed, the controlled primary crystallization of amorphous alloys yields essentially a nanophase composite of nanocrystalline primary phase dispersed within an amorphous matrix. It is remarkable that the nanocrystal number density can achieve high levels of  $10^{21}$  to  $10^{23} \text{ m}^{-3}$  at primary phase volume fractions approaching about 30% to yield ultra high strength. An equally remarkable fact is the relative high thermal stability of the nanophase composite. This is truly a novel microstructure that has revealed challenging basic issues on the governing reactions kinetics that control the structure synthesis and performance. At the same time, alternative synthesis routes have been identified based on deformation-induced alloying and glass formation that can be adapted for

processing of bulk glasses. The deformation response of amorphous alloys is sensitive to the processing during synthesis and to the influence of quenched-in crystallites.

## ACKNOWLEDGMENTS

The continued support of the Army Research Office (ARO) and encouragement from Dr. W. Mullins for studies of novel microstructure synthesis during solidification and intense plastic deformation is most gratefully appreciated.

## INTRODUCTION

Nanocrystals have long been known for their ability to color glasses and catalytic action. New understanding of nanoscale phenomena, especially the changes in the material properties with size are promising to usher in a whole new genre of applications. In this entry, a discussion of the electronic, optical, and magnetic properties of capped nanocrystals, followed by a brief elucidation of select applications is provided.

## ELECTRONIC AND RELATED PROPERTIES

As the size of nanocrystals is varied in the nanometric domain, the electronic structure undergoes various changes. The changes were theoretically addressed as early as the 1960s by Kubo and Frolich.<sup>[4]</sup> Kubo successfully predicted that a gap, now called the Kubo gap ( $\Delta$ ), will emerge as the dimensions are reduced:

$$\Delta = \frac{E_f}{3n} \quad (1)$$

where,  $E_f$  is the bulk Fermi level and  $n$  the number of free electrons in the nanoparticle (a contribution of one electron per atom is usually assumed). A natural consequence of the emergence of Kubo gap is a size-induced metal-insulator transition when the diameter of the particle is decreased to below a few nanometers.<sup>[5-7]</sup> Scanning tunneling spectroscopy (STS) measurements of nanocrystals of various metals have revealed that the nanocrystals of dimensions  $\sim 1 \text{ nm}^3$  exhibit a definitive band gap (up to 70 meV) that decreases gradually as the volume of the nanocrystal increases (see Fig. 1).<sup>[6,8,9]</sup> Photoelectron spectroscopic measurements on mass selected  $\text{Hg}_n$  nanoparticles ( $n = 3-250$ ) in the gas phase reveal that the characteristic HOMO-LUMO (highest occupied molecular orbital-lowest unoccupied molecular orbital) (s-p) energy gap decreases gradually from  $\sim 3.5 \text{ eV}$  for  $n < 3$  to  $\sim 0.2 \text{ eV}$  for  $n < 250$ , as

shown in Fig. 2. The band gap closure is predicted at  $n \sim 400$ . In addition to  $\Delta$ , nanoparticles also possess coulombic energy states that manifest themselves when actual charging and discharging events take place. Experiments have revealed that small nanocrystals possess charging energies ( $U$ ) of the order of hundreds of millielectron Volts. Therefore, in ensembles of nanocrystals, charge transport would be dominated by a hopping mechanism. A large number of studies have addressed charge-transport characteristics of nanocrystalline assemblies. Pellets of monodisperse nanocrystals, obtained by the use of bifunctional ligand that may bind to more than one nanocrystal, or by applying pressure on dried nanocrystalline matter, have been used for electrical transport measurements.<sup>[10-13]</sup> Pellets made of small Au and Pd nanocrystals exhibit non-metallic behavior with specific conductivities in the range of  $10^6 \Omega^{-1} \text{ cm}^{-1}$ .<sup>[10-12]</sup> The conductivity, however, increases dramatically with an increase in the diameter of the nanocrystals. An insulator metal transition has indeed been reported from pellets made of  $\sim 12.5 \text{ nm}$  Au and Ag nanocrystals.<sup>[13]</sup> Electrical transport measurements on layer-by-layer assemblies of nanocrystals on conducting substrates have been carried out by adoption of a sandwich configuration.<sup>[14-16]</sup>

Nanocrystalline films with bulk metallic conductivity have been realized with Au nanocrystals of 5 and 11 nm diameter spaced with ionic and covalent spacers.<sup>[15,16]</sup> The conductivity of monolayered two-dimensional arrays of metal nanocrystals has been studied with patterned electrodes.<sup>[17-22]</sup> Structural disorder and interparticle separation distance are identified as key factors that determine the conductivity of such layers.<sup>[17-20]</sup> The conductivity of such layers can be enhanced by replacing alkane thiol with an aromatic thiol insitu.<sup>[21,22]</sup> That the interaction energy of nanocrystals in such organizations can be continually varied by changing the interparticle distance was exploited by Heath and coworker who prepared a monolayer of Ag ( $\sim 3 \text{ nm}$ ) nanocrystals at air/water interface in a

**Fig. 1** Variation of the non-metallic band gap with nanocrystal size in metal nanocrystals. The bandgaps were obtained based on STS measurements. *Source:* From Ref.<sup>[3]</sup>.

Langmuir Blodgett trough and varied the interparticle distance by applying pressure.<sup>[23,24]</sup> A host of measurements including reflectivity and non-linear optical spectroscopic techniques were carried out insitu. This study led to the observation of a reversible Mott–Hubbard

**Fig. 2** Photoelectron spectra of Hg clusters of varying nuclearity. The 6p feature moves gradually toward the Fermi level, emphasizing that the band gap shrinks with increase in cluster size. *Source:* From Ref.<sup>[6]</sup>.

metal–insulator transition in the nanocrystal ensemble wherein the coulomb gap closes at a critical distance between the particles. Tunneling spectroscopic measurements on films of 2.6 nm Ag nanocrystals capped with decanethiol reveal a coulomb blockade behavior attributable to isolated nanocrystals.<sup>[24]</sup> On the other hand, nanocrystals capped with hexane and pentane thiol exhibit characteristics of strong interparticle quantum mechanical exchange (see Fig. 3). Similar behavior was observed in the case of self-assembled two-dimensional arrays of Co nanocrystals and Au nanocrystals.<sup>[25,26]</sup> By varying simple parameters in the synthetic scheme, Rao and coworkers have been able to tune the specific resistivity of a thin film of Au nanocrystals in the range of tens of megaohms to a few ohms (see Fig. 4). Along with the change in conductivity, the nature of the film also undergoes a change from that of an insulator to a metal. Schmid and coworkers as well as Pal et al. have obtained rectifying behavior from

**Fig. 3** Normalized density of states (DOS) measured from arrays of Ag nanocrystals of diameter  $\sim 2.6$  nm capped (A) decanethiol and (B) hexanethiol at various temperatures. The temperature dependence of DOS near 0V for decanethiol capped particles indicates that the films are non-metallic. In the case of hexanethiol capped nanocrystals, the DOS around 0V is temperature independent revealing the metallic nature of the film. *Source:* From Ref.<sup>[21]</sup>.

**Fig. 4** The resistance of Au nanocrystal films as a function of temperature. The films (A)–(D) were obtained by carrying out the synthesis at different temperatures: (A) 303 K; (B) 318 K; (C) 333 K; and (D) 348 K.

ensembles of nanocrystals (see Fig. 5).<sup>[27,28]</sup> Although a clear understanding is yet to emerge, it is clear that the observed rectification is related to the high charging energies of the individual nanocrystals.

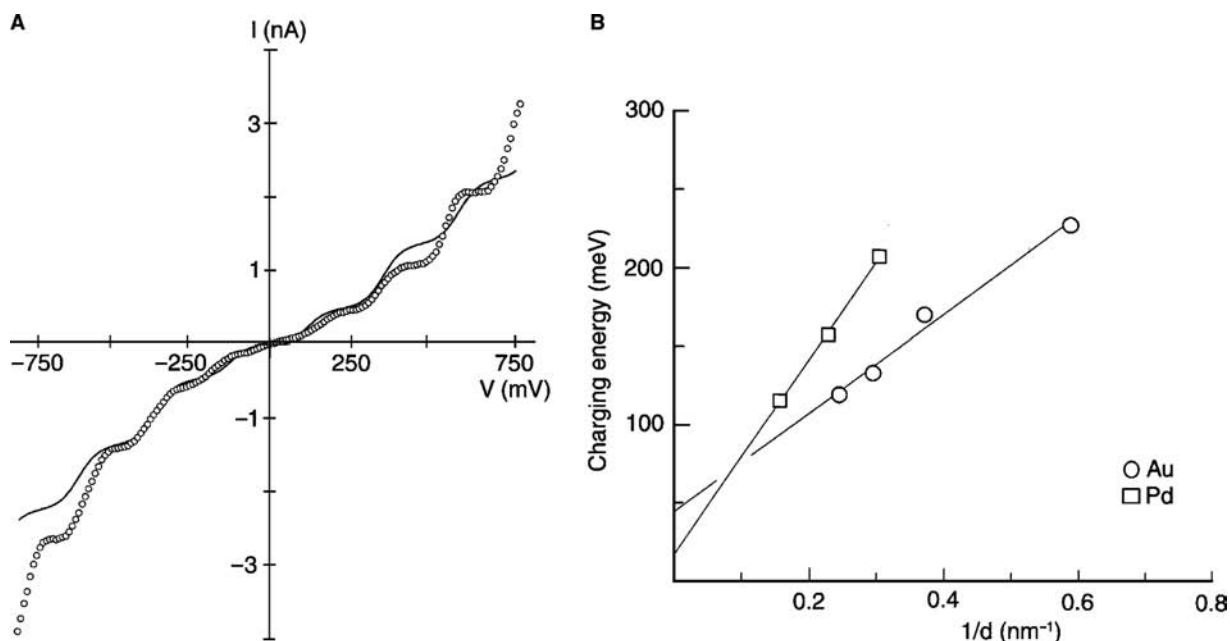

The capacitance ( $C$ ) of a nanoparticle is related to  $U$  by

$$C = U/2e \quad (2)$$

**Fig. 5**  $I$ – $V$  characteristics of dodecanethiol capped Au nanocrystals deposited on an ordered monolayer of gadolinium stearate molecules on a Si substrate.

and is size dependent. Typical values of capacitances of nanocrystals are in the range of  $10^{-18}$  F (aF). At such low capacitances, successive charging events are no longer continuous but are discrete. A measurable change in potential is brought about by varying the charge on the nanocrystal by  $e$ . This is often seen as a coulomb staircase in the  $I$ – $V$  spectra of individual nanocrystals. We have been able to identify the size-dependent changes in the coulomb staircase phenomena in Au and Pd nanocrystals (see Fig. 6).<sup>[29]</sup> It has been proposed that, by using nanocrystals, single-electron devices such as supersensitive electrometers and memory devices could be fabricated. Further, it is supposed that nano-objects could bring a new era in electronics, aptly named nanoelectronics. Proof of concept experiments to test the feasibility of using chemically prepared nanocrystals in single-electron devices have been carried out. For example, Murray and coworkers have found that a single redox reaction taking place at the surface of Au nanocrystals induces a eightfold increase in capacitance.<sup>[30]</sup> Single-electron transistors have been demonstrated with one or a few nanocrystals at the gap between electrodes.<sup>[31]</sup> Schffrin and coworkers have fabricated a nanoswitch based on a layer of Au nanoparticles on a viologen moiety anchored to Au substrate. The  $I$ – $V$  characteristics

**Fig. 6** (A)  $I$ - $V$  characteristics of an isolated 3.3 nm Pd nanocrystal (dotted line) and the theoretical fit (solid line) obtained at 300 K using a semiclassical model according to which the observed capacitance ( $C$ ) can be resolved into two components  $C_1$  and  $C_2$ , and the resistance ( $R$ ) into  $R_1$  and  $R_2$ , such that  $C = C_1 + C_2$  and  $R = R_1 + R_2$ . For  $C_1 \ll C_2$  and  $R_1 \ll R_2$ , the model predicts steps in the measured current to occur at critical voltages,  $V_c = \frac{n_c e}{C} + \frac{q_0 + e/2}{C}$  where  $q_0$  is the residual charge. (B) Variation of the charging energies of Pd and Au nanocrystals with inverse diameters ( $d$ ). Source: From Ref.<sup>[26]</sup>.

of the Au nanoparticles studied using in situ STS revealed a dependence on the redox state of the viologen groups underneath the nanoparticle. By electrochemically altering the redox state, the conductivity of the circuit could be made high or low.<sup>[32]</sup>

## Nanocomputing

Buoyed by the success of preliminary experiments, it has been supposed that nanoscopic elements could act as ingredients in future computers. Ordered arrays of nanocrystals, in principle, could be thought of as arrays of single-electron transistors (SETs), where the electrostatic interaction between neighboring SETs acts as a means of wireless communication. It has been suggested by Korotkov and Lent that simple logical operations can be performed on a circuitry consisting of arrays of SETs in the form of chains or cells with suitable insulating spacers.<sup>[34,35]</sup> An electric field applied in one direction polarizes the strings into either the 0 or the 1 state. Lent's scheme, named quantum cellular automata, instead uses a square cell consisting of five nanocrystals to denote the state of polarization. Preliminary experiments to evaluate the schemes are currently being pursued. The realization that self-assembly driven fabrication process is not capable of producing defect-free structures has fueled a search

for algorithms that can compute even with defective circuitry. Heath and coworkers have developed TeraMac, a computer that works despite a high concentration of defects in its bank of microprocessors.<sup>[36]</sup> A more radical solution called amorphous computing aims to "engineer pre-specified, coherent behavior from cooperation of large numbers of unreliable parts interconnected in unknown, irregular and time varying ways."<sup>[37-39]</sup>

## Catalysis

Nanocrystals consist of an unusually large fraction of surface atoms. For example, a nanocrystal of size 5 nm has about 80% of its atoms on the surface. This increases the surface area per unit mass and translates to a higher number of active site per unit mass and thereby makes nanocrystals extraordinarily important for catalytic applications such as in autocatalytic converters. In addition to an increased surface area, nanocrystalline metals also possess high reactivity.<sup>[40-42]</sup> When combined with a suitable support, typically a semiconducting oxide surface such as TiO<sub>2</sub> or ZnO, the nanocrystals exhibit an affinity for reactions that have no corresponding bulk analogs. For example, Goodman and coworkers have found that small Au nanocrystals supported on titania catalyze CO

**Fig. 7** C(1s) core-level spectra of CO adsorbed on Au particles supported on a ZnO substrate. The feature at 285 eV corresponds to molecularly adsorbed CO. The diameters have been obtained from the metal coverages. *Source:* From Ref.<sup>[37]</sup>.

oxidation, with the catalytic ability being markedly size dependent.<sup>[43]</sup> Another study has found that Au nanocrystals supported on ZnO exhibit a tendency to adsorb CO.<sup>[44]</sup> The activity is size dependent and is exhibited only by small nanocrystals (diameters <5 nm, see Fig. 7). The increased activity of the small particles is attributable to the charge transfer between the oxide support and the particle. It is supposed that greater understanding of nanoscale charge transfer phenomena would contribute toward understanding of such catalytic processes.

## OPTICAL PROPERTIES

The fluorescent properties of semiconductor nanocrystals have drawn wide attention because of their potential use as labels in fluorescence bioassays.<sup>[45–52]</sup> When compared to dyes currently in use, the emission from fluorescent nanocrystals is brighter and sharper. For example, Nie and coworkers have estimated that CdSe nanocrystals are 20 times brighter and 100 times more stable than a single rhodamine 6G molecule.<sup>[51]</sup> Further, the emission can be brought about by

excitation in a broad range of wavelengths. It is therefore possible to excite nanocrystals of several different sizes simultaneously with a single source and obtain a well-resolved emission at different colors. In order that the nanocrystals are biocompatible, the nanocrystals need to be water soluble and possess pendant groups at the surface, that bind to biomolecules like proteins. These changes can be brought about by tailoring the ligand shell with small DNA fragments or mercapto acids. Several *in vivo* and *in vitro* fluorescence biochemical assays have been carried out with nanocrystalline markers.<sup>[45–47,51]</sup> A few studies have sought to exploit dependence of the plasmon absorption band on the dielectric constant of the surrounding medium in metal nanocrystals to detect binding events taking place at the ligand shell.<sup>[53–55]</sup> Thus, Au nanocrystals could colorimetrically determine the successful hybridization of oligonucleotide strands bound to its surface.<sup>[56,57]</sup> It has been proposed that colorimetric sensing of heavy metal ions could be obtained by the use of carboxylic acid terminated bifunctional thiols bound to metal nanocrystals.<sup>[58,59]</sup> The changes in the electronic absorption spectra of ~5 nm Ag nanocrystals capped with lipoic acid, following the addition of the heavy ions,  $\text{Cu}^{2+}$  and  $\text{Fe}^{2+}$ , is shown in Fig. 8. Such a dampening also brings about a change in color. It is apparent that  $\text{Cu}^{2+}$  ions dampen the plasmon band more effectively than  $\text{Fe}^{2+}$ . It has been suggested that very sensitive detection of nanoparticles could be carried out by measuring the light scattered by the particles.<sup>[61,62]</sup> Yguerabid and coworkers have pioneered the use of large particles ~60 nm for carrying out biochemical assays. In contrast to detection in the liquid state, much progress has been made in surface plasmon based detection of binding events that occur over a bed of nanocrystals. Since 1990, Biacore has been marketing a surface plasmon resonance (SPR) based kit for carrying out immunoassays.<sup>[63]</sup>

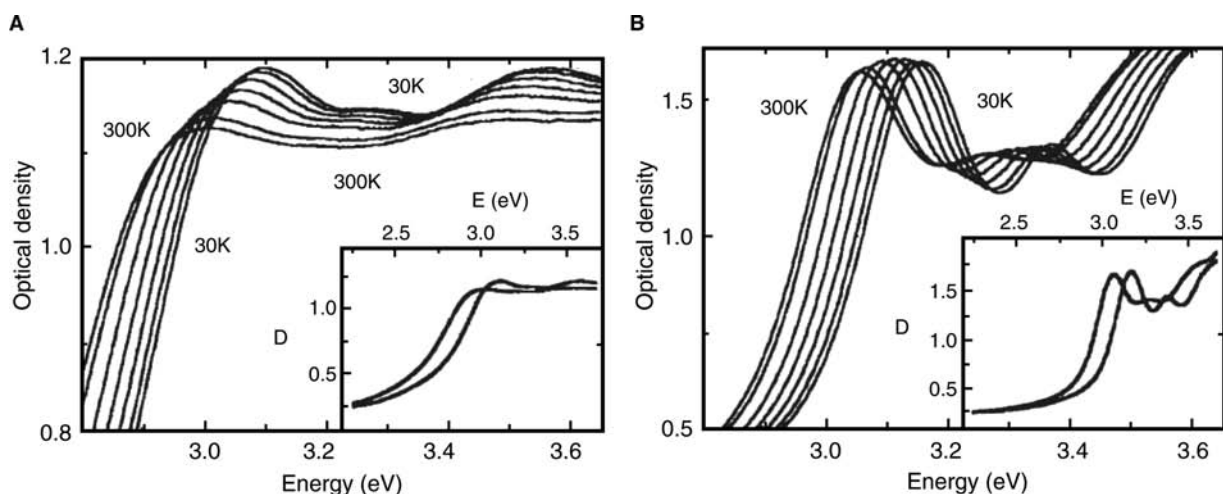

Another dimension has been added to the optical properties of nanocrystals by the recognition that the optical properties of a superlattice of nanocrystals could be different from that of the individual nanocrystals owing to interparticle interactions.<sup>[64]</sup> Typical spectra showing such a change in the case of CdSe nanocrystals are shown in Fig. 9. When present in close-packed organization, the absorption spectra of the nanocrystals are broadened and red shifted. This change has been attributed to interparticle dipolar interactions.<sup>[65]</sup> Bawendi and coworkers have studied such changes in the ensemble of CdSe nanocrystals of different diameters and have obtained evidence for long-range resonance transfer of electronic excitation from smaller to bigger nanocrystals owing to dipolar interactions.<sup>[66]</sup> In a noteworthy experiment, Weller and coworkers, prepared drop cast films of giant CdS clusters of the form  $\text{Cd}_{17}\text{S}_4(\text{SCH}_2\text{CH}_2\text{OH})_{26}$  and

**Fig. 8** Electronic absorption spectra of  $\sim 5$  nm Ag nanoparticles showing changes accompanying the addition of (A)  $\text{Cu}^{2+}$  and (B)  $\text{Fe}^{2+}$  ions. The concentrations of the ions are indicated.

$\text{Cd}_{32}\text{S}_{14}(\text{SCH}_2\text{CH}(\text{CH}_3)\text{OH})_{36}$  with diameters of 1.4 and 1.8 nm, respectively. Further, an integrating sphere was used to collect absorption data, thereby virtually eliminating errors from inhomogeneities and size distributions.<sup>[67]</sup> The experiments due to Weller also support the idea of dipolar interaction leading to the red shift and broadening. Signatures of such interactions have also been seen in the case of CdS multilayer deposits.<sup>[68]</sup> The interparticle interactions, however, could range from weak dipolar interactions to strong exchange interactions based on the interparticle separation. Delocalization of the electronic states of

nanocrystals in ensembles due to exchange interactions have been observed in experiments with CdSe nanocrystals. Gaponenko and coworkers have shown that the optical properties of an ensemble of small ( $\sim 1.6$  nm) CdSe nanocrystals are similar to that of bulk CdSe because of complete delocalization of the electronic states of individual nanocrystals.<sup>[69]</sup> Dipolar coupling interactions in metal nanocrystal assemblies such as in linear rows lead to strong optical anisotropy. The transmitted light depends on whether it is polarized parallel or perpendicular to the rows of nanocrystals. It has been suggested that such material could

**Fig. 9** Absorption spectra of thin films of close-packed (A) and isolated (B) CdSe nanocrystals at different temperatures (from right to left curves): 30, 80, 130, 180, 230, 280, and 300 K. The insets show the full-range spectrum of optical density  $D$  for the lowest and highest temperatures. A red shift and broadening of the peaks is seen in the case of close-packed films. *Source:* From Ref.<sup>[54]</sup>.

be useful as polarizing filters. Dirix et al. have pioneered a simple method of preparing such assemblies. Their method involved stretching a polyethylene film impregnated with Ag nanocrystals. Dirix et al.<sup>[70]</sup> Atwater and coworkers have suggested that coupled plasmon modes could lead to coherent propagation of electromagnetic energy, i.e., a row of metal nanocrystals could act as a nanoscale waveguide. Using an array generated by means of e-beam lithography, they have provided a proof of concept demonstration.<sup>[71]</sup>

Several polymer/polyelectrolyte-nanocrystal hybrid devices have been fabricated seeking to exploit the electro- and photoluminescent properties of nanocrystalline media.<sup>[72–81]</sup> Device fabrication in all these cases is by low-cost self-assembly based techniques. These devices utilize thin films of these hybrids obtained either by multilayer deposition or drop/spin casting methods. Thus, “solar cells” have been made from poly(2-hexylthiophene)-CdSe nanorod multilayers, lasers from drop cast films of CdSe–titania composites, and infrared emitter from multilayers of HgTe and poly(diallyl dimethyl ammonium chloride) (PDDA). White light electroluminescence is seen in multilayers of CdSe–CdS–poly(phenylenevinylene), CdTe–PDDA. White light emission has also been obtained from drop cast films consisting of a mixture CdSe–ZnS, CdS–ZnS, and poly-laurylmethacrylate. The characteristic of all the above devices can be changed by altering the nanocrystal size.

## MAGNETIC PROPERTIES

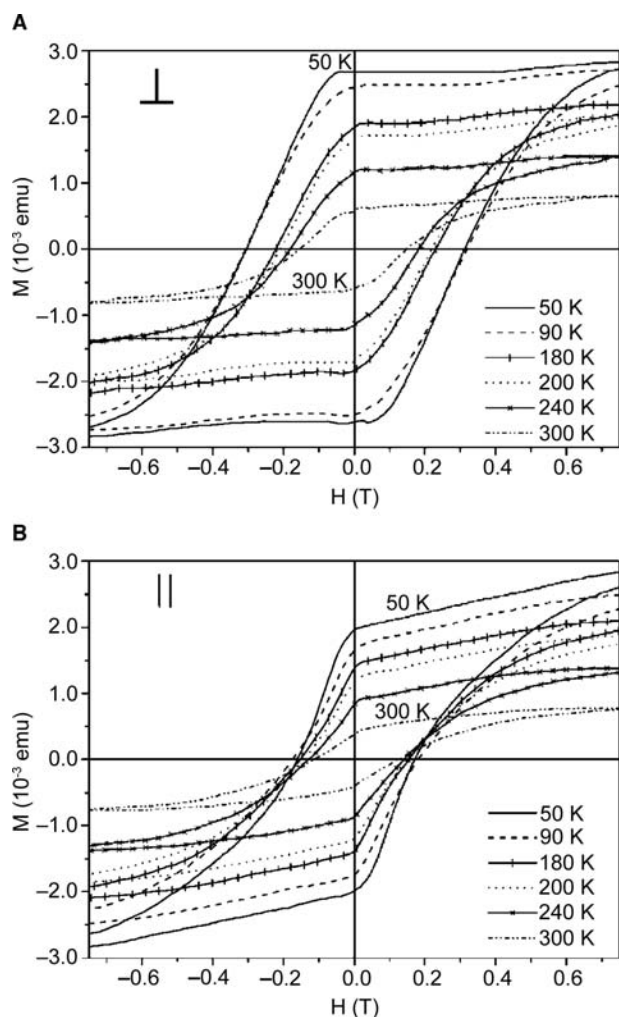

It is well known that in the nanometric domain, the coercivity of magnetic nanocrystals tends to zero.<sup>[82,83]</sup> Thus, the nanocrystals behave as superparamagnets with no associated coercivity or retentivity. The blocking

temperature that marks the onset of this superparamagnetism increases with the nanocrystal size. This scenario, however, changes in the case of interacting nanocrystals where the interparticle interaction and, hence, its magnetic properties can be tuned by varying the interparticle distance. Thus, lattices of interacting magnetic nanocrystals are considered important in the future magnetic storage devices. Further, the magnetic moment per atom is seen to increase as the size of a particle decreases.<sup>[87]</sup>

Nanocrystals of Co when organized into two-dimensional arrays exhibit a higher superparamagnetic blocking temperature compared to isolated nanocrystals, i.e., they display a higher resistance to thermal reversal of their spins than when they are isolated.<sup>[88]</sup> Sun et al. report a lattice of nanocrystals each consisting of a Fe core and a Pt shell prepared by heating Fe–Pt alloy nanocrystals.<sup>[89]</sup> Following phase segregation, the interaction between the nanocrystals increased leading to a ferromagnetic film capable of supporting high-density magnetization reversal transitions (see Fig. 10). Exchange spring magnets—nanocomposites that consist of magnetically hard and soft phases interacting via magnetic exchange coupling, have been made by carefully annealing the mixed nanocrystal array consisting of Fe–Pt and Fe<sub>3</sub>O<sub>4</sub>.<sup>[90]</sup> The easy magnetic axis of nanocrystals can be aligned by applying a magnetic field during evaporation of the colloid on a substrate to obtain films with high magnetic anisotropy.<sup>[91–93]</sup> Thus, ferromagnetic films with parallel anisotropy have been made of superparamagnetic  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanocrystals.<sup>[91]</sup> By tuning the substrate–nanocrystal interaction, the films can be made to exhibit perpendicular anisotropy (see Fig. 11).<sup>[92]</sup> Properties such as coercivity, anisotropy can be tuned by altering the size of the nanocrystals, the film

**Fig. 10** Magneto-resistive (MR) read-back signals from written bit transitions in an array of 4-nm-diameter Fe<sub>48</sub>Pt<sub>52</sub> nanocrystals. The line scans reveal magnetization reversal transitions at linear densities of (A) 500; (B) 1040; (C) 2140; and (D) 5000 flux changes per millimeter. Source: From Ref.<sup>[71]</sup>.

**Fig. 11** Hysteresis loops from a film of  $\gamma\text{-Fe}_2\text{O}_3$  deposited on Si(100) substrates at various temperatures with the substrate held (A) perpendicular and (B) parallel to the applied field direction. The increased coercivity along the perpendicular direction indicates perpendicular anisotropy caused by orientation of the easy magnetic axis of  $\gamma\text{-Fe}_2\text{O}_3$  nanocrystals perpendicular to the substrate. *Source:* From Ref. [78].

thickness or by suitably doping the nanocrystals with magnetic ions.<sup>[91–93]</sup>

### Biomedical Application of Oxide Nanoparticles

Magnetic oxide nanoparticles are considered as biocompatible as they possess no known toxicity. Superparamagnetic oxide nanoparticles have therefore found several biomedical applications.<sup>[94]</sup> By tailoring the ligand shell of magnetic particles to attach to a specific target molecule in a solution containing several different entities and subjecting the liquid to a magnetic field, separation or enhancement in concentration could be achieved. Such aids are rather important in biochemical experiments where very low

concentrations are generally employed. For example, by employing red blood cells labeled with iron oxide nanoparticles, the sensitivity of detection of malarial parasite was shown to be enhanced by Paul et al.<sup>[95]</sup> It has been proposed that hyperthermia—magnetic field induced heating of superparamagnetic particles, could be used to destroy diseased cells and thereby treat cancer. The particles are dispersed in the affected cells and an external AC magnetic field applied to bring about heating of the particles to cause destruction of the cells. Numerous studies have been carried out toward achieving this objective.<sup>[94,96]</sup> Magnetic nanoparticles also find application as magnetic resonance imaging contrast agents. This technology has been commercialized and is widely available.<sup>[94]</sup>

### CONCLUSIONS

Properties of metals and semiconductors become size dependent at the nanoscale because of associated changes in the electronic structure and charge transport. Specifically, electronic, optical, and magnetic properties of nanocrystals have gained importance in view of their potential applications. Small metal nanocrystals with discrete charge states find applications in highly sensitive electrometers and memory devices. Similarly, semiconductor nanocrystals of varying optical gap find applications in photonic materials and fluorescent markers in biochemical assays. Bimetallic and oxide nanocrystals with superparamagnetic domains have demonstrated potential as recording media. The latter especially has gained importance in cancer treatment.

## Abstract

Organization of metal and semiconductor nanocrystals into mesostructures is an important aspect of nanoscience. New methods of nanocrystal synthesis and functionalization relevant to mesoscopic assembly are described, with emphasis on procedures that deal with monodispersed nanocrystals. Programmed assemblies of nanocrystals in one, two, and three dimensions are discussed.

## INTRODUCTION

A nanocrystal is a tiny chunk of the bulk measuring a few nanometers with a finite number of atoms in it. Nanocrystals in the size range of 1–50 nm are considered important and are obtainable as sols—a dispersion of a solid in a liquid, also called a colloidal sol. Metal sols possess fascinating colors and have long been used as dyes. That such dyes indeed consist of tiny metal chunks was established as early as 1857 by Faraday,<sup>[1]</sup> but a similar realization in the case of semiconducting nanocrystals had to wait for over a century.<sup>[2,3]</sup> Modern techniques of synthesis enable one to obtain sols of metals and semiconductors that can be dried and re-dissolved like watercolors. The colloidal particles display a remarkable tendency to remain single-crystalline and are hence named as nanocrystals. Nanocrystals possess high surface area—a great fraction of the atoms in a nanocrystal is on its surface. A small nanocrystal of 1 nm diameter will have as much as 30% of its atoms on the surface, while a larger nanocrystal of 10 nm ( $\approx 1000$  atoms) will have around 15% of its atoms on the surface.<sup>[4]</sup>

An added dimension to research on nanocrystals is their size-dependent properties. The electronic, magnetic, and optical properties of a nanocrystal depend on its size.<sup>[4]</sup> In small nanocrystals, the electronic energy levels are not continuous as in the bulk but are discrete, owing to the confinement of the electron wave function to the physical dimensions of the particles.<sup>[5]</sup> This phenomenon is called as quantum confinement, and therefore, nanocrystals are also known as quantum dots. In other words, a small nanocrystal could be a very bad conductor although they are tiny silhouettes of the conducting bulk. Likewise, a tiny nanocrystal of a ferromagnet can be paramagnetic in nature. In the case of semiconductors, besides discretization of

levels, the band gap increases due to quantum confinement. In several respects, small nanocrystals behave like molecules. The nanocrystals can be discretely charged with electrons having characteristic charging energies. It means that a nanocrystal carrying an extra electron can exhibit properties different from a neutral species.

The electronic absorption spectrum of metal nanocrystals in the visible region is dominated by the plasmon band. This absorption is due to the collective excitation of the itinerant electron gas on the particle surface and is characteristic of a nanocrystal of a given size. In metal colloids, surface plasmon excitations impart characteristic colors to the metal sols, the beautiful wine-red color of gold sols being well known.<sup>[6–8]</sup> The dependence of the plasmon peak on the dielectric constant of the surrounding medium and the diameter of the nanocrystal was predicted theoretically by Mie and others at the turn of the last century.<sup>[9–12]</sup> The dependence of the absorption band of thiol-capped Au nanocrystals on solvent refractive index was recently verified by Templeton et al.<sup>[13]</sup> Link and El-Sayed<sup>[6]</sup> found that the absorption band splits into longitudinal and transverse bands in Au nano-rods.<sup>[6]</sup>

In contrast to metals, exciton peaks dominate the absorption of semiconductor nanocrystals. Thus, yellowish CdS, exhibits an excitonic absorption around 600 nm, which gradually shifts into the UV region as the nanocrystal diameters are varied below 10 nm. The absorption band can be systematically varied across ranges of a few 100 nm by changing the size of the semiconductor nanocrystal.<sup>[14–17]</sup> Brus and others proposed an independent theory to describe size quantization effects in semiconductor nanocrystals, based on the effective mass approximation<sup>[3,18]</sup> after recognizing the failure of Mie's theory. Since then, theories have grown in sophistication and rigor to include key

effects like surface structure and coupling of electronic states.<sup>[19–21]</sup> However, the understanding of the optical properties of semiconductor nanocrystals is still incomplete and careful experiments on monodisperse nanocrystals are currently being pursued to unravel the mystery.<sup>[22]</sup> In addition to interesting absorption properties, the semiconductor nanocrystals also exhibit luminescent behavior.<sup>[23–26]</sup> The emission from monodisperse semiconductor nanocrystals such as CdSe is intense, narrow, and can be brought about by excitation in a broad range of wavelengths.<sup>[26]</sup> The emission can be tuned by altering the diameter of the nanocrystal (see Fig. 1). Further, control over the emission can be exercised by varying the surface structure and controlling diameter distribution. The above factors have led to the exploration of a wide range of applications for luminescent semiconductor nanocrystals.

The shrinking dimensions of the current microelectronic devices and the realization that current lithographic processes cannot extend to the nanoworld<sup>[27]</sup> have lent tremendous thrust to research aimed at ordering nanocrystals into functional networks.<sup>[28–33]</sup> The nanocrystals akin to covalent systems self-assemble

**Fig. 1** The emission spectra of CdSe nanocrystals of different sizes (A) 2.4 nm; (B) 2.5 nm; (C) 2.9 nm; (D) 3.3 nm; (E) 3.9 nm; (F) 4.1 nm; (G) 4.2 nm; (H) 4.4 nm. The change in the emission width is due to decrease in the nanocrystals diameter distribution with increase in diameter. *Source:* Reproduced with permission from Ref.<sup>[26]</sup>.

into ordered arrays in one, two, and three dimensions under the right conditions. Lattices of nanocrystals consist of interacting nanocrystals and may exhibit novel properties arising out of such interactions. The ability to engineer such assemblies, thus, extends the reach of current lithographic techniques and holds promise for a new generation of electronics of the nanoworld.<sup>[28]</sup> In this context, synthesis and programmed assembly of nanocrystals assumes significance.

In this entry, we discuss the structure and stability of mesoscopic organizations of nanocrystals in one, two, and three dimensions obtained by using a variety of surfactants. We also examine certain unusual organizations such as clusters of nanocrystals and microcolloidal crystals.

## SYNTHETIC STRATEGIES

### General Methods

Chemical synthesis of sols of metals and semiconductors results in nanoparticles embedded in a layer of ligands or stabilizing agents that prevent the aggregation of particles. The stabilizing agents employed include surfactants such as long-chain thiols or amines or polymeric ligands such as polyvinylpyrrolidone (PVP). Reduction of metal salts dissolved in appropriate solvents produces small metal particles of varying size distributions.<sup>[34–37]</sup> A variety of reducing agents have been employed for reduction. These include electrides, alcohols, glycols, metal borohydrides, and certain specialized reagents such as tetrakis(hydroxymethyl) phosphonium chloride. Si and Ge nanocrystals can be obtained by reduction of  $\text{GeCl}_4$  or silanes with strong reducing agents such as lithium or sodium naphthalide.<sup>[38–40]</sup>

Kinetic control of precipitation (arrested precipitation) is generally used to obtain semiconductor nanocrystals such as CdS,<sup>[41]</sup> CdSe,<sup>[42]</sup> ZnS, HgTe, PbS, CuS,  $\text{Cu}_2\text{S}$ , AgI, ZnO, AgI, and  $\text{TiO}_2$ .<sup>[43–45]</sup> The nanoparticles so obtained possess a broad distribution in diameters. Thermolysis methods involving the decomposition of organometallic precursors in high boiling organic solvents is used to prepare CdSe,<sup>[46]</sup> CdS,<sup>[46]</sup> PbSe,<sup>[16]</sup> InP,<sup>[17]</sup> ZnSe, GaAs, InSb, GaP nanocrystals.<sup>[44–49]</sup> Reverse micellar methods exploit the “water pools” in water-in-oil mixtures to synthesize nanocrystals and have been successfully utilized in the preparation of Ag, Au, Co, Pt, Co, CdS, CdTe, AgS nanocrystals.<sup>[50,51]</sup> The synthesis of nanocrystals at the air–water interface as in Langmuir–Blodgett films or at a liquid–liquid interface is currently attracting wide attention.<sup>[29,52,53]</sup> CdS, PbS, and MgS nanocrystals have been prepared by exposing Langmuir–Blodgett films of fatty acids to  $\text{H}_2\text{S}$ .<sup>[54]</sup> It has been shown recently that films of metal, semiconductor, and oxide

**Fig. 2** Nanocrystalline film of Au formed at the toluene–water interface (middle). Gold is introduced as a toluene solution of  $\text{Au}(\text{PPh}_3)\text{Cl}$  while partially hydrolyzed THPC (tetrakis(hydroxymethyl)phosphoniumchloride) in water acts as a reducing agent. The film is obtained when the two layers are allowed to stand for several hours. When dodecanethiol is added to the toluene layer, the film breaks up forming an organosol (left) while mercaptoundecanoic acid added to water produces a hydrosol (right). Shown below are the corresponding TEM images showing nanocrystals. The scale bars correspond to 50 nm. Films of CdS nanocrystals could also be prepared by adopting the same methods.

nanocrystals can be prepared using a water–toluene interface.<sup>[55,56]</sup> A typical film of Au nanocrystals is shown in Fig. 2. Traditionally, clusters of controlled sizes have been generated by ablation of a metal target in vacuum followed by mass selection of the plume to yield cluster beams.<sup>[57,58]</sup> Such cluster beams could be subject to in situ studies or be directed on to solid substrates. To obtain nanocrystals in solution, Harfenist et al.<sup>[59]</sup> steered a mass-selected Ag cluster beam through a toluene solution of thiol and capped the vacuum prepared particles.

Colloids of alloys have been made by the chemical reduction of the appropriate salt mixture in the solution phase. In the case of semi-conductor nanocrystals, a mixture of salts is subject to controlled precipitation. Thus, Ag–Pd and Cu–Pd colloids of varying composition have been prepared by alcohol reduction of mixtures of silver nitrate or copper oxide with palladium oxide.<sup>[60]</sup> Fe–Pt alloy nanocrystals have been made by thermal decomposition of the Fe and Pt acetylacetonates in high boiling organic solvents.<sup>[61]</sup> Au–Ag alloy nanocrystals have been made by

co-reduction of silver nitrate and chloroauric acid with sodium borohydride.<sup>[62,63]</sup> Semiconductor nanocrystals of the form  $\text{Cd}_x\text{Mn}_{1-x}\text{S}$ ,  $\text{CdS}_x\text{Se}_{1-x}$  have been obtained by the inverted micelle methods as well as in glasses by sol–gel methods.<sup>[22,64]</sup> Alloys of controlled composition are also made by thermal decomposition of carefully chosen precursors, to achieve homogeneity. For example,  $\text{Mn}_2(\mu\text{-SeMe})_2(\text{CO})_8$  was used as selenium source to obtain  $\text{Cd}_{1-x}\text{MnSe}$  nanocrystals.<sup>[65]</sup> Au–Ag alloying and segregation has been brought about by the use of lasers on Au–Ag layered particles.<sup>[66,67]</sup>

### Size Control

The successful synthesis of nanocrystals involves three steps: nucleation, growth, and termination by the capping agent or ligand.<sup>[34–36]</sup> Though the reaction temperature and reagent concentrations provide a rudimentary control of the three steps, it is often impossible to independently control them and so the

**Fig. 3** Metal nanocrystals in closed-shell configurations with magic number of atoms.

obtained nanocrystals usually exhibit a distribution in size. Typically, the distribution is log-normal with a standard deviation of 10%.<sup>[36]</sup> Given the fact that properties of the nanocrystals are size-dependent, it is significant to be able to synthesize nanocrystals of precise dimensions with minimal size-distributions. This can be accomplished to a limited extent by size selective precipitation either by centrifugation or by use of a miscible solvent–non-solvent liquid mixture to precipitate nanocrystals. However, single crystals of large clusters of semiconducting material such as  $\text{Cu}_{147}\text{Se}_{73}(\text{PET}_3)_{22}$ ,<sup>[68]</sup>  $[\text{Cd}_{10}\text{S}_4(\text{SPh})_{16}]^{4-}$ ,<sup>[69,70]</sup>  $\text{Cd}_{32}\text{S}_{14}(\text{SC}_6\text{H}_5)_{36}\text{DMF}_4$ ,<sup>[69,70]</sup>  $\text{Cd}_{17}\text{S}_4(\text{SCH}_2\text{CH}_2\text{OH})_{26}$ ,<sup>[69,70]</sup>  $\text{Cd}_{32}\text{S}_{14}(\text{SCH}_2\text{CH}(\text{CH}_3)\text{OH})_{36}$ ,<sup>[71]</sup>  $\text{Hg}_{32}\text{Se}_{14}(\text{SeC}_6\text{H}_5)_{36}$ <sup>[72]</sup> have been obtained. Solutions of such clusters possess optical properties similar to those of the sols. Schmid<sup>[73]</sup> and Zamaraev<sup>[74]</sup> succeeded in preparing truly mono-disperse nanocrystals, which they called “cluster compounds.” These cluster compounds are like macromolecules with a core containing metal–metal bonds yet obtainable in definite stoichiometries, typical examples being  $[\text{Pt}_{38}(\text{CO})_{44}\text{H}_2]^{2-}$  and  $\text{Au}_{55}(\text{PPh}_3)_{12}\text{Cl}_6$ . The enhanced stability of  $\text{Au}_{55}$  was recently demonstrated clearly by Boyen et al.<sup>[75]</sup> who exposed a series of  $\text{Au}_n$  nanocrystals to oxidation. These

nanocrystals are bequeathed with special stability because they consist of a magic number of metal atoms, which enables the complete closure of successive shells of atoms in a cubic close-packed arrangement. The magic numbers 13, 55, 147, 309, and 561 correspond to the closure of 1, 2, 3, 4, and 5 shells, respectively.<sup>[76]</sup> A schematic illustration of magic nuclearity nanocrystals is shown in Fig. 3. Since the breakthrough, several magic nuclearity nanocrystals have been prepared including PVP-stabilized  $\text{Pd}_{561}$  nanocrystals.<sup>[77,78]</sup> In Fig. 4 are shown scanning tunnelling and transmission electron microscopic (TEM) images of polymer-protected  $\text{Pd}_{561}$  nanocrystals.

### Shape Control

Since the properties of the nanocrystals follow from the confinement of the electrons to the physical dimensions of the nanocrystals, it would be interesting to vary the shape of the nanocrystals and study the effect of confinement of electrons in such artificial shapes.<sup>[79]</sup> For example, it is predicted that light emitted from a nanorod would be linearly polarized along the growth-axis.<sup>[22]</sup> Such predictions have led to the revival

**Fig. 4** Scanning tunneling microscopy image of polymer coated  $\text{Pd}_{561}$  nanocrystals. The nanocrystals are seen as fluffy balls against plane background of the graphite substrate. The inset shows a high-resolution electron micrograph (HRTEM) of an individual nanocrystal. We see the characteristic 11 [111] fringes in the icosahedral shape measuring 2.5 nm. The diameter estimated from STM is  $\approx 3.4$  nm, the difference being due to the ligand shell.

of interest in synthetic strategies yielding non-spherical nanocrystals. Conventional methods such as due to Turkevich<sup>[35]</sup> yield in addition to spherical particles, a mixture of shapes—triangular, teardrop, etc., which

was then thought of as undesirable. Today, smarter synthetic schemes have been designed, which yield selectively nanocrystals in the form of rods, elongated spheres, cubes, and hexagons. CdSe nanocrystals in the form of rods, arrows, teardrops, and tetrapods have been obtained by careful control of thermolysis conditions such as ratio of surfactants and injection volumes.<sup>[22,80]</sup> In Fig. 5 are shown TEM micrographs of soluble CdSe nanorods of various aspect ratios. Triangular CdS nanocrystals have been obtained by inverse micelle methods.<sup>[81]</sup> Big tetrahedral Si nanocrystals as exclusive products have been obtained by careful control of the reducing conditions.<sup>[82]</sup> TEM images of Triangular CdS and Tetrahedral Si nanocrystals are shown in Fig. 6. Some shape control has also been demonstrated in the case of CdS and CdTe nanocrystals.<sup>[83,84]</sup>

### Tailoring the Ligand Shell

Nanocrystals in their native form are dominated by the surface species, the capping agents employed play a role in determining the property of the nanocrystals.<sup>[85]</sup> Hence, in addition to controlling the size and the shape of the nanocrystals, it is also necessary to tailor its surface with the right capping agent. In addition to traditional capping agents that include ions, surfactants, and polymers, a new breed of ligands—dendrimers,

**Fig. 5** (A–C) TEM images of different nanorods of CdSe with different sizes and aspect ratios, high-resolution TEM images of four nanorods are shown below. *Source:* Reproduced with permission from Ref.<sup>[78]</sup>.

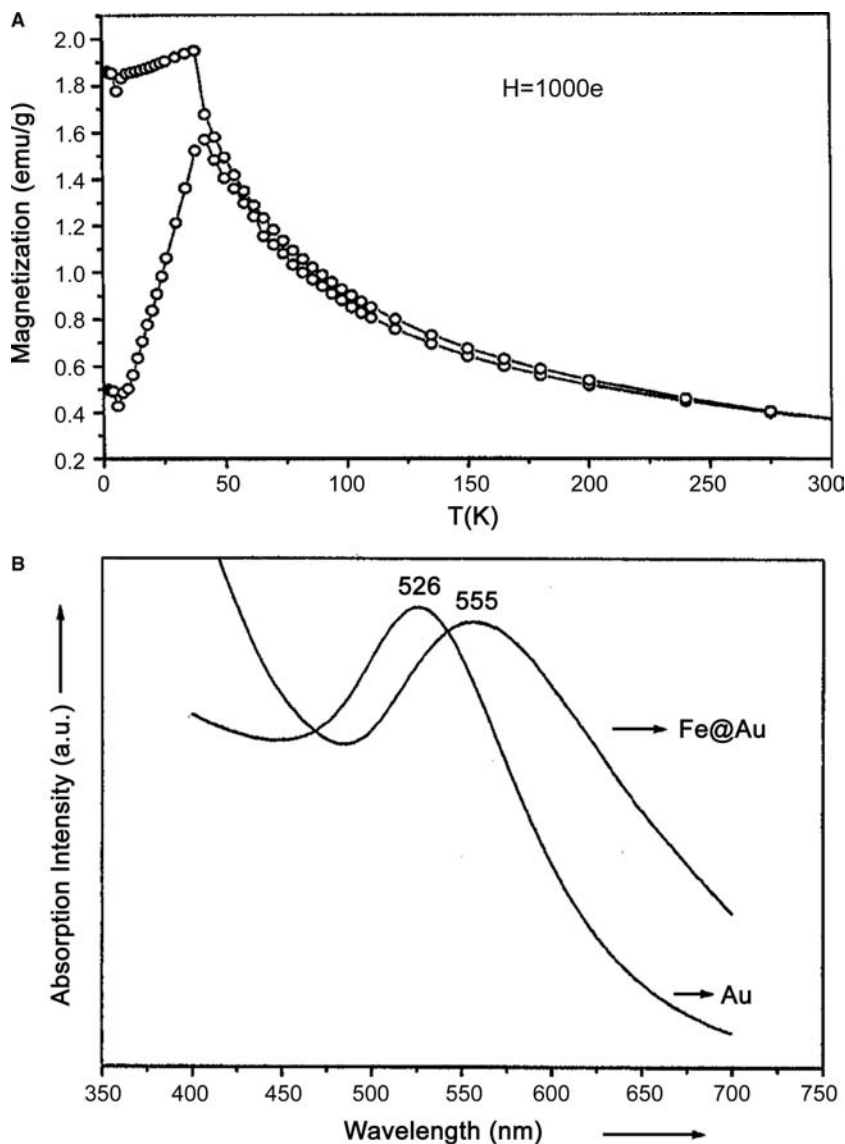

**Fig. 6** (A) TEM micrograph showing tetrahedral Si nanocrystals. The inset shows a selected area electron diffraction pattern typical of a diamond structure. (B) A high-resolution TEM image of a triangular CdS nanocrystal, power spectra is shown alongside. *Source:* Reproduced with permission from Refs.<sup>[79,80]</sup>.

hydrogen bonding fragments of protein, DNA and dyes—with pendant thiol groups as well as silica layers have been used as capping agents.<sup>[86–88]</sup> In some cases, a layer of a noble metal is used as a buffer between the core nanocrystal and the ligand shell.<sup>[89]</sup> Thus, a layer of gold lends special stability to Fe nanocrystals and helps prevent oxidation and in preserving the magnetic properties of Fe (see Fig. 7). Coating of a wider band gap material over a semiconductor nanocrystal aids in lifting the energy of surface states from in between the highest occupied and the lowest unoccupied levels, thereby enhancing the luminescence efficiency.<sup>[14,23]</sup> The lower band gap material acts as a seed for nucleation of the higher band gap material. Thus, core shell nanocrystals such as CdSe–ZnS, Si–SiO<sub>2</sub>, HgS–CdS, PbS–CdS,<sup>[44,45]</sup> ZnS–CdSe,<sup>[90]</sup> ZnSe–CdSe,<sup>[91]</sup> CdTe–HgTe nanocrystals have been obtained.<sup>[92,93]</sup>

Of special interest with regard to tailoring the ligand shells are reactions that enable the total replacement of one set of ligands with another.<sup>[94–98]</sup> These reactions also typically enable the transfer of nanocrystals from one phase to another. A novel method of thiol-derivatizing hydrosols of metal sols has been developed by Sarathy et al.<sup>[95,96]</sup> The procedure involves mixing vigorously a hydrosol containing metal particles of the desired size distribution with a toluene solution of an alkane thiol in the presence of a strong acid or reducing agent. The completion of the derivatization is marked by a vivid interchange of the colors from the aqueous layer to the hydrocarbon layer. The advantage of this method is that well-characterized metal particles can be easily thiol-derivatized in a non-aqueous medium. A variety of hydrosols of Au, Ag, and Pt have been thiolized by this procedure.

**Fig. 7** (A) Zero field cooled and field cooled magnetization curves for Fe–Au core–shell nanocrystals. The blocking temperature is 42 K. (B) Absorption spectrum showing the Au surface plasmon, shifted due to capping by Fe. For comparison, the spectrum of Au hydrosol is also shown. *Source:* Reproduced with permission from Ref.<sup>[87]</sup>.

A simple modification of this technique is shown to be effective in the case of CdS nanocrystals.<sup>[99]</sup>

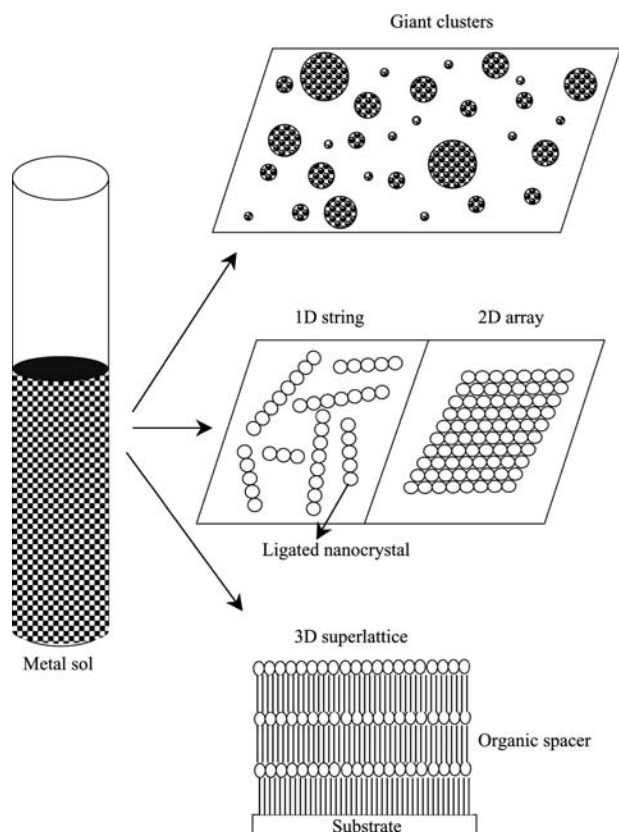

### PROGRAMMED ASSEMBLIES

Like molecular systems, nanocrystals capped with suitable ligands spontaneously assemble into ordered aggregates. That such a self-assembly can occur through a variety of weak forces is being recognized. Cooperative assemblies of ligated metal and semiconductor as well as of colloidal polymer spheres seem to occur through the mediation of electrostatic and capillary forces.<sup>[100–102]</sup> The forces that govern the nanocrystal assembly, however, are different in many ways. Surface tension, for example, plays an important role<sup>[36]</sup> because in a nanocrystal, a large fraction of

atoms are present at the surface. Surfactant molecules that self-assemble on solid surfaces have proved to be the best means of obtaining ordered arrays of nanocrystals.<sup>[102]</sup> The way in which the nanocrystals organize themselves depends critically on the core diameter, the nature of the ligand, substrate, and even the dispersive medium used.<sup>[103]</sup> Thiolized metal nanocrystals readily arrange into two-dimensional arrays on removal of the solvent.<sup>[28]</sup> Using suitable methods, they can also be put into one-dimensional organization in the form of strings or assembled in a stepwise fashion in a three-dimensional superlattice (see Fig. 8).

### One-Dimensional Arrangements

Hornayak and coworkers<sup>[104]</sup> used the ordered channels of porous alumina as templates to obtain linear

**Fig. 8** Schematic illustration of the various metal nanocrystal organizations.

arrangements of Au nanocrystals. By varying the pore size, the diameter of the nanowire could be controlled. A linear arrangement has also been obtained by coordinating Au particles ( $\approx 1.4$  nm) stabilized with phosphine ligands to single-stranded DNA oligonucleotide of the desired length and specific sequence.<sup>[105,106]</sup> Liquid crystalline phases of a genetically engineered virus–ZnS nanocrystal hybrid material was used as a template to obtain linear arrays of ZnS nanocrystal aggregates.<sup>[107]</sup> Similarly, Pt nanocrystals in the form of ribbons have been obtained using a cholesteric liquid crystalline template.<sup>[108]</sup> Organization of particles in a one-dimensional lattice has met with limited success. Heath and coworkers<sup>[109]</sup> have fabricated wires of Ag nanocrystals by compressing a dispersion of Ag (4.5 nm) nanocrystals in toluene (Fig. 9). The wires were one nanocrystal thick, a few nanocrystals wide, and extended in length from 20 to 300 nm. The interwire separation distance as well as the alignment of the wires could be controlled by compressing the film. Based on preliminary experimental observations, it has been suggested that tobacco mosaic virus tubules could serve as templates for the growth of one-dimensional lattice of quantum dots.<sup>[110]</sup>

**Fig. 9** TEM image of a continuous stratum structure of compressed LB film of Ag nanocrystals. One-dimensional strings of Ag nanocrystals are clearly seen. *Source:* Reproduced with permission from Ref.<sup>[107]</sup>.

## Two-Dimensional Arrays

Ligands based on long-chain thiols or phosphines have served as good candidates for assembling monodisperse nanocrystals on a flat substrate. Two-dimensional organizations of a variety of nanocrystals can be brought about by simply evaporating a drop of the sol on a flat substrate.

### Arrays of metal nanocrystals

Gold organosols using alkane thiols as surfactants were first prepared by Schiffrin and co-workers<sup>[111]</sup> by phase transferring gold ions and carrying out reduction in the presence of thiols. Several workers have adopted this procedure to obtain thiolized metal nanocrystals.<sup>[112–115]</sup> Whetten et al.<sup>[113]</sup> centrifuged the organosol and separated out fractions containing nanocrystals of different mean sizes, to prepare well-ordered two-dimensional arrays of size-selected Au nanocrystals. Harfenist et al.<sup>[59]</sup> found that Ag nanocrystals prepared by using a cluster beam were stable in air and formed extended two-dimensional arrays. In Fig. 10 is shown a TEM image of two-dimensional array of dodecanethiol covered Ag nanocrystals obtained by Fitzmaurice and coworkers.<sup>[114]</sup> The Ag nanocrystals were prepared following the method of Schiffrin and co-workers.<sup>[111]</sup> Well ordered arrays of

**Fig. 10** Transmission electron micrograph showing hexagonal close-packed Ag nanocrystals (diameter, 7 nm) obtained by evaporating a chloroform dispersion on a carbon substrate. The average interparticle distance is 1.5 nm. Inset shows the 2D power spectrum of the image. *Source:* Reproduced with permission from Ref.<sup>[114]</sup>.

magic nuclearity nanocrystals, Pd<sub>561</sub> and Pd<sub>1415</sub>, have been successfully obtained (see Fig. 11) after replacing their polymer coating by alkanethiols, following the phase transfer method discussed previously.<sup>[116]</sup> Long-chain fatty acids have also been used for ligating and assembling metal nanocrystals. Colloidal dispersion of Co nanocrystals capped with fatty acids were found to self-assemble to yield hexagonally ordered arrays similar to those obtained with alkanethiols.<sup>[117,118]</sup> Similarly, Ag nanocrystals capped with fatty acids of appropriate lengths yield cubic or hexagonal close-packed structures.<sup>[119,120]</sup> Schmid et al.<sup>[121]</sup> have reported an ordered two-dimensional array of small Au<sub>55</sub> nanocrystals (diameter  $\approx$  1.4 nm) on a polymer film (see Fig. 12). At the other end of the size-regime, big Au nanocrystals of 15–90 nm dimensions have also been organized into two-dimensional arrays.<sup>[122]</sup> Arrays of Au–Ag<sup>[62,63]</sup> and Fe–Pt alloy nanocrystals<sup>[61]</sup> have been obtained. Magic nuclearity Pd<sub>561</sub> nanocrystals have been exploited to make Pd–Ni core–shell particles with variable Ni loadings.<sup>[123]</sup> The nanocrystals so obtained possess a core–shell structure, where an Ni layer covers a Pd seed. The magic nuclearity Pd<sub>561</sub> nanocrystals act as high-quality seeds and promote the formation of monodisperse Pd–Ni core–shell nanocrystals. Arrays of Pd<sub>561</sub>Ni<sub>*n*</sub> (*n* upto 10,000 atoms) have been prepared after thiolizing the core–shell nanocrystals as shown in Fig. 13.<sup>[124]</sup> By a simple extension of this technique, arrays of triple layer nanocrystals of the form Pd<sub>561</sub>Ni<sub>3000</sub>Pd<sub>1500</sub> were also obtained. Methods to organize non-spherical metal nanocrystals into two-dimensional arrays have met with very limited success. Thus, hexagonal Pt as well

**Fig. 11** TEM micrographs showing hexagonal arrays of thiolized Pd nanocrystals: (A) Pd<sub>561</sub> octanethiol, (B) Pd<sub>1415</sub> octanethiol. Organized arrays of these nanocrystals extend to lengths over several microns.

as elongated silver nanocrystals have been organized into ordered two-dimensional arrays.<sup>[95,125]</sup> Interestingly, ordered two-dimensional lattices containing thiolized spherical Au particles of two different sizes have been reported by Kiely et al. (see Fig. 14),<sup>[115]</sup> who found that the nanocrystals of different radii follow the radius ratio rules formulated for alloying of different metals. Alloy arrays consisting of Au and Ag nanocrystals of different sizes have been made.<sup>[126]</sup>

#### Arrays of semiconductor nanocrystals

Murray, Norris, and Bawendi first made monodisperse CdSe nanocrystals by rapid injection of a tri-*n*-octylphosphine (TOP) solution containing dimethylcadmium and tri-*n*-octylphosphine selenide into a hot solution of TOP and TOP oxide.<sup>[46]</sup> By a simple extension of this technique, CdTe and CdS nanocrystals can also be obtained.<sup>[46]</sup> These nanocrystals could be

**Fig. 12** TEM images of  $\text{Au}_{55}$  monolayers showing a hexagonal (A) and a cubic (B) structure. The monolayers were prepared on a polyethyleneimine functionalized carbon grid. The magnified inset in (A) shows single clusters in the hexagonal form. Source: Reproduced with permission from Ref.<sup>[136]</sup>.

size-selected to yield monodisperse CdSe nanocrystals.<sup>[127]</sup> Upon drying on a flat substrate, these CdSe nanocrystals assemble into superlattices containing several layers of two-dimensionally ordered nanocrystals. Transmission electron microscopic images showing the different facets of the two-dimensional

**Fig. 13** TEM image of an ordered array of octanethiol capped (A)  $\text{Pd}_{561}\text{Ni}_{561}$  and (B)  $\text{Pd}_{561}\text{Ni}_{3000}$  nanocrystals. Ni was introduced in the form of its acetate during the reduction process. The nanocrystals were subsequently thiolized.

layers in these superlattices are shown in Fig. 15. Hexanethiol capped PbS nanocrystals, prepared by phase transferring a Pb ion into organic medium using hexanethiol, followed by reaction with  $\text{Na}_2\text{S}$  were also organized into two-dimensional lattices (see Fig. 16).<sup>[128,129]</sup> Motte et al.<sup>[64]</sup> obtained a hexagonally ordered two-dimensional array of  $\text{Ag}_2\text{S}$  nanocrystals synthesized by reverse micelle method. Ordered arrays of InP nanocrystals prepared by the thermolysis method have also been obtained.<sup>[17]</sup>

#### Arrays of oxide nanocrystals

The very first report of two-dimensional arrays was of  $\text{Fe}_3\text{O}_4$  nanocrystals.<sup>[130]</sup> Bentzon et al. observed that the ferrofluid obtained by thermolysis of iron-pentacarbonyl upon drying (over a period of several weeks) yielded well ordered two-dimensional arrays of  $\text{Fe}_3\text{O}_4$  nanocrystals. Since then, easier methods have been devised to obtain arrays of  $\text{Fe}_3\text{O}_4$  nanocrystals.<sup>[131]</sup>

**Fig. 14** A bimodal hexagonal array of Au nanocrystals. The radius ratio of the nanocrystals is 0.58. Source: Reproduced with permission from Ref.<sup>[115]</sup>.

**Fig. 15** Three-dimensional super lattices of 4.8 nm CdSe nanocrystals (A) along  $\langle 100 \rangle$  orientation, (B) along  $\langle 101 \rangle$  orientation, (C) along  $\langle 111 \rangle$  orientation. High-resolution images as well as selected area electron diffraction pattern is shown alongside in each case. *Source:* Reproduced with permission from Ref.<sup>[127]</sup>.

Two-dimensional arrays of amine capped metal oxide nanocrystals such as  $\text{Co}_3\text{O}_4$  have been obtained starting from metal oxide nanocrystals prepared by thermolysis of metal-cupferron complexes.<sup>[132]</sup> In contrast to metal nanocrystals, attempts to organize non-spherical oxide nanocrystals have met with reasonable success. Thus, tetrahedral  $\text{CoO}$  nanocrystals have been organized into extended two-dimensional arrays.<sup>[133]</sup> A rectangular superlattice made of prismatic  $\text{BaCrO}_4$  has been observed.<sup>[134]</sup> More complex arrays such as those consisting of a mixture of nanocrystals of different sizes have been obtained using  $\text{Fe}_3\text{O}_4$  and  $\text{Fe-Pt}$  nanocrystals.<sup>[135]</sup> The mixed arrays were obtained by evaporating a binary mixture of the metal oxide organosols.

#### Other two-dimensional arrangements

It is possible to obtain micrometer-sized rings of monodisperse nanocrystals such as  $\text{Ag}_2\text{S}$ ,  $\text{Ag}$  instead of extended arrays by varying the solvent evaporation

**Fig. 16** TEM micrographs showing hexagonal arrays of hexanethiol capped PbS nanocrystals. *Source:* Unpublished results from our laboratory.

rate and exploiting the resulting fluid instabilities (the marangoni effect) that occurs during evaporation.<sup>[136–140]</sup> Neat Au nanocrystals as well as CdSe–ZnS core-shell nanocrystals of various sizes have been organized into two-dimensional lattices using a protein (chaperonin) template.<sup>[141]</sup>

#### Stability and phase behavior of two-dimensional arrays

The nanocrystal organizations mentioned above are mainly entropy-driven. The two lengths involved, the nanocrystal diameter ( $d$ ) and the ligand chain length ( $l$ ), play an important role in deciding the nature of the organization, i.e., its orderliness. It has been observed experimentally that for a given diameter of the nanocrystal, the packing changes swiftly as the length of the thiol ligand is increased. The stability diagram in terms of  $d$  and  $l$  shown in Fig. 17, which illustrates that extended close-packed organizations of nanocrystals are found for  $d/l$  values  $\sim 2$ . Although entropy-driven, the above cannot be treated as hard sphere organizations. Based on a study of the effect of the solvent polarity on the self-assembly of ligated metal nanocrystals, Korgel et al.<sup>[103,114]</sup> proposed a soft sphere model taking the interparticle interaction into consideration. Accordingly, a ligated nanocrystal

**Fig. 17** The  $d$ - $l$  phase diagram for Pd nanocrystals thiolized with different alkanethiols. The mean diameter,  $d$ , was obtained from the TEM measurements on as-prepared sols. The length of the thiol,  $l$ , is estimated by assuming an all-trans conformation of the alkane chain. The thiol is indicated by the number of carbon atoms,  $C_n$ . The bright area in the middle encompasses systems that form close-packed organizations of nanocrystals. The surrounding darker area includes disordered or low-order arrangements of nanocrystals. The area enclosed by the dashed line is derived from calculations from the soft sphere model. *Source:* Reproduced with permission from Ref.<sup>[116]</sup>.

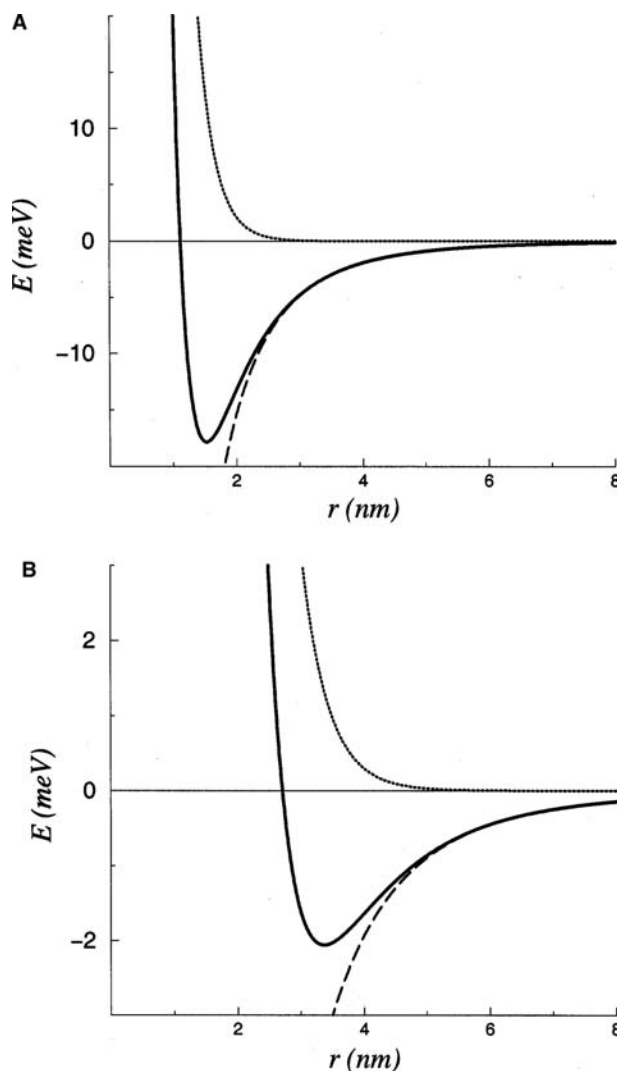

allows for penetration of the ligand shell up to its hard sphere limit. In this model, the total potential energy,  $E$ , is considered to be a result of two types of forces between the nanocrystals,

$$E = E_{steric} + E_{vdW} \quad (1)$$

$$E_{vdW} = \frac{A}{12} \times \left\{ \frac{d^2}{\tau^2 - d^2} + \frac{d^2}{\tau^2} + 2 \ln \left[ \frac{\tau^2 - d^2}{\tau^2} \right] \right\} \quad (2)$$

$$E_{steric} = \frac{50d/l^2}{(\tau - d)\pi\sigma_a^3} kT e^{-\pi(\tau-d)} \quad (3)$$

The van der Waals interaction due to the polarization of the metal cores constitutes the attractive term, and the steric interaction between the thiol molecules on the two surfaces forms the repulsive term, where  $x$  is the interparticle distance. The Hamaker constant,  $A$ , for Pd nanocrystals, in toluene for instance, has been estimated to be 1.95 eV.<sup>[142]</sup> The calculated diameter of the area occupied by the thiol molecule ( $\sigma_a$ ) on the particle surface is 4.3 Å.<sup>[114]</sup> The total energy is attractive over a range of interparticle distances, the magnitude increasing with fall in distance. There could

**Fig. 18** Variation of the two components and the total potential energy versus the separation distance between two Pd nanocrystals of 4.5 nm diameter coated with (A) octanethiol (B) dodecanethiol. *Source:* Reproduced with permission from Ref.<sup>[116]</sup>.

be a range of interparticle distances where the attractive energy from the van der Waals term exceeds the repulsive energy owing to the steric factor, giving rise to net stabilization of the two-particle system. This is illustrated in Fig. 18 in the case of 4.5 nm Pd particles. Stabilization energies of 17 and 2 meV are obtained from the calculation for particles coated with octanethiol and dodecanethiol, respectively. When the stabilization energies have moderate values, comparable with the thermal energy of the nanocrystals, ordered organizations can be expected (see the regime shown by dashed line in Fig. 17). If the  $d/l$  and hence the stabilization energy is not favorable, collapsed monolayers of nanocrystals or loosely packed structures are seen. Clearly, the interdigitation of thiol

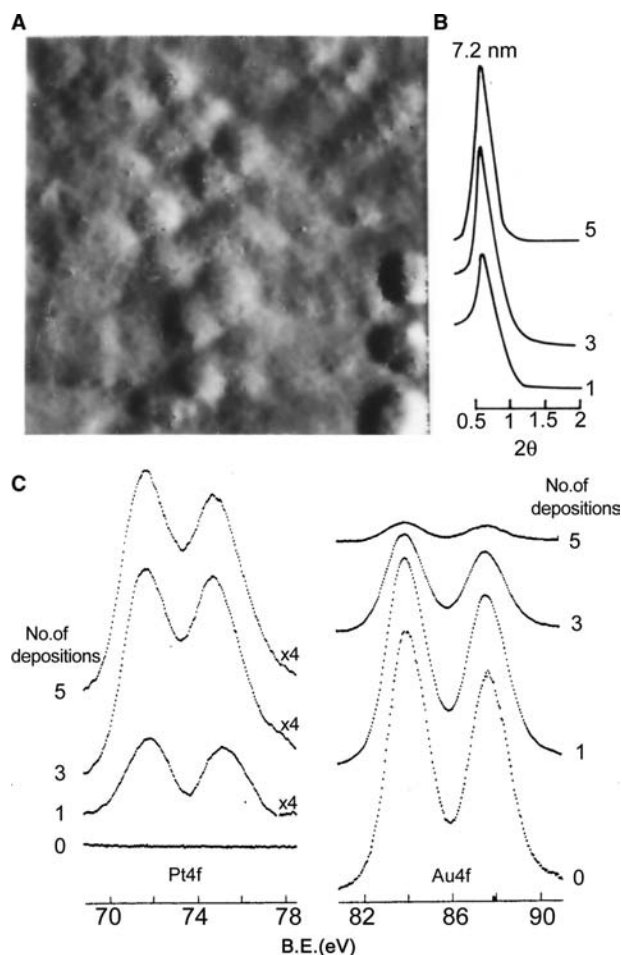

molecules plays a major role in attributing hardness to the ligated nanocrystal, which in turn decides the nature of the two-dimensional organization. A similar treatment should hold good for other metal and semi-conductor nanocrystals.

### Three-Dimensional Superlattices

Multilayer assemblies using monothiols such as those of CdSe (see Fig. 15) are generally fragile, and are not suited for use in functional devices. One of the means of obtaining robust structures involves multilayer deposition of nanocrystals and has been drawing a great deal of attention over the last few years, since they provide a convenient, low-cost means to prepare ultra-thin films of controlled thicknesses, suited for device applications. In a typical experiment, one end of a monolayer forming bifunctional spacer is tethered to flat substrates such as gold, aluminum, indium tin oxide or glass, leaving the other end free to anchor nanocrystals.<sup>[28,29]</sup> Subsequent layers can be introduced by dipping the substrate sequentially into the respective spacer molecule solution and the nanocrystal dispersion, with intermediate steps involving washing and drying. The formation of the multilayer assembly can be monitored using a variety of spectroscopy and microscopy tools as illustrated in Fig. 19. Thus, employing Au substrates and dithiols as spacers, multilayer assemblies of several nanocrystals such as Au or CdS have been accomplished.<sup>[143]</sup> One such example of layer-by-layer deposition of Pt (5 nm) nanocrystals is shown in Fig. 19. Brust et al.<sup>[144]</sup> have reported the formation of multilayers of Au nanoparticles using dithiols. These workers have confirmed the layer-by-layer deposition of particle arrays by employing UV-Vis spectroscopy and ellipsometry. Multilayers with CdS nanocrystals prepared by the reverse micelle technique and spaced with alkane were made, and measurable photocurrents were generated by these assemblies. Three-dimensional superlattices involving nanocrystals of different metals (e.g. Pt, Au) and of metals and semi-conductors (e.g. Au, CdS) have also been prepared and characterized.<sup>[143]</sup> Such assemblies can be made with polyelectrolytes such as poly(diallyldimethylammonium chloride) (PDDA), polyethyleneimine (PEI),<sup>[145,146]</sup> poly(allylamine hydrochloride) (PAH), polymers such as poly-phenylenevinylene (PPV) as well.<sup>[147,148]</sup> Thus, multilayers such as those of CdTe nanocrystals spaced with PDDA, CdSe spaced with PPV have been prepared.

### Superclusters

It has been proposed that self-similarity in metal nanocrystal organization would manifest in the form of a giant cluster whose shape and size are direct consequences of

**Fig. 19** Multilayer deposition of Pt (5 nm) nanocrystals on a polycrystalline Au substrate. After each deposition, the structure was characterized by STM, X-ray diffraction as well as by XPS. (A) STM image obtained after the second deposition showing the presence of regular arrays of nanoparticles with an interparticle spacing of 2 nm, extending over 300 nm, corresponding to the size of a typical flat terrace on the substrate, (B) X-ray diffraction pattern of the arrays after the first, third, and fifth depositions exhibiting low-angle reflections with the  $d$ -spacings reflecting the particle diameter and the inter-particle distance. (C) X-ray photoelectron spectra in the Pt(4f) and Au(4f) regions for the 5 nm Pt/Au system. The intensity of the Pt(4f) feature increases with the number of depositions, accompanied by a decrease in the Au(4f) intensity as the substrate gets increasingly shadowed due to the limited escape depth of the photoelectrons.

the nanocrystals themselves.<sup>[149]</sup> The invariance of the shell effects in metal nanocrystals with scaling is shown schematically in Fig. 20. Thus, Pd<sub>561</sub> nanocrystals would be expected to self-aggregate into a giant cluster of the type (Pd<sub>561</sub>)<sub>561</sub> under suitable conditions. The monodisperse nature of the nanocrystals is thought to be important in assisting the self-aggregation process. Formation of such clusters was observed in the mass spectra of magic nuclearity Au<sub>55</sub> nanocrystals. Secondary ion mass

**Fig. 20** Self-similarity: Schematic illustration of the formation of a cluster of metal nanocrystals (supercluster) and a cluster of superclusters. The size effects operating in nanocrystals could be invariant to scaling. *Source:* Reproduced with permission from Ref.<sup>[149]</sup>.

spectrometry indicated the presence of species with large  $m/z$  values and these were attributed to  $(\text{Au}_{13})_{55}$  giant clusters.<sup>[150]</sup> The giant clusters so obtained have, however, not been isolated or imaged. One such observation was made in the case of  $\text{Pd}_{561}$  nanocrystals where the PVP covered nanocrystals aggregated to form giant clusters.<sup>[151]</sup> The TEM image in Fig. 21 is revealing. There are regions where the nanocrystals are densely packed in the form of giant aggregates with estimated nanocrystal nuclearities corresponding to various magic numbers. It is possible that the formation of the giant clusters is facilitated by the polymer shell that encases them. Unlike in case of Pd nanocrystals coated with alkanethiols, which self-assemble to form ordered arrays, the polymer shell effectively magnifies the facets of the metallic core, thereby aiding a giant assembly of the nanocrystals.

### Colloidal Crystals

The tendency of monodisperse nanocrystals to arrange into ordered three-dimensional arrays extending to a few microns has been noticed.<sup>[136]</sup> Careful tuning of crystallization conditions have yielded crystallites of micrometer dimensions consisting of  $\text{Au}_{55}$  nanocrystals and Fe–Pt alloy nanocrystals (4.5 nm) as shown in Fig. 22.<sup>[152,153]</sup> Micron-sized crystals consisting of TOPO capped CdSe nanocrystals have previously been obtained by the groups of Bawendi and Weller.<sup>[127,154]</sup> However, it was observed that the nanocrystal arrangement in all the above crystallites was polymorphous. It is believed that such crystallites, consisting of ordered

**Fig. 21** TEM micrograph showing the giant clusters comprising  $\text{Pd}_{561}$  nanocrystals. Sample for TEM was prepared by the slow evaporation of a PVP– $\text{Pd}_{561}$  hydrosol. Giant clusters are enclosed in circles whose diameters correspond to magic numbers. The  $n$  and the values in the bracket indicate the number of nanocrystals and closed-shells, respectively.

nanocrystals, could prove to be the best candidates to study the collective properties of an ensemble of nanocrystals.

### Nanocrystal Patterning

Creating patterns of nanocrystals on surfaces has attracted wide attention. Such patterned substrates can act as templates to grow nanowires, etch masks to grow nanopillars and quantum dots.<sup>[155–157]</sup> Other than the layer-by-layer technique mentioned before, simple techniques such as spin coating have been employed to create a nanocrystalline pattern on surfaces.<sup>[158]</sup> In the example shown in Fig. 23, a direct write lithographic technique, dip pen lithography,<sup>[159,160]</sup> which relies on a cantilever used for atomic force microscopy (AFM) to write on a substrate to create patterns of Au nanocrystals on mica substrates. Thus, nanocrystals of metals and semiconductors can be patterned into rectangles of varying aspect ratios.

**Fig. 22** Colloidal crystals: (A) from Fe-Pt nanocrystals, (B) Au<sub>55</sub> nanocrystals. A schematic illustration of a Au<sub>55</sub> microcrystal along with the corresponding small angle X-ray diffraction pattern is shown alongside. *Source:* Reproduced with permission from Refs.<sup>[150,151]</sup>

## CONCLUSIONS

Nanocrystals of metal and semiconductors with diameters in the range 1–50 nm form a class of materials with unusual properties that are size-dependent. Excellent electrical conductivity that primarily characterizes a metallic state becomes a rare entity in small nanocrystals (<2 nm) owing to quantum confinement of the electronic states. Similarly, magnetic metals lose much of the coercivity with diminishing size. On the other hand, chemical properties such as reactivity may show up better at smaller sizes owing to more number of surface bonding sites and other electronic effects. Considering the importance of nanocrystals in technological applications, a large number of synthesis methods have evolved in the recent years, which

include reverse micelle and sonochemical methods besides laser ablation. Control over size and shape as well as encasing the nanocrystals with ligands of specialized functionalities have become subjects of urgent inquiry. Semiconductor nanocrystals are being established as practical alternatives to fluorescent dyes. Several exploratory devices whose characteristics are changeable by varying the constituent nanocrystal diameter have been made. While isolated nanocrystals are interesting by themselves, their organizations, of especially those which are capable of self-assembling into well-ordered arrays, have attracted greater attention. Nanocrystals anchored to fragments of DNA or likewise molecules essentially form one-dimensional organizations. When coated with long-chain alkane thiols, nanocrystals exhibit a tendency to assemble into

**Fig. 23** Contact AFM scan of a  $9\mu\text{m}^2$  area on mica substrate showing rectangles of various aspect ratios filled with Au nanocrystals. The patterns were obtained by translating an AFM cantilever dipped in a sol across the surface. The inset shows a TEM image of a similar pattern on a holey carbon copper grid, the dotted line bounds the area sought to be filled. The scale bar in the inset corresponds to 50 nm.

hexagonal arrays on flat substrates. The stability of such a two-dimensional organization depends on the diameter of the nanocrystals and the length of the ligand. Multilayers of nanocrystal arrays can also be made in a programmed way by selecting suitable spacer molecules. Patterns of nanocrystals can be tailored on suitable substrates by “dip-pen lithography”, an atomic force microscopy based technique. Another mesoscale aggregation known is the giant clusters of nanocrystals with definite nuclearities. It would be ideal to grow crystals of nanocrystals, but such efforts have met with only a limited success to date, giving micron-sized crystals. Nanocrystal organizations may exhibit properties very different from those of the individual. They are amenable to unprecedented control over the lattice, the size of the nanocrystal and interparticle separation being continuously variable over a range.

## INTRODUCTION

Carbon is everywhere around us. Its stable crystalline phase is graphite, but under some circumstances, it can be converted into its most interesting phase for applications—diamonds. Naturally, a diamond is produced inside the Earth's mantle by a high-pressure–high-temperature phase transformation of graphite. It is metastable and that is the reason why it can be recovered in mines after having migrated toward the most external shells of the Earth.

Its unsurpassed hardness, excellent transport properties, transparency, and inertness make a diamond a material of choice for many industrial applications. Synthetic diamond, produced by a high-pressure–high-temperature treatment of graphite, or by ion bombardment, is now commonly used in industries. But what happens to the carbon phase diagram when the sample size reaches the order of several nanometers?

## OVERVIEW

After the discovery of diamond inclusions (several nanometers in size) in some meteorites that had fallen on Earth, some groups have theoretically studied the relative stability of graphite and diamond as a function of particle size.

The first attempt to understand the stability of diamonds at the nanoscale was published by Badziag et al.<sup>[1]</sup> They computed the binding energy of diamond-like and graphite-like carbon clusters using fixed energy values for carbon–carbon and carbon–hydrogen bonds. They found that below a size of 3–6 nm and a number of 100–21000 carbon atoms, diamond clusters become more stable than their graphitic counterparts. After that precursor study, several groups tried to model the relative diamond-to-graphite stability with more sophisticated models. A charged cluster model was presented by Hwang, Hahn, and Yoon.<sup>[2]</sup> and Jang and Hwang.<sup>[3]</sup> At that time, the crossover between diamond and graphite was predicted to occur for clusters containing 400 atoms. In comparison with

Ref.<sup>[1]</sup>, the model used there was purely electrostatic. Other charge lattice calculations by Gamarnik<sup>[4]</sup> predict the reversal of stability to occur between 4.3 and 10.2 nm, depending on the temperature. It is worth noting that although these models have totally different ingredients and neglect the detailed structure of the clusters, such as specific surface structure or different degrees of hydrogen surface passivation, they reach the same conclusion that a diamond becomes more stable than graphite below 3–10 nm. Indeed, diamonds of several nanometers in diameter have been found or produced in a large variety of environments, as we will discuss in “Nanodiamond Sources.” Then, we will present an overview of the properties of nanodiamonds, both as isolated particles and as assemblies in films, and we will show how promising these carbon nanoparticles are for tomorrow's applications.

## NANODIAMOND SOURCES

### Nanodiamonds in the Sky

Nanoscale diamonds were discovered in 1987 by Lewis et al.<sup>[5]</sup> in meteorites. Not all meteorites contain diamonds. At this time, nanodiamonds have been found in specific types of meteorites, the so-called “carbonaceous chondrites.” Two major sources of nanodiamonds are the “Allende” chondrite (C3V type), which weighed several tons when it fell on Mexico in 1969, and also other types of chondrites, such as the Murchison meteorite (type C2).

The nanodiamonds found in these meteorites have a lognormal size distribution, with a median diameter of 26 Å, corresponding to roughly 1060 atoms. The shape of the distribution has been interpreted to be caused by growth followed by partial conversion of small grains to larger ones. The particles were shown to contain impurities, mainly hydrogen, nitrogen, and oxygen, principally in –COOH groups.<sup>[6]</sup> It is worth noting that in some cases, such as C2-type chondrites, a diamond (in its nanoscale form) is up to five times

more abundant than graphite. Further analysis of meteoritic nanodiamonds by Amarti, Lewis, and Andres.<sup>[7]</sup> revealed the nanodiamond content of the C2 meteorite to be ~400 ppm and attributed the shape of the size distribution to a condensation process.

The major question arising from those discoveries is: How and when were those diamonds produced? Daulton et al.<sup>[8]</sup> performed a detailed high-resolution transmission electron microscopy (HRTEM) study of a large quantity of nanodiamonds coming from meteorites, as well as those produced by means of detonation or chemical vapor deposition (CVD). Their work concludes that meteoritic diamond features (morphology, type of eventual twinning) are much closer to the low-hydrogen-pressure CVD process than to the high-temperature–high-pressure detonation.

These findings are of much interest to the astrophysicists community because chondrites are primitive meteorites that formed *before* the solar system. Their structure and content provide information on nuclear and chemical processes in stars and in the interstellar medium. There still remained some doubts about the fact that the nanodiamonds found in the meteorites are actually presolar.<sup>[9]</sup> Dai et al.<sup>[10]</sup> have studied other nanodiamonds, with structural features similar to the meteoritic samples, which have been found in interplanetary dust particles originating from comets or asteroids. They found that there are very few nanodiamonds in those particles—infinately fewer than in chondrites. Because comets are objects that formed earlier in the solar system than meteorites, this seems to indicate that the nanodiamonds found in the meteorites are not presolar at all.

This hypothesis is corroborated by the discovery of unexpected lines in the infrared spectra of 12 warm supergiants,<sup>[11,12]</sup> which are also carbon-rich protoplanetary nebulae. A broad absorption line centered at 21  $\mu\text{m}$  wavelength was attributed to large polycyclic aromatic hydrocarbon (PAH) molecules or some partially hydrogenated fullerenes,<sup>[13]</sup> before being attributed to nanodiamonds by Hill, Jones, and d'Hendecourt.<sup>[14]</sup> In that study, the observed infrared absorption from the interstellar dust is shown to be comparable to either nitrogen-rich nanodiamonds, or to nanodiamonds containing vacancies and/or interstitial atoms. They also noticed that some absorption features could be explained by the relaxation of part of the nanodiamonds surface toward  $\text{sp}^2$  carbon configuration. By fitting the absorption spectra with those of terrestrial diamonds, they estimate the size of these interstellar nanodiamonds to be around 2.6 and 3 nm, exactly as for meteoritic diamonds.

Other hydrogenated nanodiamond signatures have been indirectly evidenced by Van Kerkhoven, Thielens, and Waelkens.<sup>[15]</sup> around some other types of stars. In those objects, the nanodiamonds are thought to be

hydrogen-terminated, with some surface reconstructions, and could have a size ranging between 1 and 10 nm. The main conclusion of that study is that the nanodiamonds are produced in situ in the disks of stellar objects. Thus they should be present everywhere. The authors suggest that nanodiamonds are indeed present everywhere in space, but remain undetected because of the dehydrogenation of their surface for reconstruction, with the surface carbon getting  $\text{sp}^2$ -bonded.

## Nanodiamonds in Detonation Soots

As one can see, nature seems to favor the appearance of diamond nanoparticles. But it is not only in the cosmos that nanodiamonds can be found.

Indeed, pure trinitrotoluene (TNT) detonation has been shown to produce, among other carbon structures, nanocrystalline (NC) diamonds with diameters of about 10 nm.<sup>[16]</sup> By mixing TNT with some other solids such as RDX (cyclotrimethylene trinitramine— $\text{C}_3\text{H}_6\text{N}_6\text{O}_6$ ), TATB, or NIGU, and by detonating the mixture in an inert gas atmosphere, most spheroidal diamond particles produced were 4 nm in diameter.<sup>[17]</sup> Because of those first studies, the synthesis of nanodiamonds by detonation has been optimized and detonation-produced diamonds are now even commercially available. These nanodiamonds are often called “ultra dispersed diamond” (UDD) because of their very narrow size distribution. A thermodynamic model has been proposed by Vicelli et al.<sup>[18]</sup> in which the nanodiamond formation is produced from nanometric liquid droplets. Aleksenski et al.<sup>[19]</sup> performed a structural study of UDD using X-ray diffraction and small angle X-ray scattering. They evidenced a diamond cluster core of about 43 Å, the surface of which is covered by a mixture of  $\text{sp}^2$ -bonded and  $\text{sp}^3$ -bonded carbons. The authors could explain their small-angle X-ray scattering (SAXS) measurement with a model in which the diamond core is surrounded by onionlike carbon shells and nanosized graphite platelets. The thickness of these surrounding shells seems to be much dependent on the type of detonation synthesis (dry technology–gas cooling, or wet technology–water cooling). Baidakova, Siklitsky, and Vul'.<sup>[20]</sup> further analyzed the fractal dimension of the external shells of nanodiamonds. On annealing, they show that the diamond content of the particles decreases from 1200 K in favor of the formation of graphite flakes on the surface of particles and in favor of onion shells at temperatures 1300 K and higher. Similar transformations occur under electron beam annealing as well. Fig. 1 shows the evolution of the electron energy loss spectroscopy (EELS) of a UDD nanoparticle as a function of exposure time. The spectra rapidly evolve from diamond-like to amorphous-like because of heating produced by the electron beam.

**Fig. 1** Electron energy loss spectroscopy of a single nanodiamond particle. (Courtesy of T. Van Buuren and J. Plitzko.) Left: HRTEM picture of the UDD powder. The particle under study ( $\sim 3$  nm in diameter) is designated by the circle. The reader can notice the enhanced atomic planes. Right: EELS spectra as a function of exposure time.

Other detonation-produced (TNT + RDX) nanodiamonds were analyzed by Chen et al.<sup>[21]</sup> In their study, the particles were almost perfectly spherical and 4–6 nm in diameter, but some larger ( $\sim 15$  nm) spherical particles were also present. The composition analysis evidenced 87–90% carbon, 0.5–1% hydrogen, 1.6–2.5% nitrogen, and 6–10% oxygen. The authors explained the spherical shape of the particles as a consequence of the recrystallization of a liquidlike carbon droplet during the detonation. The structure was shown to be diamond, with a small proportion of  $sp^2$ -bonded carbon atoms.

The small UDD nanocrystals often aggregate in larger conglomerates, as shown in the study of Aleksenskii et al.,<sup>[22]</sup> with small distortion of the initial spherical particle shape (Fig. 2).

The structure and defects of UDD have been extensively studied. In Ref.<sup>[24]</sup>, infrared spectroscopy

**Fig. 2** Electron diffraction pattern (top left), power spectrum (bottom left), and HRTEM picture of the edge zone of a conglomerate of nanodiamonds (UDD). *Source:* From Ref.<sup>[23]</sup>.

evidences O–H, C–H, C=C, C=O, and C–O–C groups. Other surface groups are evidenced by nuclear magnetic resonance (NMR). The electron spin resonance measurement indicates that nitrogen is not present as a substitutional (paramagnetic) site inside the particle's core. However, another group<sup>[25]</sup> has measured a high concentration of paramagnetic centers. These are attributed to dangling C–C bonds located at the interface between the diamond core and the graphene sheets forming the surface. A similar paramagnetism has been observed in Ref.<sup>[26]</sup>.

**Fig. 5** Distribution of different twinning types in nanodiamonds from various origins. The meteoritic diamond originated from the Murchison meteorite (I) and the Allende meteorite (II). One can note the similarity in the twinings in meteoritic and CVD nanodiamonds. *Source:* From Ref.<sup>[8]</sup>.

### Nanodiamond CVD Production

In the process of optimizing the CVD technique for the generation of high-quality diamond films, it was shown that, under some conditions, the deposited film was no more a microcrystals assembly, but a smooth film of much smaller diamond particles (Fig. 3).

A typical CVD experiment would involve the injection of a mixture of methane and hydrogen gas in a plasma reactor. The diamond film, with variable morphologies, is deposited on a silicon substrate.<sup>[28]</sup> Under certain conditions of relative CH<sub>4</sub>/H<sub>2</sub> concentrations and substrate temperature, it has been observed that the diamond film consisted of much smaller particles. The CVD-deposited diamonds films are distinguished into three categories: microcrystalline diamonds (0.5–10 μm), nanocrystalline diamonds (50–100 nm), and ultrananocrystalline (UNC) diamonds (2–5 nm). Garcia et al.<sup>[29]</sup> reported diamond particles of 50 nm diameter by applying a negative d.c. bias voltage during the first minutes of the deposition from a mixture of 4% CH<sub>4</sub> in H<sub>2</sub>. The nanometric diamonds appear to be the first stage of diamond growth as long deposition times show them coalesce to form a microcrystalline diamond film. Gruen et al. managed to optimize the gas concentration to generate UNC diamonds.<sup>a</sup> Replacing the major part of hydrogen by argon (typical 1% hydrogen) in the plasma causes the deposition of a smooth film of nanoparticles of only a few nanometers in size (Fig. 4).<sup>[30]</sup> Those UNC films

contain only 2–5% of sp<sup>2</sup>-bonded carbons in grain boundaries and less than 1% hydrogen.

Different plasma CVD techniques are used to produce diamond films. Nanocrystalline diamond crystals with a typical size of 50–100 nm are produced by hollow cathode arc plasma CVD, or direct current glow discharge-assisted CVD, among many other experiments.<sup>[32]</sup> In that last study, a detailed analysis of the proportion of nanodiamonds to graphite shows that up to 75% of carbon is present in the film as sp<sup>3</sup>-bonded carbon in 3- to 5-nm diamond crystals. The remaining sp<sup>2</sup>-bonded atoms are mostly present in the form of a thin graphite layer (150–200 nm) present between the substrate and the UNC diamond, as well as in grain boundaries. This UNC film has been shown to be stable up to 950°C.<sup>[33]</sup>

### NANODIAMOND STRUCTURES

Nanodiamonds that are produced under those very different conditions of atmosphere, temperature, and pressure have similar size distributions. In particular, extraterrestrial nanodiamonds, detonation nanodiamonds, and ultrananocrystalline diamonds have sizes that typically range between 2 and 5 nm (Fig. 4).

The crystallinity of nanodiamonds has been tested by diffraction, but is also directly observable by electron microscopy (enhanced atomic planes in Figs. 1 and 2 transmission electron micrographs). A complete crystallographic study of nanodiamonds produced in the three ways we have described (meteoritic, detonation, and CVD-UNC nanodiamonds) has been performed by Daulton et al.<sup>[8]</sup> in an attempt to determine the origin and synthesis mechanism of meteoritic diamonds. In all those types of nanodiamonds,

<sup>a</sup>A complete review of ultrananocrystalline diamond properties and potential applications can be found in Ref.<sup>[27]</sup>.

**Fig. 6** Structure of a 0.7-nm 29-carbon atom cluster. Left: The fully hydrogenated cluster. Right: The result of surface reconstruction induced by the removal of six pairs of hydrogen atoms (circled on the left). Carbon atoms are in light grey; hydrogen atoms are in dark grey. The isosurfaces represent the lowest unoccupied molecular orbital (LUMO; here located on the C–H bonds) and the highest occupied molecular orbital (HOMO; here located at the center of the cluster) drawn at 30% of their maximal value.

twinning is often observed, preferentially for the largest particles. Twinning can take different forms, from simple twins, to multiple, to even fivefold star twins. However, the shape of the nanoparticles is globally spherical (Fig. 5).

The structure of the nanodiamond surface is little known.  $sp^2$ -bonded carbon may be present at the surface and in UNC diamond film grain boundaries.<sup>[34]</sup> Hydrogen is present in all three varieties of nanodiamonds, but other impurities have been evidenced in detonation-produced and extraterrestrial nanodiamonds.

Maillard-Schaller et al.<sup>[35]</sup> have measured the impurity content of detonation-produced nanodiamonds by Raman and X-ray photoelectron spectroscopy (XPS). The major impurity is oxygen. The nitrogen content of their samples is 1–2% and traces of N, Fe, S, and Ar are also found.  $H_2$  plasma treatment of the nanodiamonds deposited on a Si substrate by electrophoresis causes oxygen impurities to leave the sample, whereas the nitrogen content remains the same. The  $sp^3/sp^2$  content of the diamonds is unchanged by the high-temperature treatment.

**Fig. 7**  $C_{147}$  and  $C_{275}$  bucky diamonds. The diamond core atoms are represented in light grey. *Source:* From Ref.<sup>[23]</sup>.

## NANODIAMOND PROPERTIES

Very few theoretical studies of single nanodiamonds properties have been performed. Halicioglu<sup>[36]</sup> relaxed spherical nanometric diamond slabs with Brenner potentials. The so-formed structures exhibit inward relaxation from the top surface layers, the interatomic distance between neighboring atoms decreasing from the center of the cluster to the surface. They also noticed significant variations in relative cohesive energy with respect to bulk diamond. Recently, an ab initio molecular dynamics simulation, a parameter-free technique that solves quantum mechanical equations with great accuracy, was used to simulate the structure and to compute the electronic and optical properties of nanodiamonds.<sup>[23]</sup> Contrary to classical treatment, the quantum simulation of nanodiamonds yields an expansion of the cluster volume with respect to bulk diamonds. That tensile stress is at the opposite of what is observed in Si or Ge nanoparticles. The surface reconstruction of nanodiamonds has been shown to strongly affect electronic structure, as shown in Fig. 6.

When the totality of hydrogen is removed from the cluster, the surface is shown to sometime reconstruct in a specific way, forming the so-called “bucky diamonds.” These structures consist of a diamond core the surface of which is reconstructed in a fullerene-like manner (Fig. 7).

The optical properties of nanodiamonds have been studied mostly by X-ray techniques. The X-ray emission and absorption spectra of detonation nanodiamonds are very similar to those of bulk diamonds and are totally different from graphite (Fig. 8).

The differences between bulk diamonds and nanodiamonds are exciton broadening (289.3 eV) and a

**Fig. 8** X-ray emission (left) and absorption (right) spectra from highly oriented pyrolytic graphite (HOPG), bulk diamonds, and detonation-produced nanodiamonds (4 nm average size). *Source:* From Ref.<sup>[23]</sup>.

**Fig. 9** Detail of the pre-edge X-ray absorption spectra of HOPG, bulk diamonds, and detonation nanodiamonds vs. the X-ray energy in electron volts. The density of unoccupied states computed ab initio from a  $C_{147}$  bucky diamond is shown for comparison (dashed line). *Source:* From Ref.<sup>[23]</sup>.

shallower secondary minimum (302 eV). However, there are some pre-edge features in the nanodiamond absorption spectrum that are not caused by impurities and are reproducible (Fig. 9). These features could be the signature of specific surface reconstructions such as in bucky diamonds.

Other information can be obtained from Fig. 8: There is no shift in valence and conduction band maximum and minimum in comparison with bulk diamonds. This indicates that quantum confinement does not affect the electronic structure for particles 4 nm and larger. This property can also be observed on computed absorption spectra from Fig. 10.

**Fig. 10** Optical spectra of carbon clusters ranging from methane to 1-nm nanodiamonds. The spectra are computed using the time-dependent local density approximation on ab initio-relaxed cluster geometries. The dashed line shows the bulk absorption threshold computed with the same method (4.23 eV for an experimental value of 5.5 eV). *Source:* From Refs.<sup>[38,39]</sup>.

The optical properties of UDD layers have been studied optically and by XPS by Aleksenskii et al.<sup>[37]</sup> The band gap is measured to be 3.5 eV, with many energy levels present in the nanodiamonds band gap and contributing to a broad luminescence band (380–520 nm). The optical absorption of the material is attributed to threefold coordinated atoms on the surface. The unannealed sample contains 8% N and 22% O, mainly under the form of nitrate ions attached to the particle's surface.

The electron transport in ultradisperse diamonds deposited on quartz substrates has been measured by He et al.<sup>[40]</sup> The conductivity of the films is shown to decrease with annealing. Surprisingly, it is semiconducting at high temperature but the temperature dependence of the conductivity is negative at lower temperatures. This behavior is attributed to conduction through surface conduction ( $\pi$ -type because of graphite-like sheets) at low temperature and through diamond core  $\sigma$ -type conduction at higher temperature.

An interesting property of a hydrogenated diamond surface is its “negative electron affinity,” the ability of an electron that is excited in the conduction band to freely leave the material. Nanodiamonds have smaller bandgaps than bulk diamond, and for that reason are excellent candidates for low-threshold electron emission devices. The additional requirement is that the electron affinity is small, or even negative. The electron emission of the UDD film from Ref.<sup>[40]</sup> is strong and has a low field threshold (3.2 V/ $\mu\text{m}$ ). It has been attributed to grain boundaries of nanodiamond films, rather than substrates. A similar field emission study was performed on ultrananocrystalline diamond films by Krauss et al.<sup>[41]</sup> The emission is again attributed to conduction through the grain boundaries–vacuum

interface. With moderate heating (200–300°C), the photoemission yield is increased by a factor of 5.<sup>[42]</sup> When the hydrogenated UNC film is exposed to air, electron affinity is actually shown to become negative. A similar negative electron affinity has been measured after treating a film of deposited nanodiamonds obtained from detonation, but only after treating the film with H<sub>2</sub> plasma, which removes most of the impurities, except nitrogen.<sup>[35]</sup>

## NANODIAMOND NITROGEN N-DOPING

A very promising way to have nanodiamond films incorporated in technological applications is by doping them with nitrogen. The goal is to introduce carrier levels into the diamond gap (this level is located 1.7 eV below the conduction band minimum in bulk diamonds) to increase conductivity and to lower the electron emission voltage threshold. Nitrogen is a major impurity of natural diamond. As we said before, nanodiamonds produced by detonation contain a high percentage (1–2%) of nitrogen. This nitrogen is brought into the diamonds from the trinitrotoluene reactant and cannot be removed from the nanoparti-

cles.<sup>[35]</sup> The precise location of the nitrogen atoms in the nanoparticles is uncertain, but several magnetic studies have been unable to see any trace of substitutional nitrogen (known as P1 center).<sup>[24]</sup> This is surprising as nitrogen is present in N-doped CVD-produced microcrystals as a substitute to core carbon atoms.<sup>[43]</sup> A theoretical study of the grain boundaries of UNC diamonds in the presence of nitrogen impurities has been performed by Zapol et al.<sup>[44]</sup> This tight-binding density functional study shows that nitrogen substitution to carbon in the grain boundary is energetically more favorable than in the crystal's core. The conductivity increase of the N-doped film is then attributed to an increase in threefold coordinated carbon atoms caused by the nitrogen impurity. A recent ab initio molecular dynamics study<sup>[39]</sup> shows that for small diamond clusters, nitrogen is preferentially present as a substitute to surface carbon. The tensile stress evidenced in those nanoparticles<sup>[23]</sup> facilitates nitrogen inclusion in comparison to bulk diamonds, where intentional nitrogen doping has proven to be difficult. Nitrogen incorporation is shown to require more and more energy with increasing particle size (Fig. 11).

Nitrogen doping of UNC films has been studied by Bhattacharyya et al.<sup>[45]</sup> Doping is achieved by introdu-

**Fig. 11** Formation energy of 66 carbon atom clusters containing one nitrogen impurity atom as a function of the hydrogen chemical potential  $\mu_{\text{H}}$  (eV). This energy is the difference between the cluster's total energy and the energy the same number of carbon and hydrogen atoms ( $N_{\text{C}}$  and  $N_{\text{H}}$ ) would have in their most stable form (here we consider diamond and the H<sub>2</sub> molecule). The origin of  $\mu_{\text{H}}$  (eV) is taken as the energy of one hydrogen atom in the H<sub>2</sub> molecule. The thick black segments indicate the most stable structures. The stable configurations are the C<sub>65</sub>H<sub>65</sub>N and C<sub>65</sub>H<sub>39</sub>N clusters. In these, the nitrogen atom is substitutional in the particle's surface. Above  $\sim -0.02$  eV, the stable structure is a fully hydrogenated cluster in which the nitrogen atom (in blue) sits on the surface. Below this energy (this would correspond to a higher temperature and/or a lower hydrogen pressure), the stable structure has a partially reconstructed surface in which the nitrogen resides. The C<sub>65</sub>H<sub>66</sub>N and C<sub>65</sub>H<sub>40</sub>N clusters in which the nitrogen atom is substitutional to a core carbon atom are never stable (thin lines). The isosurfaces are drawn at 30% of the maximal value of the HOMO (on the nitrogen atom) and LUMO (on C–H bonds), respectively.

**Fig. 12** Computed HOMO–LUMO energy gaps for various nanodiamonds structures. Red circles: Hydrogenated nanoclusters; black squares: nanodiamonds with a  $\text{NH}_2$  surface group; green triangle: one surface substitutional nitrogen; pink diamond: four surface substitutional nitrogen atoms. The filled symbols represent the nonreconstructed, maximally hydrogenated nanodiamonds; the empty symbols represent (100) reconstructed surfaces.

cing nitrogen gas (1–20%) into the mixture fed to the CVD reactor. They achieved the highest carrier concentration and electrical conductivity ever measured for a phase-pure diamond thin film. The increase of  $\text{N}_2$  gas concentration causes larger grain boundaries and larger grains to be deposited, and increases the conductivity up to  $143 \Omega^{-1} \text{cm}^{-1}$ . This large conductivity is attributed to the large proportion of nitrogen atoms in the grain boundaries. The optical and emission properties of N-doped UNC diamond films are still under investigation. A theoretical study<sup>[39]</sup> has compared the energy gap of hydrogen-terminated nanodiamonds clusters and clusters including various nitrogen impurities on the surface as a function of size. The variation is faster for reconstructed surfaces because of the size evolution of the surface curvature. For nonreconstructed surfaces, the curvature changes little with cluster size and the energy gap remains almost constant and smaller than for H-terminated clusters (Fig. 12).

## NANODIAMONDS FOR THE FUTURE

Nanodiamonds are very promising materials for application, especially under the form of ultrananocrystalline diamond thin films. An extensive review of UNC film properties and potential applications can be found in

Ref.<sup>[27]</sup>. We have cited the perspectives offered in field-induced and light-induced emission by nitrogen-doped UNC films. They could be used to produce bright, low-voltage (cold) cathodes. They may be used in the future as microelectromechanical system (MEMS) materials. Pioneer devices have been successfully produced by Krauss et al.<sup>[46]</sup> The exceptional hardness, fracture strength, and inertness of the films, together with a smooth surface, make UNC a unique material for miniaturized mechanical systems and devices, such as cantilevers, gears, etc. The hydrogen termination of the surface also brings a “natural lubricant” to the moving devices.

UNC diamonds also have potential applications in optoelectronics, as photonic switches, electronic devices (pn junctions), etc. They are on their way to being commercially used as surface acoustic wave devices. Recent experiments have even used UNC films as support to attach ADN.<sup>[47]</sup> These devices have proven to be extremely stable and have opened the way to the integration of biology in electronics.

## CONCLUSION

Nanodiamonds have unique, fascinating properties, as isolated particles or in thin films, but many aspects still have to be understood. The interaction between nanodiamonds is largely unknown. The most intriguing fact is that all types of nanodiamonds have similar features and size distributions (independently of the production type), extreme pressure and temperature, and low-pressure CVD, and are around stars. Indeed, everywhere where scientists have looked for carbon nanostructures with a high-resolution microscope, they found nanodiamonds. Would they not be everywhere around us?

# Nanoencapsulation of Bioactive Substances

Yury E. Shapiro

Department of Life Sciences, Bar-Ilan University, Ramat-Gan, Israel

## INTRODUCTION

Nanoencapsulation is one of the most important subcategories of controlled-release bionanotechnology. Normally, active substances are encapsulated in submicrometer-sized devices made of barrier materials. These materials are designed to control the rate of release. This concept has been largely inspired by spontaneous assembling of the phospholipid liposomes as a model of biological membranes.<sup>[1]</sup> As in Nature, one has to develop preparations of nanovehicles that allow precise control over their structure and morphology. In this context, the self-assembled superstructures of surfactants (micelles, liposomes)<sup>[2]</sup> and/or polymers (nanoparticles) have proven to be valuable tools.<sup>[3]</sup>

Nanoparticles may be defined as being submicrometer (from 10 to 1000 nm) colloidal systems generally, but not necessarily, made of polymers (biodegradable or not).<sup>[4-6]</sup> Depending on the process used for their preparation, two different types of nanoparticles can be obtained, namely, nanospheres and nanocapsules. Unlike nanospheres (matrix systems where the bioactive substance is dispersed throughout the particles), nanocapsules exhibit a membrane-wall structure with an aqueous or oily core containing the bioactive substance. Thus, nanocapsules may be considered as a “reservoir” or “envelop” system. Because nanoparticles have very high surface areas, the active substance may also be adsorbed or conjugated onto the surface.<sup>[6]</sup> At present, micellar/liposomal systems have also been included under the term “nanoparticles.”

Another type of nanometer-sized carriers is an inclusion complex or clathrate, which can be assembled by inclusion of bioactive substances into molecular cavities of the so-called cavitands,<sup>[7]</sup> or dendrimers.<sup>[8,9]</sup> Natural examples of such internal-cavity-containing molecules are cyclodextrins, which are used widely for preparation of various drug formulations.<sup>[10]</sup> The outer diameter of molecular nanocapsules is in the range of 3–50 nm. The nanometer size ranges of liposomes, nanoparticles, and clathrates offer certain distinct advantages for drug delivery. Because of their subcellular size, they can penetrate deep into tissues through fine capillaries, cross the fenestration present in the epithelial lining (e.g., liver), and generally are taken up efficiently by the cells to perform the so-called

intracellular trafficking.<sup>[6,11,12]</sup> This allows direct delivery of therapeutic agents to target sites in the body followed by the controlled release.<sup>[13]</sup>

## CONTROLLED RELEASE

Controlled-release nanotechnology can solve a variety of problems regarding the effective delivery of a bioactive compound to a target to achieve good local and systemic tolerance during and after application.<sup>[14]</sup> In controlled-release systems, a drug or some other active agent is incorporated into a self-assembled carrier. The main condition of success is to design tissue-friendly and biodegradable accompanying materials.<sup>[4-6]</sup> The delivery carriers are usually required for the following reasons: 1) many effective drugs are characterized by poor aqueous solubility and need to be solubilized; 2) many drugs, such as proteins, are very fragile and need a microenvironment providing protection from hydrolysis or enzymatic degradation; 3) many drugs are highly toxic and require a carrier to shield tissues until the drug release at the targeted tissue occurs; 4) the release itself has to be designed to allow controlling; and 5) targeted delivery of drug can be attained by conjugating a specific vector to the carrier.<sup>[15]</sup>

The rate of releasing the agent depends on the nature of the carrier as well as various environmental factors (such as nature of solvent, osmotic pressure, temperature, pH of media, and so on). The controlled release, depending on rate of releasing, can be classified as triggered, pulsing, or sustained. The rate of delivery of any bioactive substance to a target tissue or reaction site is highly critical. Key advantages to the use of this technology are prolonged activity, fewer doses, fewer undesirable side effects, and reduced toxicity.<sup>[5]</sup>

Three mechanisms of controlled release can be considered: diffusion controlled (through membranes and from matrices), chemically controlled (erosion and cleavage of polymer chain or spacer connecting bioactive agent with carrier, if any), and solvent activated (osmotic pressure and swelling). Each mechanism has certain advantages and must be selected for design of carrier depending on the agent to be released as well as the conditions required to yield favorable release. Recently, significant effort has been devoted to develop

nanotechnology for controlled drug delivery devices because it offers a suitable means of delivering low molecular weight drugs, as well as macromolecules such as peptides, proteins, DNA, or genes by either localized or targeted delivery to the tissue of interest.<sup>[6,11,16,17]</sup>

## LIPOSOMES

Liposomes (or vesicles) are topologically closed nano-sized lamellar aggregates of highly ordered lipid molecules that are normally dispersed in a hydrophilic solvent, typically water. The aggregates may be formed by the combination of both polar and non-polar residues in the same lipid molecule, which is described as amphiphilic. In aqueous medium the amphiphilic molecules arrange the ordered micellar or lamellar structures depending on the concentration, in which the hydrophobic regions are brought into proximity with each other while the polar groups are exposed to water. The amphiphiles are capable of forming a variety of phases due to steric factors such as head group size, variation in the number of acyl chains, or to electrostatic effects arising from attractive or repulsive forces between adjacent polar head groups.<sup>[18]</sup> The different phases can interconvert, either by inward or outward migration of particular amphiphiles changing their shape. Heating, for example, increases the dynamic motion of hydrocarbon chains, effectively broadening the non-polar region. Changes in pH can affect an ionization of polar head groups and so alter their diameter, as can changes in their hydration level.<sup>[19]</sup> Thus, bilayer to nonbilayer transition can take place, resulting in loss of membrane barrier function. These transitions can be exploited to design liposomal carrier systems with preset release properties that are triggered by changes in their microenvironment.<sup>[19]</sup>

Normal micelles, which have only short-range order, form spontaneously when the amphiphiles are added to water. The liquid crystalline phases, which exhibit long-range order, like lamellar (cubic) and normal hexagonal phases, do not disperse spontaneously. When the lamellar phase is diluted with excess aqueous phase, it converts into spherical liposomes (Fig. 1),<sup>[2]</sup> which are widespread carriers for drugs, cosmetics, and many other types of actives.<sup>[19]</sup> Because of the presence of the aqueous core and the hydrophobic lipid bilayers, liposomes can accommodate both hydrophilic and hydrophobic actives. The liposomes can be constructed with widely different physical structures, lipid composition, and surface properties, thus enabling a great deal of control over entrapment and release of their contents.

Three kinds of liposomes are in common use. Large spherical liposomes, each consisting of numerous

**Fig. 1** Schematic structure of liposomes: (A) multilamellar vesicles, MLV, and (B) small and large unilamellar vesicles, SUV and LUV.

concentric bilayers, alternating with layers of water, are known as multilamellar vesicles (MLVs) (Fig. 1A).<sup>[2]</sup> The MLVs are simple to produce, but the volume available for solute entrapment is limited. By gentle swirling, individual lamellae are able to detach to form large unilamellar vesicles (LUVs) (Fig. 1B).<sup>[20]</sup> Because the interior of LUVs is not occupied by internal lamellae, there is ample space for incorporation of actives. This also means that cells taking up LUVs are less subject to lipid overload. However, LUVs are more fragile than MLVs. In general, MLVs and LUVs vary in their outer diameter, from 100 nm up to 10  $\mu$ m. Their large size range is considered to be a drawback for many medical applications requiring parenteral administration because it leads to rapid clearance from the bloodstream by the cells of the reticuloendothelial system (RES).

Small unilamellar liposomes (SUVs), with outer diameter in the range of 20–100 nm,<sup>[21]</sup> can be obtained by ultrasonication of MLVs.<sup>[18]</sup> Because of their small size, clearance from the systemic circulation is significantly reduced, but SUVs have a much lower capacity for drug entrapment, typically less than 1% of the material available.

## Preparation of Liposomes

### Multilamellar vesicles

Multilamellar vesicles (Fig. 2A) may be prepared from natural or synthetic lipids by suspending them in an aqueous solution maintained at a temperature above the melting point  $T_c$  of the lipid. For unsaturated phospholipids such as egg and soy phosphatidylcholine, which have  $T_c$  values below 0°C, this can be done by stirring in an inert atmosphere of nitrogen or argon to avoid lipid oxidation.<sup>[2]</sup> A small amount of the active solution is entrapped within the interlamellar spaces when lipid is hydrated, followed by the liposome formation. The loaded liposomes can be

**Fig. 2** Freeze-fracture transmission electron micrographs of liposomes: (A) MLV constituted from 0.1M mixture of tetradecyldimethylaminoxide/tetradecyltrimethyl ammonium bromide/hexanol = 9/1/20, and (B) SUV prepared from 3 wt.% didodecyldimethyl ammonium bromide in water. separated from non-encapsulated solute using centrifugation or dialysis.

The encapsulation efficiency can be increased by inclusion of a charged amphiphile, such as phosphatidylglycerol or phosphatidic acid, at a molar ratio of 10–20%, or by preliminary freeze-drying of the lipid from an organic solution followed by formation of an expanded foam with an increased surface area, which increases the amount of aqueous phase that can be incorporated.<sup>[22]</sup> The most advanced method, which was designed to achieve high levels of entrapment, particularly of sensitive biomacromolecules such as proteins and nucleic acids, is dehydration/rehydration method.<sup>[23]</sup> It allows a prolongation of exposure of solute to the lipid before its final lamellar structure has been fixed. This may be achieved by preparing MLVs in water followed by converting these to SUVs. Thus, when SUVs are mixed with a solution of the active to be entrapped, most of the amphiphile is directly exposed to the solute. At this stage, water is removed by freeze-drying to produce the vesicles in a metastable state enriched with active. Following the hydration stage, the liposomes are diluted with an isotonic buffer<sup>[23]</sup> to provide an osmotic gradient between the internal and external phases and avoid redistribution of active, and finally washed to remove the nonencapsulated material.

Lipids dissolved in organic solvents can be hydrated in solution without prior solvent removal. If the solvent is water miscible, such as ethanol or propylene glycol, it may be removed at the end of MLV preparation by dialysis or filtration. Water-immiscible solvents such as ether, chloroform, or methylene chloride may also be used, then later removed through evaporation. High-capacity multivesicular liposomes were created in w/o/w double emulsion, containing active in the inner entrapped aqueous phase.<sup>[24]</sup> Composition and conditions are chosen such that each droplet of the organic chloroform–ether disperse phase contains multiple droplets of the initial aqueous

solution of active. The organic solvents are removed under a nitrogen flow, wherein the lipid is deposited around the internal aqueous, drug-containing nanodroplets, which form separate compartments within a single liposome. The method allows encapsulation efficiencies of up to 90%, but requires specialized lipids and rather complex preparation conditions.

Different technology has been applied so far to produce a new solid lipid carrier system, the so-called solid lipid nanoparticles (SLNs).<sup>[25–28]</sup> It is rather effective for encapsulating drugs that are poorly soluble in both aqueous and organic media.<sup>[25]</sup> Solid lipid nanoparticles combine the advantages of both liposomes and polymer nanoparticles. In SLNs the liquid lipid in emulsion is replaced by a solid lipid, e.g., high-melting glycerides (trilaurin, tribehenin) or waxes (cetyl palmitate); the particles are stabilized against aggregation by natural emulsifiers (lecithin), synthetic surfactants (Miranol, Plantaren, Tween 80), or sterically stabilizing polymers (Pluronic F68).<sup>[26,27]</sup> To prepare SLN dispersions, melted lipid mixed with an active was added to a surfactant solution of distilled water at elevated temperature. After stirring, the crude pre-emulsion was homogenized under high pressure between 500 and 1500 bar, applying several homogenization cycles.<sup>[26,27]</sup> Mean particle size of prepared SLNs ranged from 100 to 300 nm.

Within SLNs, actives with a melting point below the melting point of the lipid matrix preferentially distribute to the surface of the particles.<sup>[27]</sup> Wide-angle X-ray scattering investigations suggested that good entrapment efficacy in SLNs can be achieved with lipids of low crystalline order and metastable polymorphs of the  $\beta'$  form.<sup>[28]</sup> This allows optimization of lipid composition in favor of formation of this metastable polymorph.

### Small unilamellar vesicles

Small unilamellar vesicles (Fig. 2B) can be formed easily by high-power probe or bath sonication of MLVs in an inert atmosphere by cooling to dissipate local overheating<sup>[18]</sup> and avoid disruption of lipid molecules. Alternatively, MLVs can be converted into SUVs by use of high-pressure homogenization, such as in the case of SLN, or extrusion. High-pressure extrusion involves forcing MLVs through porous membranes<sup>[29]</sup> at temperatures above  $T_c$ . As a result, lamellar fragments break away and close to form small vesicles of similar diameter to that of the pore. A particular advantage of the method is that the disruptive effects of sonication are avoided. Rapid injection of an ethanol solution of lipid into an aqueous solution also leads to production of vesicles 30 to 110 nm in diameter.<sup>[30]</sup> This method has two disadvantages as compared to sonication: high polydispersity and dilute

suspension of liposomes obtained. Acidic phospholipids such as phosphatidic acid and phosphatidylglycerol are able to form unilamellar liposomes simply by transiently increasing the pH.<sup>[18]</sup> However, this process is critical to ionic strength, presence of other lipid components, and rate of titration.

### Large unilamellar vesicles

Methods for preparing LUVs fall into two categories. The first involves removal of a lipid solubilizing agent, whereas the second applies physical modification of preformed bilayer. In the first case, the lipid is initially dissolved in an aqueous solution of the surfactant (either ionic—cholate, deoxycholate, or non-ionic—Triton 100, octylglucoside) to form mixed lipid–surfactant micelles followed by removal of the surfactant by dialysis, diafiltration, or gel chromatography.<sup>[31]</sup> With another method, a volatile solvent such as diethyl ether, petroleum ether, or dichlorofluoromethane containing dissolved lipid is infused slowly into the aqueous phase, which is maintained at a temperature above the boiling point of the solvent so that bubbles are formed.<sup>[32]</sup> The lipid molecules form a multilayer around the vapor–water interphase, and as the solvents evaporate, uni- and oligolamellar liposomes with the size range of 100–400 nm remain in dispersion. Encapsulation efficiencies up to 46% were reported.

In the more advanced reverse-phase evaporation method, the w/o emulsion containing excess lipid in the organic phase (diethyl ether) is subject to rotary evaporation. At this stage the emulsion inversion takes place. This involves collapse of inverted micelles so that their aqueous contents form the new continuous phase, while their lipid components convert into a vesicular form.<sup>[33]</sup> In the absence of cholesterol, these vesicles have an outer diameter in the range of 50–500 nm, whereas with 50 mol% cholesterol, mean diameter is about 500 nm. High encapsulation efficiencies up to 65% can be achieved using hydrophilic solutes.

Physical modification of existing bilayers involves the above-mentioned extrusion method, which is effective for obtaining both SUVs and LUVs, and exposure of SUVs to alternate cycles of freezing and thawing. These procedures lead to fusion of the SUVs followed by formation of LUVs.<sup>[29]</sup> An elegant method using fusion is based on electrostatic effect. SUVs composed of negatively charged phospholipids are mixed with calcium ions, which cause the vesicles to aggregate and then fuse.<sup>[34]</sup> This results in formation of “cochleate cylinders,” which are rolled-up portions of lipid bilayer. Chelation of Ca<sup>2+</sup> by adding EDTA results in conversion of the cochleates to LUVs.

### Applications of Liposomes

Liposomes have been widely investigated as delivery systems for treatment of cancer, as well as bacterial, fungal, viral, and parasitic diseases.<sup>[35]</sup> Liposome-based gene transfection systems have been promoted as means to achieve the transfection efficacy of viral constructs without any associated risks. Liposomes themselves can serve as immunological adjuvants. They are applied as vehicles to deliver various radioisotopes and contrast agents for use in diagnostic imaging. In general, several beneficial properties of the liposomal form of drugs and the ways of providing their targeted delivery are essential for polymer nanoparticles as well. However, because of the noncovalent interactions responsible for their formation liposomes have only limited stability and are subject to structural changes.<sup>[18]</sup>

Efficiency of both the liposomal forms and nanoparticles depends on the rate of releasing of an active substance and their clearance from the blood. Compounds with low molecular weight release rapidly. Depending on molecular weight and the ability to withstand enzymatic attack, drugs could then act either locally (e.g., hydrolysis of stored sucrose by liposomal fructofuranosidase) or, after diffusion through the lysosomal membrane, in other cell compartments (e.g., inhibition of DNA-directed RNA synthesis by liposomal actinomycin D).<sup>[35]</sup> It was shown that the rate of clearance of injected liposomes from the blood is rather rapid, dose dependent, and biphasic. Neutral MLVs and SUVs exhibit a slower rate of clearance than charged MLVs.<sup>[35]</sup> Understanding of liposomal fate and behavior led to several proposed applications. The most important fact is that liposomes with entrapped material were shown to end up in the fixed macrophages of the RES, mainly in the liver and spleen.<sup>[36]</sup> Fast blood clearance is the principal obstacle to use of liposomes for drug delivery via the parenteral route. Liposome clearance can be substantially reduced by inclusion of monosialoganglioside GM<sub>1</sub>, hydrogenated phosphatidylinositol, or PEG-substituted phosphatidylethanolamine into the bilayer.<sup>[37]</sup> The same effect may be achieved by PEG coating of liposomes—PEGylation.<sup>[38]</sup> This modification hampers detection by the RES, and led to their being called Stealth<sup>TM</sup> liposomes. The long-circulating PEGylated liposomes are considered suitable for targeted drug delivery to tumors and inflammatory foci, as well as for diagnostic imaging applications, e.g., magnetic resonance and scintigraphic imaging.

Two types of targeting are under way: passive and active. Passive targeting is limited in its scope, leads to the rather wide distribution of the drug-filled liposomes in tissues, and depends dramatically on time of circulation. Thus, tremendous efforts are being

directed at present toward the development of control together with modification of the liposome surface with molecules having recognition properties. Typical examples of such modification are antigenic determinants, including various types of membrane receptors, or antibodies (either intact or as active fragments), other proteins, lipoproteins, glycoproteins, and so on, which may associate with bilayers as they do in the living cells. One such way is ligand-coupling strategy, which was originally realized with tumor-specific antibodies, known as immunoliposomes.<sup>[39]</sup> Most of the subsequent studies have used chemical coupling to link a targeting moiety to an amphiphilic molecule inserted into the liposome bilayer. The most widely used approach involves the use of heterobifunctional cross-linking reagents for introducing thiol-ether-based linkages between the lipid anchor and the ligand (e.g., immunoglobulin).<sup>[40]</sup>

The way in which liposomes induce immune responses to antigens associated with them is still not clear, but has been attributed to a depot mechanism and the ability of liposomes and antigen content to migrate to regional lymph nodes. A novel concept, namely, production of the required vaccine antigen by the host cells *in vivo*, promises to alter vaccination, especially where vaccines are either ineffective or unavailable. The concept entails the direct injection of antigen-encoding plasmid DNA, which, after its uptake by cells, finds its path to the nucleus where it transfects the cells.<sup>[41]</sup> Antigen so produced is recognized by the host as foreign and then subjected to pathways leading to protective immunity. Simple mixing of antigen-encoding plasmid DNA or DNA itself and cationic SUV leads to neutralization of polyanionic nucleic acid chain to form a compact nanostructure, known as a lipoplex.<sup>[42]</sup> Each of these nanoparticles carries a small net positive charge, which enables them to interact with the negatively charged cell membranes and gain entry by receptor-mediated endocytosis to perform transfection.

## POLYMER NANOSPHERES

### Manufacture of Nanospheres

The first approaches used to produce polymer nanoparticles were derived from the field of latex engineering. These methods were based on *in situ* polymerization of monomers.<sup>[43,44]</sup> Despite the actual technological advances, polymerization-based methods have some drawbacks and limitations. Thus, alternative methods based on the dispersion of well-characterized preformed polymers or natural biopolymers<sup>[4,5]</sup> have been proposed.<sup>[45]</sup> Together with polymerization-based methods, these new techniques

**Fig. 3** Schematic structure of polymer nanoparticles: (A) nanospheres and (B) nanocapsules.

allow the production of both nanospheres and nanocapsules (Fig. 3).

### Polymerization Methods

Two different approaches have been considered for the preparation of nanospheres by polymerization methods, depending on whether a monomer to be polymerized is emulsified in a nonsolvent phase (emulsion polymerization) or dissolved in a solvent that is a nonsolvent for the resulting polymer (dispersion polymerization).<sup>[44]</sup>

In two types of emulsion polymerization, either conventional (o/w emulsion) or inverse (w/o emulsion), the monomer is emulsified in the nonsolvent phase with surfactant, leading to the formation of monomer-swollen micelles and stabilized monomer droplets. The polymerization reaction takes place in the presence of an initiator that creates free reactive monomer radicals. These collide with the unreactive monomers and initiate polymer chain growth, or nucleation.<sup>[44]</sup> The reaction stops when full consumption of monomer or initiator is achieved. The drug to be incorporated to the nanospheres may be present during the polymerization process. Two different mechanisms of nucleation were considered. First, the so-called micellar polymerization mechanism treats the monomer-swollen micelles as the site of nucleation and propagation.<sup>[46,47]</sup> In this case, monomer droplets serve as monomer reservoirs. The monomer molecules reach the micelles by diffusion through the continuous phase. The second mechanism is valid for monomers that are sufficiently soluble in the continuous phase. In this case, homogeneous nucleation followed by propagation can occur directly in this phase, leading to formation of oligomers.<sup>[47]</sup> When the oligomers have reached a certain length, they form primary particles stabilized by surfactant molecules present in the system. In the case of inverse emulsion polymerization, when we deal with w/o system, the water-soluble monomers cannot diffuse from the micelles through the organic phase because of their low partition coefficient.

**Fig. 4** (A) Electron scanning micrograph of insulin-loaded poly(ethylcyanoacrylate) nanospheres obtained by a polymerization technique. (B) Transmission electron micrograph of procaine hydrochloride loaded poly(lactide-co-glycolide) nanospheres obtained by precipitation method. *Source:* From Radwan, M.A.; Aboul-Enein, H.Y. J. Microencapsul. **2002**, *19* (2), 225–235. © 2002, Taylor & Francis, Ltd. From Govender, T.; Stolnik, S. et al. J. Control. Release **1999**, *57* (2), 171–185, © 1999, Elsevier.

The resulting nanospheres contain fewer polymer chains and a narrower size distribution as compared to the conventional emulsion polymerization.<sup>[48]</sup>

Both the conventional and inverse emulsion polymerization reactions were applied for the production of biodegradable poly(alkyl cyanoacrylate) (PACA) nanospheres.<sup>[49,50]</sup> In the case of conventional emulsion polymerization, the alkyl cyanoacrylate monomer is added to an aqueous acidic solution of surfactant under vigorous stirring to polymerize it following the anionic mechanism. Drug is dissolved in the polymerization medium either before the addition of monomer or at the end of the polymerization reaction. Nanospheres (Fig. 4A) are sedimented by ultracentrifugation of the obtained suspension. In the case of inverse emulsion polymerization, drug is dissolved in a small amount of water or hydrophilic solvent and emulsified in an organic phase (e.g., isooctane, cyclohexane, and hexane) in the presence of surfactants. Alkyl cyanoacrylate monomers are then added directly or dissolved in an organic solvent to the preformed w/o emulsion under stirring.<sup>[49]</sup> The system becomes milky, and nanospheres with a diameter of 200–300 nm with a narrow polydispersity are formed.

Dispersion polymerization deals with polymerization of monomers dissolved in an aqueous medium that acts as a precipitant for the polymer to be formed. Nucleation is induced in the aqueous monomer solution,<sup>[51]</sup> and the presence of stabilizers or surfactants is not absolutely necessary for the formation of nanospheres.

As mentioned earlier, polymerization methods have significant limitations, especially for formation of nanospheres.<sup>[45]</sup> First, it is very difficult to predict the molecular weight of the resulting material. This is a major drawback because the molecular weight influences the biodistribution and release of the polymer carrier. Second, the presence of free radicals or numerous H<sup>+</sup> ions generated by anionic polymerization

process can inhibit drug activity. Third, the presence of toxic unreacted monomer, initiator, and surfactant molecules requires time-consuming and, sometimes, inefficient procedures for their elimination.

### Dispersion of preformed polymers

Among the numerous synthetic polymers available for the preparation of nanospheres, the most commonly used are polyesters such as poly(lactic acid) (PLA), poly(glycolic acid) (PGA), poly(lactic-co-glycolic acid) (PLGA), poly( $\epsilon$ -caprolactone) (PLG), and poly( $\beta$ -hydroxybutyrate) (PHB).<sup>[4,5]</sup> Under physiological conditions, polyesters are generally degraded by hydrolysis into products that are well tolerated by various tissues.

**Solvent Evaporation Method.** In this method, a polymer is dissolved in an organic solvent (dichloromethane, chloroform, or ethyl acetate).<sup>[52]</sup> A drug is dissolved or dispersed into the polymer solution, and this mixture is then emulsified into an aqueous solution to make an o/w emulsion by using a surfactant such as gelatin, poly(vinyl alcohol) (PVA), polysorbate-80, poloxamer-188, etc. After the formation of emulsion, the organic solvent is evaporated either by heating or continuous stirring.<sup>[53]</sup> The double emulsion method, dealing with w/o/w emulsions, may also be used to prepare nanospheres containing water-soluble drugs.<sup>[54]</sup> Both these methods apply high-speed homogenization or sonication, which are not quite appropriate for large-scale production. In this pursuit, the following approaches have been attempted.

**Spontaneous Emulsification (Solvent Diffusion) Method.** In a modified version of the solvent evaporation method, the water-soluble solvent (acetone or methanol) along with the water-insoluble organic solvent (dichloromethane or chloroform) was used as an oil phase.<sup>[55]</sup> Because of the spontaneous diffusion of the water-soluble solvent, an interfacial turbulence is created between the two phases leading to the formation of smaller particles. As the concentration of water-soluble solvent increases, a considerable decrease in particle size can be achieved.

**Salting-Out Method.** The salting-out technique replaces chlorinated solvents with water-miscible acetone.<sup>[56]</sup> An aqueous phase saturated with electrolytes (e.g., magnesium salts) and containing PVA as a stabilizing and thickening agent is added under stirring to an acetone solution of polymer. The miscibility of both phases is prevented by the saturation of the aqueous phase with electrolytes, according to a salting-out phenomenon. The addition of the aqueous phase is continued until a phase inversion occurs and an o/w

emulsion is formed. Then, a sufficient amount of water is added to disrupt the equilibrium between the two phases and allow complete diffusion of acetone into water followed by polymer precipitation in the form of nanospheres. Other solvents (e.g., tetrahydrofuran) as well as nonelectrolytic salting-out agents (e.g., sucrose) could also be appropriate.<sup>[57]</sup> A variety of polymers can be used with this technique including PLA, methacrylic acid copolymers, and cellulose derivatives.

**Emulsification–Diffusion Method.** This method formally resembles the previous method, but its originality is in using benzyl alcohol as an organic solvent.<sup>[58]</sup> An aqueous phase containing PVA as a stabilizing and thickening agent is added to a solution of polymer in benzyl alcohol under stirring. With an excess of water, an o/w emulsion is obtained because benzyl alcohol has low miscibility with water. The precipitation of the polymer occurs due to the diffusion of benzyl alcohol into water, leading to the formation of nanospheres. By increasing the content of PVA in the external phase, it was possible to produce nanoparticles as small as 70 nm in diameter. The polymers used were PLA, PLGA, PCL, and methacrylic acid copolymers.

**Direct Precipitation Method.** This technique involves the use of polymer solution in an organic solvent that is completely miscible with the aqueous phase (acetone, ethanol, or acetonitrile) and allows nanospheres to be obtained after addition of water (with or without a surfactant) under stirring<sup>[59]</sup> (Fig. 4B). After precipitation of nanoparticles, the solvent is removed by vaporization under vacuum. Applications of this method are limited to drugs that are highly soluble in polar solvents but insoluble in water.

**Supercritical Fluid Technology.** Conventional methods such as in situ polymerization and solvent evaporation often require the use of toxic solvents and surfactants. Supercritical fluids allow attractive alternatives for the nanoencapsulation process because these are environmentally friendly solvents.<sup>[60]</sup> The commonly used methods of supercritical fluid technology are the rapid expansion of supercritical solution (RESS)<sup>[61]</sup> and the supercritical antisolvent (SAS) method.<sup>[62]</sup> A supercritical fluid is a substance that is used in a state above the critical temperature and pressure where gases and liquids can coexist. It is able to penetrate materials such as gas, and to dissolve materials such as liquid. For example, use of carbon dioxide or water in the form of a supercritical fluid allows substitution for an organic solvent.

In the RESS method,<sup>[61]</sup> a polymer is solubilized in a supercritical fluid and the solution is expanded

through a nozzle. Thus, the solvent power of supercritical fluid dramatically decreases and the solute eventually precipitates. A uniform distribution of drug inside the polymer matrix, e.g., PLA nanospheres, can be achieved only for low-molecular-mass (< 10,000) polymers because of the limited solubility of high-molecular-mass polymers in supercritical fluids.<sup>[63]</sup> In the SAS method,<sup>[62]</sup> the solution is charged with the supercritical fluid in the precipitation vessel containing a polymer in an organic solvent. At high pressure, enough antisolvent will enter into the liquid phase so that the solvent power will be lowered and the polymer precipitates. After precipitation, the antisolvent flows through the vessel to strip the residual solvent. When the solvent content has been reduced to the desired level, the vessel is depressured and the solid nanoparticles are collected.

## POLYMER NANOCAPSULES

### Manufacture of Nanocapsules

In general, all the methods for preparation of nanocapsules (Fig. 3B) are based on the self-assembly approach, which resembles aggregation of lipid molecules in aqueous solution into liposomes (Fig. 1).

#### Surface polymerization method

To overcome the instability of liposomes, lipids that are functionalized with polymerizable groups can be polymerized within vesicular structures.<sup>[64]</sup> Because of the polymerization reaction, the individual lipid molecules are interconnected via covalent bonds that stabilize the wall-forming membrane considerably. However, nanocapsules prepared from reactive lipids are rather costly.

In an analogous fashion to the lipids, amphiphilic block copolymers can also aggregate in aqueous solution to vesicular structures.<sup>[65]</sup> Block copolymer liposomes are significantly more stable than those formed from lipids due to the larger size and the lower dynamics of the underlying polymer molecules. Nevertheless, similarly to lipids they are held together solely by noncovalent interactions. Analogously to the reactive lipids, the block copolymer molecules could also be modified with polymerizable groups. Such block-copolymer-based nanocapsules can be expected to possess great potential for encapsulation and controlled release, because the physical properties of their polymer walls can be controlled by the block length or the chemical constitution of the underlying polymer molecules. So far only a few papers dealing with such nanocapsules have appeared.<sup>[66,67]</sup> In one of them the formation of vesicles from poly(isoprene)

*b*-poly-(2 cinnamoyl methacrylate) (PI-PCEMA) diblock copolymer in hexane–tetrahydrofuran mixtures was used as a starting stage.<sup>[66]</sup> The PCEMA blocks were photo-cross-linked and then the PI blocks had to be hydroxylated to make water-soluble nanocapsules. Diameter of the nanocapsules was in the range of 50–60 nm. A rather simple one-step procedure has been used to prepare vesicles of poly(2-methyloxasoline)-*b*-poly(dimethylsiloxane)-*b*-poly(2-methyloxasoline) in aqueous solution.<sup>[67]</sup> The underlying triblock copolymers were modified with methacrylate end groups without disturbing the vesicles in water, which were cross-linked under UV irradiation. Diameter of the obtained nanocapsules could be controlled in the range of 50–500 nm.

A similar concept uses just the geometry of the vesicular aggregates as a template. The interfacial polymerization of monomeric surfactants is an advanced method of this type of technique used for the preparation of nanocapsules.<sup>[68–74]</sup> For example, for the preparation of nanocapsules containing  $\alpha$ -chymotrypsin, the reverse hydrated micelles from *N,N*-diallyl-*N,N*-didodecyl ammonium bromide (DDAB) in cyclohexane entrapping enzyme in the inner aqueous cavities were polymerized by UV irradiation. After precipitation in acetone, these nanocapsules were dispersed in the aqueous medium with the aid of ionic (AOT) or nonionic (Brij-97) surfactants. Nuclear magnetic resonance spectroscopy data suggested that thereby bilayer nanocapsules with an average outer diameter of 20 nm were formed.<sup>[68]</sup> Their inner monolayer was made up of the two-dimensional poly-DDAB network, and the outer monolayer was composed of surfactant molecules.<sup>[69,70]</sup>

Another way used the ability of liposomes to solubilize hydrophobic monomers such as styrene,<sup>[71,72]</sup> acrylates, or alkylmethacrylates<sup>[3,73,74]</sup> within a bilayer. Their subsequent free-radical or UV-initiated polymerization led to the formation of a two-dimensional polymer network entrapped in the interior of the membrane (Fig. 5). The different compartments provided by the self-assembly of the lipid molecules generally serve only as a templates, which, similar to the previous case, control both the size and shape of the resulting nanocapsules. It was shown that the cross-linked polymer nanocapsules formed in vesicular dispersions are able to retain their structure even after isolation from the lipid matrix.<sup>[74]</sup>

Based on the method proposed for preparation of the PACA nanospheres,<sup>[49]</sup> PACA nanocapsules, consisting of a polymer envelope surrounding an oily core, were prepared.<sup>[75]</sup> The monomer molecules located at the surface of the oil nanodroplets, on contact with aqueous hydroxide anions, immediately polymerized at the water–oil interface, followed by the formation of a polymer wall with a mean thickness of about 3 nm.<sup>[75]</sup> It was later shown that the PACA nanocapsule morphology

**Fig. 5** Cryotransmission electron micrograph of poly (acrylic acid) hollow nanospheres obtained by polymerization method. (From Sauer, M.; Meier, W. RSC Chem. Commun. 2001, No. 1, 55–56; reproduced by permission of The Royal Society of Chemistry.)

depends on the pH of the aqueous phase, composition of the organic phase, and emulsification conditions.<sup>[76]</sup> This dependence results in formation of a mixture of nanocapsules and nanospheres. When aprotic water-miscible organic solvents such as acetone or acetonitrile were used, only true nanocapsules were obtained.

### Template approach

A similar way for producing polymer nanocapsules is to assemble a preformed polymer wall around a template particle or an oil nanodroplet that can be subsequently removed.<sup>[3]</sup> The most convenient approach is to use an oppositely charged polyelectrolyte self-assembly at charged core surfaces.<sup>[77]</sup> Not all of the ionic groups of the adsorbed polyelectrolyte are consumed by the electrostatic interactions with the surface. As a result, the original surface charge is usually overcompensated by the adsorbed polymer. Hence, the surface charge of the coated particle changes its sign and is now available for the adsorption of a polyelectrolyte of again opposite charge. Such sequential deposition produces ordered polyelectrolyte multilayers. The thickness of the wall is controlled by the number of deposition steps. To avoid a polyelectrolyte-induced particle flocculation, the rather low particle concentrations and the removal of non-adsorbed polyelectrolyte after each step are necessary. Weakly cross-linked melamine formaldehyde particles have been used as template core particles.<sup>[3]</sup> Exposure of the coated particles to an acidic solution of pH < 1.6 dissolves the core without affecting the layered polyelectrolyte wall.

Functionalized polystyrene latex nanoparticles carrying surface charges are also suitable templates for the polyelectrolyte self-assembly technique. Inorganic particles were incorporated into the adsorbed walls by a sequential adsorption of SiO<sub>2</sub> nanoparticles with negative surface charge and cationic poly(*N,N*-diallyl-*N,N*-dimethyl ammonium chloride) (PDDAC).<sup>[78]</sup> Layers with a thickness ranging from tens to hundreds of nanometers could be prepared. Removing the polystyrene core leaves SiO<sub>2</sub>/PDDAC nanocomposite capsules. Nevertheless, the long-term stability of such polyelectrolyte walls in biological fluids (e.g., in blood plasma), or in media of high ionic strength, may be rather limited.

### Coacervation method

This method uses the phenomenon of polymer-polymer incompatibility to form nanocapsules. The wall-forming polymer is dissolved in a solvent and to this solution a second polymer (called the phase inducer) is introduced followed by the formation of a two-phase system. The smartest complex coacervation process uses the interaction of two oppositely charged polyelectrolytes in water to form a polymer-rich coating solution called a coacervate.<sup>[79,80]</sup> If drug nanoparticles or nanodroplets are then added, the phase, rich with the coating polymer, engulfs the drug being encapsulated, thereby forming embryo capsules. Cooling the system causes the coacervate to gel via network formation. Gelatin is a primary polymer component of most coacervation systems.

More rigid nanocapsules can be prepared by a combination of coacervation and emulsion/suspension polymerization approaches. For example, the polymerization of divinylbenzene (DVB) in toluene/DVB swollen polystyrene latex particles or in polystyrene containing toluene droplets leads to the formation of poly-DVB nanocapsules due to limited compatibility of the chemically different polymers in solution followed by a microphase separation and the formation of a poly-DVB wall around a toluene-polystyrene core.<sup>[81]</sup> After evaporation of the internal toluene a cavity remains in the core.

Survival of the polymer walls after removing the solid or liquid core is the general goal of the coacervation method. A rather elegant approach to remove the core under mild conditions has recently been demonstrated.<sup>[82]</sup> First, the core of the particles was formed by a low-molecular-weight poly(dimethylsiloxane) around which a cross-linked organosilicon wall was formed in a second step. The poly(dimethylsiloxane) core was removed quantitatively by ultrafiltration. The remaining organosilicon envelopes obviously had rather high porosity allowing fast releasing the low molecular weight bioactives.

### Applications of Nanoparticles

Nanoparticles used as pharmaceutical forms must satisfy the following conditions: they must be free of any toxic impurities, easy to store and administer, and sterile if parenteral use is expected. One of the most promising applications of nanoparticles is their use as parenteral carriers for anticancer drugs based on their ability to accumulate in a number of tumors.<sup>[83,84]</sup> The encapsulation of a variety of anticancer drugs (e.g., doxorubicin, 5-fluorouracil, dactinomycin, and methotrexate), immunomodulators (muramyl dipeptide-L-alanyl-cholesterol), or antisense oligonucleotides mainly within PACA nanoparticles enhanced their efficacy against experimental tumors in comparison to the free drug.<sup>[84]</sup> A reduction of the general toxicity of anticancer drugs was also achieved. The most effective application of anticancer drug-loaded nanoparticles may be their use in the treatment of hepatic metastases. The incorporation of magnetic subnanoparticles into drug-containing nanoparticles and subsequent electromagnetic guidance has been shown to improve antime-tastatic efficiency by facilitating access to extravascular tumors.<sup>[83]</sup> Two other methods to achieve tumor-specific targeting were by using nanoparticles coated with either monoclonal antibodies, in order to recognize specific cell determinants,<sup>[84]</sup> or with PEG, to increase the blood circulation time of nanoparticles.<sup>[85]</sup>

The nanoparticles of PACA have gained wide popularity recently despite some major drawbacks such as the use of low-pH media and cytotoxicity.<sup>[86]</sup> To overcome these, derivatives of poly(methylidenemalonate) were prepared, i.e., poly(ethyl-2-(ethoxycarbonyl)methyleneoxycarbonyl acrylate)<sup>[87]</sup> and poly(ethyl-2-(ethoxycarbonyl) ethyl methylene malonate-co-ethylene oxide).<sup>[88]</sup> These polymers are associated with both the hydrophilic and hydrophobic functionalities providing long-time circulation of nanoparticles in blood and sustained release.

Intracellular infections are another field of application of nanoparticles. It is known that antibiotics exhibit either poor ability to penetrate the infected cells or decreased activity in intracellular compartments. PACA nanoparticles loaded with ampicillin showed high efficacy against *Listeria monocytigenes* and *Salmonella typhimurium* infections.<sup>[89]</sup> They are suitable for the specific transport of antiviral agents. Recently, PACA nanoparticles loaded with the protease inhibitor saquinavir were shown to be effective in HIV-infected human macrophage cultures.<sup>[90]</sup> The same nanoparticles loaded with primaquine, and even without any drug within, treat parasitic infections such as visceral leishmaniasis.<sup>[89]</sup> The void nanoparticles themselves have immunomodulation activity. This fact opens new prospects in the field of parasitic infections as well as in the treatment of other infections or tumors.

Nanoparticles increase the oral bioavailability of the peptide and protein drugs. For example, enhanced oral bioavailability was reported for insulin (Fig. 4A), dicumarol, and plasmid DNA encapsulated into adhesive nanoparticles made of polyanhydride copolymers of fumaric and sebacic acids.<sup>[6]</sup> The use of nanoparticles is prospective for oral delivery antigens because of their ability to control the release of proteins and to protect them from enzymatic degradation in the gastrointestinal tract. The very slow degradation rate of PMMA nanoparticles is particularly appropriate for vaccine purposes because it provides prolonged contact between the antigen and the immunocompetent cells. At the same time, coating the nanocapsules with monoclonal antibodies is expected to increase the level of absorption of entrapped vaccines and, therefore, the immune response.<sup>[90]</sup> These investigations allow one to create new generations of effective vaccines for oral immunization.

Depending on the rate of desired release, the PACA, PLA, and PLGA nanoparticles can be applied for intramuscular, subcutaneous, and topical administration. For example, the topical use of nanoparticles by the ocular route has been investigated for the treatment of chronic diseases such as glaucoma. Because of their low viscosity in suspensions, these systems can be administered as eye drops providing the sustained drug delivery.<sup>[91]</sup>

## MOLECULAR INCLUSION COMPLEXES

Molecular inclusion complexes of the host–guest type provide unprecedented “molecular nanoencapsulation”

of drugs.<sup>[10]</sup> The most advanced among them are inclusion complexes of  $\alpha$ -,  $\beta$ -, and  $\gamma$ -cyclodextrins<sup>[7]</sup> and dendrimers.<sup>[8,9]</sup>

Cyclodextrins comprise a family of cyclic oligosaccharides. Three major cyclodextrins have a shape of a bracelet built up from glucopyranose units (6 units for  $\alpha$ -, 7 for  $\beta$ -, and 8 for  $\gamma$ -cyclodextrin) (Fig. 6A). The diameter of the inner cavity varies for  $\alpha$ -,  $\beta$ -, and  $\gamma$ -cyclodextrin from 0.5 to 0.8 nm. In an aqueous solution, the slightly apolar cyclodextrin cavity is occupied by water molecules that are energetically unfavored, and therefore may be readily substituted by appropriate “guest” molecules that are less polar than water. One or a few cyclodextrin molecules can entrap one or more “guest” molecules. Most frequently, the host/guest ratio is 1:1; however, 2:1, 1:2, 2:2 (Fig. 6C–E), or even more complicated associations, such as rotoxanes, exist.<sup>[7]</sup> The formerly hydrophobic guest, upon complexation, becomes hydrophilic and effectively protected against any type of reaction, except that with cyclodextrin hydrolysis. The formed inclusion complexes can be isolated as stable crystalline substances.

Natural cyclodextrins, however, have relatively low solubility, both in water and organic solvents, which thus limits their use in pharmaceutical formulations. Recently, various kinds of cyclodextrin derivatives have been prepared to extend the physicochemical properties and inclusion capacity of natural cyclodextrins as novel drug carriers.<sup>[10]</sup> To elongate the actual cyclodextrin cavity or enhance solubility, substituents are attached to the primary or secondary hydroxyl

**Fig. 6** Chemical structure of cyclodextrins (A), the schematic representation of their O-derivatives (B), and the possible inclusion complexes 1:1 (C), 2:1 (D), and 2:2 (E).

Fig. 7 Schematic structure of a spherical dendrimer of the fifth generation.

groups situated on the two rims of the molecular bracelet. This elongation may be hydrophobic if acyl or hydroxyalkyl groups are attached. At present, the acetylated, hydroxypropylated, and sulfobutylated derivatives, mainly of  $\beta$ - and  $\gamma$ -cyclodextrins, can be considered as drug carriers<sup>[10]</sup> (Fig. 6B).

Dendrimers are highly branched cascade molecules that emanate from a central core through a stepwise, repetitive reaction sequence.<sup>[8]</sup> Such a molecule consists of three topologically different regions: a small initiator core of low density and multiple branching units, the density of which increases with increasing distance from the core, thus eventually leading to a rather densely packed shell (Fig. 7). Dendritic shielding actually amounts to an encapsulation that can create a distinct microenvironment around the core moiety and hence affect its properties. Dendrimers with amphiphilic core-shell structures were shown to look like “unimolecular micelles.”<sup>[92]</sup> Dendrimers that have internal cavities with a dense outer shell may be synthesized by controlling the last step. This has been demonstrated by the preparation of a fifth-generation poly(propyleneimine) dendrimer.<sup>[93]</sup> Because of their outer shell, these molecules can be regarded as dendritic compartments that are capable of retaining guest molecules entrapped during synthesis. If the surface *tert*-butyl groups were removed guest molecules could diffuse out of the compartments. The compact dendrimer topology is promising for both the controlled release<sup>[93]</sup> and confined biochemical nanoreactors.<sup>[8]</sup>

Dendrimers are, generally, not hollow polymer particles. Recently, elegant synthetic protocols have been developed that form the inner cavity directly from dendritic precursors. One of them is based on a polyether dendrimer with a trimesic acid ester core.<sup>[94]</sup> The molecular nanocapsules were formed by selective cross-linking of homoallyl ether groups at the surface of the dendrimer and subsequent degradation of the core region by hydrolysis (Fig. 8). An attractive possibility offered by this method is that the remaining functional

Fig. 8 Preparation of a cored dendrimer. Source: From Ref.<sup>[94]</sup> © 1999, ACS.

groups in the interior of the carrier system could serve as “endoreceptors” available for molecular recognition. This approach allows control over size and geometry of the formed nanocapsules, but preparation

is rather refined. This is still a limiting factor for possible applications of dendrimers as drug carriers.

### Applications of Molecular Inclusion Complexes

The metabolic fate of natural cyclodextrins and their derivatives given orally has been thoroughly investigated and their lack of toxicity has been demonstrated.<sup>[10]</sup> However, the intravenous or intramuscular administration of some  $\beta$ -cyclodextrin derivatives like heptakis(2,6-di-*O*-methyl)- $\beta$ -cyclodextrin in rats and rabbits increased blood urea nitrogen, creatinine, and transaminases, indicating some kidney and liver failure, while those for 2-hydroxypropyl-, 6-*O*-maltosyl- $\beta$ -cyclodextrin, and  $\beta$ -cyclodextrin sulfate at the same dosage remained within normal limits.<sup>[10]</sup> Another drawback of cyclodextrins as drug carriers is their ability to induce human erythrocytes to change their biconcave shape to monoconcave and induce lysis at higher concentrations because cyclodextrins are able to solubilize the biomembrane components. When we deal with the inclusion complex, or when the cyclodextrin cavity is modified by chemical derivatization, the effect on cell membranes can be dramatically mitigated. The above-mentioned 2-hydroxypropyl- and sulfobutyl- $\beta$ -cyclodextrin were generally found to be safe when administered parenterally in animals and humans.<sup>[95]</sup>

One of the most important functions of cyclodextrins is to enhance the aqueous solubility of included drugs. The degree of substitution markedly influences the solubilization. In general, hydroxyalkylated, sulfated, and sulfoalkylated cyclodextrins and their complexes have lower aqueous solubility than parent cyclodextrins.<sup>[10]</sup> When mono- or disaccharides are bounded to one or two primary hydroxyl groups of cyclodextrins through the  $\alpha$ -1,6-glycosidic bond, their solubility in water increases. It is remarkable that the enzymatically prepared branched cyclodextrins have higher affinity to drugs and bioavailability along with weak hemolytic activity.<sup>[96]</sup>

In oral delivery, hydrophilic and hydrophobic cyclodextrin derivatives are useful for immediate- and sustained-release type formulations. The hydrophilic cyclodextrins have been extensively applied to enhance the oral bioavailability of steroids, cardiac glycosides, anti-inflammatory drugs, barbiturates, antiepileptics, neuroleptics, antidiabetics, vasodilators, etc.<sup>[10,96–99]</sup> Recently, highly hydrophilic cyclodextrin derivatives, such as 2-hydroxypropyl-, 6-*O*-maltosyl-, and sulfobutyl- $\beta$ -cyclodextrin have been used to obtain an immediate-release formulation, which is readily dissolved in the gastrointestinal tracts, providing an enhancement of oral bioavailability of poorly water-soluble drugs.<sup>[99]</sup> On the other hand, alkylated and

acylated derivatives are useful as slow-release carriers for water-soluble drugs. Among them heptakis(2,6-di-*O*-ethyl)-, heptakis(2,3,6-tri-*O*-ethyl)-, and heptakis(2,3,6-tri-*O*-butanoyl)- $\beta$ -cyclodextrin were the first slow-release carriers to be used in conjunction with diltiazem, isosorbide dinitrate, and salbutamol.<sup>[10]</sup>

The cyclodextrin vehicles are effective in ophthalmic formulations because they do not irritate the ocular surface resulting in a fast washout of the instilled drug. Hydrophilic 2-hydroxypropyl- and sulfobutyl- $\beta$ -cyclodextrin are nontoxic to the eye and well tolerated in aqueous eye drops with low viscosity. They do not penetrate the corneal barrier, but enhance the ocular bioavailability of included lipophilic drugs like dexamethasone acetate.<sup>[100]</sup>

Cyclodextrins improve the solubility and stability of drugs in topical preparations onto the skin, thus enhancing the transdermal penetration of drugs and sustaining the drug release along with lowering their toxicity.<sup>[10]</sup> In general, hydrophilic cyclodextrins and their complexes penetrate through the skin inefficiently. However, when cyclodextrins are applied under occlusive dressing conditions, they are able to permeate the skin.<sup>[10]</sup> For example, transdermal delivery of prostaglandin E<sub>1</sub>, which is unstable and poorly permeable into the skin, in complex with a penetration enhancer, 1-[2-(decylthio)ethyl]azacyclopentane-2-one, with the aid of 6-*O*-(carboxymethyl)-*O*-ethyl- $\beta$ -cyclodextrin, leads to the treatment of peripheral vascular disorders as an alternative to parenteral injections.<sup>[101]</sup>

Cyclodextrins are effective for providing the targeted drug delivery.<sup>[10]</sup> It is known that the specific delivery of neuropharmaceuticals to the brain is obscured by the presence of the blood-brain barrier. Inclusion complexes with cyclodextrins are able to solve the permeability problem, as it was shown for inclusion complexes of psychotropic agents (phenazepam, gidazepam).<sup>[97,98]</sup> Another example is the conjugate of *N*-leucine-enkephalin and 6-amino-6-deoxy- $\beta$ -cyclodextrin.<sup>[102]</sup> Both types of prodrugs provide brain targeting followed by the sustained release. In general, the substituents introduced at primary hydroxyl groups of cyclodextrins through a spacer of appropriate length are self-included within the cavity. However, the enkephalin conjugate can accommodate other guest molecules (e.g., dothiepine) because the self-inclusion is restricted due to steric hindrance.

### CONCLUSION

It is clear that biology has much to offer nanotechnology in demonstrating how to organize, functionalize, and assemble new molecular and submolecular materials and tools to design nanosize carriers for bioactive substances. From the chemical point of view,

it is important to synthesize newer polymers and surfactants to match the hydrophilic and hydrophobic properties of the bioactive substances. Implementation of cavitands for formation of inclusion complexes can dramatically increase the loading capacity of carriers in combination with polymer nanoparticles and liposomes. Their new amphiphilic derivatives are capable of forming nanospheres and nanocapsules, presenting a high loading capacity toward both hydrophobic and hydrophilic drugs without any polymerization process. In order to provide the targeted delivery and controlled release of the bioactive substance, designing the carriers with tailored surface characteristics based on specific peptide, protein, polynucleotide, or polysaccharide motifs with preordained functions becomes the regular strategy.

# Nanofibers and Carbon Nanotubes: Novel Metal Catalyst Supports

Mark A. Keane

Department of Chemistry and Materials Engineering, University of Kentucky,  
Lexington, Kentucky, U.S.A.

## INTRODUCTION

The association of carbon nanofibers and nanotubes with heterogeneous catalysis, the focus of this entry, is twofold. The growth of ordered carbon from metal catalysts has emerged as an economically viable and selective route to a high value graphitic product. The critical catalyst characteristics that have been shown to impact on the dimensions and structure of the carbon product are discussed herein with an evaluation of the growth mechanisms that have been proposed in the literature. The established noncatalytic synthesis methodologies are described and the advantages inherent in a move to a catalytic approach are demonstrated, taking ethylene decomposition over nickel as a model system. The second catalysis/carbon connection deals with the application of nanoscale carbon substrates to disperse a catalytically active metal phase, i.e., preparation of supported metal catalysts. The advantages of carbon nanofibers/nanotubes as metal supports are discussed with an overview of recent literature that describes the catalytic application of metals anchored to structured carbon substrates.

## BACKGROUND

Carbon is unique in that it can bond in different ways to create structures with quite dissimilar properties. The discovery of the  $C_{60}$  closed-cage (nearly) spherical molecule, now commonly known as the “buckyball,”<sup>[1]</sup> multi-/single-walled nanotubes,<sup>[2,3]</sup> carbon nanofibers,<sup>[4,5]</sup> and related materials<sup>[6,7]</sup> has led to a renaissance in the study of carbon-based materials. The selective synthesis of structured carbon materials is now actively pursued and a burgeoning literature on carbon production and characterization has emerged over the past decade. This interest has been fuelled by the unique chemical and physical properties associated with these materials that can be exploited in adsorption,<sup>[8,9]</sup> hydrogen storage,<sup>[10,11]</sup> and electronics applications.<sup>[12]</sup> In addition, the remarkable mechanical properties of structured carbon can be used to good effect as additives for reinforcement purposes,<sup>[13]</sup>

while the associated high aspect ratio and metallic/semiconducting properties can impact on conductivity<sup>[5,14]</sup> in various composites. Although the potential applications are many, widespread utilization requires a low-cost means of fabricating structured carbon that exhibits a high degree of control and reproducibility.

The use of a support to disperse a catalytically active metal phase is not only of economic benefit (lower preparation costs/longer productive lifetime) but the substrate can also influence catalyst performance through electronic interaction(s) and migration effects,<sup>[15]</sup> a phenomenon that has led to the widely applied acronym SMSI,<sup>[16]</sup> i.e., “strong metal support interactions.” The use of carbon nanofibers and nanotubes as catalyst supports is now attracting appreciable research interest; the perceived advantages when compared with activated carbon, as an established metal support, are addressed. This work is still in a formative stage—a compilation of the existing literature is provided with a critical assessment of the trends that have emerged.

## CARBON NANOFIBERS AND NANOTUBES: STRUCTURAL FEATURES

The distinction between carbon nanotubes and nanofibers, as presented in the recent literature, is far from clear. In terms of aspect ratio, length of the major axis divided by width of the minor axis, both nanotubes and nanofibers are characterized by values well in excess (by orders of magnitude) of unity. Nanotube structure can be directly related to the spherical  $C_{60}$  arrangement through a structural elongation that generates a single-walled tube with nanoscale dimensions [Fig. 1(A)]. Graphite, the thermodynamically stable bulk phase of carbon, displays a turbosilicate character, i.e., closed-packed layers that can be mutually displaced in directions normal to the  $c$  axis.<sup>[17]</sup> Where there is a finite number of carbon atoms with a high density of dangling bonds, the structure “closes in” to form more energetically favorable chains, rings, and closed shells.<sup>[18]</sup> The simple single-walled nanotube

**Fig. 1** Simple schematics showing the three-dimensional structure of (A) SWNT and (B) MWNT.

(SWNT) schematic shown in Fig. 1(A) depicts a long cylinder composed of a hexagonal honeycomb lattice of ( $sp^2$ -hybridized) carbon that is essentially a folded graphene sheet where the open edges match perfectly to form a seamless structure. Closure of these tubes requires curvature to form a convex structure with fragmentation of the hexagonal lattice and incorporation of pentagon rings.<sup>[19]</sup> When produced in the vapor phase, SWNTs are known to self-assemble into larger bundles or ropes that can contain several tens of thousands of individual nanotubes.<sup>[18]</sup> Multiwalled nanotubes (MWNTs) [Fig. 1(B)] are created by the superposition of several concentric cylinders about a common central hollow core in the manner of a “Russian doll.”<sup>[2]</sup> The separation between neighboring tubes is ca. 0.34 nm, close to but typically greater than the interplanar distance of the  $d_{200}$  plane of graphite, due to the constraint induced by the curvature of the graphene planes that form the tube.<sup>[5]</sup> The outer diameter of MWNTs (prepared by an arc-discharge method) generally falls within the range 2–20 nm with an internal diameter ranging from 1 to 3 nm.<sup>[20,21]</sup> The distribution of diameters associated with SWNTs is significantly narrower, ranging from 0.7 to 1.6 nm.<sup>[21,22]</sup>

While there is a tendency in the literature to assign the term “nanotube” as a virtual “catch-all” to describe every nanoscale structured carbon, nanofibers are structurally quite distinct. While they are also graphitic in nature and characterized by a series of ordered parallel graphene layers with again an inter-layer distance of ca. 0.34 nm, the exposed surface

mainly consists of prismatic planes with high surface reactivity when compared with the basal planes of graphite. Two typical lattice arrangements are associated with carbon nanofibers, i.e., the “ribbon” and the “herringbone” orientation.<sup>[5,21,22]</sup> A simple schematic rendering of the ribbon form is given as a visual aid in Fig. 2(A), and this can be compared with the representative transmission electron micrograph (TEM) in Fig. 3(A), where the graphene layers are oriented parallel to the fiber axis. The high aspect ratio associated with carbon nanofibers is immediately evident from the scanning electron micrograph (SEM) given in Fig. 4. The alternative herringbone structure<sup>[5,23]</sup> is illustrated again as a schematic [Fig. 2(B)] accompanied by a TEM image [Fig. 3(B)]—in this instance, the parallel carbon platelets are oriented at an angle to the fiber

**Fig. 2** Schematic diagram illustrating an idealized rendering of the lattice structure in (A) ribbon and (B) herringbone carbon nanofibers.

**Fig. 3** Representative TEM images of (A) ribbon, (B) herringbone, and (C) helical carbon nanofibers.

axis. The latter arrangement can lead to deviations in the interlayer spacing toward the outer edges of the graphitic platelets making this particular nanofiber a potential candidate for adsorption applications.<sup>[9]</sup> Nanofibers also exist in the so-called platelet form where the graphene layers are oriented perpendicular to the fiber axis. “Helical” or “ropelike” nanofiber structures have also been reported<sup>[24,25]</sup> where the fibers have a coiled appearance as illustrated by the TEM image in Fig. 3(C). A measurement of the Brunauer–Emmett–Teller (BET) surface area can serve as a useful means of differentiating between carbon nanofibers and nanotubes. The nanofiber has a greater availability of edge sites, whereas the nanotube is characterized by a large exposed exterior basal plane. These features emerge from BET analyses that have yielded typical nanotube surface areas of  $<30 \text{ m}^2 \text{ g}^{-1}$ , appreciably lower than the nanofiber area which can

**Fig. 4** Representative SEM image of carbon nanofibers produced via the catalytic decomposition of ethylene.

approach  $200 \text{ m}^2 \text{ g}^{-1}$  depending on the synthesis procedure and post synthesis treatment.<sup>[2,5,26]</sup>

## CARBON NANOFIBER/NANOTUBE SYNTHESIS

The C–C covalent bond that constitutes the graphite planes is one of the strongest in nature, and the perfect lattice alignment endows these materials with high conductivity, enhanced strength, and chemical specificity. The combination of dimension, structure, and topology translates into such a diversity of unique chemical and physical properties that carbon nanofibers/nanotubes are now established as a target high-value product. The established synthesis methodologies can be conveniently divided into noncatalytic and catalytic processes.

### Noncatalytic Approach

The synthesis of graphitic carbon (nanotubes/nanofibers) is now well established by arc discharge<sup>[18,27]</sup> and plasma decomposition.<sup>[27,28]</sup> The arc-discharge technique was developed by Bacon in the early 1960s to produce carbon fibers or “whiskers,”<sup>[29]</sup> and adapted some 30 years later to generate a significant quantity of fullerenes.<sup>[30]</sup> Indeed, Iijima’s landmark reported MWNT synthesis<sup>[2]</sup> was the result of DC arc-discharge evaporation of graphite rods. While such methodologies generate a carbon product of good turbo-static quality, they also produce polyhedron carbon

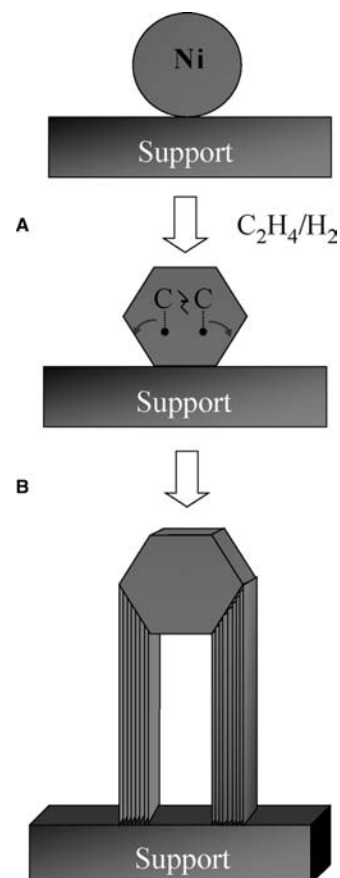

nanoparticles (low aspect ratio) and an appreciable amorphous carbon component.<sup>[28]</sup> The latter necessitates an additional involved, cumbersome, and costly purification stage in order to extract the desired structured product. In any case, these methodologies are highly energy-demanding batch processes and the amount of material that can be produced is limited. Moreover, carbon structures generated in this fashion exhibit a preponderance of defects, the high temperatures employed can induce sintering and cross-linking of the fiber/tube while the length of the carbon product is typically  $<1\ \mu\text{m}$ .<sup>[21,31]</sup> The separation step can involve a combination of chemical treatment and ultrasound, whereas purification calls for selective oxidation and/or hydrogenation.<sup>[32]</sup> Although structured carbon has been detected in benzene, acetylene, and ethylene flames,<sup>[33]</sup> flame synthesis is not viewed as a viable preparative strategy.

### Catalytic Approach

On the whole, the catalytic route can generate carbon nanofibers/tubes that are largely uniform in diameter, and scale-up of the catalytic process is far more feasible.<sup>[5,21]</sup> In general, catalytic synthesis involves the decomposition of a carbon-containing gas stream typically diluted with an inert (He, Ar) and possibly reactive ( $\text{H}_2$ ) gas flow. The yield and nature (SWNTs and/or MWNTs and/or nanofibers) of the carbon product are determined by the nature of the catalytic metal (with/without a support), the hydrocarbon source, reaction/contact time, and temperature. The fiber/tube diameter appears to be governed by the dimensions of the seed metal particle, whereas the length depends largely on the duration of reaction.<sup>[21,25,34]</sup> Cobalt-, nickel-, and iron-based catalysts have exhibited the highest carbon growth activities<sup>[5]</sup> with the formation of SWNTs requiring very small diameter seed metal particles. Taking nickel-based catalysts as a representative case, the metal has been used in unsupported<sup>[35]</sup> and supported<sup>[24,36,37]</sup> forms and as a bimetallic with copper<sup>[38]</sup> to promote carbon growth from a catalytic decomposition of  $\text{CO}$ <sup>[36,39,40]</sup> and such hydrocarbons as methane,<sup>[36,37,39]</sup> 1-butene,<sup>[8]</sup> 1,3-butadiene,<sup>[8,37]</sup> acetylene,<sup>[40,41]</sup> ethylene,<sup>[8,24,36,41]</sup> *n*-hexane,<sup>[37]</sup> and benzene.<sup>[42]</sup> Hydrogen is not an essential component in these systems, but its presence has been shown to be highly beneficial, not only in initiating the decomposition of the carbon-containing gas<sup>[43]</sup> but also as a means of exerting additional structural control on the growing carbon.<sup>[44]</sup>

The commonly accepted mechanism<sup>[5]</sup> involves reactant (carbon source) decomposition on the top surface of a metal particle followed by a diffusion of carbon atoms into the metal with precipitation at other facets

of the particle to yield the fiber/tube, which continues to grow until the metal particle becomes poisoned or completely encapsulated by carbon. Taking ethylene decomposition over supported Ni as a model system, the simple scheme included in Fig. 5 illustrates the link between the Ni site and the ultimate carbon growth. It has been shown that certain crystallographic orientation(s) of Ni favor(s) reactant decomposition, whereas a different set of faces serves to promote the precipitation of a graphitic carbon product.<sup>[45]</sup> Carbon deposition necessitates a destructive chemisorption of ethylene, i.e., loss of H atoms and C–C bond breakage. The latter is facilitated by a thermodynamically driven multiple bonding of the chemisorbed hydrocarbon with the metal surface that serves to lower the surface free energy.<sup>[21]</sup> Doping Ni catalysts with alkali halides has been shown to increase carbon yield and enhance structural order, effects that are attributed to charge transfer associated with the electronegative/

**Fig. 5** Schematic representation of the critical stages associated with the carbon growth via the decomposition of ethylene over supported Ni: (A) destructive adsorption on the Ni surface with dissolution of carbon and diffusion through the restructured metal particle and (B) precipitation of carbon at the rear face of the particle in the form of a graphite platelet with Ni particle extraction from the support.

electropositive halogen/alkali metal.<sup>[21,45]</sup> The rate-determining step is the dissolution and diffusion of carbon through the metal particle where the driving force for diffusion has been ascribed to either a temperature<sup>[46]</sup> or concentration<sup>[47]</sup> gradient. It is believed that the carbon dissolves to form a substoichiometric metal carbide prior to fiber/tube formation.<sup>[48]</sup> The metal carbide is metastable with respect to the metal and graphite and decomposes into graphite that encapsulates the metal particle. The formation of hexagonal Ni<sub>3</sub>C has been proposed as the nucleation species but is not present during steady-state growth.<sup>[24,48]</sup> The involvement of metal carbide remains a supposition where the effect of temperature on the metastable carbide-phase equilibrium must be taken into account, and, in any case, much of the available evidence is indirect and not based on (a problematic) *in situ* analysis. In terms of a concentration gradient process, the carbon concentration in the metal must be greater than that at the metal/graphite interface in order to drive the diffusion forward. Carbon species at the metal/gas interface are known to exhibit a higher solubility than carbon originating from graphite.<sup>[36]</sup> The movement of carbon atoms through the Ni metal lattice necessitates a displacement of Ni atoms as the C atom diameter exceeds the available spacing.<sup>[24]</sup> Rather than an explicit carbide assignment, carbon growth can be considered to result from a stable but fluid supersaturated solution of carbon in the metal. As shown in Fig. 5, carbon growth is accompanied by a reconstruction/faceting of the metal particle.<sup>[38,46,47]</sup> Metal faceting can lead to variations in the surface structure of the carbon which, in turn, affects the mechanical strength, texture, and chemical attributes. Where the metal interaction with the support is relatively weak, the pressure exerted on the metal/support interface due to graphite formation is of sufficient magnitude to extract the metal particle from the support. Once the metal particle is detached from the support, a fresh surface is exposed to ethylene, and growth continues with the Ni particle located on the carbon tip, as depicted in Fig. 5.

The degree of crystalline order of the carbon product is controlled by various factors including the wetting properties of the metal with graphite and the crystallographic orientation of the metal faces that are in contact with the carbon deposit, features that are ultimately reliant upon the choice of catalyst.<sup>[5,22]</sup> The arrangement of the metal atoms at the face where the carbon is deposited ultimately regulates the nature of the precipitated carbon. If the atoms are arranged in such a manner that they are consistent with those of the basal plane structure of graphite then the carbon that dissolves in and diffuses through the particle will be precipitated as an ordered structure. Conversely, if there is little or no match between the atomic

Fig. 6 Temperature-programmed oxidation (TPO) profiles for (A) model amorphous carbon and (B) carbon nanofiber.

arrangements of the depositing face and graphite, a more disordered carbon will be generated. The degree of order in carbon structures can be probed by temperature-programmed oxidation (TPO) where a move from an amorphous to a graphitic structure is accompanied by an elevation of the temperature at which gasification is induced. The TPO profiles of a sample of carbon nanofibers can be assessed against the TPO characteristics of model amorphous carbon in Fig. 6; the fiber is appreciably more resistant to gasification than the unstructured carbon. A hollow central core is evident in the low magnification TEM pictures provided in Fig. 7. This structural feature, also depicted in Fig. 5, has been attributed to a deformation or faceting of the supported metal particle that

Fig. 7 Representative TEM micrograph showing the nature of carbon nanofiber growth resulting from ethylene decomposition over Ni/SiO<sub>2</sub>.

alters the relative rate of carbon diffusion and fiber nucleation.<sup>[46]</sup>

## CARBON NANOFIBERS/NANOTUBES AS METAL SUPPORTS

Carbon as a support material is well established in heterogeneous catalysis, notably in liquid-phase applications. Activated carbon, usually derived from natural materials (e.g., coal, wood, straw, fruit stones, and shells), has found widespread use because of its high surface area/adsorption capacity coupled with cost effectiveness.<sup>[49]</sup> The high surface area associated with activated carbon (typically  $>600\text{ m}^2\text{ g}^{-1}$ ) is the result of a significant micropore content which can impose physical transport constraints in any catalytic process where the reactants must gain access to metal particles located within these micropores. Graphite is characterized by a low surface area (with limited porosity) which has mitigated against its use as a catalyst support material. Carbon nanofibers (and carbon nanotubes to a lesser extent) possess surface areas well in excess of that associated with graphite with larger pore openings and a consequent alleviation of reactant/product transport constraints. One important aspect of liquid-phase heterogeneous catalytic processes involving carbon-based catalysts is the ease of separation of the solid from solution. The recovery of the carbon nanofibers from aqueous media has been shown to be far more facile (by an order of magnitude) than phase separation involving granular activated carbon powder.<sup>[50]</sup> The nanofibers are extremely robust in nature and do not disintegrate or exhibit any appreciable damage during vigorous agitation unlike the activated carbon, which experiences considerable attrition with prolonged use. In aqueous-phase operation, the intrinsic hydrophobicity of the carbon nanofibers may also serve to aid filtration by repelling water molecules. Moreover, unlike activated carbon, separation of the fibers from solution is not accompanied by any significant loss of (fine) carbon particulates, and catalyst reuse should be greatly facilitated.<sup>[9]</sup>

Any reaction that is promoted by a heterogeneous catalyst proceeds via reactant/catalyst interaction(s) that generate(s) a surface reactive complex. These interactions may be weak, of the “nonbonding” type with the reactant staying intact while sticking to (or absorbing on) the surface. Alternatively, the interactions may involve the formation of new chemical bonds between the surface atoms and the adsorbed molecule (i.e., chemisorption), which necessarily entails extensive reorganization of the bonding within the reactant. The magnitude of the adsorption coefficient depends on the nature of the surface and the chemical identity of the reacting species. Once the reactant is

bound to the surface, it can readily undergo reactions which take place only with difficulty in the gas or liquid phases. This may result from the close proximity of reactant molecules on the surface and/or the changes in bonding consequent upon chemisorption; both are essential features of the catalytic properties of the solid. The choice of a suitable catalyst for a particular reaction depends on the stability of the complexes formed between reactant and catalyst and/or product and catalyst. These must be stable enough to form and provide an alternative pathway to the uncatalyzed reaction, but they must not be too stable as this would lead to an increase in the associated activation with a consequent lowering of reaction rate. The unique electronic, adsorption, and thermal/mechanical properties associated with carbon nanofibers and nanotubes can all play interrelated roles in the design of catalytically efficient supported metal systems. The ability of a substrate to induce electronic perturbations in the supported metal and so impact on chemisorptive and reactivity properties is well established.<sup>[25]</sup> The use of conductive carbon supports, as opposed to activated carbon, to anchor transition metals has been demonstrated to significantly affect the intrinsic metal site activity through charge transfer effects.<sup>[5,51]</sup> The high conductivity/availability of delocalized  $\pi$ -electrons can influence reactant adsorption<sup>[50]</sup> and so the nanofiber/tube can have a synergistic effect in terms of activating the reactant prior to surface reaction. Moreover, given the lower density of carbon fibers relative to amorphous carbon, the pressure required to maintain the same reactant flow through a bed of activated carbon is substantially higher, which can have significant ramifications in terms of energy usage/costs.<sup>[9]</sup> In addition, the enhanced mechanical strength and thermal shock resistance of the structured carbon substrates can also have a bearing in processes that require unavoidable high pressures/temperatures.

## Methodologies for Attaching Metals to Carbonaceous Surfaces

Supported metal catalysts are generally composed of small metal particles (1–100 nm in diameter) dispersed on a high surface area carrier. Modern catalyst formulations often include an “active” metal (Pt, Pd, Ru, etc.) with a secondary component or additive that serves as a promoter where this modification may be directed toward enhancing activity/selectivity, poison resistance, or textural properties. Conventional and commercial metal catalysts are typically prepared via wet impregnation techniques. In this approach, a metal salt precursor (nitrate, halide, etc.) is dissolved in sufficient solvent (normally water) to fill the pores of the support. The water is then evaporated, leaving only

the metal salts on the support that are then activated at elevated temperatures under  $H_2$  (metal salt decomposition with concomitant/subsequent zero valent metal formation) or flowing air (calcination to generate a supported metal oxide) with subsequent reduction in  $H_2$ . The ultimate dispersion of metal on the support is dependent on metal loading, activation temperature, pretreatment (drying/calcination), and the nature of the metal (precursor) and support. Impregnation of graphitic carbon surfaces with metal precursors in aqueous media is, however, problematic as the hydrophobic property of the nanofibers/tubes leads to difficulties with surface wetting that can adversely affect metal dispersion.<sup>[5,52]</sup> This can be circumvented by using organic solvents—the TEM images provided in Fig. 8 illustrate the nature of Pd supported on activated carbon and nanofibers prepared by impregnation of palladium nitrate from butanol. An even dispersion of Pd particles is evident on the carbon nanofibers where the majority of the Pd diameters range from <5 to 30 nm. It is instructive to note that

while the Pd particles supported on activated carbon possess a globular geometry, the metal phase on the nanofibers exhibits a faceting that is characteristic of stronger metal/support interactions. The X-ray diffractogram (XRD) associated with the Pd/nanofiber sample has a strong peak at  $26^\circ$  that is characteristic of highly structured (graphitic) carbon, a response that, as expected, is not present in the profile for Pd/activated carbon (Fig. 9). The representative high-resolution TEM image provided in Fig. 10 illustrates the carbon platelet arrangement in the carbon nanofiber support. The graphite platelets have a parallel alignment with an interplatelet spacing of ca. 0.34 nm, diagnostic of a graphitic species. The Pd phase on both supports displays a cubic geometry with the four XRD peaks at  $40.1^\circ$ ,  $46.7^\circ$ ,  $68.1^\circ$ , and  $82.15^\circ$  corresponding, respectively, to (111), (200), (220), and (311) Pd planes.

There are reports in the literature that describe nanofiber impregnation with Rh,<sup>[53]</sup> Ni,<sup>[54,55]</sup> and Fe-Cu<sup>[56]</sup> from alcohol solutions. Indeed, Pham-Huu

**Fig. 8** Representative TEM images of Pd supported on (A) carbon nanofiber and (B) activated carbon.

**Fig. 9** XRD patterns for (A) Pd/nanofiber and (B) Pd/activated carbon. The solid lines indicate peak position (with relative intensity) for cubic Pd.

et al.<sup>[48]</sup> and Reshetyenko et al.<sup>[57]</sup> have successfully impregnated graphitic nanofibers with 5% w/w Pd and 15% w/w Ni using aqueous solutions of the metal nitrate and chloride, respectively. In addition, there are

**Fig. 10** Representative high-resolution TEM image showing carbon nanofiber lattice structure.

reported instances (with varying detail) of SWNT and MWNT impregnation with  $\text{Ru}(\text{acac})_3$  in toluene,<sup>[58]</sup>  $\text{H}_2\text{PtCl}_6$  in ethylene glycol,<sup>[59]</sup> and a Pd(II)- $\beta$ -diketone in supercritical  $\text{CO}_2$ <sup>[60]</sup> to deliver metal loadings up to 10% w/w; the metal particle diameters after activation were in the range 2–4 nm. Xue et al.<sup>[61]</sup> have reported the preparation of Pd, Pt, Au, and Ag particles (7–17 nm mean diameter) supported on carbon “nanotubes” (diameter = ca. 20 nm) via thermal decomposition (in  $\text{H}_2$ ) of metal salts impregnated from acetone or water solutions. On the basis of XRD analysis, these authors claimed that the same preparative route but employing conventional graphite or activated carbon supports yielded a wider diameter supported metal phase. The task of assembling the published studies of carbon nanofiber/tube-metal composite synthesis into a database from which common trends/critical variables can be extracted is, as of yet, unfeasible because of the incomplete procedural descriptions that are typically given, notwithstanding the inconsistent nanofiber/nanotube attributions. Nevertheless, the “inertness” of these structured carbon surfaces (as prepared) is a decided issue in determining the capacity for metal uptake and the ultimate metal dispersion. Carbon nanotubes in pristine condition certainly represent an unfavorable surface for metal attachment given the low surface area, absence of functionality, and limited surface defects. This apparent constraint can be circumvented by introducing carboxylic ( $-\text{COOH}$ ), carbonyl ( $-\text{CO}$ ), and hydroxyl ( $-\text{OH}$ ) groups by means of acid treatment and/or mild oxidation.<sup>[5,20,51]</sup> Such pretreatments generate oxygen-containing surface groups which can be acidic, neutral, or basic leading to modification of the point-of-zero charge and can also serve to increase nanotube surface area.<sup>[62]</sup> This facilitates the introduction of a metal phase by ion exchange<sup>[5]</sup> and precipitation,<sup>[62]</sup> preparative routes that are sensitive to solution pH and surface charge. Some final considerations worth flagging with regard to the incorporation of a metal phase onto SWNTs/MWNTs include the possibility of filling the tubes and intercalation of metal layers in the intertube spacing, issues that have been addressed to a limited extent.<sup>[51]</sup>

### Application of Carbon Nanofiber/Nanotube Supported Metal Catalysts

High surface area activated carbon is effective as a metal catalyst support, displaying the following positive attributes:<sup>[63]</sup> 1) structural resistance in acidic and basic media; 2) pore structure that can promote shape selectivity; 3) readily prepared in a variety of physical forms (granules, extrudates, pellets, cloths, etc.); 4) a hydrophobic surface that can be modified

**Table 1** Compilation of recent studies of structured carbon use as metal supports in catalysis applications

Supported metal	Nature of the carbon support	Source/method of carbon support synthesis	Method of metal introduction	Catalytic reaction	Reference

chemically to induce varying degrees of hydrophilicity; 5) active (precious metal) phase can be readily recovered from spent catalyst by burning away the carbonaceous support; 6) lower cost of production when compared with oxide supports. Drawbacks to the use of activated carbon as metal support in catalysis include 1) structural breakdown (gasification) at elevated temperatures in a hydrogenating or oxidizing environment; 2) microporosity that can impose transport constraints which lower reaction rate; 3) presence of mineral matter (ash content) that can act as catalyst poison. A move to structured carbon circumvents these shortcomings while retaining the positive traits of carbon as support material. A compilation of published reports of nanofibers/tubes use as catalytic metal supports is provided in Table 1. This list is not presented as definitive but covers those studies where the source of the carbon support (commercial or catalytically produced) and means of metal introduction are clearly stated, and the carbon supported metal has been employed in a catalytic reaction (operated in either gas or liquid phase): these critical process parameters are identified in Table 1. The one seemingly unavoidable ambiguity lies in the nomenclature adopted to categorize the carbon support—the designation adopted in Table 1 is that which is stated in each of the papers. It is, nonetheless, revealing that the BET surface areas associated with the tabulated systems extend from <20<sup>[64]</sup> to >200 m<sup>2</sup> g<sup>-1</sup>.<sup>[53,75]</sup>

To date, the majority of the “metals on structured carbon” studies have dealt with hydrogenation of

either aromatic<sup>[26,48,52,58,64,74]</sup> or aliphatic<sup>[55,56,65,69,70,71]</sup> reactants in the gas<sup>[18,61,62,69,73–75]</sup> or liquid<sup>[19,32,56,68,78]</sup> phase. Carbon nanofibers have apparently found a more widespread application than carbon nanotubes, in part because the larger surface area of the fiber facilitates higher metal loadings. The more instructive studies incorporated “conventional” metal supports as a means of assessing the role of structured carbon in governing the intrinsic activity of the supported metal under directly comparable reaction conditions. With this in mind, it is worth highlighting the examination of gas-phase phenol hydrogenation over supported Pd where the activity delivered by Pd/nanofiber was intermediate between Pd/graphite and Pd/activated carbon (the most active), a response that was attributed to Pd dispersion and metal/support interactions.<sup>[52]</sup> In addition, Pd supported on nanofibers outperformed Pd/charcoal in the liquid-phase hydrogenation of cinnamaldehyde<sup>[26,48]</sup> as a result of the higher surface area associated with the former in tandem with metal/support interactions. Electronic effects were also ascribed to the higher activity of a Ru–Ba bimetallic supported on nanofibers when compared with conventional activated carbon.<sup>[58]</sup> Moreover, gas-phase butene and butadiene hydrogenation activity sequence has been reported<sup>[69,70]</sup> to increase in the order Ni/Al<sub>2</sub>O<sub>3</sub> < Ni/activated carbon < Ni/nanofiber, an effect that was linked to support modifications to the metal particle morphology with possible electronic perturbation to the active sites where B and P doping of the substrate

was shown to influence activity/selectivity.<sup>[70]</sup> The same activity sequence applied to the gas-phase hydrogenation of crotonaldehyde,<sup>[55]</sup> where product (butanal, butanol, and crotyl alcohol) selectivity was found to be influenced by the metal/support interactions that governed the predominant exposed crystallographic face(s). Differences in activity delivered by Fe/Fe–Cu<sup>[56]</sup> and Rh<sup>[53]</sup> supported on nanofiber, activated carbon, and oxide supports in the ethylene hydrogenation and hydroformylation, respectively, were again associated with metal dispersion/morphology and electron transfer with the support. In the liquid-phase hydrogenation of cinnamaldehyde over Pd on carbon nanotubes and activated charcoal, hydrogenation rate was slightly higher over Pd/nanotube, but the selectivity toward C=C bond hydrogenation was significantly increased, a response that was largely attributed to differences in substrate porosity and surface/volume ratio.<sup>[64]</sup>

The presence of oxygen and hydrogen (up to 30 mol% H and 15 mol% O) in surface groups associated with activated carbon has been found to have a significant effect on adsorption properties and, consequently, catalysis.<sup>[9,63]</sup> Carbon–oxygen surface groups can be formed by reaction with oxygen or other oxidizing gases (ozone, nitrogen oxides, carbon oxides, etc.) or with oxidizing solutions (nitric acid, hydrogen peroxide, sodium hypochlorite, etc.). The oxygen-containing carbon nanofiber surface groups have been shown to have a considerable impact on the liquid-phase hydrogenation of cinnamaldehyde over supported Ru<sup>[74]</sup> and Pt,<sup>[81]</sup> where activity was raised by a factor of up to 22 on removing the carbon/oxygen groups and reactant adsorption on the nonpolar fiber surface facilitated hydrogenation. The catalytic use of carbon nanofiber supports in fuel cell applications has largely dealt with “direct-methanol” fuel cells to promote the oxidation of methanol to carbon dioxide and electric current.<sup>[66,67,78]</sup> Indeed, the enhanced electronic conductivity/mechanical strength/thermal-oxidative tolerance demonstrated by carbon nanofibers can translate into wide ranging potential applications in developing fuel cell technology. The tabulated (Table 1) applications that do not entail hydrogenation or oxidation processes include ammonia synthesis,<sup>[80]</sup> methane decomposition,<sup>[72,73]</sup> ammonia decomposition,<sup>[75]</sup> and hydrazine decomposition,<sup>[77]</sup> where the absence of residual impurities on the support, electronic conductivity, and metal dispersion all impacted on catalyst performance.

## CONCLUSION

A closer association of heterogeneous catalysis with structured carbon materials is now developing in terms

of 1) use of solid catalysts to synthesize carbon nanofibers/tubes and 2) subsequent application of the fibers/tubes as catalytic metal supports. Structured carbon materials exhibit unique chemical and physical properties with as of yet untapped potential. A realization of the full potential of these materials requires the development of low-cost methodologies for a controlled (reproducible) fabrication. Flame synthesis and arc discharge/plasma decomposition are very costly/energy demanding, and the yields of carbon are low, necessitating the involvement of exacting separation/purification steps. A catalytic route, employing unsupported and supported metals to decompose a carbon-containing precursor to a structured carbon product, offers a higher degree of control, less severe operating conditions, enhanced product selectivity, and a greater facility for scale-up. While the existing literature is somewhat discordant in the assignment of the term nanotube as opposed to nanofiber as a means of categorizing the carbon product, both forms exhibit a high aspect ratio and electron conducting properties; the higher surface area and enhanced thermal stability of the nanofiber are important considerations in many catalytic applications. Introduction of a metal phase by impregnation from an aqueous solution of the metal salt is problematic given the hydrophobic character of the carbon surface, but this can be alleviated by using organic solvents. Alternatively, the carbon surface can be functionalized by acid treatment and/or mild oxidation that also facilitates the incorporation of a metal phase by ion exchange or precipitation. The catalyst precursor so formed is activated by reduction to generate a supported zero valent metal phase that has been shown to exhibit quite distinct catalytic behavior (most notably in hydrogenation reactions) when compared with conventional activated carbon and oxide supported metal systems. The consensus emerging from the literature suggests that metal particle interactions with nanofibers/tubes are quite distinct as is manifest by modifications to metal particle size, morphology, preferred exposed crystallographic planes, and electronic structure, all critical factors in determining catalytic activity and selectivity. Further catalytic/characterization studies of different carbon supported metal systems with a consideration of promoters/inhibitors as dopants and a wider range of model reactions should lead to a better understanding of the source of what must for now be described as “unique catalytic behavior.”

## INTRODUCTION

The magnetic hard disk drive has become the foremost data storage device for computer applications based on cost, capacity, performance, and miniature form factor. Although it is a mechanical, rotating disk storage device, power requirements are minimal, usually a few watts; reliability over a wide range of operating environments, from below 0°C to well over 100°C, is excellent; and costs are less than \$0.01 per megabyte. Throughout its 46-year history, hard disk drives have been the recipient of significant technological innovations which have added to the usefulness of this device, and data density on the disk surface, areal density, has increased nearly 35 million times in this period (Fig. 1).<sup>[1]</sup>

The principal magnetic components in a drive are the media or disks, and a recording head that reads and writes data (Fig. 2). These data are recorded in the form of magnetized regions on the media within a deposited thin film of magnetic alloy normally consisting of chromium, cobalt, platinum, and a fourth component as boron. Data are distributed geometrically on a series of concentric rings, or tracks, whose location has been predetermined by a process called formatting. Along these tracks, bits of data are magnetically written by an inductive element in the head, and subsequently sensed or read by the giant magnetoresistive element that is an integral part of the head structure. Fig. 3 is a schematic of the writing process with a projection of the bit length and track width for a 100 Gb/in.<sup>2</sup> areal density. Writing involves a magnetic reorienting of the very small alloy micrograins in the media, and the interface between two magnetized bits is shown in Fig. 3. To maintain an adequate signal-to-noise ratio, a large number of grains are required per bit, nearly 1000 grains. Increasing areal density involves reducing bit dimensions, requiring smaller grain diameters. In the case of 100 Gb/in.<sup>2</sup>, a grain diameter of 5 nm is projected.

Fig. 4 illustrates the history of magnetic recording head design since 1970. The transition from a ferrite, wire-wound inductive head to a thin film head in late

1970s to early 1980s was driven by progressive areal density increases. In both of these early designs, an inductive element performed both read and write functions. As areal density increased beyond 0.10 Gb/in.<sup>2</sup>, this inductive element proved inadequate to maintain an acceptable signal-to-noise ratio in reading and, in addition, the read amplitude was velocity-dependent. A second element was added to recording heads, a simple magnetoresistive (MR) [or anisotropic magnetoresistive (AMR)] sensor that now separated read and inductive write parts of the head, but shared common elements or layers of the structure. The MR element used a nickel-iron (NiFe) ferromagnetic film that consequently changed resistance when experiencing a magnetic field originating from stored bits on the rotating disk media. This modification allowed the write element to be more easily built with fewer copper coil turns than inductive heads that perform both read and write operations.

As areal densities continued to increase beyond 10 Gb/in.<sup>2</sup>, scaling of the MR element to smaller dimensions based on reading submicrometer tracks also reduced signal amplitude. A new read sensor technology was required.<sup>[2,3]</sup>

## GMR HEAD DEFINITION

In 1988, a new magnetoresistive effect was discovered in Germany and France, identified as the giant magnetoresistive (GMR) effect, using multilayers of chromium and iron synthesized by molecular beam epitaxy. When this Cr/Fe structure was tested at liquid helium, cryogenic temperatures in very strong magnetic fields of several thousand Oersteds, or about 100 times greater than what would be obtained from a rotating magnetic media in a disk drive, the result was a resistance change of as much as 50%.<sup>[4]</sup> This newly observed behavior was of great interest to magnetic recording scientists. An application of GMR as a sensor element to magnetic recording would be very valuable at high data densities, where scaling sensor dimensions into the nanometer range could still yield a readable room temperature signal amplitude, or resistance change in

Fig. 1 Hard disk areal density trend.

the presence of a magnetic field of a magnitude experienced with a recorded disk.

Subsequently, IBM researchers demonstrated that the origin of the GMR effect arose from electron spin scattering in ferromagnetic materials. Using conventional vacuum sputtering techniques, unique thin film structures were shown to exhibit the GMR effect at disk drive operating temperatures and in low magnetic fields.<sup>[5]</sup> Whereas in the early investigations, a strong antiparallel (AP) coupling within the Cr/Fe layers was the origin of GMR, IBM researchers found that the interaction of a magnetically fixed or pinned ferromagnetic layer and a magnetically free ferromagnetic layer separated by a highly conductive, non-magnetic spacer also produced the GMR effect. This free layer was free to rotate, responding to external magnetic fields from the disk, while the pinned layer remained magnetically fixed. Control of the spin-dependent current and a valve-like similarity to tunneling between

ferromagnetic layers prompted the label “spin valve” for this structure.<sup>[6]</sup>

The GMR effect varies as the cosine of the angle of magnetizations between pinned and free layers (Fig. 5), varying as

$$\cos(\theta_{\text{free}} - \theta_{\text{pinned}}) = \sin(\theta_{\text{free}}) \quad (1)$$

Considering that  $\theta_{\text{pinned}} = \pi/2$

Therefore the voltage of a spin valve, GMR sensor with width  $W$ , height  $h$ , resistance  $R$ , and a relative term called magnetoresistance  $(\Delta R/R)_{\text{GMR}}$  with current  $I$  passing through the structure is given by:

$$V_{\text{GMR}} = I\{R + (W/2h)(\Delta R/R)\eta \sin \theta_{\text{free}}\} \quad (2)$$

where  $\gamma$  is an efficiency factor which includes any misalignment of the magnetization based on demagnetizing effects.

Fig. 6 shows the read head progress for the transition to giant magnetoresistive heads (GMR) and the accompanying bit pitch and track pitch evolution including projections for future years. These advanced GMR read elements could be composed of multiple films with a total thickness of as small as  $0.01 \mu\text{m}$  with a contact-contact spacing of less than  $0.2 \mu\text{m}$ . These ultrasmall dimensions qualify GMR sensors as nanotechnology devices.

Both MR and GMR read head electrical resistance depends on a magnetic field produced by the recorded information on the disk. In the previous MR heads, this resistance change occurs in a single NiFe film, while in GMR heads, this resistance change occurs in multiple films. Whereas in a conventional NiFe MR film, the resistance change is maintained as a linear response to the disk’s field based on the

Fig. 2 Magnetic hard disk drive components.

Fig. 3 Magnetic recording basics at 100 Gb/in<sup>2</sup>.

close interaction of a magnetically soft adjacent layer (SAL), and the GMR response is intrinsically linear.<sup>[7]</sup>

There are four fundamental film types in a conventional GMR structure, although some of these films may be comprised of multiple subfilms. Fig. 5 is a cross section of a GMR read sensor and overlying inductive write element through the air bearing surface (ABS). The plane of this figure is parallel with the disk media. A GMR or free film has a variable magnetization that changes under the influence of the disk's magnetic field. The second film is a very thin conducting spacer, usually copper, with a thickness less than the mean free path of electrons. This film allows electrical current to

pass easily to the third film, also a GMR film, which has a fixed or pinned magnetization. The fourth film is a pinning film which maintains the fixed magnetization of the third film through the process of antiferromagnetic exchange coupling. Typical antiferromagnetic exchange films contain the element manganese alloyed with either iridium, platinum, or iron. In contact with both ends of the GMR film stripe is a magnetically hard region, usually composed of an alloy of chromium, platinum, cobalt, and boron. These regions maintain a stability to the GMR sensor by suppressing magnetic domain noise through the use of a longitudinal bias applied to both ends of the GMR multilayer region.

Nanodiamonds -  
Nanolithography

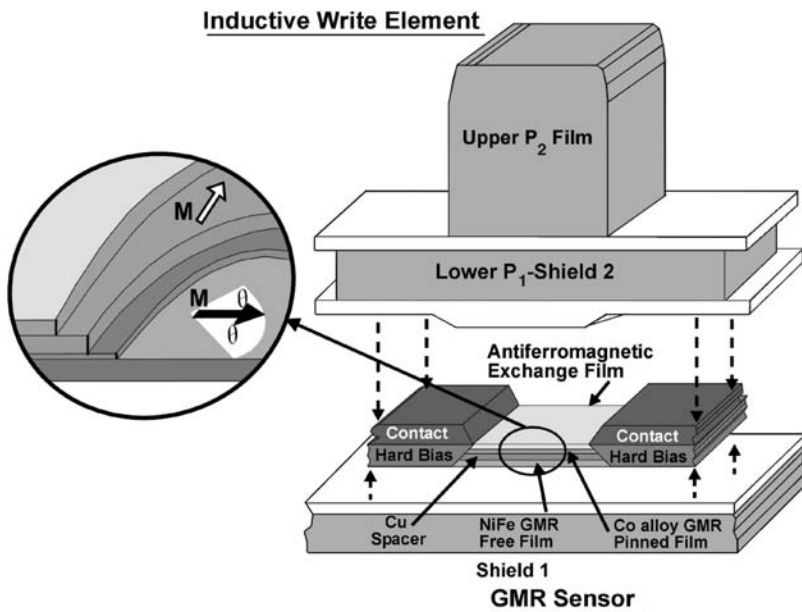

Fig. 5 GMR read sensor with section of inductive write element.

**THE GMR EFFECT**

GMR read sensors exploit the quantum nature of electrons, which have two spins, spin up and spin down. Referring to Fig. 7, a view of a GMR sensor with ABS perpendicular to the plane of the page, the multi-film structure is indicated with antiferromagnetic exchange layer, pinned layer, spacer and GMR free

layer with hard bias, stabilizing end regions, and electrical contacts. The electrical conductivity of this multi-film structure is proportional to the mean free path of electrons and the density of electrons in the films' materials. The mean free path is the distance an electron travels before a scattering event occurs, i.e., the loss of momentum through collisions with phonons or magnons within the material's lattice. Therefore,

Nanodiamonds – Nanolithography

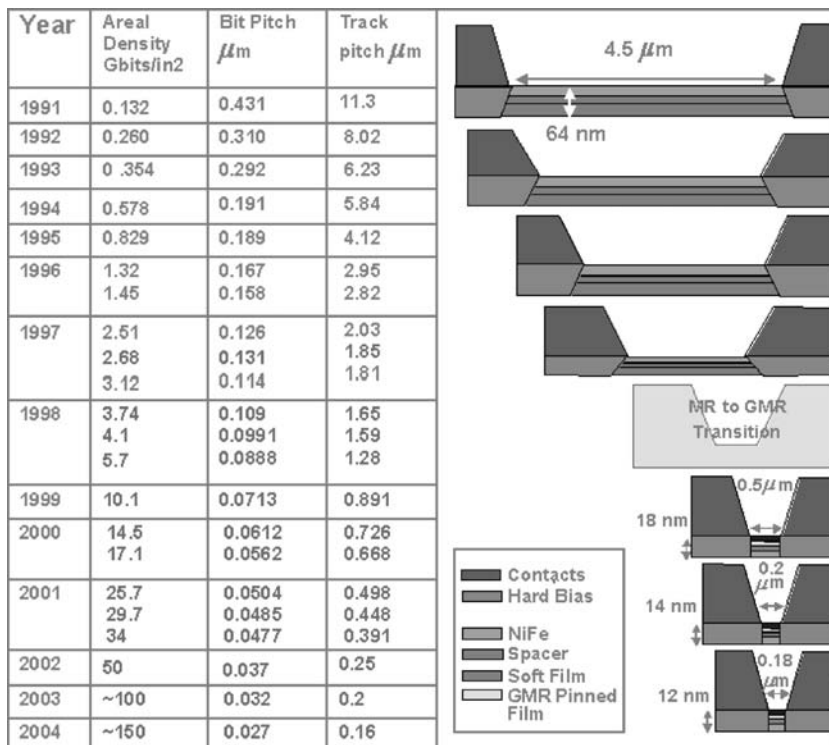

Fig. 6 MR/GMR read head evolution.

Fig. 7 GMR/spin valve operation. Source: From Ref.[2].

electrical conductivity depends on the amount of electron scattering that occurs within the multifold structure. Electron spin generates a magnetic dipole, analogous to the magnetic dipole originating from electrical current flowing within a loop of conducting wire. Electron scattering can be observed to be more prevalent in films having an opposing magnetization, i.e., mean free paths of electrons are spin-dependent.<sup>[8]</sup>

Conductivity depends on the ability of electrons to traverse the entire multifold structure, without collisions, and both spin up and spin down electron mean free paths are determined by the relative orientations of the magnetizations within each film. In Fig. 7, if these magnetizations are all parallel, as would be the case if the free NiFe layer senses a magnetic field originating from the disk media, the spin up electron's path through the free layer, across the Cu spacer, and penetrating far into the pinned layer results in a low resistance (high conductivity). Spin down electrons undergo collisions in both free and pinned layers and do not add to the conductivity. In fact, spin down electrons would not be able to penetrate far beyond the spacer layer before colliding. If all the magnetizations are antiparallel, as would be the case when no magnetic field from the media is present and the magnetization of the free layer is reversed, the distance of both spin up and spin down electrons is reduced by collisions so that neither can penetrate far beyond the spacer layer. This is the high resistance case. It can be demonstrated that the difference in conductivity between parallel and antiparallel cases for the GMR sensor can be expressed as:

$$\Delta C_{total} = \alpha(\lambda^+ - \lambda^-)^2 \quad (3)$$

where  $C$  is the sensor conductivity,  $\alpha$  is a proportionality constant,  $\lambda^+$  is the mean free path of electrons with spin parallel to the magnetization, and  $\lambda^-$  is the mean free path antiparallel. Typical GMR sensors exhibit conductivity changes of 10% from antiparallel to parallel states, although values larger than 20% have been reported in the laboratory.<sup>[9]</sup>

### INTERNAL MAGNETIC FIELDS IN GMR STRUCTURES

Fig. 8 demonstrates a GMR/spin valve linear voltage response to a changing external disk media magnetic field, which is the read process in magnetic recording. To design an efficient GMR read structure, the full linear portion of this curve is the operating response region, and is obtained by matching the free layer

Fig. 8 Spin valve response to disk magnetic field.

magnetic moment with the magnetic flux originating from the disk media.

$$M_{st} \sim M_r d \tag{4}$$

where  $M_s$  is the magnetization and  $t$  is thickness of the GMR free layer and, conversely,  $M_r$  and  $d$  are the magnetization and the thickness of the disk media layer. The GMR voltage, and therefore  $\sin \theta_{free}$ , is proportional to the time-varying disk field  $H(t)$  applied along the structure's transverse direction. The free layer magnetization is normally oriented  $90^\circ$  to this field, along the longitudinal direction of the sensor when no disk field is present, previously shown in Fig. 5. For this magnetic field "balancing" between GMR and disk moments to be effective, the net of all other magnetic forces within the GMR free layer must be zero, as shown in Fig. 9. This design objective is often referred to as the "proper bias" of the GMR read head, so that

$$H_{pinned} + H_{inter} + H_{elect} = 0 \tag{5}$$

where  $H_{pinned}$  is the magnetostatic field arising from the pinned layer,  $H_{inter}$  is the spacer coupled field between pinned and free layers, and  $H_{elect}$  is the normal induced field arising from electrical sense current flowing within the free layer. Also shown in Fig. 9 are the shield structures that function to isolate the GMR sensor from adjacent disk media magnetic fields, assuring that only one specific magnetized region of transition is read at a time. In many GMR designs, the overlying

$$H_{pinned} + H_{inter} + H_{current} = 0$$

Key: Electrons shared between layers

Fig. 9 Spin valve head (GMR) internal magnetic fields.

inductive head  $P_1$  element also serves as one side of the shield structure (Fig. 5).

### GMR STABILIZATION

Figs. 5–7 show a magnetic hard bias region contiguous to the GMR element which adds a longitudinal magnetic bias to the structure. As in MR read heads, complex multidomain regions within the NiFe free layer must be prevented from forming within the thin film. These regions would promote Barkhausen induced noise effects in the GMR sensor read back signal. Unlike the prior MR read head structures, in GMR read heads, only the free layer must make contact with the hard bias end regions because the pinned and exchange regions have a fixed magnetization in a direction perpendicular to the current flow (transverse direction). During processing, the pinned and exchange layer's magnetization is oriented by heating beyond the "blocking temperature," i.e., the temperature above which magnetization reverts to a very low value (Fig. 10). A cooling cycle in a transverse magnetic field determines the final pinned layer's magnetic orientation. As the hard bias end regions are also magnetically oriented, but in the longitudinal direction, the alloy selection for this film as well as the pinned layer is critical, based on blocking temperatures. Usually, an alloy of CoPtCr is selected for the hard bias region because its longitudinal magnetization is not affected by the thermal cycle required to set the pinned layer's transverse orientation. In addition, the pinned layer's blocking temperature must still be high enough to remain stable during heat cycling in subsequent process operations. Table 1 shows the blocking

Fig. 10 The blocking temperature.

**Table 1** Comparison of antiferromagnets for GMR/spin valves

Antiferromagnet	Blocking temperature [°C]	Exchange energy [erg/cm <sup>2</sup> ]	Critical thickness [Å]

temperature for some common antiferromagnetic alloys used in GMR heads.

### ANTIFERROMAGNETIC EXCHANGE COUPLING

Exchange coupling is a principal mechanism that determines GMR head operation, and it may be considered as the interaction between a ferromagnet (NiFe in this case) in contact with an antiferromagnet, with sample compositions as shown in Table 1. Referring to Fig. 11, a ferromagnetic material is defined as one in which all atomic dipole moments line up in the same direction; whereas in antiferromagnetic materials, the

moments of adjacent atoms line up in opposite directions. In the former material, there is a net magnetic moment while in the latter there is no net macroscopic moment. Exchange may be defined as the tendency for neighboring atomic dipoles to line parallel or antiparallel to each other, and it results from the overlap of orbiting electrons in neighboring atoms. Exchange may occur within the same material or in two different adjacent materials. In the latter case, because exchange principally occurs across distances between atoms in a solid, it can be considered a near-neighbor phenomenon and is critically dependent on the quality and purity of the interface.

If an antiferromagnetic film is deposited onto a ferromagnetic film by vacuum sputtering, a clean, contaminant-free interface results, and the atoms align themselves by exchange so that a permanent biasing layer is created, which maintains the ferromagnet oriented in a constant direction. The B/H hysteresis loop of a ferromagnet/antiferromagnet structure is shifted by an amount  $H_x$  and is a direct measure of the amount of exchange coupling occurring across the interface. The ideal antiferromagnetic material would basically be an insulator with a high exchange energy, a high blocking temperature for process stability with a narrow blocking temperature range and distribution, and with a small critical thickness.<sup>[6]</sup>

**Fig. 11** Ferromagnetic/antiferromagnetic interface structure. Source: From Ref.<sup>[11]</sup>.

### MORE COMPLEX GMR STRUCTURES

In a nanolayer GMR structure, thin (as small as a monolayer) films of Co or Fe are added to NiFe free layer / Cu spacer interface, resulting in an increase in the GMR signal amplitude up to 50%. These nanolayer films are believed to reduce the spin-dependent scattering at the interface by improving the interfacial purity of the NiFe, which could be lost by mixing with Cu during the sputtering process. The nanolayers may be

added to the NiFe free layer, or the pinned layer, or both, and many GMR read head structures attain higher GMR amplitudes through the use of nanolayers.

In a dual spin valve or dual GMR structure, the NiFe free layer is surrounded with two Cu spacers, as well as two pinned and antiferromagnetic exchange layers in an almost symmetrical configuration. This can be considered as a combination of two simple GMR structures, back-to-back and sharing a common free layer. In this case, a majority of electrons originating from this free layer can now reach a pinned layer, eliminating any electrons from these layers that do not participate in the GMR effect. It is estimated that an increase in the GMR amplitude reaches up to 33% for the dual structure. In addition, because the GMR structures are mirror images of each other, the current induced field is effectively cancelled so that proper biasing may occur independent of applied current. Conversely, because more films are involved in the dual GMR structure, the resulting resistance of the structure is lower, and this may lead to a lower overall GMR signal.

Depositing an additional layer of ruthenium or rhodium within the pinned layer was shown to stabilize the magnetization of this film and enhance the exchange field. This could allow the use of many more antiferromagnets, which previously did not have adequate fields, but had other beneficial characteristics such as higher blocking temperatures or better insulation properties. Based on the phenomenon of antiparallel (AP) coupling, the pinned layer now consists of two ferromagnetic films separated by the AP-spacer layer. This increased stabilization can also be the result of decreasing the demagnetizing field in the pinned layer, thereby reducing any rotation of the magnetization. It is estimated that a 25- to 100-times improvement in pinned layer stabilization results from AP pinning and, as areal density increases necessitate narrower and shorter GMR structures, this technique is expected to become more prevalent in read heads.

The use of a thin interposed layer of a non-magnetic metal, such as ruthenium, to create a coupling effect between two ferromagnetic layers to retain opposite magnetic orientations was recently extended to the magnetic disk structure.<sup>[11,12]</sup> This media structure, termed antiferromagnetic coupled (AFC) media, was demonstrated to exhibit good magnetic stability as areal density increases beyond 30 Gb/in.<sup>2</sup>, thereby delaying the effects of superparamagnetism. The latter phenomenon occurs when metal grains within the media become so small that the energy required to create or erase the bits of magnetically stored information is the thermal energy ( $kT$ ), where  $k$  is the Boltzmann constant and  $T$  is the operating temperature of the disk

drive) of the environment.<sup>[13]</sup> Ruthenium thicknesses of 6C( about three atomic layers) are commonly used because coupling strength oscillates with film thickness. It was found that at a thickness of maximum strength, electron waves in this ruthenium spacer constructively interfere and allow the magnetically polarized energy from one interface through to the other ferromagnetic layer. The AFC medium is projected to find application in magnetic storage for many years to come.

## GMR PROCESSING–LITHOGRAPHY

Fig. 1 indicated a 100% growth rate in areal density for magnetic recording since 1997, based on the use of GMR read sensors, in effect doubling this parameter every year. This density increase in magnetic recording originates from a shrinking in the bit cell area, which results from lithographic and processing improvements. This is in contrast to the integrated circuit (IC) field in which the transistor count in an IC device doubles every 1.5 years (roughly 60% growth rate). In the latter case, only about one-third of this increase originates from a transistor cell area or lithographic improvements. This is shown in Fig. 12, where historical IC, general IC, and IC gate features are compared with historical magnetic recording head, inductive write head width, and GMR element length. The critical head dimensions, P2w (or write width) determines the track width and GMRw, the read width for the track.<sup>[14]</sup>

It is convenient to describe the fundamentals of processing for both inductive write element and GMR read sensor, which are both integrated into a single read/write structure. The actual head processing is similar to thin film integrated circuit processing, and consists of a sequence of patterning by application of

Fig. 12 Lithographic critical feature roadmap for GMR heads and semiconductor IC.

Fig. 13 Partial microphotograph of inductive write, GMR read head.

photoresist, masking and exposure operations (lithography), film deposition, and localized material removal by etching to create the various layers and structures. In addition, the use of lift-off operations, as well as highly directional etching as special techniques for the control of vertical and horizontal dimensions of critical features, is required at these feature sizes and topographies. Fig. 13 is a top view microphotograph of the head structure and Fig. 14 identifies the principal parts as seen from this view. It can be seen that only the overlying inductive write element is visible. In Fig. 15, the actual vertical structure is indicated, in which the GMR sensor is first formed by successive depositions followed by a series of insulators and metal films which comprise the inductive element. The total device structure consists of the order of 20 layers, ranging in thickness from as thin as 1–2 nm in the GMR sensor to 3–4 μm for the pole tip of the inductive write element. Progressively higher areal densities were achieved by reducing both critical

Fig. 14 Thin film head, top view.

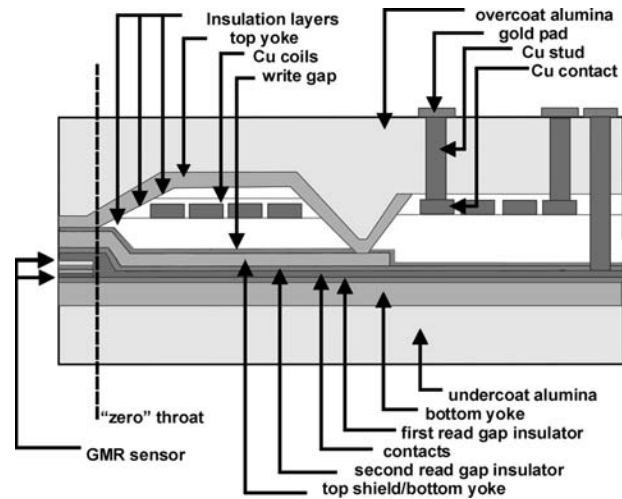

Fig. 15 Thin film head, side-section view.

thicknesses and horizontal dimensions of the head structure in a process referred to as scaling. Over the past 10 years, areal density has increased by a factor of 400, which has required a GMR sensor thickness decrease of a factor of 10–15, the sensor width MRw decreased by a similar factor, and the inductive pole tip width P2w scaled down also by a similar factor. It can be projected that further areal densities increases, which are expected as the norm in magnetic recording although probably not retaining the previous 100% growth, will involve continual decreases in these critical dimensions well into the subnanometer range for vertical GMR dimensions, and into the submicrometer range for the horizontal dimension of P2w.

An outline of typical processing operations for both inductive and GMR structures for the read/write head is shown in Fig. 16. There are four fundamental, generic operations which involve specific equipment and processes, and these are very similar to those employed in IC processes. Photo, involving the application of a

Fig. 17 Inductive head P2w processing.

photosensitive resist film and its subsequent exposure by a photo mask and UV light source; plating, or electroplating, the formation of a relatively thick metal film by an electrolytic process (this operation usually requires the preformation of a metal seed film to complete the electric circuit prior to plating); deposition, usually referring to a vacuum sputtering operation in which very thin metal films are accurately formed with precise control of composition, magnetic orientation, and crystallographic structure; and finally, patterning, which denotes the formation of elements of the head by either subtractive etching or “a lift-off” process. The latter can be illustrated by an example of the formation of the inductive pole structure, or P2w, as shown in Fig. 17. This material removal technique is applied to maintain tight control of vertical walls of a very small horizontal pattern, which is usually of the order of  $\mu\text{m}$  thick, i.e., has a high aspect ratio of as much as 10:1. As soon as the seed layer is applied and resist pattern formed in Fig. 17, the thick P2 NiFe film is electroplated. The center region is protected with a new field removal resist and exposed.

After stripping this resist and etching both field film and seedlayer, the final pole region remains. The particular topography of this P2 film originates from the requirement that the inductive yokes must encircle the copper coils and insulator layers, as shown in Fig. 15. This yoke topography for the head conforms to the multiple layers of polymers and coils, and the resulting head topography can be greater than  $10\ \mu\text{m}$ . “Zero throat” in this figure refers to the point at which the inductive throat begins and is defined by the edge of one of the polymer insulators.

## GMR PROCESS

For the formation of a GMR sensor, referring to Fig. 15, the GMR gap consists of two dielectric layers which electrically isolate the contacts and sensor from

Fig. 18 GMR head MRw processing.

the surrounding shield and inductive element. Furthermore, these electrical contacts and sensor are connected via a contiguous junction process in which a degree of geometric overlapping results. The horizontal dimensions for MRw, as well as the previous example of frame plating for P2w, require a fine-line lithographic equipment and process to form the images. These sensor dimensions define a trackwidth capability on the disk and, as areal density evolves to increased levels, these dimensions become progressively smaller. The contiguous junction process uses a critical lithography step with about  $1\ \mu\text{m}$  thick resist to form this trackwidth by a similar process to P2w—the use of a resist mask to protect the active GMR region during the subtractive removal of sensor material to define the GMR dimensions. This etching process, shown in Fig. 18, is a resist structure which exhibits a reentrant or negative wall angle and, therefore, subsequent depositions of contact metal and hard bias stabilization films do not completely seal the resist edges. This allows the resist “stencil” to be removed in this lift-off process based on the exposure of the undercut region by the dissolving in the appropriate solvent. The stencil is actually floated away in this solvent, leaving the GMR sensor defined by this structure. Subsequent processing and layers form the inductive write element.

## FUTURE SCALING OF GMR NANOLAYER SENSORS

As was previously indicated, areal density increases require further reduction in MRw by scaling of MRw in an evolutionary trend described in Fig. 6. The process challenge is to create submicrometer openings with a controlled undercut in the resist images. For example, if a future trackwidth is  $0.3\ \mu\text{m}$ , this would result in a  $0.1\text{-}\mu\text{m}$  undercut, which also would be the base dimension of the resist structure overhang, a dimension that could reduce the structural integrity

of this resist structure at its base. In addition, this overhang also determines the amount of contact to sensor overlap at the junction region, inferring that the read sensor trackwidth is fixed by both the image resist as well as control of the undercut. Future GMR sensor processing must address both image size in the resist, as determined by the exposure tool and process, as well as image profile in the resist.

The above discussion addresses track density, but another important factor for future GMR structures is scaling of thickness of the GMR sensor to higher linear (bit) densities. The GMR sensor layer thickness must be decreased to allow it to be saturated by progressively smaller magnetic transitions originating from the disk. In addition, the shield separation above and below the GMR sensor is determined by two dielectric thicknesses—top and bottom. At today's areal densities of 40 Gb/in.<sup>2</sup>, shield separations are approximately 70 nm; and the films that comprise a GMR sensor, the NiFe free layer, spacer layer, pinned layer, and antiferromagnetic exchange layer are about 2, 2, 2, and 15 nm, respectively. The latter would not be expected to scale to a smaller thickness because this value is determined by antiferromagnetic coupling to the pinned layer. Future areal density increases require that top and bottom insulating layers must be reduced to less than 25 nm, and that GMR free, spacer, and pinned films must all be less than 2 nm. It will be a challenge to demonstrate insulating layers with a high degree of electrical integrity. It does seem reasonable that this challenge will be met.

## POTENTIAL DESIGN CHANGES IN GMR SENSORS

As future scaling requirements reduce the vertical dimensions of GMR sensors, a reduction in the width of this element can also be expected. It is proposed that there is a critical width dimension, as well as a critical NiFe thickness, where the GMR effect is reduced to a very low value, i.e., the  $\Delta R/R$  of the sensor approaches a value where the resulting signal-to-noise ratio does not permit accurate reading of the data. One solution to this reduced GMR effect is to pass the sense electrical current normal to the sensor as opposed to a longitudinal direction, along the long axis of the element. This type of device, known as current perpendicular to the sensor's plane (CPP), is a significant excursion for today's current in-plane (CIP) GMR devices, and is being studied in many laboratories. A variation of this concept is to replace the metallic spacer with a very thin insulator, of the order of a few angstroms in thickness. In this structure, known as a tunnel valve or tunnel junction device, current carriers are able to tunnel through the thin insulator film

when magnetizations on either side are parallel, and are prevented from tunneling in the antiparallel case. Preparing a very thin insulator that is pin hole-free is a significant process challenge. The CPP read device may become important as areal densities increase well beyond 100 Gb/in.<sup>2</sup>.

## CONCLUSION

The GMR nanotechnology was shown to enable large areal density increases in magnetic hard disk drives, which have occurred rapidly in the past 5–10 years.<sup>[13,16]</sup> Based on the importance of magnetic storage to the computer age, a significant research-and-development effort is being maintained on a worldwide basis to enhance the read capability of GMR technology for higher areal densities, and this involves the exploration of new magnetic materials, scaling down sensor horizontal and vertical dimensions, and finally, considering alternative structures based on today's GMR sensors.

## ACKNOWLEDGMENT

The authors would like to express their appreciation to Bruce Gurney, of the IBM Almaden Research Center, for his scientific contributions to this manuscript and for his review of the final document, and for the research efforts of Dr. Gurney and many other IBM Almaden colleagues for their contributions to GMR. Additionally, the graphics and document support of Michael Xu, also of Almaden, is acknowledged.

# Nanofiltration Separations

Eric M.V. Hoek

Anna Jawor

Department of Chemical and Environmental Engineering, University of California–Riverside, Riverside, California, U.S.A.

## INTRODUCTION

The term “nanofiltration” (NF) generally refers to a class of pressure-driven membrane separation processes whereby nanometer- or larger-sized substances may be selectively removed from a carrier fluid. The name “nanofiltration” is derived from two phrases. The prefix “nano” means 1 billionth. Hence, 1 nm has a value of  $10^{-9}$  m or 10 Å. The suffix “filtration” refers to a process whereby solutes are physically separated from a solvent by passing the solution through a semipermeable barrier or medium.<sup>[1]</sup> The review that follows intends to introduce the reader to the basic concepts of nanofiltration separations, the material properties of NF membranes, the common applications of NF separations, the theory and models describing NF separation performance, and some performance limitations.

## NANOFILTRATION BASICS

Membrane processes are advanced filtration processes, which utilize separation properties of finely porous polymeric or inorganic films and are used in a wide range of industrial processes to separate biological macromolecules, colloids, ions, solvents, and gases. The development and application of membrane separation processes is one of the most significant recent advances in chemical, environmental, and biological process engineering. Membrane processes are commonly distinguished based on the main driving force, which is applied to accomplish the separation. An overview of the driving forces and related membrane separation processes is given in Table 1.<sup>[2]</sup>

Nanofiltration falls into the category of pressure-driven membrane processes, and it fills an important gap between ultrafiltration (UF) and reverse osmosis (RO). Ultrafiltration processes are intended to remove all particles, colloids, and large macromolecules, while passing small macromolecules and dissolved substances. Reverse osmosis membranes are designed to separate all dissolved solutes from their carrier solvent down to monovalent ions, dissolved metals, and

organics above a few hundred daltons (Da). Nanofiltration was originally conceived to perform water softening (i.e., removal of divalent ions in water production), but more generally intends to remove, selectively, a particular solute (e.g., divalent ion) while allowing another solute (e.g., monovalent ion) to pass with the solvent through the membrane. Fig. 1 provides another perspective of various pressure-driven filtration processes and the substances they are intended to remove.

In nanofiltration processes, a selective separation takes place across a semipermeable separation layer, which is formed over the top of a porous support. The driving force of the separation process is the pressure difference between the feed (retentate) and the filtrate (permeate) side of the separation layer of the membrane. The size of NF membrane pores in combination with the surface electrical properties allows divalent ions and uncharged solutes larger than a few thousand daltons to be highly retained, while monovalent ions and low-molecular weight organics are reasonably well transmitted. The nominal *molecular weight cutoff* for many commercially available nanofiltration membranes ranges from a few hundred to a few thousand daltons.<sup>[3]</sup> These characteristics make NF membranes extremely useful in the fractionation and selective removal of many dissolved solutes from complex process streams. Other advantages include high flux and low energy consumption (because of low operating pressure requirement), as well as reduced environmental impact compared with conventional processes such as evaporation and extraction.<sup>[4]</sup>

## MATERIALS

Nanofiltration membranes are characterized by pore diameters of about 5 Å to 5 nm and operating pressure between 5 and 40 bars. Because they significantly reject many ions, NF membranes are often wrongly categorized as “loose RO” membranes. The most notable difference between RO and NF is the ability of NF to highly reject multivalent ions, while significantly passing monovalent ions. Another distinctive feature of NF membranes is their ability to reject uncharged,

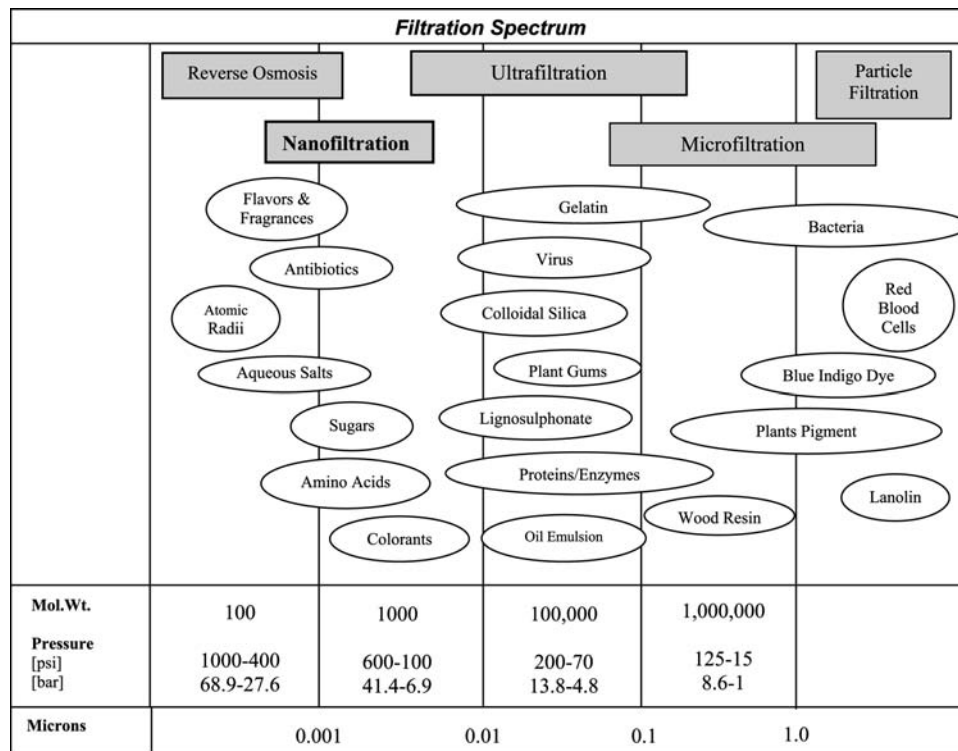

**Table 1** Driving forces and their related membrane separation processes

Driving force	Membrane process
Pressure difference	Microfiltration, ultrafiltration, nanofiltration, reverse osmosis
Chemical potential difference	Pervaporation, dialysis, gas separation, liquid membranes
Electrical potential difference	Electrodialysis, membrane electrolysis
Temperature difference	Membrane distillation

dissolved materials and positively charged ions according to the size and shape of the molecule in question. These selective separation capabilities are directly related to the membrane material properties.

It is widely known that retained organic and colloidal matter may adhere strongly to polymeric surfaces through non-covalent interactions—such as those arising from van der Waals, electrostatic, and acid–base properties of the polymer materials—and cause severe performance decline.<sup>[5–12]</sup> Nanofiltration membranes often become “fouled” by dissolved organic and colloidal matter, which is ubiquitous in many natural and industrial waters. Hence one of the challenges from a materials perspective is to create a membrane with optimal pore size, surface charge, and hydrophilic nature to effect a highly selective separation with low energy consumption, while minimizing the adhesion for fouling materials.

The array of membrane materials to select from includes polysulfone, polyethersulfone, sulfonated polyethersulfone, cellulose acetate and its derivatives, polyethylene, polypropylene, polyvinyl alcohol derivative, polyamide, polyacrylonitrile, polyvinylidene fluoride, organo-mineral complexes, ceramic, alumina, and other metal oxides.<sup>[13–18]</sup> The polysulfone materials dominate UF/MF applications for water and wastewater treatment, while contemporary RO/NF membrane usage is almost entirely limited to polyamide-based thin-film composites. Although cellulose acetate (CA) technology predates other membrane types and remains relatively inexpensive to purchase and install, the use of cellulose acetate membranes has largely been displaced by polyamide thin-film composite membranes today. Across the range of possible materials, there are two basic material types: integrally skinned asymmetric layers and thin-film composites.

**Fig. 1** Diagram known as the “filtration spectrum,” indicating schematically the place of nanofiltration among other common pressure-driven filtration processes.

## Integrally Skinned Asymmetric Membranes

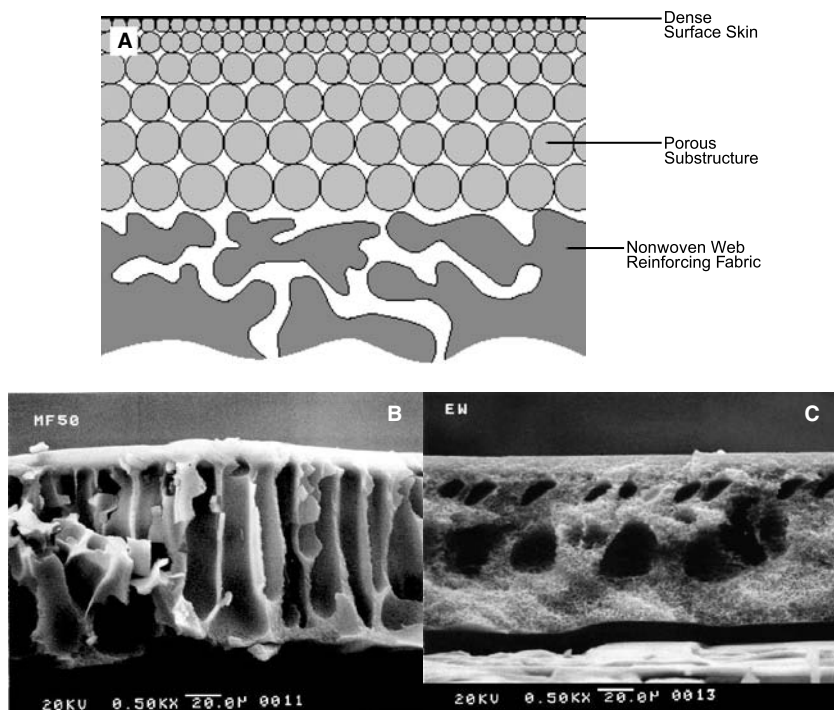

Polymeric asymmetric membranes may be prepared through a phase inversion technique. Phase inversion is a process whereby a polymer is transformed in a controlled manner from a liquid to a solid state.<sup>[16]</sup> The cross section of an integrally skinned, asymmetric phase-inversion membrane is schematically illustrated in Fig. 2(A). The most popular phase-inversion membranes may be constructed from cellulose acetate (CA), cellulose diacetate (CD), regenerated cellulose (RC), polysulfone (PS), polyethersulfone (PES), sulfonated PS or PES, polyacrylonitrile (PAN), or polyvinylidene fluoride (PVDF). Scanning electron microscope (SEM) images of PAN and PS membrane cross sections are presented in Fig. 2(B) and (C), respectively.

Polysulfone membranes formed by phase inversion are used as microfiltration or ultrafiltration membranes, or as the support layer upon which a thin-film composite RO or NF membrane is formed. However, because we have defined nanofiltration as a process by which nanometer-sized or larger-sized substances are removed from a liquid feed, any material used to perform such a separation may be considered a “nanofiltration membrane.” A characteristic of the PS membranes is that an increasing degree of sulfonation correlates with increasing water permeability and salt rejection.<sup>[19,20]</sup> Dense-skinned phase inversion membranes composed of cellulosic materials typically function as reverse osmosis membranes.

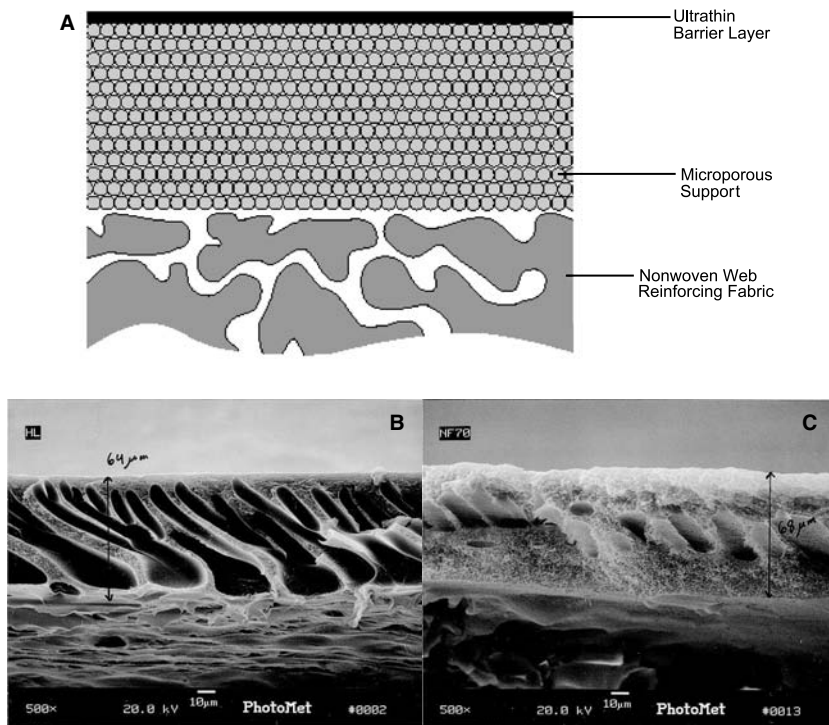

## Organic Thin-Film Composite Membranes

In 1978, efforts to improve the performance of “poly” membranes by Cadotte et al.<sup>[21]</sup> yielded composite membranes having excellent combinations of high salt rejection and water permeability. Cadotte et al.’s ideas were developed at FilmTec Corporation into a reverse osmosis/nanofiltration membrane product designated as “FT30.” The FT30 membrane is a thin-film composite membrane consisting of three layers: a polyester support web, a microporous (polysulfone) interlayer, and an ultrathin polyamide barrier (skin layer) on top. Fig. 3(A) provides a schematic illustration of a generic thin-film composite (TFC) membrane construction resembling that of FT30.

There are several clones of the FT30 membrane that are now commercially available; some are made under license from FilmTec and others are made by other proprietary synthetic routes. The skin layer of NF membranes may be as thin as 50 nm in cross section up to several hundred nanometers. The composite structure of two commercial NF membranes can be seen in the field emission SEM images of Fig. 3(B) and (C). The surface properties of TFC membranes have been studied extensively, largely in efforts to understand the role of surface properties on separation performance and fouling. In particular, studies focusing on surface charge/potential, hydrophobicity, and roughness dominate the literature (see “Membrane Properties and Performance”).

**Fig. 3** Cross-section illustration of (A) thin-film composite membrane, plus SEM cross sections of two commercially available polyamide membranes manufactured by (B) GE-Osmonics Inc. and (C) Dow-FilmTec. *Source:* illustration in (A) was adapted from Ref.<sup>[60]</sup>.

### Inorganic Thin-Film Composite Membranes

Ceramic composite membranes have been used in a number of industrial separations. They are synthesized from dispersions of silica, titania, or other metal oxide nanoparticles that are forced to agglomerate on the surface of a similar metal oxide microparticle layer. After initial formation, the material is usually sintered at high temperature to form a continuous layer. The base material of construction makes ceramic membranes particularly well suited for treating high-temperature or acidic/caustic wastewaters, as well as for high-fouling industrial streams. The extreme heat tolerance and chemical resistance of ceramics allows repeated cycles of use, cleaning with harsh physical or chemical treatments, and reuse that are unachievable with polymeric membrane materials. However, to date, ceramic membranes are much too expensive to be used in applications requiring large membrane surface area (such as water production or municipal wastewater treatment), so their use has been limited to specialty industrial separations.<sup>[22,23]</sup>

In principle, the cross-sectional structure of ceramic nanofiltration membranes has much the same look as organic TFC membranes. Fig. 4 is an SEM photo of an experimental thin-film composite ceramic membrane (courtesy of Marc Anderson of the University of Wisconsin). There are three distinct layers. A thin film comprised of small titanium dioxide ( $\text{TiO}_2$ ) nanoparticles, a middle support layer made

from larger  $\text{TiO}_2$  nanoparticles, and a structural base formed from much larger  $\text{TiO}_2$  particles. One of the current goals in ceramic membrane material research and development is to create a membrane with UF-like permeability, but NF-like selectivity. This may be achieved by taking advantage of nanoparticles with high surface charge density sintered to maintain more open pore structures than the pores in polymeric NF membranes.

**Fig. 4** Scanning electron microscope image of ceramic composite membrane showing three distinct layers of  $\text{TiO}_2$  nanoparticle construction: dense skin layer over top of nanoporous support and microporous structural support layers.

## Nanofiltration Element Design

Membrane modules are available in spiral-wound, plate-and-frame, hollow-fiber, and tubular configurations as depicted in Fig. 5. Almost all NF membranes used today employ the spiral-wound configuration. In a spiral-wound element (SWE), the membrane leaves are sealed and wrapped around a permeate collection tube. An open mesh spacer separates the active layers of membrane material on the feed side, while a similar spacer lies between the backsides of the membranes and serves as a channel for the treated water to travel to the permeate collection tube. A significant amount of research was performed in the past to optimize the design of feed spacers used in SWEs, and the currently available elements perform quite well. Generally, a thicker feed spacer is used for high fouling waters to prevent clogging of the channel cross section, which can result in a significant tangential pressure drop.

**Fig. 5** Schematic representation of the four principle membrane modules: (A) plate-and-frame; (B) spiral-wound; (C) tubular; (D) hollow-fiber. *Source:* From Ref.<sup>[61]</sup>.

## APPLICATIONS

Currently, the reduction of hardness (i.e.,  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ ) and dissolved organics from water are among the most important applications for nanofiltration membranes. However, the selective properties of NF membranes make them suitable for a wide array of unconventional applications. An important example is recovery of heavy metals (e.g., Ni, Fe, Cu, Zn, etc.) and reclamation of wastewaters from metalworking plants and textile mills. More recently, NF membranes have been adopted for use in the biotechnology and pharmaceutical industries for purification of small bioactive organic molecules such as antibiotics or separation of small organic components from biological liquids (e.g., lactic acid separation from fermentation broths, amino acid removal from protein hydrolysates, or removal of organics from municipal wastewater).<sup>[2]</sup> Timmer<sup>[2]</sup> provided a concise summary of the various applications for nanofiltration membranes that have been reported to date. This summary has been reproduced in Table 2.

## PERFORMANCE

The performance of nanofiltration membranes is defined by solvent and solute permeability, as well as fouling resistance. The summary that follows considers the roles of membrane material properties, operating conditions, and fouling, but begins by defining NF performance and the fundamental mechanisms governing NF membrane separations. Finally, mechanisms of NF membrane fouling are discussed and the role of membrane material properties on separation performance and fouling is reviewed.

### Defining NF Separation Performance

When an external pressure is imposed on a liquid adjacent to a nanofiltration membrane, the liquid will flow through the membrane in proportion to the applied pressure. Liquid flow through a NF membrane is described as a solvent flux ( $J_v$ ), which is given by a Darcy-type relation such as

$$J_v = \frac{\Delta p_{\text{eff}}}{\mu R_{\text{tot}}} \quad (1)$$

in which  $\Delta p_{\text{eff}}$  is the effective trans-membrane pressure,  $\mu$  is the permeate viscosity, and  $R_{\text{tot}}$  is the total hydraulic resistance toward solvent flow.

Dissolved solutes also flow toward the membrane by the convective flow of their carrier solvent. If the membrane inhibits transport of the solute, it will

**Table 2** Overview of nanofiltration applications in various industries

Industry	Application
Water production	Recovery of LiOH during treatment of battery waste
	Removal of degreasing agents from water
	Removal of precursors of disinfection byproducts
	Hardness removal
	Removal of natural organic matter (a.o. color)
	Removal of pesticides
	Removal of heavy metals (As, Pb), Fe, Cu, Zn, and silica
Food	Treatment of brackish water
	Demineralization of whey
	Demineralization of sugar solutions
	Recycle of nutrients in fermentation processes
	Separation of sunflower oil from solvent
	Recovery of cleaning-in-place solutions
Textile and paper	Recovery of regeneration liquid from decoloring resins in sugar industry
	Effluent treatment
	Purification of organic acids
	Removal of dyes from wastewater
	Removal of amino acids
	Recovery of water and salts from wastewater
Chemical	Recovery and reuse of chromium(III) and chromium(II)
	Recovery of water from wastewater or wastewater treatment effluent
	Recovery of bleaching solution
	Sulfate removal preceding chlorine and NaOH production
	CO <sub>2</sub> removal from process gasses
	Preparation of bromide
	Recovery of caustic solutions in cellulose and viscose production CaSO <sub>4</sub> precipitation
	Separation of heavy metals from acid solutions
	Removal of metal sulfates from wastewater
	Cleaning of machine rinsing solutions
Agriculture	Removal of nickel
	Recovery of Cu-ions from ore extraction liquids
	Al <sup>3+</sup> removal from canning industry wastewater
	Removal of phosphate, sulfate, nitrate, and fluoride
	Removal of algal toxins
	Purification of landfill leachate
	Removal of selenium from drainage water

Source: From Ref.<sup>[2]</sup>

be retained at the feed side of the membrane. The distribution of a noncharged solute at the membrane/solution interface is determined by steric exclusion. Because of its size, a solute only has access to a fraction of the total surface area of a pore, and a separation between multiple solutes can only be accomplished if the solutes are different in size.<sup>[2,14,24]</sup>

For charged solutes, two additional distribution mechanisms contribute to the separation. First,

Donnan exclusion has a pronounced effect on the separation of charged solutes by NF membranes. Because of the slightly charged nature of the membrane, solutes with an opposite charge compared with the membrane (counterions) are attracted, while solutes with a similar charge (co-ions) are repelled. At the membrane surface, a distribution of co-ions and counterions will occur, thereby causing an additional separation. Second, because of the charge of the membrane and the dipole

momentum of water, water molecules may exhibit polarization in the pore.<sup>[25]</sup> This polarization results in a decrease of the dielectric constant inside the pore, thereby making it less favorable for a charged solute to enter. However, even in a situation that the dielectric constant inside the pore is equal to that of water, a change in electrostatic free energy of the ion occurs when the ion is transferred from the bulk into the pore,<sup>[26]</sup> which can also cause ion exclusion.

After the solute distributes at the membrane/solution interface, it is transported through the membrane by convection and diffusion. At the permeate side, a second distribution process occurs, which determines the permeate concentration. The actual, or intrinsic, rejection by a nanofiltration membrane is given by

$$R_s = 1 - \frac{C_p}{C_m} \quad (2a)$$

where  $C_p$  is the permeate solute concentration and  $C_m$  is the membrane surface solute concentration. However, there is no accurate method of determining the actual membrane surface solute concentration. Because the feed and permeate solute concentrations can be measured, the solute retention is typically described by

$$R_o = 1 - \frac{C_p}{C_b} \quad (2b)$$

where  $R_o$  represents the observed solute retention and  $C_b$  represents the bulk salt concentration. Retained solutes accumulate at the membrane surface in a concentrated layer and thus diffuse back into the bulk in proportion to the concentration gradient, and hence a concentration profile develops. This phenomenon is called concentration polarization.

The performance of NF membranes has been studied extensively in terms of membrane properties, operating conditions, module geometry, and treatment train configuration. Of considerable importance are the influences of membrane filter geometry and crossflow hydrodynamics on concentration polarization (CP). Concentration polarization influences nanofiltration performance via two mechanisms. First, CP enhances the passage of retained solutes by increasing the chemical potential gradient driving diffusive transport through the membrane, and second, elevated salt concentrations at the membrane surface reduce electrostatic forces that originate from the membrane surface charge and which tend to reduce foulant deposition. Accumulation of a fouling deposit layer on the membrane surface creates an additional hydraulic resistance to permeation (over that of the membrane alone) and enhances concentration polarization.<sup>[27,28]</sup>

## Solute Transport Model

Determining the significance of various solute transport mechanisms—diffusion, convection, and electromigration—on NF membrane performance is most rigorously accomplished by coupling a model of solute transport through the membrane based on the extended Nernst–Planck (NP) equation with a CP model based on the convective–diffusion equation.<sup>[29]</sup> However, knowledge of the actual charge density of the membrane pores is required to make appropriate use of the NP model, and this is rather difficult to determine for real membranes. In addition, a cumbersome numerical scheme is required to solve the set of equations that result from coupling the local NP model with a local CP model based on the solution of the convection–diffusion equation. Coupling the solution–diffusion model and a simple mass transfer model (film theory) provides a reasonable and analytical solute transport and CP model.<sup>[30–32]</sup> While the application of a stagnant film model to membrane separations may be debated, the model provides quite reasonable prediction of NF separation performance.

The starting point for the mathematical description of NF membrane performance is the solution–diffusion model. The model assumes that solute permeation is driven by the gradient in chemical potential of the solute across the membrane.<sup>[30]</sup> Thus the flux ( $J$ ) of an individual component ( $i$ ) is represented mathematically by

$$J_i = -L_i \frac{d\mu_i}{dx} \quad (3)$$

where  $d\mu_i/dx$  is the gradient in chemical potential of component  $i$  and  $L_i$  is a coefficient of proportionality linking this chemical potential driving force with flux. The chemical potential is written as

$$d\mu_i = RTd \ln(\gamma_i c_i) + v_i dp \quad (4)$$

where  $c_i$  is the molar concentration of component  $i$ ,  $\gamma_i$  is the activity coefficient linking concentration with activity,  $p$  is the pressure, and  $v_i$  is the molar volume of component  $i$ . Following the applicable assumptions for reverse osmosis, the combination of Eqs. (3) and (4) leads to a Fick's law type of relation that is ultimately reduced to

$$J_i = B \Delta C_w = B C_w R_i \quad (5)$$

where  $B$  is the solute permeability of the membrane.<sup>[30]</sup> When the transport equation is expressed in terms of solvent flux ( $J_v$ ), the equation is generally written as

$$J_v = A(\Delta P - \Delta \pi_m) \quad (6)$$

where  $\Delta P$  is the applied pressure and  $\Delta\pi_m$  is the osmotic pressure at the membrane surface because of concentration of rejected ionic species at the surface of the membrane. The parameter  $A$  is the pure solvent permeability of the membrane, which is the inverse of the intrinsic membrane resistance,  $R_m$ .

### Solute Concentration Polarization Model

The buildup in concentration of rejected solutes at the membrane–liquid interface results in the formation of a concentrated mass boundary (“film”) layer, called the *salt concentration polarization layer*. At steady state, the solute flux through the film is constant and is related to the solvent flux through the membrane ( $J_v$ ) via the following one-dimensional, steady-state mass balance within the film layer:

$$-J_v C - D \frac{dC}{dy} = J_v C_p \quad (7)$$

where  $C$  is the local solute concentration,  $D$  is the solute diffusivity,  $C_p$  is the solute permeate concentration, and  $y$  is the distance normal to the membrane surface.<sup>[31]</sup> Integrating over the solute concentration polarization layer thickness ( $\delta_s$ ) with the appropriate boundary conditions ( $y = 0$ ,  $C = C_m$ ;  $y = \delta_s$ ,  $C = C_b$ ) results in the classic film theory equation,

$$J_v = \frac{D}{\delta_s} \ln\left(\frac{C_m - C_p}{C_b - C_p}\right) = k \ln\left(\frac{C_m - C_p}{C_b - C_p}\right) \quad (8)$$

where  $C_m$  is the membrane surface solute concentration,  $C_b$  is the bulk solute concentration,  $C_p$  is the permeate solute concentration, and the ratio of solute diffusivity ( $D$ ) to the solute concentration polarization layer thickness ( $\delta_s$ ) is set equal to the solute mass transfer coefficient ( $k$ ). This expression can be rearranged to provide a direct calculation of the concentration polarization factor ( $C_m/C_b$ ) as

$$\frac{C_m}{C_b} = (1 - R_0) + R_0 \exp\left(\frac{J_v}{k}\right) \quad (9)$$

For laminar flow in a thin rectangular channel, the mass transfer coefficient is often related to a Sherwood number ( $Sh$ ) through a relationship such as

$$k = Sh \frac{D}{d_h} = 1.85 \left( Re Sc \frac{d_h}{L} \right)^{1/3} \frac{D}{d_h} \quad (10)$$

where  $Re$  is the Reynolds number,  $Sc$  is the Schmidt number,  $d_h$  is the channel hydrodynamic diameter, and  $L$  is the channel length.<sup>[30–32]</sup> By expanding the

individual components,

$$Re = \frac{\rho u d_h}{\mu}; Sc = \frac{\mu}{\rho D}; d_h \cong 2H \quad (11)$$

Eq. (10) can be rearranged to reveal the mass transfer coefficient's dependence on flow rate, channel geometry, and solute type via

$$k = 0.808 \left( \frac{\gamma_0 D^2}{L} \right)^{1/3} \quad (12a)$$

Here  $\gamma_0$  indicates the wall shear rate, which is defined by  $\gamma_0 = 6Q/WH^2$ , where  $Q$  is the volumetric feed flow rate,  $W$  is the crossflow channel width, and  $H$  is the channel height.<sup>[32]</sup> From Eq. (12a), it becomes clear that the mass transfer coefficient represents the velocity with which a solute migrates away from the membrane surface (back into the bulk) as a function of solute diffusivity, tangential convection, and filter geometry. This explains the enhanced performance obtained from optimizing channel geometry and cross-flow hydrodynamics.

An alternative solute mass transfer coefficient has been derived for laminar flow through thin-rectangular channel with a turbulence promoting feed spacer, such as is used in a nanofiltration spiral-wound element, the mass transfer coefficient may be written as

$$k = 0.31 \left( \frac{\gamma_0 D^4}{\nu^{1/3}} \right)^{1/2}, \quad (12b)$$

where  $\nu$  is the kinematic solution viscosity. Rearranging the film theory equation provides an estimation of the *trans*-membrane osmotic pressure. The resulting expression is

$$\Delta\pi_m = C_b R T R_o \exp\left(\frac{J_v}{k}\right) \quad (13)$$

Thus osmotic pressure is directly proportional to bulk solute concentration, solute rejection, solvent flux, and solute mass transfer. More importantly,  $\Delta\pi_m$ ,  $R_o$ ,  $C_b$ , and  $J$  can be measured experimentally, so the effective mass transfer coefficient can easily be determined and compared with prediction by Eq. (13).

### Fouling and Nanofiltration Performance

Most municipal, industrial, and natural waters contain complex mixtures of dissolved, macromolecular colloidal, and particulate matter. Conventional processes used to pretreat NF feed waters fail to remove sub-micron colloids, macromolecules and dissolved matter.

This matter accumulates at the membrane surface and results in severe performance decline—a phenomenon known as *fouling*. Fouling of NF membranes may result in loss of both *solvent flux and solute retention*. A review of fouling studies reveals that the foulants of greatest concern for nanofiltration (NF) separations are colloidal matter consisting of organics, silica, clays, metal oxides (specifically iron and manganese), and microorganisms.<sup>[33–42]</sup> Fouling may be further categorized into *reversible* and *irreversible* fouling. Flux and solute retention may decline because of solution chemistry effects, concentration polarization, or colloid cake layer formation. The original membrane performance may be recovered by simply flushing the membrane with clean water, and hence these types of fouling are considered reversible. Irreversible fouling is defined as a decline in performance that can only be recovered through harsh chemical cleaning, but often only partially recovered. Frequent chemical cleaning of membranes degrades polymeric thin films, and hence reduces the life span of membranes in many applications. Furthermore, it decreases process efficiency because of the reduced flux and enhanced solute passage, requiring higher applied pressures and larger membrane area. This makes fouling a very important parameter in process design.

### Fouling Mechanisms and Models

Interactions between accumulated dissolved and colloidal matter at a NF membrane surface result in several potential fouling mechanisms. Fouling by dissolved organics and sparingly soluble salts is difficult to describe quantitatively, but colloidal fouling is better understood. Because colloids fall within the approximate size range of 10 nm to 10 μm and NF membrane “pores” are no more than a few nanometers in diameter, pore-blocking mechanisms are considered negligible. Thus the major fouling mechanisms discussed below include the hydraulic pressure drop across the foulant deposit (cake) layer and enhanced osmotic pressure effects, which were recently shown to be the predominant fouling mechanism for RO and NF membranes.<sup>[28]</sup> Most practical nanofiltration processes operate with a constant flux, so this convention will be used to describe fouling mechanisms. The objective is to be able to describe the transient applied pressure required to maintain a constant flux in light of the various transient mechanisms of fouling.

The total system pressure is a combination of the trans-membrane hydraulic ( $\Delta p_m$ ), the trans-membrane osmotic ( $\Delta \pi_m$ ), and the trans-cake hydraulic ( $\Delta p_c$ ) pressure drops and may be expressed mathematically as

$$\Delta P_{\text{total}} = \Delta p_m + \Delta \pi_m + \Delta p_c \quad (14)$$

The *trans*-membrane hydraulic pressure drop is determined by rearranging Eq. (1) to obtain

$$\Delta p_m = J_v \mu R_m \quad (15)$$

Hence by analogy, the trans-cake hydraulic pressure drop may be described from

$$\Delta p_c = J_v \mu R_c, \quad (16)$$

where  $R_c$  is the hydraulic resistance offered by the cake layer to the pure solvent.

The cake resistance may be described through the Carman–Kozeny equation, as a function of specific cake resistance (per unit thickness) and cake layer thickness,

$$R_c = r_c \delta_c = \frac{180(1 - \varepsilon)^2}{d_f^2 \varepsilon^3} \delta_c \quad (17a)$$

or specific cake resistance (per unit mass) and cake layer mass per unit membrane area,

$$R_c = \alpha_c M_c = \frac{180(1 - \varepsilon)}{\rho_f d_f^2 \varepsilon^3} M_c \quad (17b)$$

Here  $\varepsilon$  is the cake layer porosity,  $d_f$  represents the nominal foulant diameter, and  $\rho_f$  is the nominal foulant particle density. In most existing models, it is assumed that the specific cake resistance is constant in time and across the cake layer thickness and only the foulant layer thickness (or mass) changes with time.

It was recently experimentally demonstrated that diffusion of rejected salt ions was hindered within colloid deposit layers formed over nanofiltration membranes.<sup>[28,43]</sup> In addition, it was suggested that tangential flow may be hindered within a foulant deposit layer, further reducing solute mass transfer within the deposit layer. The result was elucidation of a single mechanism—“cake-enhanced concentration polarization”—capable of describing the majority of observed flux decline, as well as the observed decline in salt rejection because of colloidal fouling of NF (and RO) membranes.

The overall mass transfer coefficient was considered the sum of two mass transfer coefficients, one describing salt back-diffusion from the membrane surface through the cake layer, and one through the remainder of the salt CP layer. Incorporating the hindered mass transfer coefficient into Eq. (13) yields

$$\Delta \pi_m^* = f_{os} C_b R_o \exp \left[ \frac{J_v}{k} + J_v \delta_c \left( \frac{1 - \ln(\varepsilon^2)}{D_{\infty} \varepsilon} - \frac{1}{D_{\infty}} \right) \right] \quad (18)$$

**Fig. 6** Conceptual illustration of enhanced concentration polarization because of foulant accumulation in crossflow nanofiltration. The bulk tangential flow velocity,  $U_0$ , and the salt ion diffusion coefficient are critical parameters in determining mass transfer in the salt concentration polarization layer. Tangential flow and salt ion back-diffusion may be locally hindered in the presence of a foulant deposit layer, thus enhancing the membrane surface salt concentration and trans-membrane osmotic pressure.

where  $\Delta\pi_m^*$  is termed the “cake-enhanced osmotic pressure.”

The term in parentheses in Eq. (18) is derived by considering a thin cake layer, in which the tangential flow field is stagnant within the cake, and it represents diffusion through the cake and into the bulk.<sup>[44]</sup> This concept is illustrated in Fig. 6. The reduced salt diffusivity in the cake layer is expressed as  $\varepsilon D_\infty / \tau$ , with the tortuosity,  $\tau$ , being approximated as  $1 - \ln(\varepsilon^2)$ .<sup>[45–47]</sup> Note that in the absence of a foulant deposit layer, Eq. (18) reduces to Eq. (13) as the term in brackets reduces to  $J_v/k$ .

Combining the trans-membrane hydraulic, trans-cake hydraulic, and (cake-enhanced) trans-membrane osmotic pressure drops allows direct estimation of the total applied pressure needed to maintain a constant flux as a function of increasing deposit thickness. Of course, a priori knowledge of potential foulants is not always possible, which makes rigorous prediction of fouling phenomena difficult without some experimentation or pilot testing. Furthermore, physical or chemical polydispersity of foulants in many NF applications makes prediction of fouling behavior practically impossible. Perhaps the most important implication of enhanced concentration polarization is that an elevated solute concentration at the membrane surface may enhance solute transport through the membrane. Therefore, fouling can have severe consequences for NF separations subject to permeate water quality regulation if the separation is not designed with consideration of fouling.

## Membrane Properties and Performance

Nanofiltration membranes may be constructed of any number of polymeric organic or inorganic materials, but they most commonly appear as polyamide

thin-film composites. Commercially available polyamide NF membranes have charged, reasonably hydrophilic surfaces, which naturally repel co-ions, and to maintain electroneutrality at the membrane / solution interface, counterions are also prevented from passing through the membrane. The degree of ion exclusion increases with increasing co-ion valence because of increased electrostatic repulsion by the membrane. However, the degree of ion exclusion also decreases with increasing counterion valence because high valence counterions tend to screen out membrane surface charge. Moreover, high electrolyte concentrations cause the membrane charge to be more effectively shielded by the counterions, thus reducing the selectivity of the membrane.<sup>[48]</sup> The rejection of sodium chloride with NF varies from 0% to 50% according to the feed concentration and electrolyte composition.

Hirose, Ito, and Kamiyama<sup>[49]</sup> suggested an approximately linear relationship between membrane surface roughness and permeate flux for cross-linked aromatic polyamide TFC membranes, where permeability increased with increasing surface roughness. The linear relationship was attributed to surface unevenness of the TFC membrane skin layer, which resulted in enlargement of the effective membrane area. This is the explanation offered by most membrane manufacturers. However, Kwak et al.<sup>[15]</sup> showed that substitution of bisphenol biphenyl rings with either methyl or halogen strongly influenced rejection and permeability of aromatic polyester TFC membranes. Higher flux and lower rejection were associated with the smoother membrane surfaces obtained from methyl substitution, while lower flux and higher rejection were associated with the rougher membrane surfaces resulting from halogen substitution.

Additional work by Kwak and Ihm,<sup>[50]</sup> coupling nuclear magnetic resonance (NMR) spectroscopy and atomic force microscopy (AFM), showed an important relationship between proton spin-lattice relaxation times and permeability, regardless of surface morphological features. This indicates that membrane morphology (especially the increased surface area because of roughness) is not solely responsible for the low-pressure, high-flux performance of polyamide membranes. In fact, it suggests that the structure and thickness of the thin-film polymer network determine membrane permeability.

## Membrane Properties and Fouling

Physical and chemical properties of NF membranes (i.e., permeability, salt retention, “pore” size, etc.) control the rate and extent of colloidal fouling.<sup>[18,28,43,44]</sup> The high hydraulic resistance of NF membranes enables substantial foulant deposit layers to form

before fouling is detected, and rejection of ionic solutes exacerbates fouling by screening electrostatic interactions.<sup>[43]</sup> Other recent studies suggest that membrane surface properties also influence fouling resistance of NF membranes.<sup>[6,10,12,13,15,16,49–51]</sup> Several investigations of NF membrane fouling have explored the roles of membrane pore size, surface roughness, electrokinetic surface properties, membrane hydrophobicity/hydrophilicity, and specific chemical functionality.<sup>[51–53]</sup> Various analytical techniques have been employed for evaluating specific physical and chemical surface properties of membranes, including Raman spectroscopy (structure),<sup>[13]</sup> electron spin resonance (solute mobility in membrane polymer matrix and pores),<sup>[13]</sup> AFM, SEM, and TEM (surface morphology, structure, and pore size),<sup>[10,13,15,16,50,54,55]</sup> streaming potential (membrane surface zeta potential),<sup>[56,57]</sup> NMR spectroscopy (permeability),<sup>[50]</sup> (hydrophobicity) contact angle,<sup>[18]</sup> and X-ray photoelectron

spectroscopy (XPS, surface chemical functional groups).<sup>[58,59]</sup>

Field-emission scanning electron microscope (FESEM) images of two commercially available nanofiltration membranes are shown in Fig. 7. The two membranes exhibit RMS roughness values of (A) 12.8 and (B) 56.5 nm (taken from Ref.<sup>[43]</sup>). Additional properties of membranes (A) and (B) include zeta potentials of  $-18$  and  $-25$  mV (at 10 mM and pH 7), pure water contact angles of 51.9 and 51.7, hydraulic resistances of  $3.26 \times 10^{10}$  and  $3.13 \times 10^{10}$  Pa s/m, and salt rejections of 35% and 83% (at 30 gfd and 10 mM NaCl), respectively. Field-emission scanning electron microscope images in Fig. 7(C) and (D) are of the membranes from (A) and (B), respectively, after filtration of identical 200 mg/L suspensions of 100-nm spherical silica colloids in a 10 mM NaCl solution. Different masses of colloidal foulants accumulate on the membrane

**Fig. 7** Field-emission scanning electron microscope (FESEM) images of two commercially available nanofiltration membranes with RMS roughness values of (A) 12.8 nm and (B) 56.5 nm taken from Ref.<sup>[43]</sup>. Additional (A) and (B) membrane properties include zeta potentials of  $-18$  and  $-25$  mV (at 10 mM and pH 7), pure water contact angles of 51.9 and 51.7, hydraulic resistances of  $3.26 \times 10^{10}$  and  $3.13 \times 10^{10}$  Pa s/m, and salt rejections of 35% and 83% (at 30 gallons per square foot of membrane per day, gfd, and 10 mM NaCl), respectively. Field-emission scanning electron microscope images of fouled NF membranes in (C) and (D) show the membranes from (A) and (B), respectively, accumulate different amounts of colloidal foulants when the same feed suspension was filtered through the membranes under identical operating conditions. The membrane in (B) with significantly rougher and more negatively charged surface appears to attract a thicker deposit layer of 100 nm silica colloids than the smoother membrane in (A).

surfaces even when operating conditions (i.e., flux, crossflow, temperature, etc.) were constant.

It is not entirely clear why these membranes attract different amounts of the colloidal foulant. It has been suggested that subtle differences in physico-chemical surface properties and salt rejections may control the initial rate of deposition.<sup>[10]</sup> Differing salt rejections will yield different membrane surface salt concentrations (all other conditions being equal), and thus repulsive electrostatic interactions are suppressed creating more favorable conditions for foulant deposition. In this case, the membrane in (B) and (D) had higher salt rejection, which may have countered the slightly greater membrane zeta potential. It has also been suggested that membrane surface roughness may decrease electrostatic repulsive interactions, further enhancing colloidal foulant deposition.

## CONCLUSION

Nanofiltration separations are performed in many industries and for many applications. The key material properties of nanofiltration membranes are their selectivity, which may derive from various combinations of size, charge, and dielectric exclusion. The most common nanofiltration membranes are comprised of a thin, dense polymer film polymerized over the top of a porous membrane cast on a fabric support. The most common nanofiltration module type is the flat-sheet, spiral-wound element design. The performance of NF separations is defined by the solvent permeability and the difference between various solute permeabilities. Fouling is a major concern in most industrial and water treatment applications of nanofiltration separations because it leads to higher operating costs, deterioration of NF thin films, and decreased selectivity. Overall, nanofiltration separations offer low-cost, environmentally friendly, semiselective separation capability for a host of applications and are a promising nanotechnology.

# Nanofriction and Nanowear of Sliding Systems: Simulations

W.C.D. Cheong

Materials Science and Characterisation Laboratory, Institute of Materials Research and Engineering, Singapore, Singapore

## INTRODUCTION

The macroscopic behavior of coatings has been well documented and studied, using continuum mechanics. Failure under common tribological situations can occur not only due to coating wear but also by the debonding of the coating from the substrate. However, there are to date relatively few studies on nanometer scale characteristics of coating systems. Deformation mechanisms have been shown to be very different on the nanometer scale.<sup>[1–4]</sup> A full understanding of the mechanical behavior of diamond coating on the nanometer scale is an essential issue if coatings on the nanometer scale are to be used like its macroscale counterparts in the various applications mentioned before.

Various failure mechanisms of the substrate/coating composite on the nanometer scale are studied in this entry using molecular dynamics simulation through a parametric elastic–plastic analysis, for common nanomechanical processes. The nanomechanical processes that will be discussed are uniaxial compression, biaxial compression, indentation, and sliding.

## BACKGROUND

It has been shown that the mechanisms of friction and wear on the nanometer scale can be absolutely different from their micrometer or larger scale counterparts. It was found that friction stress is constant and of the order of the theoretical shear strength, when a sliding contact size is small. However, at a critical contact size, there is a transition beyond which the frictional stress decreases with increasing contact size, until it reaches a second transition where the friction stress gradually becomes independent of the contact size. Hence, the mechanisms of slip are size-dependent, or in other words, there exists a scale effect. This phenomenon is not observed in larger scale contacts.<sup>[5,6]</sup>

Making use of such understanding of tribology on the nanometer scale, recent developments in nanotechnology have revealed wondrous potential in modifying

surfaces on the nanometer scale. By observing lizard's feet, researchers have proven that clusters of nanometer scale contacts can provide strong adhesion just like the spatula at the ends of the hairs on a lizard's feet that allow them to walk on walls and ceilings.<sup>[7]</sup> On the other hand, based on nanostructures of the surfaces of lotus leaves, engineered surfaces with the right surface energy and nanoscopic bumps can ensure that dust particles do not stick to the surface easily, hence resulting in self-cleansing capabilities.<sup>[8]</sup>
