# Layered Double Hydroxides: Self-Assembly and Multiple Phases

Zhi Ping Xu

Paul S. Braterman

Department of Chemistry, University of North Texas, Denton, Texas, U.S.A.

## INTRODUCTION

As an important class of clay-like materials, layered double hydroxides (LDHs) possess the promising ability to combine organic anions and metal hydroxide layers, and form variable nanometer-scale precursors that could be readily developed into porous multi-metal mixed oxide catalysts or supports.<sup>[1–3]</sup> Organic–inorganic hybrid assemblies have recently received much attention because of their abundant variations in the structures and molecular interactions.<sup>[4–6]</sup> In this entry, we briefly discuss some basic issues in LDH structural chemistry, such as the underlying sandwich structure, the natures of layer cations and interlayer anions, polytypes, superlattice, crystallite growth, and morphological features. Then we focus on LDH–surfactant hybrids, including formation of various LDH phases and the corresponding anion packing, chemical convertibility between the phases and their stability, flexible morphological features and growth habits, new perspective applications with particular emphasis on our recent work.

## LAYERED DOUBLE HYDROXIDES IN GENERAL

### Basic Structure

The layered structure of LDH is closely related to that of brucite,  $\text{Mg}(\text{OH})_2$ . In a brucite layer, each  $\text{Mg}^{2+}$  ion is octahedrally surrounded by six  $\text{OH}^-$  ions, and the different octahedra share edges to form an infinite two-dimensional layer. Partial replacement of  $\text{Mg}^{2+}$  ions by  $\text{Al}^{3+}$  gives the brucite-like layers a positive charge, which in hydrotalcite ( $\text{Mg}_6\text{Al}_2(\text{OH})_{16}\text{CO}_3 \cdot 4\text{H}_2\text{O}$ ) itself is balanced by carbonate anions, located in the interlayer region (gallery) between the two brucite-like layers (Fig. 1). This gallery also contains water molecules, hydrogen bonded to layer OH and/or to the interlayer anions. Through electrostatic interactions and hydrogen bonds, the layers are held together to form the three-dimensional structure,

as shown in Fig. 1. For hydrotalcite, the repeated interlayer spacing is 0.760 nm. In general, the thickness for the brucite-like layer is taken to be 0.480 nm (0.477 nm for brucite); thus the spacing occupied by the anion (gallery height) is ca. 0.280 nm.<sup>[1–3]</sup>

### Brucite-like Layers

Besides  $\text{Mg}^{2+}$  and  $\text{Al}^{3+}$ , there are a number of divalent and trivalent cations that can form LDHs, as listed in Table 1.<sup>[11]</sup> For these ions, the only requirement is that their radii are not too different from those of  $\text{Mg}^{2+}$  and  $\text{Al}^{3+}$ . Larger ions, such as  $\text{Mn}^{2+}$ ,  $\text{Pd}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Y}^{3+}$ , and  $\text{La}^{3+}$ , are incorporated into the brucite-like layer by puckering or combining with other divalent or trivalent cations.<sup>[3]</sup> An extreme case is  $\text{Ca}_2\text{Al}$ -LDHs, in which Ca is distorted to be 7-coordinated while Al is still kept 6-coordinated.<sup>[8]</sup>

Although not as common as trivalent cations, some tetravalent cations, such as  $\text{V}^{4+}$ ,  $\text{Ti}^{4+}$ ,  $\text{Zr}^{4+}$ , and  $\text{Sn}^{4+}$ , have been introduced into the brucite-like layers to replace part of the trivalent cations in LDH compounds.<sup>[9–11]</sup> Similarly, monovalent cations, Li or  $\text{Li}_{1-x}\text{Na}_x$ , together with Al, can form a similar series of LDH compounds with atomic ratio Al/Li or Al/(Li + Na) fixed only at 2.<sup>[3]</sup> In addition, it is possible to incorporate multiple different ions into the layers to prepare an LDH as the precursor of mixed oxides with versatile functionalities and tunable physicochemical properties.<sup>[3]</sup>

The value of  $x$  in pure  $\text{M}_{1-x}^{2+}\text{M}_x^{3+}$ -LDHs is normally in the range of 0.2–0.33. Larger or smaller values may cause formation of hydroxide or hydrous oxides containing a single metal. As a result of the electrostatic repulsion between positive charges,  $\text{M}^{3+}$  ions should ideally not be adjacent in the brucite-like layer, but remain apart, which requires  $x$  to be no more than 1/3. Claims of values of  $x$  outside this range need careful substantiation because highly dispersed simple hydroxide phases can readily escape detection by powder X-ray diffraction (XRD).

**Fig. 1** Schematic representation of the hydrotalcite three-dimensional structure.

### Interlayer Anions

As for the anions located in the interlayer gallery, the choice is much more versatile. There is almost no limitation to the nature of anions in the LDHs as long as the anions do not abstract the metal ions from the hydroxide layer and have a sufficient charge density in one cross section. Anions that have been successfully incorporated include 1) common inorganic anions; 2) various organic carboxylates, sulfates, sulfonates, and oxygenates; 3) polymeric anions; 4) complex anions; 5) isopolyoxometalates and heteropolyoxometalates; and 6) some biochemical anions.<sup>[3]</sup>

**Table 1** Ionic radii of some cations with coordinate number of 6

M <sup>2+</sup>	Radius (nm)	M <sup>3+</sup>	Radius (nm)

Source: From Ref.<sup>[7]</sup>.

The various anions are very different in their structure, dimensions, and charges; however, they are all located between the brucite-like layers. Therefore their size and orientation determine the interlayer spacing. In general, the anions are oriented in such a way as to maximize the interaction with their surroundings under certain conditions. For example, planar  $\text{CO}_3^{2-}$  and  $\text{NO}_3^-$  anions are usually positioned parallel to the brucite-like layer at low  $x$  values, while at high  $x$  value, they change to tilting or alternating upper-lower orientation as a result of crowding of anions in the gallery.<sup>[3,12,13]</sup> For tetrahedral anions, such as  $\text{SO}_4^{2-}$ ,  $\text{MoO}_4^{2-}$ ,  $\text{CrO}_4^{2-}$ ,  $\text{PO}_4^{3-}$ ,  $\text{ClO}_4^-$ , and  $\text{CoCl}_4^{2-}$ , there are two possible ideal configurations: the pyramidal configuration (with its one  $C_3$  axis perpendicular to the hydroxide layer) and the edge configuration (with its one  $C_2$  axis perpendicular to the hydroxide layer). It has been found that  $\text{ClO}_4^-$  anions adopt the former configuration while  $\text{SO}_4^{2-}$  anions employ the latter.<sup>[1,3]</sup> Octahedral complexes, such as  $\text{Fe}(\text{CN})_6^{3-}$ , hydrogen bond through opposite triangles to upper and lower hydroxide layer sides, as proposed by Kikkawa and Koizumi<sup>[14]</sup> and used by Braterman, Tan, and Zhao<sup>[15]</sup> to explain the perturbation of the vibrational spectrum of cyanide groups from the ideal octahedral symmetry.

For polyoxometalates (POMs), the arrangement is highly dependent on the solution pH because the anion oligomerization degree varies from 1 to 10 with pH change from 12 to 3, as shown by Twu and Dutta.<sup>[16]</sup> In particular, polyvalent POMs and Keggin-type anions  $\alpha\text{-(XM}_{12}\text{O}_{40})^{n-}$  in LDHs act as pillars in the interlayer, giving rise to the so-called pillared LDH, and usually resulting in micropores in the gallery.<sup>[17]</sup> These may provide suitable places for some catalytic reactions to occur.

The orientations of organic anions, especially monovalent surfactant anions, lead to a range of distinct types of phases, as discussed below.

### Stacking and Polytype

We can propose many different ways for brucite-like layers to stack on top of one another; however, there are three highly symmetrical ways for the OH groups of one layer to relate to those of an adjacent layer.<sup>[18]</sup> They may be in register (giving a trigonal prism) or out of register (giving an octahedron). If out of register, the OH groups of the upper layer can be in either of two positions relating to the lower: on top of the octahedral triangle (with a cation) or the vacant triangle (without a cation), as shown in Fig. 1. It can be shown that for a two-layer repeat, there are three polytypes, all hexagonal (2H), while a three-layer repeat gives in all nine polytypes, of which only two (known as 3R<sub>1</sub> and 3R<sub>2</sub>) are rhombohedral.<sup>[18]</sup> Layered

double hydroxide minerals are known in both 2H and 3R forms, and synthetic LDHs are usually assigned to 3R<sub>1</sub>, although recently a 3R<sub>2</sub> form of synthetic hydrotalcite has been described.<sup>[19]</sup> The coexistence of two anions in the interlayer may give rise to intermediate interstratified phases. For example, the coexistence of SO<sub>4</sub><sup>2-</sup> and CO<sub>3</sub><sup>2-</sup> in the MgAl-LDH results in an alternating sequence of (brucite-CO<sub>3</sub><sup>2-</sup>)-(brucite-SO<sub>4</sub><sup>2-</sup>).<sup>[20]</sup> In the case of dicarboxylate and Cl<sup>-</sup>, the sequence is a brucite-dicarboxylate-brucite-chloride repeat unit.<sup>[21]</sup>

Long-chain organic anions will impose their own packing requirements, and, generally speaking, the OH groups of the adjacent hydroxide layers will no longer be in or out of register for close packing. The structure will then be determined by the tilting angle of the chain, and the degree of overlap between chains attached to adjacent layers, as discussed below. The incorporation of two different dicarboxylates in comparable amounts gives only the interlayer spacing expected for the larger anion despite the presence of the smaller anion in the same interlayer.<sup>[21]</sup>

### Superlattice Formation

The ideal distribution of cations within the brucite-like layer and anion in the interlayer will result in formation of superlattice. By obeying a rule analogous to Lowenstein's rule for aluminosilicates, a hexagonal superlattice (or supercell) with  $a' = 2a \sin 60^\circ = a \sqrt{3}$  ( $a'$  is the separation distance of adjacent trivalent cations, as shown in Fig. 2A) will be expected for an LDH with M(II)/M(III) = 2:1.

Complete ordering of cations has been reported for Ca<sub>4</sub>Al<sub>2</sub>(OH)<sub>12</sub>SO<sub>4</sub> · 6H<sub>2</sub>O,<sup>[22]</sup> implying such regularity in the hydroxide layers. Solin et al.<sup>[23]</sup> found a similar superlattice ordering in Ni<sub>1-x</sub>Al<sub>x</sub>-CO<sub>3</sub>-LDH ( $x = 0.33$ , i.e., Ni/Al = 2:1) from XRD patterns. There is a similar superlattice in LiAl<sub>2</sub>-CO<sub>3</sub>-LDH.<sup>[24]</sup>

In Mg<sub>2</sub>Al-benzoate-LDH, an extra reflection in XRD has been observed with diffraction distance

0.454 nm, presumably attributable to the scattering by the anions, because the difference in X-ray scattering power between Mg and Al is small. A superlattice in Ni<sub>1-x</sub>Al<sub>x</sub>-CO<sub>3</sub> and Mg<sub>1-x</sub>Fe<sub>x</sub>-CO<sub>3</sub>-LDH ( $x = 0.30$ ) has been also explained as arising from diffraction of carbonate anions.<sup>[23]</sup> It should be mentioned that the repulsion between the anions will promote such an order.

It seems reasonable to expect a related superlattice for M(II)<sub>3</sub>M(III)-LDH, as shown in Fig. 2B, with  $a' = 2a$ ; but, to the best of our knowledge, this has not yet been observed by XRD. However, this superlattice structure in a short range has been seen in the outermost layers by atomic force microscopy (AFM) and scanning tunnel microscopy (STM). Using these techniques, Cai et al.<sup>[25]</sup> and Yao et al.<sup>[26]</sup> have reported such periodicity on the surface of Mg<sub>6</sub>Al<sub>2</sub>(OH)<sub>16</sub>CO<sub>3</sub> in contact with sulfate, ferrocyanide, or ferricyanide solutions.

Even in the absence of the long-range order required for a diffraction signal, extended X-ray absorption fine structure (EXAFS) spectroscopy can detect the local (up to a few nanometers) order of the cation distribution in the hydroxide layers. Such high local ordering of the cation distribution in many LDHs, including Zn<sub>2</sub>Cr,<sup>[27]</sup> Cu<sub>2</sub>Cr,<sup>[28]</sup> Mg<sub>3</sub>Fe,<sup>[29]</sup> Co<sub>2-y</sub>Cu<sub>y</sub>Al,<sup>[30]</sup> and Co<sub>2</sub>Fe<sub>y</sub>Al<sub>1-y</sub>-LDHs,<sup>[31]</sup> has been unambiguously shown by EXAFS.

### Crystallization and Morphology

Morphology is strongly affected by the crystallization process, which depends not only on the nature of the incorporated cations and intercalated anions, but also on the details of the preparation procedure, such as reaction temperature, time, and post-treatment.

In general, as we have shown directly by pH titration,<sup>[32,33]</sup> LDH forms at a pH well below that necessary to form the most soluble hydroxide, a fact that led to the initial recognition of LDH as a distinct phase.

**Fig. 2** Hexagonal superlattices resulting from ideal cation ordering within a brucite-like layer in LDH with M(II)/M(III) = 2:1 ( $a, a' = 2a \sin 60^\circ = a \sqrt{3}$ ) and 3:1 ( $b, a' = 2a$ ). Open circles stand for M(II) and shaded circles for M(III).

We have observed two primary types of pH curves during LDH formation. One, observed with Cr(III)-containing LDH, consists of a single plateau at a pH lower than that necessary to precipitate either  $\text{Cr}(\text{OH})_3$  or  $\text{M}(\text{II})(\text{OH})_2$ ,<sup>[32,33]</sup> indicating direct formation of the LDH from solution. The more common form of pH curve, found for almost all Al-containing and Fe(III)-containing LDHs, exhibits two distinct plateaus.<sup>[32,33]</sup> The first plateau (pH  $\sim 4$  for Al and  $\sim 2$  for Fe) is associated with the formation of aluminum hydroxide or ferric hydrous oxide, while the second corresponds to conversion of this material to LDH.

In general, LDH materials initially form as aggregates of poor crystallinity and irregular shape, but these can be converted into euhedral hexagonal platelets through aging, often accelerated by hydrothermal or microwave treatments.<sup>[1,3,34,35]</sup> These treatments cause smaller and imperfect crystallites to evolve to larger and more perfect LDH particles through Ostwald ripening by a dissolution/recrystallization process. For example,  $\text{Mg}_3\text{Al-CO}_3$ -LDH, prepared by precipitating  $\text{Al}^{3+}$  and  $\text{Mg}^{2+}$  through hydrolyzing urea in a sealed vessel at 75–80°C for a month,<sup>[25]</sup> crystallized as perfect hexagons. Such hexagons normally have an aspect ratio of 10–20 with the in-plate dimension measured in micrometers (Fig. 3), indicating that growth along the *a* and *b* axes is preferred. We explain this growth habit in terms of intermolecular interactions. In LDH carbonate (*a* = 0.305 nm and interlayer spacing = 0.760 nm), there are 12.4 OH groups per square nanometer in the (*ab*) plane but only 5.0 OH groups per square nanometer in the (*ac*) or (*bc*) plane. Therefore to maximize the exposure of OH groups to the aqueous phase, i.e., more hydrogen bonds between water and OH in LDH or less surface tension, crystallite growth along the *a* and *b* axes is more favorable in energy. Moreover, the equal growth along these two

**Fig. 3** Scanning electron microscopy image of  $\text{Mg}_6\text{Al}_2(\text{OH})_{16}\text{CO}_3 \cdot 4\text{H}_2\text{O}$  with bar scale 1  $\mu\text{m}$ .

axes is the most favorable, and thus leads to the formation of hexagonal morphology. In addition, nucleation of a new layer will be less facile than growth at the edge of one that already exists.

The introduction of surfactant anions greatly changes the properties of LDH. For example, the surface hydrophilicity in LDH carbonate is totally converted to hydrophobicity. We have described this effect for LDH dodecylbenzene sulfonate,<sup>[36]</sup> but believe it to be a much more general phenomenon. These changes, related to the surfactant and its arrangement in the interlayer, remarkably affect the structure, growth habit, and morphology, as presented in the following section.

## LAYERED DOUBLE HYDROXIDE–SURFACTANT INTERACTIONS AND NANOCOMPOSITE FORMATION

### Layered Double Hydroxide Phases

We have extensively examined surfactant–LDH nanocomposite materials prepared by the anion exchange method. It is generally agreed that there are three distinct types of LDH phases. As shown in Fig. 4,  $\text{Zn}_2\text{Al}$ -stearate-LDHs show three obvious series of basal reflections, with average interlayer spacings of 3.19 (Phase I), 4.29 (Phase II), and 4.94 nm (Phase III), respectively. Very interestingly, the nominal particle thickness in all samples is nearly the same for

**Fig. 4** X-ray diffraction patterns of three  $\text{Zn}_2\text{Al}$ -stearate-LDH samples. (A) mainly Phase I; (B) mainly Phase II; and (C) mainly Phase III.

Phases I, II, and III, being 20–25, 50–60, and 50–60 nm, respectively, as inferred from the measured widths of diffraction peaks using the Debye–Scherrer equation.<sup>[37]</sup>

These three LDH phases give rise to distinct characteristic Fourier-transform infrared (FTIR) spectra. As shown in Fig. 5, each LDH phase is strongly related to the characteristic vibrations from carboxylate/carboxylic acid groups at 1350–1700  $\text{cm}^{-1}$ , summarized as follows:<sup>[38]</sup>

- Phase I: 1548 (broad, asymmetric  $\nu_{\text{COO}}$ ) and 1413 (broad, symmetric  $\nu_{\text{COO}}$ )  $\text{cm}^{-1}$ .
- Phase II: 1540 (sharp, asymmetric  $\nu_{\text{COO}}$ ) and 1398 (sharp, symmetric  $\nu_{\text{COO}}$ )  $\text{cm}^{-1}$ .
- Phase III: 1597 (sharp) with shoulders at 1610 and 1623 (asymmetric  $\nu_{\text{COO}}$ ), 1440 (weak), and 1413 (sharp, symmetric  $\nu_{\text{COO}}$ )  $\text{cm}^{-1}$ .

In addition, there is a common sharp peak at 1468  $\text{cm}^{-1}$  ( $\text{CH}_2$  scissoring).

We have titrated the LDH samples and found that Phases II and III contain neutral carboxylic acid in addition to carboxylate anions. The acid group is hydrogen bonded, and is characterized by a strong peak at 1597  $\text{cm}^{-1}$  and two associated shoulders at 1610 and 1623  $\text{cm}^{-1}$ .<sup>[39]</sup> This, together with the characteristic vibration peaks, can be understood in terms of the following packing modes.

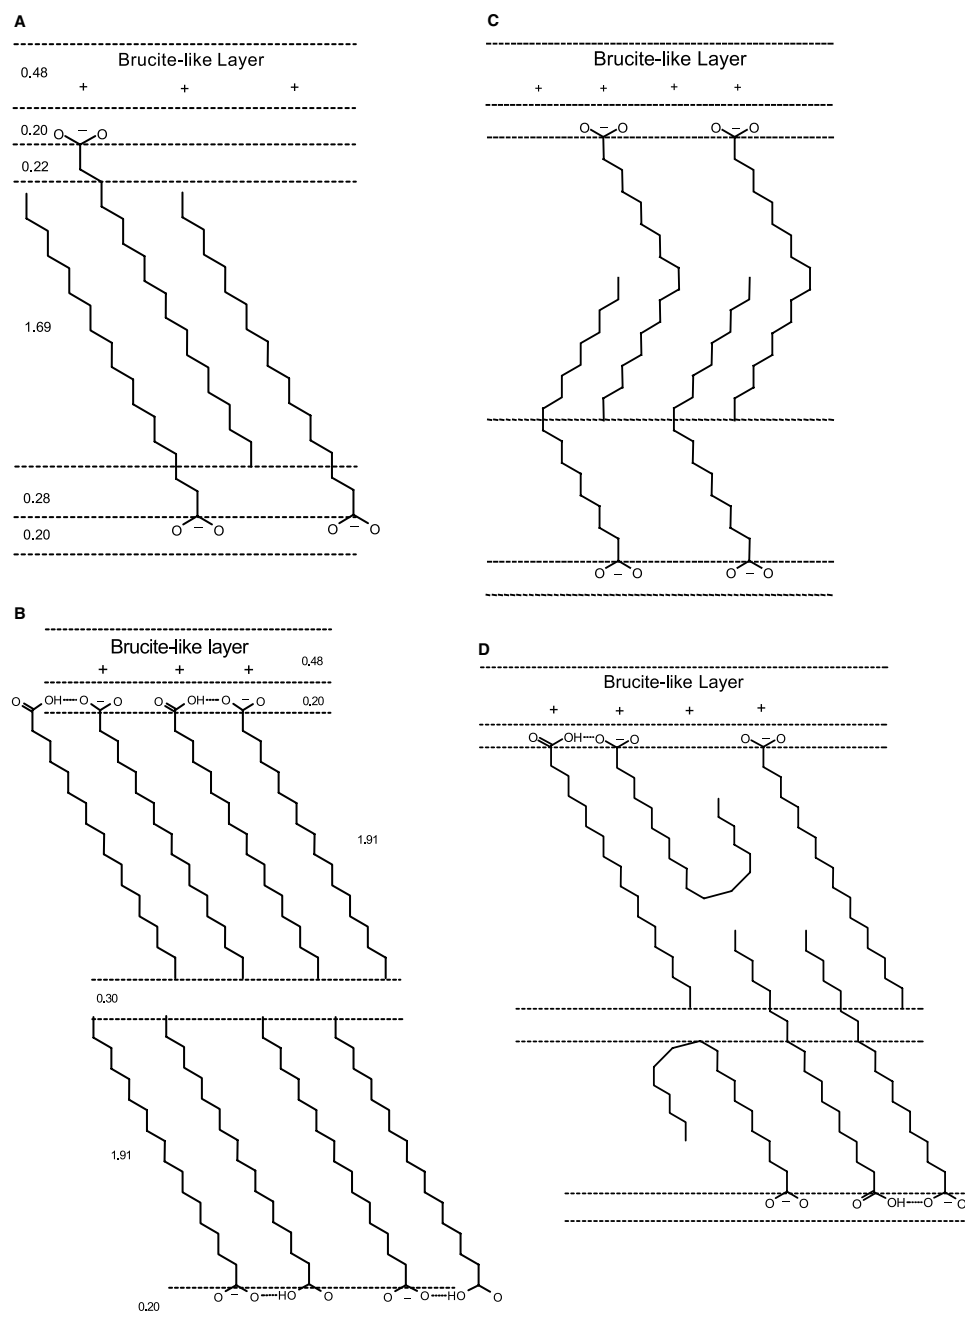

**Fig. 5** Characteristic vibration bands of  $-\text{COO}^-/\text{COOH}$  in the  $\text{Zn}_2\text{Al}$ -stearate-LDH samples of Fig. 4. (A) Phase I; (B) Phase II; (C) Phase III.

## Packing Modes

The different phases in the organo-LDH materials are supposed to be brought about by the different packing of the hydrocarbon chain in the LDH interlayer.<sup>[40]</sup> As shown in Fig. 6A for the monolayer packing (more precisely, interpenetrating packing), the two oxygen atoms in the carboxylate group are equally anchored on the hydroxide layer, which will cause the idealized extended hydrocarbon chain to be tilted at a slant angle of  $55^\circ$  (half the C–C bond angle) with an all-*trans* form.<sup>[41]</sup> The all-*trans* assignment is supported by a series of  $\text{CH}_2$  wagging bands in the range of 1150–1350  $\text{cm}^{-1}$  with an interval of 19–21  $\text{cm}^{-1}$  (Fig. 7).<sup>[39]</sup> This mode leads to a predicted interlayer spacing of 3.07 nm, unambiguously corresponding to Phase I. The actual distance, 3.19 nm, matches a tilting angle of  $61^\circ$ .<sup>[42]</sup> Based on our observations and other reports, most organic anions, including carboxylates, sulfates, sulfonates, etc. are often packed at such an angle.

The bilayer mode of Fig. 6B gives an estimated interlayer spacing of 5.00 nm, exactly the same as that found for Phase III. It also suggests hydrogen bonding of neutral COOH groups with adjacent  $\text{COO}^-$ , which is manifested in the characteristic IR spectrum of COOH/ $\text{COO}^-$  in phase III, with the asymmetrical  $\nu_{\text{COO}}$  frequency shifted from 1703  $\text{cm}^{-1}$  in the free acid to 1597  $\text{cm}^{-1}$  in the LDH gallery.<sup>[39]</sup> Most carboxylates and some secondary sulfonates use this packing, as reported elsewhere.<sup>[39–41]</sup>

However, the chain arrangement in Phase II is not as obvious as in Phases I and III. In view of the interlayer spacing, it seems to lie in between the monolayer and bilayer packing. Our experiments and other reports have shown that Phase II is formed in organo-LDH only with hydrocarbon chains longer than  $n\text{-C}_{10}\text{H}_{21}$ . Therefore we have proposed two possible packing modes in Fig. 6C, D. In the interlocking mode (Fig. 6C), the long straight chains employ a gauche configuration in the middle and are interlocked with each other. We have imposed a similar chain geometry by introducing *cis*- $\text{CH}_3(\text{CH}_2)_7\text{CH}=\text{CH}(\text{CH}_2)_7\text{COO}^-$  (oleate) into LDH, and found that the interlocking mode is the most suitable one to explain the interlayer spacing.<sup>[43]</sup> In  $\text{Mg}_2\text{Al}$ -LDH tetradecyl sulfonate ( $\text{C}_{14}\text{H}_{29}\text{SO}_3^-$ ), we have also noted this phenomenon.<sup>[44]</sup> However, this mode leaves little room for the neutral acid found to be present for saturated carboxylated/LDH materials. On the other hand, the bent chain arrangement (Fig. 6D) contains some H-bonded neutral stearic acid, in accordance with the observed results in the present case. However, it is not clear why the bending or gauche configuration occurs just in the middle part of the chain in these two modes. The nature and rigidity of packing in this

**Fig. 6** Packing modes of hydrocarbon chain: (A) monolayer; (B) bilayer; (C) interlocking; and (D) bent.

system could repay investigation by  $^{13}\text{C}$  NMR, similar to that performed by Wang et al.<sup>[45]</sup> for alkylammonium ions in montmorillonite.

It should be mentioned that Clearfield et al.<sup>[46]</sup> reported three distinct LDH phases in dodecylsulfate NiAl-, MgAl-, and ZnCr-LDHs, with different charge density in hydroxide layers. Through computer simulation, they proposed perpendicular monolayer, interdigitated, and bilayer packing modes to interpret the interlayer spacing and chain-chain hydrophobic interactions. Meyn, Beneke, and Lagaly<sup>[41]</sup> and

Carlino<sup>[40]</sup> put forward the similar perpendicular mode for packing of sulfonates and carboxylates as well.

Ideally, the packing in monolayer and bilayer has a cross section of  $0.25\text{--}0.20\text{ nm}^2$  ( $a = 0.306\text{ nm}$ , Zn/Al = 2:1), very close to that of the alkyl chains in a closely packed monolayer ( $0.20\text{ nm}^2$ ).<sup>[47]</sup> This results in very efficient hydrophobic interactions between the chains, and make the surfactant anion affinity for LDH superior to sulfate and comparable to carbonate.<sup>[36]</sup> In addition, among the three proposed modes, the packing in Phase III has full overlap between chains,

Fig. 7  $\text{CH}_2$  wagging in the range of  $1150\text{--}1350\text{ cm}^{-1}$  in the  $\text{Zn}_2\text{Al}$ -stearate-LDH samples of Fig. 4.

presumably being responsible for the strong diffraction peak at  $21^\circ$  ( $d = 0.42\text{ nm}$ ),<sup>[36]</sup> while the other two show only a weak diffraction in this region.

### Chemical Interconversion and Stability

In our experiments, we have further observed that Phase I (monolayer) can be partially converted to Phase III (bilayer) under reflux in a stearic acid solution. The appearance of new diffraction peaks in the XRD pattern (Fig. 8) after overnight reaction indicates the intercalation of neutral stearic acid. This intercalation into  $\text{Zn}_2\text{Al}$ -stearate-LDH (monolayer packing) is similar to that reported by Boehm, Steinle, and Vieweger<sup>[48]</sup> who also observed swelling of interlayer spacing of  $\text{Zn}_2\text{Cr}$ -LDH alkyl sulfate from monolayer to bilayer by intercalating *n*-alkyl alcohols or amines. The driving force for the conversion may come from the strong hydrophobic interactions because of the full overlapping and the tail-tail hydrophobic connection in the bilayer packing mode (Fig. 6). Note here that a neutral species (carboxylic acid, alcohol, or amine) is necessary to form a bilayer structure. Kanoh, Shichi, and Tagaki<sup>[49]</sup> noted the transformation of the monolayer to bilayer materials dependent on the temperature and initial stearate concentration.

In contrast, Phase III cannot be converted to Phase I by removal of acid, even in strongly alkaline solution ( $\text{pH} = 11\text{--}12$ ). This could be attributed to several

Fig. 8 X-ray diffraction pattern of  $\text{Mg}_2\text{Al}$ -stearate-LDH (initially monolayer) (a) before and (b) after reaction with stearic acid solution.

factors. It is presumably very difficult for  $\text{OH}^-$  anions to approach the gallery because the inside and outside surface of LDH particles are highly hydrophobic and repulsive to the entrance of hydrophilic  $\text{OH}^-$  groups. More seriously, the  $\text{OH}^-$  will encounter electrostatic repulsion from interlayer stearate anions when it is approaching the surface and moving into the gallery. Even if neutral  $\text{C}_{17}\text{H}_{35}\text{COOH}$  reacts with the coming  $\text{OH}^-$  to become  $\text{C}_{17}\text{H}_{35}\text{COO}^-$ , the extra anion must find its way out of the particles to maintain charge neutrality. However, its removal will break strong hydrophobic interactions as indicated above, which further limits the acid-base reaction.

As mentioned above, the bilayer packing LDH samples have neutral stearic acid inserted in the interlayer under reflux conditions. Furthermore, heating at  $150^\circ\text{C}$  in air does not lead to any noticeable change in the XRD pattern and IR spectrum. The chemical stability of these samples is in sharp contrast to phenylphosphonate LDH. As reported by Nijs, Clearfield, and Vansant<sup>[50]</sup> monovalent phenylphosphate anion ( $\text{PhP}(=\text{O})\text{O}_2\text{H}^-$ ,  $\text{p}K_a = 7.43$ )<sup>[51]</sup> can be introduced into LDH with a proper metal ratio at room temperature, but refluxing gave as the main product a layered metal phenylphosphonate compound. In addition, heating at  $115\text{--}200^\circ\text{C}$  caused the collapse of the LDH structure frame, releasing a water molecule and directly linking phosphonate and metal ion.

In general, the carboxylic acid group has a  $\text{p}K_a$  of around 5, is more acidic than monovalent

phosphonate, and should react with the hydroxide layer in a similar way. For example,  $\text{Zn}_2\text{Al}$ -stearate-LDH (bilayer packing) completely dissolves in excess acetic acid solution ( $\text{pH} = 3.2\text{--}3.6$ ) at  $90^\circ\text{C}$ . However, this material is stable in water at  $100^\circ\text{C}$  or when heated on its own to  $150^\circ\text{C}$  despite the presence of unionized carboxylic acid within the structure. Thus the hydrogen bond between  $\text{COOH}$  and  $\text{COO}^-$  (Fig. 6B) has seriously depressed the acidity of the carboxylic acid group and frozen the reaction ability of  $\text{COOH}$  toward the layer hydroxide group.

### Morphological Features and Crystallization

Because of the hydrophobic interactions and multiple packing modes of organic anions, the organo-LDHs show versatile morphological features. In general, as we had observed and as other researchers had reported, the organo-LDHs have bar-like, sheet-like, or ribbon-like particles with micrometer or sub-micrometer dimensions, with or without regular shapes.<sup>[36,43,44,52–55]</sup>

In particular, the particles in Phase I are normally not regularly shaped, as shown in Fig. 9A for a monolayer  $\text{Zn}_2\text{Al}$ -stearate-LDH prepared by exchange method. However, there are some exceptions. For example, in rare cases, the particles in  $\text{Mg}_2\text{Al}$ -LDH dodecylbenzene sulfonate develop a bar-like shape, although irregular shapes predominate.

In the scanning electron micrograph (Fig. 9C), the featured sheets for Phase III (bilayer) are rectangle-shaped, but some are curved or broken. We have also observed very long rectangle-shaped ribbons for  $\text{Zn}_2\text{Al}$ -LDH elaidate although there were some irregular sheets and/or amorphous aggregates.

Phase II of  $\text{Zn}_2\text{Al}$ -stearate-LDH has also been featured with sharply edged rectangle sheets (Fig. 9B). However, we observed different particle shapes in  $\text{Zn}_2\text{Al}$ -LDH oleate<sup>[43]</sup> and  $\text{Mg}_2\text{Al}$ -LDH tetradecyl sulfonate.<sup>[44]</sup> The former has irregular shape while the latter has well-shaped hexagons elongated along the  $a$  axis.

Thus it is seen that the morphology of organo-LDHs is much more complicated than the inorganic LDHs. The complexity can be attributed to the introduction of hydrophobic interactions. As previously mentioned, the LDH particle surface is hydrophobic, and thus there is no preferred growth along axis  $c$  or  $a$  or  $b$ . Growth along each axis has some advantages and disadvantages. As we know, the surfactant anions on the  $(ab)$  plane are held in plane through electrostatic interaction and must direct their hydrophobic tails toward the aqueous phase. This hydrophobic layer can now attract additional surfactants to form an antiparallel second layer, which

A monolayer

B bent

C bilayer

**Fig. 9** Scanning electron microscopy images of  $\text{Zn}_2\text{Al}$ -stearate-LDHs with predominant (A) monolayer, (B) bent, and (C) bilayer LDH phases. Scale bar  $1\ \mu\text{m}$ .

will facilitate nucleation of new sheets and self-promoted assembly for crystallite growth. Therefore growth along the  $c$  axis is kinetically more accessible in LDH–surfactant materials than in inorganic LDH, probably giving bar-like and ribbon-like particles.<sup>[36,43,44]</sup> As shown in Fig. 10, alternating and broadly parallel dark (hydroxide layer) and pale (organic layer) stripes are recorded by high-resolution transmission electron microscopy (HRTEM).<sup>[56,57]</sup>

**Fig. 10** Transmission electron microscopy image of  $\text{Zn}_2\text{Al-H240-LDH}$ . Scale bar 50 nm (data supplied by Dr. K. Yu).

The measured repeat distance between similar stripes is 3.3 nm, in good agreement with the interlayer spacing (3.57 nm) given by XRD. This transmission electron microscopy (TEM) image confirms a *c*-directed growth habit, in contrast to the *a*, *b* growth of the inorganic LDHs.

However, the (*ac*) and (*bc*) planes are also hydrophobic albeit less than the (*ab*) plane. Thus the final shapes depend on the balance between several factors, such as the nature of organic anions (type, chain length, chain structure, etc.) and preparative conditions (temperature, concentration, aging). Indeed, we find large varieties in morphologies between different organic LDH materials, as previously mentioned.

Because the surface of LDH surfactant crystallites is hydrophobic, it is easier for crystallites to aggregate or self-assemble through hydrophobic forces. The intermolecular hydrophobic interactions can bring about curvature to the sheets, as we have often observed in scanning electron microscopy (SEM) images. In the particular case of the dicarboxylate surfactant anion H240 [formed from the Diels–Alder addition product of acrylic acid to conjugated (9,11 and 10,12) linoleic acids], we find that the LDH derivatives can be prepared in water as spherical aggregates with diameters of 0.5–3 μm under controlled conditions of heating and stirring. This self-assembly on the millimeter scale may possibly be connected with the double-headed nature of the surfactant.<sup>[55]</sup>

### Applications of Layered Double Hydroxide–Surfactant Hybrid Materials

Layered double hydroxides are often used as polymer additives especially for polyvinylchloride (PVC).

Miyata<sup>[58]</sup> has shown that as little as 0.05–1% well-crystallized LDH improves the thermal stability and weather resistance of thermoplastic resins containing halogen and/or acidic components from the manufacturing process. In addition, chlorine-containing polymers commonly undergo degradation under heat and UV light, giving off gaseous HCl. This corrodes molding machines and may catalyze further degradation, leading to brittleness and discoloration. Layered double hydroxides are added as environmentally benign neutralizers for this acid. It has been found<sup>[59]</sup> that  $\text{MgZnAl-LDH}$  can be a very good acid absorbent. However, inorganic LDH is immiscible with polymer because of the surface tension. Fortunately, coating or intercalating surfactant anions bring about a hydrophobic surface that can well combine the hydrophilic inorganic LDH and hydrophobic polymer to make full use of LDH in polymer reinforcement. Fisher and Gielgens<sup>[60]</sup> partially exchanged LDH with anion surfactants and then mixed with monomeric materials, e.g., caprolactam, to make well-blended polymer–LDH composites.

A newly emerging technique is to incorporate delaminated LDH surfactant sheets into polymer matrix. The nanometer-scale interaction between polymer and LDH hydroxide sheets, and the tortuosity of diffusion through such a composite, may prove to exert a tremendous influence on such properties as mechanical strength and hardness, thermal stability, flexibility and durability, and impermeability.

By incorporating surfactant anions, LDH was reported by Leroux et al.<sup>[61]</sup> to exfoliate in hexanol on heating. In elegant work, Hibino and Jones<sup>[62]</sup> prepared the glycine anion derivative of  $\text{MgAl-LDH}$  and observed its complete delamination in formamide, presumably strongly assisted by glycine–solvent hydrogen bonding. We ourselves have exfoliated  $\text{Mg}_3\text{Al-stearate-LDH}$  in hexadecane, which was removed by washing with hexane and drying in vacuum. The resultant white powder was dispersed into styrene, followed by in situ polymerization. High-resolution TEM (transmission electron microscopy) images of microtomed sections showed the presence of individually dispersed  $\text{Mg}_3\text{Al-stearate-LDH}$  single layers. O’Leary, O’Hare, and Seeley<sup>[63]</sup> also found the almost complete delamination of  $\text{Mg}_2\text{Al-dodecylsulfate}$  in polar acrylate monomer solution, leading to incorporation of the delaminated sheets into the polymer matrix after polymerization in situ. This polymer/LDH nanocomposite showed a much higher thermal stability than the pure polymer itself.

The delamination of LDH surfactant and its subsequent incorporation into polymeric matrix are still under active investigation in our laboratories.<sup>[64]</sup> We are also investigating the mesoporous and/or microporous mixed oxides and carbon/oxide composites

formed by calcination of LDH surfactant derivatives, which appear to be efficient absorbents for various heavy metal ions.

## CONCLUSION

In conclusion, LDHs vary in structures and compositions. As discussed, many cations and anions are candidates for incorporation into LDH compounds. By optimizing and carefully controlling the compositions, we can make various LDHs with particular structure and properties. For example, in the case of LDH-surfactant systems, there are in some cases at least three distinct LDH phases with the same cations and anions. The delamination of LDHs using amino acids or surfactant holds promise for the production of useful polymer-LDH nanocomposites in the near future.

## INTRODUCTION

Biological molecules such as antibodies show exquisite specificity in binding to target molecules. This binding is naturally reversible, and the stability of the antibody–target complex is often a matter of concern because experiments can be compromised if it dissociates or exchanges with other molecules. Here we describe the current state of molecular technology for making specific complexes irreversible, so that target specificity is preserved while dissociation is effectively prevented. The emphasis is on antibody applications, but the same concepts apply to other binding systems.

## Statement of the Problem

One of the most important elementary phenomena in biochemistry and biology is the reversible binding of one molecule to another:

If  $A$  is an antibody and  $B$  is its target, this can be the first step in resistance to infection; if  $A$  is a drug molecule and  $B$  is its receptor, this can be the basis for pharmacological action; there are many other fitting examples. An important feature of this process is that binding is *specific*: sites on molecules  $A$  and  $B$  fit together to form a complex, but  $A$  and  $B$  do not bind indiscriminately to other molecules. Specific binding is generally achieved by complementary noncovalent interactions between  $A$  and  $B$ , such as hydrophobic bonding, hydrogen bonding, ion pairing, and pi-stacking. In biological systems, binding of  $A$  and  $B$  is usually accompanied by the release of several water molecules from the surface of each. This provides an entropy change in favor of complex formation.

Reversible binding (Eq. (1)) is quantitatively characterized by rate constants  $k_1$  and  $k_2$ , and an equilibrium constant  $K_d$ :

At equilibrium,  $k_1 [C] = k_2 [A][B]$  and

$$K_d = \frac{k_1}{k_2} = \frac{[A][B]}{[C]} \quad (2)$$

The brackets  $[\ ]$  denote concentrations, in units of mol/L, M. Rate constants  $k_1$  and  $k_2$  have different units: typically,  $k_1$  is expressed in units of  $\text{sec}^{-1}$  for the first-order dissociation process, while  $k_2$  is expressed in units of  $\text{M}^{-1} \text{sec}^{-1}$  for the second-order (bimolecular) association process. The units of  $K_d = k_1/k_2$  are then mol/L, M. A common rule of thumb is that useful pharmaceuticals should bind to their targets with dissociation constants  $K_d \leq 10^{-9} \text{M}$ . Note that when  $[A]$  equals  $K_d$ , then  $[B] = [C]$  and the target  $B$  is half-saturated (the complex  $C$  is formed with 50% yield).

The rate of the association reaction can be no faster than the rate at which  $A$  and  $B$  diffuse together, and it is usually found that  $k_2 \leq 10^9 \text{M}^{-1} \text{sec}^{-1}$ . We can use this to estimate the minimum bound lifetime of the complex. For the case  $K_d = 10^{-9} \text{M}$ , at maximum  $k_2 = 10^9 \text{M}^{-1} \text{sec}^{-1}$ , and the maximum value of  $k_1 = 1 \text{sec}^{-1}$ . From fundamental mathematics, the lifetime  $\tau$  of the average complex in Eq. (2) is  $\tau = 1/k_1$ , which in this case would be 1 sec. A bound lifetime of 1 sec would be too short for many practical applications. (Because we used a maximum value for  $k_1$ , we have calculated a minimum value for  $\tau$ . Few experimental on-rates are as large as  $10^9 \text{M}^{-1} \text{sec}^{-1}$ ; for a given  $K_d$ , if the on-rate  $k_2$  is smaller, then the off-rate  $k_1$  is also smaller, and the bound lifetime of the complex is longer.)

Biological molecules can exhibit more complicated properties than those described above. One common variation is that macromolecules may incorporate more than one binding site for target molecules, and undergo multivalent binding.

## ADDED COMPLICATIONS OF MULTIVALENT BINDING

### Elementary Kinetic Scheme has System-Dependent Terms

A ligand–receptor system in which the binding equilibrium can be more than monovalent is illustrated by the divalent antibody molecule binding to the polyvalent

target in Eq. (3). Association of the antibody to its target occurs in two distinct steps: first, the familiar association from two separate molecules with rate constant  $k_2$ , and second, a unimolecular ring-closing reaction with rate constant  $k_y \text{sec}^{-1}$ . The latter reaction involves the same ligand–receptor interaction chemistry as the bimolecular association, but here the process does not require two separate molecules to diffuse together.

It should be noted that the equilibrium constant for bivalent association is not calculated simply by squaring the equilibrium constant for monovalent association. It is commonly found for antibody binding to multivalent targets that bivalent association decreases the overall dissociation constant by a factor of 100–1000 relative to monovalent association, making binding more stable but not vastly so. However, in some cases, such as cancer cells that overexpress a particular cell-surface protein, a bivalent antibody can associate with an antigen-rich surface practically irreversibly. This has inspired considerable effort in developing systems that bind multivalently to enhance the strength of the binding interaction in practical situations. A common example is the engineering of antibodies and other proteins for multivalent binding to carbohydrates, for which monovalent binding tends to be weak.

### Effective Local Concentration

With reference to Eq. (3), it is possible to take the ratio of  $k_y/k_2$ , which is expressed in mol/L, as indicating the effective local concentration of the target in the vicinity of the monovalently bound antibody molecule. When experimental results are available, this provides an index of the density of targets on the particle in Eq. (3) and their accessibility to the second arm of the antibody molecule—a composite quantity that is difficult to calculate. The effective local concentration is sometimes a nonphysically large quantity, indicating favorable geometric and entropic properties for forming the second association.

Multivalent binding can have unwanted consequences: for example, when an antibody binds two targets on a cell surface, it can trigger the internalization of the complex and subsequent changes in the cell's behavior. Of course, if the targets are not linked

together, binding of an antibody to two targets involves two independent bimolecular association events as in Eq. (1), which does not increase binding strength. For these reasons, it is frequently desirable to enhance the strength of monovalent binding.

From the protein engineering viewpoint, reversible binding may be strengthened by combinatorially varying the amino-acid residues in the binding site, to seek mutant proteins that exhibit thermodynamically

more favorable binding.<sup>[1]</sup> There is considerable activity in developing new experimental approaches to combinatorial selection, and remarkably high binding affinities have been achieved in some cases.<sup>[2]</sup> Extrapolating this to its logical extreme leads to binding that is so strong it is not reversible.

Fig. 1 illustrates the progressive effects of increasing binding affinity (decreasing  $K_d$ ). With reference to Eqs. (1) and (2) above, this shows a semilogarithmic plot of  $[B]/[B] + [C] = K_d/K_d + [A]$  as a function of  $[A]$  for various values of  $K_d$ . Moving from right to left, we see the curves for progressively stronger binding, with their half-saturation points at  $[A] = K_d$ . The system with  $K_d = 1 \times 10^{-7} \text{M}$  has the lowest affinity, comparable to a weakly binding antibody; the system with the highest affinity,  $K_d = 1 \times 10^{-15} \text{M}$ , is comparable to the strongest-binding systems found in nature. Reducing the concentration of free target to 50% requires an amount of free antibody  $[A] = K_d$ ; reducing the concentration of free target to 1% requires an amount of free antibody  $[A] = 99K_d$ ; reducing the concentration of free target to 0.1% requires an amount of free antibody  $[A] = 999K_d$ ; and so on.

Infinite binding affinity corresponds to  $K_d = 0$ , which is the horizontal line at the bottom of Fig. 1. Here binding is irreversible and a 1:1 ratio of antibody to target is sufficient to reduce the concentration of free target to zero at equilibrium; no excess is required. Obviously, there will be practical limitations on literally achieving a zero concentration of free target with a precisely 1:1 ratio of antibody to target, because as the concentrations of antibody and target become increasingly small, the rate of the second-order association reaction ( $=k_2[A][B]$ ) tends to zero. However, a small excess of antibody can make a difference at this stage: as target  $B$  becomes depleted, the concentration  $[A]$  of antibody becomes much larger than  $[B]$  and, as a consequence, ceases to decline significantly.

## Free Ligand vs Antibody concentration

**Fig. 1** Binding curves for ligand–receptor systems with different affinities. The horizontal line at the bottom of the graph corresponds to infinite affinity.

The experimenter can control the rate of the association reaction (still  $= k_2[A][B]$ ) by choosing the amount of  $A$  to add to the system.

### PRINCIPLES OF IRREVERSIBLE BINDING

Consider an engineered monovalent antibody (fragment) that can bind irreversibly to its target. The molecular mechanism of this process is illustrated in Eq. (4), consisting of a reversible binding step followed by an irreversible locking step. The mathematics describing irreversible binding are not unlike those for bivalent binding (Eq. (3)). Conceptually, molecular recognition of the target and reversible binding is the first step in both; it is followed by an intramolecular ring closure that involves either a second binding site (Eq. (3)) or a reactive moiety in or near the first binding site (Eq. (4)).

The difference is that we replace  $k_y$  with  $k_{\text{irr}}$  and  $k_x = 0$  for Eq. (4). The most valuable situation for irreversible pharmacological targeting is when  $k_{\text{irr}} \gg k_1$ , so that the complex is formed irreversibly upon binding, without dissociation. Irreversible binding with little or no dissociation has been achieved for an antibody that binds a small molecule, using synthetic chemistry to engineer the small molecule and site-directed mutagenesis to engineer the antibody.<sup>[3]</sup> This is referred to as infinite affinity, because the off-rate is effectively zero. Because the locking reaction must occur within the lifetime of the

complex  $\tau = 1/k_1$ , infinite affinity is easier to achieve when  $k_1$  is small.

### EXPERIMENTAL BACKGROUND

In the past, enzymologists, immunologists, and other professionals prepared reactive organic molecules that resembled known enzyme inhibitors or antibody haptens, and identified important residues in the respective protein binding sites by forming stable covalent bonds and analyzing the products. The reagents have employed relatively reactive electrophiles such as isothiocyanates, sulfonyl fluorides, mustards, or nitroaryl halides.<sup>[4–7]</sup> Under appropriate conditions, these electrophiles exist for a useful period of time in aqueous solution, although they are quite reactive. When the electrophilic inhibitors are bound to their targets, the effective local concentration of protein nucleophiles (particularly thiols, but also amino groups, etc.) near the bound electrophile can lead to specific attachment to one or a few amino acid side chains.

The concepts underlying these *in vitro* experiments can be extended to developing molecules for use *in vivo*, by developing ligands that are unreactive to the many nucleophiles that occur in living systems but nonetheless react efficiently with their specific protein molecules. When the protein has a conveniently located cysteine sidechain, this can be accomplished by judicious chemical synthesis of the ligand. In some

other circumstances, a cysteine can be engineered into the protein.

The favorable situation of a uniquely reactive group advantageously placed in a binding site is not often found in nature. An exceptional example from the pharmaceutical literature is given by Fry et al.<sup>[8]</sup> who synthesized 4-anilinoquinazolines carrying mildly electrophilic acryl groups, which proved to bind irreversibly to one of the cysteine residues in the catalytic domain of the epidermal growth factor receptor (EGFR). Another work with  $\alpha,\beta$ -unsaturated carbonyl compounds as enzyme inhibitors further supports this approach to irreversibly blocking an important binding site by Michael addition to a cysteine side chain.<sup>[9]</sup> When it is part of a rapidly cleared small molecule, the  $\alpha,\beta$ -unsaturated carbonyl compound does not detectably react with nucleophiles normally present in the blood because the contact time is short and they are present in low concentration.<sup>[10]</sup> The most important nucleophiles in circulation are thiols on glutathione and other small molecules, and the free cysteine side chain in albumin.

## ENGINEERING INFINITE AFFINITY

Converting a natural protein to irreversible binding has been achieved in a few instances, by engineering a cysteine residue into a chosen position in the binding site.<sup>[3,11,12]</sup> Here the aim is to exploit the exceptional nucleophilicity of a well-placed sulfur atom to form a stable covalent bond. In applications reported so far, the other binding partner has been a small organic molecule. Thus a double engineering approach is used, relying on the tools of modern molecular biology to design and produce a mutant protein, and synthetic chemistry to produce the small molecules that target the engineered binding site on the protein.

Planning the experimental strategy is made easier if a crystal structure of a natural complex is available. Chmura, Orton, and Heares<sup>[3]</sup> referred to the crystal structure of the antibody CHA255 bound to its indium-chelate haptin.<sup>[13]</sup> Levitsky, Ciolli, and Belshaw<sup>[11]</sup> used the structure of the cyclophilin A–cyclosporin A complex.<sup>[14]</sup> In each case, amino-acid residues that were near, but not in contact with, the bound organic ligand were identified.

Chmura chose residues within the binding site of the antibody (Fig. 2). These residues, which are in complementarity determining region 3 of the light chain, were chosen because their side chains: 1) are not exposed on the outer surface of the antibody; 2) do not have any direct contacts with the bound ligand; and 3) lie within a few angstroms of the para substituent on a benzene ring in the ligand. The latter criterion allowed for ease

**Fig. 2** Crystal structure of antibody CHA255–indium chelate complex. Source: From Ref.<sup>[13]</sup>. Two residues in the wild-type antibody that are not directly involved in ligand binding but are favorably located close to the *para*-substituent of the ligand (yellow) are light-chain residues S95 and N96 (Kabat positions 93 and 94). of synthesis of a library of candidate ligands for irreversible binding. On the other hand, Levitsky chose protein residues that: 1) are exposed on the outer surface of the protein; 2) do not have any direct contacts with the bound ligand; and 3) lie within a few angstroms of a suitable site for synthetic modification of the ligand. In each case, site-directed mutagenesis was used to prepare cysteine mutants in the chosen positions. The proteins were expressed by using appropriate cell lines, and characterized by standard methods.

**Fig. 3** Electrophiles tested for: 1) lack of reactivity in complex physiological media; and 2) specific reaction with engineered antibody S95C (Fig. 2). Source: From Ref.<sup>[3]</sup>. © 2001, The National Academy of Sciences of the United States of America.

Chmura compared a set of electrophilic substituents (Fig. 3), not only for specific reaction with the engineered cysteine side chain but also for physiological clearance in animal models, settling on the acryl group.<sup>[10]</sup> This agrees with the experience of other researchers who have sought to use the Michael addition to cysteine sulfur for permanent binding under physiological conditions. The attack of a sulfhydryl group on the double bond of a nearby  $\alpha,\beta$  unsaturated carbonyl compound appears to have favorable properties for use in site-directed protein targeting under physiological conditions in vitro and in vivo. Under these conditions, the reaction is irreversible. The attachment is stable even to the conditions of boiling and reduction that accompany preparation of a sample for gel electrophoresis.

## CONCLUSION

Infinite affinity binding systems are at a very early stage. However, it seems clear that they offer unique advantages in practical applications where irreversible association is needed. A potentially fertile area is in pharmaceutical applications where elimination of a specific molecule is required. For example, antibodies against growth factors are under development as cancer therapies.<sup>[15]</sup> It may prove worthwhile to completely eliminate a particular growth factor by irreversible binding. In the area of in vitro assays, the avidin–biotin binding pair is widely used in circumstances where practically irreversible binding, e.g., of a biotinylated protein to a surface, is required. Avidin only binds biotin, and the binding is not actually irreversible. Many systems with infinite affinity are possible, offering the possibility of multiplexed sets of orthogonal binding pairs to localize different ligands permanently and specifically on the same surface. On the other hand, for those applications that require buffering the concentration of a ligand within a particular concentration range, reversible binding is intrinsically superior as long as a binding partner with an appropriate  $K_d$  is available.

## ACKNOWLEDGMENTS

I thank A.J. Chmura and Molly Orton, who started this field with their work in my laboratory. Other students and colleagues who made useful suggestions on various aspects include Brian D. Schmidt, Donald T. Corson, Stacey L. Traviglia, Todd M. Corneillie, Chung Song, and David A. Goodwin. Our research was supported by Research Grant CA16861

from the National Cancer Institute, National Institutes of Health.

## INTRODUCTION

Cell membranes define the size and shape of the cell. In addition to this structural role, the membrane has a crucial regulatory role determining what information, nutrients, and waste can permeate this barrier. The cell membrane consists of a lipid bilayer and proteins, which can be either transmembrane or associated with one leaflet of the bilayer. The dynamic organization of proteins and lipids into domains (e.g., rafts) within the bilayer is important for multiple cellular processes, such as recognition and signaling events.

The chemical recognition process occurring on the surface of membranes is the basis of a versatile and specific sensor system for the cell. Lipid bilayer systems that mimic certain aspects of cell membrane function have been employed in biosensor schemes and continue to generate great interest in the nanotechnology field. Chemical recognition events can also cause structures to form, providing a mechanism for creating controllable, dynamic nanoscale architectures. The two main platforms for studying the dynamic properties of membranes for both nanotechnology and nanoscience applications are vesicular structures, called liposomes, and supported lipid bilayers.

This entry aims to illustrate the importance of dynamic nanoscale structures in biological and model biological membranes. Applications of such structures for drug screening, biosensors, and microanalysis will be discussed. The emphasis will be on understanding what triggers structural reorganization on the nanoscale and how the temporal and spatial aspects of such reorganization can be controlled. The sophistication of the nanoscale machinery of the cell membrane offers many lessons that can be applied to the emerging field of nanotechnology.

## LIPIDS, LIPOSOMES, AND SUPPORTED BILAYERS

Lipids are amphiphilic molecules, having a hydrophobic tail and a polar head group (Fig. 1A). Most

commonly the tail consists of two fatty acid chains with an even number of carbon atoms (14–18 atoms long) and with various degrees of unsaturation.<sup>[1]</sup> In biological membranes, the key components are phospholipids, which have a phosphate at the head group position that is connected to the hydrophobic tails through a glycerol backbone. Often, another moiety, such as choline, serine, or inositol, is attached to the phosphate to form PC, PS, or PI-type lipids, respectively.<sup>[2]</sup>

In an aqueous solution, these amphiphilic lipids self-assemble into liposomes (Fig. 1B).<sup>[2]</sup> The spherical bilayer structure minimizes unfavorable interactions of the hydrophobic tail region with the water. The head group and tails determine the properties of the bilayer membrane, such as fluidity, charge density, and permeability. As recognized by Singer and Nicolson,<sup>[3]</sup> the membrane is a fluid mosaic of lipids and proteins. This fluid-mosaic model does not, however, preclude the existence of structured regions (domains or rafts) within the lipid bilayer. In fact, it is the membrane's fluidity that enables the creation of dynamic nanoscale structures. The lipids can exist in three distinct phases: a tightly packed, ordered gel phase, an intermediate liquid ordered phase, and a disordered liquid phase. The transition temperature for gel to liquid phase transitions ( $T_g$ ) decreases with decreasing chain length and degree of unsaturation. The steric hindrances, electrostatic charge, and hydrogen bonding of the head groups can also affect the transition temperature as well as the phase separation within the membrane. Such phase-separated domains (e.g., rafts) can undergo compositional fluctuations.<sup>[4]</sup> It is key to recognize that under physiological conditions, the membrane is a heterogeneous,<sup>[4]</sup> non-equilibrium<sup>[5]</sup> system.

As previously mentioned, liposomes and supported bilayers are the two main systems of interest. Supported lipid bilayers can be prepared by the classic Langmuir–Blodgett method. Alternately, liposomes can be fused with surfaces to form supported bilayers.<sup>[6]</sup> The fusion schemes for hydrophilic surfaces outlined in Fig. 2A and C result in opposite orientations of

**Fig. 1** (A) Illustration of a lipid molecule showing the hydrophobic tail region and polar head group and the chemical structure for a typical lipid (1,2-distearoyl-*sn*-glycero-3-phosphocholine, DSPC). (B) The liposome (or vesicle) that spontaneously forms when lipids are placed in aqueous solutions.

membrane faces and any incorporated proteins. In Fig. 2C, the orientation of the leaflets toward the bulk aqueous solution is preserved upon fusion. In the mechanism detailed in Fig. 2A, however, the orientation of the leaflets is reversed; that is, the inside leaflet of the liposome becomes the top leaflet of the supported bilayer. Vesicle fusion to hydrophobic surfaces (Fig. 2B) can also be accomplished but the liposomes must rupture resulting in attachment and spreading of the two leaflets of the lipid bilayer. Liposome composition, surface chemistry, vesicle size, temperature, osmotic pressure, and the presence of calcium ions are all factors that influence vesicle fusion.<sup>[7,8]</sup> Typically, supported bilayers formed by vesicle fusion maintain a thin layer of water (~10 Å) between the substrate and the adjacent membrane surface.<sup>[9–11]</sup> This supported bilayer structure is very stable (days to months) in an aqueous environment, but unstable in the presence of detergents or in air. The lateral mobility of lipids within the bilayer is maintained enabling the molecules in the membrane to diffuse over long distances.

There is a suite of tools available for the characterization of nanoscale structures in lipid bilayers. For a

description of standard methods for general liposome characterization, the reader is referred to the relevant chapters in the book by D.D. Lasic<sup>[1]</sup> and the book edited by R.R.C. New.<sup>[2]</sup> Fluorescence microscopy provides a means to attain real-time data on the dynamical structures occurring in lipid bilayer systems. Single-molecule sensitivity is achievable. Fluorescence resonance energy transfer (FRET) between a fluorescently tagged donor component and a fluorescently tagged acceptor component yields accurate distance information for short length scales. In fluorescence recovery after photobleaching (FRAP), an area on the bilayer surface is photobleached and then monitored for recovery of fluorescence intensity. The fluorescence recovery is due to fluorescently labeled molecules diffusing into the bleached area and can thus be used to measure diffusion rates to evaluate lateral fluidity.

Spatial resolution of fluorescence techniques are, however, diffraction limited to a few hundred nanometers. Unfortunately, this length is often the same size as the dynamic structures. The atomic force microscope (AFM), on the other hand, can be used to characterize features in supported bilayers with sub-nanometer resolution.<sup>[12]</sup> The AFM typically requires about a minute to capture an image. Thus it is suitable for imaging relatively static systems, or slow dynamics. Fluorescence and AFM imaging are the two techniques most relevant to the work discussed in this entry, but other methods, including neutron scattering and nuclear magnetic resonance (NMR) spectroscopy,<sup>[13]</sup> have also been applied toward dynamic nanostructures in bilayer systems.

Computer simulations are also an effective tool for understanding dynamic nanostructures in bilayer membranes.<sup>[14]</sup> Nielsen and coworkers simulated binary mixtures of lipid bilayers revealing dynamic microphase separations with length scales of tens of nanometers.<sup>[4]</sup> They further showed that this nanoscale structure affects the functional properties of the membrane. Through simulations and theoretical modeling, Gil et al. analyzed protein organization in lipid bilayers.<sup>[5]</sup> The lateral organization of transmembrane proteins can be explained by the properties of the lipid bilayer. Hydrophobic matching between lipids and the hydrophobic region of proteins can lead to an enrichment of one lipid species near the protein. As such, the lipids can mediate protein attraction or repulsion. Also, the wetting of a protein by one lipid component can lead to larger protein organization patterns.

## DYNAMIC NANOSTRUCTURES IN BIOLOGICAL AND MODEL BIOLOGICAL MEMBRANES

In this section, a few examples will be given to illustrate the importance of dynamic nanostructures

**Fig. 2** Schematic representation of the possible mechanisms for planar bilayer formation from liposomes on hydrophilic and hydrophobic surfaces. The drawings are not drawn to scale. Lipid molecules on the support are enlarged approximately 50-fold compared to a liposome. (A) Vesicle fusion on a hydrophilic surface with the leaflet orientation reversed. in biological systems. Rafts, domains, and hierarchical structures are prevalent in the cell membrane and are the predominant sites of biological activity. Subczynski and Kusumi<sup>[15]</sup> reviewed the three types of rafts (Fig. 3) found, to date, in plasma membranes. In unstimulated cells there are small, unstable (lifetimes of less than 1 msec) lipid rafts (A, A', and A'' in Fig. 3) that may have associated proteins. When receptor molecules in these unstable rafts react with ligands, they can create stabilized rafts (Fig. 3B) with lifetimes of minutes. The coalescence of these two types of rafts creates transient confinement zones (TCZs), which serve as signaling rafts (Fig. 3C) by assembling the necessary constituents to switch on a downstream signaling pathway.

Such dynamic nanostructures have been shown to be important in a variety of biological systems. Sheets, Holowka, and Baird explain how the organization of the plasma membrane likely exerts spatio-temporal control on immunoglobulin E receptor-mediated signal transduction.<sup>[16]</sup> Lipid rafts also play a key role in the immunological synapse.<sup>[17–19]</sup> The T-cell antigen receptors (TCR) are located in rafts and they become cross-linked by ligand binding. The cross-linking induces raft aggregation, causing colocalization of signaling proteins. This activates the phosphorylation of tyrosine

residues on membrane-associated proteins and starts downstream signaling.

Because the biological membrane is a complex entity, most structure and function studies are performed on simpler, well-defined model membrane systems of liposomes and supported bilayers. For example, in studies of lipid raft formation, ternary mixtures of saturated lipids, unsaturated lipids, and cholesterol have been found to spontaneously form rafts over a wide range of specific lipid species and concentrations.<sup>[20–22]</sup> In these studies, micron-sized domains were imaged via fluorescence microscopy techniques. Nanostructural features in lipid bilayers can also be revealed with AFM, although the domain shape and size have been shown to be somewhat dependent on the substrate and bottom leaflet of the supported bilayer.<sup>[23,24]</sup>

Not only do lipid–lipid interactions cause domain formation but lipid–protein interactions can also induce nanoscale structures to form. Rinia et al. reported that transmembrane WALP proteins perturb the bilayer, creating striated domains of 25 nm to 10 μm with the nanoscale striations spaced at 7.5-nm intervals.<sup>[25]</sup> Furthermore, the specific physical properties of the bilayer components can modulate enzyme activity. Honger and coworkers demonstrated that

**Fig. 3** Three types of rafts found thus far in the plasma membrane. The first type (A) is prevalent in the absence of extracellular stimulation. They are small (perhaps consisting of several molecules) and unstable (the lifetimes may be less than 1 msec) and may be the kind of raft that monomeric GPI-anchored proteins associate with. The second type of raft (B) may appear when receptor molecules form oligomers upon liganding or cross-linking. The receptors may be GPI-anchored receptors or transmembrane receptors with some affinity to cholesterol and saturated alkyl chains. Oligomerized receptors may then induce small but stable rafts around them, perhaps due to the slight reduction in the thermal motion around the cluster and the subsequent assembly of cholesterol. Given the rather stable oligomerization of the receptor molecules, the second type of raft may be stable for minutes, although the associated raft-constituent molecules may be exchanged frequently between the raft and the bulk domains. Such receptor-associated rafts are called “core-receptor rafts.” The third type of raft (C) may be formed around these core receptor rafts (although the core receptor rafts may be undergoing diffusion). Here they are called “signaling rafts,” because they are likely to be directly involved in downstream signaling from the receptor molecules, by assembling signaling molecules through the (transient and/or more stable) coalescence of rafts that may contain one or two signaling molecules. Small/unstable rafts are also likely to exist in the inner leaflet of the membrane (A') and could coalesce with the core receptor rafts (B and C), where the signaling molecule in the inner leaflet is activated, which might also leave from the signaling rafts (C and A''). *Source:* From Ref.<sup>[15]</sup>. © 2003 Elsevier Science B.V.

phospholipase A<sub>2</sub> enzyme activity correlates with the degree of microheterogeneity within the bilayer.<sup>[26]</sup>

Protein binding to receptor lipids in model membranes can also induce a membrane reorganizational process.<sup>[27]</sup> Concanavalin A (Con A) protein was found to bind to bilayers composed of the mannosamine-functionalized lipid PSMU and distearylphosphatidylcholine (DSPC). Initially, PSMU forms aggregates in DSPC, but slowly disperses following Con A adsorption to the membrane surface and binding to the

mannosamine head groups. Dispersal is attributed to Con A–Con A steric interactions, distance between receptor sites, and possible protein insertion events.

Another example of a molecular recognition-induced lipid reorganization was developed by Song, Nolan, and Swanson to detect biotoxins.<sup>[28,29]</sup> Fluorescently tagged receptors are dispersed in a fluid lipid matrix of palmitoyl, 9-octadecenenoyl phosphatidylcholine (POPC). The dispersed receptors exhibit strong fluorescence. Specific, multivalent binding of the toxin to its receptors brings the fluorophores in close proximity, causing a strong decrease in fluorescence intensity due to self-quenching. Nonspecific binding of toxins to lipid bilayers can also be used in a biosensing scheme that employs optical evanescence.<sup>[30]</sup> Pattern analysis and comparison to standards are required to assign the identity of the bound toxin, but the method is rapid and can be used for multiple toxins. The original work analyzed the binding of six different protein toxins.

## DYNAMIC NANOSTRUCTURES AS NANOTECHNOLOGY BUILDING BLOCKS

The same specificity of chemical recognition events that alter the nanostructures of biological membrane systems can be utilized to make rapid and sensitive chemical sensors. In a manner similar to the Con A-induced dispersion, the Sasaki lab has developed several synthetic receptor systems for metal ions, Hg<sup>2+</sup>,<sup>[31]</sup> Cu<sup>2+</sup>,<sup>[32]</sup> and Pb<sup>2+</sup>,<sup>[33]</sup> that are sensitive to parts per billion (ppb) levels of the analyte. In all of these cases, a receptor is synthesized with a head group specific for the metal ion of interest and with a pyrene label in the lipid tail. The receptor naturally aggregates in the DSPC lipid matrix, yielding a large pyrene excimer fluorescence peak. Once the receptors chelate the metal ions they disperse, and the monomer fluorescence peak grows in intensity while the excimer diminishes. Binding of the metal ions gives the receptor head groups a net charge; electrostatic repulsion causes their dispersal into the matrix. The AFM can capture before and after images showcasing these controllable dynamic nanostructures. **Figure 4A** shows an AFM image of a supported bilayer consisting of a receptor lipid (18-crown-6 ether functionalized lipid, PS18C6) embedded in a matrix lipid (DSPC). Islands and filaments of PS18C6-rich regions are clearly visible. These nanostructures decrease in size and intensity upon the addition of Pb<sup>2+</sup> ions (**Fig. 4B**) and removal of the ions leads to a reaggregation of the PS18C6 lipids. Fluorescence measurements indicate this reorganization occurs within seconds. The undefined dynamic nanostructures provide a starting point for the development

**Fig. 4** AFM topographic images of a 20% PS18C6/DSPC bilayer supported on a mica surface demonstrating the actuation of the film from aggregated to dispersed states with  $\text{Pb}^{2+}$  ions. The membrane in the (A) initial state, then (B) after addition of 0.1 mM  $\text{Pb}(\text{NO}_3)_2$ . All solutions were aqueous saline (0.1 M NaCl). *Source:* From Ref.<sup>[33]</sup>. © 2002 American Chemical Society.

of reversible nanoscale architectures controlled by chemical recognition events.

The Boxer laboratory has pioneered the field of micropatterning supported lipid bilayers. Because this work has been the subject of several excellent reviews,<sup>[34–36]</sup> it will only be briefly described here.

**Fig. 5** Epifluorescence images of supported membranes patterned by printing proteins. In each panel the protein is TR-BSA and is colored red, while the supported membrane regions are 2% NBD-PE-doped egg PC and are colored green. The scale bars are each 20  $\mu\text{m}$  across. (A) 20- $\mu\text{m}$  bilayer regions separated by 15- $\mu\text{m}$  protein; (B) 10- $\mu\text{m}$  bilayer regions separated by 5- $\mu\text{m}$  protein grids; (C,D) 40- $\mu\text{m}$  bilayer regions separated by 10- $\mu\text{m}$  protein grids. In panel C an octagonal spot was photobleached for 30 sec centered on the middle corral. After irradiation ceased, the lipids mix freely within each corral, creating corrals of uniform but intermediate fluorescence intensity, as seen in (D) after 360 sec of recovery. *Source:* From Ref.<sup>[40]</sup>. © 2000 American Chemical Society.

The fluid bilayers are patterned into micron-sized features by creating barriers to lateral diffusion through methods as diverse as scratching,<sup>[37]</sup> using polymer stamps to blot away lipids<sup>[38]</sup> or to microcontact print barriers,<sup>[38]</sup> and microfluidic manipulation of the lipid bilayer.<sup>[39]</sup> The supported bilayers in Fig. 5 were patterned by microcontact printing of protein (TR-BSA) barriers. After printing the proteins, vesicle fusion was used to form the supported bilayers of fluorescently doped egg-PC lipids. The bilayers only fuse to and occupy regions free of adsorbed proteins. The patterned surfaces contain the lipids within their micron-sized corrals as demonstrated by FRAP measurements (Fig. 5C and D). Although the development of these tools for patterning supported lipid bilayers has been focused on the micron scale, the tools can be scaled down into the nanoscale arena. The polymer stamps used for blotting or microcontact printing can be created with nanoscale features by using advanced photolithography or electron beam lithography and, likewise, microfluidics can be scaled to nanofluidics.

**Fig. 6** Schematic diagram of an electric field-induced reorganization of lipids in a confined patch of supported bilayer membrane. A two-component system is shown in which the negatively charged lipid (shaded) builds up a concentration gradient toward the anode side of the corral. This represents an equilibrium distribution where the field-induced drift is balanced by diffusion. *Source:* From Ref.<sup>[42]</sup>. © 1998 National Academy of Sciences, U.S.A.

The lipids within the patterned supported bilayers can be dynamically controlled on a submicron scale. The application of an electric field tangentially to the plane of the supported bilayer induces a reorganization of the charged components in a confined patch of membrane<sup>[40,41]</sup> as illustrated schematically in Fig. 6. The equilibrium concentration profile is a balance of the field-induced reorganization and Brownian diffusion. The concentration profile will be steeper for larger species, such as dimers and larger molecular aggregates, as these species will be slower diffusing.<sup>[40]</sup> Electric field manipulation takes an initially uniform membrane patch (Fig. 7A) and induces a concentration

**Fig. 7** (A) Epifluorescence image of several corrals of fluid membrane separated by scratch boundaries. The membrane is of uniform composition in the absence of an electric field. Fluorescence is from 1 mol% of *N*-(Texas Red sulfonyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine, triethylammonium salt doped into this egg-PC (90%) and DOPS (9%) membrane. (B) Epifluorescence image of a steady-state molecular reorganization induced by an applied field of 25 V/cm. The negatively charged components have built up concentration gradients toward the anode. A trace of the fluorescence intensity across the image is depicted below with the scratch boundaries marked with gray bars. The concentration profiles can be observed to a greater extent in the larger corrals. *Source:* From Ref.<sup>[41]</sup>. © 1997 National Academy of Sciences, U.S.A.

gradient (Fig. 7B) that can be dynamically reversed by switching the applied electric field. The behavior of charged species in the bilayer in response to an applied field can also be exploited to separate mixtures of membrane-associated molecules. Boxer and van Oudenaarden designed a geometrical Brownian ratchet that consists of an array of asymmetric patterned

**Fig. 8** Micropatterning, electrophoresis, and stripping of lipid bilayers. (A) Schematic diagram of a supported lipid bilayer confined or corralled by microfabricated barriers. Mobile species, illustrated by lipids with red and green head groups, freely diffuse and mix, approaching a uniform concentration across the extent of the lipid bilayer. (B) Application of an electric field induces manipulation of charged membrane components (the red lipids) and represents one method of manipulating a lipid bilayer after formation; the neutral lipids (green) do not respond to this applied field and remain homogeneous in the corral. (C) A stream of stripping solution is flowed over part of the surface under laminar flow conditions, leaving an open region on the substrate. (D) A new lipid bilayer, which could contain new biomolecular species, indicated by the lipid with blue head groups is introduced. The relative sizes and organizations of the components in these drawings are for illustrative purposes only and are not to scale. *Source:* From Ref.<sup>[39]</sup>. © 2003 American Chemical Society.

barriers on a solid support.<sup>[42]</sup> The barriers rectify the lateral Brownian motion of the molecules within the membrane inducing the various molecular species (with different diffusion coefficients) to follow distinct trajectories through the device. This application of Brownian ratchets to bilayers offers a promising way to separate membrane proteins in their native conformations.

The composition of the patterned bilayer corrals can be changed after preparation. Figure 8 details a process of applying a field to concentrate a charged species near one of the barriers (field-induced reorganization; Fig. 8B). The charged species is then selectively removed with the microfluidic flow of a stripping solution (Fig. 8C);<sup>[39]</sup> thus a new bilayer species can now be introduced (Fig. 8D). Laminar flow could be used to strip sections of the patterned bilayer, carrying the species downstream to compartments on the microfluidic chip for compositional analysis. An alternate method for changing the lipid composition after patterning uses membrane-coated beads

to deliver the new species to areas of opposite charge.<sup>[43]</sup> The beads adhere to the patterned corral through an electrostatic attraction and some lipid exchange between the beads and the patterned supported bilayer occurs. This may provide a novel mechanism for incorporating membrane proteins or glycolipids into prepatterned bilayer arrays.

These micropatterned supported bilayers have multiple applications for cell culturing and drug discovery. For example, fibronectin protein barriers for the lipid bilayers create well-defined surfaces for studying cell adhesion.<sup>[44]</sup> In addition, cell spreading can be controlled and, conceivably, directed by tuning the dimensions and geometries of the patterned bilayer. Proteins can also be included in the patterned bilayer. The incorporation of antigens creates an anisotropic environment for the study of localized stimulation of rat basophilic leukemia (RBL) mast cells.<sup>[45]</sup> Scanning electron microscopy (SEM) images (Fig. 9) clearly show that RBL cell adhesion and spreading is directed by the underlying patterned supported bilayer. This

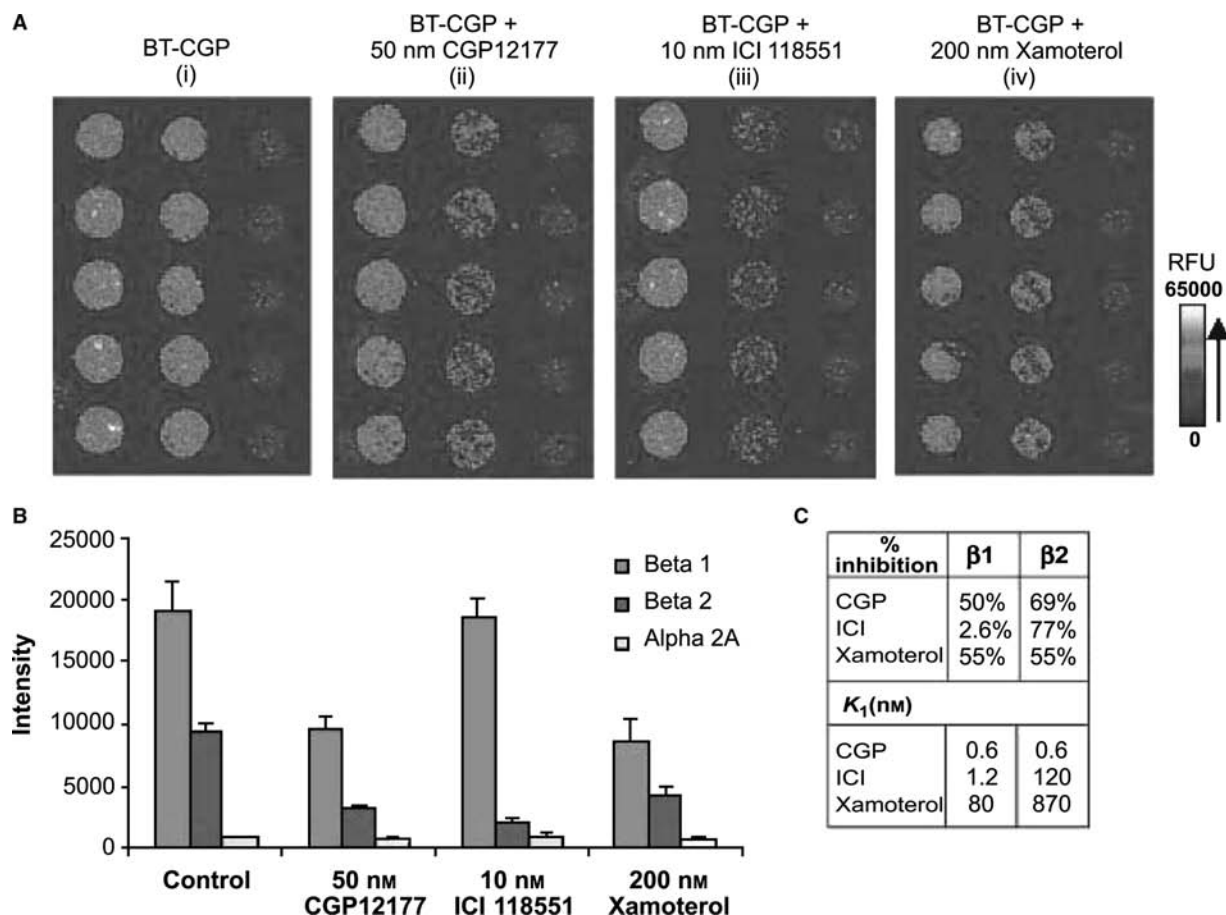

**Fig. 9** SEM images of RBL cells. (A) Resting RBL on a plain silicon surface with lamellipodia randomly spreading on the oxidized silicon substrate. Magnification:  $\times 3000$ . (B) Stimulated RBL at the corner of four patterned squares of lipids. Magnification:  $\times 2100$ . (C,D) Stimulated RBL over patterned lines of lipids. Magnification:  $\times 1250$ ,  $\times 1250$ . (C) shows gray lines where the haptened lipids were patterned. *Source:* From Ref.<sup>[46]</sup>. © 2003 American Chemical Society.

method of incorporating components in the membrane should extend to the localized confinement of other cellular receptors and provide a means to study their induced cellular responses.

Today, membrane-bound proteins account for 50% of current drug targets.<sup>[46]</sup> Yet, membrane proteins are among the most difficult to study because the protein usually requires the membrane for it to remain in its native, active conformation. Patterned membrane microarrays provide a method for studying protein–protein or protein–small molecule (e.g., drug) interactions.<sup>[47]</sup> Membrane microarrays maintain the functionality of living cell membranes while providing the simplicity and controllability of an array. The array of membrane patches can be patterned with any of the techniques mentioned above. The patches can also be printed with a quill-pin printer. This technique has

been successfully demonstrated for G-protein coupled receptor (GPCR) proteins.<sup>[46,48]</sup> GPCRs consist of seven transmembrane helices. The binding of a ligand to the extracellular side of the transmembrane helices activates a G protein on the intracellular side. The affinity of the GPCR for its ligand depends on the presence of a G protein complexed to the intracellular side. Thus it is important for G proteins to be in the membrane microarray, which is achieved with the quill-pin method. Fig. 10 shows GPCR microarray results for the determination of the affinity of a series of compounds for  $\beta_1$ ,  $\beta_2$ , and  $\alpha_2A$  subtypes of the adrenergic receptor. The BT-CGP ligand is known to be specific for  $\beta$ -subtypes and the GPCR microarray clearly shows this specificity (Fig. 10Ai) as only the  $\beta_1$  and  $\beta_2$  receptor spots show fluorescence. When the BT-CGP ligand is incubated with a microarray in

**Fig. 10** Demonstration of the use of GPCR microarrays for determining the selectivity of compounds among the different subtypes of a receptor. Each microarray consists of three columns; each column contains, from left to right, five replicate microspots of the  $\beta_1$ ,  $\beta_2$ , and  $\alpha_2A$  adrenergic receptors, respectively. (A) Fluorescence false-color images (from left to right) of the array incubated with solutions containing BT-CGP (5 nM) and mixtures of BT-CGP (5 nM) with CGP 12177 (50 nM), ICI118551 (10 nM), and xamoterol (200 nM) to the array. (B) Histogram analysis of the images in (A) showing the relative fluorescence intensities (RFU) of the arrays incubated with BT-CGP or mixtures of BT-CGP and inhibitors. (C) Table showing the amounts of inhibition and the  $K_1$  values for the inhibitors used in the experiment. *Source:* From Ref.<sup>[49]</sup>. © 2002 Wiley-VCH.

the presence of an inhibitor (e.g., CGP 12177, ICI 118551, or Xamoterol), the percent binding inhibition can be determined.

## CONCLUSION

In recent years, it has become clear that nature takes advantage of dynamic nanoscale structures in many cellular signaling pathways. As mentioned, this serves as a sensitive sensor system for the cell. The ability to monitor nanoscale features in biological systems has provided new insights into the mechanisms of this membrane activity. This article has described progress that the field of nanotechnology has made in mimicking this complex yet robust cellular component. Dynamic aggregates can be used as the basis for chemical and biosensing elements with very high sensitivity and selectivity. Spatial and temporal control of dynamic nanoscale structures in lipid membranes may serve as unique nanobuilding blocks and template scaffolds in bottom-up architectures. Advances in fabrication technology should soon enable supported lipid bilayers to be patterned at the nanoscale and, as discussed, physical methods (electric fields and fluid flows) are already in place for dynamically controlling the lipids in a patterned corral. The near future should bring efforts to combine physical control with chemical control to create more complex dynamic nanoscale structures with lipid membranes for nanotechnology applications.

Detroit, Michigan, U.S.A.

## INTRODUCTION

Liposomes serve as models for cells<sup>[1]</sup> and show increasing applications in medical and nonmedical fields.<sup>[2,3]</sup> Unilamellar vesicles are prepared from multilamellar vesicle (MLV) dispersions either by sonication<sup>[4]</sup> or extrusion.<sup>[5]</sup> The shape stability of liposomes is important in the understanding of membrane fusion, as well as in drug delivery and gene therapy. Therefore it has been the subject of numerous theoretical<sup>[6–9]</sup> and experimental studies.<sup>[10–15]</sup> Atomic force microscopy (AFM) images a surface by scanning a sharp tip attached to a cantilever at a close distance to the surface.<sup>[16]</sup> AFM is the newest tool for liposome study because it provides nano-scale analysis of liposome shape and mechanical properties simultaneously. AFM provides surface topographical images with spatial resolution close to 1 Å and force-vs.-distance curves with detection limit close to  $10^{-12}$  N. AFM has become the preferred method for imaging soft materials such as molecular crystals, proteins, and living cells.<sup>[17]</sup> This entry describes new features of adsorbed vesicles by AFM investigation. AFM imaging and force measurement were conducted simultaneously in liquid on adsorbed but intact unilamellar vesicles with sizes less than 50 nm. The unilamellar vesicles were made by sonication from egg yolk phosphatidylcholine (EggPC) dispersion. The AFM tip can be moved on top of individual vesicles so that mechanical properties of the smallest vesicles can be measured at the nanometer scale. The EggPC vesicle undergoes reversible shape changes from convex to flattened and concave shape with increasing image force. In addition to the monotonic repulsion because of vesicle resistance to the AFM tip advancement and compression, there exist several characteristic breaks in the force-vs.-distance curves. Hertz analysis of the slope of repulsion gives a measure of vesicle elastic properties. The Young's modulus ( $E$ ) and the bending modulus ( $k_c$ ) of the adsorbed EggPC vesicles were measured to be  $(1.97 \pm 0.75) \times 10^6$  Pa and  $(0.21 \pm 0.08) \times 10^{-19}$  J, respectively. The breaks in the

force curve are interpreted as the tip jumping across the bilayer.

## AFM STUDIES OF ADSORBED VESICLES—LITERATURE REVIEW

Most AFM studies of adsorbed vesicles involve supported phospholipid bilayers (SPBs), with or without proteins, from ruptured and fused vesicles. Only a few articles addressed the structure of adsorbed yet unruptured vesicles. Shape instability, size, and softness of vesicles often prevent unambiguous AFM imaging. Perhaps the earliest images of intact liposomes were obtained by Shibata-Seki et al.<sup>[18]</sup> from dipalmitoyl phosphatidylcholine (DPPC) and cholesterol mixture. Others subsequently confirmed the characteristic features of adsorbed vesicles as first reported. The features include the following:

1. Flattened spheres with length/width ratio less than 1 (about 0.4 in their case); and
2. Image quality dependence on contact pressure either by changing image force or by using tips of different curvatures.

Egawa and Furusawa reported a conical relief image of sonicated phosphatidylethanolamine (PE) vesicles with a diameter around 100 nm adsorbed on its own bilayer.<sup>[19]</sup> The conical image was attributed to unruptured yet flattened vesicles with a height/diameter ratio of 0.175. Thomson et al.<sup>[20]</sup> imaged liposomes 70 nm in diameter made from *p*-ethylmyristoyl phosphatidylcholine (EDMPC) and cholesterol mixture on aminopropylsilane-modified mica. Closely packed liposomes were imaged but can be easily disturbed by the scanning process. The paper by Reviakine and Brisson<sup>[21]</sup> provided many details about vesicle adsorption and fusion by AFM imaging. In the entry, supported vesicular layer (SVL) was used to differentiate adsorbed and intact vesicles from adsorbed and single-bilayer disks as in SPBs. It was found that vesicles of all sizes adsorbed on mica, but only vesicles

with sizes below a critical rupture radius remained intact. The bilayer disks exhibited a constant height of 5 nm, whereas the intact vesicles exhibited a height variation from 10 to 40 nm. The shape of liposomes was found to change both with applied image force and adhesion between biotin and streptavidin, which were incorporated into the vesicle and substrate layer, respectively.<sup>[22]</sup> Kumar and Hoh<sup>[23]</sup> reported intact vesicles of phospholipid and cholesterol mixture that exhibited a saucerlike structure in addition to the usual rounded protrusion (domelike structure). The saucerlike structure was attributed to wetting and fusion near the edge of the vesicle. A force curve was obtained on the intact vesicle, which showed monotonic repulsion with onset at 15 nm. The flattening from the outer edges toward the center was studied as a function of time by Jass et al.<sup>[24]</sup> and was described as the first step in a multistep processes leading toward the formation of SPBs.

In addition to nanoscale imaging, AFM enables direct force measurements between the tip and the surface by moving an AFM tip up and down over one point on the sample surface. The force-vs.-distance curves on soft materials consist of not only surface interactions such as van der Waals, electrostatic, hydration, and steric forces before contact but also bulk mechanical properties of soft materials after contact.<sup>[25–27]</sup> By collecting force curves over the scanned area (the so-called force volume), a map of mechanical property variation can be generated in force volume imaging.<sup>[28]</sup> The Young's modulus of the Torpedo synaptic vesicles was calculated to be in the range of  $2\text{--}13 \times 10^5$  Pa by fitting the indentation part of the AFM force curve to the Hertz model.<sup>[25]</sup>

AFM studies offer new insights into the adsorption, spreading, fusion, and self-healing of liposomes. Compared with other micromechanical methods such as shape fluctuation method,<sup>[10–12]</sup> magnetic field-induced orientation,<sup>[13]</sup> and micropipette aspiration method,<sup>[14,15]</sup> AFM can provide information on the following:

1. Adsorbed liposomes of small sizes between 20 and 100 nm;
2. Mechanical property variation at nanoscale;
3. Local deformation and rupture events induced by the tip; and
4. Surface and adhesive forces.

AFM measurements focus on the properties of vesicle population with the smallest sizes because large vesicles rupture into bilayers on adsorption. Small liposomes with sizes between 50 and 150 nm were found to passively target several different tumors because this size range is a compromise among loading efficiency (which increases with increasing size), stability (which

decreases with increasing size), and the ability to extravasate in tissues with enhanced vesicular permeability (which decreases with increasing size).<sup>[3]</sup> Size control may be a simple way for targeted drug delivery because vesicle distribution among different organs and tissues is related to its size.

## AFM IMAGING AND FORCE MEASUREMENT ON UNILAMELLAR VESICLES

In our work, sonicated unilamellar EggPC vesicles with diameters less than 50 nm, adsorbed on mica, were studied by AFM liquid tapping and liquid contact mode imaging as well as direct force measurement. The AFM tip was moved on top of individual vesicles so that the mechanical properties of the smallest vesicles could be measured at the nanoscale. The EggPC vesicle underwent reversible shape changes from convex to flattened and concave shape with increasing image force. In addition to the monotonic repulsion because of vesicle resistance to AFM tip advancement and compression, there existed several characteristic breaks in the force-vs.-distance curves. Hertz analysis of the slope of repulsion gave a measure of vesicle elastic properties. The breaks in the force curve were interpreted as the tip jumping across the bilayer. We attempt to gain a clear understanding of various factors that may affect the stability and morphology of small unilamellar vesicles on adsorption. We aim at perfecting the method to measure the mechanical properties of the vesicles based on AFM approach and retraction force curves. We report the Young's modulus and the bending modulus of adsorbed vesicles extracted from AFM force curves by Hertz analysis. The results are compared with those obtained on giant vesicles.

## EXPERIMENTAL METHODS

We followed a well-established recipe to prepare sonicated unilamellar vesicles (SUVs).<sup>[4]</sup> EggPC with 99% purity was purchased from Sigma. Deionized water with a resistivity of 18 M $\Omega$ cm was obtained from a Barnstead Nanopure water purification system. Grade 2 muscovite ruby mica from United Mineral and Chemical was used as support for vesicles because it is molecularly smooth and hydrophilic. MLV solution was obtained by dissolving appropriate amounts of EggPC lipids in chloroform/methanol (2:1 vol/vol) and by evaporating the solvent with nitrogen. After drying in a desiccator connected to a rotary vacuum pump for 30 min, the lipids were resuspended by stirring them in an aqueous buffer solution (20 mM NaCl) at a concentration of 0.5 mg/mL. SUVs were produced

from the MLV suspension by sonication to clarity (about 1 hr) in a Branson 2200 bath sonicator. The suspension was kept in an ice bath during the sonication process. Sonicated samples were centrifuged for 1 hr at 16,000 rpm to remove large lipid fragments by Sorvall OTD70B Ultraspeed Centrifuge. SPBs were prepared via the extrusion method. Multilamellar EggPC solution was extruded through a polycarbonate membrane with an average pore size of 200 nm using a LiposoFast extruder from Avestin. The extrusion method produced larger vesicles that ruptured into bilayers on adsorption.

AFM imaging and force measurement were conducted using a Nanoscope IIIA atomic force microscope from Digital Instruments equipped with an E scanner with a maximum scan area of  $16 \times 16 \mu\text{m}^2$ . The scanner was calibrated following the standard procedures provided by the manufacturer. The fluid cell (Digital Instruments) was washed with deionized water, ethanol, and deionized water before each experiment. Freshly cleaved mica was mounted onto a stainless steel disk using a sticky tab. After the substrate was brought to a close distance from the AFM tip, the freshly prepared EggPC vesicle solution was injected through a silicone rubber tubing into the fluid cell, sealed by a silicone rubber O-ring. The EggPC vesicle solution was allowed to incubate on mica at room temperature for 1 hr. Excess vesicles were removed by flushing the fluid cell with buffer solution followed by pure water, and the images were obtained in pure water. The microscope was allowed to thermally equilibrate for 30 min before imaging. Scanning rates between 1 and 5 Hz were used. Room temperature was maintained at  $22 \pm 1^\circ\text{C}$ . Images were recorded in liquid contact mode or liquid tapping mode using standard silicon nitride ( $\text{Si}_3\text{N}_4$ ) integral tips (NP type).

All force curves presented here were obtained with the same AFM tip so that the force values can be directly compared. The radius of the contact tip ( $33.2 \pm 6.6 \text{ nm}$ ) was calibrated by imaging the TGT01 gratings (Mikromasch).<sup>[29]</sup> The spring constant of the cantilever was calibrated using the deflection method against a reference cantilever (Park Scientific Instruments) of known spring constant ( $0.157 \text{ N/m}$ ).<sup>[30]</sup> The calibrated spring constant ( $0.17 \pm 0.05 \text{ N/m}$ ) was used in all force curve calculations. Force curves were obtained in liquid contact mode only. Multiple force curves were obtained on the vesicle layer and on the bilayer. It was impossible to locate the tip exactly on top of the center of a vesicle. Therefore multiple force curves were obtained around a vesicle, and the force curve with the largest repulsion onset was selected. The time to record an approach and retraction force curve cycle was about 1 sec. The force calibration plot is converted to a force-vs.-distance plot by defining the point of zero force and the

point of zero separation.<sup>[31]</sup> Zero force is determined by identifying the region at a large separation, where the deflection is constant. Zero separation is determined from the constant compliance region at high force where deflection is linear with the expansion of the piezoelectric crystal. Both the approaching and retracting force curves are reported, unless otherwise specified.

To determine the elastic properties of SUVs, the force-vs.-distance curve was fitted to the Hertz model  $\delta = AF^b$ , where  $\delta$  is the indentation on the vesicle and  $F$  is the load force. The Young's modulus  $E$  can be calculated from  $A$  using the following equation:<sup>[25]</sup>

$$|z - z_0| - (d - d_0) = 0.825 \times \left[ \frac{k^2(R_{\text{tip}} + R_{\text{ves}})(1 - \nu_{\text{ves}}^2)^2}{E_{\text{ves}}^2 R_{\text{tip}} R_{\text{ves}}} \right]^{1/3} (d - d_0)^{2/3} \quad (1)$$

The indentation  $\delta$  equals the difference between the cantilever distance  $z - z_0$  and the cantilever deflection  $d - d_0$ , where  $z$  is the z-scan position,  $z_0$  is the contact point,  $d$  is the deflection of the tip, and  $d_0$  is the non-contact deflection. The Poisson's ratio of the vesicle  $\nu_{\text{ves}}$  was assumed to be 0.5. The calibrated cantilever spring constant  $0.17 \text{ N/m}$  was used as the value of  $k$ .  $R_{\text{tip}}$  and  $R_{\text{ves}}$  are the radii of the AFM tip and vesicle, respectively. Only data with indentations less than 10 nm were used in our calculations to ensure elastic behavior. The bending modulus  $k_c$  is deduced from the Young's modulus.<sup>[32]</sup>

$$k_c = \frac{Eh^3}{12(1 - \nu_{\text{ves}}^2)} \quad (2)$$

where  $h$  is the bilayer thickness.

The size distribution of vesicles in the solution was studied by dynamic light scattering (Nicomp 370 Autodilute Submicron Particle Sizer; Pacific Scientific). Polystyrene (diameter =  $32 \pm 1.3 \text{ nm}$ , Nanosphere TM size standards; Duke Scientific) was used as the calibration standard. The light scattering cell was from VWR Scientific. A He-Ne laser (wavelength =  $632.8 \text{ nm}$ ) was used. Data were taken at  $23^\circ\text{C}$ .

## RESULTS

### Imaging in Liquid Tapping vs. Liquid Contact Mode

Images of EggPC vesicles were obtained in both liquid contact mode and liquid tapping mode. Fig. 1 shows the amplitude and deflection images for liquid tapping

**Fig. 1** AFM images and cross-section profiles of EggPC vesicles on mica by tapping mode (A) and contact mode (B). The image size is  $1 \times 1 \mu\text{m}^2$ . The height profile belongs to the particle pointed by the arrow obtained in height image. (A) Amplitude image with  $z$ -scale = 20 nm. (B) Deflection image with  $z$ -scale = 5 nm.

and liquid contact, respectively, and the cross-sectional height profiles from the corresponding height images. The images consist of spherical objects on a flat background. The lateral width or diameter of the spheres was measured to be  $48.6 \pm 11.4$  and  $69.3 \pm 12.8$  nm on the sectional height profiles of tapping and contact, respectively. The diameter is taken from the width of the peak at the baseline in sectional height profiles. The lateral width values are higher than the vesicle diameter in solution ( $37.0 \pm 7.9$  nm), obtained by dynamic light scattering. The discrepancy is generally attributed to the flattening of vesicles on the surface

and the tip, casting its shadow over the object (the so-called tip convolution effect). The height of vesicles from sectional height profiles in tapping and contact mode was determined to be  $13.9 \pm 2.2$  and  $3.9 \pm 0.4$  nm, respectively. These values are consistent with previous studies<sup>[18,21,23]</sup>. The height value from tapping mode is about 40–50% of the vesicle diameter in solution. Causes for the unreasonably low height values from contact mode are postulated as follows:

1. Bound vesicles may move during contact mode imaging.
2. The vesicles are severely compressed by the tip.

The intermittent contact motion of the tapping tip is known to reduce frictional and adhesive forces on the sample surface. Our results show that by minimizing image force, it is possible to obtain stable images of unruptured vesicles in both liquid tapping and liquid contact mode. The vesicles were stable within 2 hr of observation, unless the area was repeatedly scanned. Tapping causes less deformation of the vesicle, and it can maintain a smaller image force than contact mode.

### Morphological Change of Vesicles

With increasing image force by decreasing the setpoint in tapping mode, EggPC vesicles exhibited three distinctive morphologies: convex-shaped vesicles, where the highest point is at the center, as shown in Fig. 2A; disk-shaped vesicles with uniform height across much of the vesicle, as shown in Fig. 2B; and concave-shaped vesicles, where the center is depressed, as shown in Fig. 2C. The lateral diameter of the vesicle increased from  $48.6 \pm 11.4$  nm for convex shape to  $73.7 \pm 11.5$  nm

**Fig. 2** AFM height images obtained by tapping mode with different shapes. The image size is  $0.75 \times 0.75 \mu\text{m}^2$ .  $z$ -scale = 20 nm. The height profile across the dotted line is given. (A) Convex vesicles. (B) Planar vesicles. (C) Concave vesicles.

**Fig. 3** Tip compression scheme on vesicle morphology. (A) Vesicle in solution. (B) Convex vesicle imaged with minimum image force. (C) Planar vesicle imaged with intermediate indentation. (D) Concave vesicle imaged with the highest indentation.

for disk shape and to  $89.8 \pm 6.6$  nm for concave shape. The morphological change was reversible under varying image forces. The convex-shaped vesicles are similar to the conical relief and domelike structures in other studies.<sup>[19,23]</sup> The disk-shaped vesicles are similar to saucerlike vesicles.<sup>[23,24]</sup> There exists no prior report of concave-shaped SUVs by AFM, to the best of our knowledge. Although the saucerlike vesicles were cited as an intermediate state of vesicle fusion because of adhesion between the vesicle and the substrate, the morphological changes observed here could only be attributed to the compressive tip. The small size of the SUVs means that adhesion alone is not enough to collapse the vesicle edge to form saucerlike vesicles.<sup>[7]</sup> The morphological change because of tip compression is schematically illustrated in Fig. 3. A convex shape is obtained in the lowest indentation region of the force curve, a planar shape is obtained at an intermediate indentation, and a concave shape is obtained at the highest indentation. For the concave shape, when the tip moves across the vesicle with an

**Fig. 4** Force-vs.-distance curve in pure water between the tip and the mica during approach.

**Fig. 5** Force-vs.-distance curve and AFM amplitude image of EggPC bilayer patches. The arrow illustrates jump-in break. Section profile along the dotted line in the corresponding height image is shown. Scan size is  $1 \times 1 \mu\text{m}^2$ .  $z$ -scale = 20 nm.

applied force held more or less constant, the amount of indentation is largest at the center of the vesicle. Several factors may contribute to maximum depression at the center:

1. It is known that the mechanical response of thin films couples to the substrate, which results in an increase (50%) of the apparent modulus.<sup>[33]</sup> The coupling increases with decreasing film

**Fig. 6** Force-vs.-distance curves on the EggPC vesicle. Two jump-in events during approach and two jump-out events during retraction are marked by arrows.

**Fig. 7** Scheme of the tip effect on vesicle during approach force measurement. (A) Elastic compression of vesicle top fraction. (B) Tip penetration of the upper bilayer. (C) Further compression with tip bridging the gap. (D) Tip penetration of the lower bilayer.

thickness. Therefore the tip indents more in the central region of a sessile droplet.

2. A high-volume percentage of material is bound by the surface near the edge of a droplet and spreads less on compression of the tip. Contrarily, at the center of the vesicle, less resistance exists against squeezing of the trapped liquid portion.

### Force Measurement on EggPC Vesicles

The force curve between the tip and the substrate was obtained in pure water as reference. Fig. 4 shows a weak and long-range repulsion with force maximum =  $0.11 \pm 0.02$  nN at separation =  $2.6 \pm 0.3$  nm, followed by a strong attraction with force minimum =  $-0.10 \pm 0.04$  nN just before contact. The discontinuity in the force curve, called the jump-in point, is because of an attractive force gradient exceeding the spring constant. The force profile, similar to reported ones, is attributed to electrostatic repulsion coupled to attractive van der Waals interaction.<sup>[34,35]</sup>

The force curves between the tip and the adsorbed vesicle layer were measured in pure water. To distinguish vesicles from bilayers, EggPC bilayer film was prepared by fusion of large extruded vesicles. Fig. 5A and B shows the force curve and image on the EggPC bilayer, respectively. Fig. 5A shows repulsion starting at  $6.6 \pm 0.4$  nm and a jump-in point at  $4.6 \pm 0.3$  nm with maximum force =  $1.8 \pm 0.3$  nN. This force curve agrees with previous force measurements on supported lipid bilayer films.<sup>[36,37]</sup> The sudden reduction in tip and substrate separation at jump-in corresponds to the removal of the bilayer segment from the gap, most probably by a lateral pushout mechanism. The maximum steric barrier was reported to be proportional to the surface excess of the film, and can be used to compare packing density within similar adsorption class.<sup>[38]</sup> The repulsion onset value coincides with thickness =  $6.3 \pm 0.6$  nm by AFM sectional analysis in Fig. 5B. The bilayer film thickness agrees with the hydrated bilayer thickness measured by x-ray diffraction.<sup>[39]</sup> The repulsion up to the jump-in point can be described as a combination of hydration, steric force, and mechanical deformation of bilayer films. The force curves measured on the lower, flat background in both extruded and sonicated

vesicle adsorption cases (not shown here) were similar to Fig. 4, without the distinct, short-ranged repulsion. It should be concluded that mica was not fully covered in either adsorption case.

Fig. 6 represents a typical force curve captured on vesicles. Although it is impossible to place the tip exactly at the center of the vesicle, the force curve with the largest onset repulsion distance was selected from a set of force curves obtained in the vicinity of a vesicle, and was used to represent the interaction between the apices of the AFM tip and the vesicle. The onset force distance = 32.2 nm in Fig. 6 falls in the range of measured vesicle sizes between 30 and 40 nm. The repulsion was not continuous, but displayed characteristic force breaks. During approach, one or two breaks were observed around 19 and 7 nm, respectively. Although the exact locations of the breaks varied somewhat, the gap distance between the beginning and the end point of the jump-in was constant at  $4.8 \pm 0.4$  nm. During retraction, a similar jump-out gap was also observed, although apparently not as well defined. This unique gap distance coincides with lipid bilayer thickness. We hypothesize that during approach, the bilayer portion at the top of the vesicle gives way to the pressing tip and slides aside, followed by continuous compression of the tip on the vesicle, until the tip approaches and breaks through the bottom portion of the bilayer enclosure. It is surprising that the vesicle maintains its enclosed shape, whereas the tip bridges

**Fig. 8** Indentation vs. load force for both experimental data and fit by the Hertz model.

**Table 1** Young's moduli of biological samples

Material	Young's modulus $E$ (MPa)	Method	Remarks	Reference
Synaptic vesicles	0.2–1.3	Force mapping	Size: 90–150 nm adsorbed on mica	[25]
DMPC/DOPC vesicles	15	Osmotic swelling	Size: 160–180 nm in solution	[40]
EggPC vesicles	$1.97 \pm 0.75$	Force plot	Size: < 60 nm adsorbed on mica	This work

DMPC = dimyristoylphosphatidylcholine; DOPC = dioleoylphosphatidylcholine.

across different parts of the bilayer shell. The stepwise deformation during approach is shown in Fig. 7:

1. Compression of vesicle
2. Breakthrough of top portion
3. Further compression of vesicle with tip bridging the top portion
4. Breakthrough of bottom portion with tip spanning the whole vesicle.

The process was reversed during retraction except that the vesicle was stretched to 150% of its intrinsic diameter before the final detachment of the tip from the vesicle. This adhesive interaction may also contribute to the shape stability of the vesicle bridged by the AFM tip. The force curves were repeated at the same spot, indicating that no permanent deformation occurred by tip breakthroughs. Vesicles are known to self-heal after perforation because of high line tension.

The initial slope in the approach force curve correlates to the local bending modulus of the vesicle, and therefore was used to calculate the Young's modulus of the adsorbed SUVs based on Hertz model, as in Eq. (1). The fit is shown in Fig. 8. The calibrated tip

radius value 33 nm was used for  $R_{\text{tip}}$ , and experimentally determined force onset distance  $z_0$  was used to calculate  $R_{\text{ves}} (= z_0/2)$ . The calculated Young's modulus is  $1.97 \pm 0.75$  MPa. Bending modulus is calculated (according to Eq. (2)) to be  $(0.21 \pm 0.08) \times 10^{-19}$  J, assuming that bilayer thickness  $h = 4.57 \times 10^{-9}$  m and Poisson's ratio  $\nu_{\text{ves}} = 0.5$ .

The calculated values are compared with literature values in Tables 1 and 2. The calculated Young's modulus for adsorbed SUVs is close to those measured on adsorbed synaptic vesicles between 0.2 and 1.3 MPa on mica.<sup>[25]</sup> The calculated value is one order of magnitude smaller than the value measured in solution by the osmotic pressure method (about 15 MPa).<sup>[40]</sup> The calculated value is affected by the choice of tip radius, spring constant, contact point, and liquid environment. The calculated bending modulus is in the same range as that reported in the literature, with different methods between  $10^{-20}$  and  $10^{-19}$  J (Table 2).<sup>[10–14,41–44]</sup> The variation in bending modulus values is attributed to the following:

1. Different experimental methods
2. Sample purity and

## CONCLUSION

This entry describes AFM imaging and force measurement on sonicated unilamellar EggPC vesicles whose diameter is less than 50 nm. AFM measurements on adsorbed vesicle layers on mica were conducted using liquid tapping and liquid contact mode. The small vesicles were remarkably stable and did not rupture under the scan conditions. The shape of the vesicle changed from a concave shape in the lowest indentation region of the force curve to a planar shape, and to a concave shape at higher indentations. The mechanical deformation of the vesicle was also apparent during force-vs.-distance measurements when a vesicle was gradually pressed against the AFM tip. The indentation curve converted from the force-vs.-distance curve was fitted to the Hertz spherical contact model to extract the Young's modulus of the vesicle. The calculated Young's modulus and the bending modulus of the small adsorbed vesicles are  $(1.97 \pm 0.75) \times 10^6$  Pa and  $(0.21 \pm 0.08) \times 10^{-19}$  J, respectively. The elastic constants are compared with literature values from various micromechanical tests of liposomes. The force curves showed various gaps with a fixed gap distance equal to the lipid bilayer thickness. These gaps are interpreted as an abrupt jump of the AFM tip across the top or bottom portion of the bilayer enclosure during approach and retraction. It can be inferred that the vesicle maintains its enclosed morphology during tip breaking by bridging the bilayer gaps. Adhesion between the tip and the cross-sectional contact of the bilayer is necessary for the apparent shape stability of penetrated vesicles. The retraction force curve and gaps need further mechanical analysis. The AFM method offers new insights into adsorption, spreading, fusion, self-healing, and mechanical properties of liposomes at the nanoscale. The AFM method may pave the way for incorporating genes, proteins, and medicines into specific cells and locations with molecular precision in drug delivery and gene therapy.

# Liquid Crystals and Nanostructured Surfaces: Detecting Protein Binding

Yan-Yeung Luk

Department of Chemical Engineering, University of Wisconsin–Madison,  
Madison, Wisconsin, U.S.A.

## INTRODUCTION

Studies of nanometer-scale phenomena represent one of the most flourished areas in science at the beginning of 21st century.<sup>[1]</sup> While the early activities have focused on fabricating well-defined nanomaterials and their novel properties, few have demonstrated a workable functional principle that can be developed into tangible applications. On the other hand, the protein binding events that orchestrate the biological activities in living cells (so-called cell signaling pathways (occur at nanometer scale. [Scheme 1](#) shows a schematic representation of the complexity of one of such signaling pathway. The protein binding events can be first induced at membrane proteins by either a physical or chemical signal or an internal stimulus such as hormone.<sup>[2]</sup> The dimerization or phosphorylation of membrane proteins leads to a series of protein binding events in the cytosol. The final binding event in the cytosol may lead to the transport of a protein into the nucleus that induces gene expression to produce a new protein. The new protein expressed signals a biological response in the form of new activities, such as cell death, proliferation, disease, or expression of white blood cells.

Deciphering the protein binding events in such complicated and interconnected signaling pathway will lead to molecular-level understanding of the physiology of living system as well as drug design. However, the scope of the problem demands a rapid and global approach. Because the quantity of protein involved on chip-based assay is little and the detection scheme can be highly parallel, surface-based proteomics tools have the potential to increase the rate of discovery and the scope of investigations aimed at understanding protein function, modification, and regulation in cell signaling processes as well as the study of protein–drug interactions.<sup>[3,4]</sup>

This entry describes a new detection method for protein binding events by using a well-controlled nanotopography on surface and the unique optical properties (birefringence) of liquid crystals. The development of this method integrated knowledge from multiple disciplines including self-assembled monolayers (SAMs),

liquid crystals, protein immobilization, and molecular biology. In the following, the effect surface topography and chemistry on the alignment of liquid crystal is first investigated. Then, the influence of surface-bound proteins on the alignment of liquid crystal is reported. Establishing the response of liquid crystal to surface-bound protein, a general scheme is designed to support biospecific protein binding on surface. Last, the binding activities of the immobilized protein on nanostructured surface toward specific and non-specific antibodies are detected by the molecular organization (orientations) of liquid crystals in contact with the surfaces where binding occurs.

## BACKGROUND

Self-assembled monolayers (SAMs) of alkanethiols on gold provide a class of versatile substrates for biological studies.<sup>[5]</sup> This class of surfaces is particularly useful because of several unique properties. First, monolayer formed from alkanethiols on gold substrate presents a structurally well-defined surface. Second, because of the powerfulness of organic synthesis developed over the past decades, almost any desired organic compound (including alkanethiols) could be synthesized so long as the compound is stable under condition of application. Hence a vast variety of functional groups can be presented on surfaces to tailor the surface chemistry at desire. [Scheme 2](#) shows the functionalized alkanethiols used in this review and a schematic representation of the SAMs. Recently, SAMs that resist protein adsorption and cell attachment are also developed providing a class of model surfaces for studying specific interactions of proteins and cells.

Liquid crystal is a delicate phase of materials that existed in between crystal and liquid.<sup>[6]</sup> This phase has the fluidic property of a liquid crystal and, at the same time, has the optical property of a crystal. The coexistence of these properties in liquid crystals rises from the orientational order of molecules. This orientational order gives each molecule a preferred orientation relative to each other that is absent in an isotropic liquid, while each molecule in liquid crystal

**Scheme 1** A schematic presentation of cell signaling pathway from cell membrane to nucleus.

still bears the translocation freedom. Thus all the terms used for characterizing crystals such as packing, defect, and symmetry elements are also applicable to liquid crystal. Hence the texture of a liquid crystal, which reflects the organization of the mesogens and the degree of order in the bulk of the liquid crystal, can be readily viewed under a polarizing microscope. Based on the detailed molecular organization in the phase, liquid crystals are further classified into smectic (layer-like), nematic (thread-like), and discotic (disk-like).

**Scheme 3** demonstrates a schematic representation of the organization of a crystal, a smectic, a nematic liquid crystal, and an isotropic liquid. One character that is common to both crystal and liquid crystal is the almost ubiquitous existence of defects. These defects disrupt the local organization of molecules (or atoms in the case of crystals) preventing the crystal or liquid crystal from forming a perfect crystal. However, one of the most exquisite phenomena in liquid crystals is that the orientational order can transmit up to  $100\ \mu\text{m}$  or  $10^6$  before being disrupted by defects.

An implicit, but aptly useful aspect of the transmission of this orientational order of liquid crystals is that it bridges and amplifies the interactions at molecular level to micrometer-scale phenomena. Because most of the biological interactions occur at nanometer scale, and liquid crystalline phases exist ubiquitously in the membranes of cells, liquid crystals and biological systems share common characters such as they both break the symmetry of isotropy and bear structural order to different extent. In this entry, this unique property of orientational order in liquid crystal is explored to form the basis for a new detection scheme for protein binding events on nanostructured surfaces.

## NANOSTRUCTURED SURFACES

Vapor deposition of gold atoms on surfaces in high vacuum ( $\sim 10^{-7}$  to  $10^{-8}$  Torr) leads to polycrystalline gold films.<sup>[7]</sup> This polycrystalline gold film is particularly useful because it supports the self-assembly of alkanethiols that form well-organized monolayers with well-defined structure.<sup>[8]</sup> The exact detailed structure of these monolayers is still much in research, but it is generally known that the alkanethiols complex with surface at the (1,1,1) facet of the polycrystalline gold forming a two-dimensional crystalline with each

**Scheme 2** Chemical structure of alkanethiols used for protein immobilization and controls experiments, and a schematic presentation of the two-dimensional crystallinity of the SAMs.

**Scheme 3** Molecular order in different state of matter.

alkanethiol tilted  $30^\circ$  from the normal of the surface.<sup>[9]</sup> This well-organized and close-packed structure of alkanethiols on gold is absent from other monolayers. For example, on silica surface, the monolayer structure formed by alkyl silane is not close-packed and is poorly organized because of the large spacing between each alkyl silane.

Abbott et al.<sup>[7,10]</sup> further discovered that different experimental setups of the deposition of gold atoms also lead to subtle but significant topographical structures in the gold films. Fig. 1 demonstrates three different experimental setups of the deposition of gold

atoms that lead to different topography at nanometer scale on surfaces. These three different depositions are named as uniform deposition (Scheme 4A and B), oblique deposition (Scheme 4C and D),<sup>[7]</sup> and gradient deposition (Scheme 4E and F).<sup>[10]</sup> By uniform deposition, the substrates are positioned normal to the incidence of gold atoms, and the substrates are rotating during the time period of deposition. In this mode of deposition, the topography on the surface of the gold film is uniform or isotropic. By oblique deposition, the substrates are positioned at an oblique angle relative to the incidence of the gold atoms (Scheme 4C and D). In this mode of deposition, the gold atoms “hit” the substrate at a fixed oblique angle. Thus the surface features (topography) on the gold film parallel and perpendicular to the direction of gold deposition are no longer degenerate.

To characterize the gold films at a resolution of nanometer scale, Skaife and Abbott<sup>[11]</sup> applied atomic force microscopy (AFM) to sample the topography of the gold surfaces. Fig. 1A is an AFM micrograph showing the surface features of a gold film deposited at an angle of incidence of  $45^\circ$  measured from normal of the substrate. A coarse inspection of Fig. 1A indicates that the surface is rough and consisted of grains of gold crystalline with diameters of roughly 25 nm. However, by mere visual inspection of AFM micrograph, no anisotropy (or difference) can be observed in the texture/roughness between the direction parallel and perpendicular to the gold deposition.

To characterize the roughness quantitatively, Skaife and Abbott measured the contour lengths across a family of directions relative to the direction of gold deposition with different sample lengths. Fig. 1B shows an example of the cross-section profile of the roughness scanning across the direction parallel to the direction of gold deposition. The total length of this cross-section profile represents the contour length of the topography on the surface and thus a direct measure of the surface roughness. A long contour length implies high roughness and vice versa. The measured

**Fig. 1** (A) Image ( $350 \times 350 \text{ nm}$ ) of an obliquely deposited film of gold obtained by AFM with the direction of deposition parallel to the scanning direction. The insets are fast Fourier transforms of the real-space images. The gray scale of contrast in the real-space images corresponds to a variation in height ( $z$ -axis) of 8 nm. Note that  $0^\circ$  denotes a direction parallel to the direction of gold deposition, and  $90^\circ$  denotes a direction perpendicular to the direction of gold deposition. (B) Cross-sectional topographical profile of the obliquely deposited gold film in (A). (C) Contour lengths calculated from AFM images of obliquely deposited films of gold shown in (A). Sampling lengths are 4, 8, 12, 20, and 40 nm. Source: From Ref.<sup>[11]</sup>.

**Scheme 4** Setups for vapor deposition of ultra-thin gold films by electron beam evaporator.

contour length (roughness) of the surface, however, depends on the dimension of the sample length that is used to measure the surface roughness. Similar to a ruler, if the sample length is much larger than the surface features, each measurement will cover multiple surface features (grains) and thus no longer measure the roughness on the surface. Fig. 1C plots a family of the contour lengths across different directions on the topography of an obliquely deposited gold film with different sample lengths ranging from 4 to 40 nm. The measured contour lengths increase with decrease in the sample lengths. This is consistent with the fact that a small sample length measures more the roughness at nanometer scale. However, more importantly, with small sample lengths (4 to 12 nm), the contour lengths are longer in the direction parallel to the gold deposition than perpendicular to the gold deposition. This anisotropy in the topography of obliquely deposited gold films starts to vanish when the sample lengths reach around 30 to 40 nm. This result indicates that the topography of surface on an obliquely deposited gold film bears a maximum roughness in the direction parallel to the direction of gold deposition and a minimum roughness in the direction perpendicular to the direction of gold deposition. Because the amplitude of the roughness is approximately 1 to 2 nm (Fig. 1B) and the anisotropic roughness appears on a minimum length scale of roughly 30 to 40 nm, the anisotropic topography can be idealized as a corrugation with the amplitude of 1–2 nm and the wavelength of 30–40 nm.

By gradient deposition, a substrate of 7 cm in length is positioned at an oblique angle close to the source of the gold atoms (Scheme 4E and F). Because at close proximity to the gold source, the oblique angle of gold

deposition onto the surface varies along the substrate following a simple equation:

$$\theta = \arctan[(x + b)/a]$$

where  $\theta$  is the oblique angle of incidence of gold atoms measured from normal,  $x$  is the position on the substrate measured from the bottom of the substrate,  $b$  is the vertical distance measured from the bottom substrate to the level of the gold source, and  $a$  is the horizontal distance measured from the horizontal position of the substrate to the gold source. In this mode of deposition, because the angle of deposition changes gradually and continuously along the substrate, a gradual and continuous change (gradient) in the anisotropic topography is created in the gold film.<sup>[10]</sup>

#### EFFECT OF ANISOTROPIC TOPOGRAPHY ON LIQUID CRYSTAL ALIGNMENT

While the anisotropy in the topography of the gold film prepared by oblique deposition (or gradient deposition) is subtle, it affords drastic effect on the alignment of liquid crystals. Studies using nematic liquid crystals show that when brought in contact with surfaces that do not have an anisotropic topography, nematic phase such as 4-cyano-4'-pentylbiphenyl (5CB) adopts random orientations on surfaces.<sup>[7]</sup> However, when brought in contact with anisotropic topography of gold films by oblique deposition, 5CB assumes a uniform orientation with the principal (long) axis of the mesogens lying in an azimuthal direction parallel to the direction of minimum roughness of

**Fig. 2** Optical appearance (crossed polars) of 5CB sandwiched between two obliquely deposited gold films with Saran wrap ( $12\ \mu\text{m}$ ). Both gold films were the direction of gold deposition parallel to each other. The orientation of the sample relative to one of the cross polars is indicated below the liquid crystal image. A schematic representation of the azimuthal orientation of the liquid crystal with respect to the topography is shown to the right. *Source:* From Ref.<sup>[15]</sup>.

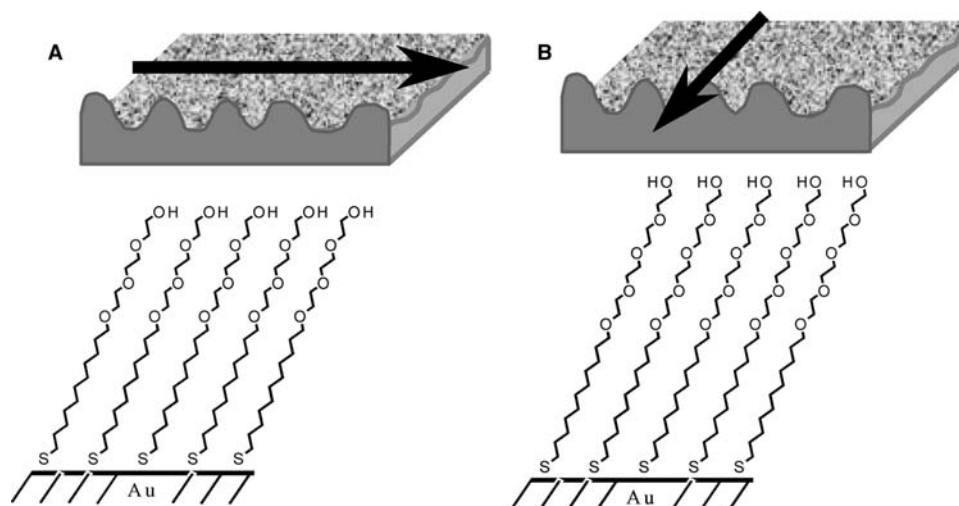

the anisotropic topography (Fig. 2).<sup>[7]</sup> This uniform orientation represents a single crystal without any defects giving a uniform texture under the polarizing microscope. Furthermore, much like a single solid crystal, liquid crystal with uniform orientation modulates the intensity of the polarized light with maximum extinction when the director of the liquid crystal is perpendicular to either one of the crossed polarizers, and minimum extinction with the director is  $45^\circ$  relative to either one of the crossed polarizers.

## EFFECT OF SURFACE CHEMISTRY ON LIQUID CRYSTAL ALIGNMENT

The mechanistic origin of the uniform orientation and azimuthal direction of the principle axis of liquid crystal as a result of such small, subtle anisotropy in the nanometer-scale topography is not entirely understood and is still the subject of on-going research. However,

the orientation of mesogens is known to minimize the elastic distortion within the liquid crystal when brought in contact with a surface. In general, it is most stable for the azimuthal direction of the principal axis in the uniform orientation of liquid crystal to lie in the direction of minimum roughness of the topography. It is important to note that the next energetic minimum (a metastable one) for liquid crystal alignment is actually the uniform orientation with the azimuthal alignment in the direction of *maximum* roughness. The energetic difference between the two azimuthal alignments is small, ca.  $0.015\ \text{mJ m}^{-2}$ .<sup>[11]</sup> Hence the azimuthal alignment of the uniform orientation turns out to be highly sensitive to the molecular details (and chemical functionality) of the monolayers of alkanethiols assembled on obliquely deposited gold film. For example, on obliquely deposited gold films, 5CB aligns in the azimuthal direction of minimum roughness on SAMs formed from pentadecanethiol, but aligns in the azimuthal direction of maximum roughness on SAMs formed from hexadecanethiols.<sup>[12]</sup> The subtle difference between the two SAMs is only the orientation of the terminal methyl groups at the surface of each monolayer.

A more important class of SAMs is oligo(ethylene glycol)-terminated alkanethiols on gold substrate (Scheme 5). Monolayers formed from these alkanethiols are particularly useful for biological researches and applications because they resist the non-specific adsorption of proteins and adhesion of cells.<sup>[13]</sup> The structure and dynamics of this class of SAMs are believed to be intimately related to their ability to resist protein adsorption and cell adhesion and thus are under intense research.<sup>[14]</sup> While methyl-terminated SAMs are well organized, the

**Scheme 5** Azimuthal orientation (indicated by arrow) of the uniform planar alignment of 5CB on oligo(ethylene glycol)-terminated SAMs.

conformational homogeneity and flexibility of the terminal ethylene glycol groups are not definitely known.

Interestingly (and luckily), 5CB aligns uniformly on oligo(ethylene glycol)-terminated SAMs supported by gold films possessing an anisotropic topography (obliquely deposited at  $40^\circ$  measured from normal of the glass substrate). Furthermore, when supported on obliquely deposited gold films (Scheme 5B), 5CB aligns in the azimuthal direction of maximum roughness on tri(ethylene glycol)-terminated SAM (Scheme 5A), but aligns in the azimuthal direction of minimum roughness on tetra(ethylene glycol)-terminated SAMs.<sup>[15]</sup> This result is both significant and useful. First, it indicates that the oligo(ethylene glycol)'s are largely well organized at surface in contact with an organic phase (5CB) and thus shed light for the large effort of probing the structure of oligo(ethylene glycol) at surface. Because bare gold films uniformly align the nematic phase of 5CB in the azimuthal direction of minimum roughness, the azimuthal orientation observed on the surfaces covered with tri(ethylene glycol)-terminated SAMs suggests that molecular-level interactions between the SAMs and 5CB are important in determining the alignment of 5CB. Second, the uniform alignment of liquid crystals on these oligo(ethylene glycol)-terminated monolayers provides a great potential for combining use of liquid crystals with surfaces that supports exclusively bio-specific interactions.

## DETECTION OF PROTEINS BY MASKING THE TOPOGRAPHY

Because the sizes and dimensions of many proteins (5–20 nm in their longest dimension) are comparable to the spatial scale of the nanometer-scale topography of the obliquely deposited gold films, proteins bound to surfaces can mask or erase the topography of the surface. The uniform alignment of liquid crystal, on SAMs not supporting bound protein, can be disrupted by the presence of bound protein (Scheme 6).<sup>[16]</sup> The

**Scheme 6** Illustration of detection scheme for protein on nanostructured surfaces by the use of liquid crystals.

non-uniform alignment of the liquid crystal is readily distinguished from the uniform alignment by using polarized light microscopy. It should be noted that this scheme of detecting proteins on surface is direct and does not require any secondary interactant or labeling.

The magnitude of the anisotropy within the topography of the gold films depends on the oblique angle of deposition of the gold atoms.<sup>[17]</sup> At higher oblique angle (measured from normal of the substrate) of deposition, the magnitude of the anisotropy between the direction parallel and perpendicular to the direction of gold deposition is higher. By bringing the silica substrates closer to the source of gold for deposition, the end of the substrate that are farther from the gold source will have a larger oblique angle than the end of the substrate that are closer to the gold source (Scheme 4E). Thus a gradient in the anisotropy of the topography is created across the substrate. With this gradient in the topography, protein adsorbed on surface will mask the topography with low anisotropy to greater extent than the topography with high anisotropy.<sup>[10]</sup> An idealized representation of protein adsorbed on surface with gradient in the topography is shown in Fig. 3A.

Fig. 3B shows optical images of liquid crystal cell comprised of 5CB in contact with protein BSA adsorbed on gold film (7 cm in length) with gradient in topography. Two distinct regions are observed in Fig. 3B. First, in regions of the gold film deposited at  $56^\circ$  (gold thickness of  $\sim 13$  nm), BSA masks the topography of the surface resulting in nonuniform alignment of the liquid crystal. When the alignment of the liquid crystal is nonuniform, there is little modulation in the optical appearance of the liquid crystal when it is rotated between crossed polarizers. Second, in regions of the gold film deposited at  $63^\circ$  (gold thickness of  $\sim 7$  nm), the liquid crystals are uniformly oriented in contact with BSA on the surface. While the liquid crystal image is distinct in either region of the surface, the presence of the adsorbed BSA is confirmed by ellipsometry.<sup>[10]</sup> This result suggests that protein (BSA) adsorption on surface sufficiently masks the region of low anisotropy causing a nonuniform alignment of 5CB. But the topography of the gold film with high anisotropy is sufficiently pronounced that adsorption of BSA can no longer mask the topography that orients the liquid crystal. Furthermore, it indicates that the topography of the gold film can be adjusted by choosing particular angles of deposition for optimal reporting of the presence of protein on nanostructured surfaces.

This gradual change in the liquid crystal orientation represents continuous transformations in the orderliness, uniformity, and symmetry across the solvent structure at the interface. The essence of this transformation is demonstrated by the artwork by M.C.

**Fig. 3** (A) Schematic representation of protein bound on surface with gradient topography. The extent of masking of the topography is indicated above the image. (B) Optical appearance (crossed polars) of liquid crystal sandwiched between two gold films supporting BSA. Both gold films were deposited at an angle of incidence that changes from 56.5° to 63.5° across the length of the slide. The image shows the entire length of a microscope slide. (C) The artwork “transformation” by M.C. Escher. Source: From Ref.<sup>[10]</sup>.

Escher (Fig. 3C). It is worth noting that while the artwork itself does not bear any specific scientific implication, the idea behind transcends across multiple areas in science from liquid crystal orientation on nanostructured surfaces (demonstrated here) to proposed Kibble mechanism in cosmology.<sup>[18]</sup>

### PROTEIN BINDING VIA NTA–Ni(II) HIS-TAG COMPLEXATION

Immobilization of oriented proteins and rapid detection of specific binding events on surfaces are two key challenges for surface-based proteomics tools. Conventional surface-based protein assays such as enzyme-linked immunoassays (ELISA) have typically relied upon rudimentary surface chemistries, such as the use of hydrophobic surfaces to promote antibody adsorption.<sup>[19]</sup> Adsorption of BSA is also often used to minimize non-specific adsorption. The nanometer-scale structure of surfaces used in conventional surface-based proteins assays is not typically controlled. Recently, however, advances have been reported on both fronts. First, surfaces with well-defined chemical functionalities have been reported for biological studies. These surfaces use self-assembled monolayers (SAMs) of  $\omega$ -functionalized alkanethiols on gold to oligo(ethylene glycol)<sup>[13]</sup> or polyol groups<sup>[20]</sup> that have been demonstrated to resist nonspecific protein adsorption and cell attachment. Second, preparation of surfaces with anisotropic nanometer-scale topography and the opportunities of using this topography in combination with liquid crystals on biological assays have also been reported.<sup>[12,21,22]</sup>

The regulation of proteins in cell signaling pathways often involves activation or deactivation. Activation,

such as phosphorylation, enables specific binding events between proteins that ultimately regulate cellular processes. Mitogen-activated and extracellular signal-related protein kinase (MEK) is one of such proteins in cell signaling pathways [mitogen-activated protein kinase (MAPK) cascade].<sup>[23,24]</sup> Detection and characterization of MEK are of substantial interest in cell biology. Here a general immobilization scheme is used to tether MEK on nanostructured surfaces, and liquid crystals are used to detect its presence on surface and further binding activities with antibodies.

Many immobilization schemes have been developed to afford oriented protein on surfaces.<sup>[25–27]</sup> The immobilization of protein on SAMs is guided by past work of Sigal et al.<sup>[28]</sup> This general scheme is based on the use of mixed SAMs presenting nitrilotriacetic (NTA) (**1**) and tri(ethylene glycol) (**2**) (Fig. 4). Nitrilotriacetic was used because, when complexed with Ni(II) ions via a tetravalent chelate, the NTA–Ni(II) complex can specifically bind proteins that present a sequence of six histidines (His-tag) at the amino end of the protein. His-tags are commonly incorporated into the amino end of the primary sequence of recombinant proteins to facilitate purification by metal-affinity chromatography.<sup>[29]</sup> The tri(ethylene glycol)-terminated alkanethiol, **2**, functions as a diluent of the NTA-terminated alkanethiol to prevent non-specific protein adsorption. With a background surface of ethylene glycols, all proteins bound to the surface were immobilized either by complexation to NTA–Ni(II) or by specific binding to the immobilized His-tag protein.

His-tag MEK were first immobilized on gold films that possessed nanometer-scale topography and presented mixed SAMs formed from **1** and **2** [following chelation of the Ni(II) with the surface]. Because the chelation of Ni(II) ions by **1** within the mixed

**Fig. 4** General scheme for immobilization of proteins on mixed SAMs formed from NTA-terminated alkanethiols, **1**, and tri(ethylene glycol)-terminated alkanethiols, **2**. Each nitrilotriacetic acid group on the SAM chelates a Ni(II) ion, which is subsequently recognized and bound by the histidine tags of the protein to be immobilized. The histidine-tagged protein functions as a receptor that binds a second protein. The tri(ethylene glycol)-terminated SAM resists nonspecific protein adsorption. *Source:* From Ref.<sup>[15]</sup>.

monolayer is a requirement for specific binding of the His-tag MEK, a control experiment was conducted by binding of His-tag MEK to mixed SAMs without Ni(II) ions. Because the sensitivity of liquid crystal to bound protein can be enhanced by decreasing the anisotropic topography within a gold film (achieved by decreasing the oblique angle of deposition of gold film),<sup>[17]</sup> gold films prepared by oblique deposition at a low angle (30° from normal) were used. Mixed SAMs formed with low percentages of the NTA-terminated alkanethiols (5% **1** and 95% of **2** in ethanol) were used to afford a low surface coverage of NTA so that two

experiments are aimed to detect difference as a result of small amount of protein specifically immobilized on surface.

The optical appearances of nematic phases of 5CB contacted with SAMs-treated NiSO<sub>4</sub> and then the His-tag MEK are shown in Fig. 5A. The optical appearance of the 5CB was nonuniform and the extent of modulation of light as the sample was rotated between the cross polarizers was low confirming that no preferred azimuthal orientation is present within the sample. In contrast, when the SAM was treated with deionized water instead of NiSO<sub>4</sub> solution and

**Fig. 5** Optical images (crossed polarizers) of nematic 5CB supported on MEK-treated mixed SAMs (**1/2**: 20/80 in ethanol) on gold films obliquely deposited at 30°. The mixed SAMs were incubated in either (A) 50 mM NiSO<sub>4</sub> or (B) deionized water for 2 hr prior to incubation in 0.5 μM of His-tag MEK for 5 hr. The mixed SAMs supported on the anisotropic gold films were aligned with the direction of minimum roughness on each surface parallel to each other. *Source:* From Ref.<sup>[15]</sup>.

then His-tag MEK, 5CB assumed a uniform alignment on the surface. A strong modulation of the intensity of light was measured as the sample was rotated between cross-polarizers (Fig. 5B). By comparing the optical appearance of the liquid crystal in Fig. 5A and B, the orientation of 5CB is disrupted only when the surface is treated with both Ni(II) ions and His-tag MEK. This result indicates that His-tag MEK binds specifically to the Ni(II) NTA complex within the SAMs. This conclusion is further supported by the increase of ellipsometric thickness only after the surface is treated with both Ni(II) ions and His-tag MEK. Because the size of MEK is comparable to the scale of the topography on the obliquely deposited gold films, bound His-tag MEK masks the topography of the surface from the liquid crystal, thus resulting in nonuniform alignment of the liquid crystal.

### SPECIFIC BINDING OF ANTIBODIES TO IMMOBILIZED PROTEINS

To investigate the binding activity of the immobilized MEK on surface, specific anti-MEK immunoglobulin G (IgG) and non-specific streptavidin immunoglobulin G (IgG) were used as model binding partners of MEK to demonstrate the possibility of using liquid crystals to detect binding events on surfaces that involve MEK. The presence of a second protein bind to the immobilized receptor will mask the nanometer-scale topography to greater extent. Fig. 6 demonstrates a schematic representation of changes in the topography upon binding of an antibody to the immobilized protein. Because the liquid crystal is sensitive to the magnitude of the anisotropy in the topography, the alignment of liquid crystal on surfaces supporting bound proteins can be made uniform by increasing the anisotropy of the topography on the surface. Whereas gold films deposited at an angle of  $30^\circ$  provide an anisotropic topography that is facile for reporting bound MEK using liquid crystal, gold films deposited at  $40^\circ$  instead of  $30^\circ$  are used to obtain uniform alignment of liquid crystal on the surface with

MEK present. On these gold films, mixed SAMs with higher surface density of NTA (1/2: 20/80 in ethanol) were used to investigate the orientational response of liquid crystal to IgG bound to His-tag MEK immobilized on the surface.

After incubating the SAMs in His-tag MEK ( $0.1 \mu\text{M}$  in PBS, pH 7.2) for 2 hr, ellipsometric measurement indicated a thickness of  $\sim 1.9 \text{ nm}$  of MEK. In contrast, a layer of MEK having a thickness of only  $\sim 0.9 \text{ nm}$  was bound to SAMs presenting low density of NTA (1/2: 5/95 in ethanol). Next, substrates immobilized with MEK were incubated with solutions containing either anti-MEK IgG ( $0.5 \mu\text{M}$ ) or antistreptavidin IgG ( $0.5 \mu\text{M}$ ) for 5 hr.

Fig. 7A shows the optical textures of nematic 5CB in contact with immobilized His-tag MEK on gold obliquely deposited at  $40^\circ$ . A strong modulation in the intensity of light was observed as the sample was rotated between crossed polarizers, indicating a largely uniform planar alignment of the liquid crystal. With the ellipsometric thickness of  $1.9 \pm 0.5 \text{ nm}$  of MEK bound on surface, this result shows that this amount of immobilized MEK is not sufficient to mask the influence of the topography of the gold film (obliquely deposited at  $40^\circ$ ) on the orientation of the liquid crystal.

Whereas 5CB on surfaces presenting immobilized His-tag MEK that was treated anti-MEK IgG ( $\sim 150 \text{ kD}$ ) assumed non-uniform orientations with little modulation of the intensity of polarized light (Fig. 7B), a control experiment in which antistreptavidin IgG was used instead of anti-MEK IgG yielded a liquid crystal with a uniform alignment (Fig. 7C). Ellipsometric measurement confirmed the increase of thickness only when specific anti-MEK IgG is used. Whereas surfaces with immobilized MEK treated with anti-MEK IgG showed an increase of  $\sim 3.3 \pm 1 \text{ nm}$  in thickness, no increase in thickness was detected after treatment with antistreptavidin IgG. Both of the experiments showed that the results are consistent with the specific binding between the immobilized MEK and the anti-MEK IgG in solution. Furthermore, specific binding of the second protein (anti-MEK IgG)

**Fig. 6** Schematic illustration of changes in the surface topography due to binding of an antibody to immobilized His-tag MEK on a SAM supported on a surface possessing nanometer-scale topography. The approximate topography of the surface supporting the bound protein is indicated by the dashed line. *Source:* From Ref.<sup>[15]</sup>.

**Fig. 7** Optical images (crossed polarizers) of nematic 5CB supported on MEK-treated mixed SAMs (1/2: 20/80 in ethanol) on gold films obliquely deposited at  $40^\circ$  that were exposed to PBS solution containing the following proteins prior to contact with nematic 5CB: (A) His-tag MEK, (B) His-tag MEK and anti-MEK IgG, and (C) His-tag MEK and anti-streptavidin IgG. The schematic representation of the protein binding events is shown to the left of the liquid crystal images. *Source:* From Ref.<sup>[15]</sup>.

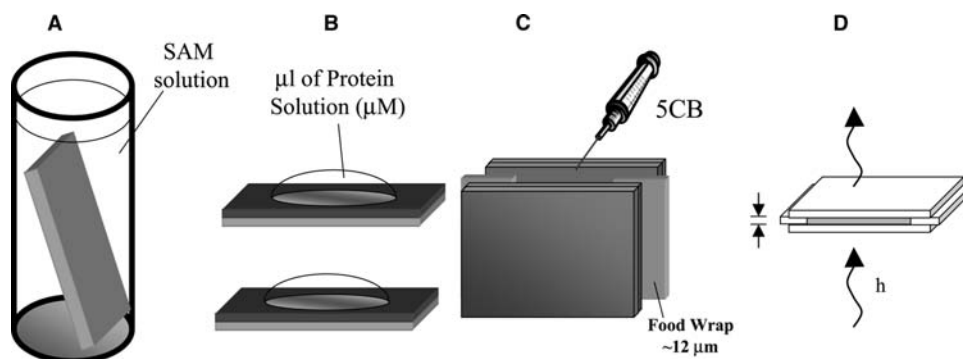

sufficiently masks the topography of gold films obliquely deposited at a higher angle ( $40^\circ$ ) and thus is readily reported by the nonuniform orientation of liquid crystal.

## EXPERIMENTAL

The experimental procedures such as organic synthesis, gold deposition, ellipsometry, and AFM measurements are well documented in the referenced literatures. However, the unique experimental procedures pertaining to protein binding assays using liquid crystals in this work bear a beauty of brevity and are described

here. Scheme 7 demonstrates a four-step procedure that completes an assay of protein binding starting from surface preparation. An example is shown below.

Mixed SAMs of **1** and **2** (prepared from 5% of **1** and 95% of **2** in ethanol) was immersed in 50 mM of  $\text{NiSO}_4$  for 2 hr (Scheme 7A) and then incubated the rinsed surfaces in PBS containing  $0.5 \mu\text{M}$  of His-tag MEK for 5 hr (Scheme 7B). Upon removal of the samples from contact with the His-tag MEK, the surfaces were rinsed with PBS buffer (pH 8.2). Two substrates with immobilized protein (or treated with second protein) were spaced with a Saran wrap ( $12 \mu\text{m}$ ) to create a liquid crystal optical cell. Nematic 5CB was injected

**Scheme 7** Experimental procedures for label-free protein assays on nanostructured surfaces for the use of liquid crystals.

into the cell at a temperature above the nematic-isotropic transition by capillary motion (Scheme 7C). Last, the cell was placed under a polarizing microscope, and the texture of the 5CB was examined and analyzed.

## CONCLUSION

In summary, using liquid crystal in combination with SAMs supported on nanostructured gold films, protein binding events can be readily detected without using secondary protein reporter or any labeling. Several unique characters make the use of liquid crystals with nanostructured gold films power for biological studies. First, the liquid crystal is sensitive to both the nanometer-scale topography and the molecular details of the organic monolayer on surface. Second, the liquid crystal can be masked from the nanometer-scale topography by the presence of surface-bound protein. Third, the anisotropy of the nanometer-scale topography can be adjusted by varying the angle of oblique deposition. Fourth, the combination of liquid crystal and nanostructured surfaces is completely compatible with sophisticated surface chemistry (mixed ethylene glycol monolayer) that prevents nonspecific protein adsorption and supports biospecific interactions. Fifth, by increasing the anisotropy of the topography of the nanostructured surfaces, multiple biospecific protein binding events can be detected. Together, these results suggest that nanostructured surfaces supporting biospecific interactions combined with liquid crystals form the basis of a general and facile method for detecting protein binding events on surfaces directly.

## ACKNOWLEDGMENTS

This research was supported by funding from the Office of Naval Research (Presidential Early Career Award for Science and Engineering to Professor Abbott, N00014-99-1-0250), Materials Research Science and Engineering Center on Nanostructured Materials and Interfaces (NSF-DMR-0079983) at University of Wisconsin, and the Biophotonics Partnership Initiative of NSF (ECS-0086902). The author would like to thank Professor Abbott for his support and encouragement throughout the course of some of the above research.

## Abstract

External accessibility to the molecular world requires a hierarchy of devices and addressing protocols. The paradigmatic example is that of a molecular memory, arranged in about  $N^2$  cross-points (each containing  $10^3$  reprogrammable molecules), defined by  $2N$  nanoscopic wires, addressed by  $\log_2(2N)$  lithographically defined gates. For  $N = 10^5$ , this gives  $10^{13}$  molecules (the molecular scale),  $10^{10}$  cross-points and  $2 \times 10^5$  lines (the mesoscopic scale), and  $1 + 5 \log_2(10)$  addressing gates (the macroscopic scale). This complex hierarchy requires the development of new techniques able to merge the ones involved in the top-down route, characteristic of the macroscopic scale, with the ones involved in the bottom-up route, characteristic of the nanoscopic scale.

## INTRODUCTION

From the fundamental point of view, the properties of matter can be distinguished on the grounds of their scaling behavior:

- (Ma) On the *macroscopic scale* (the one described by classical physics), the properties of matter remain substantially unchanged when the size of the considered system is progressively reduced; replicas of the system have negligible statistical dispersion.
- (Me) On the *mesoscopic scale*, the properties of matter change substantially when the size of the system is progressively reduced; replicas of the systems have usually large statistical dispersion.
- (Mi) On the *microscopic scale* (the one described by quantum physics) matter cannot be shrunk; all replicas of the system are rigorously identical; the upper limit of this scale is the molecular one, (Mo).

## LITHOGRAPHY AND ITS LIMITS

Of course, this description is matched to the thermodynamic properties of simple systems. When the functional properties of the systems are prevailing over the thermodynamic ones, the system is usually referred to as a *device*—something “which is formed by design”.<sup>[1]</sup> It may happen that devices working on a certain length scale work, even better, on a lower length scale. The combination of better properties with lower cost of materials has led to the development of *miniaturization techniques*. The most spectacular achievement in this field has been the development of the integrated-circuit (IC) technology.

The evolution of ICs has been dominated by the idea of scaling down its basic constituent—the metal-oxide-semiconductor (MOS) field-effect transistor (FET). In turn, this has required the development of suitable lithographic techniques for its definition on smaller and smaller length scales. There are several generations of lithographic techniques, usually classified according to the medium required for the definition of the wanted features on photo- or electro-sensitive materials (resists): standard photolithography (436 nm, Hg *g*-line; refractive optics), deep ultraviolet (DUV) photolithography (193 nm, ArF excimer laser; refractive optics), immersion DUV photolithography (refractive optics), extreme ultraviolet (EUV) photolithography (13.5 nm, plasma-light source; reflective optics); electron beam (EB) lithography (electron wavelength controlled by the energy, typically in the interval  $10^{-3}$ – $10^{-2}$  nm).

This generation of techniques has grown to match what seems to be the fundamental issue of IC production: increase the integration scale by decreasing the MOS-FET size. The industrial system has succeeded in that, but the cost of ownership has in the meanwhile dramatically increased, because of either the required investment per machine,

DUV  $\ll$  immersion DUV  $\ll$  EUV,

or the throughput,

EB  $\ll$  DUV.

The dramatic cost explosion necessary for the reduction of the feature size (see Fig. 1) has thrown doubts on the possibility of continuing the current

**Fig. 1** Exponential increase with time of the cost of lithographic systems.

increase of density (by a factor of 2 each 18 months for memories or each 24 months for microprocessors) beyond the next 10 years.

The impossibility of preparing horizontal features on the nanometer length scale via conventional lithography, the poor technical maturity of the advanced lithographic (extreme-ultraviolet, synchrotron-radiation in the X-ray region, or electron-beam) tools necessary for their preparation, and the huge investment cost expected for IC mass production, have generated a strong interest for the development of alternative lithographic methods or of non-lithographic techniques for the definition of geometries on the nanometer length scale.

To overcome these limits, other routes have been proposed as alternatives to the *top-down route* that has characterized the evolution of microelectronics; the *bottom-up route*, in which the circuit is generated via the self-assembly of nanoscopic (typically molecular) devices, and the *hybrid route*, in which such molecular devices are arranged in a hosting microelectronic frame to form a circuit.<sup>[2,3]</sup>

Since the architecture of the hybrid IC remains substantially controlled by its microelectronic part, the hybrid route does not require a complete rethinking of the circuit. The hybrid route may thus be seen as a *conservative extension of microelectronics into nanoelectronics*, where the nanoelectronic (molecular) devices are otherwise produced (with synthetic methods of chemistry) and assembled on a microelectronic frame. *The hybrid route may thus be seen as a kind of host-guest technology, in which the host is demanded to microelectronics while the guest is demanded to chemistry.*

The structure that seems to pose less problems for the integration of molecular devices in microelectronic circuits is the crossbar one, in which a lower array of  $N$

wires crosses an upper array of  $N$  wires and the  $N^2$  overlapping regions (*cross-points*) are prepared to host nanoscopic devices.

## PROCESSING CROSSBARS

The property that has attracted the maximum of interest for possible application of molecules in electronics is the bistability manifested by some of them: under the application of a suitable difference of electric potential, a molecule may undergo electronic and structural changes, in turn responsible for large conductance difference.<sup>[4]</sup> The ideal arrangement for the exploitation of bistable molecules is based on their insertion in a crossbar structure, in turn defined by two arrays of conducting wires arranged in parallel planes and oriented perpendicularly to one another.<sup>[5-8]</sup>

The first demonstrators of molecular crossbar memories exploited the spontaneous formation of monolayers of functional molecules with thiol termination(s) on metal films to produce their self-assembly inside the cross-points of the crossbar.<sup>[9]</sup> The process, according to which the first molecular memory was prepared, employed thiol-terminated rotaxanes as reprogrammable cells. The molecules were embedded between the metal layers forming the crossbar via a process that can be sketched as follows:

- (XB1), deposition and definition of the first-level (“bottom”) wire array;
- (XB2), deposition of the active reconfigurable molecules, working also as vertical spacer separating lower and upper arrays; and
- (XB3), deposition and definition of the second-level (“top”) wire array.

The above XB approach, with double metal strips, has however been found to have serious limits:

- The organic active element is incompatible with high-temperature processing, so that the top layer must be deposited at room or slightly higher temperature. This need implies a preparation based on physical vapor deposition, where the metallic electrode results from the condensation of metal atoms on the outer surface of the deposited organic films. This process, however, poses severe problems of compatibility, because isolated metal atoms, quite irrespective of their chemical nature, are mobile and decorate the molecule, rather than being held at its outer extremity.<sup>[10-12]</sup>
- A safe determination of the conductance state of bistable molecules requires the application of a voltage  $V$  appreciably larger than  $k_B T/e$  (with  $k_B$  being the Boltzmann constant,  $T$  the absolute

temperature, and  $-e$  the electron charge), say  $V = 0.1\text{--}0.2\text{ V}$ . Applied to molecules with typical length around 3 nm, this potential generates an electric field, of the order of  $5 \times 10^5\text{ V cm}^{-1}$ , sufficiently high to produce metal electromigration along the molecules.<sup>[13]</sup>

- The energy barrier for metal-to-molecule electron transfer is controlled by the polarity of the contact, in turn increasing with the electronegativity difference along the bond linking metal and molecule.<sup>[14]</sup> The use of thiol terminations for the molecule, as implicit in the XB approach, is expected to be responsible for high-energy barriers because of the relatively high electronegativity of sulfur.

A solution to the electromigration problem, eliminating metal contacts, can be achieved preparing the bottom electrodes in the form of silicon wires (as done in Ref.<sup>[15]</sup>) and the top electrodes in the form of conducting  $\pi$  conjugated polymers (as suggested in Ref.<sup>[16]</sup>).

- (XB<sup>+1</sup>), deposition and definition of the bottom array of poly-silicon wires;
- (XB<sup>+2</sup>), deposition of the active (reconfigurable) element, working also as vertical spacer separating lower and upper arrays; and
- (XB<sup>+3</sup>), deposition and definition of the top array of conducting  $\pi$ -conjugated polymer.

This process requires the development of grafting techniques to both poly-silicon and the  $\pi$ -conjugated polymer. The development of the process would certainly be simplified using the same material for upper and lower wires.

The use of poly-silicon as material also for the top array seems impossible because poly-silicon is almost uniquely prepared via chemical vapor deposition at temperatures (600–700°C) that are incompatible with organic molecules (certainly destroyed at a temperature of 400°C). The only way to overcome this difficulty consists thus in a process, XB\*, where the two poly-silicon arrays defining the crossbar matrix are prepared *before* the insertion of the organic element:

- (XB\*1), preparation of a bottom array of poly-silicon wires;
- (XB\*2), deposition of a sacrificial layer as vertical spacer separating lower and upper arrays;
- (XB\*3), preparation of a top array of poly-silicon wires crossing the first-floor array;
- (XB\*4), selective chemical etching of the spacer; and
- (XB\*5), insertion of the reconfigurable molecules in a way to link upper and lower wires in each cross-point.

Of the three considered processes (XB, XB<sup>+</sup>, and XB\*), the most conservative one is certainly based on

double-silicon strips and is thus expected to be of easiest integration in IC processing.

Limiting the attention to this structure, the hybrid circuit is formed by two zones: the *nano-zone*, containing the crossbar and hence hosting the molecular devices, and the *litho-zone*, hosting the conventional CMOS circuitry. Nano- and litho-zones are interconnected by the strips (addressing lines), which take the function of rows and columns of the crossbar memory.

The process for the production of the nano-IC should comprise a *zeroth mask*, protecting (with Si<sub>3</sub>N<sub>4</sub> or SiO<sub>2</sub>) the nano-zone from the *front-end initial stage*, where transistors, capacitors, and short-range poly-silicon interconnections are defined. At a certain point of this stage, the protection of the nano-zone is removed and the poly-silicon seed is allowed to cross the nano-litho frontier, thus initiating the construction of the crossbar. After its conclusion, the nano-zone is protected (once again with Si<sub>3</sub>N<sub>4</sub> or SiO<sub>2</sub>) and the *front-end final stage* is carried out. The process goes to completion as in standard IC process. After that, the dielectric layer protecting the nano-zone is selectively removed and the *grafting* of the active elements to the poly-silicon strips is achieved by the simple exposure to the organic molecules: the molecules are addressed to the wanted regions simply by the appropriate distribution of chemical potentials. In turn, that requires the ability to control the chemical terminations of the surfaces of the most important IC films. The passivation with organic resins of the overall nano IC completes the process.

In addition to the said reorganization of the IC process, the implementation of the hybrid silicon-organic architecture XB\* requires, however, the solution of a number of problems. The major ones seem the following:

1. the setup of an economically sustainable technology for the preparation of crossbar with cross-point density (say,  $10^{11}\text{ cm}^{-2}$ ) higher than the maximum bit density projected by the International Technology Roadmap for Semiconductors;<sup>[17]</sup>
2. the linkage of the addressing lines to the silicon circuitry for writing and sensing;
3. the design and synthesis of the reconfigurable molecules; and
4. the grafting of the functional molecules to those cross-points via batch processing.

This entry is devoted to analyze whether XB\* can be adapted to solve problems 1 and 2. Problems 3 and 4 are considered in articles<sup>[19,20]</sup> respectively.

## CROSSBAR PRODUCTION WITH GEOMETRIES ON THE NANOMETER LENGTH SCALE WITHOUT USING ADVANCED LITHOGRAPHY

Needless to say, the crossbar structure may be prepared with any lithographic method. The use of standard lithography (up to DUV) results in systems on the macroscopic scale. The use of advanced lithography (or even of the non-lithographic methods described in the following) produces instead systems on the mesoscopic scale. In view of the intrinsically large statistical variability of the properties of mesoscopic systems, the circuit architecture should be self-aligned.

The crossbar structure satisfies this need because the fabrication of cross-points does not require any alignment, being the self-aligned result of two subsequent definition. Moreover, the geometries of each mask are so simple (parallel lines) to allow their production on the mesoscopic scale with techniques not involving advanced lithography.

These non-conventional techniques are based on the following technological skills:

- the control of film thickness (say, along the “vertical” direction), which is possible down to

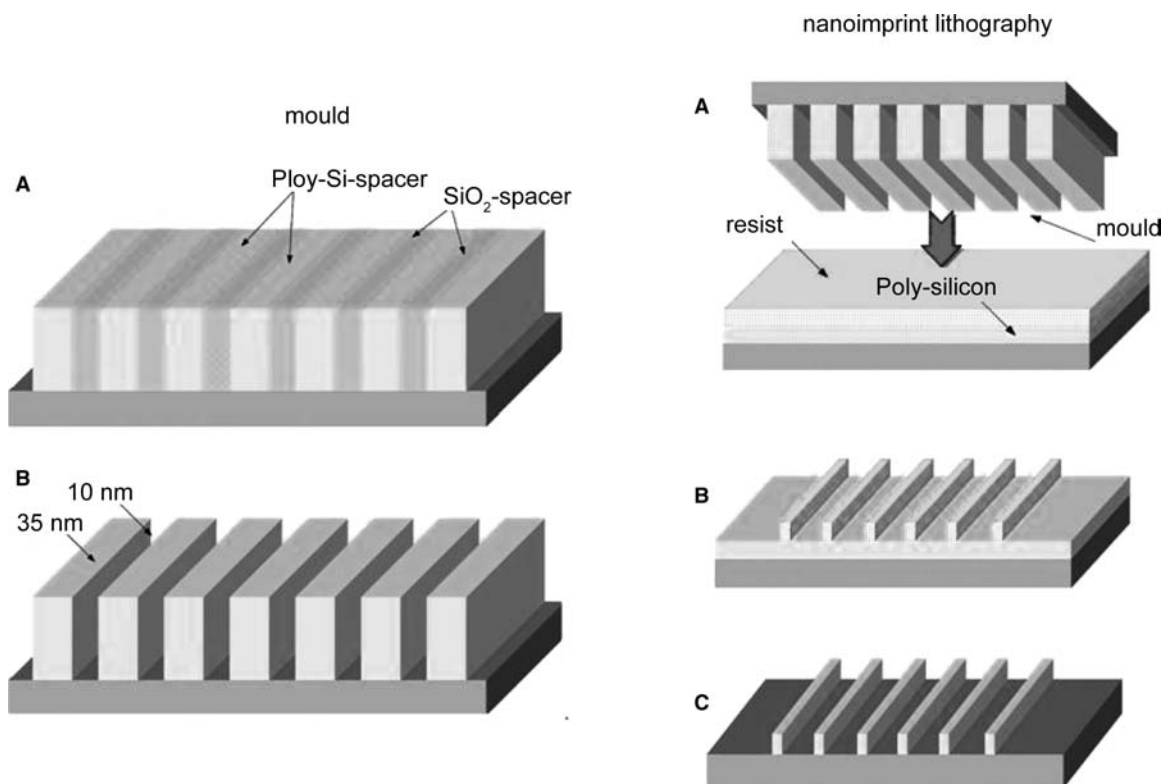

the sub-nanometer length scale provided that the film is sufficiently homogeneous; and

- the transformation of horizontal features (i.e., surface layers with thickness  $t$ ) into vertical features (i.e. columns, called spacers, of width  $t$ ).

### Collective Preparation

The first method (originally proposed by Natelson et al.<sup>[18]</sup> and later implemented practically by another collaboration<sup>[19]</sup>) is essentially based on the sequential alternate deposition of two films A and B, characterized by the existence of a preferential etch for one (say, A) of them. After cutting at 90°, polishing, and controlled etching of A, one eventually gets a mold that can be used as an imprinting mask, as sketched in Fig. 2. This technique is referred to as imprint lithography (IL); actually it is a *contact* (rather than proximity) lithography.

The first practical application of this idea was provided by Melosh et al., who prepared a contact mask for IL with pitch of 16 nm by growing on a substrate a quantum well via molecular beam epitaxy, cutting the sample perpendicularly to the surface, polishing the newly exposed surface, and etching selectively the different strata of the well.<sup>[21]</sup>

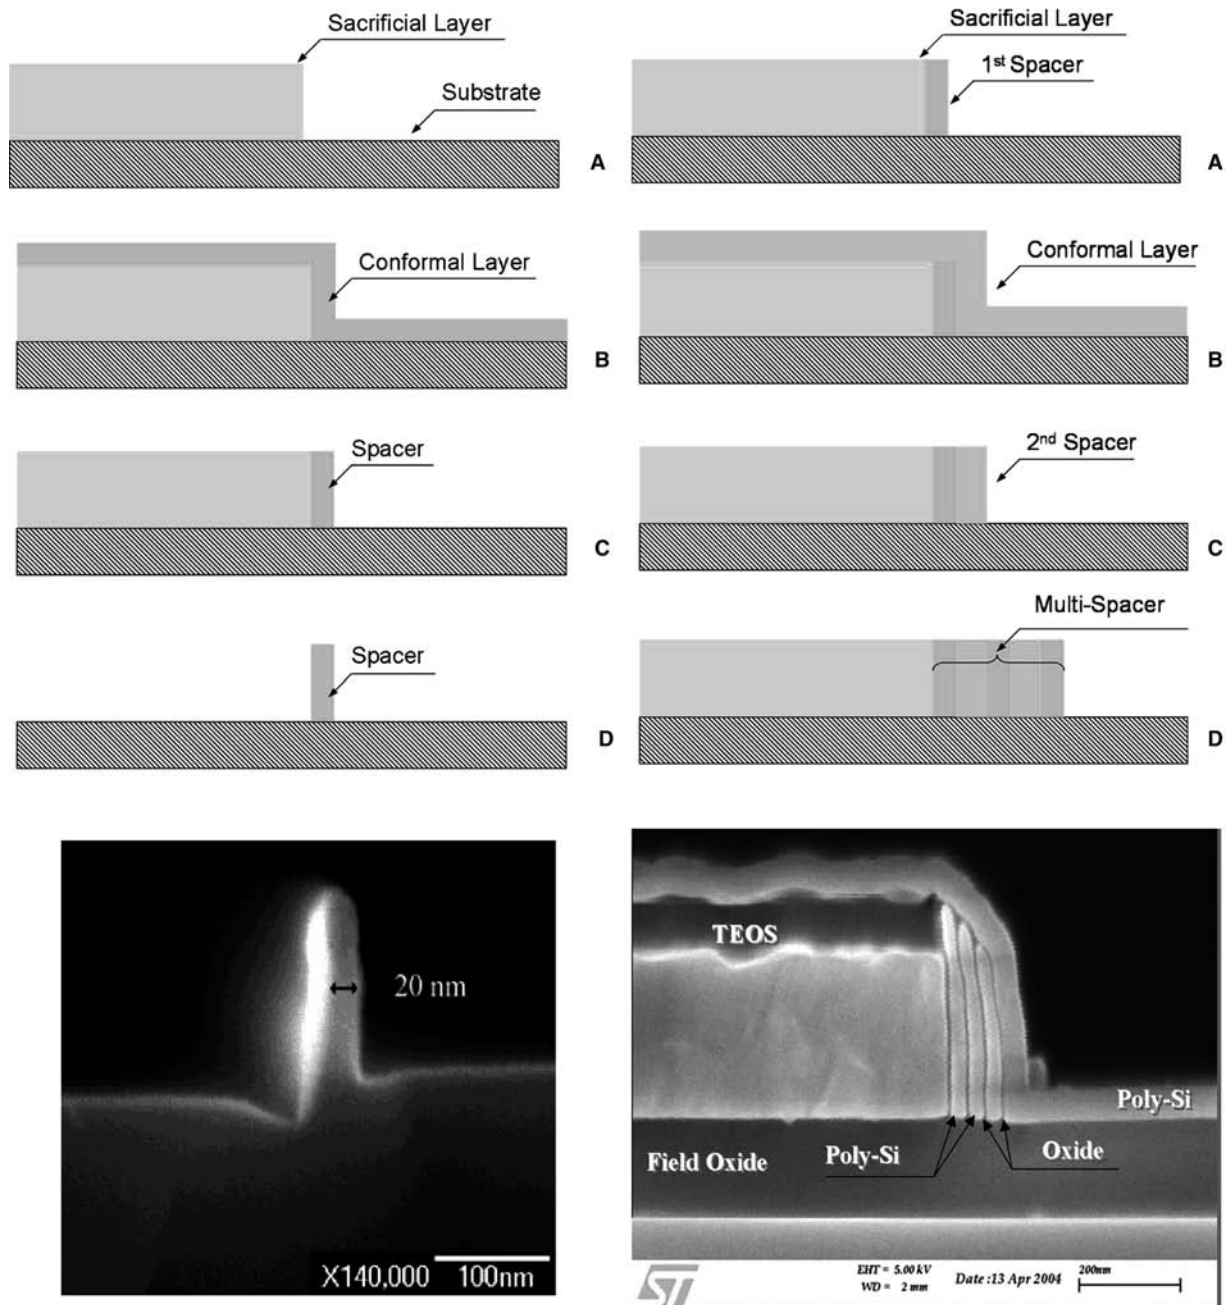

**Fig. 2** Preparation of a mold via selective etching in multilayered structure (*left*) and its use as a contact mask for imprint lithography (*right*).

## Sequential Preparation

Another route is the multi-spacer patterning technique (S<sup>3</sup>PT), in turn an extension of the spacer patterning technique (SPT).

The SPT is based on the definition of a suitable seed, the conformal deposition of a poly-silicon film of assigned thickness, and its anisotropic etching completed with the formation of a sidewall. The upper part of Fig. 3 sketches the process, whereas the lower part

**Fig. 3** *Upper left:* A sequence for obtaining sublithographic features via the spacer patterning technique: (A) deposition of a layer and lithographic definition of a vertical step by means of an anisotropic etching; (B) deposition of a conformal layer; (C) anisotropic etching; (D) selective chemical etching of the sacrificial layer. *Lower left:* An example of structure produced via SPT [taken from Ref.<sup>[26]</sup>]. *Upper right:* The multi-spacer patterning technique: (A) fabrication of a first spacer by means of the SPT; (B) deposition of a novel conformal layer; (C) anisotropic etching and fabrication of a second array of another material; (D) iteration of the sequence (B)–(C). *Lower right:* An example of an S<sup>3</sup>PT multi-spacer (with pitch of 35 nm and formed by a double layer poly-Si|SiO<sub>2</sub>) resulting after three repetitions of the SPT. *Source:* Taken from Ref.<sup>[25]</sup>.

shows the cross-section of a wire produced via this technique.

The S<sup>n</sup>PT is just an extension of the SPT. It is based on the idea that a wire array of  $2n$  bars is produced via a sequence of  $n$  conformal depositions and anisotropic etchings. This idea, proposed and developed by Cerofolini et al.,<sup>[22–24]</sup> is shown on the right of Fig. 3: the upper right part sketches the process; the lower part shows instead how poly-silicon arrays separated by SiO<sub>2</sub> dielectrics with sub-lithographic pitch (35 nm) can indeed be produced. The minimum pitch reported as producible via this technique is 20 nm.<sup>[25,26]</sup>

### Comparing IL with S<sup>n</sup>PT

Although both IL and S<sup>n</sup>PT allow the preparation of deeply sub-lithographic features with comparable pitches; however, these techniques manifest large differences:

- Whereas in IL all wires are defined collectively, in S<sup>n</sup>PT they are constructed sequentially.
- In IL, all wires have the same height,<sup>[19]</sup> while in S<sup>n</sup>PT the wire height decreases progressively with the order of preparation.
- Similarly, the separation between bottom and top wires in IL is independent of the wire, whereas in S<sup>n</sup>PT it can be varied from one top wire to the subsequent one tuning the thickness of oxide before poly-silicon deposition.
- Moreover, the geometry obtained via IL is necessarily formed by parallel wires, while the geometry obtained via S<sup>n</sup>PT may be more complex in relation to the mask used to define the sacrificial layer.

### NANOWIRE DEMULTIPLEXING

If the availability of nanofabrication techniques is fundamental in establishing a nanotechnology, not less vital is the integration of the nanostructures with higher-level structures: Once the crossbar structure is formed, it is necessary to link it to the conventional silicon circuitry. As clearly stated in a scholium to Ref.<sup>[27]</sup>, “the difficulties in communication between the nanoworld and the macroworld represent a central issue in the development of nanotechnology.”

Although the importance of addressing nanoscale elements in arrays goes beyond the area of memories (and will be critical to the realization of other integrated nanosystems such as chemical or biological sensors, electrically driven nanophotonics, or even quantum computers), in the following the attention will however be limited to the problem of addressing cross-points in nanoscopic crossbar by means of

externally accessible lithographic contacts. This is a difficult task because the current devices at the forefront of the technology are characterized by a feature size of 45 nm (half pitch).

Several strategies have been adopted to attack this problem:

- The complicate circuitry required by binary-code demultiplexing is avoided using nanoscopic addressing circuits, embodying in themselves the ability to address single cells. In the first demonstrator, they were prepared by “vertical” growth of variously doped silicon wires, first chemical-vapor deposited and then randomly arranged horizontally to link the nanoscopic lines to the lithographic lines.<sup>[28,29]</sup> As far as the exact way such links cover the nanoscopic lines is not exactly known—this technique does not allow to know a priori which cell is addressed. “This was a rudimentary demonstration vehicle, and neither vehicle nor probably the programming technique could be extended to the much larger arrays required for practical interest”.<sup>[30]</sup> A conceptually similar technique was developed by the collaboration of Ref.<sup>[30]</sup>; however, using a consistent solution with the CMOS technology. In this solution, where one-to-one correspondence between nano- and litho-wires is achieved via rotation of a very small angle, the lithographic lines need to be defined with the same pitch as the nanoscopic lines.
- The idea of using small misalignment to access the nanoscopic circuitry was perhaps first proposed by Likharev with the name of cmol circuit (see Refs.<sup>[31–33]</sup> for recent reviews). In Likharev approach, the contact is achieved with the growth of pyramids whose base is matched to the lithographic feature and whose summit is matched to intersect one and only one nanoscopic line. The misalignment guarantees this occurrence but makes it impossible to know the correspondence between cross-point and wire pair.
- A misalignment-tolerant random-interconnect architecture was hypothesized by the proponent of the crossbar structure.<sup>[5,34]</sup> In this way, a large amount of cells are left out of control (being either not addressed or such that different cells are identified with a unique code) and a special logic must be employed to manage this situation, eliminating unaddressed cells and possibly exploiting redundancy (TERAMAC approach).<sup>[35]</sup> Needless to say, this deal is convenient only if the non-functioning cells are a minority and the circuitry required to manage the randomness remains relatively simple. That these conditions may really be satisfied in practice is not clear, especially if the expected cross-point density ( $10^{11} \text{ cm}^{-2}$ ) is compared with

the soon achievable density ( $10^{10} \text{ cm}^{-2}$ ) for NAND memories, whose control is deterministic.

In the following, the attention will only be focused on arrangements allowing a deterministic access to all cross-points and using two length scales—the sub-lithographic one (possibly down to a few nanometers) and the lithographic one. In particular, three methods will be discussed: one suitable for all kinds of nanoscopic crossbars (irrespective of their preparation procedure) and the others specific of crossbars prepared by the S<sup>n</sup>PT.

### The Horizontal Beveling Technique

The first technique is reminiscent of the beveling technique once used, together with micro-sectioning and staining, for the measurement of junction depth (and more recently of carrier concentration profiles using spreading resistance techniques); because of this, it will henceforth be referred to as horizontal beveling technique (HBT).

Consider as above an array of  $n$  conductive parallel wires aligned in the  $x$  direction with width  $l_y$  and pitch  $L_y$ , so densely arranged that they cannot be singularly accessed photolithographically and thus cannot be linked to the hosting microelectronic circuit.

A kind of hardware demultiplexing is possible via the following process: after the deposition of a protective insulating cap, a bar with width  $b$ , oriented in a direction tilted by a small angle  $\alpha$  with respect to the  $x$  direction and so long as to cross all wires, are defined and this pattern is used to etch the underlying insulating cap (see Fig. 4). This process will result in the exposition of  $N$  rhomboids with pitch  $\Delta_x$  and major side  $\delta_x$

in the  $x$ -direction given by

$$\Delta_x = L_y / \tan \alpha, \quad (1)$$

$$\delta_x = b / \sin \alpha, \quad (2)$$

the area of each open contact being thus  $bl_y / \sin \alpha$ . The orientation is chosen in such a way that both  $\delta_x$  and  $\Delta_x$  are in the reach of (not necessarily electron-beam) lithography. Because of Eqs. (1) and (2), which is certainly possible for sufficiently small  $\alpha$ . Since the method produces from an array with pitch  $L_y$  another array with pitch  $\Delta_x$  [controlled uniquely by the orientation angle  $\alpha$  of the cutting bar, see Eq. (1)], it may be viewed as a kind of *pitch converter*. This method is immediately extended from one to two arrays by defining two bars (one per row and one per column).

Even this method, proposed by Cerofolini and Mascolo,<sup>[36,37]</sup> is based on controlled misalignment. Compared with the one proposed by Likharev, it has the advantages of greater consistency with the current IC technology and of specifying exactly the location of the addressed cross-point. Since each cross-point can be addressed independent of the remaining ones, this architecture is suitable for random-access memories (RAMs).

### Fusing Adjacent Lines in S<sup>n</sup>PT

After the demonstration that the S<sup>n</sup>PT can be used for the preparation of nanowire arrays, Cerofolini and Mascolo proposed another addressing strategy exploiting specific features of this technology.<sup>[36,37]</sup> The process starts with deposition of a film (e.g., of  $\text{Si}_3\text{N}_4$ ) and its photolithographic definition to form a seed with the pattern shown in Fig. 5A. The pattern is

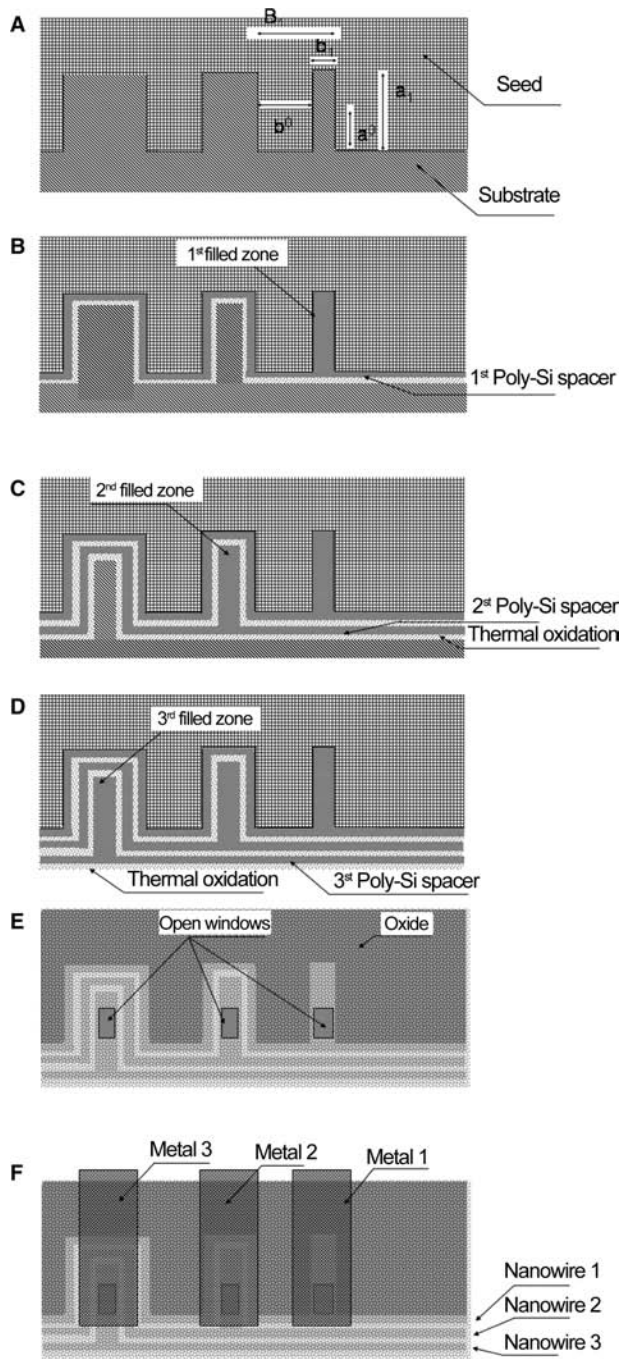

Fig. 4 The trick adopted for contacting each wire in the horizontal beveling technique.

**Fig. 5** Plan view of the mask able to contact single wires using the spacer patterning technique.

derived from the rectilinear edge required for the multi-spacer preparation with the addition of  $n$  rectangular indentations, of sides  $b_k$  (“width,” parallel to the border) and  $a_k$  (“depth,” perpendicular to the border);  $k$  runs from 1 to  $n$  and enumerates the wire in the array. The pitch  $B_k$  describing the indentation sequence is assumed to be given by

$$B_k = b^0 + b_k, \quad (3)$$

where  $b^0$ , the separation between vicinal indentations, does not vary with  $k$ ; instead  $a_k$  is assumed, at least temporarily, to be independent of  $k$  and given by

$$a_k = a^0 + (n - 1)t_{sp}, \quad (4)$$

where  $t_{sp}$  is the width of the double spacer formed by a poly-silicon spacer (with width  $t_{Si}$ ) and an oxide spacer (with width  $t_{ox}$ ),  $t_{sp} = t_{Si} + t_{ox}$ , and the meaning of  $a^0$  will be discussed later.

In  $S^nPT$ , alternate spacers of poly-silicon and oxide are grown after conformal deposition and anisotropic etching. This process results in the reproduction indentations only if  $b_n > 2nt_{sp}$ . If this condition is not satisfied, at a certain stage of the  $S^nPT$  the indentation is completely filled. Suppose now that the indentation width  $b_k$  satisfies the following condition:

$$b_k = 2t_{Si} + 2(k - 1)t_{sp}. \quad (5)$$

When condition (5) is satisfied, the first  $S^nPT$  step fills the first indentation (Fig. 5B); the inspection of Fig. 5 shows that this phenomenon extends progressively to the  $k^{\text{th}}$  indentation with the order  $k$  of bar deposition. After step  $k$ , the central region of each indentation up to the  $k^{\text{th}}$  is filled with a poly-silicon bar of width  $2t_{Si}$ ; the remaining part of the cave is filled with  $(k - 1)$  double layers each of width  $t_{sp}$ . At the end of the  $S^nPT$  (Fig. 5D) all indentations have their central zone connected with only one nanowire running out of the original indentation.

After the  $S^nPT$  completion, the process continues with the deposition of a dielectric film ( $\text{SiO}_2$ ) on the whole structure and with the definition of  $n$  rectangular windows (of nominal sides  $a^0$  and width  $2t_{Si}$ ) aligned on the central zone of each cave (Fig. 5E). The process is concluded with the deposition of a metal film and the definition of  $n$  metal strips contacting the single nanowires.

The functions  $a^0$  and  $b^0$  are now clear:  $a^0$  controls the area metal–poly-silicon contacts, whereas  $b^0$  is determined by the minimum allowed distance between metal strips (Fig. 5F).

The process described above has the great advantage of allowing the definition of the nano-litho contacts simultaneously to the formation of the wire array. It is, however, stressed that the considered architecture is quite demanding about the mask. To evaluate the tolerance, we observe that the maximum width  $b_k^{\text{max}}$  of the  $k^{\text{th}}$  indentation must be not so large as to allow the formation therein of filaments of the  $(k + 1)^{\text{th}}$  wire:

$$b_k^{\text{max}} = 2kt_{sp}; \quad (6)$$

the minimum width  $b_k^{\text{min}}$  of the  $k^{\text{th}}$  indentation must instead be so large as to guarantee that the  $k^{\text{th}}$  wire

therein is certainly connected to the wire forming the crossbar:

$$b_k^{\min} = 2(k - 1)t_{\text{sp}} + t_{\text{Si}}, \quad (7)$$

where the wire continuity has been assumed to be certain when the wire has a thickness  $t_{\text{Si}}$ . Combining Eqs. (6) and (7), one has

$$\begin{aligned} b_k^{\max} - b_k^{\min} &= 2t_{\text{sp}} - t_{\text{Si}} \\ &= t_{\text{sp}} + t_{\text{ox}}; \end{aligned} \quad (8)$$

In the case of Fig. 3 (with  $t_{\text{sp}} = 35$  nm and  $t_{\text{ox}} = 5$  nm), Eq. (8) gives a tolerance, of  $\pm 20$  nm, compatible with the current technology. It is however noted that the mask opening the contacts in the worst case (7) should have a maximum size (along the wire) of just  $t_{\text{sp}} + t_{\text{ox}}$ ; in the example of Fig. 3  $t_{\text{sp}} + t_{\text{ox}} = 40$  nm, inconsistent with the current technology. This value would run in the range achievable with standard photolithography only taking a larger value of  $t_{\text{ox}}$ .

The process is not optimized. Area occupancy can be reduced taking, instead of the constant value  $a_k$  of Eq. (4), a value varying with  $k$ . For instance, choosing

$$a_k = a^0 + (k - 1)t_{\text{sp}} \quad (9)$$

still allows the nano-to-micro link saving more space.

The crossing of these  $n$  nanowires with the analogue ones, perpendicularly oriented and lying on a parallel plane (obtained by the deposition or growth of an oxide of thickness adapted to the molecular size) results in the crossbar. Since the access to each single cross-point is independent of the other, the described addressing strategy is suitable for application to RAMs.

### Energetic Filtering

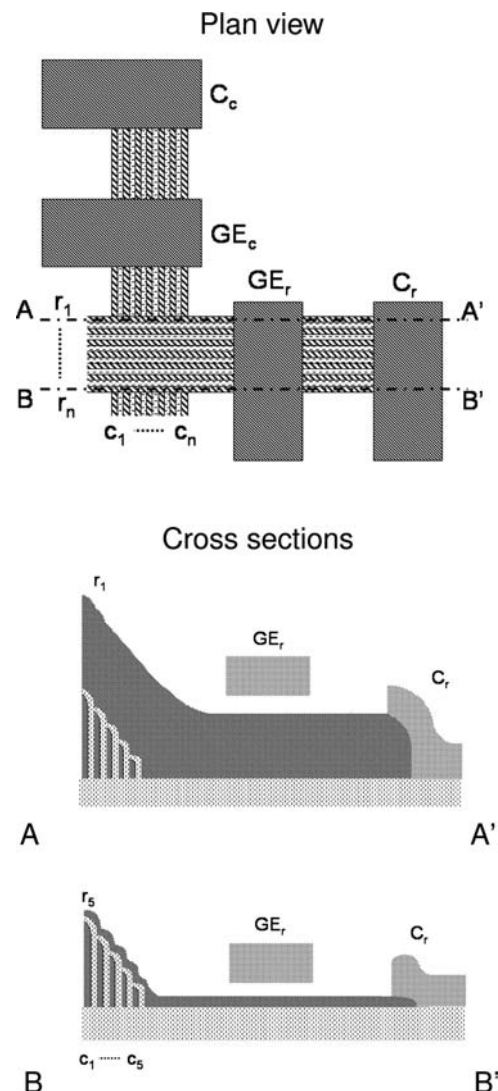

Whereas in IL all wires are defined collectively, in  $S^n$ PT they are constructed sequentially. The batch fabrication would make preferable IL over  $S^n$ PT unless one were able to use the sequential array deposition for the external recognition of single wires.

An inspection of the right side of Fig. 3 shows that multispacer patterning results in wires whose height is progressively reduced with the order of preparation (the reader will easily convince herself or himself that the amount of this decrease can be magnified in a controlled way via slight changes in the  $S^n$ PT). Cerofolini proposed to exploit this spatial difference for the recognition and separation of single nanoscopic wires by electrical probes.<sup>[38]</sup>

In this case, the crossbar is built before the addressing system, exactly as in “The Horizontal Beveling

Technique.” Let  $r_i$  and  $c_j$  denote the  $i^{\text{th}}$  row and  $j^{\text{th}}$  column, respectively, and  $(r_i, c_j)$  be the cross-point they define. All the rows  $r_i$  (columns  $c_j$ ) run below a photolithographically defined electrode  $\text{GE}_r$  ( $\text{GE}_c$ ) and finally terminate at a unique photolithographically defined contact  $C_r$  ( $C_c$ ), as it is well represented in the cross-sections in Fig. 6. The process is arranged in a way that electrodes  $\text{GE}_r$  and  $\text{GE}_c$  are separated from the underlying wires by an insulator of fixed thickness. Exploiting the electrodes as self-aligned masks, the nanowires are highly doped everywhere but below the electrodes via ion implantation and subsequent thermal activation of a suitable dopant.

This configuration reminds us of a transistor in depletion mode, where  $\text{GE}_r$  and  $\text{GE}_c$  operate as control

**Fig. 6** Plan view of the crossbar and of the lithographically defined contacts (*up*) and views projected on planes AA' and BB' perpendicular to the surface and crossing the tallest and smallest row lines, respectively (*down*).

gates, the underlying slightly doped sector of nanowire as the semiconductor channel, and the adjacent highly doped sectors as drain and source. If no voltage is applied on gates with respect to the body, the carriers are free to move in the whole nanowire; if a repulsive voltage is applied, the channel is depleted and no current flow between  $C_r$  and  $C_c$ . In principle, the voltage necessary to disable a nanowire decreases with its height.

For assigned poly-silicon nanowire doping and insulator thickness, it exists at least one couple of voltage values of  $GE_r$  and  $GE_c$ , which makes only the highest wires,  $r_1$  and  $c_1$ , not totally depleted. In this case, the current  $I_{(1,1)}$  flowing from the contact  $C_r$  to the contact  $C_c$  is controlled by the conduction state of cross-point ( $r_1$ ,  $c_1$ ) alone. If the voltage of  $GE_c$  is modified in such a way that even the wire immediately shorter,  $c_2$ , is enabled, the current flowing from  $C_r$  to  $C_c$  becomes the sum of the current  $I_{(1,1)\cup(1,2)}$  flowing through ( $r_1$ ,  $c_1$ ) and ( $r_1$ ,  $c_2$ ). If  $I_{(1,1)}$  was memorized, the current  $I_{(1,2)}$  flowing through ( $r_1$ ,  $c_2$ ) (giving its state) is obtained as difference  $I_{(1,1)\cup(1,2)} - I_{(1,1)}$ .

Reiterating the argument to all cross-points, the states of each of them can be determined provided that the information contents of all cross-points are memorized in a buffer memory. This implies that only a small part of the crossbars can be read in parallel, because each one needs the availability of a circuitry for analog-to-digital conversion and for the manipulation of the information.

By the time, the addressing system depends only on the different heights of the nanowires induced by the S<sup>PT</sup> technology. Some modification can be introduced to optimize the process. If the poly-silicon wires are doped singularly (for instance, via gas-phase doping during each poly-silicon deposition), the difference in the threshold voltage from one wire to the subsequent may be enlarged. Also the oxide thickness between wires and electrodes  $GE_r$  and  $GE_c$  can be varied, achieving the same result about threshold voltage tuning, even if this procedure is quite more demanding for technology.

## INTRODUCTION

While the prefix nano- became the scientific buzzword for the last decade of the 20th century, nanotechnology has become the technology driver for the 21st. Although nanotechnology really means the ability to fabricate and control functioning structures integrated over size scales ranging from nanometers to centimeters, “smaller” has captured the imagination of the public and funding agencies.

The semiconductor industry is an example built on the foundations of nanotechnology. Integrated semiconductor devices have become progressively smaller to improve performance and accommodate an increase in functional density. This obsession has driven the industry for the last 30–40 yr. As device densities increase and component dimensions shrink, the relative effect of the on-chip wiring on performance progressively increases. Many performance issues can be ameliorated by the introduction of low-*k* insulators as replacements for silicon dioxide, thus stimulating a flurry of interest in these materials.

In this entry, we have focused on the need for new low-*k* insulators, the timing for introduction of new materials and processes, the chemical nature of the dielectrics and methods of application, the role of porosity in future dielectric insulators and we end with opportunities beyond porous materials. We have tried to focus on the new materials and chemistry; the review does not deal extensively with the characterization and integration of low-*k* films, except in the context of current integration processes and concerns. The topic of the review is particularly timely given the key role that new materials will play in evolutionary complementary metal oxide semiconductor (CMOS) device performance and the fact that the first truly low-*k* materials are just now appearing in volume chip manufacturing.

## BACKGROUND

For many years, semiconductor manufactures have produced new generations of products according to Moore’s Law, which states that device densities on

chips should approximately double every 18–24 mo.<sup>[1,2]</sup> Fig. 1 shows a relative size comparison for a number of common objects. Scaling in semiconductors has required a continuous reduction in device dimensions. The transistors and other active electronic devices are integrated into the substrate (usually silicon) and are connected with each other and to the outside world by a myriad of on-chip wiring. This interconnect wiring, on-chip insulation, and local packaging is often referred to as the back-end-of-the-line (BEOL), while the active devices on the substrate constitute the front-end-of-the-line (FEOL) portion of the chip. Advanced chips many contain hundreds of millions of active devices with the interconnect wiring distributed over 8–10 vertical wiring levels and approaching 10,000 m in cumulative length. All of this is integrated on chips with 1–3 cm<sup>2</sup> total surface area. A typical BEOL configuration is illustrated schematically in Fig. 2, while Fig. 3 shows a number of chip cross-sections from some commercial processor chips. Both Figs. 2 and 3 also show an actual IBM seventh generation CMOS microprocessor from which the insulating oxide has been removed to reveal the copper BEOL wiring.

As device dimensions decrease and device densities increase, chip performance degrades owing to signal delays and cross talk between the conductor lines. Signal propagation delays are characterized by the product of metal resistance times the capacitance of the lines (RC), which has the dimensions of time.<sup>[3]</sup> Various equations describing the signal delays and power consumption are shown in Fig. 4. The RC delay depends on the resistivity of the wiring metallurgy, the dielectric constant(s) of the insulating media, and the dimensions and configuration of the metal lines. The relatively recent change in metallurgy from aluminum to copper has reduced the resistivity of the metal by about 30%, providing a significant improvement in performance.<sup>[4]</sup> Copper metallurgy is now standard for advanced logic devices and will remain so for the foreseeable future. The difficulty in gas phase etching of copper has necessitated the development of polishing processes [chemical mechanical polishing (CMP)] to planarize metallized structures. Such an integration technique is known as a damascene process and can

Fig. 1 Relative size comparison of common objects.

be further characterized as either single or dual damascene (Fig. 5) depending on whether the lines and layer-connecting vias are processed separately or together.<sup>[5]</sup> Further examination of Fig. 4 shows that the dielectric constant of the on-chip insulating media has a strong influence on both signal delays and power consumption. Until the end of the last decade, this insulator was invariably SiO<sub>2</sub> with a dielectric constant

ranging from 3.9 to 4.2 depending on the deposition and/or processing technique. Signal delays and power consumption are currently driving the search for low-*k* alternatives to SiO<sub>2</sub>. The replacement of silicon dioxide has proved much more difficult than anticipated. For example, the International Technology Roadmap for Semiconductors (ITRS) predicted in 1999 that the 90 nm device generation would employ insulators with

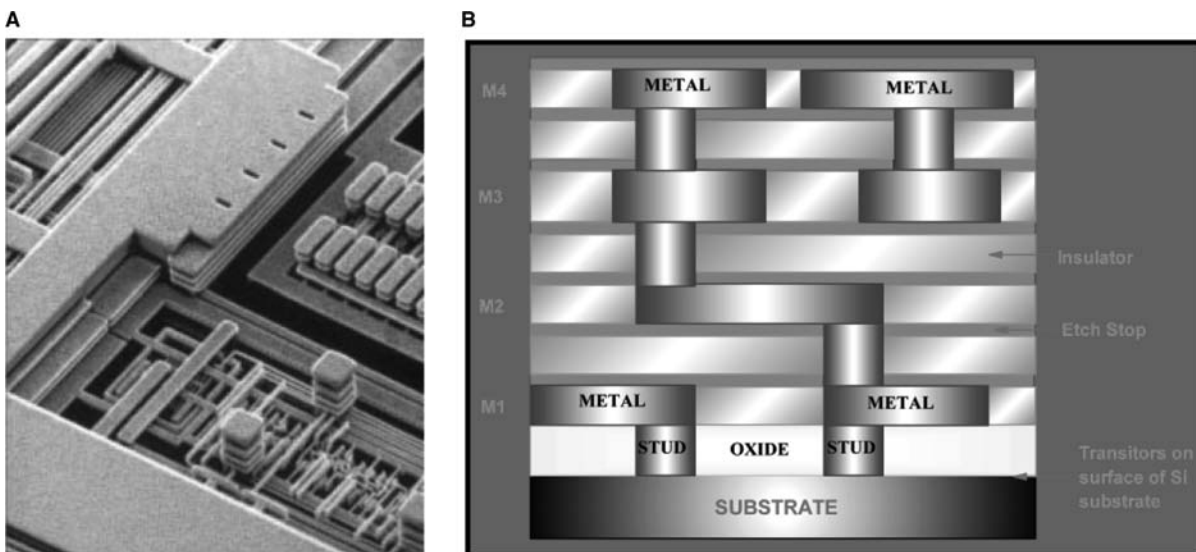

Fig. 2 (A) IBM CMOS seventh generation microprocessor with silicon dioxide insulator removed. (B) Schematic of on-chip BEOL wiring showing insulator and wiring levels.

Low-Dielectric Constant Materials for On-Chip Applications

dielectric constants between 1.3 and 1.4 in 2005 (Table 1). Reality is that current 90 nm production node uses insulators with dielectric constants around 3.0<sup>[6,7]</sup> and the revised 2004 ITRS roadmap predicted

porous materials with  $k < 2.4$  at 65 nm in 2007.<sup>[8]</sup> In fact, the situation has changed again with most of the industry targeting a bulk dielectric  $k$  value of 2.7 (non-porous) for the 65 nm node and the first introduction of porous materials at the 45 nm node ( $k = 2.2-2.4$ ) projected for production in 2009-2010.

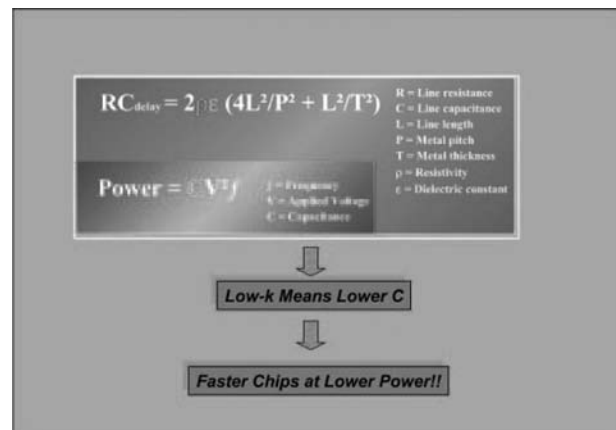

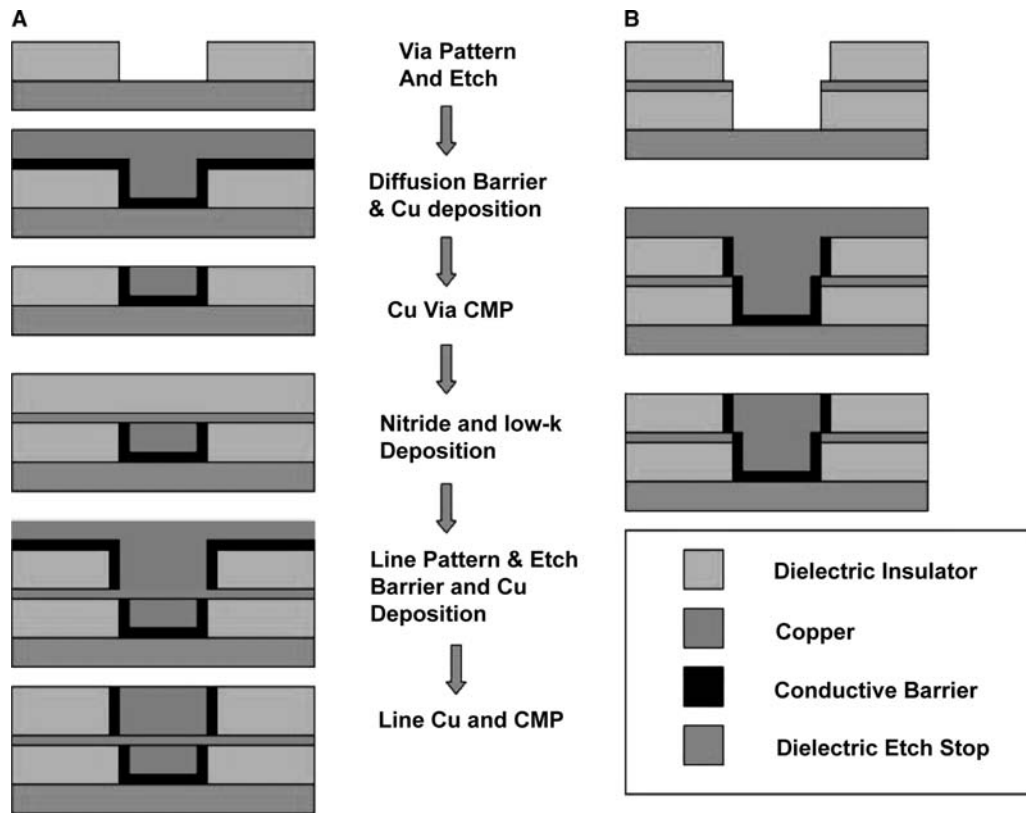

Fig. 4 RC delay and power consumption as a function of BEOL wiring capacitance.

LOW-K DIELECTRIC INSULATORS

Table 2 shows the types of materials that have been auditioned as replacements for silicon dioxide at various times. On the right hand side of the table are a set of challenging integration properties that have evolved primarily from the extensive use of SiO<sub>2</sub>. The materials in the table may be roughly divided into two classes: 1) those materials that are more inorganic in nature represented primarily by cross-linked organosilicates and 2) organic materials represented by various high-temperature organic polymers (polyarylenes, polyarylene ethers, and polyazoles). The former have good electrical and thermal properties, but are

**Fig. 5** Damascene processing for Cu interconnects; CMP is used for planarization of deposited metal (A), single damascene processing (B), and dual damascene (line and via) procedure.

fragile and prone to cracking, while the later are tough but soft with higher thermal coefficients of expansion and lower thermal stabilities. While initially both classes of materials were considered as candidates, the current situation is that the inorganic materials

have currently moved to the forefront and will be very difficult to displace. The difficulty in finding an acceptable replacement for silicon dioxide has placed a premium on dielectric extendibility i.e., maintaining a very similar elemental composition albeit with

**Table 2** Material candidates for replacement of silicon dioxide BEOL insulator and integration requirements required based on the use of silicon dioxide on-chip insulators

Dielectric material	<i>k</i>	Integration requirements
Silicon dioxide	3.9–4.5	Thermal stability to 450°C
Fluorosilicate glass (FSG)	3.3–4.0	Dielectric constant <3.0 (dense)
Polyimides	3.1–3.4	<2.2 (porous)
HSSQ	2.9–3.2	High T <sub>g</sub>
Diamond-like carbon (DLC)	2.7–3.4	Low moisture absorption
Carbon-doped oxide/SiCOH	2.8–3.2	Good adhesion (caps hardmasks liners, substrates, etc.)
Parylene N	2.7	
Benzocyclobutenes	2.6–2.7	Good mechanical properties
Fluorinated polyimides	2.5–2.9	Chemical compatibility (no reaction with metallurgy, liners, etc.)
MSSQ	2.6–2.8	
Polyarylene ethers	2.7–2.9	vs. Solvent resistance
Polyarylenes	2.6–2.7	Compatibility with CMP
Fluorinated DLC (F-DLC)	2.4–2.8	High etch selectivity
Parylene-F4	2.4–2.5	Reasonable shelf life
Fluoropolymers	1.9–2.1	Environmental compliance Low cost
Porous organics	2.1–2.2	
Xerogels (silica)	2.0–2.3	Pores sizes <1/10 of minimum features
Mesoporous silica	2.0–2.2	
Porous HSSQ/MSSQ	1.4–2.2	

No single candidate meets all requirements.

progressively decreasing dielectric constants for subsequent device generations. There is no true dielectric extendibility without embracing the concept of porosity, which brings with it a new set of materials problems (e.g., pore size and distribution, poor mechanical properties, reduced thermal conductivity, and contamination issues). The only common dense organic polymers with dielectric constants in the 2.0–2.2 range are heavily fluorinated (e.g., Teflon and Teflon-AF). The presence of substantial amounts of fluorine bound to carbon causes thermal issues (temperatures >400°C) particularly in the presence of common interconnect metallurgy (Cu, Ta, TaN, W, etc.). For this reason, the use of porous materials eventually seems inevitable, although the industry will delay implementation as long as possible, certainly until the 45 nm technology node. In addition to the standard integration issues shown in Table 1, there are a number of porosity-specific integration criteria: e.g., pores must be small relative to minimum device dimensions, the pore distribution should be uniform, the porous surfaces must be uniformly covered by added integration layers (caps, hardmasks, etch barriers, liners, etc.), contaminant uptake must be minimized and localized, the materials must show high strength and toughness

under low density conditions, and others. Given the requirements, it is little wonder that the introduction of any new low-*k* materials and porous materials in particular into products has been progressively delayed.

### CVD vs. Spin-on

Dielectric materials can also be classified according to their method of application. In this regard, materials can either be deposited from the gas phase by CVD or plasma enhanced chemical vapor deposition (PECVD) or by spin-on techniques. Gas phase techniques were the mode of application of silicon dioxide and capital accumulation in semiconductor manufacturing heavily favors this technique for future low-*k* materials. On the other hand, spin-on techniques are well established and are currently used primarily for the application of liquid photoresists. Generally speaking, the equipment costs for CVD processes are higher, but the materials costs are lower than for spin-on applications. The CVD processes have already been adopted at the 90 nm node ( $k \sim 3.0$ )<sup>[6,7]</sup> and provide the strongest candidates for the 65 nm node ( $k \sim 2.7$ ). These materials

**Table 3** Common chemical vapor deposition (CVD) precursors to carbon-doped oxide films: 3-TMS monomer requires an oxidizing coreagent (e.g., N<sub>2</sub>O) to produce Si–O–Si bonds in film

Molecule	Si-CH <sub>3</sub> /Si	Si-O/Si	Si-H/Si	Structure

3MS	3:1	N/A	1:1	

will not be significantly porous. The first appearance of porous materials will be at the 45 nm node and even there only at the levels where low-*k* materials provide the maximum performance benefits. Table 3 shows some typical CVD dielectric precursors. Most viable candidates contain the elements of C, H, O, and Si.

When oxygen is not present in the precursors, it is usually introduced in the form of a plasma oxidant e.g., oxygen, N<sub>2</sub>O, H<sub>2</sub>O<sub>2</sub>, CO<sub>2</sub>, etc. The film products have complicated cross-linked structures comprised of rings and chains and are known collectively as carbon-doped oxides (CDO) or SiCOH materials. The dielectric constants and 3-D structures can be tuned to some degree by varying the plasma and deposition conditions. Depending on the tool supplier and monomer(s) employed, the dielectric products are designated by various vendor names, e.g., Aurora (ASM), Black Diamond (Applied Materials), and Coral (Novellus). Some common CVD precursors are shown in Table 3, each with its own champion. In spite of the availability of spin-on candidates for *k* = 2.6–3.0, including polyarylene ethers (VELOX, Schumacher/Air Products,<sup>[9]</sup> and Flare, Honeywell<sup>[10]</sup>) and polyarylenes (SiLK, Dow Chemical),<sup>[11]</sup> CVD-deposited CDO materials will dominate both the 90 and 65 nm device generation nodes.<sup>[8]</sup> While the electrical and thermal properties of CVD-deposited CDO materials can be excellent, the

mechanical properties are less so—a situation that will be exacerbated by the transition from dense to porous materials. Fortunately, critical mechanical properties such as modulus, fracture toughness, and fracture energy can often be improved by postdeposition e-beam or UV treatment.<sup>[12,13]</sup> Such postdeposition treatment becomes essential for porous materials regardless of the mode of application (vide infra).

## Mechanical Properties

Fracture energies, fracture toughness, and cohesive energies are important parameters related to the mechanical properties of the film.<sup>[14]</sup> For fragile materials such as organosilicates, they are related to the formation and propagation of devastating cracks. However, measurement of fracture energies, fracture toughness, and cohesive energies is not trivial, often requires specialized equipment, and is time consuming and tedious. For this reason, the film modulus is often used as a predictor of mechanical properties. Modulus together with film stress are important contributors to the mechanical properties of thin films. Fracture toughness, fracture energy, and modulus are interrelated as shown below in Fig. 6. Modulus is the easiest of these properties to measure in thin, constrained films.

The most widespread measurement technique is nanoindentation, which produces values for both the modulus and the hardness.<sup>[15,16]</sup> This technique can, however, result in inaccurate values for very thin films, is prone to substrate effects, and is less applicable for fragile and crushable materials. More recently, surface acoustical wave spectroscopy (SAWS) has been used to study film properties in constrained systems, particularly for very thin films.<sup>[17–19]</sup> The numbers from SAWS measurements are almost always lower than those generated by nanoindentation, sometimes significantly so. The actual difference in the modulus values measured by the two techniques also depends on the structure and composition of the films. Techniques for the complete characterization of thin film insulators (thermal, mechanical, and electrical), both dense and porous, have been recently reviewed by Maex et al.<sup>[20]</sup> and will not be discussed in detail here.

## POROUS MATERIALS

The transition from dense to porous materials is inevitable for dielectric constants less than 2.4. Porous spin-on materials have a longer history starting with silica aerogels (formed by solvent extraction with supercritical CO<sub>2</sub>)<sup>[21,22]</sup> and evolving to xerogels where the solvent occupying the pores is removed by successive solvent exchange and careful thermal processing.<sup>[23–25]</sup> Higher boiling solvents have also been trapped in films that are cross-linked with gas phase catalysts (e.g., NH<sub>3</sub>) and serve ultimately as pore generators.<sup>[26]</sup> For silica xerogels, porosities of 70–80% are common and dielectric constants of <2.0 have been demonstrated, although the mechanical properties are quite poor. One problem with silica matrices, aside from the high dielectric constant of the dense matrix, is that they tend to be hydrophilic, leading to the uptake of water and other polar contaminants

during processing. A potential solution to this problem is post-porosity silylation<sup>[27,28]</sup> (hexamethyldisilazane is often utilized) to passivate the reactive sites. For this job, many reagents have been auditioned in the gas phase, in solution, or dissolved in supercritical CO<sub>2</sub>. The lack of surface tension effects in supercritical fluids (SCFs) allows the reagents to be introduced into small features without difficulty.<sup>[29,30]</sup> Silylation, particularly with multifunctional reagents, can also lead to improved mechanical properties of porous films. An alternative approach to the formation of porous hydrophobic materials is to substitute more hydrophobic monomers such as methyl triethoxysilane for tetraethyl orthosilicate either completely or in mixture in the sol–gel process. The result is the formation of an intrinsically more hydrophobic matrix (vide infra).

## Porosity without Added Pore Generators

In general, there are many ways of introducing porosity into thin films. A number of them can be used to generate nanoporous organic and inorganic films. These techniques may be roughly divided into those that do not require sacrificial pore generators (porogens) and those that do. Without porogens, the amount of porosity that can be introduced is limited although *k* values down to 2.2 seem to be attainable in some cases. There are a number of techniques that can be used to generate porosity without adding a sacrificial porogen. A non-comprehensive list would include: 1) introduction of free volume into the films via the use of large and poorly packing substituents;<sup>[31]</sup> 2) the use of SCFs, which dissolve in and plasticize the films such that nucleation sites can be produced to introduce nanoscopic porosity;<sup>[32]</sup> 3) the generation of particles with a predetermined shape and reactive functionality on the particle surface, which can subsequently be sintered to produce a matrix containing interstitial volume;<sup>[33,34]</sup> 4) the incorporation of particles containing meso and/or microporosity already into a reactive matrix followed by sintering to incorporate the particle into the matrix;<sup>[35]</sup> and 5) assembly of porous yet shape-persistent particles into a contiguous array to introduce porosity. Some of these techniques have been applied for the generation of both organic and inorganic porous films. For example, recently route (1) has been auditioned for the generation of thermally stable organic polymer films and dielectric constants as low as 2.4 have been demonstrated. Amorphous nanoporous polymer films have been produced using polyimides and supercritical CO<sub>2</sub> at high temperatures, although the procedure has yet to be demonstrated for thin films of <10 μm using route (2). There are a number of porous organosilicate materials where the porosity is introduced by

**Fig. 6** Mechanical properties of constrained thin films; (insert) four-point bending technique for measurement of fracture energies (*G*).

the interstitial packing of preformed functionalized particles. These particles can be composed of primarily surface functionalized silica or more hydrophobic versions containing substituted organosilicate particles. Using this technique, dielectric constants as low as 2.2 have been reported without the need for sacrificial porogens. This technique is capable of producing films with reasonable mechanical properties that can be further improved by post-porosity treatment.

### Porosity through Addition of Sacrificial Pore Generators

A large amount of effort has been devoted to the generation of porosity by the removal of a sacrificial pore generator (porogen). Using such an approach, sub-2.0 dielectric constants may be realized. This approach is applicable both for CVD and spin-on materials. The porogens may be small molecules, aggregates, oligomers or organic polymers; they can be chemically attached to the matrix<sup>[36,37]</sup> or not, but they must be easily removed without destroying the matrix material. This removal may be thermal, initiated by ionizing radiation, photochemically induced, or employ some combination of techniques. Removal of the porogens must be delayed until the mechanical properties of the matrix are developed (thermosetting resins) and can resist the potentially pore-collapsing capillary forces associated with the formation of the voids.

Early entries into the nanoporous polymer dielectric arena included porous organic polymers such as polyimides,<sup>[38,39]</sup> polyarylene ethers [Velox-ELK, Schumacher,<sup>[40]</sup> and GXP-3 (Honeywell)], polyarylenes (SiLK, Dow Chemical),<sup>[41]</sup> and others. With the exception of the polyimides, all viable candidates utilize thermosetting resins. The most advanced material is SiLK Y from Dow Chemical, which uses a polyarylene matrix and a thermally labile polymeric porogen.<sup>[41]</sup> While organic polymers can be thermally stable and are often quite tough, they are intrinsically soft and have higher expansion coefficients than inorganic-like materials. For these reasons, the industry has moved to organosilicates and the organic polymers have been utilized mainly in building hybrid structures<sup>[42]</sup> containing both inorganic and organic polymeric dielectrics—a compromise structure designed to mitigate the deficiencies of both material classes.

Porous organosilicates derived from porogens have received considerable attention and have recently been realized in CVD processes by the incorporation of small molecule porogens, often terpene derivatives or other unsaturated hydrocarbons.<sup>[43–45]</sup> Although the number of porous CVD candidates and amount of accumulated data lag far behind the spin-on materials

currently, a number of strong CVD candidates have arisen for the 45 nm technology node, which likely will utilize a material with dielectric constant in the 2.4–2.5 range. The history and options for porous organosilicates from spin-on materials are much more numerous. Porogens for spin-on organosilicates include small molecules,<sup>[46]</sup> polymers with various molecular architectures, amphiphilic block copolymers (vide infra), cross-linked nanoparticles,<sup>[47]</sup> and amphiphilic core shell materials that behave like nanoparticles without the need for extensive cross-linking.<sup>[48,49]</sup>

There is extensive literature on the formation of mesoporous films (defined by IUPAC convention as pores ranging from 2–50 nm in size) using self-organized amphiphiles to template the hydrolytic condensation of reactive monomers such as tetraethylorthosilicate.<sup>[50–55]</sup> For these examples, the templating surfactants have included cationic materials, non-ionic amphiphiles, amphiphilic block copolymers, and others. Regular structures can be produced in this manner and the process is adaptable to both spin and dip coating. In these cases, the structure is produced by evaporation-induced self-assembly and the hydrolytic process is templated by the organized structures. Calcination ultimately produces pores and the pore size can be tuned to some extent by the amphiphile. Such a process has recently been demonstrated with hydrophobic alkoxy silane monomers, obviating the need for post-porosity treatment characteristic of porous silica.<sup>[56–59]</sup> An interesting variant of this templated condensation uses preorganized block copolymer films, which are subsequently phase-selectively mineralized with hydrolyzing organosilicate monomers and water in  $\text{SCCO}_2$ .<sup>[60,61]</sup> The catalyst is selectively incorporated into the hydrophilic phase and the structure of the organized block copolymer is maintained upon mineralization. Also, recently it has been demonstrated that low-*k* porous films could be generated from colloidal zeolite nanocrystals produced using templating surfactants under hydrothermal conditions.<sup>[62–64]</sup> Upon calcination of thin films of solution-spun nanocrystals, low-*k* materials with surprising mechanical properties are formed.

Amorphous, randomly oriented porous organosilicates can also be produced using porogen molecules. For any sacrificial porogen process, the decomposition of the porogen must occur after the matrix has developed enough strength to resist the capillary forces associated with pore generation. These thermally labile porogens are often oligomers or polymers. A variety of thermosetting organosilicates have been employed. Many organosilicates are hydrolysis-condensates produced from alkyl- and aryl-substituted silane monomers. The most common candidates have been silsesquioxanes (SSQs,  $\text{RSiO}_{1.5}$ )<sub>n</sub> produced by acidic hydrolysis of appropriately substituted monomers.<sup>[65]</sup>

**Fig. 7** Solid state  $^{29}\text{Si}$  NMR spectra for organosilicate insulators: (A) spin-on methyl silsesquioxane spectra, sample cured to  $425^\circ\text{C}$ ; (B) PE-CVD-deposited CDO derived from OMCATS.

These structurally complex materials are available in a variety of structures and molecular weights, depending on the hydrolysis conditions. In general, these materials may be thermally cured to produce organosilicate films with acceptable thermal and electrical properties. Depending on the substitution, the dielectric constants of the densified organosilicates can range from 2.8 to 3.3, values substantially lower than those for silicon dioxide. Invariably, however, these materials form fragile films, which are prone to cracking, particularly in films thicker than  $1\ \mu\text{m}$ . The CVD-deposited CDOs often have similar elemental compositions, but are much more structurally complex. This is obvious in

Fig. 7, which shows solid state  $^{29}\text{Si}$  nuclear magnetic resonance (NMR) spectra of a cured, solution-spun MeSSQ material together with that of a CVD-deposited CDO derived from octamethylcyclotetrasiloxane (OMCATS). Although the functionality is similar in both cases, the CVD material is structurally much more complex. Because of the wide range of deposition parameters available for CVD and PE-CVD processes (temperature, pressure, reagent flow rates, plasma power, etc.), films with widely varying electrical and mechanical properties can be produced from the same precursor. This is not usually the case for spin-on materials where composition is fixed and the processing parameters are limited. NMR<sup>[66]</sup> and infrared<sup>[67,68]</sup> are the spectroscopic techniques that are most often used for structural analysis of cross-linked organosilicate films.

In general, both solution-spun and CVD-deposited organosilicates are fragile and must be enhanced by postcure treatment, usually using e-beams or energetic UV photons. Mechanical properties become an integration issue because of damascene processing, chip dicing, wire bonding, and other processes that require mechanically robust materials. Other troubling integration issues for organosilicates include dielectric damage upon plasma etching and plasma stripping of the developed photoresist. These issues are exacerbated in the transition from dense to porous materials. In spite of these problems, organosilicates are currently the materials of choice for the 90 nm technology and beyond.

### Nucleation and Growth vs. Templating

The simplest route to the generation of porous, spin-on organosilicates is a blending approach that involves

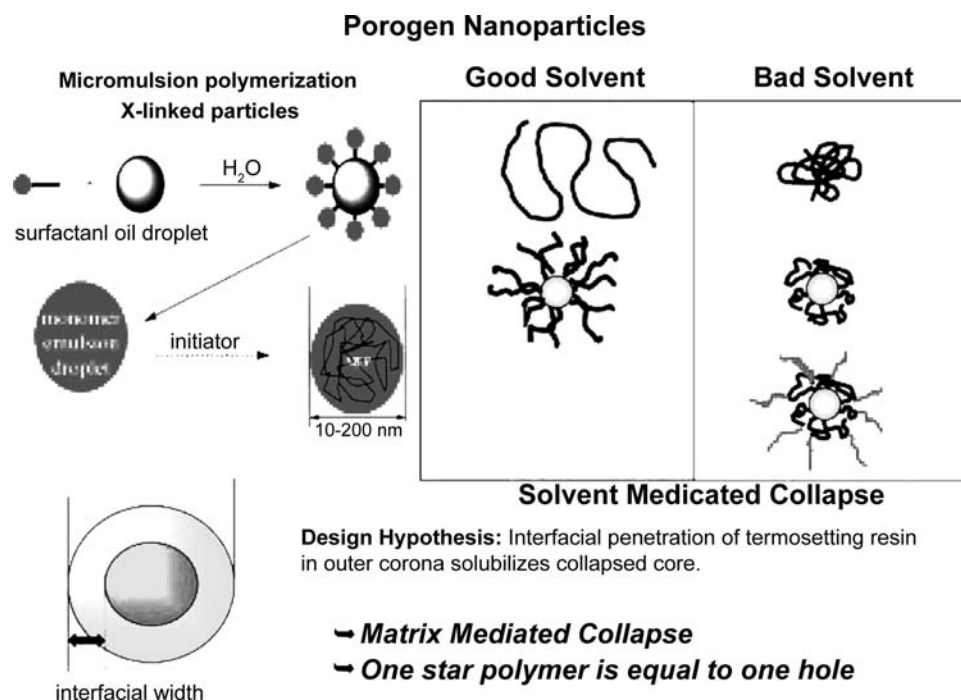

**Fig. 8** Blending scheme for the spin-on generation of organosilicate nanohybrids and nanoporous thin films; organosilicate resin and miscible/compatible porogen are mixed in a suitable spinning solvent.

mixing the thermosetting organosilicate that will become the matrix material with the organic porogen. Such a process is shown in Fig. 8. Although small molecules such as cyclodextrins<sup>[46]</sup> have been utilized, the most common porogen molecules are low-molecular-weight organic polymers. As most polymer mixtures are immiscible,<sup>[69]</sup> the porogen molecule must be tailored to be compatible with the organosilicate before vitrification. This usually requires strong interactions of the polymer functionality and/or the chain ends with the end groups of the SSQ prepolymers to prevent macroscopic phase separation.<sup>[70–72]</sup> As a result, low porogen molecular weights and high end-group functionality are beneficial. For this reason, stars, dendritic, and hyperbranched homo- and copolymers have been studied in some detail.<sup>[73–77]</sup> A requirement for the formation of nanoscopic hybrid domains and porosity is that the porogen must be either miscible or compatible with the organosilicate prior to curing. Phase separation must be limited until significant vitrification of the matrix has occurred, which limits domain growth (kinetically restricted). Such a process, where the components are initially miscible and phase separate after the matrix cures is called nucleation and growth (N&G), which leads to random pores, that can be quite small. A large number of blends that ultimately form porous organosilicates may be described as N&G processes. Characteristics of this type of process are random pore distributions

often with irregular shapes and dependence of the pore size and size distribution on parameters such as loading level, porogen and resin structure, porogen molecular weight, film processing conditions, etc. While N&G can be operationally simple with the right materials, control of the process is often not.

As mentioned, nucleation and growth formation of phase-separated nanodomains requires that the porogen be initially miscible in the resin precursor and phase separate after vitrification. Nanoporous organosilicates can also be made by a templating process using organic nanoparticles. For this, the nanoparticles must be compatible with the resin precursor, but not miscible. This usually requires a particle with a corona shell, which interacts strongly with the matrix precursors. Compatibilized, highly cross-linked nanoparticles have been prepared by microemulsion polymerization. These highly cross-linked examples have been used as porogens with SSQ precursors and nanoporous films with dielectric constants as low as  $k = 2.0$  have been demonstrated. Shipley has been sampling such materials for some time under the name of Zirkon.<sup>[47]</sup> The porosity in these samples seems to be randomly dispersed throughout the film and is sub-4 nm—a significant achievement using microemulsion polymerization techniques.

Recently it has been demonstrated that extensive cross-linking of organic nanoparticles is not always necessary for templating the condensation of

**Fig. 9** Templating particle-like behavior from core-shell amphiphiles with minimal cross-linking; hydrophobic core collapses in polar media but the particles are compatibilized by corona substitution to prevent aggregation; (top left) a schematic of a classic top-down approach to cross-linked nanoparticles by microemulsion polymerization.

**Fig. 10** TEM cross-sections of porous MeSSQ films: (A) porosity generated by N&G porogen [poly(propylene glycol)]; (B) porosity generated by templating using core-shell amphiphilic stars (polystyrene core-PEG methacrylate corona).

organosilicates. In this regard, core-shell polymeric unimolecular amphiphiles with little or no cross-linking have been exercised as porogens in organosilicate thermosetting resins.<sup>[48,49]</sup> These materials are basically core-shell block copolymer amphiphiles where the hydrophobic core collapses in the presence of the polymer SSQ prepolymer, but aggregation is prevented by the polar, compatibilizing corona. This concept is illustrated schematically in Fig. 9. The core for the templating nanoparticle was polystyrene (anionic polymerization) while the corona was a polyethylene glycol (PEG) methacrylate shell (formed by atom transfer polymerization from the end-functionalized multiarm (20–40 arms) stars. A significant result for the templated polymerization is that one particle produces one pore (loading levels <30 wt.%) and that the size and shape of the pore is determined by the porogen molecule itself. A further distinguishing feature is that over a porogen range from 5% to 35%, the pore sizes are essential constant and only the number density changes. This is a significant difference relative to N&G processes. Fig. 10 shows a comparison of TEM micrographs for both N&G and templating porogens. In general, templating processes are easier to control and depend on fewer material and processing variables than N&G procedures. The main difficulty seems to be in the synthetic routes to small particles required for integration, which are compatible with the matrix polymers. This is a particular problem when the core-shell block copolymers are prepared by tandem polymerization processes. A more successful approach is surface small molecule or oligomer attachment, which limits the size of the polar corona. Most bottom-up procedures are easily applicable for particles in the 10–40 nm range while particles <5 nm or more than 50 nm present more of a synthetic challenge.

## CONCLUSIONS

In summary, continual evolutionary progress in CMOS devices with scaling requires progress in imaging techniques and lithographic materials, new high-*k* materials for the FEOL transistors, advances in processing, metallurgy, hardmasks, etch stops, liners, and especially low-*k* insulators for the BEOL. For the latter, the search has been driven mainly by the desire to minimize RC delays and cross talk, although power issues are becoming more important. However, the replacement of silicon dioxide as the BEOL insulator has proven much more difficult than anticipated, explaining the dramatic slip in the schedules as defined by the various ITRS roadmaps. At least 10 years after the realization that low-*k* replacements for silicon dioxide could be a major performance enhancer for devices beyond the 180 nm device node, people are still arguing whether spin-on or CVD provides the most versatility for the future. In the short term, at least for the 90 and 65 nm nodes, it appears that CVD processes have gained the upper hand. Even here, there is room for some imaginative chemistry in the development of precursors to address current materials and integration limitations. For porous materials required for the 45 nm node and beyond, there are still questions that remain, e.g., CVD vs. spin-on how much porosity, porogen vs. non-porogen approaches, bound vs. unbound porogens, etc. The key here will be dielectric extendibility over multiple technology nodes. This becomes critical because the integration of new materials is very difficult. It seems likely that CMOS technology will extend now at least through the 25 nm node generation. Although the use of porous materials seems inevitable, an important question is how much porosity is necessary for the future and if

and when we should gradually change over to the use of air gaps where air constitutes the volume bulk of the dielectric. In this regard, a number of imaginative schemes directed toward air gap dielectrics, some of which utilize sacrificial materials have already appeared.<sup>[78–82]</sup>

## INTRODUCTION

Bioconjugation of nanoparticles (NPs)<sup>[1–14]</sup> is the attachment of specific biological molecules or components to nanoparticles. The resulting structures represent the convolution of biotechnology and nanotechnology, and yield hybrid materials, processes, and devices that can utilize both the unique optical and magnetic properties of NPs and highly selective binding of biological interactions. The combination of these features can potentially make a prominent impact in current biomedical technologies, and possibly in nanoelectronics, microphotonics and related fields. Antigen and antibody interaction is a naturally occurring immunology interaction of the biological defense system, and has been widely used as molecular recognition method for medical diagnostics and detection of biological threat agents.<sup>[15]</sup> The bioconjugation of NPs with antigens and antibodies are interesting and important as a method for their organization in more complex structures, and as a pathway to new sensing and imaging technologies. In the viewpoint of biologically programmed assembly of nanostructures,<sup>[12,16,17]</sup> the similarity of sizes of NP and proteins limits the overall number of affinity ligands around one semiconductor core to a few proteins leading to, for instance, 1-, 2-, 3-, and 4-valent quantum dots. The practical aspect of NP-antigen/antibody conjugation is related to the further development of immunoluminescence as a technique that affords highly sensitive and specific detection of various biological and non-biological analytes of military and civilian importance.

Colloid gold nanoparticles have been used in labeling antigens and antibodies as contrasting agents of various immunoassays,<sup>[18–20]</sup> however, their sensitivity is limited by the nature of colorimetric detection. Luminescence spectroscopy is more sensitive than absorption spectroscopy because of its substantially better signal-to-noise ratio. We observed the excited-state

dipole–dipole coupling between NPs of different sizes in the constructed immunocomplex, which results in the excitation energy transfer from NPs of smaller diameters to those with bigger diameters, i.e., Förster resonance energy transfer (FRET). The detection limits of analytical processes based on FRET can be as low as 10 ppt, with a linear dynamic range of 0.1–1000 ppb,<sup>[21,22]</sup> while the utilization of antibodies enables the selective detection of substrates, which may differ only by a few atoms. Highly luminescent semiconductor NP, or quantum dots, are a new class of luminescence materials providing a number of advantages over organic dyes. They can be made in a single-step synthesis, with precisely controlled size distribution and tunable emission spectrum. Compared to organic dyes such as Rhodamine, this new class of luminescent material are 20 times brighter and 100 times more stable against photobleaching, and one-third as wide in spectra linewidth.<sup>[3]</sup> Therefore luminescence nanoparticles will have tremendous potential in biomedical imaging and diagnostic applications.

Typically, NPs are synthesized by arrested precipitation in the presence of organic molecules strongly coordinating to metal ions, such as thiols or phosphines.<sup>[23,24]</sup> The simplified description of the product is a semiconductor core coated with a monolayer of organic molecules attached to surface metal sites. The core of the NPs is highly crystalline, which is a prerequisite for strong luminescence. Many different thiol derivatives may be used for the stabilization of II–VI nanoparticles. The terminal end of the thiol can be conveniently used for further functionalization of nanoparticles and for conjugation to biological molecules by either nonspecific electrostatic absorption or specific conjugation reactions. Most antigens and antibodies are proteins, have a number of amino acids that provide functional groups which can be chemically conjugated, such as  $-\text{NH}_2$  (lysine, and N-terminal),  $-\text{COOH}$  (aspartic acid, glutamic acid, and C-terminal), and  $-\text{SH}$  (cysteine).

The direct NP–protein conjugation method frequently used is the 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC)/*N*-hydroxysulfosuccinimide (sulfo-NHS) reaction (Scheme 1).<sup>[20,25–27]</sup> NHS-conjugated proteins have the highest bioactivity among other conjugates, as established by several comparative studies.<sup>[28–30]</sup> The carboxylic acid group of thiolglycolic acid-stabilized NPs will form amide bond with the primary amine groups of the protein, or, the amine groups of a cysteine-stabilized NPs can link to the carboxylic acid group of protein.

To explore and demonstrate the potential of NP Bioconjugates, we used EDC/sulfo-NHS reaction to conjugate different-sized CdTe NPs to two antigen/antibody systems: 1) bovine serum albumin (BSA) and anti-BSA IgG (immunoglobulin G)<sup>[8]</sup> and 2) *Brucella suis* and its antibody Bru-38 (Anti-GBa-O side chain). Antigens were conjugated to red-emitting CdTe NPs, while green-emitting NPs were attached to the corresponding antibodies. FRET was observed upon the formation of immunocomplex between the complementary antigens/antibodies. the competitive inhibition of FRET by unlabeled antigens was investigated.

## METHODOLOGY

The optimized EDC/sulfo-NHS conjugation protocol is as follows: a reaction mixture containing 0.05 mM CdTe NP, 1.5–2.5 mg/mL antigen or antibody, 0.05 M NHS, and 0.05 M EDC in pH 7.0 PBS buffer was prepared and kept in room temperature for 2–4 hr, then stored overnight at 4°C. This allows the unreacted EDC to hydrolyze and lose its activity. After

that, a small amount of precipitate is formed, likely consisting of unconjugated NPs, which are known to agglomerate and become non-emissive at fairly low pH. The precipitate (if any) is removed by centrifugation. The stock, ready-to-use solution of the product was stored at 4°C. Optionally, the conjugates can be dialyzed with Spectra/Por<sup>®</sup> 4 membrane with molecular weight cut-off 12,000–14,000 (Spectrum Laboratories, Inc.) in pH 7.4 phosphate-buffered saline (PBS) to remove the small molecules.

The NP bioconjugates were characterized by gel electrophoresis, gel permeation high-performance liquid chromatography (HPLC), circular dichroism (CD), fluorescence spectroscopy, and enzyme-linked immunosorbent assay (ELISA) test. Optical absorption spectra were obtained on a Hewlett-Packard 8453 diode array spectrophotometer using 1-cm quartz cuvettes. Fluorolog 3 and Fluoromax 2 from JY SPEX were used to register the luminescence spectra. The right-angle registration mode with no intermediate filters was utilized in all measurements. All FRET experiments were carried out after centrifugation of the solutions to remove all particles aggregated as a result of oxidation and coagulation. The quantum yield of NP luminescence was determined by using Rhodamine B in ethylene glycol ( $\lambda_{\text{max}} = 580 \text{ nm}$ , quantum yield 1) as a standard as described elsewhere.<sup>[7,8]</sup> The luminescence intensity does not decrease even after the samples were stored for over a month at 4°C. Gel permeation HPLC experiment was carried out on an HP-1090-II instrument equipped with Jordi GPC column 500A with physical dimensions of  $300 \times 7.8 \text{ mm}$ . Deionized 18 M $\Omega$  water was used as an eluent. The optical adsorption signal was monitored at 254 nm by a diode array detector.

**Scheme 1** Schematics of the sulfo-NHS/EDC conjugation reaction.

**Fig. 1** Native and SDS-PAGE electrophoresis of CdTe bioconjugates on 4–20% gradient Tris–HCl precast gels (Bio-Rad). Left panel—native, stained by Coomassie Blue. Center panel—SDS-PAGE, stained by Coomassie Blue. Right panel—SDS-PAGE, luminescence image (excitation 360 nm). Wells: 1) BSA; 2) green-emitting NP-BSA; 3) anti-BSA IgG; 4) red-emitting NP-IgG; N) Free CdTe NPs; L) standard protein ladder, molecular weight are marked on the side in kiloDaltons (kDa). Note that in native electrophoresis, the position of the band is not linearly proportional to the molecular weight, because of the different charge status of each sample. *Source:* From Ref.<sup>[8]</sup>. © 2002, American Chemical Society.

## RESULTS AND DISCUSSION

### Investigate the Formation of NP-BSA and NP-Anti-BSA Bioconjugates by Electrophoresis

The native electrophoresis results (Fig. 1, left panel) show that both NP-conjugated BSA (well 2) and anti-BSA IgG (well 4) bands become more mobile in the electric field than the unlabeled biospecific ligands (wells 1 and 3). The BSA monomer band shifts from the relative marker of 65 to 47 kDa, which demonstrates that the high negative charge of the NP and their compactness overcomes the increase of their mass as a result of labeling. Note that the commercial BSA shows two other bands at 100 and 150 kDa, corresponding to BSA–BSA dimer and globulins, respectively. This observation agrees with the specifications of Sigma; these compounds have minor influence on the biospecific reactions discussed below. Both of these bands shift synchronously with BSA monomer to smaller masses after the NP conjugation. By mixing NP with BSA and IgG without adding coupling reagents (EDC and sulfo-NHS), no evidence of nonspecific binding was observed in native gel electrophoresis.

The mobility of the proteins in sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) (Fig. 1, center panel) is determined by the mass/charge ratio of denatured protein chains carrying SDS, which imparts negative charge to them. Interestingly, the band positions of NP-labeled and unlabeled proteins virtually coincide at the 65-kDa marker (Fig. 1, center panel). Similar to the native gel results, the increase of mass resulting from the addition of NPs to the protein is compensated by the

increase of the overall charge density of the conjugate. Unlike NP-BSA, the SDS-PAGE band of NP-IgG conjugate remains at 150 kDa, while the free IgG is mostly broken apart into small molecular weight fragments as a result of SDS and heating treatment (Fig. 1, center panel, wells 3–4). Considering the SDS-PAGE data, we emphasize three factors. 1) Estimates of molecular masses based on gel electrophoresis results can give erroneous outcomes for bioconjugates from highly charged NPs. Different experimental techniques must be used for this purpose. 2) A brief heat treatment (150 sec) at 96°C was used for the preparation of SDS-PAGE samples. Because high-temperature denaturation destroys the tertiary structure of the protein, little non-specific binding of NP and BSA is to be expected after that. Therefore the observation of NP luminescence in the SDS-PAGE bands demonstrates covalent linkage between protein and the semiconductor units. 3) Bioconjugation to NP may increase the stability of antibodies. The relative intensity of the SDS-PAGE bands indicates that the conjugated antibodies are more resilient to this temperature than the unlabeled ones. The unlabeled antibodies (well 3) are mostly broken apart by SDS and heating into small fragments, showing up as band at 40–50 kDa; whereas for NP-IgG conjugates, this band has significantly lower intensity—the antibody remains mostly intact. The latter effect was reproduced in several control experiments.

The direct evidence of the successful conjugation of CdTe to BSA and IgG can be found from the luminescence analysis of the gel plates. The NP conjugate bands show strong luminescence, while the free proteins do not show any detectable signal in the luminescence image (Fig. 1, right panel). As before,<sup>[7]</sup> the gel pieces cut out of the gel plates in the area of the

conjugate bands reveal the luminescence spectra with identical peaks to the original NPs.

### Confirm the Formation of NP-BSA and NP-Anti-BSA Bioconjugates by HPLC

The formation of NP bioconjugates was also confirmed by HPLC size exclusion chromatography (Fig. 2), which is complementary to electrophoresis. The original BSA revealed three HPLC peaks congruent to the three bands seen in gel electrophoresis (Fig. 1). Because the species with higher molecular weight are eluted at shorter retention times, the observed HPLC peaks at retention times 7.8, 6.8, and 5.4 min should be attributed to BSA monomer, BSA dimer, and globulins, respectively. After conjugation to CdTe, the same three peaks can be seen at 6.5, 5.3, and 4.2 min, all being shifted to higher molecular weight, as expected for the attachment of NPs to proteins. Considering that the approximate molecular weight of 5.0-nm red-emitting CdTe attached to BSA is 240 kDa (specific density of CdTe is 6.2 g/cm<sup>3</sup>), the HPLC peak shift for monomeric BSA shows that not more than one NP is attached to this protein. Similar behavior can be observed for the bioconjugates of IgG. An HPLC peak attributed to free IgG was observed at 6.7 min, while shifting to 6.1 min after conjugation to green-emitting NP of ca. 2.5 nm in diameter. Their molecular mass is estimated to be 30 kDa; therefore, the HPLC molecular weight shift corresponds to the attachment of about one quantum dot per IgG as well. We want to emphasize that the estimates of NP-protein composition of the conjugates should be taken with caution and should be treated as preliminary data. The retention of NPs and polymers/proteins in gel permeation media may

follow different scaling schemes, and therefore introduce an unforeseen error in them. No free BSA or large oligomeric NP-BSA agglomerates with gradually increasing molecular masses can be detected in elution curves (Fig. 2). Besides such oligomers, the luminescent bands seen at the starting line in gel electrophoresis can possibly originate from aggregates produced by accumulation on dust particles, rather than multiple chemical cross-linking because of BSA's tendency to adsorb on many surfaces.<sup>[31]</sup>

### Study Structure of NP-BSA and NP-Anti-BSA Bioconjugates by CD Spectroscopy

The integration of antigen and antibody structure after NP conjugation was confirmed by CD spectroscopy, which shows little change between both BSA and NP-BSA conjugate, as well as the anti-BSA and NP-anti-BSA pair. These data show that the tertiary structure of both proteins remains mostly intact after conjugation.<sup>[8]</sup>

### Examine Biological Activity of NP-BSA and NP-Anti-BSA Bioconjugates by ELISA

The antigen-antibody binding affinity was retained for both conjugates as evaluated by standard ELISA experiments.<sup>[8]</sup> NP-IgG retained 25–50% of binding affinity to free BSA, as compared to free IgG, while NP-BSA retained almost 100% of binding capability to unmodified antibody. The decrease in NP-IgG binding affinity is believed to be a result of partial blocking of binding sites 1) by NP positioned close to the N terminal of the IgG and 2) by other bioconjugates in forming dynamic aggregates. The luminescence properties of NPs remained unchanged in the conjugates as measured by fluorescence spectroscopy.

### FRET Study of NP-BSA and NP-Anti-BSA Bioconjugates

When NP-IgG (anti-BSA) with green luminescence are combined with NP-labeled BSA with red luminescence, the NP-IgG/BSA-NP immunocomplex should form. As expected, a significant enhancement of the NP-BSA's red emission at 611 nm and the corresponding quenching of the green emission of NP-IgG at 555 nm are observed after the self-assembly of the labeled biospecific ligands in the immunocomplex (Fig. 3). The mutual affinity of the antigen and antibody brought the NPs close enough together to allow the resonance dipole-dipole coupling required for

**Fig. 2** HPLC gel permeation elution curves for: 1) BSA and 2) NP-BSA. Source: From Ref.<sup>[8]</sup>. © 2002, American Chemical Society.

**Fig. 3** FRET-based detection of BSA in solution. 1) NP-BSA; 2) NP-BSA + NP-IgG; 3) BSA + NP-BSA + NP-IgG. Concentrations: NP-BSA  $5 \times 10^{-7}$  M, NP-IgG  $5 \times 10^{-7}$  M, BSA  $2 \times 10^{-6}$  M. Source: From Ref.<sup>[8]</sup>. © 2002, American Chemical Society.

FRET to occur. Thus the energy of the excitonic state in the green-emitting NP was transferred to the similar state of the red-emitting NP with lower exciton energy. FRET efficiency is particularly high for green/red NP pairs because of the strong overlap of their emission and absorption spectra. Importantly, when unlabeled BSA was added to the immunocomplex, it competitively bound to NP-IgG, and replaced NP-BSA in the immunocomplex, thereby inhibiting the FRET process. Consequently, the green emission peak of NP-IgG at 555 nm can be observed again, while the red emission peak at 610 nm shows decreased intensity.

**Fig. 4** Result of FRET-based detection limit—concentrations:  $1.5 \times 10^{-8}$  M BSA, NP-BSA  $3.8 \times 10^{-9}$  M NP-BSA and  $1.6 \times 10^{-9}$  M NP-IgG.

Following this approach, we were able to clearly detect as low as  $1.5 \times 10^{-8}$  M BSA (Fig. 4). Unlike ELISA, the described detection process does not require the multiple binding and washing steps. High-concentration egg albumin, which does not bind to anti-BSA IgG, shows no influence on FRET between NP-IgG and NP-BSA. It demonstrates the high biospecificity of the prepared conjugates and virtually absent interference from the non-complimentary proteins.

### Study of NP-Conjugated *B. suis* and Its Antibody

After successfully demonstrating FRET-based detection in the BSA/anti-BSA model system, we examined it with a more practical antigen–antibody system. We obtained whole-cell killed *B. suis* and the corresponding antibody Bru 38 (anti-GBa-O side chain) and prepared the green NP-conjugated *B. suis* and red NP-conjugated Bru 38 according to the NP-anti-BSA protocol. We used CdTe/CdS NPs with green emission (561 nm) and red emission (601 nm) for the conjugation experiment. The concentration of Bru38 used in the synthesis was 3 mg/mL and the final concentration in the conjugation was 1.2 mg/mL. The concentration of *B. suis* (estimated from optical density, OD 600 nm absorption value) used in the synthesis was  $2.7 \times 10^{-12}$  M ( $1.6 \times 10^9$  cells/mL) and the final concentration in the conjugation was  $7 \times 10^{-13}$  M ( $4 \times 10^8$  cells/mL). The conjugated *B. suis* was purified by centrifuge and washed with 0.1 M PBS buffer three times. Native and SDS-PAGE gel electrophoresis

**Fig. 5** FRET-based detection of *Brucella suis* in solution. 1) NP-anti-*B. suis*; 2) NP-*B. suis*; 3) NP-*B. suis* + NP-anti-*B. suis*; 4) *B. suis* + NP-*B. suis* + NP = anti-*B. suis*. Concentration: NP-anti-*B. suis* (Bru38)  $2 \times 10^{-7}$  M, NP-*B. suis*  $3.3 \times 10^{-15}$  M ( $2 \times 10^6$  cells/mL), *B. suis*  $1.3 \times 10^{-14}$  M ( $8 \times 10^6$  cells/mL).

**Fig. 6** FRET transfer kinetics between NP-*B. suis* and NP-anti-*B. suis* showing the influence of the presence of *B. suis*. The FRET is qualified by the intensity of the red-emission peak (601 nm). Concentrations: NP-anti-*B. suis* (Bru38)  $8 \times 10^{-8}$  M; NP-*B. suis*  $1.6 \times 10^{-15}$  M ( $10^6$  cells/mL); *B. suis*  $6.5 \times 10^{-15}$  M ( $4 \times 10^6$  cells/mL).

results of the conjugated Bru 38 are very similar to the NP-anti-BSA conjugate. Although the surface of the bacteria is complex, it should contain numerous primary amine sites for the NP binding, and many of these binding sites should be close enough to the antibody-binding site to allow FRET to occur. Considering the much larger size of bacteria, multiple attachments of NPs on a single bacterium is expected; however, we did not verify it at this stage.

Similar to BSA results, we observed (Fig. 5) FRET as expected when we mixed NP-anti-*B. suis* with the NP-*B. suis* solution. It results as a fluorescence enhancement of the red-emission NP-anti-*B. suis* at 601 nm. The present unlabeled *B. suis* bound to NP-Bru 38 and competitively inhibited the FRET process, and dramatically reduced the fluorescence enhancement at 601 nm.

Binding kinetics, as well as specificity of the FRET, has been studied, and the results are shown in Fig. 6. The presence of unlabeled *B. suis* inhibited the FRET process. The full reaction takes about an hour to finish, because of the antigen/antibody binding nature. However, FRET and competitive inhibition effect can be clearly observed a few minutes after mixing the components together.

## CONCLUSION

Luminescence NPs represent a new class of biological labeling reagents with advantages over traditional dyes. To demonstrate the potential of this class of

materials, two complementary antigens and antibodies systems were labeled with thiol-stabilized green- and red-emitting CdTe NPs. They retain substantial bioactivity and can form the corresponding immunocomplex, which pairs NPs with different emission properties in a supramolecular assembly. Quenching of the green-emitting NPs and the enhancement of the luminescence of their red-emitting counterparts signify the presence of FRET in the immunocomplex. The introduction of unlabeled antigen into the complex solution induced the competitive inhibition of FRET. The exceptional specificity of immunocomplex reactions affords unique possibilities for assembling organized assemblies of NPs and other nanocolloids. After synthetic optimization such as enhancement of the luminescence quantum yield of the bioconjugates, FRET effects can be exploited in biosensing as well as in hybrid photoelectronic devices.

## ACKNOWLEDGMENTS

We thank NSF SBIR (grant #DMI-0109778), AFOSR STTR (grant #F49620-00-C-0058) and the Memorial Institute for Prevention of Terrorism (MIPT) for financial support of this research. We thank Natasha Mamedova, OSU Department of Chemistry, for performing some experiments, and Dr. John Wycoff, OSU College of Veterinary Medicine, for providing the *B. suis* bacteria sample.

## INTRODUCTION

Ferrofluids are synthesized colloidal mixtures of non-magnetic carrier liquids, typically water or oil, containing single-domain, permanently magnetized particles, typically magnetite, with diameters on the order of 5–15 nm and volume concentration up to about 10%.<sup>[1–6]</sup> A 10% by volume magnetite ferrofluid would have a saturation magnetization of about 0.0560 T = 560 G (1 T = 10,000 G). Brownian motion keeps the nanoscopic particles from settling under gravity and a surfactant layer, such as oleic acid, surrounds each particle to provide short-range steric hindrance and electrostatic repulsion between particles to prevent particle agglomeration. A polymeric layer surrounding each nanoparticle may also serve this purpose. These nanoparticle coatings allow ferrofluids to maintain fluidity even in intense, high-gradient magnetic fields. The study and application of ferrofluids, invented in the mid-1960s,<sup>[7]</sup> involves interdisciplinary science and technology integrating chemistry, fluid mechanics, and magnetism. Because of the small particle size, ferrofluids involved nanoscience and nanotechnology from their inception.

Conventional ferrofluid applications use d.c. magnetic fields from permanent magnets for use as liquid O-rings in rotary and exclusion seals,<sup>[8–10]</sup> bearings, as dampers in stepper motors and shock absorbers, in magnetorheological fluid composites,<sup>[11,12]</sup> for heat transfer in loudspeakers,<sup>[1–5]</sup> in inclinometers and accelerometers, for grinding and polishing, and in magnetocaloric pumps and heat pipes.<sup>[1,13]</sup> Ferrofluid is used in over 50 million loudspeakers each year. Almost every computer disk drive uses a magnetic fluid rotary seal for contaminant exclusion<sup>[14]</sup> and the semiconductor industry uses silicon crystal-growing furnaces that employ ferrofluid rotary shaft seals. A representative seal can withstand a pressure difference of up to

1.5 MPa (~15 atm) at a speed of 7000 rpm.<sup>[15]</sup> Ferrofluids are also used for the separation of magnetic from non-magnetic materials and for the separation of materials by their density using a non-uniform magnetic field to create a magnetic pressure distribution in the ferrofluid that causes the fluid to act as if it has a variable density that changes with height.<sup>[1,16]</sup> Magnetic materials are attracted to the regions of strongest magnetic field, whereas non-magnetic materials are displaced to the regions of low magnetic field with matching effective density. Magnetomotive separations use this selective buoyancy for sink–float separation of materials such as ore minerals,<sup>[16]</sup> one novel application being the separation of diamonds from beach sand.<sup>[17,18]</sup>

Ferrofluids are a multifunctional medium<sup>[2]</sup> that allow applications in each of its constituent disciplines of chemistry, fluid mechanics, and magnetism. With modern advances in understanding nanoscale systems, current research focuses on synthesis,<sup>[19–23]</sup> characterization,<sup>[20,22–27]</sup> and functionalization<sup>[21,22,28–34]</sup> of nanoparticles with magnetic and surface properties tailored for application as microelectromechanical/nanoelectromechanical sensors, actuators, in microfluidic/nanofluidic devices, as nanobiosensors, as targeted drug delivery vectors, in magnetocytolysis of cancerous tumors, in hyperthermia, in separations and cell sorting, for magnetic resonance imaging (MRI), and in immunoassays.

## FERROFLUID SYNTHESIS

### Ferrofluid Composition

The current “nanotechnology” focus on nanoscale devices is new, but the synthesis and formulation of magnetic nanoparticles in ferrofluids has been fairly well established in science and engineering over the last

**Fig. 1** Ferrofluid as a colloidal dispersion of permanently magnetized nanoparticles of radius  $R_p$ , on the order of 5 nm, possessing a permanent dipole moment with domain magnetization  $M_d$ . A stabilizing dispersant layer of thickness  $\delta$ , on the order of 1–2 nm, is adsorbed on the magnetic particle's surface.

four decades.<sup>[1–6,17,32–38]</sup> As illustrated in Fig. 1, ferrofluids generally consist of suspensions of permanently magnetized nanoparticles up to about 10% by volume, with diameters on the order of 5–15 nm and with adsorbed surfactant/polymer dispersant layers of approximately 2 nm thickness,<sup>[39]</sup> undergoing rotational and translational Brownian motion in a suspending fluid. A transmission electron microscopy (TEM) electron micrograph at 500,000 $\times$  magnification of approximately 6-nm-diameter iron oxide particles to be utilized in commercial grade ferrofluid is shown in Fig. 2.

### Ferrofluid Colloidal Stability

Colloidal stability involves competition between thermal energy  $= kT$  and magnetic energy  $= \mu_0 M_d H V$ , where  $k = 1.38 \times 10^{-23}$  J/K is Boltzmann's constant,  $T$  is the absolute temperature [in K],  $\mu_0 = 4\pi \times 10^{-7}$  H/m is the magnetic permeability of free space,  $M_d$  is the particle magnetization [in A/m],  $H$  is the magnetic field [in A/m], and  $V = \pi D^3/6$  m<sup>3</sup> is the magnetic volume of a spherical ferrofluid nanoparticle of diameter  $D = 2R_p$  [in m<sup>3</sup>].<sup>[1]</sup>

Stability against settling in a magnetic field requires that the thermal energy be large compared to the magnetic energy:

$$\frac{kT}{\mu_0 M_d H (\pi D^3/6)} > 1 \Rightarrow D < (6kT/(\pi\mu_0 M_d H))^{1/3} \quad (1)$$

For the typical magnetite ferrofluid nanoparticle with  $M_d = 4.46 \times 10^5$  A/m (or, equivalently,

**Fig. 2** A TEM electron micrograph at 500,000 $\times$  magnification of a mixture of  $\text{Fe}_3\text{O}_4$  and  $\text{Fe}_3\text{O}_2$  iron oxide particles. The average diameter is  $5.9 \pm 0.4$  nm, with a standard deviation of 2.3 nm. Particles are coated with a surfactant and are utilized in the preparation of a commercial-grade ferrofluid. Source: Ferrotec Corporation.

$\mu_0 M_d = 0.56$  T) in a magnetic field of  $H = 10^4$  A/m ( $\mu_0 H \approx 0.013$  T) at room temperature ( $T = 298$  K), Eq. (1) yields  $D < 11.2$  nm.

Commercially available ferrofluids with a volume concentration  $\phi$  of magnetic particles with magnetization  $M_d$  have a saturation magnetization  $M_s = \phi M_d$  up to about 0.1 T, but calculations show that an upper limit of saturation magnetization can be 0.21 T for 16-nm-diameter magnetite particles, 0.48 T for 8.7-nm cobalt particles, and 0.55 T for 7.8-nm iron particles.<sup>[40]</sup>

### Ferrofluid Preparation

The two primary methods of preparing particles in the nanosize range are grinding<sup>[7]</sup> and precipitation.<sup>[41]</sup> The first commercial ferrofluid was prepared in the mid-1960s by wet grinding of magnetite in kerosene starting from micron-sized particles in a ball mill. It takes about 500–1000 hr to reach  $\sim 10$  nm diameter. Chemical precipitation methods are much faster, and thus are most often employed to produce small magnetic nanoparticles.<sup>[1–6]</sup> The overall chemical reaction for

precipitation of ferrofluid nanoparticles is:<sup>[41]</sup>

where  $\text{Fe}_3\text{O}_4$  is magnetite with a divalent/trivalent iron ion ratio of  $\text{Fe}^{\text{III}}/\text{Fe}^{\text{II}} = 2$ . Following precipitation, the small particles are resuspended in a mixture of a surfactant and an organic solvent.

An easy and economical method for preparing an aqueous ferrofluid in less than 2 hr reacts iron(II) and iron(III) ions in an aqueous ammonia solution to form magnetite ( $\text{Fe}_3\text{O}_4$ ):

The magnetite is then mixed with an aqueous tetramethylammonium hydroxide  $[(\text{CH}_3)_4\text{NOH}]$  solution to form a stabilizing surfactant coating.<sup>[17]</sup>

A ferrofluid using a liquid metal carrier is desirable for high thermal and electrical conductivity applications. A liquid mercury ferrofluid with 2% by weight iron was made with a saturation magnetization of about 700 G. However, stabilizing surfactants have not yet been found for liquid metals, and so, to date, no stable conducting ferrofluid has been made.<sup>[1,42,43]</sup>

Whereas conventional ferrofluids are opaque, Xerox has developed a new series of water-based ferrofluids based on hydrogel technology with high optical transparency for colored magnetic toner and ink applications.<sup>[44]</sup> Using maghemite ( $\gamma\text{-Fe}_2\text{O}_3$  particles) in the size range of 2–10 nm, Xerox produced transparent colloids ranging in color from light amber to dark red with saturation magnetization greater than 400 G.

## FERROFLUID MAGNETIZATION

### Magnetization Relaxation Time Constants

When a d.c. magnetic field  $\vec{H}$  is applied to a ferrofluid, just like a compass needle, each magnetic nanoparticle with magnetic moment  $\vec{m}$  experiences a torque  $\mu_0\vec{m} \times \vec{H}$ , which tends to align  $\vec{m}$  and  $\vec{H}$ . There are two important time constants that determine how long it takes  $\vec{m}$  to align with  $\vec{H}$ :<sup>[1,45]</sup>

$$\tau_B = 3\eta V_h/kT; \quad \tau_N = \tau_0 e^{(KV_p/kT)} \quad (4)$$

The Brownian rotational relaxation time  $\tau_B$  describes the hydrodynamic process when the magnetic moment is fixed to the nanoparticle and surfactant layer of total hydrodynamic volume  $V_h$ , and the whole rotates in a fluid of viscosity  $\eta$  to align  $\vec{m}$  and  $\vec{H}$ . For the spherical

nanoparticle in Fig. 1,  $V_h = 4\pi/3(R_p + \delta)^3$ . The Néel time constant  $\tau_N$  is the characteristic time for the magnetic moment to align along the particle's easy axis with  $\vec{H}$ , without particle rotation. The parameter  $K$  is the particle magnetic anisotropy and  $V_p = 4\pi/3R_p^3$  is the volume of magnetic material alone. The literature gives different values for the anisotropy constant of magnetite, over the range of 23,000–100,000 J/m<sup>3</sup>, whereas  $\tau_0$  approximately equals  $10^{-9}$  sec. Recent work<sup>[46]</sup> has used Mössbauer spectroscopy to show that the value of  $K$  is size-dependent, increasing as particle size decreases and gives a value of  $K = 78,000 \text{ J/m}^3$  for 12.6-nm-diameter magnetite nanoparticles. The total magnetic time constant  $\tau$  including both Brownian and Néel relaxation is given by:<sup>[1,45]</sup>

$$\frac{1}{\tau} = \frac{1}{\tau_B} + \frac{1}{\tau_N} \Rightarrow \tau = \frac{\tau_B \tau_N}{\tau_B + \tau_N} \quad (5)$$

The time constant  $\tau$  is dominated by the smaller of  $\tau_B$  or  $\tau_N$ . For  $K = 23,000 \text{ J/m}^3$  with 12.6-nm-diameter magnetite nanoparticles at  $T = 300 \text{ K}$ ,  $\tau_N$  approximately equals 336 nsec, whereas for the same size particles and temperature with  $K = 78,000 \text{ J/m}^3$ ,  $\tau_N$  approximately equals 368 msec. For a ferrofluid with a representative fluid viscosity of  $\eta = 0.001 \text{ Pa sec}$  and with a surfactant thickness  $\delta = 2 \text{ nm}$ ,  $\tau_B = 1.7 \mu\text{sec}$ . Thus we see that with  $K = 23,000 \text{ J/m}^3$ , the effective time constant is dominated by  $\tau_N$ , whereas for  $K = 78,000 \text{ J/m}^3$ , the effective time constant is dominated by  $\tau_B$ . Experiments with ferrofluid particles of the order of 10 nm diameter have found effective magnetic relaxation times by fitting theory to experimental measurements. The computed Brownian relaxation time<sup>[47]</sup> thus indicated that  $K$  has value on the order of  $78,000 \text{ J/m}^3$ , as recently reported<sup>[46]</sup> rather than previously used values on the order of  $23,000 \text{ J/m}^3$ . Brownian and Néel relaxation are lossy processes leading to energy dissipation and causing complex susceptibility to have an imaginary part measurable using spectroscopic magnetometry.<sup>[48]</sup> These losses lead to heat generation using time-varying magnetic fields, which can be used for localized treatment of cancerous tumors.

In rotating magnetic fields, the time constant  $\tau$  of Eq. (5) results in the magnetization direction lagging  $\vec{H}$ ; therefore a time average torque acts on each nanoparticle, causing the particles and surrounding fluid to spin.<sup>[1,49–62]</sup> This leads to new physics as the fluid behaves as if it is filled with nanosized gyroscopes that stir and mix the fluid. In a flow field, if the nanoparticles spin to cause secondary flow in the direction opposite to the local vorticity of the flow, the driving pressure must increase to maintain the initial flow, in the same way as if the fluid viscosity increased. Similarly, if the nanoparticles spin to cause secondary

flow in the same direction as the local vorticity of the flow, the driving pressure can decrease for the same initial flow, in the same way as if the fluid viscosity decreased. Thus the nanoscale flow field resulting from the spinning nanoparticles can result in an increase or decrease of effective magnetoviscosity. A decrease in viscosity that is controllable by magnetic field amplitude and frequency has been termed “negative viscosity.”<sup>[63–67]</sup> The torques described above can drive ferrofluid flow for microfluidic and nanofluidic pump applications, or generate heat by viscous dissipation of spinning nanoparticles.

### Langevin Magnetization Characteristic

Ferrofluid equilibrium magnetization is accurately described by the Langevin equation for paramagnetism:<sup>[1–6,45]</sup>

$$M = M_s \left[ \coth \alpha - \frac{1}{\alpha} \right]; \quad \alpha = \mu_0 m H / kT \quad (6)$$

where  $M$  and  $H$  are collinear,  $M_s = Nm = M_d \phi$  is the saturation magnetization when all magnetic dipoles with moment  $m = M_d V_p$  and magnetic nanoparticle volume  $V_p$  with magnetization  $M_d$  are aligned with  $H$ ,  $N$  is the number of magnetic dipoles per unit volume, and  $\phi$  is the volume fraction of magnetic nanoparticles in the ferrofluid. For the typically used magnetite nanoparticle ( $M_d = 4.46 \times 10^5$  A/m or  $\mu_0 M_d = 0.56$  T), a representative volume fraction of  $\phi = 4\%$  with nanoparticle radius  $R_p = 5$  nm ( $V_p = 5.24 \times 10^{-25}$  m<sup>3</sup>) gives a ferrofluid saturation magnetization of  $\mu_0 M_s = \mu_0 M_d \phi = 0.0244$  T and  $N = \phi / V_p \approx 7.6 \times 10^{22}$  magnetic nanoparticles/m<sup>3</sup>.

Fig. 3 shows Eq. (6) plotted together with magnetization measurements of four different ferrofluids at various temperatures.<sup>[68]</sup> At low magnetic fields, the magnetization is approximately linear with  $\bar{H}$ ,  $\bar{m} = \chi_m \bar{H}$ , where:

$$\chi_m = \mu_0 m^2 N / (3kT) \quad (7)$$

is the magnetic susceptibility, related to magnetic permeability as  $\mu = \mu_0(1 + \chi_m)$ . For our representative numbers at room temperature and 10-nm-diameter magnetite particles, we obtain  $\chi_m \approx 4.24$  and  $\mu / \mu_0 \approx 5.24$ . The universality of the Langevin curve of Eq. (6) for different ferrofluids, different nanoparticle sizes, and different temperatures is demonstrated in Fig. 3.

**Fig. 3** Measured magnetization (dots) for four ferrofluids containing magnetite particles ( $M_d = 4.46 \times 10^5$  A/m, or, equivalently,  $\mu_0 M_d = 0.56$  T) plotted with the theoretical Langevin curve (solid line). The data consist of Ferrotec Corporation ferrofluids: NF 1634 Isopar M at 25.4°C, 50.2°C, and 100.4°C, all with fitted particle size of 11 nm; MSG W11 water-based at 26.3°C and 50.2°C, with fitted particle size of 8 nm; NBF 1677 fluorocarbon-based at 50.2°C, with fitted particle size of 13 nm; and EFH1 (positive  $\alpha$  only) at 27°C, with fitted particle size of 11 nm. All data fall on or near the universal Langevin curve indicating superparamagnetic behavior. *Source:* From Ref.<sup>[68]</sup>.

### Magnetocaloric Effect

The temperature dependence of magnetization causes ferrofluids to exhibit the magnetocaloric effect whereby magnetic materials can heat up in a magnetic field and cool down when the magnetic field is removed.<sup>[1,69]</sup> This allows a direct and efficient conversion of magnetic work to heat with no mechanical moving parts, or, if the cycle is reversed, refrigeration or heat pumping is obtained. If the magnetic field  $H$  of a magnetic material with magnetization  $M(H, T)$  is increased by an amount  $\Delta H$ , adiabatic demagnetization results in a decrease of temperature:

$$\Delta T_{\text{decrease}} = \frac{T \Delta H}{C_H} \frac{\partial M(H, T)}{\partial T} \quad (8)$$

where  $C_H$  is the heat capacity at constant  $H$ .<sup>[38]</sup> For example, using iron in a 20-T magnetic field, the adiabatic temperature drop is 53°C.<sup>[1]</sup>

For a heated magnetic fluid with a change in magnetization of  $\Delta M$  in a magnetic field  $H$ , the pressure increase is:

$$\Delta p \approx (\mu_0 \Delta M) H \quad (9)$$

For  $\Delta M \approx 5 \times 10^4$  A/m in a  $\mu_0 H = 1$  T magnetic field, the pressure drop is  $\Delta p \approx 5 \times 10^4$  Pa ( $\approx 1/2$  atm).<sup>[1]</sup>

## Magneto-Optical Effects

Anisotropy from non-spherical nanoparticles orienting in an applied magnetic field causes birefringence (also known as the Cotton–Mouton effect, where the refractive index changes along axes parallel and perpendicular to the magnetic field), dichroism (change in light color dependent on direction of light polarization), and Faraday rotation (the plane of linearly polarized light is rotated when a magnetic field is applied parallel to the direction of light propagation).<sup>[70,71]</sup> Birefringence causes incident linearly polarized light to become elliptically polarized at some angle to the applied magnetic field. If the birefringent ferrofluid is placed in an optical polariscope, the transmitted light intensity varies with applied magnetic field magnitude and direction. Such a configuration can be used as a light shutter or as a magnetometer. After removing a magnetic field, the transient birefringence can be measured to determine the Brownian relaxation time of Eq. (4) from which the hydrodynamic nanoparticle size can be determined. Such magneto-optical relaxation measurements have also been used to determine the binding reactions of antibodies to their antigens through increases of nanoparticle size.<sup>[72]</sup>

## FERROHYDRODYNAMICS

### Ferrohydrodynamic Bernoulli's Law

The magnetic force density acting on an incompressible ferrofluid is:<sup>[1,73]</sup>

$$\bar{F} = \mu_0(\bar{M} \cdot \nabla)\bar{H} \text{ N/m}^3 \quad (10)$$

so that ferrofluids move in the direction of increasing magnetic field strength.

When  $\bar{M}$  and  $\bar{H}$  are collinear, this force density modifies Bernoulli's equation for inviscid and irrotational flow to:

$$-\rho \frac{\partial \psi}{\partial t} + p + \frac{1}{2} \rho v^2 - \rho \bar{g} \cdot \bar{r} - \mu_0 \int_0^H M dH = \text{constant} \quad (11)$$

where  $\rho$  is the ferrofluid mass density [in kg/m<sup>3</sup>],  $\psi$  is the velocity potential defined as  $\bar{v} = -\nabla\psi$ ,  $p$  is the pressure [in Pa],  $v|\bar{v}|$  is the magnitude of the fluid velocity  $\bar{v}$ ,  $\bar{g}$  is the gravitational acceleration vector, and  $\bar{r} = x\bar{i}_x + y\bar{i}_y + z\bar{i}_z$  is the position vector. The magnetic term in Eq. (11) is the magnetic contribution to fluid pressure and describes such magnetic effects as the shape of a ferrofluid meniscus; flow and instabilities

of a ferrofluid jet such as for magnetic fluid inkjet printing; operation of magnetic fluid seals, bearings, and load supports; magnetic fluid nozzles; and magnet self-levitation in a ferrofluid.<sup>[1,73]</sup> Ferrofluids in a non-uniform magnetic field can be used to separate material mixtures according to their densities, known as sink–float separation. With gravity directed in the  $-z$  direction, the apparent density of ferrofluid with density  $\rho$  when  $H = 0$  is:<sup>[35]</sup>

$$\rho_a = \rho - \frac{\mu_0 M}{g} \frac{dH}{dz} \quad (12)$$

## Fluid Instabilities

Ferrofluids exhibit a wide range of very interesting lines, patterns, and structures that can develop from ferrohydrodynamic instabilities.<sup>[61]</sup> Figs. 4 and 5 illustrate the ferrofluid hexagonal peaking behavior resulting from a magnetic field perpendicular to the free surface of a ferrofluid layer.<sup>[1,74,75]</sup> The peaks initiate when the magnetic surface force exceeds the stabilizing effects of fluid weight and surface tension. In Fig. 6, the gearlike structure results from the radial perpendicular field instability when a small magnet is placed behind a ferrofluid drop confined between closely spaced glass plates. In a rotating magnetic field, this “star wheel” will rotate and can function as a gear, flow stirrer, or pump. Possible further microdevice and nanodevice applications could result from solid

**Fig. 4** Hexagonal peaking patterns of about 1 cm spacing result when a perpendicular magnetic field is applied to a layer of Isopar M magnetic fluid with saturation magnetization of 400 G. The peaks initiate when the magnetic surface force exceeds the stabilizing effects of the fluid weight and surface tension. The image with a magnetic field of about 330 G shows the sharp peaks with a hexagonal base pattern. *Source:* From Ref.<sup>[61]</sup>.

**Fig. 5** Another view of the perpendicular field instability including a crown of peaks on the glass container wall edge when a 400-G magnetic field is applied to Isopar M ferrofluid. The containing vessel has a 15-cm diameter. *Source:* From Ref.<sup>[61]</sup>.

structures made from a ferrofluid that is solid at room temperature but becomes liquid at slightly elevated temperature, such as by using a paraffin-based ferrofluid. If the ferrofluid is heated and then cooled in the presence of a magnetic field, solid magnetic nanostructures can be fabricated such as the gearlike structure in Fig. 6. Solid spiked structures with shapes like those in Figs. 4 and 5 may be useful for forming high electric fields at the tips that can be used in charge injection devices. Figure 7 shows the labyrinth instability that results when a magnetic field is applied tangent to the thin dimension of the ferrofluid layer confined between closely spaced glass plates.<sup>[76–78]</sup>

**Fig. 6** Gearlike structure that results when a small 5-mm-diameter permanent magnet, with strength of about 1200 G, is placed behind a small Isopar M ferrofluid droplet confined between glass plates with 1 mm gap. *Source:* From Ref.<sup>[61]</sup>.

**Fig. 7** Labyrinth instability that results when a 1-mm-thick layer of Isopar M ferrofluid between glass plates is stressed by a magnetic field of about 150 G tangent to the thin dimension of the ferrofluid layer. The line thickness is about 200  $\mu\text{m}$ . *Source:* From Ref.<sup>[61]</sup>.

The labyrinth forms because the induced magnetic poles on the top and bottom surfaces of the ferrofluid create a magnetic field that opposes the applied field, the so-called demagnetization field, so that the magnetic field in the ferrofluid is less than the magnetic field in the non-magnetic region outside the ferrofluid. Because the ferrofluid is attracted to regions of strong magnetic field, a comblike interfacial instability develops and the interface forms thin lines that move away from the ferrofluid layer. Such fine lines may be useful for lithography and printing applications.

### Rotating Magnetic Field Torque-Driven Phenomena

Attention has shifted to rotating magnetic field phenomena, where the magnetization relaxation time constant of Eq. (5) creates a phase difference between magnetization and magnetic field, so that  $\bar{M}$  and  $\bar{H}$  are not in the same direction. This causes a magnetic torque density:<sup>[55–62,79]</sup>

$$\bar{T} = \mu_0 \bar{M} \times \bar{H} \quad \text{N/m}^2 \quad (13)$$

which causes the magnetic nanoparticles and surrounding fluid to spin. The concerted action on the order of  $10^{22}$ – $10^{23}$  nanoparticles/ $\text{m}^3$  leads to interesting microdrop behavior. A ferrofluid spherical microdrop, about 20  $\mu\text{m}$  in diameter, in a rotating magnetic field of intensity from 50 to 1000 A/m over a frequency range of 4 Hz–4 kHz forms a set of complicated shapes of loops, worms, and stars at intermediate strength fields and a “spinning starfish” shape with

**Fig. 8** Spiral and intricate structure shapes with simultaneously applied d.c. and 20-G, 25-Hz rotating magnetic fields to fluorocarbon-based ferrofluid drops with  $\sim 400$  G saturation and low field magnetic susceptibility  $\sim 3$  confined between two glass plates with a 1.1 mm gap. The ferrofluid is surrounded by a 50/50 mixture of isopropyl alcohol and deionized water, which prevents ferrofluid wetting of the glass plates. (i)–(iii) have  $50 \mu\text{L}$  of ferrofluid. (i) shows the ferrofluid drop before the magnetic field is applied. (ii) The d.c. axial field is first increased to 100 G to cause the radially spiking labyrinth pattern. (iii) The clockwise rotating field is turned on and the spikes begin to curl in on themselves, forming a smooth spiral pattern. (iv)–(vi) have  $200 \mu\text{L}$  of ferrofluid. The test cell is first placed in the clockwise rotating field, which causes a counterclockwise flow that holds the fluid drop together without spikes. In (iv), a 100-G d.c. axial field is then gradually applied, causing the ferrofluid drop to appear to expand before the phaselike transition to (v) at a critical d.c. magnetic field strength around 100 G. (vi) The magnetic field is increased from 100 to 250 G. *Source:* From Ref.<sup>[81]</sup>.

many arms at high magnetic field, all corotating with the magnetic field.<sup>[53]</sup>

Other new ferrohydrodynamic phenomena with simultaneously applied d.c. and rotating magnetic fields are shown in Fig. 8 for a ferrofluid contained between glass plates with a 1.1 mm gap.<sup>[80,81]</sup> Two experiments are shown in Fig. 8. The first experiment, images (i)–(iii), uses  $50 \mu\text{L}$  of ferrofluid, brings the d.c. axial field up to 100 G, and then turns on the clockwise rotating field. Image (i) shows the circular ferrofluid drop before the magnetic field is applied, whereas image (ii) shows the spiking labyrinth pattern formed

by the ferrofluid after only the d.c. axial field has been applied. Then the clockwise rotating field is applied and the spikes begin to curl in on themselves, eventually forming the smooth spiral pattern shown in image (iii) after some of the spikes are absorbed into the larger structure. The smooth spirals form as the clockwise rotating magnetic field causes counterclockwise viscous shear flow on the outside ferrofluid surfaces, which returns on the inside surfaces.

The second experiment, with  $200 \mu\text{L}$  of ferrofluid, is seen in images (iv)–(vi) and is the result of first placing the cell in the clockwise rotating field and then

gradually applying a 100-G d.c. axial field. This results in the originally round ferrofluid drop appearing to expand in image (iv) before the phase transition to image (v) at a critical d.c. magnetic field strength around 100 G, evolving to image (vi) as the d.c. magnetic field is further increased to 250 G.

These intricate patterns can possibly have applications as self-assembling structures in fluidic devices, printing, separations, etc.

### Application to Power Transformer Cooling

With the development of a ferrofluid transformer oil that meets electrical property and breakdown requirements of high-power transformers,<sup>[82]</sup> there has been recent applied research<sup>[83–92]</sup> to use ferrofluid physical, mechanical, and thermal properties together with the magnetic body force density of Eq. (10) for enhanced cooling of power transformers. Heat generated by the windings and magnetic core produces temperature gradients in the ferrofluid, where there is also a non-uniform magnetic field. It is also thought that the high a.c. magnetic field in the vicinity of the windings and oil ducts can cause magnetic particle stirring that reduces ferrofluid thermal gradients. Measurements for 10- and 50-kVA transformers showed up to about 12°C lower operating temperature for ferrofluid transformer oil than for non-magnetic transformer oil.<sup>[88,89]</sup> Because the 10-nm-diameter ferrofluid particles are so small, they appear to have no deleterious effect on the oil electrical breakdown strength.<sup>[90]</sup> The enhanced cooling method uses the temperature dependence of ferrofluid magnetization described by the Langevin relation, so that the magnetic susceptibility  $\chi_m$  in Eq. (7) decreases as temperature increases. Thus, hot ferrofluid in the vicinity of the transformer windings has a lower magnetic permeability than cold ferrofluid. Then, cool (high magnetic permeability) ferrofluid is attracted to high magnetic field regions near the transformer windings as hot (low magnetic permeability) ferrofluid is displaced. Thus, the temperature gradients in a transformer can be used to induce magnetic permeability gradients that cause cooling ferrofluid motion and the resulting convective flow enhances transformer cooling. As an additive, a ferrofluid concentrate can be used to extend the lives of millions of aging transformers. As a new technology, ferrofluid transformers may be smaller, more efficient, and possess improved dielectric capabilities. A related analysis models a laminar and turbulent pipe flow that is applicable to transformer duct flows and validates a set of ferrohydrodynamic equations including the effects of nanoparticles interacting with magnetic fields and thermal/flow gradients.<sup>[93]</sup>

## APPLICATIONS TO NANOELECTROMECHANICAL AND MICROELECTROMECHANICAL SYSTEMS

### Advantages of Magnetic Field Devices

To demonstrate the advantages of magnetic field-based microelectromechanical systems (MEMS) and nanoelectromechanical systems (NEMS) devices over the usual electric-field based devices, we can compare representative electric and magnetic energy densities.<sup>[61]</sup> An electric field device is generally limited by the maximum allowed electric field without electrical breakdown, typically  $E \approx 10^8$  V/m for small-scale devices that take advantage of the Paschen curve at small gaps to raise the electrical breakdown strength of air (e.g., a variable capacitance micromotor may use 150 V across a 1.5- $\mu\text{m}$  gap).<sup>[94]</sup> Magnetic field devices have no limitations analogous to electrical breakdown and the maximum magnetic flux density is on the order of the saturation magnetization of single-domain magnetic nanoparticles, which is about  $B \approx 2.1$  T for single-domain iron particles. The resulting electric and magnetic energy densities are then:

$$\begin{aligned} W_e &= 0.5\epsilon_0 E^2 \approx 4.43 \times 10^4 \text{ J/m}^3; \\ W_m &= 0.5B^2/\mu_0 \approx 1.75 \times 10^6 \text{ J/m}^3 \end{aligned} \quad (14)$$

This possible increase in energy density and corresponding forces for magnetic devices has the added advantage of increased reliability as there are no catastrophic failure mechanisms analogous to electrical breakdown. Potential new NEMS applications using ferrofluid nanoparticles, with and without carrier fluid, include nanoduct flows, nanomotors, nanogenerators, nanopumps, nanoactuators, and other similar nanoscale devices.<sup>[61,95]</sup>

### Magnetic Nanoparticle Sensors and Actuators

The capability to actuate ferrofluids through magnetic fields and magneto-mechanical coupling makes them attractive for MEMS/NEMS applications,<sup>[61,96–99]</sup> as well as for energy conversion schemes.<sup>[95]</sup>

The essential principles of magnetic nanoparticle sensors and actuators are illustrated in Fig. 9. Single magnetic nanoparticles can be trapped in nanofabricated wells surrounded by a nanocoil. The nanocoil can then serve to sense a voltage when open-circuited, or a current when short-circuited, or, with imposed current, can drive nanoparticle rotation, much like in the operation of macroscopic generators or motors. Imposed flow over the nanowell would serve to drag the magnetic nanoparticle into rotation. Such rotation

**Fig. 9** Proposed surface-immobilized magnetic nanoparticle-based flow sensors and actuators.

would result in a time-varying magnetic flux in the nanocoil, causing induced open-circuit voltage or short-circuit current. The induced voltage or current can be measured and used to determine the flow rate of the fluid, or can be used as a micropower source converting flow kinetic energy to electrical energy. The reverse operation with proper multiphase time-varying currents, through a set of such coils to cause a rotating magnetic field, would result in magnetic nanoparticle rotation and flow actuation. Both single wells and arrays are possible, allowing for sensing and actuation of flow over whole surfaces of a micro-electromechanical or nanoelectromechanical device consisting of nanoscale electromagnets, coupled with wells to hold the magnetic nanoparticles.

The fabrication procedure for micron-sized electromagnets and micron-sized gold wires has been demonstrated<sup>[100,101]</sup> and was successfully used to trap and manipulate collections of magnetic nanoparticles and atoms. At liquid nitrogen or helium temperatures in vacuum, the wires could carry currents of several amperes with a current density of  $\sim 10^8$  A/cm<sup>2</sup> and a power dissipation of  $\sim 10$  kW/cm<sup>2</sup>, producing magnetic fields to 0.3 T.

Representative present technology can fabricate gold coil windings that are about  $3\ \mu\text{m}$  thick and  $10\ \mu\text{m}$  wide, with center-to-center spacing of  $20\ \mu\text{m}$ , and can support a current density as high as  $10^{11}$  A/m<sup>2</sup>.<sup>[100]</sup> A representative maximum current of 3 A produces a magnetic field of about 0.1 T. Fig. 10 extends the concepts in Fig. 9 and shows a proposed micropower supply method for possible space applications. Waste heat is converted to ferrofluid flow using a vapor bubble pump that controllably causes magnetic particle rotation, which generates a time rate of change of magnetic flux through a nearby coil.<sup>[61]</sup> A 10-nm-diameter magnetite nanoparticle with a magnetization of 0.56 T would have a total magnetic flux of about  $4 \times 10^{-17}$  Wb. If this nanoparticle rotated next to our representative coil at an angular speed of 1000 rps with all the magnetic flux of the nanoparticle linking the coil, the induced peak voltage would be about  $3 \times 10^{-13}$  V. The conductivity of gold is  $4 \times 10^7$  S/m so that the resistance of a gold wire of length  $100\ \mu\text{m}$  with a cross section of  $10 \times 3\ \mu\text{m}^2$

**Fig. 10** Schematic diagram of a proposed micropower supply method that takes waste heat to cause a time-varying flow that controllably rotates ferrofluid nanoparticles so that there is a time-varying magnetic flux through a coil that induces a current through a load. *Source:* From Ref.<sup>[61]</sup>.

would be about  $0.08\ \Omega$ . The short circuit peak current would be the ratio of the voltage divided by the coil resistance, or approximately 4 pA. The maximum power that could be delivered by this single nanoparticle generator would be about  $10^{-24}$  W. If confined to a single plane, there could be as many as  $10^{16}$  such single nanoparticle generators per square meter. If connected in series, the open circuit peak voltage could be as high as  $3000\ \text{V/m}^2$  of generator surface, whereas if connected in parallel, the short circuit peak load current could be as high as  $40,000\ \text{A/m}^2$  of generator surface, or in more practical units for nanoscale devices, about  $0.04\ \mu\text{A}/\mu\text{m}^2$  of generator surface area. The delivered time average power would then be on the order of  $10^{-8}\ \text{W/m}^2$ .

Of course, practical packing constraints, small wafer sizes, smaller nanoparticle rotation rates, magnetic flux leakage (so that the nanocoils do not link all the magnetic flux), nanoparticle sticking, nanoparticle confinement, and other non-idealities and problems of controlling motions of nanoparticles would lower these idealized large values, but these “back-of-the-envelope” preliminary calculations indicate the practical possibility of generating useful levels of micropower for selected applications, such as in space where plentiful waste heat can be used to cause ferrofluid flow to generate electricity, along the lines shown in Fig. 10.

Similar devices with submicron dimensions allow for single-particle manipulation and sensing. Trapping of nanoparticles would occur because of magnetophoretic forces,<sup>[102,103]</sup> analogous to dielectrophoretic trapping of particles,<sup>[104,105]</sup> where magnetic nanoparticles are attracted to the position of maximum magnetic field strength. A micromachined particle separator  $2 \times 3\ \text{mm}$  in size was fabricated on a silicon wafer. Electromagnetic coils using 500 mA of d.c. current generated a  $\sim 0.03$ -T magnetic field to separate  $\sim 1\text{-}\mu\text{m}$

magnetite particles from a water suspension at a velocity of  $\sim 1$  mm/sec in a channel that was  $90 \mu\text{m}$  deep and  $100 \mu\text{m}$  wide.<sup>[103]</sup>

### Microfluidics/nanofluidics

Ferrofluid devices can be a major component of a micro total analysis system ( $\mu\text{TAS}$ ), also known as “lab-on-a-chip.” The magnetic pressure generated in a ferrofluid is:<sup>[96–98]</sup>

$$p_m = \mu_0 \int_0^H M(H) dH \quad (15)$$

Ferrofluid plugs act as valves when placed near a stationary magnet and do not require any power. Hermetic sealing of a channel  $250 \mu\text{m}$  wide,  $150 \mu\text{m}$  deep, and  $9.5$  mm long has been achieved using a  $400$ -G hydrocarbon-based ferrofluid with  $42$  cP viscosity and a  $1200$ -G magnet, generating a magnetic field-induced change in pressure of  $p_m \approx 13.5$  Pa.<sup>[97]</sup> Ferrofluid microplugs have been able to sustain a pressure difference up to  $1700$  Pa.<sup>[99]</sup>

A number of micropumps use moving magnets to push ferrofluid microplugs that then displace non-magnetic fluids.<sup>[96–99]</sup> A circular channel of  $\sim 1$  cm diameter with  $250 \mu\text{m}$  depth and  $2$  mm channel width containing a  $125$ -G hydrocarbon-based ferrofluid pushing water had a flow rate of  $45.8 \mu\text{L}/\text{min}$  with an  $8$ -rpm motor rotating a  $3500$ -G permanent magnet at speed  $3.75$  mm/sec, generating a pressure of  $1200$  Pa.<sup>[99]</sup>

An electromagnetic ferrofluid pipette was designed to accurately dispense liquid volumes smaller than  $0.2 \mu\text{L}$ .<sup>[106]</sup> The pipette consisted of four electromagnets with a total of  $160$  turns around a  $1.8$ -mm air gap holding the pipette tube. A small hydrocarbon-based ferrofluid plug of  $600$  G saturation magnetization and  $1.43$  Pa sec viscosity in the pipette would move with  $0.6$  A total current applied to the electromagnets, causing a ferrofluid pressure rise up to  $770$  Pa. The ferrofluid would move at a speed of  $0.9$  cm/sec in about  $1.5$  sec and would dispense  $90$  nL of water. The position of the ferrofluid plug was controlled to within  $0.2$  mm.

### BIOMEDICAL APPLICATIONS

There are a number of methods in which magnetic nanoparticles can be used for biomedical applications:<sup>[107–110]</sup>

1. Magnetic nanoparticles can bind to drugs, proteins, enzymes, antibodies, or organisms.
2. Magnetic nanoparticles can be directed to organs, tissues, or tumors using an external magnet for therapeutic effect.

**Fig. 11** Proposed surface-immobilized magnetic nanoparticle-based nanobiosensor.

3. Dissipation in alternating and rotating magnetic fields can cause heating of magnetic nanoparticles for use in hyperthermia.

Such chemotherapeutic applications require particles to be able to pass through organ and tissue capillary systems without threat of vessel embolism and be able to transport pharmacologically active materials with an effective release mechanism of the drug at the target site. All components for the drug carrier system must be non-toxic, biodegradable, and/or removable.<sup>[111]</sup>

As an example application, Fig. 11 shows a surface-immobilized nanoelectromechanical flow sensor or actuator that may operate for detection of biological molecules and organisms. Magnetic nanoparticles functionalized with a surfactant coating for specific binding to a biological molecule or organism would be placed in the nanowells. A biological liquid medium would then flow over the nanosensor array. If the biological molecule or organism of interest is present in the medium, then specific binding with the magnetic nanoparticles would result, thus hindering their rotation. This, in turn, would result in a measurable change in the induced current through the nanocoils. In this way, a surface-immobilized flow-through nanobiosensor may be developed.

Magnetorelaxometry is a technique used to measure the binding or immobilization of a magnetic nanoparticle through measurement of changes in magnetic relaxation time following the removal of an applied magnetic field. Small free nanoparticles have magnetization decay because of Brownian relaxation, with time constant  $\tau_B$  of Eq. (4) increasing when additional molecules are bound to the nanoparticle because of the increased hydrodynamic volume  $V_h$ . The Néel relaxation time only depends on the magnetic material volume  $V_p$  and so is independent of non-magnetic material binding to a magnetic nanoparticle. If the nanoparticle is bound to a solid phase and has restricted motion, the magnetization predominantly decays by Néel relaxation. By determining if magnetization relaxation is occurring through Brownian or Néel

mechanisms, the binding conditions of nanoparticles to molecules or fixed material are determined.<sup>[112]</sup>

Suitability for biotechnological and biomedical applications of magnetic nanoparticles and ferrofluids is being determined through fundamental studies of magnetic nanoparticle cell toxicity, biocompatibility, and transport for such applications as separations, magnetic resonance imaging, drug delivery, cytolysis (cell destruction), hyperthermia, colloid extractants, cell sorting, and immunoassays. A brief summary of current research follows.

### Magnetocytolysis

Classical hyperthermia induces damage to cells and tissues, enhances radiation injury to tumor cells, and improves chemotherapeutic efficacy. A local thermal effect is desired within cancerous tissues while leaving normal tissues unaffected.<sup>[113,114]</sup> Heating between 41°C and 46°C generally reduces the viability of cancer cells and increases their sensitivity to radiation and chemotherapy. Temperatures up to 56°C (thermoablation) lead to cell death.<sup>[113–116]</sup> Magnetic materials for hyperthermia of biological tissues have been used since at least the late 1950s. Over a diameter range of 5–10 nm, the effective relaxation time of Eq. (5) in magnetite varies over two orders of magnitude. Ferrofluid subdomain particles (~10 nm diameter) absorb more power at reasonable a.c. magnetic fields than by hysteresis heating of multidomain particles (~1 μm).<sup>[114–118]</sup>

Small amounts of magnetic fine particles in radio-frequency (rf) magnetic fields can easily rise in temperature to cause cell death. For example, for a magnetic field intensity of 6.5 kA/m at 300 kHz, Néel relaxation has peak dissipated power density of about 10<sup>10</sup> W/m<sup>3</sup> for magnetite nanoparticles of about 9 nm radius, decreasing to about 10<sup>8</sup> W/m<sup>3</sup> at 7 nm radius and to 10<sup>6</sup> W/m<sup>3</sup> at 12 nm radius. Hysteresis losses are about 10<sup>6</sup> W/m<sup>3</sup> at 9 nm nanoparticle radius, rising to about 10<sup>10</sup> W/m<sup>3</sup> for nanoparticles larger than about 10 nm particle radius. Calculations and confirming measurements show that a temperature rise of about 16°C in about 30 min results from a 3-mm radius sphere of crushed magnetite embedded in a gel in a magnetic field of 17.6 kA/m at 300 kHz.<sup>[119]</sup>

To study the biological effects of a.c. magnetic field excited ferrofluids, both in vivo and in vitro studies have been done in cancer cell lines and spontaneously induced tumors in animal models.<sup>[118]</sup> The term magnetic fluid hyperthermia (MFH), which uses a.c. magnetic fields to heat target areas containing magnetic fluids, is suggested for this new cancer treatment method. It has been shown<sup>[120]</sup> that MFH is able to inactivate tumor cells in vitro to at least the same

extent as water bath hyperthermia and that there is no cytotoxic effect of intracellularly administered dextran-ferrite magnetic particles.<sup>[121,122]</sup> An in vivo study<sup>[123]</sup> using transplants of a mammary carcinoma showed that high doses of MFH were able to induce tumor control in 44% of the cases up to 30 days after therapy.

Trials carried out on human and mouse macrophages (leukocytes, white blood cells) without a magnetic field and in a constant magnetic field did not observe any cytolysis or toxic effects.<sup>[124]</sup> Under an alternating magnetic field of 100 G at a frequency of 1 MHz, the temperature of a concentrated ferrofluid increases from 37°C to 80°C in about 2 min. Magnetocytolysis experiments were carried out using very low concentrations of magnetic nanoparticles, such that no increase in the temperature of the bulk solution was evidenced. After being subjected to alternating fields for 5 min, it was observed that 40–50% of the mouse and human macrophages are killed, but only 3–6 hr after application of the oscillating field. It was found that binding of the magnetic nanoparticles to the cell membrane is essential for cytolysis.

For iron oxide nanoparticles of 10 nm diameter deposited into tumors in mice and exposed to a 6500-A/m, 400-kHz magnetic field for 4 min, the local heating, called “magnetic thermoablation,” raised the tumor temperature by ~62°C, causing therapeutic irreversible damage to the tumor.<sup>[125]</sup> Similar measurements in mice using water-based dextran-ferrite magnetic fluid in a 9300-A/m magnetic field at 0.88 MHz raised the tumor temperature by ~45°C, with 33% tumor regression and mouse life span increases of 150%.<sup>[126]</sup>

### Drug Delivery

The use of biocompatible ferrofluids as a delivery system for therapeutic drugs is commonly called “magnetic drug targeting.”<sup>[127–129]</sup> Mitoxantrone, a chemotherapeutic agent that inhibits DNA and RNA synthesis, was ionically bound to magnetic nanoparticles and was directed to cancerous tumor sites in rabbits using a 1.7-T magnet focused on the tumor. Complete tumor remissions with no adverse side effects were obtained using only 20% of the normal mitoxantrone dosage.<sup>[130]</sup> Similar success was achieved using ferrofluids labeled with iodine in a 0.6-T magnetic field.<sup>[131]</sup>

Magnetic targeting of anticancer drugs reversibly bound to magnetic fluids to locally advanced tumors can be achieved using magnetic fields directed to the tumor surfaces from outside the patient.<sup>[118,132]</sup> Phase I clinical trials using this approach in patients with advanced and unsuccessfully pretreated cancers or

sarcomas showed successful magnetic drug targeting with epirubin<sup>[118]</sup> and epirubicin.<sup>[132]</sup> Based on magnetic resonance tomographic techniques, pharmacokinetics, and the histological detection of magnetite, it was shown that ferrofluids could be successfully directed by externally imposed magnetic fields to the tumors in about one half of the patients.

Superparamagnetic nanoparticles were surface-modified with poly(ethylene glycol) (PEG) and folic acid, respectively, to improve their intracellular uptake and ability to target specific cells.<sup>[133]</sup> It was found that PEG modification of nanoparticles resulted in decreased uptake by macrophages, whereas folic acid modification did not result in any change in uptake by macrophages. However, both PEG and folic acid modification resulted in increased internalization of magnetic nanoparticles in breast cancer cells.

## Separations

Separation techniques are important for purification of biological materials and for identification of organisms, cells, and genomic materials. Application of a magnetic field to a suspension of magnetic nanoparticles confined between planar sheets causes the nanoparticles to self-organize into a regular array of columns. The column spacing can be controlled from submicron to 100  $\mu\text{m}$  by varying gap width, nanoparticle size, and concentration. Such a self-assembled array of magnetic particles was used to separate large DNA in a micro-channel in about 30 min, in contrast to the usual pulsed field agarose gel electrophoresis method, which takes about 12–24 hr.<sup>[134]</sup> Because pore size control from about 1–100  $\mu\text{m}$  can be obtained without the need for sophisticated microlithography, there are many separation applications envisioned for DNA, cells, proteins, organelles, and microparticles or nanoparticles.

Magnetic fluids have also been used as magnetically responsive extractants usable in treating aqueous media contaminated with organic compounds. In one study,<sup>[135]</sup> magnetite ( $\text{Fe}_3\text{O}_4$ ) nanoparticles of  $\sim 7.5$  nm nominal diameter coated with a  $\sim 9$ -nm bifunctional polymer layer composed of a hydrophilic poly(ethylene oxide) (PEO) outer region and a hydrophobic poly(propylene oxide) (PPO) inner region were prepared. With the advantages of very high surface area and decreased diffusion lengths, these magnetic fluids were shown to have high capacity for organic solutes, similar to that of analogous PEO–PPO–PEO block copolymer micelles. Efficient magnetic nanoparticle recovery using high-gradient magnetic field separation (HGMS) has been shown and incorporated into a proposed water purification process.<sup>[135]</sup>

Magnetic cell sorting schemes based on quadrupole fields<sup>[136]</sup> and in microfabricated magnetic arrays<sup>[137]</sup>

have been developed. The objective was to develop economical, high-throughput, high-purity, and high-recovery alternatives for separation of heterogeneous cell populations based on expression of particular surface markers.

An efficient magnetic vector/effector synthesis procedure was developed to target membrane receptors in target cells for subsequent separation.<sup>[118]</sup> This system was used to target, separate, and count damaged red blood cells. Applications of this technology include: 1) quality testing of human blood during storage in vitro;<sup>[138]</sup> 2) studies of the evolution of erythrocyte populations during parasitic pathologies such as *malaria*<sup>[139]</sup> and *Alzheimer's* disease;<sup>[140]</sup> and 3) detection of membrane modifications involved in complex biological processes such as apoptosis (programmed cell death).

## Immunoassays

Immunoassays are widely used in biology and medicine for the determination of the composition of complex samples such as blood by labeling one of the reaction components with radioisotopes, enzymes, or fluorescent dyes. Magnetic nanoparticle labels offer advantages as they are inexpensive to produce, are stable, and can be safely and easily stored, handled, and disposed of without problems of radioactivity or environmental contamination.<sup>[141]</sup>

Antibodies were coupled with magnetic nanoparticles and reacted with their solid-phase adsorbed antigen. The samples were first placed in a magnetic field of 1500 A/m and then the remanent magnetization in the absence of magnetic field was measured in a superconducting quantum interference device (SQUID) magnetometer. This measurement technique investigated the binding of monoclonal antibodies (MABs) to collagen type III using Dextran-coated iron oxide nanoparticles with 13 nm mean diameter. Then polystyrene tubes used as sample containers were incubated with the antigen collagen type III so that the antigen was adsorbed onto the tube wall. The measured magnetic moment after switching off the magnetic field is entirely caused by the remanent magnetization of nanoparticles with hindered mobility because of their binding to the antigen fixed at the tube wall. Unbound nanoparticles relax by Brownian relaxation and have no net remanent magnetization. For this method to work, the Néel relaxation time must be longer than the measurement period, typically about 100 sec, which requires larger size magnetic particles on the order of  $>20$  nm diameter for magnetite particles.<sup>[141,142]</sup>

## Magnetic Resonance Imaging

Magnetic materials are highly opaque to x-rays and, with 8–10% volume concentration in ferrofluid, offer

comparable image quality to conventional barium sulfate.<sup>[2,143]</sup> Magnetic nanoparticles, conjugated to various MABs, peptides, or proteins, show potential applications for in vivo monitoring of brain intercellular communication and target-oriented magnetic resonance imaging in animal and human brains.<sup>[144]</sup> Dextran-coated superparamagnetic iron oxide is commercially available for MRI and has been used for localization and diagnosis of brain and cardiac blood obstructions and for liver lesions or tumors, where the nanoparticles tend to accumulate because of the difference in tissue fluidity and endocytotic processes (incorporation of substances into cells).

Approximately 7-nm-sized magnetite nanoparticles coated with polymeric starch were injected into a rat brain. The magnetic nanoparticles were well distributed within the dorsal hippocampus, demonstrating the feasibility of using magnetite nanoparticles for in vivo MRI of the rat brain.

### Bacterial Threads of Nanomagnets

Magnetotactic bacterial threads can be used to direct the self-assembly of ordered magnetic microstructures.<sup>[145]</sup> *Bacillus subtilis* strain FJ7 is a mutant strain that can be cultured with intertwining filaments to form weblike structures. A thread was dipped into an aqueous colloidal suspension containing 10-nm-diameter magnetite nanoparticles between the cell strings to form threads of magnetic materials with an estimated nanoparticle density of  $10^{18}$  particles/cm<sup>3</sup> and a volume fraction of about 7%.

### CONCLUSION

This entry has described the integrated chemistry, fluid mechanics, and magnetic nanoscience and nanotechnology of magnetic fluids with summary reviews of ferrofluid synthesis: composition, colloidal stability, and preparation; ferrofluid magnetization: relaxation time constants, magnetization characteristic, magnetocaloric effect, and magneto-optical effects; ferrohydrodynamics: Bernoulli's law of pressure and flow, instabilities, and rotating magnetic field torque-driven phenomena; applications to microelectromechanical/nano-electromechanical systems: magnetic nanoparticle sensors, actuators, and microfluidic devices; and biomedical applications: drug delivery, hyperthermia, immunoassays, magnetic resonance imaging, separations, and cell sorting. These topics span the range from the nanosize magnetic nanoparticles to the concerted action from  $10^{22}$  to  $10^{23}$  magnetic nanoparticles/m<sup>3</sup> to cause macroscopic pressure and flow. Continuing research will integrate ferrofluid

nanotechnology to MEMS/NEMS fabrication capability by modification and tailoring of magnetic nanoparticle suspension properties for specific new high-technology applications as sensors, actuators, and biomedical tools.

# Magnetic Nanocarbon

T. L. Makarova

*Department of Experimental Physics, Institute of Physics, Umeå University, Umeå, Sweden*

## INTRODUCTION

Carbon is unique among the elements in the vast number of allotropies and compounds that it can form. The diversity of carbon's electronic structure is reflected in its electrical properties: carbon with a tetrahedral spatial structure (diamond) is an insulator; carbon with a planar structure (graphite) is classified either as a semi-metal or a zero-gap semiconductor; the linear structural form of carbon (carbyne) as well as spherical carbon molecules (fullerenes) are semiconductors; whereas, cylindrical forms of carbon (nanotubes) can be either semiconductors or metals, depending on their geometric structure. Theoretical studies have shown that specific features of the electronic structure of carbon could give rise to ferromagnetic or superconducting correlations retained at high temperatures.

There is no physical law that prohibits magnetic ordering in the structures containing only light elements such as carbon; however, there are strong reasons why high-temperature ferromagnetism in carbon is hard to expect. A major requisite for magnetism in an all-carbon structure is the presence and stability of carbon radicals. The occurrence of radicals that can introduce an unpaired spin is cut down by the strong ability of pairing all valence electrons in covalent bonds. These reasons may explain the difficulties experienced in the preparation of magnetic carbon compounds. Certain defects exist that drastically change magnetic properties of carbon. Bulk crystalline graphite is a strong diamagnet with magnetic susceptibility second only to superconductors. Theoretical works show that graphite containing certain types of defects can exhibit spontaneous magnetization. This review collects the experimental studies of the carbon-based magnets and describes the current status of the theoretical work.

## BASIC THEORIES ON CARBON MAGNETISM

Almost without exception, carbon modifications—graphite, diamond, fullerenes, and carbon nanotubes—are diamagnetic.

Diamagnetism of diamond<sup>[1]</sup> is described in a simple model based on magnetic contributions of localized

electrons: two Langevin diamagnetic terms,  $\chi_c$  and  $\chi_v$ , arising from the core and valence electrons, respectively, and a Van Vleck paramagnetic susceptibility  $\chi_{vv}$ . The Van Vleck term results from virtual magnetic dipole transitions between the valence band and the conduction band. The absence of Landau diamagnetism,  $\chi_L$ , and Pauli paramagnetism,  $\chi_P$ , is due to the absence of the states at the Fermi level. The magnetic moment of diamond is temperature independent.

Graphite has an anisotropic diamagnetic susceptibility.<sup>[2]</sup> If the magnetic field is perpendicular to the basal plane, the graphite susceptibility is larger than for any other substance, excluding superconductors. The in-plane susceptibility is very small as it is close to the diamagnetic susceptibility of a carbon atom. For graphite, only one contribution to  $\chi$ , namely the large and anisotropic orbital contribution of valence electrons  $\chi_v$ , is usually considered in theoretical approaches. Pauli paramagnetism in ideal graphite should be absent.

The electronic properties of graphite planes of finite size (graphenes) differ radically from those of bulk graphite. Calculating magnetic susceptibility of graphenes, one must take into account not only the sum of  $\chi_c$ ,  $\chi_v$  and  $\chi_{vv}$ , but also the Pauli paramagnetism  $\chi_P$ , Landau diamagnetism  $\chi_L$  of conduction electrons and the Curie paramagnetism  $\chi_C$ . The diamagnetic susceptibility of graphene planes of a finite size is primarily controlled by the concentration of charge carriers, and this concentration in turn depends on structural defects. Three types of defects in graphite can be recognized provisionally: edges of the planes, porosity, and so-called topological defects (Gaussian curvature).

Nanographene is defined as a nano-sized two-dimensional flat hexagon-network of  $\pi$ -electron system. According to theoretical suggestions, the presence of edges in nanographene produces an edge-inherited non-bonding  $\pi$ -electronic state (edge state) in addition to the  $\pi$ - and  $\pi^*$ -bands, resulting in an entirely different electronic structure from bulk graphite, where the localized spins of the edge state play an important role in the unconventional nanomagnetism.<sup>[3]</sup>

If graphite has a steplike surface, localized states, caused by the cut of a graphite sheet, appear at the Fermi level, localized near the step.<sup>[4]</sup> Two recognized

types of edges of a graphene plane are armchair and zigzag. Peculiar electronic properties of zigzag edges were first investigated by M. Fujita.<sup>[5]</sup> It is typically assumed that, in real conditions, a zigzag-type edge is stabilized by a single hydrogen atom. If each carbon atom of an edge is bonded to two hydrogen atoms, this type of edge is referred to as a *bearded edge*.<sup>[6]</sup>

Long and narrow graphenes are called *ribbons*, and can be characterized by the type of long edge and by the number of cells  $N$  between the edges. Zigzag-type ribbons are always metallic; whereas, the armchair ribbons are metallic only if  $N = 3m - 1$ , where  $m$  is an integer. Narrow and long graphene ribbons with zigzag edges feature a sharp peak in the density of states at the Fermi energy; whereas such a peak is not observed in the case of bulk graphite. A specific feature of the zigzag ribbons is the appearance of a pair of almost flat bands on the Fermi energy.<sup>[7]</sup> The charge density in the flat band state is strongly localized on the zigzag-edge sites. These edge states are of primary importance in the case of nanosized graphite.<sup>[8]</sup> The extremely high density of states at the Fermi level in graphite ribbons leads to paramagnetism. The presence of flat energy bands near the Fermi level has a considerable influence on the graphite electronic structure with zigzag edges. A consideration of the effects of electron–electron interactions in the frame of the Hubbard model shows that there can be a spontaneous magnetic ordering in nanographite. In the case of the zigzag-type strips, a ferrimagnetic structure is possible, the appearance of magnetic ordering controlled by the magnitude of the surface deformation caused by the electron–phonon interaction.<sup>[9]</sup>

A graphite *honeycomb* plane with hexagonal holes (porous graphite) has an electronic structure different from the ideal plane. Flat bands appear systematically in the electronic structure, implying the occurrence of spin ferromagnetism when the electron correlation is turned on. It is predicted that organic ferromagnetism can appear in a *superhoneycomb* bipartite structure.<sup>[10]</sup> It is shown theoretically that the energy-band structure of porous graphite allows for the separation of spin and charge.<sup>[11]</sup>

Variations in the graphene curvature due to the appearance of heptagons and pentagons instead of hexagons also change the magnetic properties of bulk graphite. This curvature occurs owing to the Stone–Wales rearrangement:<sup>[12]</sup> the rotation of two neighboring carbon bonds by an angle  $\pi/2$  transforms four hexagons into two pentagons and two heptagons. The periodic system of these defects completely changes the energy-band structure of graphite. A non-dispersive band is formed along one of the directions and the peak in the density of states caused by defects is located near the Fermi level.<sup>[13]</sup>

Bulk graphite is the most typical diamagnetic material, but nanographite is characterized by the dependence of electronic structure on edge structures. The electronic structure around the Fermi level may be highly degenerated, and this degeneracy can cause magnetic instability. It is suggested that the basic magnetic mechanism is spin polarization in these highly degenerate orbitals or in a flat band.<sup>[14]</sup>

## EXPERIMENTAL EVIDENCE

Magnetic ordering at high temperatures in carbon-based compounds has been persistently observed since 1986 with the main results summarized in Table 1. It is important to note that the structural unit giving rise to carbon ferromagnetism is unknown. Bulk carbon ferromagnets as recently as 2005 did not exist. The materials described in Table 1 contain only a small part of ferromagnetic substance and, therefore, the structural determination of the ferromagnetic phase is impossible. Therefore, Table 1 does not identify the structure of the material, but does indicate the substance chosen as the starting material for the production of magnetic carbon.

Table 1 also shows the room temperature values of magnetization, values of the Curie temperature, and the amount of transition metal impurities in the samples. Methods of impurity analysis are abbreviated as follows: inductively coupled plasma atomic emission spectroscopy (ICP); atomic absorption spectroscopy (AAS); electron probe microanalysis (EPMA); x-ray fluorescence analysis (XRF); Rutherford backscattering (RBS); mass spectroscopy (MS); energy dispersive spectroscopy (EDS), and particle-induced x-ray emission (PIXE). The abbreviation *ppm* indicates part per million in weight, i.e., mg/kg or  $\mu\text{g/g}$ . We assume that the abbreviation *ppb* in some papers also means *ppm*.

## CRITICAL ANALYSIS OF EXPERIMENTAL RESULTS

Analysing reports in the literature on the synthesis of carbon-based organic materials that exhibit magnetic ordering at room temperature and higher, it may be observed that the ferromagnetic carbonaceous compounds have several features in common.

Bulk magnetization is rather low. Low magnetization values apparently contradict to the high temperatures of the magnetic ordering transition.

In some instances, these values were increased by one to two orders of magnitude using the magnetic separation. In nearly all cases, the authors note that they could not find structural or chemical differences between the magnetic and non-magnetic parts. It is

Oxygen eroded graphite	$M_s = 0.58$ emu/g	320 K	AAS, x-ray fluorescence analysis (XRF), energy dispersive spectroscopy (EDS) 60–90 ppm Fe, 3–8 ppm Cu	[61][62]
Proton irradiated graphite	$M_s \cong 0,005$ emu/g $M_r = 0,00045$ emu/g		PIXE 2.1 ppm Fe 0.4 ppm Ni	[63][64]

likely that the only example where this difference is unquestionable is photopolymerized fullerene, as dissolving in toluene removes nonreacted monomeric fullerenes and the residue shows an increased magnetization.<sup>[52]</sup>

Remnant magnetization  $M_r$  is small compared to the saturated  $M_s$  value,  $M_r \leq 0.1 M_s$ . This feature may be attributed to a superparamagnetic behavior, although the coercive force is not zero and the temperature dependence of the value is small. We note, however, that carbon magnets are not expected to exhibit a large hysteresis because of the small spin-orbit coupling. Spin-orbit coupling is small or negligible for light atoms because it scales with the fourth power of the atomic number.

Saturation magnetizations in pyrolytic magnetic carbons are nearly temperature-independent up to temperatures well above 295 K. Curie temperature in several cases is close to the decomposition temperature.

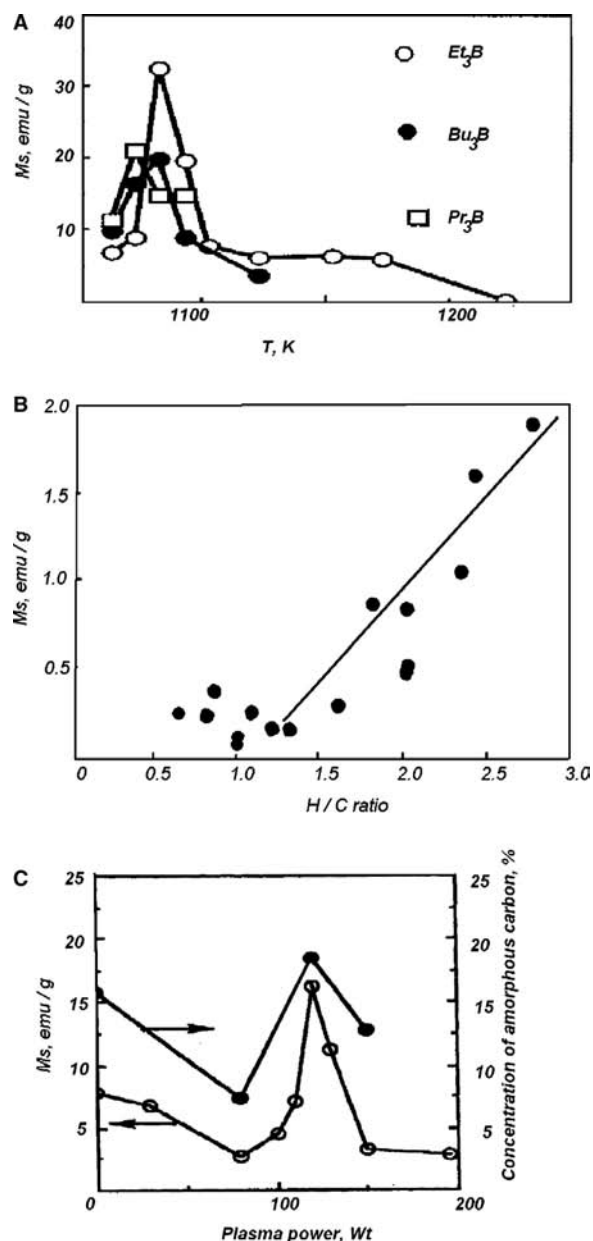

Results are poorly reproduced. Organic magnetic materials are produced by the chemical processes that involve a large number of reactions, and the results are hard to duplicate. Recent results where the chemical methods are supplemented by the physical ones: proton bombardment, laser ablation, oxygen erosion, pressure-temperature treatment, and photolysis, appear to be more repeatable.<sup>[59–64]</sup>

Magnetic properties of the synthesized substances are very sensitive to the synthesis conditions, especially preparation temperature. Deviations from an optimal temperature, that is specific for a certain process, lead to a quick decay of bulk magnetization. Fig. 1A illustrates this effect.

In earlier attempts to produce ferromagnetic carbonaceous compounds, the most successful ones are the processes involving the pyrolysis of organic compounds. The common features of these processes are heating organic substances in a complex (steplike) way, sometimes in the presence of a magnetic field, and stopping the processes halfway to graphitization. This process yields a highly oriented graphite-like material with a high concentration of unpaired spins. Clear features of room temperature magnetic ordering were observed in some cases. Again, there is a series of similarities between the substances reported by different authors.

The choice of the starting material to be pyrolyzed is important. Several authors mention isomeric effect where magnetic carbons are produced from the branched isomers. In other words, the geometric arrangement of radicals is important for attaining an ordered spin structure.

The *ratio* between the concentrations of hydrogen and carbon [H] and [C] in the starting material is particularly critical. As soon as this ratio exceeds 1.5, a sharp increase in the saturation magnetization of the

**Fig. 1** (A): Dependence of the observed saturation magnetization at 298 K on the pyrolysis temperature for triethylboranes ( $Et_3B$ ), tributylboranes ( $Bu_3B$ ) and tripropylboranes ( $Pr_3B$ ); (B): Dependence of saturation magnetization of carbon-based magnetic materials on the hydrogen-carbon ratio in the starting material; (C): Plasma power dependence of the saturation magnetization value at room temperature (solid circles) and amorphous carbon content of the carbon material (open circles).

reaction product is observed. A parallel between the hydrogen-related magnetic properties of pyrocarbons and the proton-induced magnetic ordering in graphite can be drawn (Fig. 1B).

Patents describing methods for preparing carbonaceous ferromagnets frequently include stopping the synthesis process at the mid-course to graphitization.

Properties of magnetic carbon materials made by pyrolysis of diverse organic compound monomers at around 1000°C are strongly related to the radicals and hydrogen atoms generated during the pyrolysis process and to the degree of amorphousness of the material.

Studies of a large number of ferromagnetic materials obtained from various nitrogen-containing substances showed that the structure of these materials is most often amorphous and disordered. In order to reveal the structural–magnetic correlations, samples of ferromagnetic carbon were subjected to various doses of plasma treatment, after which the percentage of amorphous carbon and the value of magnetization were measured. A one-to-one correspondence between the above two parameters was observed. The higher the content of amorphous carbon, the higher the spontaneous magnetization (Fig. 1C).

Some of the carbon magnets are unstable and lose the room-temperature ferromagnetic properties during one day, like carbon nanofoam, or in one year, like proton-bombarded graphite of hydrogenated fullerenes. The theoretical models should take into account metastable carbon structures.

## INFLUENCE OF IMPURITIES

It is seen from Table 1 that, in some cases, the experimental data does not give convincing proof for the intrinsic origin of the effect. In cases where the amount of impurities is given, the magnetization values are one or two orders of magnitude (but not several orders) larger than the value that could be expected if all impurities formed sufficiently large clusters. This value can be easily estimated from Table 2.

It cannot be excluded that part of the results listed in Table 1 can be caused by extrinsic reasons, especially taking into account the fact that the results are poorly

reproduced. Trivial sources of iron include air pollution, magnetic separations, grinding, and catalysts.<sup>[65]</sup> A nontrivial origin of magnetic behavior in contaminated carbon-based materials may result from the special arrangement of the spins of metallic ions being arranged in such a way that they are strongly coupled to an organic polymeric backbone.<sup>[65]</sup>

However, in order to contribute to the total magnetization of the samples, the impurities must interact magnetically. A good example of unconventional ferromagnetism is the one in diluted magnetic semiconductors where 1%–10% of transition metal ions are added to semiconductors or oxides. Ferromagnetism is induced in very rare occasions and only on the samples with special structure. Simple addition of transition metals does not lead to ferromagnetic properties, as no interaction pathway is provided. The incorporation of several atomic percents of transition metals, combined with the optimized synthesis conditions, leads to ferromagnetism. The mechanism, either carrier-induced, double-exchange or bound magnetic polaron formation, is still under debate. Various other theories (band ferromagnetism, carrier induced ferromagnetism, flat band theory, excitonic models, etc.)<sup>[66]</sup> have been reported as explanations for the ferromagnetism in these materials. A recent model of exchange in dilute ferromagnetic semiconductors suggests that the exchange is mediated by donor electrons in a spin-polarized impurity band.<sup>[67]</sup>

## NONTRIVIAL IMPURITY EFFECTS

Even if the extrinsic sample magnetization, calculated with the help of Table 2, is close to the experimental magnetization value, one cannot exclude non-trivial mechanisms. One of the mechanisms, contact-induced magnetism, was suggested by Cooley et al.<sup>[68]</sup> The effect of triggering carbon magnetism by the presence of

**Table 2** Maximum values of magnetization caused by 1 ppm of the impurities provided the impurities are in the ferromagnetic form

Type of impurity	Maximum magnetization, emu/g	Curie temperature, K	Comment
Iron, $\alpha$ -Fe	0.00022	1045	
Magnetite, $\text{Fe}_3\text{O}_4$	0.000092	860	Ferrimagnetic, Verwey transition at 118 K
Magnetite, $\text{Fe}_2\text{O}_3$	0.00008	880	Ferrimagnetic
Hematite, $\text{Fe}_2\text{O}_3$	0.0000004	950	Canted antiferromagnetic; Morin transition at 260 K
Iron carbide, $\text{Fe}_3\text{C}$	0.00013	483	
Trevorite $\text{NiFe}_2\text{O}_4$	0.00005	860	
Nickel, Ni	0.000055	630	
Cobalt, Co	0.000161	1400	

transition metals was found in extraterrestrial graphite,<sup>[68]</sup> carbon nanotubes,<sup>[69]</sup> and x-ray dichroism experiments on C/Fe layers.<sup>[70]</sup>

In some experimental works on organic compounds,<sup>[71–75]</sup> the authors indicate that the presence of ferromagnetic ions induces carbon ferromagnetism during the synthesis process. The procedure was as follows: charcoal was impregnated with the aqueous solution of cobalt acetate and, after adsorption of cobalt ions, the piece was hydrogenated and heated to 1000 K. Dilute hydrochloric acid treatment at 360 K during 48 h was used to dissolve cobalt from the specimen. After this, the x-ray fluorescence analyser did not detect any cobalt concentration in the carbon specimen. Magnetization measurements, before and after cobalt removal, indicated that the contribution of cobalt ions or cobalt metal in the signal is very small.

## NONMETALLIC IMPURITIES

There are many theoretical and experimental confirmations that, under certain conditions, magnetism arises without transition-metal elements. The best known example of a magnetic *p*-compound is molecular oxygen, which orders in antiferromagnetic fashion at 24 K. Non-metallic impurities, as well as intrinsic defects in metal-free compounds, may offer a path to realizing unique ferromagnetic materials. It is shown, theoretically, that ferromagnetism can be induced in CaO with calcium vacancies,<sup>[76]</sup> boron, carbon, or nitrogen-doped CaO,<sup>[77]</sup> calcium pnictides (i.e., CaP, CaAs, and CaSb with the zinc blend structure). The pnictides are the compounds of phosphorus, arsenic, antimony, and bismuth.<sup>[78]</sup> There are persistent indications of small ferromagnetic moments in CaB<sub>6</sub>,<sup>[79]</sup> that depend on sample stoichiometry and heat treatment<sup>[80]</sup> and are observed in impurity-free disordered thin films.<sup>[81]</sup> Lattice defects were suggested as a source of magnetism in another system with closed-shell configuration, HfO<sub>2-x</sub> films.<sup>[82]</sup>

In the case of carbon, two types of non-metallic impurities are considered. One type is trivalent elements like nitrogen and boron. The other type is hydrogen.

The role of hydrogen is particularly important. The entrapment of hydrogen by dangling bonds at the nanographite perimeter can induce a finite magnetization.<sup>[83]</sup> The same mechanism occurs in the case of hypergraphites, i.e., structures with edges where completely degenerate states appear.<sup>[84]</sup> Combination of the magnetic and non-magnetic edge structures (by means of hydrogenation, fluorination, or oxidation) is proposed as a guiding principle to design magnetic nanographite: a magnetic material made only from

light elements.<sup>[85]</sup> Another model includes absorption of hydrogen atoms on vacancies in graphite<sup>[86]</sup> and nanotubes.<sup>[87]</sup> A simple spin model was used to illustrate the mechanism through which chemically bonded hydrogen leads to a ferromagnetic ground state in polymerized fullerenes.<sup>[88]</sup>

Irradiation with hydrogen ions (protons) was shown to produce ferromagnetic spots on samples of highly oriented pyrolytic graphite. Magnetic force microscope studies showed that a magnetic signal appeared in an irradiated region and that this signal varied in an applied external field. Similar experiments on irradiation with helium ions do not yield a magnetic contrast. The explanations of the effects are based on the formation of di-hydrogenated and mono-hydrogenated edges or on the absorption of hydrogen atoms on irradiation-induced vacancies.

Non-metallic impurities like hydrogen, boron, and phosphorus are suggested to trigger ferromagnetism in diamond.<sup>[89]</sup> It has been shown experimentally that doping nanodiamond with nitrogen (<sup>15</sup>N) and carbon (<sup>12</sup>C) leads to ferromagnetic hysteresis behavior at room temperature. Doping was performed by means of ion implantation. Magnetic moment of nitrogen-implanted samples was higher than that of carbon-implanted samples.<sup>[90]</sup>

## MAGNETIC NATURE OF INTRINSIC CARBON DEFECTS

The magnetic properties of common bulk materials are determined mainly by choice of constituting elements from the periodic table. In nanometer-scale materials, the shapes or boundaries in nanostructures play important roles in determining the characteristics of electron states and generate various types of magnetic interactions, opening a possibility for the creation of nanoscale magnets consisting solely of nonmagnetic elements.<sup>[91]</sup>

The analysis of experimental and theoretical data shows that certain similarities between the magnetism of organic molecules and carbon-based structures can be found.

Long-range magnetic ordering requires the following conditions: the existence of spin carriers, the interaction among these spins, and the propagation of these interactions.

The first obvious problem is the occurrence and, more importantly, stability of carbon radicals. There are two ways to obtain unpaired spins in organic molecules.<sup>[92]</sup>

One way is based on the charge transfer process between the electron donor and the electron acceptor. The resulting open shell anions and cations bear unpaired spins.

**Fig. 2** Magnetic nature of intrinsic carbon defects. (A): vacancy in graphite; (B): hydrogenated vacancy on graphite; (C): pentagon-one dangling bond; (D): zigzag edge carbon atoms; (E): Stone–Wales defect.

Another method of obtaining open shell molecules is the generation of free radicals. The main problem in this case is the stability of the radicals.<sup>[93]</sup> The stability can be increased by the steric protection of the unpaired electrons, the use of Coulombic electrostatic repulsions to keep the radicals apart, or the introduction of electronegative heteroatoms.

Similar ways have been proposed for the carbon-based materials. Proposed mechanisms leading to the generation of the unpaired electrons are the following:

- Vacancies in graphite, both ordinary (Fig. 2A) and hydrogenated (Fig. 2B), create new states below the Fermi level. The extra  $\pi$ -electrons are induced to the system when vacancies are introduced. For non-interacting vacancies, these extra electrons give rise to an unpaired spin associated with the vacancy.<sup>[94]</sup>
- Formation of pentagon-one dangling bond, also called 5-1db (Fig. 2C).<sup>[95]</sup>
- Edge states appearing on zigzag edge carbon atoms (Fig. 2D).<sup>[96–101]</sup> The localized spins are considered to originate from the nonbonding edge states of the  $\pi$ -electrons.
- Stone–Wales defects<sup>[102]</sup> (Fig. 2E) and related structures with negative Gaussian curvature.<sup>[103]</sup>

Is it realistic to expect ferromagnetism or ferrimagnetism as an intrinsic feature of a pure  $\pi$ -electron system like graphite?

Interaction between the magnetic centers without entering a chemical reaction seems to be the main problem for the organic magnets. Propagation of magnetic interactions largely depends on the arrangement of the radicals in the crystal.

Several strategies have been proposed in order to achieve this spontaneous magnetization:<sup>[92]</sup>

- Orthogonal orbitals.<sup>[104]</sup> When the overlap between the magnetic orbitals is zero, i.e., the orbitals are orthogonal, the magnetic interaction is ferromagnetic whereas, in the case of antiferromagnetic interaction, the kinetic term is dominant.
- Spin polarization (McConnell I mechanism)<sup>[105]</sup> for ferromagnetic coupling (not ordering). This involves a special spatial arrangement of neighboring radicals. Ferromagnetic coupling is expected when a region of negative spin density in one molecule overlaps with a region of positive spin density in another molecule.
- Chains of alternating electron-donor and electron-acceptor species. (McConnell II mechanism).<sup>[106]</sup> This mechanism for ferromagnetic coupling, not ordering, was proposed for charge-transfer salts where the single occupied molecular orbitals of the donor in the neutral state are degenerate. The triplet state of the neutral donor induces a triplet state in the charge-transfer state through a configuration admixing of an excited state with a ground state. Such a triplet state is propagated along the donor-acceptor chain.
- The ferrimagnetic approach is based on the construction of chains containing alternating magnetic centers with unequal spin values. This approach has led to the design of a novel class of organic magnets, coordination polymers.<sup>[107]</sup>
- Weak ferromagnetism<sup>[108,109]</sup> in an antiferromagnetic structure where there exists a canting angle between the magnetic moments of different sublattices with opposite signs of the magnetic moments.

The importance of topologically dependent  $\pi$ -electronic structure is emphasized by Sugawara and Matsushita.<sup>[110]</sup> An arrangement of  $sp^2$  carbons that creates a branched  $\pi$ -system exhibits magnetism due to the appearance of unpaired electrons. The researchers working on creating carbon-based magnets point out the necessity of branched precursors.

A theoretical prediction of a ferromagnetic carbon with magnetization higher than that of  $\alpha$ -Fe was published more than a decade ago.<sup>[111]</sup> The proposed intermediate graphite-diamond structure with alternating  $sp^2$ – $sp^3$  hybridized carbon atoms has never been realized technologically. A possible method for attaining this structure is the creation of defect-containing graphite or diamond structures.

The possibility of ferromagnetism in disordered graphite samples has been predicted on more than one occasion. The underlying mechanism is the existence of unpaired spins at defects, induced by a change in the coordination of the carbon atoms.<sup>[112]</sup> Several works discuss theoretical models that address the effects of electron-electron interactions and disorder in graphene planes.<sup>[113,114]</sup>

It has been shown experimentally that the peculiar, edge-related electronic states in nanographite lead to such novel phenomena as spin glass states, magnetic switching, and edge-state spin gas probing.<sup>[115]</sup> Direct observations of irradiation-induced magnetic ordering in graphite and nanodiamond raise hopes that this effect can lead to a development of a controllable method for producing magnetic carbon materials.

## CONCLUSIONS

Recently, it has become evident that pure carbon can show strong paramagnetism and even ferromagnetism. These properties appear to arise from specific features of the carbon structure and bonding, namely the edge states, dangling-bond states, sterically protected spins, carbon adatoms, and carbon vacancies. Production of bulk quantities of these materials is still at an early stage.

Magnetic systems based on nanostructured carbon are expected to display novel properties not found in metallic systems. There are two fundamental differences. First, the electrons in p-orbitals are delocalized, in contrast to the electrons in d- and f-orbitals. Second, spin-orbit coupling for the light elements is small or negligible. Inconvenient electronic properties of nanocarbon and experimentally observed novel magnetic phenomena are expected to find applications in molecular spintronic, as a large variety of magnetic functions can be produced by modifying its structure on nanoscale. We expect that the desired modifications will be produced by electron beam lithography, chemical modification, ion bombardment, or laser irradiation.

# Magnetic Nanomaterials: Conventional Synthesis and Properties

Dajie Zhang

Center for Nondestructive Evaluation, Johns Hopkins University,  
Baltimore, Maryland, U.S.A.

## INTRODUCTION

Nanophased magnetic materials have wide applications in magnetic recording device,<sup>[1]</sup> ferrofluids,<sup>[2–4]</sup> and biomedical science.<sup>[5–7]</sup> Nanoscale particles are considered to have a size range from 1 to 100 nm. Particles within this size range usually have hybrid properties different from those of the bulk solid or the molecular/atomic species. The unique properties of nanoscale particles can be attributed to two basic phenomena. The first is that the number of atoms at the surface and/or interface in these materials is comparable to that of atoms located in the crystal lattice. Therefore the chemical and physical properties, which are normally determined by the structure of the bulk lattice, become increasingly dependent upon the atoms at the surface and interface. The high number of atoms on the surfaces of nanoparticles form a layer of “damaged” lattice with a higher energy state; therefore these particles are highly unstable and more reactive. The second phenomenon is the “quantum-size effect” or “quantum confinement effect.” When particles approach the nanometer-size range, their electronic and photonic properties can be significantly modified as a result of the absence of a few atoms in the lattice and the regional relaxation of the lattice structure.<sup>[8,9]</sup>

The small size and rich surface/interface structure of magnetic nanomaterials can lead to properties quite different from those of the bulk. Studies on magnetic nanomaterials will not only provide information about the structure–property relations of magnetic nanomaterials but also help generating new ideas and technologies for the fabrication and application of these materials. The first part of this review will describe common fabrication techniques for magnetic nanomaterials. The second part will give a brief introduction to the theoretical aspects of fine particle magnetism; experimental results on some of these topics will also be discussed.

## FABRICATION OF MAGNETIC NANOMATERIALS

Magnetic nanomaterials can be categorized into three types based on their structural and compositional characteristics. The first types are magnetic nanoparticles or clusters. They are free-flowing magnetic powders of nanometer sizes. The second types of magnetic nanomaterials are nanostructured or nanophased magnetic materials. They are either bulk magnetic materials with nano-sized grains, or magnetic nanoparticles/clusters embedded in random within a non-magnetic bulk matrix. The later are often called magnetic nanocomposites. The third types of magnetic nanomaterials are nano-sized magnetic particles or magnetic “dots” organized in either two- or three-dimensional arrays in a long-range order. The various types of magnetic nanomaterials require different fabrication techniques; and in many cases, several techniques are combined to obtain a certain type of material.

Magnetic nanoparticles of metals, such as iron, cobalt, and nickel, can be prepared in many ways. The biggest challenge is to protect these particles from oxidation. The traditional methods for the preparation of ultrafine iron, cobalt, or nickel particles include the inert-gas evaporation method and the chemical reduction method. Small iron particles can be generated by evaporating iron metal in an inert gas atmosphere<sup>[10]</sup> or by chemical reduction of iron ions in solution or iron compounds in solid state. The obtained magnetic metal particles were stabilized by slowly exposing them to oxygen over a long period of time to form a layer of oxides on the surfaces of the particles. The common disadvantage of these methods is the reduction of average magnetization intensities of the particles. Iron particles obtained usually have magnetization intensities of about 700 to 900 emu/cm<sup>3</sup> and consist of as much as 50% to 70% of oxides by volume. Coating the surface of small magnetic metal particles

with a non-magnetic matrix to protect them from oxidation is a useful method to obtain air-stable nano-scale magnetic metal particles.<sup>[11]</sup> These coating materials can be metals, oxides, polymers, and surfactants. When metallic coating materials are used, these metals should be immiscible with iron, cobalt, or nickel, or intermetallic alloys would be formed which contain no single-phase nano-sized clusters of pure iron, cobalt, or nickel.

There are two important methods to fabricate small Fe, Co, or Ni clusters homogeneously within a matrix of coating material. The first is the coevaporation method. Fe, Co, or Ni can be coevaporated with a second component, which can be a metal, an oxide, or other types of materials. The evaporation is carried out either in vacuum or in an inert atmosphere. Electric heating is usually the first choice, while other heating methods such as sputtering can be applied to evaporate materials that are not easily evaporated by electric heating. Particle size can be selected from 1 to 1000 nm by controlling the pressure of the inert gas, the type of gas, and the evaporation rates of the starting materials. The diameter of the particles produced is roughly proportional to the pressure of the inert gas and the atomic weight of the gas. If evaporation rate is raised, the distribution of particle size becomes wider and the average particle size increases. Examples for the evaporation-produced particles include iron grains of sizes from 5 to 8 nm dispersed in an amorphous  $\text{Al}_2\text{O}_3$  matrix by cosputtering Fe and  $\text{Al}_2\text{O}_3$ ,<sup>[12]</sup> Fe– $\text{SiO}_2$  and Fe–BN granular solids obtained from Fe,  $\text{SiO}_2$ , and BN targets by using RF magnetron sputtering,<sup>[13]</sup> Fe(Co)/Ag particles with Fe of about 17 nm and Co of about 110 nm, and Fe/Mg particles with Fe of about 2.6 to 40 nm.<sup>[14]</sup>

Mechanical alloying, also known as high-energy ball milling, is another effective way to obtain a homogeneous mixture of two materials immiscible under normal conditions. The starting materials are fine powders in the sizes of a few to a few hundreds of microns produced by conventional methods. Often, the starting materials are either a mixture of a magnetic material and a non-magnetic matrix material, or a mixture that would undergo chemical reactions under milling to produce a magnetic phase. If no chemical reactions occur during the milling process, depending on the time of milling and energy applied, the as-milled samples can be either atomic mixtures of the starting materials or mixtures of small clusters of the starting materials, in which one or both of the components still maintain a short-range order. Heat treatment can be applied to the as-milled samples to introduce phase separation and increase the grain sizes. Examples of samples produced by mechanical alloying include Fe– $\text{SiO}_2$  nanocomposite materials,<sup>[15]</sup>  $\text{Al}_{100-x}\text{Fe}_x$  amorphous powder,<sup>[16]</sup>  $\text{Fe}_{100-y}\text{M}_y$  powder blends

with  $\text{M} = \text{Al}$ ,  $\text{Si}$ , and  $\text{Cu}$  and  $y < 50$ ,<sup>[17]</sup> nanocrystalline  $\text{Ni}_3\text{Al}$ ,<sup>[18]</sup> and  $\text{Sm}_2\text{CO}_{17}$  alloy nanoparticles and  $\text{BaFe}_{12}\text{O}_{19}$  synthesized by a mechanochemical process.<sup>[19,20]</sup>

The melt-spun method, which is a liquid-quenching technique, is often used to produce nanostructured magnetic materials such as amorphous or granular Fe-, Co-, or Ni-based metastable alloys. Fe-based nanostructured alloys were usually prepared with this method.<sup>[21,22]</sup> The amorphous alloys were prepared by arc melting of Fe together with a non-magnetic metal, followed by melt spinning in an inert atmosphere. Melt-spun techniques can produce metastable alloys of metals that are normally immiscible in liquid state. Heat treatment can later be applied to induce phase separation and grain growth of the metals.

Chemical reactions, such as liquid-phase reduction of metal ions,<sup>[23,24]</sup> hydrogen reduction of metal salts,<sup>[25]</sup> decomposition of organometallic compounds,<sup>[26,27]</sup> and hydrothermal or radiation-assisted reactions,<sup>[28,29]</sup> are very useful methods to produce amorphous metal powders or nanometer-sized metal crystallites. Simple chemical coprecipitation reactions are an economical way to produce various types of nanometer-sized oxides or mixed oxides magnetic particles such as iron oxides or ferrites.<sup>[30–33]</sup> Zeolites and graphitic materials are good matrices for the encapsulation of angstrom-sized metal clusters. Cobalt clusters of 7 Å were incorporated into zeolites by first subliming cobalt carbonyl compound  $\text{Co}_2(\text{CO})_8$  onto dehydrated Na-X zeolite at room temperature, and later decomposing the cobalt carbonyl compound by using an argon microwave plasma.<sup>[34]</sup> Superparamagnetic Fe particles with a size of about 4 Å dispersed in graphite matrices were also prepared by incorporating iron carbonyl compound  $\text{Fe}(\text{CO})_5$  and  $\text{Fe}_2(\text{CO})_9$  into matrix materials followed by thermal decomposition of the iron carbonyls.<sup>[35]</sup> Clusters of up to 28 Fe atoms were introduced into the supercages of NaY zeolite by ion exchange of  $\text{Fe}^{2+}$  for  $\text{Na}^+$  followed by reduction to  $\text{Fe}^0$  with solvated electrons and  $\text{Na}^-$  ions.<sup>[36]</sup> Small clusters of Fe were also fabricated within the pores of ZSM-5 zeolite.<sup>[37]</sup>

Metal clusters can also be coated with another metal by chemical reduction methods. Chatterjee et al.<sup>[38]</sup> produced iron particles with diameters of around 8 nm loosely packed within nanometer-sized copper particles by hydrogen reduction at 450°C of gel powders obtained from the aqueous solutions of ferric nitrate and copper nitrate. The chemical reduction of gels containing nickel and palladium salts also produced Pd-coated Ni nanoparticles.<sup>[39]</sup>

A sol–gel route followed by reduction treatment is an effective technique to produce metal–glass and metal–ceramic nanocomposites. For the preparation of Fe– $\text{SiO}_2$  or Ni– $\text{SiO}_2$  nanocomposites, hydrated Fe

or Ni chlorides or nitrates and an appropriate amount of silicon tetraethoxide were mixed into an alcohol-water solution and a clear gel was formed after a few hours or a few days. The gel was then dried and ground into small particles. Chemical reductions in a hydrogen atmosphere at high temperatures (500–800°C) were carried out to produce metal clusters within the silica gels. Metal particles with diameters ranging from a few to a few tens of nanometers could be obtained. Varying the metal ion concentrations and reduction temperature<sup>[40]</sup> can control the sizes of the metal particles.

The formation of alumina, aluminosilicate/iron, cobalt, and nickel magnetic nanocomposites followed a slightly different route.<sup>[41]</sup> Porous gels of alumina or aluminosilicate were prepared first. Then the metallic phase was introduced by immersing the gels in aqueous solutions of metal nitrates (iron, cobalt, or nickel nitrates) to allow the diffusion of metal ions into water trapped within the pores of the gels. After heat treatment in hydrogen at 600°C, nanocomposites with iron, cobalt, or nickel clusters of 5 to 70 nm were obtained.

Microemulsion is one of the latest techniques explored to prepare encapsulated magnetic clusters. Surfactant, S, dissolved in organic solvents, can form spherical aggregates.<sup>[42]</sup> These aggregates can be formed with and without the presence of water. When the medium is completely free of water, the aggregates are very small and polydisperse. Large and monodisperse surfactant aggregates can be formed in the presence of water. The amount of water present in the medium usually determines the sizes of the aggregates. As water molecules are attracted to the polar ends of the surfactants, a “water pool” is formed in the polar core of the surfactant aggregates, with its size being determined by the water-surfactant molar ratio  $w$  ( $w = [\text{H}_2\text{O}]/[\text{S}]$ ). According to Pileni,<sup>[43]</sup> aggregates containing only a small amount of water ( $w < 15$ ) are usually called reverse micelles, and they are called microemulsions when a large amount of water molecules ( $w > 15$ ) is contained in the droplets. However, the terms reverse micelle and microemulsion are often used as an equivalent description without the consideration of the values of the water-surfactant molar ratios.

The water-in-oil structure of reverse micelles makes them microreactors that can host chemical reactions to produce nanometer-sized inorganic clusters.<sup>[44]</sup> Coprecipitation reactions inside reverse micelles can produce nanometer-sized particles of compounds such as quantum-confined semiconductor clusters, and chemical reduction of metal ions performed in micelle solutions can produce surfactant-coated metal clusters. Rivas et al.<sup>[45]</sup> prepared iron particles with a diameter of less than 100 nm by using microemulsions consisting

of an aqueous solution, *n*-heptane, and surfactant AOT (Bis-2-ethyl hexyl sodium sulphosuccinate). At first two microemulsions were prepared, one with FeCl<sub>2</sub> and the other with the reducing reagent NaBH<sub>4</sub>. Then the two microemulsions were mixed and the chemical reduction took place through the exchange of matter by diffusion between the different droplets. A high-temperature reduction in hydrogen was later carried out at 500°C to prevent unwanted oxidation. Chen et al.<sup>[46]</sup> synthesized cobalt particles in the size range of 18 to 44 Å in diameter with the microemulsion technique. First, CoCl<sub>2</sub>·6H<sub>2</sub>O was dissolved in an 11 wt.% didodecyldimethylammonium bromide (DDAB) solution in toluene at concentrations of 0.005 to 0.02 M, where DDAB is a cationic surfactant. A blue solution was formed with Co<sup>2+</sup> ions trapped in H<sub>2</sub>O/DDAB micelles. Then an aqueous solution of NaBH<sub>4</sub> was added to reduce the Co<sup>2+</sup> ions into metallic cobalt particles. The small cobalt particles were coated with a layer of DDAB surfactant molecules when the toluene was removed. Other examples of magnetic nanoparticles synthesized in water-in-oil microemulsions include stable colloidal Fe<sub>3</sub>O<sub>4</sub> particles<sup>[47]</sup> and ultrafine barium ferrite powders.<sup>[48]</sup>

The latest effort in the production of nanophased magnetic materials involves the fabrication of highly ordered two- or three-dimensional nanophased magnetic material arrays or nanowires.<sup>[49–51]</sup> Such efforts will aid the development of magnetic devices based on magnetic nanomaterials, such as high-density magnetic storage media. When magnetic nanoparticles/nanowires uniform in size/shape are arranged into an ordered structure with identical spacing, each of these nanoparticles/nanowires could act as a single bit. This could greatly enhance the memory capacity of the magnetic device.

There are three general approaches that could lead to the formation of ordered magnetic nanostructures. The first approach is based on the tendency of some magnetic colloidal nanoparticles to settle into a long-range ordered structure through self-organization. Magnetic particles with uniform morphology and a narrow size distribution can be dispersed in a solvent, either with or without the aid of a surfactant. When such a dispersion of magnetic nanoparticles is placed on a solid substrate and let dry under controlled conditions (temperature, atmosphere), particle arrays of two- or three-dimensional long-range order can be formed through particle self-assembly when the solvent is removed. Cobalt nanoparticle arrays have been fabricated via such a process.<sup>[52,53]</sup> The second approach is the formation of ordered magnetic nanostructures with the aid of a template. Well-organized arrays of silica spheres of uniform size can be formed through the hydrolysis of Si(C<sub>2</sub>H<sub>5</sub>O)<sub>4</sub>. Under appropriate reaction conditions, perfect spherical microparticles with very

small size distribution can be formed.<sup>[54]</sup> These micro-particles of silica will form an array with periodic surface geometry when allowed to settle onto a glass substrate by natural sedimentation. Cobalt film was first grown onto the surface of the silica array by ultrahigh-vacuum electron-beam evaporation, then the formed cobalt film was allowed to undergo a controlled oxidation process. The oxidation will fully convert the thinner Co films on the side regions of the spheres into cobalt oxide but leave the thicker Co films on the top of the spheres only partially oxidized to allow the formation of an ordered array of isolated metallic cobalt “magnetic dots.”<sup>[54]</sup> Three-dimensional cobalt nanocrystal arrays were also deposited from a suspension of cobalt nanocrystals onto a highly oriented graphite substrate with the aid of an applied magnetic field parallel to the substrate.<sup>[55]</sup> When a magnetic field was not present during the deposition, the deposited films showed no long-distance order for the cobalt nanocrystals. With the presence of an applied magnetic field, the deposited cobalt nanocrystals formed regular stripe patterns.<sup>[55]</sup> Alumina membranes with ordered pore arrays could serve as templates for the formation of magnetic nanowire arrays. Such porous alumina films can be formed by the anodization of aluminum. Well-organized pores with diameters of nanometer in size and micron in length can be obtained within these films. Magnetic nanowire arrays of Fe, Co, and Co–Cu alloy were fabricated within the alumina pores by electrochemical deposition.<sup>[56–59]</sup> Nuclear track-etched polycarbonate membranes also have pore structures similar to those of anodized aluminum films; therefore they can also serve as templates for the formation of magnetic nanowire arrays.<sup>[60,61]</sup> However, unlike alumina templates, polycarbonates cannot allow annealing after the nanowires are formed.

The most practical and versatile method for the fabrication of nanomagnetic arrays may be the nanolithography process. Magnetic dots can either be evaporated onto a template produced by electron or ion-beam etching, or by etching of predeposited metal films on a substrate through a resist.<sup>[62,63]</sup> Scanning tunneling microscopy (STM) and atomic force microscopy (AFM) can also be employed to aid the formation of ordered nanoscale magnetic structures. In such processes, particles are deposited one by one with the aid of the STM or AFM tip.<sup>[64,65]</sup>

## PROPERTIES

### Magnetic Domain and Superparamagnetism

All magnetic effects are derived from the movements of particles that have both mass and electric charge.

These particles include electrons, holes, protons, as well as positive and negative ions. A spinning electric charged particle is called a magneton, or a magnetic dipole. The magnetic moment of an atom is the vector sum of all its electronic moments. Diamagnetism arises when the magnetic moments of all the electrons of an atom are so oriented that they cancel one another out, so the atom as a whole does not possess a net magnetic moment. When cancellation of electron moments is only partially achieved, the atom will have a net magnetic moment. The varieties of magnetism arise from the different magneton alignments. Based on its magnetic behavior toward an applied field, a magnetic matter can be described as paramagnetic, antiferromagnetic, ferromagnetic, or ferrimagnetic.<sup>[66]</sup>

In ferromagnetic materials, magnetons are associated in groups. A magnetic domain (also called a Weiss domain) refers to a volume of ferromagnetic material in which all magnetons are aligned in the same direction by the exchange forces. The concept of domains distinguishes ferromagnetism from paramagnetism. Also, the domain structure of a ferromagnetic material determines the size dependence of its magnetic behavior. When the size of a ferromagnetic material is reduced below a critical value, it would become a single domain. Fine particle magnetism has traditionally dealt with size effects, which are based on the magnetic domain structure of ferromagnetic materials. It assumes that the state of lowest free energy of ferromagnetic particles has uniform magnetization for particles smaller than a certain critical size and non-uniform magnetization for large particles. The former ones are generally referred to as single-domain particles, while the latter are called multidomain particles. In earlier studies, Kittel<sup>[67,68]</sup> estimated the critical single-domain size for spherical particles of some ferromagnetic materials to be roughly 150 Å. Kittel and his colleagues were also the first to clearly show the existence of single-domain particles through experiment.<sup>[69,70]</sup> According to the magnetic domain theory, the critical size of the single domain is affected by several factors including the value of the magnetic saturation, the strength of the crystal anisotropy and exchange forces, surface or domain-wall energy, and the shape of the particles.<sup>[67,71]</sup>

In magnetic studies on fine particles, the coercivity is the single property of most interest. It must be at least above several hundred oersterds (Oe) to be of any value for permanent magnetic application. The coercivity of fine particles is a good example for size-dependent characteristics. It has been found that as the particle size is reduced, the coercivity increases to a maximum, and then decreases toward zero (Fig. 1).<sup>[70,72]</sup> Although the magnetic behavior of small particles has not been fully understood, certain relationship between particle size and coercivity has

**Fig. 1** Schematic illustration of the coercivity–size relations of small particle systems. *Source:* From Refs.<sup>[70], [72]</sup>.

been established based on a uniaxial and monodispersed non-interacting particle system. As the particle size decreases below single-domain, the coercivity  $H_C$  of such particles is<sup>[70,71]</sup>

$$H_C = H_C(0)[1 - (D_S/D)^{3/2}] \quad (1)$$

and  $H_C(0)$  is given as  $2K/M_S$ , where  $D_S$  is the critical size for single-domain behavior,  $D$  is the particle size,  $H_C(0)$  is the coercivity when temperature  $T$  approaches zero,  $K$  is the anisotropy constant, and  $M_S$  is the saturation magnetization. Another version of the coercivity of single-domain particles, showing its temperature dependence, is written as<sup>[70]</sup>

$$H_C = H_C(0)[1 - (T/T_B)^{1/2}] \quad (2)$$

where  $T_B$  is the blocking temperature for ferromagnetism–superparamagnetism transition.

Single-domain size could be experimentally estimated when the coercivity reaches a maximum. Gong et al.<sup>[73]</sup> studied the magnetic properties of Fe, Co, and Ni ultrafine particles prepared by evaporation in an inert atmosphere. They found that the maximum  $H_C$  was 450, 1000, and 1500 Oe, respectively, for Ni (310 Å), Fe (210 Å), and Co (200 Å) at room temperature. They also calculated the sizes of these particles based on formula given by the domain theory, and the results were 424 Å (Ni), 196 Å (Fe), and 192 Å (Co), respectively. Zhang, Klabunde, and Sorensen<sup>[74]</sup>

**Fig. 2** Size and temperature dependence of coercivities of iron crystallites in the [Mg]Fe systems. *Source:* From Ref.<sup>[74]</sup>.

examined the coercivities of [Mg]Fe particles at various temperatures. Coercivities reached maximum for Fe with size of about 20 nm (Fig. 2) for all the temperatures. Such behavior of coercivities was also observed in granular solids consisting of a magnetic element and a non-magnetic matrix, such as Fe–SiO<sub>2</sub><sup>[75]</sup> and Fe<sub>x</sub>Cu<sub>1-x</sub>.<sup>[76]</sup> In these magnetic granular solids, coercivity first reaches a maximum with the increase in the concentration of the magnetic element, then gradually decreases with the further increase in the magnetic element concentration. The behaviors of coercivities of granular solids could also be considered as a size effect. With the increase of concentration of the magnetic phase, the average size of the magnetic grains within these materials could increase from below single-domain size, through single-domain size, to multidomain size.

When the size of single-domain particles further decreases below a critical diameter, the coercivity becomes zero, and such particles become superparamagnetic. Thermal effects cause superparamagnetism. In superparamagnetic particles, thermal fluctuations are strong enough to spontaneously demagnetize a previously saturated assembly of particles. A superparamagnetic specimen has zero retentivity and coercivity. Therefore it has no hysteresis. Also, magnetization curves measured at different temperatures superimpose when  $M$  is plotted as a function of  $(H/T)$ .<sup>[70]</sup> These two aspects were well illustrated by the magnetic behavior of fine iron particles dispersed in solid mercury.<sup>[77]</sup>

Superparamagnetic behavior arises from the time-dependent thermal relaxation process of ferromagnetic materials. If a magnetic particle is very small (typically  $\leq 100$  Å), it will exhibit serious thermal relaxation effects which tend to reduce the coercivity force and lead to a time-dependent magnetization. For isolated uniaxial single-domain particles with negligible interactions, the Néel–Arrhenius law gives the relaxation time of the magnetic moment in zero-field:<sup>[71]</sup>

$$\tau = \tau_0 \exp(KV/k_B T) \quad (3)$$

In Eq. (3)  $\tau_0$  is a frequency factor related to gyromagnetic precession and is often taken as  $\tau_0 \cong 10^{-9}$ – $10^{-13}$  sec,  $K$  is the effective anisotropy constant,  $V$  is the particle volume, and  $k_B$  is Boltzmann's constant. For a bulk ferromagnetic material, the thermal relaxation time is much higher than the measurement time. When the relaxation time reaches the measurement time due to the decrease of particle size, the transition from ferromagnetic behavior to superparamagnetic behavior occurs.

The intrinsic time-dependent behavior of ferromagnetic materials at finite temperatures can be used to predict the critical size and the blocking temperature for superparamagnetism. However, this basic theory based on the Néel model of single-particle system is often insufficient to describe magnetic relaxation process because of the complex nature of most magnetic systems. In real systems, factors affecting the time-dependent relaxation of single-domain particles include particle size distribution,<sup>[78]</sup> anisotropy energy distribution,<sup>[79–81]</sup> dipole–dipole coupling between particles,<sup>[82–84]</sup> and the presence of an applied field.<sup>[85,86]</sup> For an individual real system, experimental results and theoretical studies are often combined to determine the dominating factors in the relaxation process in order to achieve the best description. The existence of a distribution of energy barriers leads to a logarithmic decay of magnetization in time and can be described as<sup>[83,87]</sup>

$$M(t) = M_0 - S \ln(t) \quad (4)$$

where  $S$  is called magnetic viscosity. For a system of particles with a distribution of anisotropy energies, there will be a distribution of blocking temperatures. For a measurement time  $\tau$ , the Néel law gives the median blocking temperature,  $T_B$ , as<sup>[86]</sup>

$$T_B = \frac{KV}{k_B [\ln(\tau/\tau_0)]} \quad (5)$$

When two measuring times  $\tau_1$  and  $\tau_2$  are selected, two median blocking temperatures  $T_{B1}$  and  $T_{B2}$  will be

obtained as

$$\frac{T_{B1}}{T_{B2}} = \frac{\ln(\tau_2/\tau_0)}{\ln(\tau_1/\tau_0)} \quad (6)$$

both  $\tau_0$  and the anisotropy energy  $KV$  can be determined.<sup>[86]</sup> For a system of previously saturated uniaxial particles with an applied field  $H$  along the easy axis, the relaxation time is given by<sup>[85]</sup>

$$\tau = \tau_0 \exp \left[ \frac{KV}{k_B T} \left( 1 - \frac{H}{H_K} \right)^2 \right] \quad (7)$$

where  $H_K$  is anisotropy field. For interacting particles, magnetic relaxation is a Curie-Weiss behavior and is described by a Vogel–Fulcher law<sup>[83]</sup>

$$\tau = \tau_0 \exp \left[ \frac{KV}{k_B T(T - T_0)} \right] \quad (8)$$

where  $T_0$  is the spin freezing temperature.

### Magnetization Temperature/Size Dependence and the Bloch Law

According to Bloch, the magnetization due to spin wave fluctuation is described as<sup>[88]</sup>

$$M(T) = M(0)(1 - BT^b) \quad (9)$$

In Eq. (9),  $M(T)$  is the temperature-dependent magnetization,  $B$  is the Bloch constant and  $b$  is the Bloch exponent. The exponent is given by  $b = 3/2$  for a three-dimensional bulk system and has been well defined.

By using calculation on spin waves, Mills and Maradudin<sup>[89–91]</sup> found Bloch exponent remained  $b = 3/2$  for “non-bulk” surface materials, and the Bloch constant for the surface was expected to be twice that of the bulk. By using spin wave simulations, Wildpaner et al.<sup>[92,93]</sup> studied particles of various sizes and found stronger temperature dependencies with decreasing size, and the magnetization temperature relation did not fit Eq. (9). More importantly, spin excitations were found to be inhomogeneous through the particle. Hendriksen, Linderoth, and Lindgård<sup>[94]</sup> considered the spin wave spectrum of nanometer-sized particles by solving the Heisenberg Hamiltonian. Again the excitations were a function of radial position in the particles, and the overall result was a prediction that the exponent  $b$  should increase above the bulk value of  $3/2$  inversely proportional to the particle size.

Experimental investigations of  $M(T)$  for nanoparticles gave a mixed story. Pierce et al.<sup>[95]</sup> studied the magnetization of macroscopic surfaces and found

results consistent with Mills and Maradudin. Linderoth et al.<sup>[96]</sup> followed up their calculations<sup>[94]</sup> with a measurement on Fe–C particles with a diameter of 3.1 nm and found  $b = 1.9$  in qualitative agreement with their theory. Xiao and Chien<sup>[97]</sup> studied iron imbedded in SiO<sub>2</sub> at ~50% volume fraction. The iron particle size was 2–3 nm. They found  $b = 3/2$  with  $B_{\text{surf}} \cong 10 B_{\text{bulk}}$ . Chen et al.<sup>[98]</sup> studied MnFe<sub>2</sub>O<sub>4</sub> particles and found  $b$  in the range 1.5–1.9 for sizes in the range 5–15 nm.

The effect of particle size on magnetization of magnetic nanoparticles has to be taken into consideration when magnetization–temperature dependencies of particles of various sizes are studied under various temperatures. In experimental investigations, the average magnetic moments of the magnetic atoms in these particles are either found enhanced or depressed compared to those of the atoms in bulk materials. Billas, Châtelain, and de Heer<sup>[99]</sup> used a molecular beam deflection method to study the magnetic moment of small Fe, Co, and Ni clusters containing several tens to several hundreds of atoms at temperatures between 80 and 1000 K. They found that clusters with fewer than 400 atoms generally had larger magnetic moments than the bulk. Douglas et al.<sup>[100]</sup> studied the magnetic properties of free cobalt clusters with a similar method, and they found an internal magnetic moment per atom of  $2.24 \pm 0.14 \mu\text{B}/\text{atom}$  for cobalt

clusters containing 65 to 215 atoms, which is substantially higher than the bulk value of cobalt.

Coevaporation of a magnetic metal with a non-magnetic matrix material can produce very small magnetic metal clusters embedded within the non-magnetic matrix.<sup>[101]</sup> This not only provides oxygen-free nanometer-sized magnetic clusters that can be studied in air but can also produce magnetic nanoparticles with various sizes by annealing these matrix-isolated metal clusters at different temperatures. Zhang et al.<sup>[102–104]</sup> prepared BCC-Fe nanoparticles by coevaporating Fe with Mg or MgF<sub>2</sub> in a pentane vapor, followed by annealing at various temperatures ranging from 100 to 600°C. Low-temperature annealing (below 430°C) produced a series of Fe nanoparticles ranging from 3 to 18 nm, as confirmed by XRD and TEM. The SQUID magnetometer was used for magnetic measurements. The saturation magnetization  $M_S$  was determined by  $H^{-1} \rightarrow 0$  extrapolation using fields of  $H \leq 55 \text{ K Oe}$  (Figs. 3 and 4). Both the [Mg]Fe and [MgF<sub>2</sub>]Fe systems show increasing temperature dependencies of  $M_S$  with decreasing particle size. The concave upward dependence of  $M_S$  vs.  $T$  in Fig. 4 for the 3-nm-diameter [MgF<sub>2</sub>]Fe sample even indicates a Bloch exponent  $b < 1$ . The [MgF<sub>2</sub>]Fe samples also show a significant magnetization quench, especially for smaller particles. It is believed that this quench is

**Fig. 3** Saturation magnetization vs. temperature for different size iron crystallites in the [Mg]Fe systems. *Source:* From Ref.<sup>[102]</sup>.

**Fig. 4** Saturation magnetization vs. temperature for different size iron crystallites in the [MgF<sub>2</sub>]Fe systems. *Source:* From Ref.<sup>[102]</sup>.

**Fig. 5** Saturation magnetization depression relative to its values at  $T = 0$  K vs. temperature for different size iron crystallites in the  $[\text{Mg}]\text{Fe}$  system. *Source:* From Ref.<sup>[102]</sup>.

**Fig. 6** Saturation magnetization depression relative to its values at  $T = 0$  K vs. temperature for different size iron crystallites in the  $[\text{MgF}_2]\text{Fe}$  system. *Source:* From Ref.<sup>[102]</sup>.

due to an electron donation from  $\text{MgF}_2$  coating material to the unfilled minority d band of the iron.

Double logarithmic graphs of the magnetization depression vs.  $T$  were plotted for both the  $[\text{Mg}]\text{F}$  and  $[\text{MgF}_2]\text{Fe}$  systems (Figs. 5 and 6). The form of Bloch law [Eq. (9)] implies that the magnetization depression  $M_S(0) - M_S(T)$  is a power law with temperature ( $T$ ). Thus if Bloch law holds, a double logarithmic graph of these quantities will yield straight lines, the slopes of which will be the Bloch exponent  $b$  and with intercepts related to  $BM_S(0)$ . The data presented all fall in line to imply that Bloch's law holds for these particles.<sup>[102]</sup>

Linear fit of Eq. (9) to the data also yielded the Bloch parameters  $b$  and  $B$  plotted in Figs. 7 and 8. The results of both the  $[\text{Mg}]\text{Fe}$  and  $[\text{MgF}_2]\text{Fe}$  systems indicated that nanoparticles still obey the Bloch law, but with decreasing size, the Bloch exponent  $b$  falls from the bulk value of  $b = 3/2$  to smaller values, while the Bloch constant rises from the bulk values by orders of magnitude.<sup>[102]</sup> Also, the chemistry of the interface can affect the size-dependent properties of  $M(T)$ . Recent studies on the magnetic properties of oxide-coated iron nanoparticles by Banerjee et al.<sup>[105]</sup> provided some quantitative agreement to the results on the  $[\text{Mg}]\text{Fe}$  and  $[\text{MgF}_2]\text{Fe}$  systems. Four oxide-coated Fe samples, with sizes of 4.9, 5.5, 9.5, and 11.1 nm, were synthesized by an electrodeposition

**Fig. 7** Bloch exponent  $b$  as a function of iron crystallite size. Dashed line is the bulk value. *Source:* From Ref.<sup>[102]</sup>.

**Fig. 8** Bloch constant  $b$  as a function of iron crystallite size. Dashed line is the bulk value. Source: From Ref.<sup>[102]</sup>.

method. For the samples with the sizes of 4.9 and 11.1, the values of the Bloch exponent  $b$  were 0.79 and 1.1, both smaller than the bulk value of 3/2. The saturation magnetization values of these samples were also found depressed as compared with the theoretical value.

For a three-dimensional bulk system at a low temperature, Bloch law can also be written as<sup>[106]</sup>

$$M(T) \cong M(0)(1 - BT^{3/2} - CT^{5/2}) \quad (10)$$

Curve fitting by using the original Bloch law equation could give  $b \cong 2$ . And this may explain why  $b$  was near 2 in some nanoparticle systems such as Fe-C<sup>[96]</sup> and Ni.<sup>[107]</sup> Bloch's  $T^{3/2}$  law is based on an infinite ideal three-dimensional system and it is not always suitable for all real systems. The foundation of the Bloch law based on classical theories of solid-state physics should still hold for magnetic nanomaterials. However, the unique characteristics of the nanostructured materials should also be addressed when these theories are employed to describe the behaviors of nanomaterials. For a thin film, one of its dimensions is limited, for a nanowire, two dimensions could be reduced, and for very small particles, all three dimensions may be reduced. Nanoparticle systems have a high surface volume fraction. In order to emphasize the two-dimensional nature of the surface, Bloch law could be written as

$$M(T) = M_{\text{core}}(0)(1 - BT^{3/2}) + M_{\text{surface}}(0) \times (1 - CT) \quad (11)$$

If magnetic coupling exists between the surface and the soft core, and the surface becomes dominant in determining the overall magnetization process of the particle, then Bloch law could also be written as

$$M(T) \cong M(0)(1 - BT) \quad (12)$$

And for extremely long magnetic nanowires, they could be considered as one-dimensional systems and  $M(T)$  could be linear to  $T^{1/2}$ .

### The Effect of Particle Shape on Magnetic Properties

Single-domain magnetic nanoparticles can become the building blocks of high-density magnetic memory devices.<sup>[108–110]</sup> However, merely decreasing the size of the memory bits would not be adequate to form high-density magnetic recording systems. The signal/noise ratio is another important factor determining the quality of magnetic memory. For ordered single-domain magnetic particle arrays to become desirable magnetic memory elements, they should have both high remanence and high coercivity. Remanence and coercivity are determined by anisotropy forces, which are affected by many factors. One of the important anisotropies is shape anisotropy, which is directly associated with the shape of the nanomagnet.

Most magnetic nanoparticles in the size ranges of several nanometers do not have well-defined shapes and often appear spherical. Spherical particles do not have shape anisotropy; therefore their shapes do not affect important magnetic properties such as coercivity, remanence, hysteresis, and susceptibility. Studies of larger particles with stable and defined non-spherical geometric shapes could reveal the influence of shape on magnetic properties due to shape anisotropy. Arrays of magnetic particles in the size range from 35 to 500 nm with nearly uniform shapes and identical sizes were fabricated by using high-resolution electron beam lithography with a standard lift-off pattern transfer process.<sup>[111]</sup> The shapes of nanomagnets in these arrays include elliptical, triangular, square, pentagonal, and circular geometries, and adequate spacing between particles was allowed for some arrays to eliminate interparticle interaction. The influence of size, shape, and thickness on the magnetic properties of these nanomagnets was carefully examined with both theoretical modeling and experimental measurement by Cowburn.<sup>[111]</sup> It was found that there were two distinct phenomena that could be attributed to the shape and size effects on magnetic properties. The first is the small deviations from uniformity in the magnetization field within the nanostructures. Such deviations could give rise to higher-order anisotropy terms due to

configurational anisotropy, and these anisotropies could dominate the overall magnetic properties. The second phenomenon is the existence of competition between quantum mechanical exchange energy and classical magnetostatic energy. This competition will not only determine whether a nanoparticle exhibits single-domain behavior, but also control configurational anisotropy by defining non-uniformity in magnetization.

For smaller circular nanomagnets of 100 nm in diameter and 10 nm in thickness, hysteresis loops showed a high remanence and a low switching field, which is typical single-domain behavior. For larger circular nanomagnets of 300 nm in diameter and 10 nm in thickness, hysteresis loops showed a sudden loss of magnetization at near zero-field. This phenomenon indicates a “flux-closing” configuration that may be characterized by a “vortex” phase in which the magnetization vectors were parallel to the nearest edges at all positions along the particle surfaces. The hysteresis loops of magnetic arrays containing thin triangular, square, and pentagonal nanomagnets were very different from each other; and they were also different from the loops of conventional unstructured material. The multifold anisotropy fields of these materials were attributed to a phenomenon called configurational anisotropy, which was associated with the geometric shapes of the nanomagnets. The elliptically shaped nanomagnets clearly showed easy-axis behavior characterized by high remanence and high coercivity; therefore they are the best choice for patterned nanomagnet arrays.<sup>[111]</sup> He et al. compared the magnetization behaviors of single-domain and multidomain, square and elliptical cobalt nanomagnet arrays, and they also concluded that elliptical cobalt nanomagnets were preferred to form a single-domain demagnetization state.<sup>[112]</sup>

### Surface Effects and Interparticle Interactions

Fine particle magnetism has always been dealing with two very common aspects of small particle behavior, namely, the surface/interface effect and interparticle interactions. The reduced geometry at particle surface/interface often leads to the relaxation of crystal lattice. This will generate an inhomogeneous spin structure throughout the whole particle, with spins at the surface behaving very differently compared with those in the core. For a ferromagnetic particle, this type of non-linear spin structure can be described as a ferromagnetic core with aligned spins, and a structurally disordered surface spin structure. The surface spin structure resembles a spin-glass-like state, with the surface spins not oriented at random but inclined to the direction of the net magnetization through exchange

interaction with the core.<sup>[113]</sup> Surface spin canting has been demonstrated in 6-nm  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> prepared by chemical precipitation,<sup>[114]</sup> NiFe<sub>2</sub>O<sub>4</sub> nanoparticle prepared by grinding with oleic acid in kerosene,<sup>[115]</sup> NiFe<sub>2</sub>O<sub>4</sub> prepared by chemical precipitation,<sup>[116]</sup> and ball-milled CuFe<sub>2</sub>O<sub>4</sub>.<sup>[117]</sup> Surface/interface effects can also come from either magnetic or non-magnetic coatings formed due to the oxidation of metal particle surface or the presence of a surface coating or matrix. Many abnormalities of fine particle magnetism can be attributed to the surface effects. For example, for oxide-coated or matrix-hosted nanoscale Fe, Co, and Ni particles, interactions between particles and the coating materials may modify the coercivity of the system. Therefore magnetic coercivity in these systems is somewhat considered as a surface/interface property. Hadjipanayis et al. explained the coercivity behavior of the oxide-coated Fe clusters as the result of the interaction between the soft Fe<sub>2</sub>O<sub>3</sub> shell and the hard Fe core.<sup>[118]</sup> This gave the high coercivity at low temperature and its strong temperature dependence. The whole particle may become magnetically soft when the core is very small and fluctuation of the magnetic moment of the shell dominates the overall magnetic properties.

Non-interacting single-domain magnetic nanoparticles are superparamagnetic below certain temperatures. However, when particles are brought closer together, dipole/exchange interactions can occur. Such interactions will increase the effective energy barriers for spontaneous magnetization. For a densely packed but disordered assembly of superparamagnetic particles, the interparticle interactions can be inhomogeneous, thus giving rise to a distribution of effective energy barriers for spontaneous magnetization. Fiorani et al.<sup>[119]</sup> studied relaxation properties of 4.7-nm  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> with increasing strength of interparticle interaction and discovered that the very weakly interacting particles can be well described by the Néel–Brown model for superparamagnetism. For particles with weak to medium interaction, Néel–Brown model still applies if interparticle interaction is accounted for. For strongly interacting particles, the result of such distribution of energy barriers is the transformation from pure superparamagnetism to a glass collective state resembling spin glasses, but with its own distinct features. Zysler et al.<sup>[120]</sup> compared the blocking behaviors and hysteresis cycles of amorphous (Fe<sub>0.26</sub>Ni<sub>0.74</sub>)<sub>50</sub>B<sub>50</sub> nanoparticles (mean diameter 2 nm) and the same nanoparticles dispersed in a polymer with a 0.3 wt.% ratio for the nanoparticles. Results from the polymer-dispersed sample, with a mean interparticle center-to-center distance of 18 nm, showed good agreement with the model of non-interacting particles. For non-dispersed particles, strong interparticle interaction was observed. The  $M_{ZFC}$  had a maximum at a

temperature  $T_{\max} \approx 100$  K, which was higher than that of the dispersed sample (55 K). Above  $T_{\max}$ , the non-dispersed sample could still be described as superparamagnetic if interparticle interaction is considered. Below 50 K, the non-dispersed sample underwent a regime change as indicated by its magnetization and hysteresis behaviors. It is believed that the low-temperature state is a collective glassy-like state, which is characterized by a randomly frozen assembly of correlated particle moments.

The coupling particle moments of interaction of magnetic nanoparticles at low temperatures could give rise to a new magnetic order if the particle moments are parallel. Such magnetic ordering is called superferromagnetism.<sup>[121]</sup> Superferromagnetism should behave similarly to normal ferromagnetic materials, but with much higher magnetic moment.

### Giant Magnetoresistance Effect

Magnetoresistance is defined as the fractional change in resistance or resistivity of a material induced by an applied magnetic field relative to the resistivity either at zero field,  $\rho(0)$ , or at the saturation field  $H_s$ ,  $\rho(H_s)$ :<sup>[122,123]</sup>

$$\left(\frac{\Delta\rho}{\rho}\right)_0 = \frac{\rho(H) - \rho(0)}{\rho(0)} \quad (13)$$

or

$$\left(\frac{\Delta\rho}{\rho}\right)_{H_s} = \frac{\rho(H) - \rho(H_s)}{\rho(H_s)} \quad (14)$$

Giant magnetoresistance (GMR) was first discovered in Fe/Cr magnetic superlattices.<sup>[124]</sup> Baibich et al.<sup>[124]</sup> first suggested GMR in Fe/Cr magnetic superlattices as the result of spin-dependent electron transmission between Fe layers through the thin Cr interfaces. This spin-dependent electron transport between ferromagnetic Fe layers was facilitated by the interplay of orientation of the Fe layers induced by the magnetic field. The spin-dependent electron transmission through an interface, also referred to as spin-dependent scattering, is called the “two-current model.” Other effects, such as exchange coupling, spin-value effect, and periodic density of states, were also considered to be the reasons for GMR in thin films.<sup>[123]</sup>

Giant magnetoresistance effects in granular films were first discovered in heterogeneous granular Cu–Co alloys<sup>[125]</sup> and in Co–Cu and Fe–Cu granular alloys,<sup>[126]</sup> and were later observed in many other granular systems.<sup>[123,127–129]</sup> A granular magnetic metal system is generally referred to as a material consisting of nanoscale magnetic metal granules (clusters)

embedded in a non-magnetic matrix. Although magnetic granular films lack defined structures, the mechanism of spin-dependent scattering could still be applied to explain the GMR phenomenon in these materials. Rather than going through a layer-to-layer electron transport process, the neighboring magnetic granules, under an aligning magnetic field, could undergo electron transfer through the non-magnetic interfaces. Giant magnetoresistance in granular metals was found to be dependent upon the size, shape, as well as the concentration of the magnetic granules.<sup>[130]</sup> Initially, it was believed that GMR could only exist in granular metal/metal systems because of the absence of metallic conductivity in metal/insulator systems such as Fe–Al<sub>2</sub>O<sub>3</sub>.<sup>[123]</sup> Recent studies have shown that GMR can also be found in metal/insulator granular films. The magnetoresistance in these films is called tunneling magnetoresistance (TMR). Tunneling magnetoresistance in metal/insulator films occurs when electrons are transferred between magnetic clusters by a spin-dependent tunneling effect through tunneling junctions or grain boundaries. The probability of spin-dependent tunneling depends on many factors including particle size, shape, distribution, the nature of the particle/matrix interfaces, and film thickness.<sup>[131–133]</sup>

### Quantum Tunneling of Magnetization

Quantum tunneling of magnetization, or macroscopic quantum tunneling (MQT), is a phenomenon that describes quantum mechanically the non-conservation of magnetization along a certain axis between different energy configurations.<sup>[77,134–137]</sup> Consider the classical case of superparamagnetism to ferromagnetism transition in a single-domain particle. For a small single-domain ferromagnetic particle with its entire spins (magnetic moments) aligned along an easy axis in an applied field, the overall magnetic relaxation process of the particle can be described as a single macroscopic degree of freedom, with all the individual spins acting as a total moment (spin) of the particle. This is a thermodynamic process whereas magnetic relaxation of the system has a linear relation to temperature as described by the Arrhenius law  $\tau = \tau_0 \exp(\Delta E/k_B T)$ . When temperature drops below a certain point, all the individual spins in the small ferromagnetic particle will be frozen out because of crystal anisotropy, and the spontaneous magnetization  $M$  will be close to saturation magnetization value  $M_0$ . When a magnetic field  $H$  is applied along the opposite direction of the original spontaneous magnetization  $M$ , a metastable state arises with  $M$  being antiparallel to  $H$ . To overcome such a metastable state and achieve a stable magnetization state with  $M$  being parallel to  $H$ , spontaneous magnetization must overcome certain energy barriers.<sup>[134]</sup>

These potential energy barriers generally originate from two sources: anisotropy energy barriers due to intrinsic crystal anisotropies, and possible barriers caused by the pinning of domain walls by defects.<sup>[138]</sup> As these energy barriers have no direct relations with temperature, magnetic relaxation will no longer be temperature dependent. Chudnovsky and Gunther considered a simple spherical ferromagnetic system with an energy barrier  $E_a$  as<sup>[134]</sup>

$$E_a = (K_{\parallel} + K_{\perp} \sin^2 \phi) \sin^2 \theta - MH(1 - \cos \theta) \quad (15)$$

with  $H$  in the  $-z$  direction, and  $K_{\parallel}$  and  $K_{\perp}$  being parallel anisotropy and transverse anisotropy, respectively. By combining the classical equation for  $M$  and their own theory of quantum nucleation, they gave a crossover temperature  $T^*$  for quantum tunneling as<sup>[134]</sup>

$$T^* = (3/8)h\gamma(K_{\parallel}K_{\perp}\varepsilon)^{1/2}/k_B M_S \quad (16)$$

where  $\varepsilon$  is  $(1 - H/H_C)$  and  $H_C$  is coercivity. From the above we can see that a high crossover temperature is expected for a sample with high anisotropy energies and low saturation magnetization. Furthermore, the magnetic tunneling of a system at a certain temperature could also be achieved by controlling the external magnetic field. Tejada et al. estimated the range of  $T^*$  to be 0.1–5 K for small magnetic particles with high magnetic anisotropy.<sup>[139]</sup>

In real systems, there can be a broad distribution of energy barriers. Under such conditions, there is no longer a single crossover temperature below which quantum tunneling occurs, and the magnetic relaxation process theoretically could be both temperature and field dependent. The time-dependent magnetization for such systems would be<sup>[138,139]</sup>

$$M(\tau) = M_0[1 - S(T, H) \ln(\tau/\tau_0)] \quad (17)$$

where  $M_0$  is the magnetization at  $\tau_0$  and  $S(T, H)$  is magnetic viscosity. At high temperatures, magnetic viscosity is temperature dependent and is called thermal viscosity  $S_T$  and  $S_T \sim T$ . At very low temperatures, magnetic viscosity is independent of temperature and is called quantum viscosity  $S_Q$ .<sup>[139]</sup>

There are several types of magnetic tunneling mechanisms.<sup>[140]</sup> Although ample experimental evidence has been obtained to suggest the existence of these processes, it is not easy to achieve quantitative agreements between theory and experiment results in many systems. This may be because many systems studied have been assemblies of particles with heterogeneous parameters that lead to unknown barrier

energy distributions. These various energy barriers could be different crystal anisotropy energies originating from non-uniform particle sizes or shapes, or due to the simultaneous precipitation of different domain walls in the blocking process. In addition, other small particle behaviors, such as particle interactions, could be confused with macroscopic quantum tunneling without detailed analysis.<sup>[141,142]</sup> Tejada et al.<sup>[139]</sup> studied the magnetic relaxation of small ferrofluid particles  $\text{Fe}_3\text{O}_4$  (36 Å),  $\text{FeC}$  (60 Å), and  $\text{CoFe}_2\text{O}_4$  (50 Å) by examining the hysteresis loops, time-dependent magnetization, magnetization relaxation times, and magnetic viscosity at temperatures above and below the blocking temperature  $T_B$ . At  $T \geq T_B$ , these particles exhibited typical superparamagnetic thermal relaxation behaviors. At  $T \ll T_B$ ,  $S(T, H)$  became linear to  $T$ , suggesting weak interactions between the particles. At extremely low temperatures, relaxation time, coercivity, and magnetic viscosity  $S(T, H)$  all appeared independent of  $T$ , suggesting quantum tunneling of magnetization. The crossover temperatures,  $T_c$ , were estimated as about 0.5, 1, and 2.5 K for  $\text{Fe}_3\text{O}_4$ ,  $\text{FeC}$ , and  $\text{CoFe}_2\text{O}_4$ , respectively. Tejada and Zhang<sup>[138,140]</sup> studied several different types of materials including single-domain particles (SDPs) and granular solids with SDPs embedded within. These materials included  $\text{CrO}_2$  recording tapes, antiferromagnetic horse-spleen ferritin, and magnetic thin film of  $\text{TbFe}_3$ . They observed quantum magnetic tunneling effects in these systems with experimental values of  $T_c$  ranging from 2 to 5.5 K. Rather sharp crossover from thermal to quantum state for these samples was observed, suggesting that dissipation had very little effect on magnetic tunneling. Peng et al.<sup>[143]</sup> studied monodispersed ferromagnetic Co clusters coated with an antiferromagnetic  $\text{CoO}$  shell and observed enhanced coercivities (2–8.5 K Oe) and quantum magnetization behavior with a crossover temperature of 8 K. The high coercivities and high crossover temperature were attributed to the enhanced uniaxial anisotropy caused by the ferromagnetic–antiferromagnetic coupling between the Co core and the  $\text{CoO}$  shell.

Unlike assemblies of small magnetic particles with inhomogeneous sizes and properties, high-spin molecular clusters have uniform chemical characteristics and can be defined with certain parameters. Therefore they could be better candidates for the studies of quantum magnetic relaxation process. Friedman et al.<sup>[144]</sup> examined the low-temperature relaxation of a superparamagnetic and highly anisotropic molecular cluster compound  $\text{Mn}_{12}\text{O}_{12}(\text{CH}_3\text{COO})_{16}(\text{H}_2\text{O})_4$ , and they observed stepwise magnetization with periodic increase of external field, as well as much faster magnetization relaxation near these steps. They described this as a process called resonant tunneling of magnetization. They suggested that  $\text{Mn}_{12}$  molecule had two

symmetrical ground states  $m = S$  and  $m = -S$ , due to uniaxial anisotropy, with  $S$  being the total spin of the molecule ( $S = 10$ ). When an external field was applied, the symmetry between two ground states was destroyed and this led to the formation of a metastable state and a new ground state. The metastable state first resonated with an excited state associated with the new ground state, then degenerated into the new ground state. The energy levels of the states depend not only on temperature but also on the applied field; therefore such quantum tunneling is a “thermally assisted” and “field-tuned” process.

## CONCLUSION

The studies on the fabrication and properties of magnetic nanomaterials have made great progress. Many well-established techniques have found success in the preparation of magnetic nanomaterials of various sizes and structures. In the studies of magnetic properties, both theoretical and experimental efforts have demonstrated that fine particle magnetism is not only a result of the reduction of size, but also due to surface/interface effects and the interaction of particles. The fundamental theories of solid-state physics that describe the magnetic properties of bulk materials can still be applied to magnetic nanomaterials, if the unique structural aspects and collective behaviors of nanoparticles are taken into consideration. Theoretically, future effort should be focused on the improvement of the modeling of magnetic properties of nanometer-sized particles. Although theoretical modeling for clusters consisting of a few to a few tens of atoms has been well established, there is still a need for dependable approaches to the calculations of nanometer-sized particles. Experimentally, further improvement in the fabrication techniques should lead to more effective ways to generate particles with controllable size and uniform morphology, and better methods to handle and study individual particles. The availability of “identical” particles, and the techniques to put a single or a few of such particles under study, not only would enable closer examination of size-dependent magnetic properties, but could also, through nano-manipulation, enable them to become building blocks for magnetic devices.

## INTRODUCTION

The synthesis of nanomaterials presents a great interest not only for elucidation of basic research problems, but also for practical applications. Because of the presence of very small size nanoparticles, these materials acquire new properties that differ from those of bulk materials of the same composition.<sup>[1]</sup> As a result of the special magnetic properties of small particles, nanomaterials find promising use in various applications: ferrofluids, information storage media, magnetic refrigeration, magnetic resonance imaging, etc.<sup>[2]</sup>

Ferrites—magnetic materials—are composed of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and another metallic oxide MO<sub>n</sub>. The general formula of ferrites is  $x\text{MO}_n \cdot y\text{Fe}_2\text{O}_3$ . If M is a divalent metal ion with ionic radius,  $r < 1 \text{ \AA}$ , a spinel ferrite is formed:  $\text{MO} \cdot \text{Fe}_2\text{O}_3$  ( $n = 1$ ). The “spinel structure” proceeds from the natural combination MgAl<sub>2</sub>O<sub>4</sub> called “spinel.” Spinel ferrite structure consists of a cubic close-packed oxygen arrangement, in which the cations reside on tetrahedral and octahedral interstices. The unit cell is obtained by the union of two face-centered cubic oxygen sublattices along each of three directions. This results in 64 tetrahedral sites (A) and 32 octahedral sites (B). Only 8 sites A and 16 sites B are occupied by cations in a stoichiometric spinel. The spinel compounds mainly belong to the space group Fd3m and the lattice parameter is  $\approx 8.5 \text{ \AA}$ . Occupation of all the tetrahedral sites with divalent metal ions yields a normal spinel structure, while occupation of the octahedral sites with the divalent metal ions yields an inverse spinel structure. Ferrites can adopt both a normal spinel structure ( $\text{M}^{2+} = \text{Zn}^{2+}, \text{Cd}^{2+}, \text{Mn}^{2+}$ ) and an inverse spinel one ( $\text{M}^{2+} = \text{Fe}^{2+}, \text{Co}^{2+}, \text{Ni}^{2+}, \text{Cu}^{2+}$ ). Ferrites constitute a broad and important class of magnetic ceramic materials, with important technological applications which cover electronic and electrotechnical devices, heterogeneous catalysts, cement products, paints, and plastics.<sup>[3,4]</sup> The magnetic properties of ferrites (magnetic saturation, magnetization, and coercivity) change

drastically when the size of particles becomes very small.<sup>[5]</sup> For this reason, the idea that synthesizing ferrites with nanometer-sized particles (nanoferrites) would help obtaining materials with superior magnetic properties is of great interest.<sup>[6,7]</sup>

## THE COMPLEXATION METHOD FOR SYNTHESIS OF FERRITES

The method of preparation plays a very important role in determining the chemical, structural, and magnetic properties of spinel ferrites. Ferrites are commonly produced by the ceramic technique that involves high-temperature solid-state reactions between the constituent oxides, carbonates, or oxalates. The particles obtained by the ceramic method are large and of non-uniform size. The products obtained by sintering are, in most cases, nonreproducible in terms of their magnetic properties.<sup>[8–11]</sup> Because the average particle sizes and the particle size distribution of nanoferrites affect very much their magnetic properties, the control of these parameters is crucial. To overcome the difficulties arising from the ceramic route, wet chemical methods, such as coprecipitation,<sup>[6,7,12–14]</sup> hydrothermal processing,<sup>[4,15,16]</sup> and sol-gel technique,<sup>[17]</sup> were designed and employed. The control of colloid chemistry properties that determine the stability of microemulsions and self-assembling of nanoparticles is particularly recommended for the synthesis of nanoferrites.<sup>[2,18–21]</sup> The essential requirements of obtaining well-controlled uniformity and high-purity materials make these chemical methods the preferred choice.

The nature of precursors plays a very important role in the synthesis of nanoferrites. In many cases, the use of a particular precursor may affect the structure of materials at the molecular level, thus improving the homogeneity and increasing the dispersion of resulted products. Considerable efforts have been made to develop chemical synthesis routes that yield precursors having two or more metal ions included in the same

molecular entity. Synthesis routes, in which polynuclear coordination compounds with two or more metal ions are formed as precursors, are preferred because these compounds are capable of giving mixed oxides by thermal decomposition.<sup>[22–24]</sup>

Synthesis of nanoferrites by thermal decomposition of polynuclear complex compounds is a non-conventional chemical method that belongs to “chimie douce” (soft chemistry). This method is sometimes referred to as the complexation method for synthesis of ferrites.

Compared to classical methods, the complexation method offers a series of advantages:

- The distribution of chemical species is homogeneous at the molecular level.
- The decomposition of coordination compounds is simultaneous with, or is immediately followed by, formation of a ferrite.
- The temperature of ferrite formation is much lower than the temperature range of ceramic processes.
- Because of the relatively low temperature of formation, the ferrites obtained through the complexation method are characterized by ultrafine particle granulation and high specific surface areas.

Over the past 20 years, the chemistry of polynuclear coordination compounds has developed spectacularly and now it could be regarded as a well-established branch of coordination chemistry. In spite of all this progress, information regarding the use of polynuclear coordination compounds as precursors of ferrites is limited.

The successful application of the complexation method for synthesis of nanoferrites requires two important steps:

- A detailed study on the formation of the polynuclear complex compounds to establish the parameters that influence the synthesis, such as the combination ratio of elements, the nature of the ligand, the pH of the reaction medium, the temperature, etc.
- A study on the mechanism of their thermal decomposition, accompanied by the characterization of the obtained ferrites.

The polynuclear coordination compounds, which may successfully be used as precursors for ferrite formation, should generate by decomposition only volatile products. The ligands that largely satisfy this requirement are the anions of polycarboxylic and polyhydroxy carboxylic acids: citrate, acetate, oxalate, etc. Thus there are various variants of the complexation method for ferrite synthesis encountered in the literature, which are named according to the acid employed as the complexing agent (e.g., citrate, acetate, oxalate, and malate methods). In [Scheme 1](#), these alternative methods are presented together with the self-propagating

combustion. We consider this last method, in which the combustion occurs in situ, together with the group of methods based on thermal decomposition of polynuclear coordination compounds.

## FERRITES OBTAINED BY THERMAL DECOMPOSITION OF POLYNUCLEAR COORDINATION COMPOUNDS

### Citrate Method

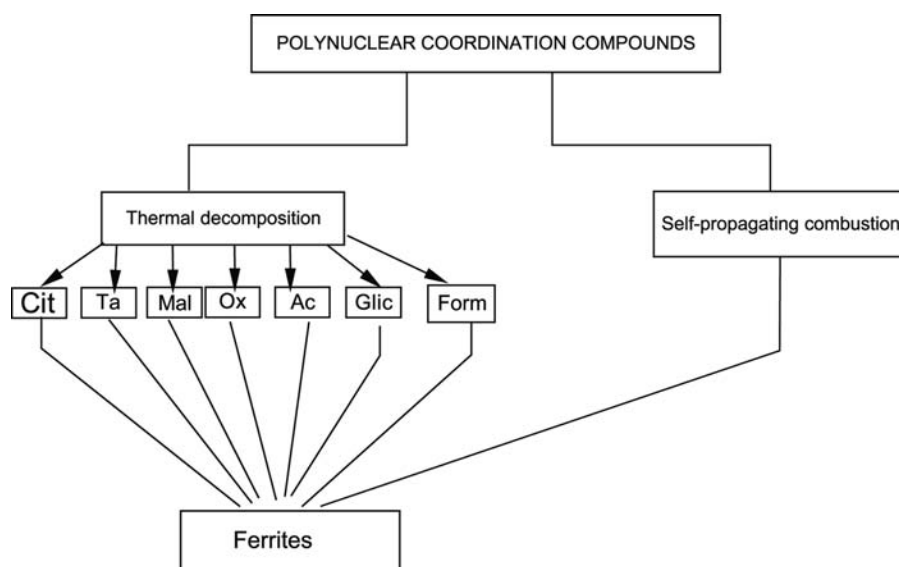

Synthesis of ultrafine ferrites by the citrate precursor technique is the only synthesis route that has enjoyed so far technological applications.<sup>[25–27]</sup> It requires the use of precursor solutions containing the metal ions and citric acid in the desired ratio. Dehydration is carried out in revolving evaporators under a pressure of a few millimeters of Hg at 70°C; it is stopped before the viscosity becomes high. Dehydration is completed by drying for an additional 3 to 24 hr in a vacuum oven at temperatures below 100°C. This procedure yields transparent glasses, uniformly colored, completely amorphous to X-ray diffraction. The materials present no evidence of non-homogeneity. Moderate temperatures are sufficient for the pyrolysis of the precursors (500–600°C). When the expected mixed oxides do not form at this temperature, pyrolysis is conducted at, or above, the lowest temperature necessary for product formation. Thus the  $\text{Fe}_2\text{Mn}_{0.5}\text{Zn}_{0.5}\text{O}_4$  nanoferrite was obtained after 2 hr of thermal treatment at 500°C. The X-ray pattern indicated formation of a pure, perfectly homogeneous phase, with particle sizes in the range between 30 and 100 Å.<sup>[25]</sup>

Verma et al.<sup>[28]</sup> have prepared by this method high-resistivity nickel–zinc ferrites:  $\text{Ni}_{1-x}\text{Zn}_x\text{Fe}_2\text{O}_4$  with  $x = 0.2, 0.35, 0.5,$  and  $0.6$ . They observed that these Ni–Zn ferrites have resistivity  $\geq 10^8 \Omega \text{ cm}$  which is higher by 2 orders of magnitude than that reported ( $\leq 10^6 \Omega \text{ cm}$ ) for ferrites prepared by the conventional ceramic method. This is attributed to better purity and homogeneity of these ferrite powders.

An alternative of this method was proposed for Ni–Cu–Zn ferrite powders with compositions:<sup>[29]</sup>

( $x = 0, 0.02, 0.04, 0.06$ ). A mixed solution containing metal nitrates and citric acid in a 1:1 ratio (pH value of the solution was adjusted to  $\sim 7$  using ammonia) was poured into a dish and heated at  $\sim 135^\circ\text{C}$  until it transformed into a dried gel. The dried gel burned in a self-propagating combustion to form a loose ash. The synthesized nanoferrites powders could be sintered by heating for 5 hr at  $900^\circ\text{C}$  in air. These nanoferrites are characterized by high magnetic permeability.

 Ox = oxalate method  
 Ac = acetate method  
 Gli = glycolate method  
 Form = formate method

**Scheme 1** Polynuclear coordinator compounds-precursors for ferrites.

Attempts to separate complex citrates from the reaction medium were very difficult because of their high solubility. Prasad, Vijayalakshmi, and Gajbhiye [30] have succeeded the isolation of a citrate precursor with the general formula  $\text{Co}_3\text{Fe}_6\text{O}_4(\text{C}_6\text{H}_6\text{O}_7)_8 \cdot 6\text{H}_2\text{O}$ . Ultrafine particles of  $\text{CoFe}_2\text{O}_4$  were obtained by decomposition of this precursor. The citrate polynuclear compound was characterized through elemental chemical analysis and IR spectrum. It was difficult to predict the bonding positions of metal ion sites with the citric acid. Therefore based on thermal analyses, chemical analyses, and gas analyses and X-ray diffraction (XRD), infrared (IR), and nuclear magnetic resonance (NMR) data, the authors have proposed the following mechanism. The decomposition of the citrate complex compound occurs in one or two major steps, depending on the heating rate in static or in flowing air atmosphere. For heating rate of  $5^\circ\text{C}/\text{min}$ :

For heating rate of  $10^\circ\text{C}/\text{min}$

When the heating rate is  $5^\circ\text{C}/\text{min}$ , the hexahydrate cobalt iron citrate precursor was isolated by removing the lattice water around  $120^\circ\text{C}$ . The first step represents the major reaction in the thermal decomposition of the citrate precursor. During this process, the metastable acetonedicarboxylate complex,

$\text{Co}_3\text{Fe}_6\text{O}_4\text{-(C}_5\text{H}_6\text{O}_6)_8$ , is formed. In the second step, the complete internal conversion of carboxylate groups, methylene, and hydroxyl groups takes place to form acetone and  $\text{CO}_2$  gas. In the IR spectrum of this intermediate compound, the characteristic bands of  $\nu_{\text{sym}}\text{CH}$  ( $\sim 2900\text{ cm}^{-1}$ ),  $\nu_{\text{asym}}\text{COO}$  ( $1570\text{ cm}^{-1}$ ), and  $\nu_{\text{sym}}\text{COO}$  ( $1400\text{ cm}^{-1}$ ) are absent. Some amount of  $\text{CO}_2$  gas is adsorbed on the  $\text{CoFe}_2\text{O}_4$  lattice because of the large surface area.

When the heating rate is  $10^\circ\text{C}/\text{min}$ , the first and the second steps occur simultaneously at a lower temperature ( $120\text{--}160^\circ\text{C}$ ). At the same time, a large amount of gases ( $\text{CO}$ ,  $\text{CO}_2$ , water vapors, and acetone) is released. The compound  $3(\text{CoFe}_2\text{O}_4) \cdot 14\text{CO}_2$  obtained was X-ray-amorphous. The adsorbed  $\text{CO}_2$  gas disappears only by heating at  $250^\circ\text{C}$  for more than 1 day.

The complete crystallization of the  $\text{CoFe}_2\text{O}_4$  amorphous phase occurs above  $280^\circ\text{C}$ , as confirmed by its XRD pattern. This crystalline phase  $\text{CoFe}_2\text{O}_4$  shows the crystallite size in the range of  $7.5\text{--}34\text{ nm}$ .

Sainamthip and Amarakoon<sup>[31]</sup> synthesized ultra-fine ferrite powders (Mn–Zn ferrite) by alcoholic dehydration of citrate/formate solution. This method consists of spraying or atomizing an aqueous citrate/formate solution containing the metal ions in the desired ratio into a bath of a hygroscopic liquid (acetone or alcohol), which rapidly removes water. A bright yellow citrate complex is obtained. Thermal decomposition of this precursor yields a fine, high-purity, homogeneous ferrite. The success of powder preparation depends on the water content in the starting solution, the pH of the solution, the amount of alcohol used, and the drying step. Low-temperature calcination ( $350^\circ\text{C}$  in air) for decomposition, followed by calcinations at  $900^\circ\text{C}$  for 4 hr in an enclosed vessel, leads to submicrometer-sized ferrite powders with an important degree of agglomeration.

The citrate method is simple and inexpensive. It is a promising method for the synthesis of high-performance nanoferrites.

### Tartarate Method

The capacity of tartaric acid to form coordination compounds is well known. This capacity originates in the following structural characteristics:

- The presence of four potentially ionizable H atoms.
- The presence in the molecule of several coordination positions.
- The tendency of molecular association because of the polydentate nature of the tartarate anion.

Although the factors that influence the structure of the complex species are known, their individual

contribution in assuming one structure or another is hard to establish. Tapscott, Belford, and Paul<sup>[32]</sup> published an exhaustive study on the anionic homodinuclear species in which two metallic ions are bonded in bridged position through two tartarate tetradentate ligands. In the literature, there are relatively few studies concerning the coordination compounds in solid state with tartaric acid as ligand.<sup>[33]</sup> The multiple function of the ligand is responsible for its capacity to form heteropolynuclear coordination compounds.<sup>[34]</sup>

To establish to what extent such heteropolynuclear coordination compounds may represent the raw materials for spinel ferrites formation, the following systems have been studied:<sup>[35]</sup>

$2\text{Fe(III)} : \text{M(II)} : \text{tartaric acid}$

$\text{M(II)} = \text{M(II)}, \text{Co(II)}, \text{Zn(II)}$

and

$2\text{Fe(III)} : [0.5\text{M(II)} : 0.5\text{M'(II)}] : \text{tartaric acid}$

$\text{M(II)} = \text{Co(II)}; \text{M'(II)} = \text{Zn(II)}$

$\text{M(II)} = \text{Co(II)}; \text{M'(II)} = \text{Mn(II)}$

The study of the chemistry solution of the tartaric acid has evidenced the dependence of the nature of the polymeric species on the pH of the reaction medium. For this reason, the behavior of the above systems depended on the selected reaction medium pH (pH = 1–2 and pH = 6–7, respectively) at constant  $\text{M}^{n+}/\text{tartaric acid}$  ratio [ $2\text{Fe(III)}:1\text{M(II)}:4\text{-tartaric acid}$ ].

The following types of compounds were obtained:

pH = 1 – 2

$[\text{Fe(III)}_2\text{M(II)}(\text{C}_4\text{O}_6\text{H}_3)_2(\text{C}_4\text{O}_6\text{H}_4)] \cdot x\text{H}_2\text{O}$

$\text{M(II)} = \text{Co(II)}, \text{Zn(II)}, \text{Mn(II)}$

$[0.5\text{M(II)} + 0.5\text{M'(II)}] : \text{Co(II)} + \text{Zn(II)};$

$\text{Co(II)} + \text{Mn(II)}$

$x = 2 - 4$

pH = 6 – 7

$(\text{NH}_4)_2[\text{Fe(III)}_2\text{M(II)}(\text{C}_4\text{O}_6\text{H}_3)_2(\text{C}_4\text{O}_6\text{H}_2)] \cdot x\text{H}_2\text{O}$

$\text{M(II)} = \text{Mn(II)}, \text{Co(II)}, \text{Zn(II)}$

$[0.5\text{M(II)} + 0.5\text{M'(II)}] = \text{Co(II)} + \text{Zn(II)};$

$\text{Co(II)} + \text{Mn(II)}$

$x = 2 - 4$

The formula of these compounds was established by correlating elemental chemical analysis with physicochemical measurements (IR, UV-Vis spectra, and magnetic and thermogravimetric runs).

The IR spectra recorded for the two types of compounds suggest the coordination of both carboxylic groups existing in the molecule of tartaric acid at metal ions. The band at  $1750\text{ cm}^{-1}$  of tartaric acid, assigned to  $\nu_{\text{C=O}}$  is replaced in the spectra of the compounds by the two bands  $\nu_{\text{as(OCO)}}$  and  $\nu_{\text{s(OCO)}}$ . The analysis of these spectra within  $1000\text{--}1100\text{ cm}^{-1}$  range shows a considerable difference between the spectrum of free tartaric acid and those of the two compounds. In the tartaric acid spectrum, the peak at  $\sim 1097\text{ cm}^{-1}$  is assigned to the C-O stretching vibration of OH secondary group. In the spectra of complexes, this band splits and shifts toward lower frequencies ( $1085\text{--}1059\text{ cm}^{-1}$ ). The splitting could be assigned to a different bonding of the two secondary OH groups present in the molecule of the acid. Thus one can advance the hypothesis that the two secondary OH groups coordinate at two different metal ions.

The analysis of electronic spectra and their second derivatives recorded within  $9000\text{--}50000\text{ cm}^{-1}$  for both types of compounds supplied data about the stereochemistry of metal ions. For example, the spectrum of  $(\text{NH}_4)_2[\text{Fe}_2^{\text{III}}\text{Co}^{\text{II}}(\text{C}_4\text{O}_6\text{H}_3)_2(\text{C}_4\text{O}_6\text{H}_2)] \cdot x\text{H}_2\text{O}$  shows one low intensity absorption band at about  $11000\text{ cm}^{-1}$  which may be assigned to the spin-forbidden transition  ${}^6\text{A}_{1g} \rightarrow {}^4\text{T}_{1g}$  for Fe(III)( $d^5$ ) ion, in an octahedral high spin configuration. Another band at  $\sim 18560\text{ cm}^{-1}$  could be assigned to  ${}^4\text{T}_{1g} \rightarrow {}^4\text{T}_{1g}(\text{P})(\nu_3)$  transition, characteristic to Co(II) ion in a high spin octahedral configuration. All compounds are paramagnetic. The experimental values of magnetic moments are lower than the theoretical ones. This difference could be assigned to the antiferromagnetic interaction between metal ions.

The thermal decomposition of the intermediate complex compounds was further studied. For the first type of compounds, the following scheme was advanced:

For the compounds from the second group, the following scheme was suggested:

The spinel ferrites were formed at a temperature above  $320\text{--}350^\circ\text{C}$ , but the crystallinity was quite low. An additional thermal treatment was required to obtain a good crystallinity product (e.g., 7 hr at  $700^\circ\text{C}$  for  $\text{Fe}_2\text{ZnO}_4$ ; 5 hr at  $800^\circ\text{C}$  for  $\text{Fe}_2\text{CoO}_4$ ) (Fig. 1).

Also used for obtaining of mixed cadmium-cobalt and cadmium-nickel ferrispinel:<sup>[36,37]</sup>

the following tartarates complex precursors:

were obtained by adding a sodium tartarate solution to the mixture of metal-sulfate solutions. The pH of the reaction medium was adjusted to a low-enough value ( $\text{pH} < 6$ ). Acetone was added to ensure high yield of compounds. In addition, acetone influences

Fig. 1 Powder XRD patterns of the final thermolysis products of  $(\text{NH}_4)_2[\text{Fe}_2\text{Co}(\text{C}_4\text{O}_6\text{H}_4)_3(\text{OH})_4] \cdot 4\text{H}_2\text{O}$ .

the homogeneity and the stoichiometry of the fine-grained powders. These tartarates precursors were decomposed and calcined for 2 hr at 700°C and slowly cooled afterward (3°C/min) to room temperature. The polycrystalline powders were reground and recalcined for 2 hr at 700°C. The X-ray diffraction patterns of all the compositions indicated the formation of a single-spinel phase with cubic structure. Mean crystallite size varied in the range of 24–35 nm ± 10%. The formation of these ferrispinel was also studied by electrical conductivity, thermoelectric power, magnetic susceptibility, magnetic hysteresis, and Mössbauer spectroscopy.

### Oxalate Method

Oxalic acid enjoyed a special attention, among the carboxylic acids that can operate as a ligand, because of its multiple coordination capacity, either as a monodentate ligand (bonded to the oxygen atoms of the same carboxylic group), as a bidentate ligand (bonded at one oxygen atom from each carboxylic group), or as a tetradentate ligand (double bridge between two or four metal ions).

Although several investigations focused on coprecipitation processes as well as on decomposition of complex oxalates, the information regarding the precipitation and the decomposition conditions that decisively influence the purity of the final oxide phase are scarce.

Thermal analysis of complex oxalates of the type:

where M(II) = Ni(II), Co(II), (Ni, Zn), and (Mn, Co) leads to the conclusion that the decomposition is apparently a low-temperature phenomenon and the structure of spinelic phase depends to a great extent on the thermal treatment applied.<sup>[38]</sup>

In the systems:

where M(II) = Mg(II), Zn(II), and Mn(II).

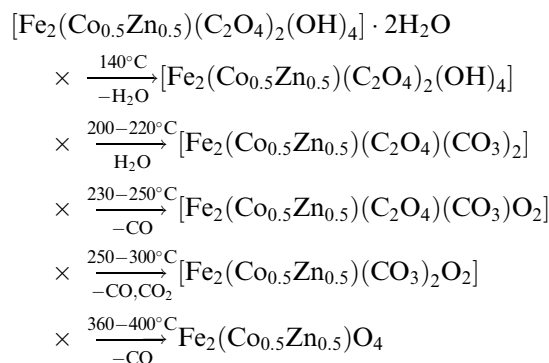

Brezeanu et al.<sup>[39–41]</sup> have synthesized and characterized the following series of polynuclear coordination compounds that serve as precursors of spinelic ferrites:

Extension of these studies to the systems:<sup>[42]</sup>

where M(II) = Zn(II), Mn(II) resulted in isolation and characterization of a wide range of complex compounds depending on the pH of the reaction medium, the  $M^{n+}/mC_2O_4^{2-}$  ratio, and the nature of precipitating agent (B = NH<sub>4</sub>OH 12.5%; KOH 40%) (Table 1). These compounds were characterized by IR and electronic spectra and by magnetic measurements. The optimal conditions of decomposition of these polynuclear coordination compounds for obtaining ferrites were established by means of thermal analysis data. The following decomposition route is advanced as an example:

**Table 1** Coordination compounds obtained in 2Fe(III):(Co<sub>x</sub>M<sub>1-x</sub>):mC<sub>2</sub>O<sub>4</sub><sup>2-</sup> System (x = 0, 0.5; M(II) = Zn, Mn)

The IR spectrum of the intermediate product at 350°C shows the characteristic bands of carbonate anion [ $\nu_{\text{as}}(\text{CO}_3^{2-})$  at 1430  $\text{cm}^{-1}$ ,  $\delta(\text{CO}_3^{2-})$  at 880  $\text{cm}^{-1}$  (out of plane), and  $\delta(\text{CO}_3^{2-})$  at 700  $\text{cm}^{-1}$  (in plane)]. The IR spectrum of the final product shows strong absorption bands at  $\sim 580 \text{ cm}^{-1}$  ( $\nu_1$ ) and  $\sim 400 \text{ cm}^{-1}$  ( $\nu_2$ ) characteristic to  $\text{Fe}_2\text{Co}_{0.5}\text{Zn}_{0.5}\text{O}_4$  spinel ferrites. The X-ray diffraction pattern confirms the formation of Co–Zn ferrite (Fig. 2). Mean crystallite sizes of 90–100 Å were obtained.

Because the  $\text{CuFe}_2\text{O}_4$  is an important deep oxidation catalyst for volatile organic compounds removal and air purification, we tried to obtain this spinel oxide by the pyrolysis of polynuclear oxalate complexes.<sup>[43]</sup> To establish the optimal conditions of polynuclear compound isolation, the following systems were studied:

where  $x = \text{Cl}^-$ ,  $\text{NO}_3^-$  and  $m = 2, 10$ .

For a complete precipitation, the pH of the medium was adjusted with a solution of  $\text{NH}_4\text{OH}$  12.5% (pH  $\sim 5$ –6). The slurries were filtered, washed with water and ethanol, and dried in vacuum on  $\text{P}_4\text{O}_{10}$ . The polynuclear compounds have the following molecular formulae:

Fig. 2 Powder XRD patterns of the final thermolysis products of  $[\text{Fe}_2(\text{Co}_{0.5}\text{Zn}_{0.5})(\text{C}_2\text{O}_4)_2(\text{OH})_4] \cdot 2\text{H}_2\text{O}$ .

The IR spectra of the oxalate compounds are usually dominated by two strong bands in the 1650–1550 and 1400–1300  $\text{cm}^{-1}$  ranges, arising from C–O stretching vibrations. In the case of  $\text{C}_2\text{O}_4^{2-}$  anion, the band assignment is complicated by its multiple coordination ability. The spectra of these compounds are a proof. Thus the splitting of  $\nu_{\text{asym}}(\text{OCO})$  and  $\nu_{\text{sym}}(\text{OCO})$  vibrations in the spectrum of compound I suggests two different coordination modes for  $\text{C}_2\text{O}_4^{2-}$  anions: as a tetradentate bridge and as a chelate ligand. For compound II, only the chelate bonding is evidenced. The reflectance spectra reveal an octahedral high spin environment of the  $\text{Fe}^{3+}(\text{d}^5)$  ions and a pseudotetrahedral one of  $\text{Cu}^{2+}(\text{d}^9)$ . The stereochemistry of the  $\text{Fe}^{3+}$  and  $\text{Cu}^{2+}$  ions is supported also by Mössbauer and electron paramagnetic resonance (EPR) results.

The polynuclear oxalate compounds decompose in the temperature range 80–400°C. The X-ray diffraction patterns of the thermolysis products show:

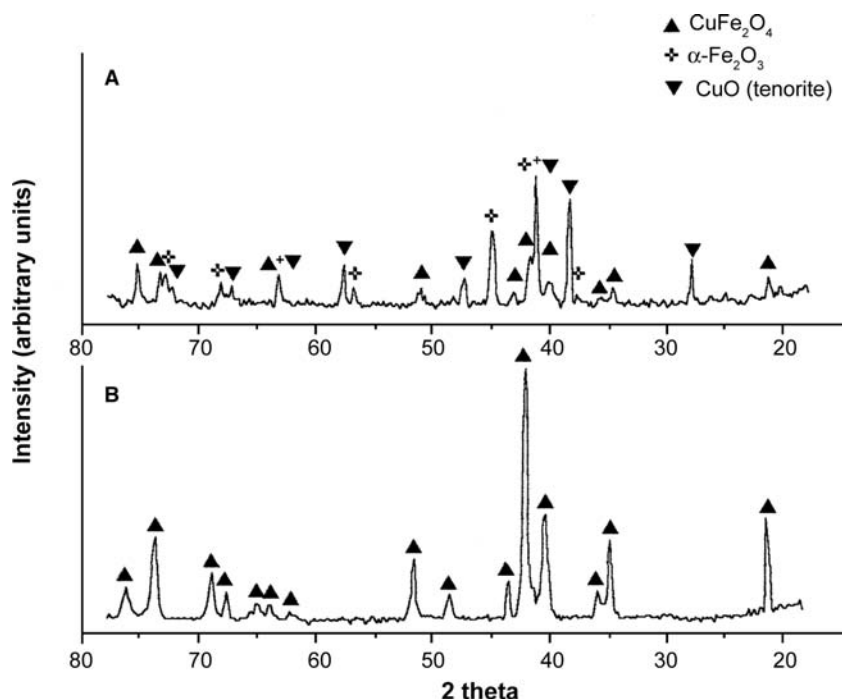

- The formation of  $\text{CuFe}_2\text{O}_4$  (as the main product) together with  $\alpha\text{-Fe}_2\text{O}_3$  (hematite) and  $\text{CuO}$  (tenorite) by the pyrolysis of compound I.
- The formation of a single  $\text{CuFe}_2\text{O}_4$  tetragonal phase by the decomposition of compound II. The mean crystallite size was  $\sim 100 \text{ Å}$  (Fig. 3).

The results are supported by Mössbauer measurements on these powders (Fig. 4). In the case of the first thermolysis compound, the Mössbauer spectrum exhibits, besides the two characteristic sextets of  $\text{CuFe}_2\text{O}_4$ , a sextet belonging to a residual  $\alpha\text{-Fe}_2\text{O}_3$ . The Mössbauer spectrum of the second oxide exhibits only the two magnetic sextets characteristic of the  $\text{CuFe}_2\text{O}_4$  tetragonal phase. The value for the saturation magnetization (26.89  $\text{emu g}^{-1}$ ; 1  $\text{emu g}^{-1} = 1 \text{ A m}^2 \text{ kg}^{-1}$ ) for the pure  $\text{CuFe}_2\text{O}_4$  tetragonal phase is in accord with the literature data.<sup>[44]</sup>

These results reveal the importance of the precursor nature on the formation conditions and properties of the final product. The specific molecular architecture of compound II, which consists of a succession of Fe–Fe–Cu units with iron linked via OH bridges shorter than the length of oxalate ones, favors the solid-state ferritization during thermal decomposition.

### Malonate Method

The selection of malonic acid as a ligand is justified by its excellent coordination ability. Moreover, the multiple function of this ligand is responsible for its capacity to form species containing an unusual type of carboxylate bridge (this coordination mode is sometimes called “malonate coordination mode.”<sup>[45]</sup>)

**Fig. 3** Powder XRD patterns of the final thermolysis products of (A)  $(\text{NH}_4)_8[\text{Fe}_2\text{Cu}(\text{C}_2\text{O}_4)_8]$  and (B)  $[\text{Fe}_2\text{Cu}(\text{C}_2\text{O}_4)_2(\text{OH})_4] \cdot 4\text{H}_2\text{O}$ .

Lanthanide malonate and copper (II) malonate complexes have been extensively studied<sup>[46–48]</sup> but no detailed studies of the malonate complexes as precursors for spinel mixed oxides are available.

Our study<sup>[49]</sup> was focused on the use of malonate coordination compounds as precursors for the spinel ferrites. Furthermore, this idea was supported by the results obtained in a recent study about the thermal stability of malate cobalt complexes<sup>[50]</sup> where malonate–cobalt complexes as intermediates were formed.

To obtain the single and mixed compounds, the following systems were studied:

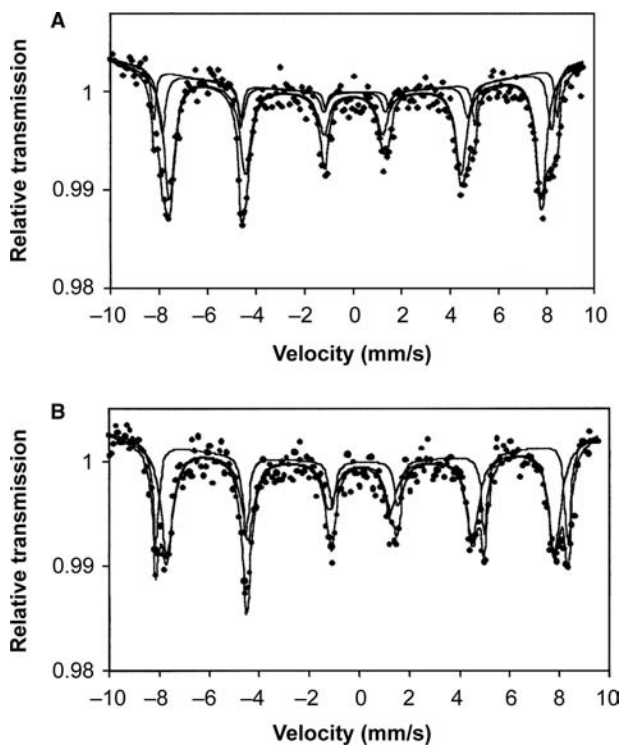

Elemental chemical analysis and physicochemical measurements (IR, UV–Vis spectra, and thermal analysis) have indicated that the coordination compounds correspond to the following general formulae:

Based on experimental data, and by similarity with the literature ones, the probable structure for these malonate complex compounds is proposed as shown in Fig. 5.

To identify the formation temperature of the cobalt ferrite, the thermal decomposition of the polynuclear malonate complex was investigated. The decomposition

**Fig. 4** Mössbauer spectra of the final thermolysis products of (A)  $(\text{NH}_4)_8[\text{Fe}_2\text{Cu}(\text{C}_2\text{O}_4)_8]$  and (B)  $[\text{Fe}_2\text{Cu}(\text{C}_2\text{O}_4)_2(\text{OH})_4] \cdot 4\text{H}_2\text{O}$  at  $25 \pm 1^\circ\text{C}$ .

**Fig. 5** Probable structure of  $[\text{Co}(\text{C}_3\text{O}_4\text{H}_2)(\text{H}_2\text{O})_{2.5}]$  and  $(\text{NH}_4)_2[\text{Fe}_2\text{Co}(\text{C}_3\text{O}_4\text{H}_2)_2(\text{OH})_6(\text{H}_2\text{O})_2]$ .

starts at about  $55^\circ\text{C}$  with two partially overlapped endothermic stages. They are followed by the complex decomposition ( $138\text{--}300^\circ\text{C}$ ) for which the DTA curve evidenced three processes: an endothermic one first, followed by two exothermic ones. The following decomposition scheme may be written:

$$x + y = 6$$

The final product obtained after the pyrolysis of the complex compound was calcined for 5 hr at  $300^\circ\text{C}$ . The X-ray diffraction pattern confirmed the formation of ultrafine  $\text{CoFe}_2\text{O}_4$  (Fig. 6) with particles sizes ranging between 50 and 80 Å.

### Acetate Method

The homotrinnuclear acetates with mixed valence and the heterotrinnuclear ones are, at present, the largest group of isostructural compounds which offer a wide field of studies on possible interactions between metal ions.<sup>[51]</sup> These compounds represent also one of the most important sources of raw materials for spinelic ferrites. X-ray diffraction analysis of these compounds has revealed that the symmetric

**Fig. 6** Powder XRD patterns of the final thermolysis products of  $(\text{NH}_4)_2[\text{Fe}_2\text{Co}(\text{C}_3\text{O}_4\text{H}_2)_2(\text{OH})_6(\text{H}_2\text{O})_2]$ .

$[\text{Fe}_2^{\text{III}}\text{M}^{\text{II}}\text{O}(\text{RCOO})_6\text{L}_3]$  cluster structures are unique (Fig. 7). The three iron atoms lie at the corners of an equilateral triangle with an oxygen atom in the middle. The carboxylate ions bridge the iron atoms so that each pair of iron atoms is connected by two bridges.

The selection as precursors for obtaining of ferrites of  $[\text{Fe}_2^{\text{III}}\text{M}^{\text{II}}\text{O}(\text{CH}_3\text{COO})_6(\text{H}_2\text{O})_3]$  compounds, where  $\text{M}(\text{II}) = \text{Fe}(\text{II}), \text{Co}(\text{II}), \text{Ni}(\text{II}), \text{Mn}(\text{II}),$  and  $\text{Zn}(\text{II})$ , is justified by a series of arguments, such as:

- The compounds contain the two metals in the exact 2:1 ratio  $[2\text{Fe}(\text{III}):1\text{M}(\text{II})]$  which is necessary to form the ferrite.

**Fig. 7** Structure of  $[\text{Fe}_3\text{O}(\text{CH}_3\text{COO})_6(\text{H}_2\text{O})_3]$ .

- The ligands decompose at low temperature and according to a simple mechanism.
- The reaction yield remains adequate even for variations within wide limits of the parameters that control the process.

The other two methods for ferrite synthesis (glycolate and formate methods) are based on the thermal decomposition of the oxotrinuclear compounds.

The homonuclear complex species:

where R = CH<sub>3</sub> and H were separated as intermediates in the process of obtaining magnetite.<sup>[52]</sup>

The thermolysis of the oxotrinuclear acetate occurs in three steps. The first step, between 50°C and 150°C, entails a weight loss of about 8%, which corresponds to the elimination of three coordinated water molecules. In the second step, between 200°C and 400°C, a weight loss of 52% is recorded, corresponding to the decomposition of [Fe<sub>3</sub>O(CH<sub>3</sub>COO)<sub>6</sub>] complex. This loss is accompanied on the differential thermal Analysis (DTA) curve by a strong exothermic effect. The residue (39.96%) corresponds to Fe<sub>3</sub>O<sub>4</sub> that is oxidized, turning into α-Fe<sub>2</sub>O<sub>3</sub>. X-ray analysis of the final product showed the characteristic lines of α-Fe<sub>2</sub>O<sub>3</sub>. The thermal analysis of this compound was coupled with identification of gaseous products resulted through mass spectrometry. The decomposition of the acetate complex shows loss of water in a first stage (maximum of 75%), followed by the loss of acetone in two steps (at about 280°C and 320°C), and finally by elimination of CO (~400°C) (Fig. 8).

The decomposition of the oxotrinuclear acetate supports the following scheme:

The study of the thermal decomposition of the polynuclear coordination compound [Fe(III)<sub>2</sub>Ni(II)O(CH<sub>3</sub>COO)<sub>6</sub>(H<sub>2</sub>O)<sub>3</sub>] showed in the temperature range of 350–400°C that the process ends up with the formation of the spinel phase. Thus the temperature required to form NiFe<sub>2</sub>O<sub>4</sub> is 400°C. The crystallinity of the samples was improved by 5-hr thermal treatment at 400°C.<sup>[53]</sup> At temperatures higher than 400°C, hematite was present, as an impurity, besides NiFe<sub>2</sub>O<sub>4</sub>. The mechanism of Ni-ferrite formation may be presented as in Scheme 2. The oxide phases were identified by Mössbauer spectroscopy. Formation of NiFe<sub>2</sub>O<sub>4</sub> from magnetite/maghemite, which was

Fig. 8 Thermal decomposition in vacuum of [Fe<sub>3</sub>O(CH<sub>3</sub>COO)<sub>6</sub>(H<sub>2</sub>O)<sub>3</sub>], β = 16°/min.

visualized first, suggests its germ role in spinel lattice. The intermediate oxide phases react fast to form structurally ordered solid solutions of Fe<sub>3</sub>O<sub>4</sub>–NiFe<sub>2</sub>O<sub>4</sub> type that gradually convert into NiFe<sub>2</sub>O<sub>4</sub>. The inversion degree and the size of crystallites increase with the duration of the thermal treatment applied.

Walker, Breen, and Applett<sup>[54]</sup> have discovered a new class of metal carboxylates that appeared to be similar to the other basic carboxylates of iron: Fe<sub>3</sub>O(MEEA)<sub>7</sub> · 5.5H<sub>2</sub>O where MEEA = 2-[2-(2-methoxy)etoxy]etoxyacetate (MeOCH<sub>2</sub>CH<sub>2</sub>OCH<sub>2</sub>CH<sub>2</sub>OCH<sub>2</sub>COO<sup>-</sup>).

The similar composition of the iron MEEA salt to the basic carboxylate suggested that it might also have a similar trinuclear cluster. The mass spectroscopy of Fe<sub>3</sub>O(MEEA)<sub>7</sub> · 5.5H<sub>2</sub>O supports this hypothesis because the largest fragment observed corresponds to Fe<sub>3</sub>O(MEEA)<sub>7</sub> · H<sub>2</sub>O. However, the IR spectrum of Fe<sub>3</sub>O(MEEA)<sub>7</sub> · 5.5H<sub>2</sub>O indicates that the bonding is different from that of the acetate. The stability toward hydrolysis of Fe<sub>3</sub>O(MEEA)<sub>7</sub> · 5.5H<sub>2</sub>O is another factor that differentiates it from other “Fe<sub>3</sub>O” polynuclear carboxylates. [Fe<sub>3</sub>O-(RCOO)<sub>6</sub>L<sub>3</sub>] hydrolyzes to give dimers such as Fe<sub>6</sub>O<sub>2</sub>(RCOO)<sub>12</sub> or larger clusters such as Fe<sub>11</sub>O<sub>6</sub>(OH)<sub>6</sub>(RCOO)<sub>15</sub>, while Fe<sub>3</sub>O(MEEA)<sub>7</sub> · 5.5H<sub>2</sub>O may be dissolved in water without change in composition.

The precursor for the nickel ferrite was obtained by solving 0.5 M equivalent of Ni(NO<sub>3</sub>)<sub>2</sub> in Fe<sub>3</sub>O

**Scheme 2** Mechanism of Ni-ferrite formation.

(MEEA)<sub>7</sub> · 5.5H<sub>2</sub>O solution. The formula of this liquid nickel ferrite precursor may be written as [Fe<sub>3</sub>O(MEEA)<sub>7</sub>][Ni(NO<sub>3</sub>)<sub>2</sub>] · 2H<sub>2</sub>O. Thermogravimetric analysis indicated dehydration at 125°C followed by burning out of the organic and nitrate ions over the range 150–330°C. The XRD pattern of the material showed that it is amorphous. However, a sample heated to 400°C demonstrated that a well-crystallized phase of pure nickel ferrites was formed. These results confirm our previous works on obtaining of NiFe<sub>2</sub>O<sub>4</sub> from oxotrinuclear acetate compounds.

### Formate Method

The nature of formate compounds utilized as precursors of ferrites is influenced by the pH of the reaction medium.

For this reason, the following systems were studied:<sup>[55]</sup>

where M(II) = Mn(II), Co(II), Ni(II), and Fe(II)

where M(II) = Mn(II) and M'(II) = Co(II) in two different pH ranges (3–3.5 and 7–7.5, respectively).

- At pH = 3–3.5, oxotrinuclear formate compounds similar with the basic acetate complexes were obtained:

- At pH = 7–7.5, only the species (NH<sub>4</sub>)<sub>2</sub>[Fe<sub>2</sub>Co(HCOO)<sub>2</sub>(OH)<sub>8</sub>] was obtained.

The IR spectra of the oxotrinuclear formates evidenced strong bands at 580–590 and 585 cm<sup>-1</sup>, respectively, which could be assigned to ν<sub>as</sub>(M<sub>3</sub>O) units.

The thermal decomposition of the polynuclear compounds was investigated. The final products obtained at about 600–650°C were analyzed by X-ray diffraction. The diffractograms indicated the formation of spinelic ferrites (Fig. 9) with mean crystallite sizes of 70–90 Å.

The decomposition of the oxotrinuclear formate.<sup>[52]</sup>

supports the following scheme:

**Fig. 9** Powder XRD patterns of the final thermolysis products of (NH<sub>4</sub>)<sub>2</sub>[Fe<sub>2</sub>Co(HCOO)<sub>2</sub>(OH)<sub>8</sub>].

**Fig. 10** Thermal decomposition in vacuum of  $[\text{Fe}_3\text{O}(\text{CH}_2\text{COO})_6(\text{HCOOH})_3]$ ,  $\beta = 16^\circ/\text{min}$ .

The decomposition of this compound (Fig. 10) shows the loss of  $\text{HCOOH}$  in a first stage (of two steps between  $100^\circ\text{C}$  and  $200^\circ\text{C}$ ) followed by a gradual loss (above  $200^\circ\text{C}$ ) of  $\text{HCOO}$  radical simultaneously with fragments originating from the decomposition of this radical.

Magnetite ( $\text{Fe}_3\text{O}_4$ ) is obtained at temperatures lower than  $250^\circ\text{C}$  (the lines characteristic of  $\text{Fe}_3\text{O}_4$  are present on the X-ray diagrams of the product obtained on calcination at  $220^\circ\text{C}$ ). The X-ray analysis of the oxide obtained at  $300^\circ\text{C}$  shows the lines characteristic of maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ). Calcination at  $600\text{--}700^\circ\text{C}$  results in the conversion of  $\gamma\text{-Fe}_2\text{O}_3$  into  $\alpha\text{-Fe}_2\text{O}_3$  modification.

### Glycolate Method

The glycolic acid (hydroxyacetic acid) is the simplest representative of the polyhydroxycarboxylic acids with many coordination possibilities because of the presence in the molecule of both carboxylic and hydroxy groups.

The isolation and the characterization of the polynuclear coordination compounds, potentially precursors for ferrites, were carried out from the systems<sup>[56]</sup>

where  $\text{M(II)} = \text{Co(II)}$  and  $\text{Ni(II)}$ .

To determine the nature of the species formed and, especially, to establish the stability range of these species, three pH intervals have been selected for the synthesis: 2–2.5, 3–5, and 6.5–8.0.

The results of the elemental analysis indicated that the polynuclear compounds have the following composition as a function of the pH reaction medium:

$$\text{pH} = 2 - 2.5$$

$$\text{pH} = 3 - 5.0$$

$$\text{pH} = 6.5 - 8.0(\text{NH}_4)_3$$

or

To obtain data concerning the ligand bonding, IR spectra were recorded over  $400\text{--}4000\text{ cm}^{-1}$  for all these compounds. These spectra were compared with those of the free ligand and of the sodium salt. The examination of these IR spectra has shown the coordination through the monodentate  $\text{COO}^-$  group and the OH group in compounds I and III and the coordination of the bidentate bridging  $\text{COO}^-$  group ( $\Delta\nu_{\text{as}} - \nu_{\text{s}} = 170\text{ cm}^{-1}$ ) in compound (II); this participation correlated to the existence of  $\nu(\text{M}_3\text{O})_{(\text{as})} \sim 590\text{ cm}^{-1}$  pleads for an oxotrinuclear configuration.

The electronic spectra were recorded in the  $400\text{--}1000\text{ nm}$  range. Analysis of all spectra suggests the assignment of an octahedral configuration to  $\text{Fe(III)}$  ions as well as to  $\text{M(II)} = \text{Co(II)}$  and  $\text{Ni(II)}$  for all the polynuclear compounds. The magnetic moments values of paramagnetic compounds ( $\mu = 7.27$  Bohr magnetons for  $[\text{Fe(III)}_2\text{CoO}(\text{CH}_2(\text{OH})\text{COO})_6(\text{H}_2\text{O})_3]$  and  $\mu = 6.38$  Bohr magnetons for  $(\text{NH}_4)_3[\text{Fe(III)}_2\text{Ni}(\text{CH}_2(\text{OH})\text{COO})_3(\text{OH})_8]$ ) are smaller than those obtained by summing up the magnetic moments of the metal ions. This indicates that antiferromagnetic interactions were present, as generally expected in such polynuclear compounds.

The thermal decomposition of these compounds was investigated to establish the decomposition steps and the optimal conditions for the conversion into spinelic phase. The first step corresponds to the loss of the three water molecules. The second step, a very complex one, corresponds to the decomposition

Fig. 11. Powder XRD patterns of the final thermolysis products of  $[\text{Fe}_2^{\text{III}}\text{CoO}(\text{CH}_2(\text{OH})\text{COO})_6(\text{H}_2\text{O})_3]$ .

of the glycolate ligands and the formation of the spinel phase. This final product was analyzed by X-ray diffraction. The diffractograms suggested the formation of spinel ferrite (Fig. 11).

## FERRITES OBTAINED BY COMBUSTION METHOD

Fine particles spinel ferrites are useful for the preparation of ferromagnetic liquids.<sup>[57]</sup> The synthesis of these nanoferrites continues to be a challenge to chemists and material scientists.

One of the most recent synthesis strategy used to eliminate the difficulties of classical methods is the “combustion synthesis,” also known as “self-propagating high-temperature synthesis” (SHS). The combustion method has been used in the preparation of a large number of technologically important oxides (refractory oxides, magnetic, semiconducting oxides, insulators, catalysts, sensors, etc.). In recent years, there is a growing interest in the combustion synthesis of materials because this method is simple, fast, economic, and yields high-purity products.

The SHS method was developed by Patil et al.<sup>[58–61]</sup> and during the last decade, a number of review works on the combustion method have already been published. The combustion method uses the energy produced by the exothermic redox decomposition of a

mixture of metal nitrates with an organic compound. In the combustion, the mixtures of nitrates and organic compounds behave similarly to conventional oxidants and fuels. The reaction is carried out by dissolving metal nitrates and fuel in a minimum amount of water and heating the mixture to evaporate water in excess. The resulting viscous liquid ignites and undergoes self-combustion, producing ashes that contain the oxide products. During the combustion, exothermic reactions take place. Gases such as  $\text{N}_2$ ,  $\text{H}_2\text{O}$ , and  $\text{CO}_2$  evolve, favoring the formation of fine particle ashes.<sup>[57]</sup>

The exothermicity of the combustion is controlled by the nature of the fuel and the ratio oxidizer/fuel. Fuels are organic compounds: hydrazine (H) and its derivatives (monomethyl, unsymmetric disubstituted methyl hydrazines and hydrazides), hydrazine carboxylic acid ( $\text{N}_2\text{H}_3\text{COOH}$ ), oxalyldihydrazide (ODH) ( $\text{CON}_2\text{H}_3$ )<sub>2</sub>, maleic hydrazide ( $\text{C}_4\text{H}_4\text{N}_2\text{O}_2$ , MH), malonic dihydrazide ( $\text{C}_3\text{H}_8\text{N}_4\text{O}_2$ , MDH), tetraformyl tris-azine ( $\text{C}_4\text{H}_{16}\text{N}_6\text{O}_2$ , TFTA), urea ( $\text{CH}_4\text{N}_2\text{O}$ , U), etc. The stoichiometric composition of the metal nitrate–fuel mixture is given by the equivalence ratio  $\Phi_e$  which reflects the relative ratio fuel/oxidizer. In propellant chemistry, the species  $\text{M}^{2+}$ ,  $\text{M}^{3+}$ ,  $\text{M}^{4+}$ , C, and H are considered to be reducing with the corresponding valences +2, +3, +4, +4, and +1. Elemental oxygen is an oxidizing species with valence 2. All of these organic fuels are at the same time very good ligands. The strategy for using hydrazine and its derivatives, urea and tetraformyl tris-azine, as fuels involves complexation with appropriate metal ions. For this reason, we regard the combustion method as a thermal decomposition of polynuclear coordination compounds in situ.

The metal hydrazine compounds:<sup>[58,61]</sup>

have low ignition temperature ( $<300^\circ\text{C}$ ) and, once ignited, decompose autocatalytically to yield fine particle oxides.

Hydrazine has a great affinity for  $\text{CO}_2$  and forms the hydrazine carboxylic acid ( $\text{N}_2\text{H}_3\text{COOH}$ ). The hydrazine carboxylate anion,  $\text{N}_2\text{H}_3\text{COO}^-$ , is a bidentate ligand, which can form coordination compounds such as:

where  $\text{M}(\text{II}) = \text{Mg}(\text{II}), \text{Mn}(\text{II}),$  and  $\text{Zn}(\text{II})$

Together with hydrazine, it can form coordination compounds with mixed ligands:

where M(II) = Mg(II), Co(II), Mn(II), Fe(II), Ni(II), Cu(II), and Zn(II)

where M(II) = Mg(II), Mn(II), Co(II), Zn(II), and Cd(II)

$$x = 0.2, 0.4, 0.5, 0.6, 0.8$$

These complexes and their solid solution have low ignition temperatures (120–300°C) and decompose or combust in air with evolution of NH<sub>3</sub>, H<sub>2</sub>O, and CO<sub>2</sub> to yield fine particle oxides. These powders have a narrow size distribution with average agglomerate particles of 5–50 nm. The fine particulate nature is attributed to evolution of a large amount of gases (NH<sub>3</sub>, H<sub>2</sub>O, and CO<sub>2</sub>) that help to dissipate the heat, thereby preventing the oxides from sintering.

If the fuel is oxalyldihydrazide (CON<sub>2</sub>H<sub>3</sub>)<sub>2</sub>, the theoretical equations proposed by Suresh and Patil<sup>[59,62]</sup> for the complete combustion of the redox mixtures to obtain spinel oxides are:

The formation of a spinel phase was confirmed by its characteristic powder XRD pattern. The spinel ferrites show considerable X-ray line broadening owing to the fine particle nature. The crystallite size of MFe<sub>2</sub>O<sub>4</sub> where M(II) = Mg(II), Mn(II), Co(II), Ni(II), Cu(II), and Zn(II) are in the range 15–30 nm.

Another important, very simple fuel is urea (CON<sub>2</sub>H<sub>4</sub>). The property of urea to form ureates with inorganic salts has been known for over 50 years. The usual way of their synthesis is the isothermal evaporation of aqueous solutions containing an inorganic salt and urea. The final product is a compound in which the water molecules may be partially or completely substituted by urea.

Using compounds containing urea and two or more metal ions as precursors of spinel ferrites opens very interesting reaction routes.<sup>[63,64]</sup>

For this reason, the following systems were investigated:

where M(II) = Ni(II), Co(II), and Zn(II).

The compounds containing Fe(III), M(II), and urea as ligand (in the best ratio 2:1:6) were separated by two synthesis methods:

- A solid-state method.
- A coprecipitation method.

Both synthesis methods lead to the formation of the same polynuclear compound:

where M(II) = Ni(II), Co(II), and Zn(II).

The IR spectra of these compounds compared with that of urea indicate the coordination of urea to metal ions through oxygen atoms. This coordination mode leads to a decrease of the CO stretching bands.<sup>[65]</sup> Bands assigned to the vibration mode of NO<sub>3</sub><sup>-</sup> anion were also identified.

The thermal analyses performed for these compounds showed that the decomposition occurs above 110°C in four stages of weight loss. The first one, associated with an endothermic effect, is a result of the release of four molecules of urea. The second one, a strong exothermic effect, is a complex process; the decomposition of the two remaining urea molecules takes place together with the nitrate anions. The last two steps correspond to the oxidation of the decomposition urea product.

The nanosized ferrite powders were obtained with crystallite sizes in the range of 40–60 nm. The Mössbauer spectra indicated superparamagnetic behavior. The combustion synthesis applied for the obtaining of nanoferrites is a very promising procedure. The combustion process is simple, rapid, and has the advantages of the wet chemical methods. As Prof. Patil himself described very eloquently this method,<sup>[61]</sup> “The materials arise from the combustion residues (ash) like a “Phoenix,” the mythological bird that burnt itself on pyre and arose from the ashes with renewed youth to live again.”

## CONCLUSION

The complexation method—comprising the thermal decomposition of the polynuclear complex compounds and the self-autocombustion method—is one of the most promising methods for obtaining of nanoferrites.

In the synthesis of nanoferrites, the precursors play a very important role. The use of a particular precursor may affect the materials' structure on a molecular level. Using appropriate precursors ensures the homogeneity and the highly dispersed state of the resulted materials.

The polynuclear coordination compounds with two or more metallic ions included in the same molecular entity satisfy all of these requirements:

- The atomic distribution is homogeneous at molecular level.

- The decomposition of compounds is simultaneous with, or is immediately followed by, formation of ferrite.
- The temperature of ferrite formation is much lower than that used in the classical methods.
- Because of this relatively low temperature of the formation, the ferrites are characterized by ultrafine granulation and high specific surface area.

In this entry, we emphasized the important role of the coordination chemistry in the nanoparticle science. As Busch<sup>[66]</sup> stated in his review, "Coordination chemistry is a field that spawns fields...; It is foundational to other burgeoning fields, for example solid-state chemistry, extended and mesoscopic materials, photonic materials, models for solid surface and molecular electronics, machines and devices. The enormous extension of the field reflect its fundamental nature: the principles are so basic that they have immediately application as undreamed of new substances..."

# Magnetic Nanoparticles

Valérie Cabuil

Université Pierre et Marie Curie, Paris, France

## INTRODUCTION

Magnetic particles are well known for their use in recording devices. For such an application that involves information storage, the nature, size, and shape of the particles are important parameters. These particles are usually made of magnetite ( $\text{Fe}_3\text{O}_4$ ), maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ), cobalt ferrite ( $\text{Fe}_2\text{CoO}_4$ ), or chromium dioxide ( $\text{CrO}_2$ ). They are spherical or acicular, and are usually micron-sized.<sup>[1]</sup> These particles are deposited on a substrate, and only magnetic properties of the systems are considered.

In this entry, we shall not focus on magnetic particles as magnetic pigments, but as special colloids. Indeed, we shall describe the synthesis and properties of particles whose diameters are smaller than 15 nm, and thus are subject to Brownian motion.

## OVERVIEW

Nanometric magnetic particles can be prepared by grinding a magnetic material, typically a ferrite, for several weeks using chemical synthesis.<sup>[2]</sup> Many synthesis procedures are used, according to the nature of the magnetic particles: iron oxide particles are usually obtained using a precipitation method; synthesis of metallic particles needs more subtle processes. The main difficulty is in getting monodispersed samples in a nanometric range. Nevertheless, it is an important point because the magnetic properties of particles vary based on their size. The materials constituting the particles are ferromagnetic or ferrimagnetic materials.<sup>[3]</sup> Because of their small diameters, the particles under consideration are magnetic monodomains, which means that each particle has a permanent magnetic moment whose intensity is proportional to the particle's volume and to the specific magnetization of the material. Depending on this volume, this moment is either blocked in the easy axes of magnetization, or is free to rotate inside the grain. In this last case, the grain is said to be "superparamagnetic."<sup>[4]</sup> For even smaller particles, the magnetic order will disappear.

Because of their small size, magnetic nanoparticles can be dispersed in a liquid carrier.<sup>[5]</sup> A superparamagnetic

colloidal dispersion (usually called ferrofluid) is then obtained.<sup>[6]</sup> Such a dispersion is stable for years, contrary to the so-called "bitter fluid" or to the magnetorheological fluids that are dispersions of micron-sized particles. It does not settle with time—neither when a magnetic force is applied and is not magnetic in zero field but becomes magnetized when a magnetic field is applied.<sup>[7]</sup> It is able to move under the action of a magnetic force and indeed finds numerous applications in the field of mechanics. Because the entry on "Magnetic Nanoparticles in Fluid Suspension: Ferrofluid Applications" covers this aspect in depth, this entry will only touch on this area of research. A key condition for the development of ferrofluid-based applications is that the colloidal dispersion has to be stable. To prevent particle aggregation because of van der Waals forces or magnetic dipolar interactions, interparticle repulsions have to be "chemically" created. Oxide particles can be directly dispersed in water, provided the pH value is such that the surface hydroxyl groups are ionized.<sup>[8]</sup> In this case, electrostatic repulsions prevent particles from aggregation.<sup>[9]</sup> Particles can also be coated by surfactants or polymers, especially when they have to be dispersed in oily media, and steric repulsions are, in this case, responsible for the stability of the system.<sup>[10]</sup> Obtaining stable dispersions of magnetic particles is an important point for applications, but on the theoretical point of view, such dispersions are also original examples of colloids, with additional interparticle interactions, that are tunable using an external parameter (i.e., the magnetic field). These dispersions have, in addition, many original properties because of their global response to a magnetic field. This response can be a "magnetic" one (the medium becomes magnetized), but also an optical one (the medium becomes birefringent) or a rheological one (the medium becomes structured).<sup>[6,7,9]</sup>

These properties can be transmitted to more complex media: glasses,<sup>[11]</sup> polymeric gels,<sup>[12]</sup> lyotropic systems (nematics<sup>[13]</sup> and smectics<sup>[14]</sup>), and microscopic colloids (emulsions,<sup>[15]</sup> latex,<sup>[16]</sup> and liposomes<sup>[17]</sup>), which then obtain a response to a magnetic field of small intensity. For example, orientational transition of self-organized phases of surfactants<sup>[18]</sup> and deformation of liposomes<sup>[19]</sup> have been observed in low-intensity magnetic fields. Magnetic nanoparticles have also been introduced in inorganic or polymeric gels

as viscosity probes, analyzing their magneto-optical response.<sup>[20]</sup>

These magnetic nanoparticles should find numerous applications. Nevertheless, until now, except for the “ferrofluid applications” in the field of commercial mechanics,<sup>[21]</sup> few applications have been developed. The challenge seems to be in the field of biomedical applications in the next few years.<sup>[22,23]</sup>

## PREPARATION PROCEDURES

According to the chemical nature of the particles (metallic or oxide particles), synthesis procedures will be very different.

## Chemical Nature of Particles

Magnetic nanoparticles are, of course, constituted of a magnetic material: a ferromagnetic material or a ferrimagnetic one.<sup>[3]</sup> In a ferromagnetic or ferrimagnetic material, specific interactions exist between the spins of atoms and lead to an ordering of the spins in parallel or antiparallel directions (Fig. 1). This spontaneous ordering of individual magnetic moments results in a magnetic moment per unit volume that is called its *specific magnetization*  $M_s$ , but it disappears above a given temperature, which is called *Curie temperature*. Please note that although ferromagnetism and ferrimagnetism are formally different, they lead to the same macroscopic magnetic properties, and the word “ferromagnetism” is often used in place of “ferrimagnetism,” even in this entry.

Table 1 lists several ferromagnetic or ferrimagnetic materials, in order of increasing magnetization.

Unfortunately, the more magnetic materials (metals) are, the more easily they are oxidized; this tendency to oxidation is enhanced when materials become powder. Consequently, the most commonly used magnetic materials as colloidal particles are iron oxides because they are cheap and easy to obtain.

## Magnetite and Maghemite Particles

The most widely known magnetic iron oxide is magnetite ( $\text{Fe}_3\text{O}_4$ ). Indeed, the first magnetic nanoparticles were

**Fig. 1** The three types of cooperative magnetism. Antiferromagnetism does not lead to macroscopic magnetism.

**Table 1** Some commonly used ferromagnetic or ferrimagnetic materials ( $T_c$  is the curie temperature, and  $M_s$  is the saturation magnetization of the material)

Material	Type of magnetism	$T_c$ (°C)	$M_s$ (kA/m)
Chromium dioxide ( $\text{CrO}_2$ )	Ferrimagnetic	117	410
Maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ )	Ferrimagnetic	590	414
Cobalt ferrite ( $\text{CoFe}_2\text{O}_4$ )	Ferrimagnetic	520	422
Magnetite ( $\text{Fe}_3\text{O}_4$ )	Ferrimagnetic	585	470
Nickel $\text{Ni}(\alpha)$	Ferromagnetic	358	485
Cobalt $\text{Co}(\alpha)$	Ferromagnetic	1131	1400
Iron $\text{Fe}(\alpha)$	Ferromagnetic	770	1707

obtained by grinding magnetite grains in ball mills, in the presence of a surfactant and a liquid carrier. The surfactant, at the same time, helps in grinding and prevents particle aggregation. This process costs time (about 1000 hr) and leads only to surfactant-coated particles.<sup>[2,24]</sup>

Chemical synthesis of colloidal magnetite is now widely used. It has been known for a long time: aqueous mixtures of ferric and ferrous salts are mixed with an alkali to induce the precipitation of a black hydrophilic magnetic product, which is constituted of magnetite particles—negatively charged and associated with the counterions of the alkali.<sup>[25]</sup> According to the experimental conditions of the synthesis, the particle size can be roughly controlled.<sup>[26,27]</sup> The particles are rocklike (Fig. 2A) and the system is always polydispersed in size, but the average diameter can be monitored between 5 and 14 nm through the nature of the alkali, its concentration, the concentration of the ferric and ferrous salt, the  $\text{Fe(II)/Fe(III)}$  ratio, the ionic strength, the temperature, the way of admixing the reactants, and the efficiency of stirring.<sup>[26]</sup> Once all these parameters are fixed, the result of the synthesis is reproducible. Concerning magnetite, the situation can be summarized this way. Magnetite nanoparticles are obtained at room temperature and, for a given concentration of ferric and ferrous species, an increase of pH induces a decrease of particle size, sodium hydroxide leads to particles smaller than ammonia (for the same pH), an increase in ionic strength induces a decrease in particle size, and an increase in the  $\text{Fe(II)/Fe(III)}$  ratio increases the particle size. Another way to reduce particle size is to add to the synthesis mixture a molecule-chelating iron species. For example, it is known that carboxylate species interfere with the formation and growth of ferric oxides. Performing the synthesis of colloidal magnetite in citrate

**Fig. 2** TEM pictures of ferrite nanoparticles (A) and iron particles (B).

or tartrate species allows the reduction of the average particle diameter to 3 nm.<sup>[28]</sup> However, particle size distribution remains rather wide. Synthesis using micelles has been proposed to control the size distribution.<sup>[29]</sup> Processes using iron(III) acetylacetonate in organic media have been recently proposed to produce monodisperse magnetite particles.<sup>[30]</sup> Please note that nature is also able to synthesize colloidal magnetite (e.g., magnetotacticum bacteria produce nanometric magnetite particles).<sup>[31]</sup>

Colloidal magnetite gets oxidized easily. If it is kept under usual atmosphere, it quickly oxidizes, and the product often called maghemite is, in fact, bertholide [i.e., a ferric oxide whose composition is between that of magnetite ( $\text{Fe}_3\text{O}_4$ ) and maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ )]. That is the reason why magnetite is sometimes deliberately oxidized to maghemite, by dispersing the magnetic particles in acidic medium and stirring them with ferric nitrate.<sup>[10]</sup> The maghemite particles obtained are then chemically stable in alkaline or acidic medium. The saturation magnetization of maghemite is slightly lower than the one of magnetite, but the difference of magnetization is largely counterbalanced by the gain of chemical stability.

### Other Ferric Oxides

Many ferric oxide materials with a spinel-like structure ( $\text{MFe}_2\text{O}_4$ ,  $\text{M} = \text{Co}, \text{Mn}, \text{etc.}$ ) can be obtained as

nanoparticles. The synthesis of cobalt ferrite particles and manganese ferrite particles has been widely described.<sup>[32–35]</sup> The process is again a precipitation of the oxide using an alkali, but the synthesis conditions to obtain magnetic nanoparticles depend on the nature of the oxide synthesized. For example, cobalt ferrite particles are more rapidly obtained at 90°C, using sodium hydroxide or methylamine.<sup>[33]</sup> Such particles are highly unstable in acidic medium: they are completely dissolved, leading back to the initial mixture. The same problem exists with manganese ferrite particles. Coating particles with a thin amorphous ferric oxide shell prevent this dissolution and stabilize the samples in acidic media.<sup>[32]</sup>

M can stay for a mixture of two metallic species (e.g., Zn and Mn, Ni or Co). Compounds with such a composition  $\text{M}_{1-x}\text{Zn}_x\text{Fe}_2\text{O}_4$  have magnetic properties that are continuously dependent on the value of  $x$  (when  $x = 1$ , the compound  $\text{ZnFe}_2\text{O}_4$  is no more ferrimagnetic at room temperature). The problem is to control the particle size at the same time, which is dependent on  $x$  and the magnetic properties.<sup>[34]</sup>

Again synthesis using micelles has been described to produce calibrated cobalt ferrite,<sup>[33,36]</sup> or zinc–cobalt ferrite nanoparticles.<sup>[37]</sup> Surfactant of the type metal dodecyl sulfate [ $\text{Fe}(\text{DS})_2$ ,  $\text{Co}(\text{DS})_2$ , or  $\text{Zn}(\text{DS})_2$ ] are synthesized and mixed in micelles; addition of an alkali again induces the formation of particles.

### Metallic Particles

Metallic particles seem to be more interesting than oxides because their specific magnetization is higher (Table 1). Nevertheless, metallic particles are highly oxidizable and often lose their high magnetization because of oxidation. Different processes have been developed.

Decomposition of metal carbonyl compounds is a convenient method that allows one to obtain large amounts of monodisperse metal particles. Cobalt particles are prepared from dicobalt octacarbonyl ( $\text{Co}_2(\text{CO})_8$ ).<sup>[38–40]</sup> Iron particles are obtained from iron pentacarbonyl ( $\text{Fe}(\text{CO})_5$ ).<sup>[41,42]</sup> In the case of iron particles, the solvent is usually toluene or decalin, and the stabilizing agent is either oleic acid, or a polymer as polyisobutene. Usually, the metallic particles obtained this way have narrower size distributions than the ferrite particles (Fig. 2B). Nevertheless, their magnetization is always lower than the one of the bulk material because of surface oxidation and carbon incorporation. The surfactant or the polymer dispersed in the solvent is supposed to catalyze the reaction, to prevent particles from aggregating and to protect them against oxidation. Unfortunately, for this last point, the efficiency of the surfactants or polymers tested is not as promising.

Decomposition of iron octacarbonyl in the presence of ammonia has been described as leading to iron-nitride particles ( $\text{Fe}_3\text{N}$ ), which has a high saturation magnetization and a good chemical stability.<sup>[43]</sup> The particle diameter is monitored between 5 and 10 nm, through the  $\text{Fe}(\text{CO})_5$  content.

Reduction of metal salts by strong reducing agents such as borohydrides is another method to obtain metallic particles, but it is difficult to obtain colloidal objects with reasonable polydispersity without using reverse micelles. For example, nanosized particles, with diameters on the order of 6 nm, are obtained from the reduction of cobalt bis(2-ethylhexyl)-sulfosuccinate ( $\text{Co}(\text{AOT})_2$ ) involved in  $\text{Na}(\text{AOT})$  micelles.<sup>[44]</sup> Nearly monodispersed cobalt nanocrystals were obtained by reduction of cobalt chloride at high temperature in the presence of stabilizing agents.<sup>[45]</sup> A special case is the one of iron particles dispersed in mercury that have been obtained by electrolytic reduction of metal salt solutions, or of colloidal solutions of iron oxide in a supporting electrolyte.<sup>[46]</sup> Nanometric particles are obtained, but the prevention of particle agglomeration is the key problem and is still under study.

A third method uses the evaporation of metal in a vacuum in the presence of a solvent containing a surfactant.<sup>[47]</sup> This technique produces metal particles, the size of which depends on the time during which samples are heated and the amount of surfactant.

### Polydispersity of Samples

Polydispersity is the main problem encountered when working with nanoparticles. It can be solved, in some cases, by the choice of the synthesis process, or by size-sorting processes once the particles are synthesized.

In the case of ferric oxide particles, the average diameter is easily controlled through the experimental conditions of synthesis, but the system is always polydispersed. The particle size distribution is well described using a log-normal distribution of diameters (Fig. 3):

$$P(d) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{\ln^2(d/d_0)}{2\sigma^2}\right)$$

In usual products synthesized by a coprecipitation method, the polydispersity  $\sigma$  ranges between 0.3 and 0.4. This corresponds to a rather wide distribution. Synthesis using micelles reduced polydispersities but never obtained monodisperse samples.<sup>[48]</sup> Centrifugation and magnetic separation can be alternative procedures.<sup>[49]</sup> A size-sorting process has been proposed to reduce significantly the polydispersity down to 0.15. It is based on the thermodynamic properties of colloidal dispersions ("Phase Behavior of Dispersions of

Fig. 3 Two examples of log-normal distribution of diameters.

Magnetic Nanoparticles") and has already been used to obtain monodispersed emulsions.<sup>[15]</sup> It is described in the case of positive or negative ferrite particles dispersed in water in Refs.<sup>[49,50]</sup> Such dispersions are stabilized by the electrostatic repulsions between particles. These repulsions depend on the ionic strength in the aqueous solution and can be reduced by addition of an electrolyte in the medium. The screening of the repulsions induces a reversible phase separation between a liquid phase dense in colloids and a liquid phase poor in colloids. If both phases are separated and analyzed, it is found that the dense phase contains the bigger particles, and the light phase contains the smallest ones. Performing this process two or three times, it is possible to fractionate the size distribution and obtain almost monodispersed samples with a reasonable yield.

Metallic particles are usually obtained with a very low polydispersity (Fig. 2) and size sorting is indeed unnecessary.

### MAGNETIC PROPERTIES

Because of their colloidal size, the magnetic particles under consideration here and whose synthesis is described above have magnetic properties that are strongly modified with respect to the properties of bulk materials.

#### Bulk Ferromagnetic Materials

In ferromagnetic or ferrimagnetic materials, the order results in high magnetostatic energy.<sup>[3,51]</sup> To reduce this energy, the bulk material divides into domains, called magnetic monodomains, separated by the so-called "Bloch walls." Each monodomain has a permanent magnetization vector, which is oriented, in zero field, to minimize this magnetostatic energy (Fig. 4). In zero field, this magnetization vector has a given crystallographic direction, which is one of the

Fig. 4 Magnetic domains in zero field.

so-called “easy axes of magnetization.” In some materials, there are three easy axes of magnetization; in others, only there is only one axis. In the first case, it is told that the material has a cubic anisotropy; in the second instance, it has an axial anisotropy. Moving the magnetic vector away from an easy axis of magnetization costs energy, which is called the energy of anisotropy ( $E_a$ ). This energy depends on constants called the magnetocrystalline anisotropy constants (denoted  $K$ ), which are a function of the material under consideration.

On the macroscopic point of view, the magnetization of a ferromagnetic (or a ferrimagnetic) material in zero field is equal to zero, and its magnetization curve (magnetization as a function of the applied magnetic field) is a shape characteristic of a ferromagnetic material with a hysteresis loop (Fig. 5A).

### Magnetic Properties of Fine Particles

The diameter of the colloidal particles under consideration here are always smaller than the dimension of a

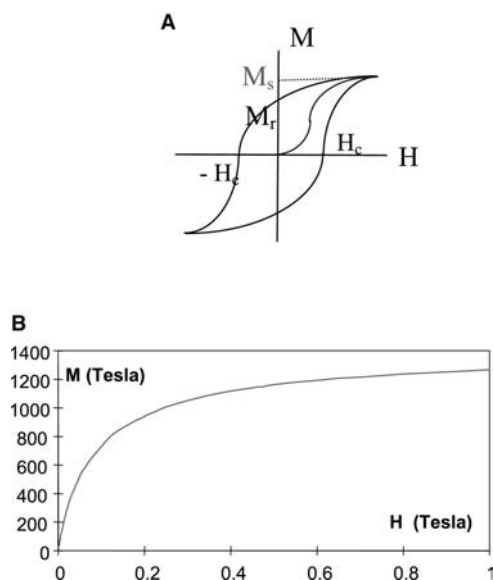

Fig. 5 (A) Scheme of the magnetization curve of a ferromagnetic (or ferrimagnetic) material. (B) Real magnetization curve of a superparamagnetic material.

magnetic domain. It means that each particle is a magnetic monodomain and has a permanent magnetic moment, whose intensity  $\mu$  is proportional to the specific magnetization of the material constituting the grain ( $M_s$ ), and to the volume of this grain ( $V$ ):

$$\mu = M_s V$$

$M_s$  is usually lower than the magnetization of the bulk material for several reasons. The first is relevant for oxidized materials; for example, metallic particles' specific magnetization, if submitted to oxidation, will fall down—and this change will be more dramatic as the particle surface increases. But even for particles stable with respect to oxidation, the local disorganization of the surface leads to a lowering of the specific magnetization.<sup>[7]</sup>

For 7-nm-diameter maghemite particles, a typical value of  $\mu$  is  $5.4 \times 10^{-20} \text{ A m}^2$ , which corresponds to about  $6000 \mu_B$ .<sup>[52]</sup>

The direction of this moment is fixed in the direction of an easy axis of magnetization. Nevertheless, the nature of the anisotropy (cubic one or uniaxial one) depends on the particles' shape and size. The value of the energy of anisotropy is also modified compared with the value of the bulk material. For an uniaxial anisotropy, it is given by:

$$E_a = K_{a \text{ eff}} V$$

where  $V$  is the volume of the monodomain, and  $K_{a \text{ eff}}$  is the anisotropy constant of the material in the grain. This anisotropy constant depends now on the particle shape, particle size, and the interactions between grains. It is difficult to propose a calculation of such an energy, but experimental magnetization or Mössbauer measurements have allowed estimations for ferrite particles.<sup>[37]</sup>

For a given material and a given temperature, the energy of anisotropy decreases when the particle size decreases. Under a given diameter, it becomes the same order of magnitude as the entropic term  $kT$ : this means that the magnetization vector fluctuates around the easy axis of magnetization, with a characteristic relaxation time (Néel relaxation time) such as  $\tau = \tau_0 \exp(E_a/kT)$  ( $\tau_0$  is on the order of  $10^{-10}$  sec). This phenomenon is called superparamagnetism (by comparison with the paramagnetic behavior of isolated magnetic moments, and by opposition to the ferromagnetic behavior of the bulk material) and the particle is called a “soft dipole.” For a given temperature, according to the nature of the material, the diameter below which superparamagnetism is observed differs. For example, at room temperature, 5-nm-diameter maghemite particles have a superparamagnetic behavior, although cobalt ferrite particles have a

ferromagnetic behavior. But please note that the colloids under consideration here are always polydispersed in size and, at a given temperature, an assembly of such colloids presents a rather large distribution of relaxation times. Some studies have tried to relate the anisotropy of cobalt ferrite grains to the particle size.<sup>[53,54]</sup> A complete description of the magnetic properties of nanoparticles needs to take into account surface effects: the surface disordered spins fluctuate and hinder the dynamics of the magnetic moment associated with a particle. Surface anisotropy can be more important than the volume.<sup>[55]</sup>

On a macroscopic point of view, the shape of the magnetization curve of a diluted assembly of superparamagnetic grains is well described by the Langevin formalism (Fig. 5B):

$$M(H) = M_s \left( \coth \frac{\mu H}{kT} - \frac{kT}{\mu H} \right)$$

The polydispersity has to be taken into account and can modify the shape of the curve because of its high influence on  $\mu$ .<sup>[52]</sup>

## COLLOIDAL DISPERSION OF MAGNETIC NANOPARTICLES

As mentioned earlier, because of their colloidal dimensions, magnetic nanoparticles can be dispersed in a liquid carrier, and a stable colloidal dispersion, usually called “magnetic fluid” or “ferrofluid,” can be obtained.<sup>[6]</sup> Such dispersions conjugate the properties of usual colloidal dispersions and the magnetic properties of the nanoparticles dispersed. Indeed, oily magnetic fluids have found many commercialized applications (special seals and bearings, moving coils speaker, inertia dampers, etc.)<sup>[56]</sup> and many other conceptual ones (captors, magnetic ink, magnetic levitation, magneto-optical devices, etc.).<sup>[57]</sup>

### Processes for the Dispersion of Magnetic Colloidal Particles in Liquid Carriers

#### Oily carriers

Organic solvents are often needed for commercialized applications. That is the reason why most of the particle synthesis processes involve a step during which a surfactant is added to the mixture, to adsorb on particles and to provide them an affinity for the oily media.<sup>[58,59]</sup> The surfactant avoids aggregation of particles in the oily liquid carrier, and the resulting product is a stable colloidal dispersion of magnetic particles. Surfactants are, for applications, commercial

products. Oleic acid is often used because it is one of the best surfactants for dispersing metal oxide particles in hydrocarbon media. But it cannot be used for dispersion of particles in aromatic oils or chlorinated solvents. In fact, the choice of a surfactant is not a trial-and-error work.<sup>[10,60,61]</sup> It is always a single-chain surfactant and the chemical nature of the chain is a function of the nature of the liquid carrier. For example, dispersion in aromatic oils is possible with surfactants having an aromatic cycle in their tail. The choice of the polar head is determined by the nature of the particle surface. Oleic acid is a good surfactant for ferric oxide particles because the carboxylic acid group is a good chelating agent of Fe species.<sup>[62]</sup> But even when the affinity of the surfactant for the surface is strong, it has to be kept in mind that desorption can occur (e.g., when diluting the colloidal dispersion with the liquid carrier). This is a serious limitation for applications as for theoretical studies.

Polymeric species, again introduced during the synthesis of particles, are sometimes described as stabilizers, in the case of metallic particles.<sup>[39,40]</sup> In some other cases, they are grafted as macrosurfactants on the particles after synthesis.<sup>[63]</sup>

Anyway, the result is that, at the present time, it is possible to obtain dispersions of magnetic nanoparticles in a wide variety of media: alkane, aromatic solvents, chlorated solvents, ketones, phthalates, and commercial oils derived from silicon oils, resins, etc. Some dispersions are commercialized; others are laboratory products.

#### Aqueous solvents

Aqueous solvents are also used for the dispersion of ferrite particles, usually for fundamental studies or biomedical applications.<sup>[64]</sup> In this case, the dispersions are stabilized, thanks to particle surface charges. Indeed, a metal oxide surface in water has a specific acid–base behavior, which leads to anionic or cationic surface charges according to the value of the pH, which are called “structural charges”.<sup>[8]</sup> When particles have a sufficient number of structural charges, electrostatic repulsions can stabilize their dispersion in water or in a brine solution. Unfortunately, for the magnetic ferric oxides constituting the magnetic particles under consideration (cobalt ferrite, maghemite, etc.), particles have a sufficient amount of surface charges only for strongly alkaline media (pH > 11) or strongly acidic ones (pH < 3).<sup>[9]</sup> As an example, it has been found that 7-nm-diameter maghemite particles have 80 structural charges at pH 2, 25 at pH 3, and only 8 at pH 4.<sup>[65]</sup>

Such a pH range is not suitable for applications, but can be modified by adsorption of small organic molecules (e.g., citrate species). The latter provide to the surface their own acid–base behavior and ensure negative surface charges for particles for any pH higher

than 3.<sup>[9,65]</sup> Moreover, it has been found that dispersions of citrate-coated particles were astonishingly stable in brine solution for electrostatically stabilized systems, indicating that adsorption of citrate leads to additional short-range repulsions of steric origin.<sup>[66]</sup> To modify the pH stability range of their dispersions, the particles can also be coated by silica or by molecules such as dimercaptosuccinic acid. This last molecule is of particular interest as it allows a further grafting of biological species through thiol bridges.<sup>[67]</sup>

The number of structural charges is not, in fact, the relevant parameter to explain the stability of electrostatically stabilized aqueous colloidal dispersions. As a matter of fact, the nature of the counterions of particles (charge and size) is of great importance because these counterions will condense on the charged surface, leading to an “effective surface” charge, inferior to the structural one and is the relevant parameter to quantify the electrostatic repulsions.<sup>[68]</sup> Highly charged and small counterions have to be avoided to obtain stable dispersions. That is the reason why tetramethylammonium has often been used in the case of dispersions of negatively charged ferrite particles, and nitrate anions in the case of positively charged particles.<sup>[25]</sup>

### Phase Behavior of Dispersions of Magnetic Nanoparticles

Dispersions of magnetic nanoparticles are special examples of colloidal dispersions because to the usual interparticle interactions (van der Waals attractions, electrostatic repulsions, or steric repulsions) are added the anisotropic dipolar magnetic interactions between the monodomains.<sup>[69]</sup> As a consequence, the total interparticle potential, which controls the structure and the phase behavior of the dispersion, becomes, theoretically, anisotropic. This is a rather original behavior and many theoretical papers dealing with dipolar fluids take dispersions of magnetic nanoparticles as an experimentally available example of dipolar fluid.<sup>[70–79]</sup> Theories predict for dipolar fluids in the high-dipole concentration regime the existence of a ferroelectric liquid phase,<sup>[73,75,76,80–84]</sup> or a ferroelectric crystal,<sup>[84]</sup> but, until now, such phases have never been observed. When the system is diluted, theories predict that the key parameter is the ratio of the dipolar attractions to the isotropic ones.<sup>[72,75–77,84]</sup> if this ratio is high, chains of dipoles, described as living polymers, are formed; if it is low, a “gas–liquid”-like phase transition can be observed. Application of a magnetic field to such systems has been considered for a long time. Authors who predict chains in zero field predict in magnetic field a phase transition between a “gas of chains” and a “liquid of chains,” or a phase separation leading to elongated drops of dense phase that

do not contain chains, according to the form given to the total interparticle potential.<sup>[75,76]</sup> Please note that refinements are now available to take into account the polydispersity.<sup>[78]</sup>

Interparticle interactions in magnetic fluids are van der Waals attractions, and dipolar magnetic interactions and repulsions, which depend on the nature of the dispersion:

1. The potential relative to the *van der Waals interactions* is isotropic and, for two spherical colloids of radius  $R$  separated by  $r$ , is given by:

$$U_{\text{vdw}} = -\frac{A}{6} \times \left[ \frac{2R^2}{r^2 - 4R^2} - \frac{2R^2}{r^2} + \ln \left( 1 - \frac{4R^2}{r^2} \right) \right]$$

where  $A$ , the Hamaker constant, can be estimated on the order of  $A = 10^{-19}$  J for metals and metallic oxides.<sup>[85]</sup>

2. The potential relative to *magnetic dipolar interactions* between two dipoles is anisotropic and is given by the formula:

$$\frac{U_{\text{dip}}(r)}{kT} = \frac{\gamma}{4\pi} (2 \cos \theta_1 \cos \theta_2 - \sin \theta_1 \sin \theta_2 \cos \varphi)$$

where  $\theta_i$  is the angle between the dipolar moment of a particle  $i$  and the vector joining the centers of two particles, and  $\varphi$  is the azimuthal angle between both dipoles. The reduced parameter  $\gamma = \mu_0 m_s^2 V^2 / kTr^3$  ( $V$  is the volume of a particle,  $m_s$  is the specific magnetization of the material, and  $r$  is the distance between particles) characterizes the strength of the magnetic coupling between particles. The average dipolar term is attractive and is usually calculated in two limit cases:<sup>[65,86]</sup> the case of low coupling in zero field ( $\gamma/4\pi \ll 1$ ), corresponding to the case of small moments or (and) large separations, and the case of high coupling ( $\gamma/4\pi \gg 1$ ), corresponding to the case of high moments separated by small distances.

For maghemite particles, with a diameter of 7 nm, the reduced parameter  $\gamma$  leads to a dipolar term in zero field, which is small compared with van der Waals attractions whatever the interparticle distance is.<sup>[65,87,88]</sup> Indeed, in zero field, usual ferrite magnetic fluids behave as isotropic systems. Thus as in any other colloidal dispersion, the range of attractions compared with the range of repulsions controls the phase

diagram of the system: if attractions are short-range, “fluid–solid”-like phase transitions are expected; if there are long-range attractions in the system, a critical point can exist, and “gas–liquid”-like, “liquid–solid”-like, and “gas–solid”-like transitions can be observed.<sup>[86,89–91]</sup> The theoretical treatment to describe such a behavior is not specific of magnetic fluids, and literature on this subject exceeds the present entry. We just emphasize here that aqueous dispersions of citrate-coated maghemite nanoparticles have allowed to experimentally investigate all the possible interactions regimes. At low ionic strength, electrostatic repulsions dominate interparticle interactions, and the phase diagram is one of an isotope-repulsive system. At high ionic strength, repulsions are screened and the interparticle potential is an isotope-attractive Lennard–Jones-like one in zero field.

The equation of state  $\Pi = f(\phi)$  of an aqueous dispersion of 7-nm-maghemite particles covered by citrate species has been constructed [using small-angle neutron scattering (SANS) and osmotic compression experiments] in several cases.<sup>[86–91]</sup> Such an equation is analogous to the equation of state of gases. Particles are compared with the molecules of a real gas, and the liquid carrier is compared with a continuum.  $\Pi$ , the osmotic pressure, is the pressure of the gas of particles.  $\Pi/\phi$  is a function of  $\phi$  that allows to check if the interactions between the particles are attractive or repulsive ones. It has been shown that it is possible with this unique system in zero field, varying the ionic strength and the temperature, to observe all the phase behaviors predicted by theories. At low ionic strength, the phase diagram is similar to the repulsive spheres and “gas–solid”-like transitions are observed for high-volume fractions of colloids. Nevertheless, the residual polydispersity, even if small, avoids to obtain a colloidal crystal and glasses are obtained.<sup>[90]</sup> At high ionic strength, the phase diagram is similar to the one of an atomic system and “gas–liquid”-like transitions are observed.<sup>[87]</sup> a phase dense in colloids nucleates inside a phase poor in colloids. A critical point has been localized. This noticeable richness of behaviors is because of the presence at the same time of monitorable electrostatic repulsions, strong steric repulsions because of the citrate coating, and long-range van der Waals attractions associated with the dipolar ones.<sup>[86]</sup>

In zero field, for these particles, chains have never been found. But using iron particles (that have a higher magnetic moment), chains have been observed even in zero field.<sup>[92,93]</sup>

The effect of a magnetic field depends on the range of the repulsions. In strongly repulsive systems, the application of a magnetic field will not macroscopically modify the aspect of the dispersions. Nevertheless, nanometric investigation, using SANS, shows that the structure of the suspensions is sensitive to the field,

a model of magnetic interactions explaining the under-field anisotropy of the SANS nuclear contribution.<sup>[94]</sup> However, in the regime of low repulsions, the dispersions are very sensitive to the application of a magnetic field, even macroscopically: “gas–liquid”-like phase transitions can be induced by the application of the field.<sup>[9]</sup>

### Some Properties of Dispersions of Magnetic Nanoparticles

The colloidal dispersion of magnetic nanoparticles has several original properties. Because the entry on “Magnetic Nanoparticles in Fluid Suspension: Ferrofluid Applications” covers this aspect in depth, here we shall only say few words on the magnetic and magneto-optical properties of these dispersions.

#### Magnetic properties

A colloidal dispersion of magnetic nanoparticles, whatever its nature, has a superparamagnetic behavior provided it is not too concentrated in particles in the absence of interparticle magnetic interactions (volume fraction lower than 1%).<sup>[7]</sup> Thus its magnetization curve is described by the Langevin formalism (Fig. 5B). This property has two origins. First, it may be because of the fact that the magnetic particles themselves are superparamagnetic (“Magnetic Properties of Fine Particles”). But even if all the particles were ferromagnetic, the behavior of their dispersion would be superparamagnetism because of the Brownian motion of particles in the carrier. Thus two characteristic times control the magnetic response of the colloidal dispersion—the Néel time (“Magnetic Properties of Fine Particles”) and the Brownian rotational relaxation time— $\tau_B = 3\eta V/kT$ , where  $\eta$  is the viscosity of the medium into which the particles are dispersed and  $V$  is their volume.<sup>[95]</sup> The relaxation process that is more rapid will control the relaxation. This provides magnetic fluids interesting frequency-dependent properties.<sup>[96,97]</sup>

#### Magneto-optical properties

These properties have been described for ferrite particles<sup>[98–106]</sup> and cobalt ferrite. In a zero magnetic field, a colloidal dispersion of such nanoparticles is an optically isotropic solution, but when a magnetic field is applied, it becomes anisotropic. When a beam of polarized light passes through a dispersion of nanometric ferrite particles (sufficiently diluted to limit absorption), according to the relative direction of the wave vector with respect to the magnetic field, linear anisotropy (field perpendicular to the wave vector) or circular anisotropy (field parallel to the wave vector)

will be observed. Linear anisotropy is characterized by linear birefringence and linear dichroism measurements. Circular anisotropy is characterized by Faraday rotation and ellipticity measurements. Both anisotropies increase as the magnetic field increases, and disappear without remanence when the magnetic field is cut off if the carrier is liquid. Nevertheless, they do not have exactly the same microscopic origin. Circular anisotropies behave as magnetization with respect to the magnetic field, although birefringence is related to the Brownian alignment of the particles (and not the Néel alignment of the moment) and follows the second Langevin law.<sup>[100]</sup> Trapped in a silica matrix, the dispersed magnetic nanoparticles can indeed be used to produce components for ellipsometry.<sup>[107]</sup>

### MAGNETIC COLLOIDAL PARTICLES ASSOCIATED WITH OTHER COLLOIDAL SYSTEMS

Magnetic nanoparticles have been introduced these last years in several complex media, either as probes to characterize the viscosity (and subsequently the structure) of the medium,<sup>[11,12,20,89,108]</sup> or to obtain field-dependent materials.<sup>[13–19]</sup> Such a mixture of a colloidal system with another has chemical and physico-chemical limitations.

### Hybrid Magnetic Materials: A Problem of Chemistry and of Physico-Chemistry

In any case, an eventual chemical incompatibility between the nanometric magnetic particles and the host colloid has to be examined first. A modification of the pH, an increase of the ionic strength, and adsorption or desorption of the charge-determining species or of the surfactants can occur during the mixing process or a few weeks after. The latter case is especially harmful because it can be unnoticed and leads to important interpretation errors. In the case of mixtures of self-assemblies of surfactants with particles, if the surfactant can adsorb on the ferrite particles, the properties of both the lyotropic system and the dispersion of nanoparticles will be modified. But even mixtures of purely inorganic systems can raise problems. For example, some clays are chemically stable only between pH 9 and pH 10: magnetic nanoparticles stable for these precise values have to be used to mix them with such a clay.<sup>[89,108]</sup> Chemistry of magnetic colloids is now sufficiently well developed to succeed in solving such problems.

As soon as the chemical stability of both colloidal systems is controlled, it has to be verified that one of the colloids will not “stress” the other one. As a matter

of fact, each colloidal system is characterized by its own osmotic pressure, and it can be roughly said that the system that has the higher osmotic pressure will impose its own pressure to the other one, which can then destabilize.<sup>[67]</sup>

### Magnetic Colloidal Particles as Viscosity Probes for the Characterization of Gels

As soon as particles can be dispersed in a medium, the medium will carry a magnetic field of induced birefringence (cf. “Some Properties of Dispersions of Magnetic Nanoparticles”). This birefringence disappears when the field is cut off, and its decrease is related to the Brownian motion of particles and their random orientations. The characteristic relaxation time is related to the diffusion coefficient of Brownian rotation of the particles in the carrier ( $\tau_B = 3\eta V/kT$ ) and becomes a measure of the local viscosity of the medium surrounding the particles, as soon as the latter are dispersed as individual grains in this medium ( $V$ , the hydrodynamic volume of the particles, must not vary during the experiment). This result makes the magnetic nanoparticles suitable probes to test the viscosity of several media at a nanometric scale<sup>[109]</sup> and allows, as a consequence, one to have an idea of the nanometric structure of a material. For example, if particles are able to rotate in a glass obtained by sol-gel process, it means that condensation is not complete or that heterogeneities exist into which nanometric objects are able to move. If the particles are really trapped in the silica matrix, a permanent birefringence can be remained.<sup>[11]</sup>

Another example is provided through the characterization of laponite gels.<sup>[89,108]</sup> Laponite is a synthetic clay, constituted by small discotic particles. These can be dispersed in water, but over a given volume fraction, a gel is obtained. Mixing nanometric maghemite particles in very low concentration with laponite particles (solving the problems of chemistry mentioned in “Hybrid Magnetic Materials: A Problem of Chemistry and of Physico-Chemistry”), it has been possible to investigate the local viscosity of laponite gels by measuring the relaxation decay of the birefringence signal of the probes. It has been found that in some macroscopically solid gels, the nanometric particles are able to rotate and feel the same viscosity as the one of water. This indicates the existence of mesoscopic liquid domains in the apparently homogeneous gels.

Magnetic polymeric hydrogels have also been synthesized, trapping nanometric maghemite or cobalt ferrite particles in polyacrylamide networks. Relaxation of a birefringence experiment has shown that according to the nature and amount of cross-linker

and to the particles' diameter, these particles are able or not able to rotate in the mesh of the network.<sup>[20,110,111]</sup>

### Magnetic Colloidal Particles to Induce a Magnetic Response to Lyotropic Systems

Magnetic fields or electric fields are often used to modify lyotropic systems: orientational transitions are induced in nematics or smectics,<sup>[112]</sup> liposomes are deformed by the application of an electric field.<sup>[113]</sup> Incorporation of a very small amount of magnetic colloidal particles in such systems can induce very impressive responses to low-intensity magnetic fields.

#### Magnetic liquid crystals

Several so-called "ferrosmeectics" have been synthesized. Surfactant-coated particles have been introduced in the cyclohexane part of the pseudo-ternary system water/sodium dodecyl sulfate/pentanol/cyclohexane.<sup>[14,114,115]</sup> Bidimensional packing of magnetic layers alternating with non-magnetic ones was obtained and it has been shown that this lamellar system, stabilized by Helfrich repulsions, can admit a great amount of particles and orientates in magnetic fields of low intensity. The origin of the coupling between the particles and the lyotropic systems is still not well established, with the coefficient of translational diffusion of the particles in the plane of the lamellae not modified by their confinement.<sup>[116]</sup> Later, negatively charged magnetic nanoparticles have been introduced in the aqueous part of the same system, and the role of the nature of the membrane interaction has been evidenced, modifying the system from a purely electrostatic one to a sterically stabilized one.<sup>[117]</sup> Indeed, pure electrostatic systems such as the binary one (didodecylammonium bromide/water) do not admit many particles, excluding them from the lamellar structure under the form of a dense magnetic aqueous phase.<sup>[63]</sup>

Ferromematics have also been obtained by mixing anisotropic micelles with maghemite nanoparticles.<sup>[13,118]</sup> The lyotropic system was, in this case, the ternary mixture potassium laurate/decanol/water and, surprisingly, stable ferromagnetic samples have been obtained by mixing this system with positively charged maghemite particles.<sup>[13]</sup> The phase diagram of the hybrid system has been constructed in the vicinity of the nematic area showing that the existence domain of the hybrid is very narrow.<sup>[119]</sup> Nevertheless, it exists and allows one to observe the so-called "Frederickz transitions" in low field (lower than 100 Oe).<sup>[118]</sup> Even if not explained on the microscopic point of view, the analysis of the dependence of the threshold magnetic field on the thickness of the sample and the volume fraction of magnetic oxide is explained by assuming a superparamagnetic behavior of the grains,

but a strong coupling between the latter and the nematic matrix.

### Liposomes, Emulsions, Capsules, and Latex

Incorporation of magnetic nanoparticles in lyotropic systems (as phospholipidic vesicles) or in polymeric ones (as latex) is usually performed in biotechnological applications. For example, magnetic latex is a commercial product used for cell labeling and cell sorting (i.e., for in vitro applications).<sup>[120,121]</sup> Magnetic liposomes have many conceptual applications especially for in vivo applications.<sup>[122–126]</sup>

Until now, the so-called "ferroliposomes," obtained by encapsulation of maghemite nanoparticles in dioleoylphosphatidylcholine (DOPC) vesicles, have been essentially considered for their unique physical properties.<sup>[19,127]</sup> They are able to move in a magnetic field gradient and giant liposomes elongate when a magnetic field is applied. From the analysis of the modification of the liposome shape, it is possible to obtain some information on the properties of the DOPC membrane bending modulus.<sup>[19]</sup> For applications, small unilamellar liposomes have now been considered. Several procedures are possible to encapsulate the particles in the liposomes, but, first of all, these particles have to be negatively charged to avoid a quick adsorption on the phospholipid on their surface, and to be citrate-coated to disperse in water at pH 7.<sup>[9,62]</sup> Then they can be introduced in the liposomes by a multiple emulsion process, either through a spontaneous swelling in water of phospholipidic bilayers stuffed with magnetic particles, or by swelling of the liposomes in a magnetic fluid, followed by the separation of the non-encapsulated particles.<sup>[17,127]</sup>

Magnetic multilamellar vesicles (oignons) can also be obtained by dilution of a lamellar phase containing magnetic particles.<sup>[128]</sup>

Synthesis of magnetic emulsions<sup>[15]</sup> and magnetic capsules<sup>[129]</sup> has also been described. These systems are interesting transpositions at the microscopic scale of nanoscopic particles. For example, chaining these magnetic objects with the application of a magnetic field is observed with a microscope or by light scattering and may have many interesting properties.<sup>[16]</sup> The main limitation of the technology at the present time is the polydispersity of the object synthesized.

## TECHNIQUES FOR THE CHARACTERIZATION OF MAGNETIC COLLOIDAL PARTICLES

### Particle Size

The particles under consideration here have diameters on the order of 10 nm. This implies the use of techniques

allowing size determination in the nanometric range. It has to be kept in mind that the systems are always polydispersed. Few techniques give the particle size distribution; most methods give average diameters, and it is repeated here that the log-normal size distribution given in “Metallic Particles” leads to average diameters such as:  $\langle d^n \rangle = d_0^n \exp(n^2 \sigma^2 / 2)$ .<sup>[130]</sup>

*Transmission electron microscopy (TEM)* allows one to calculate particle size and shape. It is well suited for magnetic particles as they are constituted of heavy metals such as iron or cobalt. Its data may provide a histogram of diameters, and log-normal size distribution can be adjusted to obtain  $d_0$  and  $\sigma$ .

*X-ray diffraction on powders* allows one to check the crystallographic nature of particles and provides an average diameter such as  $d_{RX} = d_0 \exp(2.5\sigma^2)$ .

*Magnetization measurements* allow one to obtain the particle size distribution also, through the analysis of the shape of the magnetization curve.<sup>[7,51]</sup> For sufficiently magnetic systems, this is constructed by using a vibrating magnetometer (called “Foner”). Particles have to be well dispersed in a solid or liquid carrier. The size obtained has to take into account the specific magnetization of the material constituting the particles.

*Small-angle neutron scattering and small-angle X-ray scattering (SAXS)* also allow one to find the particle size and shape, as soon as particles are dispersed in a carrier. The analysis of the form factor of diluted suspensions of magnetic nanoparticles allows one to verify that particles are well described as spheres [ $I(q)$  proportional to  $q^{-4}$  in the high  $q$  range], and the gyration radius found is usually in good agreement (taking into account the polydispersity effects) with the TEM results.<sup>[64,131]</sup>

The hydrodynamic radius of particles when dispersed in a solution can be obtained from *dynamic light scattering* but also from the experiment of *relaxation of birefringence* (cf. “[Magnetic Colloidal Particles as Viscosity Probes for the Characterization of Gels](#)”). Indeed, the relaxation time, when the viscosity is known, becomes a measure of the particle’s hydrodynamic volume.<sup>[98,132]</sup> The diameters obtained by these techniques are always much higher than the other ones because they are hydrodynamic diameters and because they are averages providing an important weight to the polydispersity. Relaxation of birefringence can, in that way, be used to characterize the binding of biological molecules on particles.<sup>[133]</sup>

### Nature of the Surface Coverage

Adsorption isotherms have to be constructed to determine the amount of species (surfactants, polymers, or ions) adsorbed on particles. It is not specific to magnetic particles and will not be developed here, but is

discussed in the entry on “Nanoparticles: Generation, Surface Functionalization, and Ion Sensing.” Please just note that the main difficulty in the case of nanometric particles is to separate the particles from the supernatant without modifying the adsorption phenomena.

### Interactions between Particles

Again the interactions between particles are not specific to magnetic particles and are discussed in “Nanoparticles in Solutions: General Interactions.” Nevertheless, these particles have been revealed to be good examples of colloidal systems. SAXS and SANS have allowed to determine the structure factor of several aqueous and non-aqueous dispersions of magnetic nanoparticles.<sup>[64,90,94]</sup> Direct measurements of osmotic pressure have also been performed.<sup>[65,86,90]</sup> Using these techniques, it has been possible to propose a reasonable form for the interparticle interaction potential.

### APPLICATIONS INVOLVING MAGNETIC NANOPARTICLES

As stated at the beginning of this entry, magnetic recording is not the only application of magnetic nanoparticles. As a matter of fact, superparamagnetic particles are not able to keep magnetic information. Applications involving magnetic nanoparticles can be classified in two categories: technological applications involving magnetic fluids (ferrofluids applications)<sup>[21]</sup> and applications taking advantage of some particular properties of the nanoparticles, especially the biomedical applications.<sup>[22,23]</sup>

Ferrofluids applications will not be detailed here because they are not really concerned with the colloidal aspect of the system. Nevertheless, they are the only applications of magnetic nanoparticles truly commercialized at this point.

The other application fields concerning magnetic nanoparticles are conceptual ones:<sup>[57]</sup> optics (realization of birefringent components) and microwave technology (dispersions of particles can be wave guides or microwave absorbants) are some examples.

Applications in the field of biotechnology and medical imaging are in full expansion<sup>[22,23,135]</sup> (e.g., Ref.<sup>[134]</sup>). Dispersion of magnetic nanoparticles is already commercialized as contrast agents for magnetic resonance imaging.<sup>[135–141]</sup> They can be used as drug carriers at the same time.<sup>[142]</sup> But the problem of the biodistribution of magnetic probes is not fully solved. Particle size and surface coating both are parameters that have to be controlled. Another promising application is the treatment of tumors using magnetothermolysis: an a.c.

magnetic field applied to magnetic nanoparticles that induces an increase of temperature and cell hyperthermia.<sup>[143]</sup> Concerning in vitro applications of magnetic nanoparticles, the latter are now commercialized.<sup>[22,23]</sup> Nevertheless, they have to challenge the magnetic latex and emulsions that are widely commercialized for rapid bioseparation processes. This area still leads to sparkling new results.<sup>[144]</sup>

## CONCLUSION

Magnetic nanoparticles are original colloids because of their magnetic properties. Improved manipulation of these properties is a permanent challenge for scientists involved in the chemistry of materials. On the theoretical point of view, it is interesting to note that colloidal dispersions of such particles have proven to be excellent experimental systems, allowing one to illustrate the phase behavior of colloids. More and more, these particles are used as probes to test other colloidal systems, and new colloids, hybrid ones, are born from these works. The development of their applications in the field of biotechnology is the new challenge now.

## INTRODUCTION

Moore's Law has been the most famous symbol of the power of high technology in the last half of the 20th century. In 1965, Moore<sup>[1]</sup> predicted that the number of transistors on a computer chip would double every 18 months. Indeed, the number of transistors has grown at a compound annual rate of 39% per year (Fig. 1) for more than 30 years.<sup>[2]</sup> Meanwhile, the data storage density of magnetic hard drives has matched the pace of growth in data storage density (36% per year) until 1990, when it accelerated to 79% per year. Both technologies have grown at an amazing pace, providing higher-performance computing and higher-capacity data storage at lower costs, thereby fueling growth of the Internet. However, both technologies face scientific challenges that threaten to limit continued growth.

Modern magnetic data storage devices record data as magnetized bit cells in thin films, either polycrystalline metal films or particulate films (acicular iron particles in a polymer matrix).<sup>[3]</sup> Each bit cell contains many grains or particles, and the signal-to-noise ratio depends on the number of particles in the bit volume.<sup>[4]</sup> The data storage density of state-of-the-art hard disk drive systems is 100 gigabits per square inch,<sup>[5]</sup> and the information storage industry is now pursuing basic research aimed at densities beyond 1 terabit per square inch.<sup>[6]</sup> Increases in data storage density are achieved by scaling down the bit size, i.e., the bit length (increasing the bits per inch), the track width (increasing the track per inch), and the film thickness. In 2002, the bit cell dimension in state-of-the-art hard disk media was approximately  $50 \times 400$  nm. If densities were to increase at a rate of 41% per year over the next decade (less than the last decade), then the bit cell would be  $4 \times 4$  nm in 2012 (Fig. 2). This is less than the size of a single grain in current media and would necessitate a new paradigm in magnetic recording. The reduction in bit size using conventional recording methods means

that magnetic grains and particle sizes must be decreased. However, the superparamagnetic limit threatens to limit the bit sizes that can be achieved using conventional recording methods. Superparamagnetism arises when the thermal stability factor ( $KV/kT$ ) becomes small, where  $K$  is the anisotropy constant,  $V$  is the particle or grain volume,  $k$  is the Boltzmann constant, and  $T$  is the temperature.  $KV$  gives the magnetic anisotropy energy for a magnetic grain or particle, and as the volume decreases, the anisotropy energy decreases. As the ratio of anisotropy energy to thermal energy ( $KV/kT$ ) decreases, the thermal stability of the magnetization decreases (i.e., subject to thermally activated magnetization reversal). When  $KV/kT$  is less than about 60, long-term data storage (>10 years) is no longer reliable. Of course, the grain size can be decreased if  $K$  is increased. This has led to increased interest in materials with high values of magnetocrystalline anisotropy, and the  $L1_0$  phase of FePt has found particular scrutiny because of its very high value of  $K_u$  ( $6$  to  $10 \times 10^7$  erg/cm<sup>2</sup>).<sup>[7]</sup>

Here we report our progress on solving basic materials science problems, whose solution would enable self-assembled FePt nanoparticles to be used in high-density magnetic recording. We describe the synthesis of FePtAg, FePtAu, FePtCu, or FePtCo ternary alloy nanoparticles. The effect of added Ag, Au, or Cu on temperature required to transform the particles from the fcc phase to the  $L1_0$  phase is reported along with the effect of added Co on the magnetic properties.

## FePt NANOPARTICLES

A team from IBM first reported the synthesis of nearly monodisperse 3- to 4-nm diameter FePt nanoparticles and self-assembly of the particles into close-packed films and magnetic recording in the films.<sup>[8]</sup> We found that we could reliably reproduce their synthetic procedure.<sup>[9]</sup> The particles were prepared by heating

**Fig. 1** Comparison of the growth of data storage density for magnetic disks (solid circles) and the number of transistors on a computer chip (solid squares).

a solution of platinum acetylacetonate and 1,2-hexadecanediol in dioctyl ether to 100°C. Iron pentacarbonyl, oleyl amine, and oleic acid were added, and the reaction mixture was heated to boiling (~280°C) for 30 min, giving a black dispersion of FePt nanoparticles. Adding ethanol precipitated the particles, which were isolated by centrifugation. The particles were redispersed in hexane and reprecipitated by adding ethanol. Repeated cycles of dispersion and precipitation removed impurities and somewhat narrowed the size distribution.

As prepared, the FePt particles were single crystals with a disordered face-centered cubic structure and were superparamagnetic. The particles had an average diameter of 3.5 nm and a distribution of particle diameters of about 5% of the average. They had a coating of organic surfactants and could be dispersed in hydrocarbon solvents. When dispersions in a 50/50 mixture of hexane and octane were cast onto a solid substrate (either a silicon wafer or a carbon-coated copper TEM grid) and the solvent evaporated slowly, the particles self-assembled into films containing close-packed arrays (Fig. 3). If the solvent evaporated too rapidly, the particles had positional disorder. Using octane lowers the solvent evaporation, allowing the particles to find their lattice positions as the films form.

The X-ray diffraction curves for films containing Fe<sub>48</sub>Pt<sub>52</sub> particles showed two diffraction peaks, the 111 peak and the 200 peak, indicative of a disordered fcc phase. The films were heat-treated for 30 min either in a tube furnace with flowing 2% hydrogen in argon

( $T = 350^{\circ}\text{C}$  to  $500^{\circ}\text{C}$ ) or in a vacuum annealer ( $T = 550^{\circ}\text{C}$  to  $700^{\circ}\text{C}$ ). After heat treatment at temperatures above  $500^{\circ}\text{C}$  in an inert atmosphere, the L<sub>1</sub>0 001 and 110 peaks appeared. The fcc 200 peak split into two peaks, the L<sub>1</sub>0 200 and 002 diffraction peaks. The 111 peak moved to higher values of  $2\theta$  and the  $d$ -spacing decreased to the bulk value for FePt ( $d_{111} = 219.7$  pm). The position of the  $d_{111}$  peak could be used as a measure of the degree of transformation, which depended on the heating temperature (Fig. 4). While being heated at these temperatures, the organic surfactant decomposed, leaving a carbonaceous char.

**Fig. 2** The incredible shrinking bit—road map for future bit cell dimensions in magnetic hard drive systems.

Fig. 3 TEM image of self-assembled FePt nanoparticles.

There was considerable loss in particle positional order and particle agglomeration.<sup>[10]</sup> This is a problem because it defeats the object of preparing small particles with a narrow distribution of sizes and self-assembling them into highly ordered structures.

As the particles transformed to the  $L1_0$  phase, the coercivity increased, reflecting the high anisotropy of the phase. For films containing weakly interacting

Fig. 4 Effect of heat treatment temperature on the value of the  $d$ -spacing for the 111 diffraction peak.

single-domain particles,  $H_c$  will depend on the magnetic anisotropy energy,  $K$ , and the volume,  $V$ , of the particle. As prepared, the spherical particles had very small anisotropy with  $KV < 25k_B T$ , the particles were superparamagnetic, and  $H_c = 0$ . The bulk anisotropy of fully ordered  $L1_0$  FePt is  $K \sim 6\text{--}10 \times 10^7$  erg/mL,<sup>[6]</sup> which, for fully ordered 4-nm diameter FePt particles, would give  $KV/k_B T \sim 48\text{--}81$  and the films would exhibit a high room-temperature coercivity. For films containing weakly interacting single-domain particles with randomly oriented easy axes, the coercivity would be expected to follow the Sharrock equation, given by<sup>[11]</sup>

$$H_c = H_0 \left\{ 1 - \left[ \frac{k_B T}{KV} \ln(f_0 t) \right]^{2/3} \right\} \quad (1)$$

where  $f_0$  is an attempt frequency of the order of  $10^9\text{--}10^{11}$  Hz and  $t$  is the effective measuring time.  $H_0$  is the low-temperature or short-time coercivity given by  $H_0 \sim K/M_s$ , where  $M_s$  is the saturation magnetization. For highly ordered FePt nanoparticles, Eq. (1) predicts high coercivities; however,  $H_c$  will depend on temperature and particle size. Fig. 5 shows a plot of the room-temperature coercivity as a function of heat treatment temperature for films containing self-assembled  $\text{Fe}_{48}\text{Pt}_{52}$  nanoparticles. After heat treatment at 350°C or 400°C, the films were still superparamagnetic, with no coercivity. Only after heat treatment at 450°C did the films become ferromagnetic and show some coercivity. Heat treatment at higher temperatures gave higher values of coercivity as the transformation to the  $L1_0$  phase was more complete. Scherrer analysis of the linewidth of the 111 diffraction peaks for the films heated to temperature over 500°C showed increased crystallite size, suggesting particle sintering.<sup>[12]</sup> Particle coalescence has also been shown in high-resolution TEM studies of FePt films that have been heat-treated at temperatures above 500°C.<sup>[10]</sup> Accordingly, in interpreting this increase in coercivity, it is difficult to separate the effect of increasing the magnetocrystalline anisotropy of the particles as a result of transforming to the  $L1_0$  phase from the effect of increasing particle volume as a result of sintering.

The problem of transforming the particles from the fcc phase to the  $L1_0$  phase is somewhat vexing. Heat treatment at temperature in excess of 500°C caused degradation of the organic surfactants, leading to loss in particle positional order. Furthermore, as the heat treatment temperature exceeds 550°C, there is extensive particle coalescence. Particle coalescence increases the switching volumes, which defeats the purpose of making small particles. The solution to this problem could be to heat-treat at lower temperatures, thereby decreasing the amount of particle coalescence.

**Fig. 5** Effect of heat treatment temperature on the coercivity of films containing Fe<sub>48</sub>Pt<sub>52</sub> nanoparticles.

However, heat treatment at lower temperatures results in incomplete phase transformation, giving films with a distribution of order parameters and, in turn, a distribution of magnetic anisotropies, which is detrimental to high-density magnetic recording. It would be highly desirable if the fcc to tetragonal phase transformation could be carried out at lower temperature, at least below temperatures where the particles coalesce, preferably below temperatures where the surfactants decompose.

### FeCuPt NANOPARTICLES

Our interest in finding means of lowering the temperature required for transforming the FePt particles from the fcc to the L1<sub>0</sub> phase led us to add copper to the FePt nanoparticles. We were motivated by literature reports that adding copper to sputter-deposited FePt films greatly reduced the L1<sub>0</sub> ordering temperature. Maeda et al.<sup>[13]</sup> reported that for films containing [FePt]<sub>85</sub>Cu<sub>15</sub>, the coercivity was 5000 Oe after annealing at 300°C, while H<sub>c</sub> for FePt films was only a few hundred oersted after annealing at 300°C. Takahashi, Ohnuma, and Hono<sup>[14]</sup> found that adding 4 at.% Cu

into FePt sputtered films decreased the temperature required for fcc to L1<sub>0</sub> ordering from 500°C to 400°C. They suggested that the addition of Cu lowered the melting point for the alloy, increasing the atomic mobility, thereby enhancing the kinetics of ordering.

These reports suggest the possibility of lowering the temperature needed to bring about the fcc to L1<sub>0</sub> phase transformation for FePt nanoparticles by adding copper. This led us to devise a method to prepare FePtCu ternary alloy nanoparticles that was quite similar to the synthesis of FePt nanoparticles,<sup>[15]</sup> except for adding a source of Cu and using diphenyl ether as the solvent. A solution of platinum acetylacetonate, copper bis(2,2,6,6-tetramethyl-3,5-heptadionate), and 1,2-hexadecanediol in diphenyl ether was heated to 80°C. Iron pentacarbonyl, oleyl amine, and oleic acid were added and the mixture was heated to reflux (~260°C) for 30 min to give a black dispersion. After cooling to room temperature, the particles were precipitated by adding ethanol and isolated by centrifuging. As with the FePt nanoparticles, the FePtCu nanoparticles were repeatedly redispersed and reprecipitated to remove impurities and narrow the particle size distribution. Varying the relative ratio of Fe, Pt, and Cu charged to the reaction mixture varied the

**Fig. 6** TEM image of self-assembled  $\text{Fe}_{45}\text{Pt}_{44}\text{Cu}_{11}$  nanoparticles.

particle composition. However, the amount of Fe in the particles was much less than the amount of Fe charged into the reaction as iron pentacarbonyl. Particles with the compositions  $\text{Fe}_{55}\text{Pt}_{35}\text{Cu}_{10}$ ,  $\text{Fe}_{45}\text{Pt}_{44}\text{Cu}_{11}$ ,  $\text{Fe}_{48}\text{Pt}_{40}\text{Cu}_{12}$ , and  $\text{Fe}_{35}\text{Pt}_{50}\text{Cu}_{15}$  were prepared.

Self-assembled films consisting of close-packed FePtCu nanoparticles were prepared in exactly the same manner as for the FePt nanoparticles (Fig. 6). The average particle size was 3.5 nm, and the particles were single crystalline with a disordered fcc structure. There was no evidence either in the TEM images or the X-ray diffraction curves (Fig. 7) for particles other

**Fig. 7** X-ray diffraction curves for films containing FePtCu nanoparticles as-prepared.

**Fig. 8** Effect of heat treatment temperature on the X-ray diffraction curves for films containing  $\text{Fe}_{45}\text{Pt}_{44}\text{Cu}_{11}$ .

than a ternary FePtCu alloy. There were no apparent diffraction peaks due to fcc copper. The films were heated in a tube furnace in an atmosphere containing 4%  $\text{H}_2$  in Ar, and X-ray diffraction was used to determine the amount of phase transformation. Results for the composition  $\text{Fe}_{45}\text{Pt}_{44}\text{Cu}_{11}$  (Fig. 8) were typical of the other compositions. Only after heat treatment above 550°C did the particles begin to transform to the  $L1_0$  phase. The copper remained in the particles; otherwise, the 111 peak for fcc Cu would have appeared near  $2\theta = 43^\circ$ . Only after heating at 700°C did the  $L1_0$  phase completely form, as seen by the sharp 001 and 110 diffraction peaks and the splitting of the fcc 200 peak into the  $L1_0$  200 and 002 peaks. The ternary Fe–Pt–Cu phase diagram shows a range of compositions for FePtCu where a single  $L1_0$  phase is formed and other compositions where the  $L1_0$  phase and the fcc phase coexist.<sup>[17]</sup> In both phases, Cu is substituting for iron. Careful examination of the X-ray diffraction curves for the films heat-treated at 700°C (Fig. 8) revealed an extra peak near  $2\theta = 48.5^\circ$ , between the  $L1_0$  200 and the 002 peaks. This peak may be a result of the presence of a small amount of the fcc phase. The extra peak was not seen for  $\text{Fe}_{48}\text{Pt}_{40}\text{Cu}_{12}$ .

The hysteresis curve in Fig. 9 was measured for the  $\text{Fe}_{45}\text{Pt}_{44}\text{Cu}_{11}$  particles heat-treated at 700°C and is typical of the curves for the other compositions also heat-treated at 700°C. The shape of the curve suggests a mixture of hard and soft magnetic phases, and it could be decomposed into hard and soft loops. The hard component coercivities of  $\text{Fe}_{45}\text{Pt}_{44}\text{Cu}_{11}$ ,  $\text{Fe}_{48}\text{Pt}_{40}\text{Cu}_{12}$ , and  $\text{Fe}_{35}\text{Pt}_{50}\text{Cu}_{15}$  were greater than 5000 Oe and were comparable to that of  $\text{Fe}_{48}\text{Pt}_{52}$ .

**Fig. 9** Magnetic hysteresis curve for  $\text{Fe}_{45}\text{Pt}_{44}\text{Cu}_{11}$  heat-treated at  $700^\circ\text{C}$  (solid curve). The curve was decomposed into a hard magnetic component (dotted curve) and a soft magnetic component (dashed curve).

The soft component coercivities were less than 1500 Oe. In all cases, the shape of the loops suggests that the maximum field of the magnetometer was not sufficient to saturate the loops and that the actual coercivities are higher. These results are in agreement with the X-ray diffraction results that suggest phase separation of the FePtCu particles into  $L1_0$  and disordered fcc phases. The hysteresis loop for the  $\text{Fe}_{48}\text{Pt}_{40}\text{Cu}_{12}$  particles had the smallest soft magnetic fraction (<20%), which was consistent with the fact that the X-ray diffraction (XRD) showed no evidence of a cubic phase. The soft magnetic phases may also consist of iron oxides, which if disordered, would not exhibit well-defined XRD peaks. The effect of heat treatment temperature on coercivity is plotted in Fig. 10, where the hard component coercivity was used at the highest annealing temperature for the films containing FePtCu particles. The coercivity for the  $\text{Fe}_{48}\text{Pt}_{52}$  nanoparticles began to increase after heat treatment above  $450^\circ\text{C}$ , while the coercivity for the FePtCu nanoparticles only increased after heating to  $550^\circ\text{C}$ . Only after heat treatment at  $650^\circ$ , where the X-ray diffraction curves indicated that the particles had largely transformed to the  $L1_0$  phase, did the coercivity for the hard component for the FePtCu nanoparticles match that for the FePt nanoparticles.

The addition of Cu to FePt nanoparticles did not lower the temperature required for the fcc to  $L1_0$  phase

transformation. This was unexpected because the transformation occurs at temperatures in the range of  $300^\circ\text{C}$  to  $400^\circ\text{C}$  in FePtCu sputtered films. Instead, the FePtCu nanoparticles had to be heated to temperatures as high or even higher than the temperature required to transform the FePt nanoparticles. The reason for the different effect of additive Cu in chemically synthesized nanoparticles and sputtered films is not well understood. One factor may be grain size. It has been shown that additive Cu promotes grain growth in sputtered FePt films and chemical ordering has been shown to increase with grain size.<sup>[16]</sup> There has been also a recent report that, for FePt sputtered films, relief of film stresses occurs in the course of the phase transformation process,<sup>[17]</sup> whereas there is no film stress for the self-assembled FePtCu nanoparticles.

Our FePtCu results led us to try to incorporate other metals into FePt particles. A recent report compared the effect of additive Cu, Ag, and Au on the chemical ordering of sputtered FePt films.<sup>[18]</sup> In agreement with previous reports,<sup>[10,11]</sup> Cu was found to promote the  $L1_0$  ordering for FePt. During annealing, copper did not appear to phase-segregate and large grain growth occurred. On the other hand, Ag and Au additives tended to phase-segregate from the FePt, thus limiting the FePt grain size. Adding silver to CoPt/ $\text{SiO}_2$  granular films was found to promote the CoPt  $L1_0$  ordering process, thereby reducing the

**Fig. 10** Effect of heat treatment temperature on the coercivity for films containing  $\text{Fe}_{48}\text{Pt}_{52}$  (filled circles),  $\text{Fe}_{55}\text{Pt}_{35}\text{Cu}_{10}$  (triangles),  $\text{Fe}_{45}\text{Pt}_{44}\text{Cu}_{11}$  (upside-down triangles),  $\text{Fe}_{48}\text{Pt}_{40}\text{Cu}_{12}$  (squares), or  $\text{Fe}_{35}\text{Pt}_{50}\text{Cu}_{15}$  (open circles) nanoparticles.

ordering temperature by  $100^\circ\text{C}$ , compared with  $\text{CoPt}$ .<sup>[19]</sup> This result encouraged us to prepare FePt nanoparticles containing Ag.

### FePtAg AND FePtAu TERNARY ALLOY NANOPARTICLES

FePtAg or FePtAu ternary alloy nanoparticles were made using the same procedure as for the preparation of FePtCu nanoparticles, except that silver acetate was used to prepare FePtAg nanoparticles<sup>[20]</sup> and gold acetate was used to prepare FePtAu nanoparticles.<sup>[21]</sup> The relative amount of Ag or Au in the particles could be systematically varied by varying the amount of silver acetate or gold acetate in the reaction mixture. For the case of Ag, we obtained compositions  $[\text{FePt}]_{100-x}\text{Ag}_x$ , where  $x = 0, 4, 15, 18,$  or  $30$ , while for  $[\text{FePt}]_{100-x}\text{Au}_x$ ,  $x = 8, 12,$  or  $24$ . In all cases, the particles had a disordered fcc lattice, were superparamagnetic, and self-assembled into films containing close-packed arrays of particles.

The FePtAg films were heat-treated under flowing 2% hydrogen in argon for 30 min at temperatures ranging from  $300^\circ\text{C}$  to  $500^\circ\text{C}$ . The X-ray diffraction pattern for the film containing  $[\text{FePt}]_{88}\text{Ag}_{15}$  heat-treated at  $350^\circ\text{C}$  (Fig. 11) showed a hint of the 001 and 110  $L1_0$  peaks. After heat treatment at  $400^\circ\text{C}$ , the peaks due to the  $L1_0$  phase were clearly present, and there was also a shoulder on the low  $2\theta$  side of the 111 peak. After heat treatment at higher temperatures, this

**Fig. 11** Effect of heat treatment temperature on the X-ray diffraction curves for films containing  $[\text{FePt}]_{88}\text{Ag}_{12}$  nanoparticles.

shoulder became a separate peak consistent with the Ag 111 diffraction peak, indicating that the Ag atoms had left the FePt particles. For the sample heat-treated at  $500^\circ\text{C}$ , the Ag 200 diffraction peak could also be seen. Similarly, the X-ray diffraction curves for

**Fig. 12** Effect of heat treatment temperature on the X-ray diffraction curves for films containing  $[\text{FePt}]_{85}\text{Au}_{15}$  nanoparticles.

[FePt]<sub>85</sub>Au<sub>15</sub> in Fig. 12 show the effect of heat treatment temperature on the fcc to L1<sub>0</sub> phase transformation. The L1<sub>0</sub> 001 and 110 diffraction peaks were apparent after heat treatment at 350°C and increased in intensity when heated to higher temperatures. After heating at 500°C, the Au 111 diffraction peak appeared at  $2\theta = 38.2^\circ$ , which indicated that gold had also phase-separated from the FePt particles. Adding Ag or Au to FePt nanoparticles lowers the temperature required to transform the particles to the L1<sub>0</sub> phase. In both cases, the Ag or Au atoms leave the particles, providing vacancies that allow the Fe and Pt atoms to move to their L1<sub>0</sub> lattice positions at lower temperatures than for pure FePt.

Magnetic measurements on annealed FePtAg and FePtAu films support the findings from the X-ray diffraction measurements that the addition of Ag and Au significantly reduces the required annealing temperature for obtaining L1<sub>0</sub> order. Fig. 13 compares the hysteresis loops for films containing [FePt]<sub>88</sub>Ag<sub>12</sub> and Fe<sub>48</sub>Pt<sub>52</sub> nanoparticles after heat treatment at 400°C for 30 min. The Fe<sub>48</sub>Pt<sub>52</sub> film was still superparamagnetic ( $H_c = 0$ ), while  $H_c$  for the [FePt]<sub>88</sub>Ag<sub>12</sub> film was 3400 Oe. A plot of film coercivity as a function of heat treatment temperature (Fig. 14) showed a clear benefit of adding Ag into the FePt nanoparticles. The [FePt]<sub>88</sub>Ag<sub>12</sub> films showed an increase in coercivity at heat treatment temperatures some 100°C to 150°C lower than that for the Fe<sub>48</sub>Pt<sub>52</sub> films. The effect of additive Ag on the coercivity enhancement depended on the concentration and was largest in the range 12–15%.

Fig. 13 Comparison of the magnetic hysteresis curves for films containing Fe<sub>48</sub>Pt<sub>52</sub> or [FePt]<sub>88</sub>Ag<sub>12</sub> nanoparticles.

Fig. 14 Effect of heat treatment temperature on the coercivity of films containing either Fe<sub>48</sub>Pt<sub>52</sub> or [FePt]<sub>88</sub>Ag<sub>12</sub> nanoparticles.

Fig. 15 shows the coercivity as a function of annealing temperature for different Au concentrations. The coercivity increases as a function of Au concentration up to 24% Au. It can be seen that the effect of 15% and 24% Au is even greater than Ag up to an annealing temperature of 450°C. The coercivity enhancement for 24% Au occurs at temperatures about 150°C below that for FePt with no additive.

Fig. 15 Effect of heat treatment temperature on the coercivity of films containing FePt Au nanoparticles.

**Fig. 16** TEM image of self-assembled  $\text{Fe}_{49}\text{Co}_7\text{Pt}_{44}$  nanoparticles. The inset is the low-angle electron diffraction pattern.

### FeCoPt NANOPARTICLES

The FePt nanoparticle synthesis can also be modified to prepare FeCoPt nanoparticles by a simultaneous polyol reduction of platinum acetylacetonate and cobalt acetylacetonate and the thermal composition of iron pentacarbonyl.<sup>[22]</sup> The solvent was dioctyl ether, the reducing agent was 1,2-hexadecane diol, and a mixture of oleyl amine and oleic acid was the

surfactant. The FeCoPt particles were isolated and purified in the same manner as for FePt nanoparticles. This gave particles with an average diameter of 3.5 nm that self-assembled into close-packed arrays of particles (Fig. 16). The relative amounts of platinum acetylacetonate, cobalt acetylacetonate, and iron pentacarbonyl were varied to produce nanoparticles with different compositions (Table 1). As prepared, the particles had a disordered face-centered cubic structure and were superparamagnetic.

The films of the self-assembled FeCoPt nanoparticles were heat-treated in a tube furnace with flowing 2% hydrogen in argon to transform the particles to the  $L1_0$  phase. In this case, we used the quotient  $c/a$  as a measure of the degree of transformation to the  $L1_0$  phase, where  $a$  is the  $a$ -axis unit cell length and  $c$  is the  $c$ -axis unit cell length. For the films heat-treated at 600°C for 30 min, small increases in the amount of Co had little effect on the ability of the particles to transform to the tetragonal phase. Values of  $c/a$  in Table 1 were in the range 0.971 to 0.976 for  $\text{Fe}_{48}\text{Pt}_{52}$ ,  $\text{Fe}_{49}\text{Co}_7\text{Pt}_{44}$ , and  $\text{Fe}_{40}\text{Co}_{17}\text{Pt}_{43}$ . Heat treating at 700°C for 30 min decreased the values of  $c/a$  to 0.964–0.966. However, further increasing the Co content inhibited the transformation.  $\text{Fe}_{34}\text{Co}_{19}\text{Pt}_{47}$  or  $\text{Fe}_{23}\text{Co}_{27}\text{Pt}_{50}$  was only completely transformed after heat treatment at 700°C for 3 hr. Heat treatment also increased the average crystallite size, as measured by Scherrer analysis of the 111 peak in the X-ray diffraction. There was a slight increase in average crystallite size upon annealing at 550°C. The crystallite size increased greatly when annealing at temperatures beyond 600°C. These results are in agreement with a

recent paper by Dai, Sun, and Wang,<sup>[10]</sup> which reported that FePt nanocrystals coalesce to form larger grains when annealed at temperatures above 600°C. For films having small amounts of Co and annealed at 600°C, the average crystallite size decreased with increasing Co content. However, the films annealed at other temperatures showed little effect of composition on crystallite size. The films containing higher amounts of Co (Fe<sub>34</sub>Co<sub>19</sub>Pt<sub>47</sub> and Fe<sub>23</sub>Co<sub>27</sub>Pt<sub>50</sub>) were not as susceptible to coalescing. Annealing at 600°C for 30 min resulted in smaller increases in average crystallite size. Even after 1-hr annealing at 700°C, the average crystallite size was still smaller than that for the films containing lower amounts of Co.

After annealing, the films were ferromagnetic with an in-plane coercivity that depended on the annealing temperature and the composition (Table 1). The coercivity for the film containing Fe<sub>48</sub>Pt<sub>52</sub> and annealed at 700°C was so high that the electromagnet on the alternating gradient magnetometer (maximum field 18 kOe) could not saturate the sample and only a minor loop was obtained. For films heated at 600°C or 700°C, having similar values of *c/a* and similar average crystallite sizes, the coercivity decreased as the cobalt content increased. This can be qualitatively explained by the lower value of magnetocrystalline anisotropy for CoPt ( $K_u = 4.9 \times 10^7$  erg/cm<sup>3</sup>) relative to FePt (6.6 to  $10 \times 10^7$  erg/cm<sup>3</sup>). However, when completely transformed by annealing at 700°C for 3 hr, the film with the highest Co content, Fe<sub>23</sub>Co<sub>27</sub>Pt<sub>50</sub>, had a high coercivity ( $H_c = 9090$  Oe). This could not be explained by grain size because the average crystallite size was comparable (18.9 nm) to that for the samples annealed at 700°C for 1 hr. The magnetic properties of the films containing self-assembled Fe<sub>*x*</sub>Co<sub>*y*</sub>Pt<sub>100 - *x* - *y*</sub> particles were consistent with the properties of thin alloy films prepared by rf sputtering<sup>[23]</sup> or by electron beam evaporation.<sup>[24]</sup> Films prepared by rf sputtering at low temperatures (<400°C) had a disordered fcc structure and a low coercivity. After annealing at 650°C to 700°C in vacuum, the films transformed to the tetragonal phase and had high coercivities that decreased with increasing cobalt content. For the case of the particles described in our work, the relationship between the coercivity of the films and the cobalt content was complex, particularly for the films having high cobalt content.

Films containing self-assembled FePt alloy nanoparticles are promising candidates for granular thin film media in future high-density magnetic hard disk systems. A number of problems must be solved before they can find application. Perhaps the most challenging problem is how to maintain the highly ordered structure without particle coalescence/sintering after annealing to transform the particles to the tetragonal phase. We have also found that films containing

partially transformed FePt particles have a broad distribution of magnetic anisotropies.<sup>[9]</sup> One explanation is that there was extensive particle coalescing leading to a distribution of particle sizes. This underscores the need to find annealing conditions where the particles transform without coalescence. Another explanation is that the broad distribution of magnetic anisotropies arises from a broad distribution of degrees of transformation from the fcc to the L1<sub>0</sub> phase. This suggests that one must completely transform the particles to the tetragonal phase to achieve a narrow distribution of magnetic anisotropies. However, in the case of FePt, the magnetocrystalline anisotropy is so high that the completely transformed particles had coercivities in excess of 10,000 Oe, much too high to be useful in magnetic recording. The Fe<sub>*x*</sub>Co<sub>*y*</sub>Pt<sub>100 - *x* - *y*</sub> alloy particles described here provide an opportunity to prepare self-assembled films that are completely transformed but have lower coercivity.

## CONCLUSION: OUTLOOK FOR FePt NANOPARTICLES AS GRANULAR MAGNETIC RECORDING MEDIA

The large magnetocrystalline anisotropy, coupled with the ability to make very small particles that self-assemble into highly ordered arrays of particles, make FePt nanoparticles a serious candidate for future high-density magnetic recording systems. To realize this application, a number of materials science problems must be solved. Methods must be found to lower the temperature required for transformation to the L1<sub>0</sub> phase to avoid degradation of the particle positional ordering and sintering. We have made progress along those lines by incorporating Ag or Au into the particles. Better yet, it would be desirable to prepare the L1<sub>0</sub> phase directly, and other groups are pursuing this approach.<sup>[25]</sup> The very high magnetocrystalline anisotropy for FePt gives films with very high coercivity, perhaps too high for recording using current head technology. The industry is examining thermally assisted recording, where a laser locally heats the recording layer, thereby lowering the coercivity allowing writing lower fields. This raises issues including the temperature dependence magnetic properties of the FePt nanoparticles and the thermal stability (both chemical and physical) of both the particles and the matrix. A new matrix must be found that renders the films tribologically robust. The carbonaceous char arising from decomposition of the oleyl amine and oleic acid surfactants left after heat treatment would not be suitable.

Perpendicular recording, where the magnetization of the data bit is directed perpendicular to the plane of the film, is being given serious consideration as the

means to achieve very high bit densities.<sup>[26]</sup> To support a perpendicular recording scheme, the magnetic easy axis (i.e., the crystallographic *c*-axis) must be directed perpendicular to the film. No one has yet reported achieving either in-plane or perpendicular anisotropy for films containing FePt nanoparticles. An obvious approach would be to heat-treat the particles in a magnetic field, and we have attempted this without success. We suspect that heat treatment to transform the particles to the L<sub>1</sub><sub>0</sub> phase occurs at temperatures above the Curie temperature; therefore there is no force directing the magnetic anisotropy.

## INTRODUCTION

The objective of this entry is to describe the different types of photochemical and photophysical reactions on nanoparticles and their application with special emphasis on recent work.

## OVERVIEW

Nanoparticles can be used as single particles in solution (colloids) or arrays of particles with a specially designed architecture again in solution or on a suitable support. Membrane coating is often necessary for stabilization of aqueous or organic solutions of isolated particles. In particle arrays, special linker molecules may be used in order to realize an optimal interparticle distance.

Membrane-coated nanoparticles are functionalized for optical functions by covalent attachment of chromophores to the membrane or to the particle surface. Mixed monolayers of lipids and amphiphilic dyes are also common. The enclosed or adsorbed dyes are used for the construction of photochemical reaction centers as well as in the analysis of special membrane properties such as rigidity and regioselective interaction with solutes.

Photochemical reaction centers are realized either by covalent dyads or by noncovalent long-distance dimers. Triads have also been realized. Nanoparticles provide a large surface to light-absorbing chromophores as well as the possibility to transfer electrons to electrodes. Functionalized membrane coatings allow the construction of long-distance dimers of redox active molecules for light-induced charge separation.

Three different types of colloidal particles are currently used: metals, semiconductors, and insulators. Colloids of noble metals (gold, silver, copper) are characterized by their chemical stability and by surface plasmon absorptions in the visible range, which interfere with the photophysics of dyes. Semiconductor

particles with a narrow bandgap absorb in the visible region and are prone to corrosion. Semiconductors with a wide bandgap, on the other hand, are more stable but absorb only in the UV region. Dyes absorbing visible light are then applied as sensitizers in order to use sunlight. Insulating particles are not appropriate for the construction of photochemical cells but are promising carriers for studies of charge separating molecular assemblies.

## GOLD AND OTHER METAL PARTICLES

Gold particles have been used most frequently. They can be easily prepared by different methods. The citrate reduction method<sup>[1]</sup> yields nearly monodisperse spheres with typical diameters of about 20 nm. Particles of this size remain dispersed for many days and their curvature is low enough to allow the construction of closed membrane systems in water. Weakly bound citrate leads to a negative surface charge. Particles of silver, palladium, and platinum may be prepared by the same method.<sup>[2–5]</sup> Borohydride reduction, on the other hand, yields much smaller particles (1–5 nm). Their high curvature does not allow the formation of a closed membrane. Monolayer-protected gold clusters (MPCs) are obtained by reaction with alkane thiols, which form a covalent bond to the gold surface. The surface of the nanoparticles can be varied from hydrophilic to hydrophobic by selecting appropriate head groups on the other end of the attached thiol.<sup>[6,7]</sup>

Other routes of particle production include the electrochemical synthesis of size-selective nanostructured palladium clusters in tetrahydrofuran<sup>[8]</sup> and a photochemical method of making size-controlled spherical metal particles in a nonaqueous, but highly polar and viscous medium. Complexes of gold, silver, palladium, and platinum have been reduced by the photochemically formed carbamoyl radicals.<sup>[9]</sup> Small particles were sterically stabilized by polyvinylpyrrolidone (PVP), the size being determined by the ratio PVP/metal complex.

A ratio of 5/1 yielded, for example, particles of 12 nm (Au), 15 nm (Ag), 10 nm (Pt), and 16 nm (Pd). The gold particles were pure enough to show single-electron tunneling (SET) in the current–voltage dependence (the 1.8-nm stabilizer shell serves as a tunnel junction). This makes the particles interesting for nanoscale electronic circuits.

The functionalization of the monolayer opens the way to a variety of photophysical and photochemical reactions, which are strongly influenced by the collective excitation of metal electrons, leading to the size-dependent plasmon absorption. This leads, however, to heating of the probe upon strong excitation, problems in the measurements of transient absorptions of adsorbed dyes, energy transfer to the metal, and reduced quantum yields for all the reactions of the chromophore from the excited singlet state. Analytically, the plasmon absorption has been used to probe the dielectric properties of surface-bound molecules,<sup>[10]</sup> and the distance between coupled particles if aggregation of the particles occurs.<sup>[11]</sup>

Photoreactions have been useful in exploring the properties of monolayers on planar gold surfaces. Photoextrusion of nitrogen from aryl azide<sup>[12,13]</sup> and diazoketones,<sup>[14,15]</sup> E-Z photoisomerization of stilbenes<sup>[16]</sup> and azocompounds<sup>[17]</sup> as well as photodimerization reactions<sup>[18–21]</sup> have been well characterized. On gold nanoclusters electron transfer reactions are very often examined; they occur from donors either to relay molecules or directly to the metal. *cis–trans* Isomerization of molecules with double bonds and cycloadditions have, however, also been studied. The latter are very much enhanced if the reporter molecules are close to each other and in proper orientation. If dimerization, followed by charge transfer, occurs in the excited state, excimer fluorescence may be studied as a measure of distance. As a further photophysical reaction, energy transfer can also be used to probe the membrane order.

## Energy Transfer

Singlet energy transfer is measured by fluorescence quenching of suitable chromophores. The plasmon absorption band of metallic particles is usually broad and energy transfer occurs with a wide range of fluorescent dyes. The transfer from donors to acceptors depends on the distance: the efficiency of a transfer between a point dipole and a nearby flat metal surface decreases with the third power; for extended molecules close to curved particle surfaces with an intermediate exponent between 3 and 6 is expected. Monolayers on small particles are usually fluid and the chain density decreases with increasing chain length because of the high curvature. Motional freedom, thermal

flexing, and chain folding lead to altered energy transfer efficiencies.

Imahori et al.<sup>[22]</sup> have shown that the energy transfer between tetraphenylporphyrin, coupled to a gold surface by a C12-alkanethiol spacer, and gold is much more effective in the case of a SAM on planar gold (111-surface) as compared to particles of 5-nm diameter (MPC). The lifetime of the porphyrin fluorescence is shortened from 9.5 nsec to 0.04 and 0.15 nsec, respectively. Additionally a 9.1-nsec phase (15% of total amplitude) appears on the particles, suggesting a second type of monolayer structure. The portion of unquenched porphyrin molecules is only 3% for mixed monolayers. Lifetime measurements thus result in additional information on the homogeneity of the monolayers. Energy transfer is more efficient in SAMs than in MPCs. The origin of this effect is not known.

Aguila and Murray<sup>[23]</sup> have investigated the energy transfer of dansyl chromophores bound to gold clusters of 5–8 nm (C2 to C15 linkers) in mixed monolayers. In this environment the fluorescence is reduced to 1% of that of the free dye by energy transfer. The emission intensity increased with the effective distance, provided that the linker had about the same length as the surrounding alkanethiolates (C4–C12). For longer linkers the emission decreased and became dependent on the load with the dansyl label, i.e., the stiffness of the outermost part of the disordered layer (Fig. 1).

The distance-dependent energy transfer from a methylene blue-type fluorophore (*Alexa 488*) to a metal surface<sup>[24]</sup> has been exploited to measure changes of chemisorption with respect to the electrode potential on a polycrystalline gold electrode. In the potential range of  $-0.7$  to  $+0.2$  V only reversible reorientation of the charged chromophore occurred. For potentials lower than  $-0.8$  V and higher than  $+0.2$  V, an exponential increase of fluorescence was observed. This was related to the reduction and oxidation of the Au–S bond and release of the fluorophore into the solution. An additional spacer of 12 C-atoms between the chromophore and the thiolate moiety decreased the sensitivity toward the potential, because the van der Waals forces between the alkane chains became dominating.

## Excimer Fluorescence

The excimer fluorescence of pyrene is a good tool to investigate order and dynamics of alkane monolayers on surfaces. Excimers are not formed in homogeneous solution of low concentration. The fluorescence behavior after the addition of a gold colloid depends on the nature of the pyrene side chain. If this does not contain a thiol group for binding to the gold the monomer fluorescence is somewhat decreased because of ineffective energy transfer to the gold. On binding

**Fig. 1** Monolayer protected cluster (“MPC”) of an HSC<sub>10</sub>-coated Brust gold particle after partial exchange with HSC<sub>10</sub>COO<sup>-</sup> and coupling with dansyl cadaverine and fluorescence intensities with 17 (upper curve) and 6 dansyls (lower curve) per MPC. Fluorescence increases linearly with concentration in both cases. The dye molecules do not interact. *Source:* From Ref.<sup>[23]</sup>.

through a thiol group hydrophobic aggregates are formed and a strong excimer fluorescence appears. This has been shown by Chen and Katz<sup>[25]</sup> for protected thiols. A pyrene-thioester and a pyrene-thiocarbonate bind noncovalently to the surface of 12.5-nm citrate-gold particles with binding constants of  $7.2 \times 10^7$  and  $1.7 \times 10^8 \text{ M}^{-1}$ , respectively. The change from excimer to monomer fluorescence has also been taken as a measure for the gold-catalyzed hydrolysis

of the ester and carbonate bonds, which leads to the appearance of the pyrene moieties in the bulk solution.

Pyrene excimer fluorescence has also been used to detect changes in interparticle interactions for capped gold particles.<sup>[26]</sup> Freshly prepared Brust-type gold particles (3.2–3.7 nm) capped with pyrenyl-decanethiol or -heptadecanethiol showed practically no excimer fluorescence. The monomer fluorescence was quenched by 99% by energy transfer to the gold particles.

**Fig. 2** Fluorescence of pyrene-coated particles increases with ageing because interdigitation leads to excimers. *Source:* From Ref.<sup>[26]</sup>.

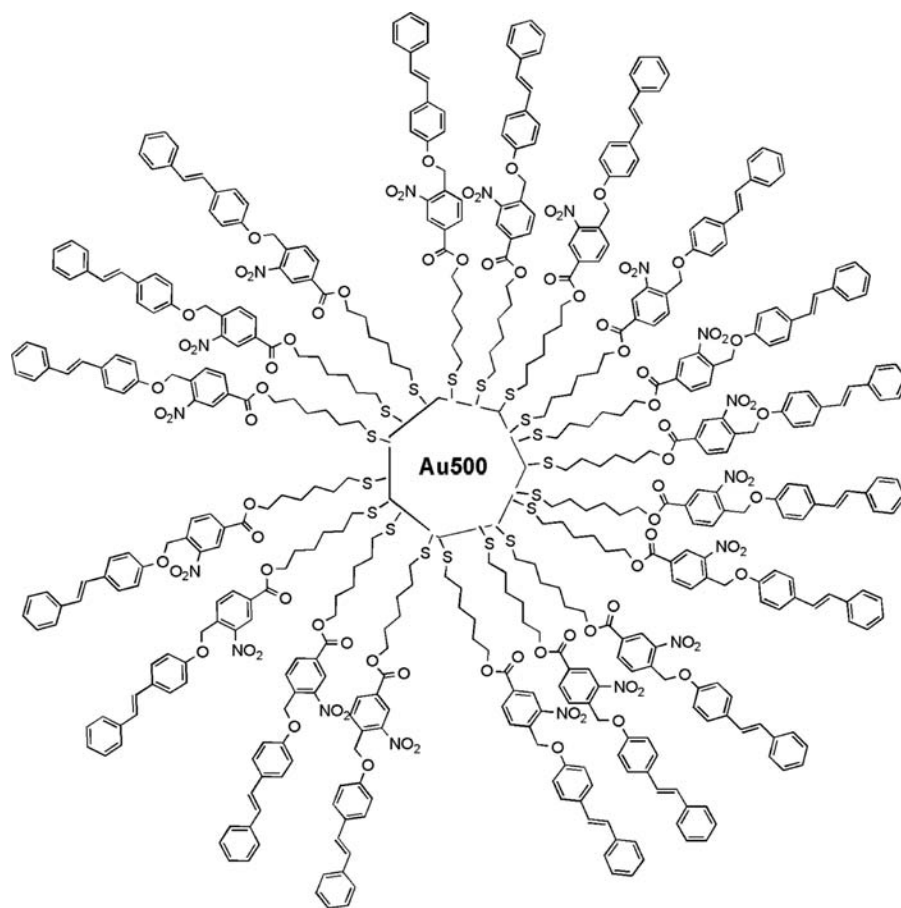

Although 43% (C-10) and 31% (C-17) of the surface gold atoms were covered with the thiol, most of the pyrene units were not oriented in a face-to-face manner. Upon ageing for up to 300 hr the fluorescence increased, especially the excimer emission. This was traced back to aggregation of the gold particles, leading to interdigitation of the alkyl chains resulting in a stacking of the pyrene units. The higher intensity of the excimer fluorescence for the short-chain pyrene provides further evidence for the chain density gradient for alkanethiolates on gold nanoparticles. The decay of the fluorescence was biexponential with lifetimes of 4.3 and 22 nsec for the monomer

fluorescence of fresh solutions. For aged samples only the lifetime of the longer-lived excited species was increased to 35 and 30 nsec for the two preparations. This indicates that there may be different binding sites on the gold surface leading to different excited states (Fig. 2).

#### **trans-cis Isomerization, Cyclodimerization, and Benzylic Cleavage**

The realization of dimerization necessitates two molecules in near neighborhood; isomerization, on the

**Fig. 3** Photodimerization of stilbene chromophore was only observed in ordered and flexible domains on particles with high curvature. *Source:* From Ref.<sup>[28]</sup>.

other hand, needs some space around the molecule. Both reactions are optimized under opposite conditions. Fluid monolayer coatings favor cleavage reactions which are linked to release molecules.

The comparison of three photochemical reactions, *trans-cis* isomerization, cyclodimerization, and benzylic cleavage of thioalkyl-azobenzenes and -stilbenes in homogeneous solution and in monolayers on 2.5-nm gold particles and on planar gold,<sup>[27,28]</sup> yielded valuable information about the effects of monolayer packing. Photoisomerization was found to be independent of the alkyl chain length in homogeneous solution with quantum yields of  $10^{-1}$  and  $3 \times 10^{-4}$  for the azobenzene and stilbene species, respectively. In a tightly packed monolayer on planar gold it was sterically blocked. In the more loosely packed monolayers on the small gold particles, isomerization occurred with reduced quantum yield. An additional decrease of the yield was found after shortening the alkyl chain from 12 to 4  $\text{CH}_2$  groups. Quenching of the excited state by the metallic core became dominant. The dependence on the distance was exponential with an attenuation constant of  $\beta = 0.5$ , which is smaller than expected for through-bond coupling. If a nitrobenzyloxy group was

introduced into the alkyl chain, photocleavage occurred. Parallel observation of isomerization and cleavage pointed to strong metal-based non-radiative quenching of the excited state. The significance of packing and steric hindrance became evident in stilbene photodimerization experiments. It was not observed in solution or in monolayers on planar gold but occurred on gold particles with a very low quantum yield of  $2\text{--}4 \times 10^{-6}$ , depending on the distance (Fig. 3).

Similar conclusions with respect to the rigidity of the monolayers have been drawn by Evans et al.<sup>[29]</sup> Photoswitching between the *cis* and *trans* states of alkane-derivatized azobenzene was not possible in single-component monolayers on planar gold. It has only been realized in mixed monolayers with free volume introduced by a spacer molecule with three ethyleneoxy units and especially in mixed monolayers of C6-thiol-azobenzene and mercaptophenol on 3.2-nm particles.

The Norrish-Young type II photochemical reaction has been used to probe the properties of a variety of ordered media including cyclodextrins, zeolites, liquid crystals, and micelles. At first the reaction was investigated in an MPC capped with a mixed monolayer of

**Fig. 4** Benzophenone is only released, if the benzophenone head groups are separated by unreactive molecules and on curved surfaces. *Source:* From Ref.<sup>[30]</sup>.

short alkanethiol and mercaptoundecanophenone by Kell, Stringle, and Workentin.<sup>[30]</sup> Irradiation released free benzophenone, irrespective of the length of the spacer alkanethiol (C-6 or C-12), but not in its absence. Whether fragmentation or cyclization is the main pathway to products depends greatly on the conformational flexibility of the triplet 1,4-biradical, which is formed from the  $n,p^*$  triplet excited state of the carbonyl group. If the volume, which is necessary for cyclization motions, is not available, only fragmentation occurs. The resulting terminal vinyl group on the MPC can then be used for further modification (Fig. 4).

### Miscellaneous Reactions

An interesting example for the interaction of a chromophore with the metal particle is the binding of methylaminopyrene on spherical gold particles of 5–8-nm diameter.<sup>[31]</sup> Because of internal charge transfer, pyrene is only weakly fluorescent in THF solution. On binding to the gold surface the electron-donating ability of nitrogen was decreased. As a result the fluorescence yield was increased from 0.09 to 0.48 (chelation enhancement). A second indication of the binding was the appreciable red shift of the absorption and fluorescence bands.

A phthalocyanine thiol bound to Brust-type gold particles with diameters ranging from 2 to 4 nm and associated with the TOAB phase transfer reagent generated singlet oxygen upon irradiation with visible light more effectively than without gold. The quantum yield increased from 0.45 to 0.65. TOAB promotes solubility in polar solvents, which is essential for a possible application in photodynamic therapy.<sup>[32]</sup>

Upon illumination of thiocyanine (TC)-J aggregates in solution, an ultrashort excited state was formed. Its relaxation was intensity dependent and dominated by exciton-exciton annihilation. On bulk silver surfaces ultrafast quenching of the exciton and its fluorescence occurred. The same was true on gold nanoparticles. The binding of the dye aggregate via two sulfonate groups was reported originally by

Kometani et al.<sup>[33]</sup> who applied gold, silver, and composite Au/Ag particles with diameters of about 10 nm. The absorption spectra were measured and simulated using the Maxwell-Garnett treatment. On silver particles after fsec-excitation at 417 nm (140-fsec time resolution) a charge separated state with a lifetime of 300 psec was observed<sup>[34]</sup> by absorption changes at 475 nm close to the sharp absorption band of the J aggregate on silver at 481 nm. The exciton of the J aggregate is then of course strongly coupled to the silver particle plasmon. Photoexcitation of this resonance leads to very fast electron transfer of the TC aggregate to the metal. In the case of gold particles the plasmon energy is too low for such coupling (2.38 vs. 3.1 eV for Ag).

Rhodamine 6G has been used as a reporter molecule for changes in aggregation and morphological changes of the gold clusters. The 2-nm particles, prepared by rhodanide reduction,<sup>[35]</sup> did not exhibit surface plasmon absorption, for which the diameter must be at least 5 nm,<sup>[36]</sup> and bound rhodamins 6G as a monomer. On increasing the Au/dye ratio, aggregation was shown by a blue shift of the dye absorption (H aggregate) and the appearance of a plasmon band at 537 nm. Twenty-five minutes of laser irradiation at 532 nm lead to melting and growth of the particles, due to plasmon excitation.<sup>[37]</sup> This was indicated by the broadening of the plasmon band and by an increase of the monomer fluorescence of rhodamine at 545 nm, originating from molecules released into the bulk solution (Fig. 5).

### Well-Defined Assemblies of Nanoparticles

Arrays of nanoparticles have been prepared by salt-induced aggregation,<sup>[38–42]</sup> Langmuir techniques,<sup>[43]</sup> surface assembly,<sup>[44–46]</sup> or crystallization.<sup>[47]</sup> The motive for such preparations is the special nonlinear optical properties of collective metal nanoclusters. They show large surface-enhanced Raman signals<sup>[44–46]</sup> and large first hyperpolarizabilities.<sup>[38–42]</sup> A necessary condition is a well-defined symmetry and interparticle spacing, which is not always met in the preparations mentioned above.

**Fig. 5** Model of possible morphological changes of gold-dye cluster arrays upon laser irradiation. *Source:* From Ref.<sup>[37]</sup>.

It may be realized more easily by covalent bridges between the particles.<sup>[48,49]</sup> Gold particles were connected, for example, by thiol-functionalized oligo-phenylacetylenes.<sup>[50]</sup> The intensity of hyper-Rayleigh scattering (HRS), i.e., incoherently scattered second harmonic light, was especially high for noncentrosymmetric trimers, which was traced back to enhanced values of first hyperpolarizability. These properties are also of interest for nanoscale electronics.

Defined aggregates can also be obtained by non-covalent interactions. Two-dimensional (2-D) assemblies with hexagonal packing of 5-nm gold particles (Bust-type) were formed by adsorption of tetrapyrrolylporphyrin to the surfaces. Optically, this was shown by the red shift (512 to 610 nm) and broadening of the plasmon absorption as well as of the porphyrin Soret band from 25 nm half width in solution to 45 nm. The porphyrin dye acts as a reporter molecule and as a trigger of a defined aggregation.<sup>[51]</sup> Surface-enhanced resonance Raman scattering (SERRS) was also observed (Fig. 6).

**Fig. 6**  $H_2TpyP$  stands perpendicular on the gold surface and causes aggregation. (From Ref.<sup>[51]</sup>.)

### Photoelectrochemical Cells

A photoelectrochemical cell consists of a charge separating system attached to a macroscopic electrode and a redox electrolyte carrying charges to a counter electrode. If self-assembled monolayers (SAMs) of electron transfer dyades or triades are directly bound to the working electrode, the light absorption in these 2-D arrays is normally low. The use of photosensitive nanoparticles in contact with the electrode yields 3-D array electrodes with high surface and high absorbance.

The conventional method to get a 3-D array of a charge separating system makes use of bifunctional bridge compounds and of electrostatic interactions to form a multilayered system. Lahav et al.<sup>[52,53]</sup> used indium-doped tin oxide (ITO) electrodes coated by aminosiloxane. Negatively charged gold nanoparticles (diameter: 13 nm) were self-assembled on the ITO electrode, followed by a positively charged charge-separating (CS) system. Repetition produced a multilayer system. The CS system consisted of either a Zn protoporphyrin–viologen dyade or a catenane, consisting of a cyclo-bis-viologen-phenylen and a Ru(bipy) derivative. Following excitation of the porphyrin the excited electron is conducted to the ITO electrode via the gold particles. The quantum yields of the corresponding photochemical cells [with ethylenediaminetetraacetic acid (EDTA) as electron donor and a graphite counter electrode] were  $\phi = 10^{-3}$  ( $\lambda = 544$  nm) for the porphyrin system and  $\phi = 10^{-4}$  ( $\lambda = 434$  nm) for the Ruthenium system. These numbers, referring to the short-circuit current, are relatively low. This is because of the poor contact between the CS system and the gold particles (Fig. 7).

Better results are obtained if the photosensitizer is directly bound to the gold particles. Sudeep et al.<sup>[54]</sup> electrodeposited functionalized gold particles on a nanostructured  $SnO_2$  electrode, made by annealing a  $SnO_2$

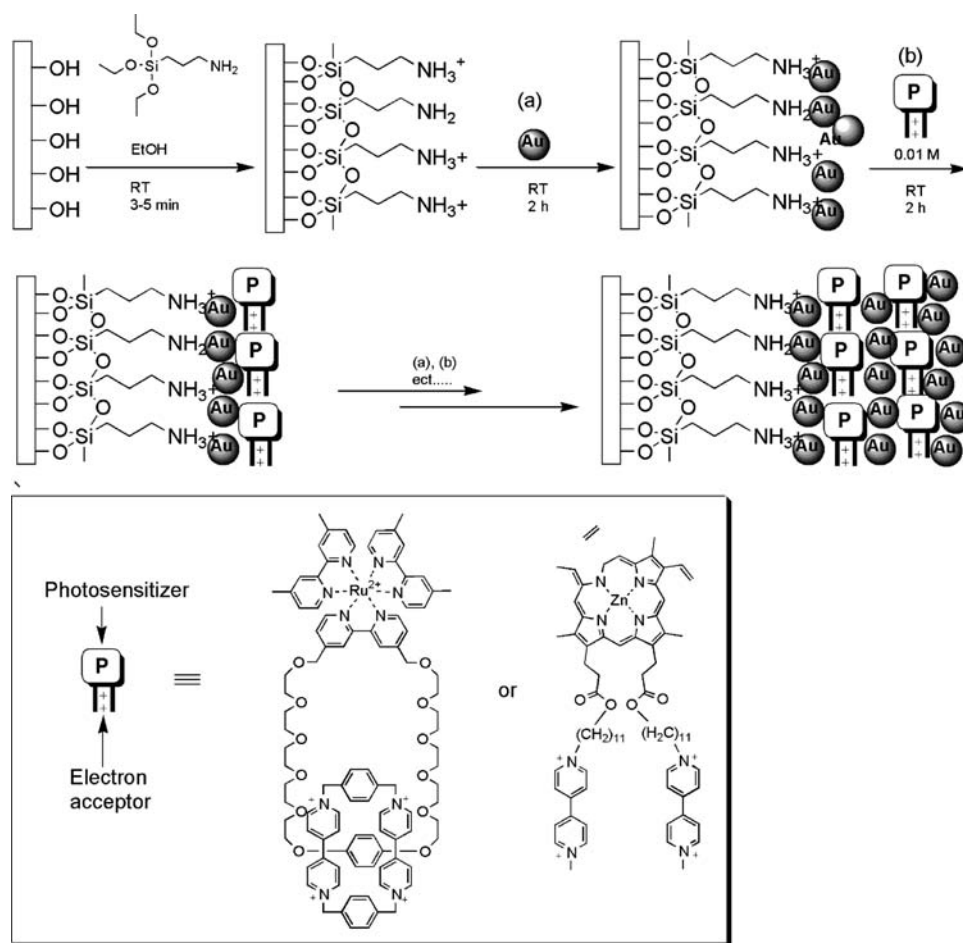

Fig. 7 Model of the gold-nanoparticle arrays on an ITO electrode for photocurrent production. Source: From Ref.<sup>[53]</sup>.

film on an optically transparent electrode (OTE). The charge separating system consisted of a light-absorbing fullerene electron donor bound to 3-nm gold particles via a modified alkanethiol chain. The light-induced electron transfer to the gold particles was optimized by the redox electrolyte  $J^-/J_3^-$  in high concentration. An incident photon to photocurrent efficiency (IPCE) of  $8 \times 10^{-3}$  (at 450 nm) was achieved (Fig. 8).

Another efficient approach is to precipitate the gold particles directly on a flat gold electrode and to bind an electron transfer dyade afterwards.<sup>[55]</sup> The dyade consisted, for example, of a rutheniumbipyridyl complex as light-absorbing electron donor, connected via a C7 bridge to viologen, as electron acceptor, and a second bridge (C6) to the final thiol group bound to the citrate gold particles. In such a photochemical cell with triethanolamine as electron donor and a Pt-counter electrode the photocurrent was 15 times higher than in a cell in which the RuVS dyade was directly bound to the flat gold electrode. This factor corresponds to the enhanced concentration of RuVS as achieved by binding to the nanoparticles. The photocurrent efficiency was  $8 \times 10^{-3}$  (at 460 nm).

High IPCE was, however, also achieved on flat gold electrodes without nanoparticles by increasing the absorption cross section of the sensitizing electron donor. Imahori et al.<sup>[56]</sup> prepared mixed SAMs of a ferrocene-porphyrin-fullerene electron transfer triad and of a boron-dipyrrin sensitizer, which transfers energy to the porphyrin. An IPCE as high as  $1.6 \times 10^{-2}$  (at 430 nm) was thus achieved.

### Construction of Form-Stable Gaps in Monolayers

Li and Fuhrhop<sup>[57]</sup> used a totally different approach for capping and functionalizing gold particles. Multiply charged derivatives of tetraphenylporphyrins were directly bound to the gold surface in a flat-lying position. Long-chain thiols with two secondary amide groups were then self-assembled around them. As a result of hydrogen bonding the monolayers were rigid and impermeable to compounds, which dissolve in fluid membranes. The diameter of above 20 nm of the particles allowed the formation of totally closed membranes. The curvature was not too high. Form-stable

**Fig. 8** Model of fullerene-thiol-coated gold nanoparticles, their absorption spectrum (—) and photocurrent action spectrum (---). The inset shows the on-off response upon illumination at 400 nm. *Source:* From Ref.<sup>[54]</sup>.

gaps of  $2 \times 2 \times 2$ -nm size with rigid walls were thus formed. The rigidity has been proven by fluorescence quenching experiments. The porphyrins on the surface showed only a very weak rest fluorescence as a result of energy transfer quenching. It was totally quenched by paramagnetic metalloporphyrins of the same size as the porphyrin at the bottom of the gap by forming a heterodimer. Porphyrins with larger side groups were not able to enter the rigid gaps and quench the fluorescence. Such size discrimination did not take place when the surface layer around the porphyrins consisted of octadecanethiol without rigidifying amide groups. On flat gold electrodes, long-distance (1–2 nm) heterodimers were also established with a fitting porphyrin being attached to amine substituents at the rigid walls of the gap<sup>[58,59]</sup> (Fig. 9).

## SEMICONDUCTOR NANOPARTICLES

Semiconductors can be optically excited. But the internal charge separation is not stable. The electrons in the conduction band and the holes in the valence

**Fig. 9** Model of a gold nanoparticle coated with a rigid diamide monolayer containing 2-nm gaps with a porphyrin at the bottom. The head group of the diamido amphiphile is an oligoethylene ether. *Source:* From Ref.<sup>[57]</sup>.

band have to be brought to reaction with added electron acceptors and donors, respectively. In this way charge separation can be stabilized. Much of the work with semiconductor particles is thus focused on the conversion of sunlight into chemical energy (e.g., hydrogen production) or electrical energy (photoelectrochemical cells). For the absorption of light the size of the bandgap is essential. The coupling to electron

acceptors and donors depends on the position of the conduction and the valence band. It must be noticed that these properties are size dependent in the quantum (Q) particles.<sup>[60]</sup> Narrow bandgap semiconductors such as cadmium sulfide (CdS),<sup>[61]</sup> cadmium selenide (CdSe),<sup>[62]</sup> lead sulfide (PbS),<sup>[63]</sup> and silver sulfide (Ag<sub>2</sub>S)<sup>[64]</sup> are excitable with visible light. Wide bandgap semiconductors such as titanium dioxide (TiO<sub>2</sub>),<sup>[65]</sup> zinc oxide (ZnO),<sup>[66]</sup> and tin dioxide (SnO<sub>2</sub>)<sup>[67]</sup> are only sensitive in the UV. Spectral sensitization is therefore an important approach to making wide band semiconductors attractive for solar energy conversion.<sup>[68,69]</sup> A chromophore absorbing in the visible range is attached to the particle surface. The excited electron of the chromophore is injected into the conduction band of the semiconductor. Thus in most cases the semiconductor surface is solely modified by dyes; additional monolayer coatings may improve solubility and longevity in the chosen solvent.

A different approach to enlarging the wavelength range of absorption is the coupling of two semiconductor particles with wide and narrow bandgap in mixed particle assemblies.<sup>[70]</sup> Either nanostructured films containing nanoparticles of different semiconductors (e.g., ZnO and CdS) are prepared by coprecipitation.<sup>[71]</sup> Heterostructures of the core-shell type are formed by controlled precipitation of semiconductor molecules of one type (shell) on the presynthesized nanoparticles of another type (core), e.g., CdSe/ZnS.<sup>[72]</sup> Photocatalytic water splitting with such systems was introduced by Henglein<sup>[73]</sup> and Duonghong, Ramsden, and Graetzel<sup>[74]</sup> both in 1982. It should be noted that in most cases the semiconductor particles used in photocatalytic studies (synthesis of organic compounds) are rather large (100 nm) with no quantum size effects.

## Spectral Sensitization

Charge ejection from excited dyes or charge injection into the conduction band of semiconductor particles is the key reaction for the construction of photoelectrochemical cells of technical interest. At first, electron injection was not determined directly. Photocurrents were measured in electrode systems with polycrystalline layers of TiO<sub>2</sub> loaded with different dyes.<sup>[75–80]</sup> From the current efficiency IPCE and the absorption of the dye quantum yields of injection from 87% to 100% were calculated. Direct measurement of the luminescence yield of the ruthenium complex on TiO<sub>2</sub> particles gave a value of only 60%.<sup>[75]</sup> Later,<sup>[81]</sup> fluorescence and transient absorption changes were measured on colloidal TiO<sub>2</sub> electrodes, consisting of SnO<sub>2</sub> conductive glass and a film of 25 nm TiO<sub>2</sub> particles. Chlorin e6 and Cu-chlorophyllin were used as sensitizers. Comparison of the fluorescence lifetime of

chlorin e6 on TiO<sub>2</sub> and ZrO<sub>2</sub>, where charge injection is not possible, yielded a rate constant for the electron injection of  $2.2 \times 10^9 \text{ sec}^{-1}$ . The constant was nearly 10 times smaller ( $3 \times 10^8 \text{ sec}^{-1}$ ) for the copper compound, where electron transfer starts from the triplet state and was determined from the phosphorescence lifetimes. Transient absorption changes after 10 nsec of excitation of the dye indicated the formation of its cation radical and of the electron injected into the TiO<sub>2</sub> conduction band. In the absence of a redox electrolyte (J<sup>-</sup>) the recovery of the ground-state absorption of the dye and the decay of the products of charge separation were identical. The addition of J<sup>-</sup> caused a fast reduction of the cation radical, whereas the absorption of the electron stayed for more than 100 msec.

Fsec-time resolution is necessary to the study of the dynamics of electron injection. This was done for fluorescein 27 adsorbed to 2.4-nm TiO<sub>2</sub> particles.<sup>[82]</sup> The absorption of the injected electrons had a rise time of 300 fsec, which is identical to the decay time of the stimulated emission of the dye. The recombination was much slower, which was explained by the validity of the Marcus formula in the inverted region. The kinetics was multiexponential with a very wide distribution of rates, ranging from 25 psec to nanoseconds and microseconds. Normally, in such a case, a distribution of energetically different trap sites for electrons is suggested. Here a red shift of the transient absorption within 25 psec was found, explained by vibrational cooling and perhaps solvation and structural relaxation of the initial product state, leading to a time-dependent  $\Delta G^0$ .

Ashbury et al.<sup>[83]</sup> studied the effect of the bridge length of the binding ligand of re-polypyridyl complexes. They also obtained evidence for the injection of hot excited state electrons.<sup>[84]</sup> Bonhote et al.<sup>[85]</sup> studied the structural effect of different Ru-dye molecules. The best yield of charge separation was obtained for the system in which the excited electron was localized on the ligand bound to the semiconductor surface.

Electron injection is expected to be especially effective from a highly polar excited state of the dye. This has been verified by comparison of two coumarin dyes bound to TiO<sub>2</sub> particles through a carboxyl group.<sup>[86]</sup> Coumarin C 343 is a four-ring-system and the electron injection occurs from a normal intramolecular charge transfer (ITC) state with a quantum yield of 0.6. In the second dye, 7-diethylaminocoumarin-3-carboxylic acid (D-1421), the ICT state was able to relax to the more polar twisted intramolecular charge transfer (TICT) state. The overall quantum yield of electron injection from both excited states was 0.9, i.e., 50% higher than for C343, for which rotation of the nitrogen moiety is not possible. The products of the reaction, the dye radical cation, and the electron

in the  $\text{TiO}_2$  conduction band were shown by picosecond laser flash photolysis.

### Photocurrents in Photoelectrochemical Cells

For a long time the construction of efficient photoelectrochemical cells was hampered by the fact that monolayers of dyes on planar electrodes absorb usually less than 1% of the incident light. Graetzel<sup>[75–80]</sup> used polycrystalline  $\text{TiO}_2$  (anatase) electrodes with a roughness of 200. Thus in the beginning the second problem, that of charge injection, was attacked.  $\text{Fe}(\text{CN})_6^{4-}$  which forms a charge transfer complex with  $\text{TiO}_2$  yielded an IPCE of 0.37 only;<sup>[76]</sup> the metalloporphyrin  $\text{ZnTPPC}$ <sup>[77]</sup> was only slightly better (0.42). A number of ruthenium complexes were examined.<sup>[87]</sup> The normal *tris*-bipyridin complex did not bind sufficiently. Carboxylic groups turned out to be necessary. Ruthenium complexes with two and three carboxy-bipyridin ligands were used and gave values of 0.62 and 0.73 for the IPCE.<sup>[75,78,79]</sup> For the latter ligand the importance of type and concentration of the redox electrolyte were determined.<sup>[79]</sup>  $\text{J}^-$  turned out to be better (0.73) than  $\text{Br}^-$  (0.56); and for hydroquinone the initially used concentration of 1 mM was too low (0.44) and had to be increased to 0.1 M (0.74). A very good value (0.83) was obtained with coumarin.<sup>[80]</sup> Other groups also tried merocyanines.<sup>[88]</sup> The importance of carboxyl groups for binding of a dye to the  $\text{TiO}_2$  surface was again shown by comparing the photocurrent action spectra of chlorophyll, chlorins, and mesoporphyrins.<sup>[89]</sup> Copper-chlorophyllin was not better than copper-chlorin, indicating that conjugation of the carboxyl group to the  $\pi$ -electron system of the dye was not advantageous.

O'Regan and Graetzel published in 1991 the design of the first photoelectrochemical cell which could compete with photovoltaic cells.<sup>[90]</sup> The progress was based on the use of a 3-D network of  $\text{TiO}_2$  nanoparticles (15 nm size), coated with a charge-transfer dye and fixed as a film of 10- $\mu\text{m}$  thickness on a conducting glass support. The large surface allowed binding of a higher amount of the dye than before. The dye was a trimeric ruthenium complex  $\text{RuL}_2 (\mu\text{-(CN)Ru(CN)L}_2')_2$ , with bipyridine and bipyridine-dicarboxylic acid as ligands. With lithium-iodide as a redox electrolyte an IPCE of 0.84 was achieved. The overall energy conversion yield was 7.1–7.9% in simulated solar light and 12% in diffuse daylight. The next step was to improve the redox electrolyte by changing to solid systems. P-type semiconductors<sup>[91]</sup> and organic materials<sup>[92]</sup> were tested with disappointing results. An amorphous organic hole transporting material, namely, tetrakis (*N,N'*-dimethoxyphenyl-amine)-spirobifluorene (OMeTAD), was then successful.<sup>[93]</sup> The energy efficiency was 33%

**Fig. 10** Model of the electron injection (inj.), regeneration (reg.), recapture (rec.), and hopping in the mesoporous  $\text{TiO}_2$  solar cell heterojunction. *Source:* From Ref.<sup>[93]</sup>.

with Ru-bis(dicarboxy-bipyridyl)-bis-rhodanid complex as a sensitizer (Fig. 10).

CdS nanoparticles were covered with thiolated oligonucleotides and then cross-linked with DNA. The assembly was connected with a gold electrode by double-stranded DNA.<sup>[94]</sup> Photocurrents were observed in the presence of TEOA upon irradiation at 405 nm where the CdS particles absorb. Conduction band electrons from particles near the electrode were directly ejected into the electrode. Electrostatic binding of  $\text{Ru}(\text{NH}_3)_6^{3+}$  to the DNA increased the current. Obviously, the ruthenium complex was active as electron relay (Fig. 11).

Nanocomposite Ni/ $\text{TiO}_2$  films were derivatized with hexacyanoferrate to form nickel salt (NHF).<sup>[95]</sup> Under chopped illumination photocurrent signals indicated photoelectron-hole recombination, mediated by the hexacyanoferrate redox electrolyte, if the potential was below the NHF redox regime. At higher potentials the oxidized NHF centers accepted electrons from the excited  $\text{TiO}_2$  with enhanced quantum yield. If a nickel electrode was derivatized with hexacyanoferrate and  $\text{TiO}_2$ , the electrode exhibited bipolar photoactivity: the photocurrent switched from cathodic to anodic. Below the NHF potential the photogenerated holes from  $\text{TiO}_2$  were transferred to reduced NHF sites; above the NHF potential, the electrons were transferred to oxidized NHF sites as in the composite film. This result underlines the importance of the microenvironment (Fig. 12).

### Hydrogen Production

After a burst of articles in the early 1980s, little work has been done on hydrogen production recently. TiO<sub>2</sub> and Nb<sub>2</sub>O<sub>5</sub> nanoparticles have been used in integrated systems for light-induced vectorial electron transfer and hydrogen production.<sup>[96]</sup> The electron

**Fig. 12** Model of nickel hexacyanoferrate (NHF) films on TiO<sub>2</sub> or nickel electrodes. Type I was photoactive above an applied potential of 0.4 V. Type II switches from cathodic to anodic photobehavior upon change of potential or Ni(II)/Ni(III) ratio.

transfer system consisted of an electron donor, Ruthenium-bipyridyl-dicarboxylate as a sensitizer, the semiconductor as initial electron acceptor, and a viologen as electron relay to the platinum catalyst. This system was spatially organized by a linear channel zeolite (zeolite L or mordenite), which was internally platinized. The semiconducting quantum particles were grown by hydrolysis within the channels and on the external surface of the zeolites. The channel openings (0.71- and 0.65-nm diameter) did not allow the entrance of the ruthenium complex, which was adsorbed exclusively on the surface of the external particles. The viologens were able to enter the channels. In this way the electron donors were separated from the hydrogen catalyst. Despite very efficient initial charge separation no hydrogen (TiO<sub>2</sub> system) or hydrogen with only 0.01% quantum yield (Nb<sub>2</sub>O<sub>5</sub>) was evolved in the presence of a reversible electron donor (e.g., J<sup>-</sup>). The quantum yield was, however, 1% at 450 nm for the system zeolite/TiO<sub>2</sub>/MV<sup>2+</sup>/RuL<sub>3</sub><sup>2+</sup> in the presence of sacrificial electron donors such as TEOA or EDTA. It should be noted that the initial charge injection from the Ru complex into the semiconductor particle is essential for the success. Without the particles with self-assembly of the MV<sup>2+</sup> and Ru(Bipy)<sub>3</sub><sup>2+</sup> onto/into the zeolites very little hydrogen was produced. On the other hand, the H<sub>2</sub>-evolution rate was highest in the case of direct bandgap excitation (Fig. 13).

Magnetic - Mesoporous

## SILICA PARTICLES

Silica particles are usually prepared by the method of Stöber, Fink, and Bohn<sup>[97]</sup> which is the polycondensation of tetraethoxysilane (TES). It leads to a dense SiO<sub>2</sub> network, if the conversion of SiOEt groups and the cross-linking are perfect. Otherwise, the hydrophilic and charge stabilized particles contain nanosized pores. The negative surface charge has been used to stabilize the products of photo-induced charge separation.<sup>[98]</sup> More recently, interest has grown in concentrated dispersions of the silica particles. For this purpose sterically stabilized core-shell particles have been synthesized by surface esterification with octadecanol.<sup>[99]</sup> These organosilica particles are dispersed in organic solvents and several different colloid phases have been produced: colloidal fluids with only short-range positional order, colloidal glasses with a frozen-in fluid structure, colloidal crystals with long-range positional correlations, and thermotropic gels. These systems are of special interest, when single particles become visual by covalently bound fluorescent dyes. There are three possible positions for the dye: on the particle surface (type a), in a thin shell in the particle interior (type b), and distributed in the volume of an inner core (type c). All three types have been realized by introducing the dye at different stages of the particle synthesis. Isocyanate derivatives of fluorescein, coumarin, azobenzene, and pyrene have been used to be covalently bound to the silane coupling agent 3-aminopropyl-triethoxysilane (APS).<sup>[100]</sup> Type c particles<sup>[101,102]</sup> were applied in studies by fluorescence confocal scanning laser microscopy (FCSLM), type b particles<sup>[103]</sup> in fluorescence recovery after photobleaching (FRAP) experiments. Apart from these investigations centered around the question of interparticle structure and particle diffusion, photochemical studies have not been undertaken. A new method of preparing dye-labeled particles has recently been published.<sup>[104,105]</sup> Trimethoxymethylsilanes (TMOMS) were used for the synthesis together with chlorobenzyl-trimethoxysilane, leading to lower cross-link density and higher porosity as compared to the particles from TES. Thus carboxylate derivatives of the dyes were able to diffuse through the micropores and were bound by esterification with the chlorobenzyl group. For particles to be stable in aqueous medium, the coating has to be carried out with bifunctional compounds, one group being a terminal amino group.

Fuhrhop<sup>[106]</sup> started the Stöber synthesis with silicon tetrapropoxide and aminated the surface with a silylchloride derivative. Judging from TEM pictures the particles of at least 60-nm diameter had a smooth surface. In a further derivatization step gaps in monolayers, as already realized on gold particles, were constructed. Tetracarboxyphenylporphyrin was covalently

**Fig. 14** Model of a porphyrin-based membrane gap. (Fuhrhop, unpublished.)

bound to the surface through four amide bonds. Polyoxyethylene as terminal group rendered the particles especially hydrophilic. In contrast to the case of porphyrin bound to gold particles the photophysical properties of the porphyrin were similar to that of corresponding porphyrins in solution (e.g., the fluorescence yield). The triplet state was detected by absorption changes around 780 nm with a relaxation time larger than in solution. Negatively charged *o*-naphthoquinone-sulfonate was able to penetrate to the porphyrine and to accelerate the triplet relaxation by electron transfer (the singlet state was also affected) (Fig. 14).

Silica particles are commercially available in different qualities. Cab-O-Sil, which has been sintered at 500°C, is the least porous material and best suited for the attachment of monolayers. Mallouk<sup>[107]</sup> has formed multilayers by alternating assembly of  $\alpha,\omega$ -bis-phosphonic acid-bolaamphiphiles and Zr(IV)-salts on Cab-O-Sil particles terminated by phosphonic acid.

## CONCLUSION

Membrane coating of nanoparticles enables to vary the properties and interactions of individual particles, thereby also determining their stability in a given solvent. The ordering of these membranes is less than that of SAMs on planar surfaces and therefore a subject of intense research. Photochemical and photophysical reactions of dyes incorporated into the membranes help to elucidate the order and other properties of the membranous coatings, especially on gold particles. On silver and gold particles, surface-enhanced reactions such as Raman and resonance Raman scattering

are analytical tools. Fluorescent dyes on silica particles are used to investigate the structure of concentrated colloidal solutions. On semiconductor particles, dye coatings have a more practical purpose: sensitization for the absorption of visible light makes the particles interesting in the context of solar energy conversion. The construction of photoelectrochemical cells, the production of hydrogen, and the photochemical detoxification of waste materials, especially in water, are projects that will still become more important in the future. The general trend is to leave the single-particle systems and come to the design of assemblies of nanoparticles with a well-defined architecture. The particles are cross-linked by membranes or polymers, provided with dyes or other molecules, to realize defined distances and surfaces with special properties and finally to arrive at new complex composite materials. Until now for photochemical reactions the large surface of the particles has been the decisive advantage over planar surfaces. The size dependence of optical, electrochemical, and thermodynamic properties of quantum particles has scarcely been exploited and is surely more essential for the design of special optical materials for nonlinear optics and of nanoelectronic circuits.

## INTRODUCTION

The quest for new molecular sieves in the late 1980s led Mobil researchers to the discovery of a family of nanostructured mesoporous materials known as M41S.<sup>[1–3]</sup> MCM-41 is undoubtedly the best known and most widely studied of this family of materials, each synthesized via a self-assembled liquid crystal mechanism involving sol–gel precursors which form a hexagonally packed rod-shaped micelle structure.<sup>[4]</sup> The other members of the M41S family are the cubic (MCM-48) and lamellar (MCM-50) forms. This entry describes the progression of M41S materials from discovery through characterization and development. ExxonMobil has very recently commercialized MCM-41 for an undisclosed application. Its decade-long journey from initial identification to commercial application is similar in duration to that of many novel materials. Yet there were many unique challenges posed by the synthesis and development of such a novel material. This is its story.

## THE DISCOVERY OF THE M41S MATERIALS FAMILY

Like most discoveries of novel materials, the discovery of Mobil's M41S mesoporous molecular sieves was an unanticipated outcome of the application of observational skills, knowledge, and techniques developed over many years of effort in synthesizing large pore catalytically active frameworks. Like many major petroleum companies, Mobil had a material synthesis effort attempting to identify new zeolites that could selectively convert high molecular weight petroleum-based molecules. In the mid-1980s, Mobil Technology Company had a significant effort in developing pillared layered materials. This class of materials, theoretically, offered the ability to tune pore size, active site density,

and composition; variables that the traditional aluminosilicate zeolites did not possess. By varying the pillar size and pillar density, the Mobil researchers learned that pore systems could be tuned for the desired application. The pillar composition also appeared to be adjustable so various chemistries could be effected. Unfortunately, although significant progress was made in designing these pillared layered materials,<sup>[5]</sup> realistically these materials did not have sufficient thermal and hydrothermal stability or catalytic activity to be used in most petroleum processes. Furthermore, the pillar composition could not be as varied as initially conceived. Toward the end of the decade, a small group of researchers at Mobil's Paulsboro Laboratory approached this effort of discovering large pore frameworks by attempting to combine both the concepts of the pillared layered materials and the formation of zeolites. The approach was to consider that some zeolites were formed via layered intermediates. Thus if this intermediate could be isolated and used as a layered composition to form pillared porous materials; the resultant product would be composed of crystalline walls that would be thermally stable and catalytically active. This concept had credibility because of a new layered framework that was discovered during that time.<sup>[6]</sup> It was designated by Mobil as MCM-22 (MWW).

We noted that upon thermal treatment of the as-synthesized MCM-22, the X-ray diffraction pattern of the material shifted to higher  $2\theta$  values, similar to that of swollen layered materials when the intercalate is removed. In layered materials the low-angle lines associated with the interlayer distance shifted to lower  $d$ -spacings consistent with the removal of the organic template intercalate and the collapse of the layers. However, in the as-synthesized MCM-22 sample, this shift of the  $d$ -spacings, upon thermal treatment, was subtle,  $\sim 2\text{--}3 \text{ \AA}$ , and the base crystalline framework remained relatively unaffected. This suggested that

the MCM-22 zeolite was composed of crystalline layers that were linked together by weak chemical bonds during the synthesis. Upon thermal treatment, these chemical linkages became much stronger, as the layers condensed onto each other.

Using the as-synthesized zeolite material, with the template intact and prior to any thermal exposure, we attempted to delaminate or separate these crystalline layers of the MCM-22 “precursor.” A pillared layered material resulting from this delamination and subsequent pillaring was obtained and identified as MCM-36.<sup>[7,8]</sup> The process involved the initial intercalation of the layers using an alkyltrimethylammonium compound followed by the insertion of stable inorganic pillars using a reactive silica source such as tetraethylorthosilicate.

The layered zeolite precursors, exemplified by the MCM-22 case, differed from their layered predecessors such as clays and layered silicates in possessing layers with high zeolite activity and porosity. Obviously, these were very attractive from the catalyst standpoint. Another feature distinguishing the layered zeolite precursors from the other layered materials was their resistance to swelling by ion exchange with neutral or mildly basic media, such as quaternary ammonium salts or amines. It was only with the introduction of a quaternary ammonium surfactant in a hydroxide form, specifically cetyltrimethylammonium hydroxide solution obtained by anion exchange of the halide solution with hydroxide, that successful swelling of the layered zeolite precursor was demonstrated. The use of an apparently equivalent medium, a mixture of surfactant halide and another hydroxide, instead of the anion exchanged surfactant hydroxide, was ineffective.<sup>[9]</sup>

This general approach of interrupting zeolite syntheses, isolating the layered zeolite precursors, and using these potential crystalline layered materials as reagents to form large pore active catalysts was investigated for other zeolite families such as ZSM-35, or synthetic ferrierite. In this system, the ferrierite sheet, pre-Fer, may be the principal building unit of the resultant zeolite material. To optimize the formation of these layered precursors, several reaction conditions were identified and imposed on the traditional zeolite synthesis. The zeolite synthesis was interrupted prior to any X-ray diffraction evidence of crystallinity. The interruption could be initiated at any point within ~25% to 75% of the total expected synthesis time. High concentrations of the intercalate, an alkyltrimethylammonium salt, at high pH were added to this interrupted zeolite precursor media. In other syntheses, a reactive silica source, tetramethylammonium silicate, was also added as a potential pillaring agent. These new synthesis mixtures were then subjected to additional hydrothermal treatment in an attempt to form the zeolite-layered

hybrid. In many instances, the resulting product exhibited some very unusual properties.

The X-ray diffraction pattern was essentially featureless except for one broad low-angle peak at about  $2^\circ 2\theta$ . This X-ray diffraction pattern was intriguing because the original zeolite templating agent still existed in the synthesis composition. Apparently, the reaction conditions and time and temperature sequence were changed during the addition of the quaternary salt. This inhibited the formation of the originally intended zeolite. Normally, even this low-angle line might not have been observed, except that we were using a chromium X-ray source instead of the typical copper tube. The chromium source, which is very useful for low-angle peak detection, was a remnant from our pillared layered material research effort. The other unusual properties on this unknown material were the extremely high BET surface areas and hydrocarbon sorption capacities. These BET surface area values, typically  $>600 \text{ m}^2/\text{g}$ , were many times those normally observed for zeolite samples. The hydrocarbon (*n*-hexane and cyclohexane) sorption capacities were in excess of 50 wt.%, also abnormally high compared to our typical microporous samples. In fact, our analytical laboratories initially incorrectly believed that their test equipment was broken or out of standard because of the results obtained from these initial mesoporous materials.

In a separate and concurrent synthesis study, the cetyltrimethylammonium hydroxide was used directly as a structure-directing agent in zeolite-like hydrothermal syntheses. The product properties were similar to those generated in the layered zeolite precursor systems, i.e., characterized by a low-angle line in an X-ray diffraction pattern corresponding to large *d*-spacing and unusually high BET surface area and adsorption capacities. Thus both interrupted zeolite precursor systems and direct introduction of cetyltrimethylammonium hydroxide as a template resulted in the mesoporous molecular sieve products. As described below, subsequent detailed characterization studies allowed elucidation of the nature of these remarkable materials.

Obviously, these abovementioned unusual physical properties are characteristics of the mesoporous molecular sieves. However, with only one broad low-angle X-ray diffraction peak and the uniquely high values for both surface area and hydrocarbon sorption as data, this was insufficient to fully identify the nature of these materials. We initially concluded from this one broad X-ray diffraction peak material that we had completely disrupted the interlayer connectivity of layered zeolite hybrids, and the resulting X-ray diffraction was simply a repeat of the thickness of the layered precursor of about 4.0 nm. A key in the identification of this new class of porous materials was the observation, by TEM analyses, of a trace amount of MCM-41 in one

**Fig. 1** The initial discovery by TEM analysis of MCM-41. Source: From Ref.<sup>[1]</sup>.

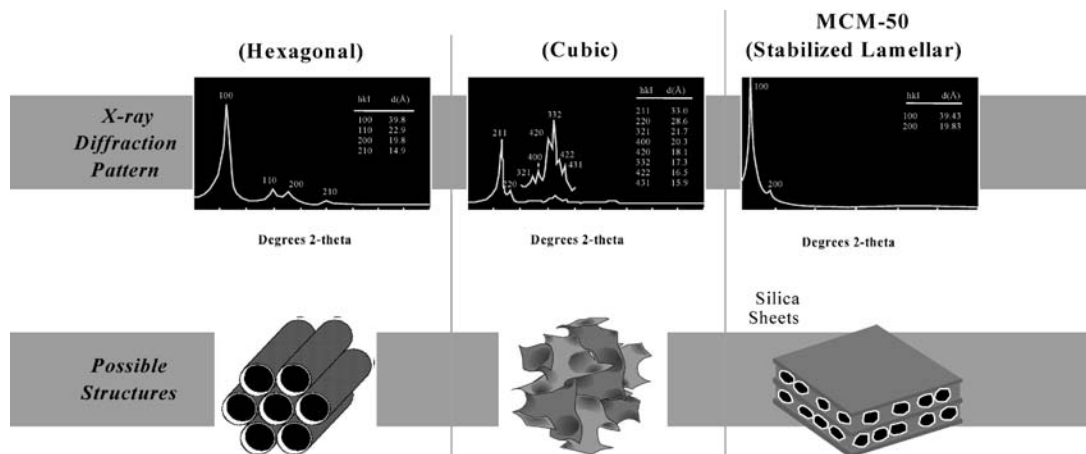

of our samples. At this time, our small research group had the luxury of having as one of the members, a microscopist, Mike Leonowicz, who typically would conduct analyses on some of our more unusual samples. The observation of trace quantities of MCM-41, the uniform hexagonal pore structure, in one of the interrupted synthesis preparations provided us with hard evidence of this new class of materials (Fig. 1).

In a relatively short time, we were able to produce sufficient excellent quality samples of MCM-41 to characterize these materials by X-ray diffraction, pore size distribution, sorption capacities, and NMR and to evaluate them for catalytic applications. Many researchers at both the Paulsboro and Princeton Laboratories were involved in this effort. In all cases, we were analyzing a new class of materials that presented unique data. For example, the pore size distribution was remarkable; the narrow pore size appeared to be like that of microporous materials but within the mesopore range. As mentioned previously, the hydrocarbon sorption capacity was unique. Benzene sorption isotherms clearly indicated pore condensation inflections at benzene partial

pressures indicative of mesopore size channels. These inflections were typically not observed with microporous materials because of the low partial pressures needed. We were also able to synthesize various pore size materials using both different alkyl chain lengths of the cationic surfactant as well as taking advantage of micellar swelling.<sup>[10]</sup> These techniques improved our knowledge of micelles and liquid crystal chemistry improved. Both this knowledge base and the resultant samples helped to establish the basis for the mechanism of formation of these materials.

In retrospect, the synthesis conditions that we were using to try and obtain our layered zeolite hybrids, high pH, high surfactant concentration, and a reactive silica source, were synthesis conditions conducive to the formation of the mesoporous molecular sieves. The discovery and identification of other members of this new class of porous materials, MCM-48 and MCM-50, came several months later as a result of a detailed study relating the effect of surfactant concentration on the silica reagent (Fig. 2). The discovery of these additional two members of the mesoporous molecular sieve family was another key factor in developing the proposed mechanism of formation.

The discovery of this new class of materials, mesoporous molecular sieves, posed several challenges for our understanding of the formation of porous materials. Our first conclusion, based on both the hexagonal ordering of the pores, as seen in TEM analyses, and the XRD pattern, was that we had discovered one of the crystalline phases predicted by Smith and Dydrich,<sup>[11]</sup> known as the 81(n) family of frameworks. The theoretical XRD pattern of this family almost matched that of some of our best samples of MCM-41. It was not until we obtained the silica NMR data that we determined that our material was not typical of crystalline frameworks that we had expected. The realization that XRD patterns could be generated by the order of the

**Fig. 2** The M41S family of materials including MCM-41, MCM-48, and MCM-50.

**Fig. 3** The role of quaternary directing agents. *Source:* From Refs.<sup>[1]</sup> and <sup>[4]</sup>.

pores and not the crystalline structure was another key feature of this new class of porous materials.

The mechanism of formation was also a challenge, which led to many long debates within our research group. We initially approached the concept of formation of these materials like traditional zeolite chemists. Our first premise was that the materials were formed by some sort of templating structure or pore filling agent. This meant, in the case of the mesoporous molecular sieves, that the templating agent was an aggregation of molecules and not the discrete molecules that normally template microporous structures (Fig. 3). Based on our limited knowledge of liquid crystal structures and micelles, we initially concluded that the liquid crystal structure existed prior to the formation of the molecular sieve. In the case of the MCM-41, this would be the hexagonal liquid crystal phase.

However, this simple mechanistic pathway was not universally accepted within our group of researchers.

Alternatively, it was proposed that the silicate reagent also affected the formation of these materials. And it was this proposed route that gathered more popularity as more data were obtained. A significant set of data appeared to help establish the preferred mechanistic route. This was a group of experiments that studied the effect of various levels of surfactant (SUR) as a function of silica. By changing the SUR/Si molar ratio we were able to synthesize MCM-41, -48, and -50 while keeping all of the other synthesis conditions the same.<sup>[12,13]</sup> These conditions would then exclude the possibility of any preformed liquid crystalline phase prior to the formation of the silicon phase, as we used the same surfactant solution and concentration for all experiments, only changing the amount of silica added. These data supported the concept that the anion, in this case, the silicate species, significantly affected the formation of the resultant template of the mesoporous molecular sieves (Fig. 4). These data were some of the

**Possible mechanistic pathways for the formation of MCM-41**  
1- liquid crystal phase initiated and 2 - silicate anion initiated.

**Fig. 4** The proposed mechanism of formation pathways. *Source:* From Ref.<sup>[1]</sup>.

evidence that led us to propose the possible mechanisms of formation that we published in our initial entries.<sup>[1,4]</sup>

In retrospect, both proposed pathways proved to be valid. The predominate pathway appears to be the anionic species initiated one (using cationic surfactants). This concept was explained and expanded upon by many researchers, specifically by the group at the University of Santa Barbara headed by Galen Stucky.<sup>[14,15]</sup> A Michigan State University group, headed by Tom Pinnavaia, expanded this mechanistic pathway further to include neutrally charged directing agents such as polymers.<sup>[16,17]</sup> Later, researchers at the University of South Hampton demonstrated the other proposed pathway, originally labeled the liquid crystal phase initiated pathway.<sup>[18,19]</sup> Attard and his co-researchers used a preformed liquid crystal phase to synthesize both a silica and a metal (platinum alloy) mesoporous molecular sieve.

### M41S SYNTHESIS DEVELOPMENT

When contrasted with the development of many high silica zeolites, MCM-41 posed several synthetic challenges that were immediately evident after its discovery. The first of these was the need to remove an inordinately large amount of surfactant that remained occluded in the pores of this mesoporous molecular sieve. Compared to a typical 5 to 8 wt.% organic component in most high silica zeolites, MCM-41 contained as much as 50 wt.% organic. Organic structure directing agents (SDA) are typically removed from zeolites by careful calcination or ion exchange. Calcination is normally preferred because of the ease with which the gaseous effluent can be handled. Ion exchange is normally more difficult either because of the ionic selectivity of the zeolite for the SDA or because the SDA may literally be locked inside of the zeolite by virtue of being situated at pore intersections or in the super cages. While the bulky hexadecyltrimethylammonium cation in MCM-41 was more amenable to ion exchange than the SDA in most unidimensional pore zeolites, the pH of the exchange step had to be carefully monitored. In the absence of CTMA the material was extremely sensitive to alkaline conditions. The ion exchange route was also attractive because it allowed us to recover the majority of the expensive surfactant. The surfactant recovered from the ion exchange step could be easily combined with that recovered from the residual mother liquor. In the initial synthesis preparations, a significant amount of the surfactant remained in the mother liquor. It was clear that organic recovery and subsequent recycle use would substantially reduce the manufacturing cost. Several routes for recovering the

surfactant from the as-synthesized MCM-41 were evaluated.

A second challenge was the need to develop an agreed upon protocol for determining MCM-41 product quality both during the synthesis and immediately following drying and post-processing. While MCM-41 is a highly ordered structure, its walls are amorphous. We found that the surface area, hydroxyl content, wall thickness, and even the pore diameter were highly dependent on synthesis conditions. Whereas X-ray powder diffraction can be used to very quickly quantify the crystallinity of zeolites, this was not the case in MCM-41 or any of the M41S materials. The pH of the synthesis liquor for zeolites can also be followed as a rough indicator of the crystallinity of these structured materials. However, this protocol was not useful for determining the precise degree to which a fully formed MCM-41 material is obtained. It remained for the final product to be treated to remove the surfactant before a good assessment of MCM-41 product quality could be made through adsorption capacity and low-angle X-ray peak location.

A third challenge was to change the silica reagents from expensive tetramethylammonium silicate (TMA-Si) and tetraethylorthosilicate (TEOS) to more reasonably priced sources. While cost was an important consideration, the availability, handling, and disposal issues associated with TEOS were most compelling. Identification of alternate reagents brought about a whole new series of problems associated with material and phase purity and the impacts on subsequent catalytic performance.

Fundamental studies of the mechanism of MCM-41S formation provided insight into a convenient laboratory synthesis route.<sup>[20]</sup> Our studies showed that high quality MCM-41 with consistently uniform 4.0-nm pores could be produced in the laboratory under very reasonable conditions. X-ray analyses showed that the preferred synthesis conditions produced materials exhibiting four peaks with positions corresponding to hexagonal symmetry. Subsequent analysis confirmed that the MCM-41 had high BET surface area, a large pore capacity, and very narrow pore size distribution as discerned by its nitrogen adsorption/desorption isotherm.

While much of the development was based upon our previous experience with the commercialization of high silica zeolites, one major difference was the apparent ease with which MCM-41 could be formed. Our initial studies showed that the M41S family of materials could be formed at much milder conditions than zeolites. In fact, it was quickly found that pure material could be formed even at ambient conditions and in relatively short duration (i.e., 6 to 12 hr) syntheses. However, the ease of making this material was deceptive, because the stability of MCM-41 varied

significantly with synthesis conditions. Usually, the stability increased with synthesis time and temperature.

Surprisingly, our analysis of fully dried “retained” samples that were placed in storage for several weeks with the occluded surfactant still present showed that the material became amorphous with time. This reversal produced a series of concerns regarding the stability of the material to storage even under mild conditions. Later studies showed that the synthesis conditions and the prompt removal of the surfactant were critical to improving the stability of mesoporous M41S. The studies also suggested that calcination was preferred to ion exchange for applications where hydrothermal stability was important.

Synthesis efforts within Mobil in the early and mid-1990s focused in two objectives: 1) identify and develop to a modest scale commercially attractive routes for producing MCM-41 materials with a range of pore diameters and acidity; and 2) broaden the compositional range and synthesis approaches to produce additional exploratory materials. The progress was closely linked to parallel catalytic evaluation studies looking at a range of applications (vide infra). Exploratory materials syntheses first focused on the production of both aluminosilicate and metalloaluminophosphate M41S materials including silicoaluminophosphate. Almost simultaneously, studies were initiated around the incorporation of metals either during the synthesis or post-synthesis. Later, in recognizing that these mesoporous materials were slightly less acidic than zeolites, we carried out studies aimed at incorporating acidity by post-treatment techniques such as impregnating MCM-41 with heteropoly acids.

We recognized very early on that these materials had uncharacteristically large surface silanol concentrations. NMR studies showed that nearly 40% of the silicon atoms located on the surface of the walls could be associated with hydroxyls. The silanols can be functionalized to modify M41S pore size and the hydrophobicity as well as serve as anchoring sites for attachment of selective groups for separation applications. The availability of large quantities of silanol groups led to a series of functionalization studies. The work provided the foundation for the synthesis of phase transfer catalysts built around M41S as well as the underlying concepts needed for anchoring the aforementioned heteropoly acid catalysts.

## FUNCTIONAL PRODUCT DEVELOPMENT CHALLENGES

The functional form of molecular-sieve-based catalysts and adsorbents is a tablet, pellet, or extrudate where the active material is incorporated as a component with materials such as binders, weighting agents, or

other active materials. Among the challenges addressed during development was the potential for collapse of the mesoporous structure under the pressures implicit in the forming steps. As crystalline structures, zeolites have the rigidity needed to withstand inordinately high point pressures. However, M41S materials with amorphous walls surrounding large amounts of occluded surfactant had to be viewed differently.

Binding of M41S materials where the surfactant had been removed prior to forming proved to be even more challenging. Not only was the collapse of the pores a more significant concern, but intrusion and pore blockage from some of the gel-type binder systems became an important consideration. Solubilization of the binder system and loss of physical integrity during ion exchange of uncalcined particles also had to be addressed. While calcination remained an attractive process option for removing the hexadecyltrimethylammonium structure directing agent post-forming, the burden on the gaseous effluent abatement systems proved a considerable obstacle.

Most commercial applications of molecular sieves are developed around volumetric constraints, where the challenge is to load as much of the active material as possible into a given volume. This drives product development programs toward formed products with higher levels of the active component and lower levels of binder or weighting components with the limits being set by physical (e.g., crush) strength. The framework density of M41S is approximately 70% of typical zeolites. This translates directly into a lower particle density. Thus, balancing the fraction of M41S in the formed particle with the fraction and type of binder and weighting agent in the finished particle became a key consideration in maximizing the amount of M41S in the process vessel.

## APPLICATIONS OF MCM-41

Because evaluations of larger pore exfoliated pillared layered materials were already under way at the time of its discovery, MCM-41 was able to be quickly screened for a number of applications of interest to Mobil. Not surprisingly, most of these focused on petroleum refining, polymer, and petrochemical manufacture applications. Later, applications outside of the core petroleum and petrochemical businesses were identified. Much of this story can be traced through the ExxonMobil patent literature.

Because the initial commercial application of MCM-41 remains undisclosed by ExxonMobil, and very few results from the applications directed research have been published, we will focus on information provided in issued US patents as well as on similar studies published in the open literature. That the first

commercial application of such a scientifically exciting new material required nearly a decade is an interesting story in itself. The protracted development resulted not nearly as much from the technical hurdles implicit in the identification of a commercially attractive route for synthesis, forming, and activation of MCM-41, as it did from the difficulty in identifying a commercial application with the technical incentives, inherent risk profile, and economics required to justify the introduction of such a unique new material.

In the following, MCM-41 is discussed in terms of its attributes as: 1) a refining catalyst or catalyst component; 2) a petrochemical catalyst or catalyst component; and 3) an adsorbent or material otherwise used for separation. Additional applications such as sensors, optical guides, and fuel cell electrodes are also highlighted. Unless otherwise indicated, the MCM-41 materials used in these studies had diameters of approximately 4.0 nm. However, this does not connote that the same material was used throughout. Composition (e.g., aluminum content) varied considerably depending upon targeted application and synthesis conditions. This review of applications examined by ExxonMobil is not intended to be exhaustive. Comprehensive surveys of potential applications of mesoporous materials, including MCM-41, have been published by On, Desplantes-Giscard, and Danumah<sup>[21]</sup> and Zhao, Lu, and Miller.<sup>[22]</sup>

## CATALYTIC APPLICATIONS OF MCM-41

### Refining and Polymerization Catalysis

Kresge et al.<sup>[23–25]</sup> describe a broad range of hydrocarbon conversion processes over MCM-41 including aromatic dealkylation, cracking, and hydrocracking. Their work established the catalytic activity of MCM-41 and its ability to perform both as a solid acid catalyst and as a catalyst support for hydrocarbon conversions in general. No performance comparisons were made with other solid acid catalysts.

### Catalytic Cracking

Catalytic cracking is the most widely deployed catalytic petroleum refining process. Nearly 35 wt.% of all gasoline is produced by cracking of gas oils and atmospheric resid over large pore ultrastable Y (USY) zeolite catalysts. The products include both fuel and petrochemical feedstocks. For many years, researchers have looked for larger pore alternatives to USY or to large pore materials to supplement the effectiveness of USY in fluidized catalytic cracking (FCC) particularly for processing heavy hydrocarbons. Aufdembrink et al.<sup>[26]</sup>

examined MCM-41 alone and in combination with USY for catalytic cracking vacuum gas oils and atmospheric resids. The catalysts were mildly steamed to simulate equilibrated FCC regeneration conditions. Their performance comparisons showed that equilibrated MCM-41 was superior to amorphous silica–alumina both in its cracking activity and in its propensity for producing larger amounts of gasoline at equivalent coke yield. Comparisons at equivalent conversions to gasoline, distillate, and light gases, showed that MCM-41 was more selective for heavy oil conversion, again producing more gasoline than the amorphous silica–alumina. This is shown in Table 1.

However, in a similar gas oil cracking comparison, MCM-41 was not nearly as active or as gasoline selective as USY, although it was more selective in converting the heavier fractions in fully formulated catalysts. This comparison is shown in Table 2.

Similar investigations by Corma et al.<sup>[27]</sup> suggested that fresh MCM-41 had unique cracking selectivities, producing significantly higher amounts of gasoline and less coke than USY, but that the selectivity disappeared once the material was steamed under simulated FCC regeneration conditions. Corma et al.<sup>[28]</sup> concluded that MCM-41 partially collapsed when steamed to produce a material resembling silica–alumina. The corollary was that MCM-41 lacked the hydrothermal stability needed for it to be useful as an FCC catalyst component.

Nickel and vanadium are present in small concentrations especially in heavier hydrocarbon feedstocks where they tend to degrade typical FCC catalyst performance as they accumulate on the catalyst. In a recent study, Balko, Chester, and Quinones<sup>[29]</sup> found that MCM-41 could be used as an FCC catalyst component to very effectively trap and concentrate the metals so that they are much less deleterious to FCC catalyst performance. MCM-41, when used at low levels (5 to 30 wt.%) in conjunction with the USY zeolite, acted as a metals “getter” and protected the cracking function by effectively passivating the metals. MCM-41 could be added as a component in the cracking catalyst particle or could be added as a separate particle.

### Oligomerization Catalysts

Pelrine et al.<sup>[30,31]</sup> evaluated a chromium-impregnated MCM-41 as an oligomerization catalyst for the production of high viscosity synthetic lubricants. Evaluations were carried out in a fixed bed reactor using 1-decene and reaction temperatures ranging from 120°C to 182°C at LHSV = 1.9 to 2.0 hr<sup>-1</sup>. The analysis showed that MCM-41 could produce a significantly higher viscosity product than, for example, a commercial Cr/SiO<sub>2</sub> polymerization catalyst under the same

reaction conditions. The same reaction catalyzed by chromium acetate-impregnated and calcined MCM-41 was used to demonstrate the concept and utility of functionalized MCM-41.<sup>[32]</sup> Bhore et al.<sup>[33]</sup> extended the oligomerization concept to Ni/MCM-41 catalysts for dimerization of lower molecular

weight olefins. The principal application was for C<sub>3</sub> to C<sub>10</sub> olefin dimerization primarily to produce gasoline. In their study the performance of Ni/MCM-41 catalysts compared favorably to Ni-based Dimersol® catalysts.

**Table 2** Comparison of 35% MCM-41 and 35% USY catalysts<sup>a</sup> in catalytic cracking of Joliet sour heavy gas oil (516°C, fixed-fluidized bed reactor; 1 min on stream, catalyst/oil = 2 to 6)

Le, Thompson, and Yokomizo<sup>[34]</sup> used MCM-41 to selectively react the C<sub>3</sub>–C<sub>5</sub> olefins in a mixed stream of lower molecular weight (MW) olefins and paraffins with the intent of producing a heavier oligomer stream that could be readily separated from the lower MW paraffin-enriched stream. Reaction conditions used in the study were 120°C, 10.3 MPa, and LHSV = 1.8 hr<sup>-1</sup>. The resulting oligomers were highly branched and could be converted to tertiary olefins suitable for a number of applications via subsequent selective disproportionation or cracking over, for example, a zeolitic catalyst. Specific applications are for the production of tertiary C<sub>4</sub> and C<sub>5</sub> olefins for subsequent paraffin-olefin alkylation or oxygenate production.<sup>[35]</sup>

Bhore et al.<sup>[36]</sup> investigated metals-free MCM-41 for the oligomerization of olefins for the production of higher molecular weight products as, for example, fuels, lubricants, fuel additives, and detergents. For acid-catalyzed propylene oligomerization, they found MCM-41 particularly selective for trimer and tetramer synthesis, materials that are well suited for clean gasoline. Reaction temperatures ranged from 40°C to 250°C and pressures ranged from 0.1 to 13 MPa.

## Hydrocracking

MCM-41 alone, or in combination with zeolites such as USY, has been examined as the active component in vacuum gas oil and lube hydrocracking catalysts. Degnan et al.<sup>[37–39]</sup> examined the performance of NiW-impregnated USY/MCM-41/Al<sub>2</sub>O<sub>3</sub> catalysts and found them to be superior in activity and comparable in selectivity to several commercial distillate selective hydrocracking catalysts. The work was further extended to hydrocracking heavier feedstocks to produce lubricants.<sup>[40–42]</sup> Fig. 5 compares the hydrocracking activity of NiW/MCM-41 and a conventional NiW/fluorided alumina lube hydrocracking catalyst

for conversion of heavy slack wax at 13.7 MPa, 1 LHSV. The comparison, at equivalent conditions of 13.8 MPa, LHSV = 1 hr<sup>-1</sup>, shows that MCM-41 is more active for conversion of this heavy hydrocarbon feed.

Work by Apelian et al.<sup>[40]</sup> and Marler and Mazzone<sup>[41–42]</sup> also showed that MCM-41 could be combined with a strong hydrogenation function to subsequently hydroisomerize the heavy hydrocrackate to produce high-quality, low pour point lubricants. In a similar study, Corma et al.<sup>[43]</sup> compared the mild hydrocracking performance of NiMo (12 wt.% MoO<sub>3</sub>, 3 wt.% NiO) supported on MCM-41 with that of amorphous silica-alumina and USY zeolite catalysts with the same Ni and Mo loadings. The feedstock was vacuum gas oil. The MCM-41 catalyst was superior to the other catalysts in hydrodesulfurization, hydrodenitrogenation, and hydrocracking activities in single-stage hydrocracking. When a hydrotreating stage was used in front of the hydrocracking stage, the USY catalyst became more active than the MCM-41 catalyst, but MCM-41 was still significantly more active than the amorphous silica-alumina catalyst. Most importantly, the MCM-41 catalyst distillate selectivity was better than that of USY and was very similar to the silica-alumina catalyst. A number of other studies have also pointed to MCM-41 as a superior distillate selective hydrocracking catalyst.<sup>[44–45]</sup>

## Hydrodemetallation

Vanadium, nickel, iron, and other trace metals pose problems in processing heavy oils because they foul catalysts and cause undesirable side reactions. Kresge et al.<sup>[46]</sup> showed that MCM-41 (*d*-spacing > 1.8 nm) was very active for removing trace metals from petroleum residua and shale oils. Nickel- or molybdenum-impregnated MCM-41 extrudates (MCM-

**Fig. 5** Comparison of the hydrocracking activities of NiW/MCM-41 and NiW/fluorided alumina demonstrating the superior cracking activity of the MCM-41 catalyst. Source: From Ref.<sup>[40]</sup>.

Fig. 6 Hydrodemetallation activity comparison—effect of MCM-41 pore diameter. (From Ref.<sup>[47]</sup>.)

41/Al<sub>2</sub>O<sub>3</sub>) were found to be particularly selective for the removal of iron, vanadium, nickel, and even arsenic. Shih also found that staging MCM-41 materials of different pore sizes, with the largest pore size material positioned first to see the oil, was a particularly effective strategy for hydrodemetallation.<sup>[47]</sup> Fig. 6, taken from Shih's patent, shows the effect of MCM-41 pore diameter on metals uptake effectiveness using hydrodesulfurization (HDS) activity as a basis for comparison. As metals accumulate on the catalyst they tend to poison HDS activity. The comparison shows that MCM-41 with 8.0-nm pores has a greater metals capacity than smaller pore MCM-41.

## Hydrogenation

Given its large surface area (>600 m<sup>2</sup>/g) and its large concentration of silanol groups that are easily functionalized or ion exchanged, MCM-41 is an obvious choice as a support material for metals in both precious and base metal hydrogenation catalysts. Evaluations by Baker et al.<sup>[48]</sup> and Degnan et al.<sup>[49]</sup> showed that MCM-41 was more active than other conventional supports for long-chain olefin and heavy aromatic hydrogenation. The specific applications cited are for polyalphaolefin (PAO) saturation for synthetic lube hydrofinishing and for alkylaromatics hydrogenation for color and viscosity index (VI) improvement. Similarly, Borghard et al.<sup>[50]</sup> demonstrated that metal impregnated MCM-41 is a very active catalyst for the saturation of highly aromatic feedstocks under relatively mild hydrogenation conditions. Hydrotreating highly aromatic cracked distillate stocks with NiMo- or CoMo/MCM-41 or other strong hydrogenation metals supported on MCM-41 to produce low

aromatic distillates, e.g., for high-quality diesel fuels, is described by Apelian, Degnan, and Shi<sup>[51]</sup>

Similarly, Corma, Martinez, and Martinez-Soria<sup>[52]</sup> found that MCM-41 provided an excellent medium for dispersion of Pt particles, and that the Pt/MCM-41 catalysts were superior in overall hydrogenation activity for naphthalene saturation when compared to Pt supported on amorphous silica-alumina, zeolite USY,  $\gamma$ -alumina, and silica. These investigators demonstrated that sulfur tolerance was a strong function of molecular sieve aluminum content. Pt supported on USY and Al-rich MCM-41 was superior in sulfur tolerance to Pt located on the other supports. They were able to confirm the sulfur tolerance in the hydrogenation of a mildly hydrotreated light cycle oil (LCO) containing approximately 70 wt.% aromatics and 400 ppm sulfur.

## Hydroisomerization

When combined with a strong hydrogenation function (e.g., Pt or Pd) MCM-41 is an effective long-chain paraffin isomerization catalyst once trace nitrogen and sulfur compounds are removed. This is shown in the aforementioned hydroprocessing patents<sup>[42,48]</sup> where Marler and Mazone demonstrated that MCM-41 could be used to improve the viscometric properties of hydroprocessed or synthetic lubricating oils. Del-Rossi, Hatzikos, and Huss<sup>[53]</sup> extended the hydroisomerization studies to lower molecular weight hydrocarbon feeds and found that noble metal MCM-41 catalysts are both active and selective for isomerization of C<sub>4</sub> to C<sub>8</sub> paraffins. Similar results were obtained by Chaudhari et al.<sup>[54]</sup> in their analysis of noble-metal-impregnated MCM-41 for *n*-hexane isomerization.

### Olefin Disproportionation

Higher molecular weight olefins can be converted to lower, more highly branched and often more valuable lower molecular weight olefins through disproportionation. The process is not used widely but has the potential for providing incremental lower molecular olefins as a feedstock for paraffin–olefin alkylation for fuels or for petrochemical applications. Le and Thompson<sup>[55,56]</sup> determined that MCM-41 was an attractive cracking catalyst for the conversion of light olefinic gasoline to propylene and isobutylene.

### Light Olefin-Paraffin Alkylation

MCM-41 is an attractive support for either Lewis or Bronsted acids used in the alkylation of C<sub>4</sub> to C<sub>12</sub> isoparaffins with <C<sub>10</sub> olefins.<sup>[57,58]</sup> The principal application of low molecular weight isoparaffin–olefin alkylation is for the production of high-octane C<sub>5</sub> to C<sub>12</sub> isoparaffins for gasoline. These studies highlighted the ability of MCM-41 to concentrate the acid and increase its effectiveness by nearly an order of magnitude over the free acid as measured by the amount of alkylate produced at the same volumetric acid to oil ratio. Typical reaction conditions for both Bronsted (H<sub>2</sub>SO<sub>4</sub>) and Lewis (BF<sub>3</sub>) acid/MCM-41 catalyzed paraffin–olefin alkylation were –20°C to 200°C, 0.7 to 1.4 MPa, and an isobutane/2-butene molar ratio of 10:1. The reactions were carried out in batch reactors for a preset duration.

Kresge et al.<sup>[59]</sup> and DelRossi et al.<sup>[60]</sup> found that the performance of MCM-41 for this application could be improved if the activity of MCM-41 could be increased through the addition of heteropoly acids via, for example, impregnation with phosphotungstic acid, H<sub>3</sub>PW<sub>12</sub>O<sub>40</sub>. In batch experiments with 50:1 isobutane/2-butene molar ratio, 121°C, 3.4 MPa, incorporation of 50 to 75 wt.% of the heteropoly anion, via impregnation, significantly improved both the catalyst activity and the yield of desirable trimethylpentane (TMP) and dimethylhexane (DMH) isomers. Comparison catalysts prepared by impregnation of equivalent loadings of H<sub>3</sub>PW<sub>12</sub>O<sub>40</sub> onto high surface silica and high surface alumina did not produce nearly equivalent activities or TMP and DMH yields. This comparison is shown in Table 3.

## PETROCHEMICAL CATALYSIS

### Aromatics Alkylation

MCM-41 is an effective catalyst for olefin alkylation of single-ring aromatics under milder conditions than are used in, for example, ZSM-5. Le<sup>[61]</sup> evaluated MCM-41 combined with an alumina binder for the production of ethylbenzene via benzene alkylation and found that the same ethylene conversion could be achieved at a reaction temperature that was 40°C lower than with ZSM-5. Polyalkylated benzene yields were higher, but MCM-41 produced no undesirable xylenes. Conditions

were 2.1–3.4 MPa and a benzene/ethylene (molar ratio = 10:1).

Le<sup>[62]</sup> also identified MCM-41 as an attractive catalyst for single- and multiring aromatic alkylation with higher molecular weight olefins. Higher molecular weight olefins are used to alkylate aromatics to produce linear alkyl benzenes (LABs). Linear alkyl benzenes are the basis for linear alkyl benzene sulfonate (LAS). Linear alkyl benzene sulfonate is used widely as a large component in liquid detergents. Le's work is focused on the alkylation of mono- and polycyclic aromatics for lube additive and detergent applications.

### PHASE TRANSFER CATALYSTS

Hellring and Beck<sup>[63]</sup> found that MCM-41 containing a stabilized onium ion, such as cetyltrimethylammonium (CTMA) cation, could effectively catalyze dual-phase reactions within the MCM-41 pores. To demonstrate the concept, Hellring and Beck reacted water insoluble bromopentane with potassium iodide in an agitated aqueous medium to produce iodopentane. Addition of CTMA-MCM-41 to the stirred dual-phase mixture greatly increased the reaction rate. The results implied that CTMA, which is amphiphilic, is able to concentrate bromopentane and increase its interaction with iodide, which is closely associated with the CTMA cation.

### CATALYTIC DECOMPOSITION OF NITROGEN OXIDES

Vanadium- and titanium-impregnated high surface area alumina or silica is a commercially attractive selective catalytic reduction (SCR) catalyst for NO<sub>x</sub> reduction. Beck et al.<sup>[64]</sup> compared several TiV/MCM-41 samples with conventional metal-oxide-based SCR catalysts and found the MCM-41 materials were comparable in both NO<sub>x</sub> removal selectivity and activity. The ability of the high surface area of MCM-41 to support large amounts of highly dispersed titanium and vanadium was believed to account for the high activity of the MCM-41 catalyst.

### APPLICATION OF MCM-41 TO SEPARATIONS

MCM-41 can be used to separate at least one component from a mixture of gaseous or liquid components as described in the patent of Beck et al.<sup>[65]</sup> The examples provided in this reference relate mainly to separation of higher and lower viscosity components of a mixture. The concept of using MCM-41 alone or as a composite in a membrane or as an active component in chromatographic separation media is described by

Herbst et al.<sup>[66]</sup> Among the contemplated uses are size exclusion applications such as the bioseparation of endotoxins or pyrogens. In another study, Kuehl<sup>[67]</sup> examined MCM-41 as a selective sorbate for the removal of large molecules such as polynuclear aromatics (PNAs) from fluids and gases. The applications range from wastewater and catalyst regeneration gas cleanup to the reduction of PNAs in hydrocarbon fuels.

### OTHER APPLICATIONS

A wide array of other MCM-41 applications have been investigated, each based on the unique composition, uniform pore size, and extraordinarily high surface area of the M41S family of materials. While the reviews by On et al.<sup>[21]</sup> and Zhao et al.<sup>[22]</sup> have described many of these, we want to highlight three applications to illustrate the breadth of potential applications outside the realm of catalysts and adsorbents. The first relates to the use of MCM-41 and M41S materials as key components in microoptical and microelectronic applications. Beck et al.<sup>[68]</sup> determined that M41S materials, when processed to include quantum clusters of semiconducting inorganic or organic compounds, have unique nonlinear optical properties useful as frequency mixers, frequency doublers, and parametric amplifiers. Extended uses are for beam steering, optical switching, and image processing.

In the second application, MCM-41 is used as a central component in a sensor device.<sup>[69]</sup> Electrical, optical, or gravimetric systems designed around MCM-41 detect, for example, the presence of specific gases, changes in pH, or the presence of metal ions. The examples describe a range of biological, chemical, and physical sensor applications including the selective detection of benzene, ammonia, nickel, formaldehyde, and carbon monoxide.

Finally, Ozin et al.<sup>[70]</sup> describe the use of M41S (nickel/platinum)-yttria-zirconia M41S materials as thermally stable electrode materials in solid oxide fuel cells. The mesoporous materials, which are synthesized in aqueous media using glycometallates and metal complexes, have the highest known surface area of any form of (metal)-yttria-stabilized zirconia and thus improve the efficiency of solid oxide fuel cells.

### CONCLUSION

For many new materials, traversing the path from discovery to commercial application can take as long as a decade. This was certainly true for MCM-41, the most widely studied representative of a new class of materials known as the M41S family. Commercialization of

MCM-41 required approximately 10 years as issues surrounding scale-up of the synthesis, raw materials selection, and post-processing had to be addressed. However, the major challenge was associated with identification of an application where the performance advantages justified the risks and costs associated with the targeted commercialization. Initial commercializations of truly new materials are, by their very nature, expensive and associated with a large degree of uncertainty. The initial application bears all of the developmental costs which normally represents a significant hurdle in the development of any truly "step out" material.

Now that MCM-41 is commercial, we anticipate that several new applications will be pursued. Work on mesoporous materials such as M41S continues in many laboratories around the world as witnessed by the consistent increase in both M41S-related patents and publications since the discovery of MCM-41, the first member of this family, in 1989.

# Metal Clusters on Oxides

Ivan Stensgaard

Department of Physics and Astronomy, University of Aarhus, Aarhus, Denmark

## INTRODUCTION

Metal clusters on oxides play a profound role in modern-day society because such systems are the basic ingredients in catalysts used for environmental protection, refining of fossil fuels, and production of chemicals. In the automotive three-way catalytic converter, for example, chemical reactions take place on nanometer-scale metal particles of Rh, Pt, and/or Pd distributed on an oxide of a high surface area, typically alumina.

Catalysis has thus been the main motivation for research on metal clusters on oxides. The improved ability to control the size and distribution of metal clusters coupled with the development of techniques for better characterization of the structural, electronic and chemical properties of metal clusters on oxides (primarily scanning probe techniques) has spurred an increased research activity in the field. Consequently, a series of interesting new results have been obtained, which have demonstrated how, e.g., the properties of the metal clusters may change in the nanometer-scale regime due to quantum size effects.

Atomic-scale investigations of industrial catalysts are hampered by the complexity of the systems. In this entry emphasis will therefore be on metal clusters on oxides prepared and investigated in laboratory research environments, i.e., under ultrahigh vacuum (UHV) conditions. The advantage of such model systems is that they lend themselves much more readily to investigations based on a large variety of surface science tools. The entry is intended to give the reader an overview of the techniques for synthesis and characterization of model systems, as well as to address important issues that are relevant for metal clusters on oxides in general. For further reading, reference is given to a number of reviews on metals on oxides.<sup>[1–5]</sup>

## SUBSTRATE PREPARATION, GROWTH, AND CLUSTER MORPHOLOGY

Fig. 1 shows an image of a ruthenium catalyst for ammonia synthesis recorded with high-resolution

transmission electron microscopy (HRTEM).<sup>[6]</sup> The Ru metal clusters appear as dark, almost circular regions on a lighter background of  $\text{MgAl}_2\text{O}_4$ . The experimental challenge of investigating (at the atomic level) systems of a structural complexity such as that in Fig. 1 is still so formidable that strong efforts are made to derive information from structurally simpler systems. In the following, focus will be on techniques for creating model systems of metal clusters on oxides.

## Substrate Preparation

Typically, the metal clusters are supported on low-index surfaces of crystalline metal or semiconductor oxides, such as MgO,  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$ ,  $\text{Fe}_2\text{O}_3$ , ZnO, and  $\text{SiO}_2$ . The surface science of metal oxides has been treated in an excellent monograph.<sup>[7]</sup> Unfortunately, the preparation of clean and well-ordered oxide surfaces on a bulk specimen still remains an experimental challenge.<sup>[1]</sup> The standard procedures for creating clean, well-ordered *metal* surfaces include polishing and etching, followed by ion sputtering to remove impurities and annealing to reestablish the crystal order. Such procedures, when applied to oxides, will, in many cases, lead to poor order or loss of stoichiometry due to preferential sputtering and/or thermally induced segregation.

As an alternative, in situ cleavage of bulk oxide specimens under UHV may be considered. However, materials such as  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , and  $\text{TiO}_2$  are difficult to cleave successfully in the sense that the cleavage plane will not coincide with an extended low-index plane, and that the surface may locally be very rough. Successfully cleaved surfaces can be used for one-shot experiments. To remove deposited metal, sputtering/annealing cycles are necessary.

Being large band gap materials the oxides are strongly insulating, adding to the difficulty and a severe drawback because when working with oxide surfaces most experimental techniques involve electron transfer, leading to charging effects. The charging problem has spurred the development of alternative schemes, where the oxide is made conductive by the introduction of point defects, or the oxide is grown

**Fig. 1** High-resolution TEM micrograph of a ruthenium catalyst for ammonia synthesis. The almost circular dark regions are Ru metal clusters. The oxide is  $\text{MgAl}_2\text{O}_4$ . Source: From Fig. 3 of Ref.<sup>[6]</sup>, with permission of Kluwer Academic Publishers.

in the form of an ultrathin film on a metallic substrate<sup>[1-4,8,9]</sup> that allows for electric transport through the film, e.g., in the form of a tunneling current.

Examples of the two types of alternative schemes are shown in Fig. 2 in the form of scanning tunneling microscopy (STM) images of a  $\text{TiO}_2$  bulk crystal surface and an  $\text{Al}_2\text{O}_3$  thin film surface. Titanium dioxide is used extensively, not only for heterogeneous catalysts, but in several other technologically important areas such as photocatalysis and sensor technology. Bulk  $\text{TiO}_2$  in its rutile form has a band gap of 3 eV, but thermal reduction under vacuum leads to oxygen

**Fig. 2** STM images of oxides. (A) A clean  $\text{TiO}_2$  (110) surface ( $13 \times 13 \text{ nm}^2$ ). The bright lines are rows of Ti atoms. The bright dots imaged between the Ti rows (see circle) are vacancies in rows of oxygen atoms which are in bridge positions relative to underlying Ti atoms. The two dark lines are antiphase domain boundaries relieving strain due to a mismatch between the film and the substrate ( $20 \times 20 \text{ nm}^2$ ).

deficiencies which create a shallow donor level in the gap, giving rise to a sufficiently increased conductivity for performing experiments such as STM on the surface.<sup>[7,8]</sup> The (110) surface of  $\text{TiO}_2$  in its rutile form shown in Fig. 2A is the most intensively studied  $\text{TiO}_2$  surface and it has become a prototype of a metal oxide.<sup>[10]</sup> Aluminum oxide (alumina),  $\text{Al}_2\text{O}_3$ , is extremely important in both ceramics and catalysis. A band gap of 8–9 eV makes  $\text{Al}_2\text{O}_3$  an excellent insulator, and  $\text{Al}_2\text{O}_3$  surfaces are not easily accessible for surface science experiments. Fortunately, thin alumina films can easily be prepared.<sup>[8,9]</sup> Oxidation at elevated temperatures, for example, of a (110) NiAl alloy single crystal surface results in the formation of an alumina film.<sup>[3,11]</sup> The ensuing film depicted in Fig. 2B has a thickness of only  $\approx 0.5 \text{ nm}$ , less than the thickness of a unit cell of  $\gamma\text{-Al}_2\text{O}_3$  or  $\alpha\text{-Al}_2\text{O}_3$ , but nevertheless sufficiently thick to have most of the properties of  $\gamma\text{-Al}_2\text{O}_3$ .<sup>[3]</sup> And importantly, electron transport through the film is easily achieved, facilitating, e.g., STM investigations.

## Metal Deposition

The standard technique for metal deposition on extended oxide surfaces is vapor deposition, where a metal in close proximity to the oxide is heated to a temperature at which the metal has a suitable vapor pressure. Metal atoms will then impinge on the oxide surface at thermal energy. At room temperature (RT), the reevaporation probability for metal atoms is generally very low, i.e., the sticking probability is close to unity.

After landing, the metal adatoms may diffuse on the surface with a diffusion constant  $D$  determined by

$$D = (\nu a^2/4) \exp(-E_d/kT) \quad (1)$$

for 2-D diffusion. Here  $\nu$  is a frequency factor of the order of  $10^{13} \text{ Hz}$ ,  $a$  is the distance between neighboring adsorption sites,  $E_d$  is the energy barrier for diffusion,  $k$  is the Boltzmann constant, and  $T$  the absolute temperature. Diffusion can therefore be enhanced by an increase in temperature.

In a time interval  $\tau$  the diffusing adatoms will travel a root-mean-square (rms) distance  $l$  given by

$$l = (4D\tau)^{1/2} \quad (2)$$

For sufficient metal coverage the diffusion process leads to nucleation. If the diffusing metal atom attaches itself to a surface defect (such as a step edge), the nucleation is heterogeneous. If, on the other hand, diffusing adatoms meet and form stable nuclei, the nucleation is termed homogeneous. In general, only a

few atoms need to agglomerate to form stable nuclei. The minimum number of other adatoms that a diffusing metal adatom must meet to form a stable nucleus is called the critical cluster (or island) size. Thus if a metal dimer is stable, the critical cluster size is one.

Continued metal evaporation does not lead to an ever-increasing density of clusters. The saturation density  $N$  is determined by parameters such as the rate  $R$  at which atoms impinge on the surface, the temperature  $T$ , the frequency factor  $\nu$  from the diffusion constant  $D$  (Eq. (1)), the diffusion barrier  $E_d$ , and the critical cluster size  $i$ .<sup>[12]</sup> It is important to realize that for a given metal–oxide system, the saturation density of clusters can be controlled by changing the substrate temperature during nucleation and/or the evaporation rate  $R$ .

When the saturation density of clusters has been reached, the clusters will grow by attachment of further adatoms. Although exceptions exist, the growth modes can conveniently be divided into three classes: *Frank van der Merwe* growth in which the metal grows layer-by-layer across the entire surface, *Volmer–Weber* growth in which metal grows as 3-D islands separated by bare oxide, and *Stranski–Krastanow* growth which starts as layer-by-layer growth, but with 3-D islands appearing after a few monolayers. Based on a model in which the cluster is treated as a liquid droplet on the support surface it is possible to have some preconception of the growth mode of a particular metal–oxide system. If  $\gamma_{\text{met}}$  and  $\gamma_{\text{ox}}$  denote the surface energies of the metal and the oxide, respectively, and  $\gamma_{\text{int}}$  the interface energy, the following rule can be established.<sup>[13]</sup>

$$\gamma_{\text{ox}} \geq \gamma_{\text{met}} + \gamma_{\text{int}} : \text{layer-by-layer growth} \quad (3a)$$

$$\gamma_{\text{ox}} < \gamma_{\text{met}} + \gamma_{\text{int}} : \text{3-D cluster growth} \quad (3b)$$

Expressions (3a) and (3b) apply to the thermodynamical equilibrium. It is important to note that film growth is a kinetic process which does not take place at thermodynamic equilibrium (growth is incompatible with equilibrium!). The expressions are therefore applicable only to growth conditions which are close to equilibrium. As the free energies of the mid-to-late transition metals and the noble metals are frequently larger than the free energies of the supporting oxides, 3-D growth rather than layer-by-layer growth is to be expected for such systems. This is, indeed, confirmed by experiments.<sup>[1]</sup> In the following, 3-D cluster growth is assumed.

### Cluster Morphology

The thermodynamic equilibrium shape of a *free* metal cluster can be found from the Wulff theorem<sup>[14]</sup> if the

surface free energies of the low-index surfaces are known. The basis of the theorem is that for a given volume, the equilibrium shape must be determined by minimizing the total surface free energy. The ensuing theorem states that the ratio between the real-space distance  $d_i$  from the cluster center to the facet plane  $i$  and the surface energy  $\gamma_i$  of this facet is a constant:

$$d_i/\gamma_i = c \text{ (constant)} \quad (4)$$

Fig. 3A shows a free cluster with a shape determined by the relative values of the surface energies  $\gamma_{100}$ ,  $\gamma_{110}$ , and  $\gamma_{111}$ . A cross section of the cluster along the (110) plane is shown in Fig. 3B. The relative area of the different facets clearly depends on the relative values of  $\gamma_{100}$ ,  $\gamma_{110}$ , and  $\gamma_{111}$ .

If the metal cluster is formed on an oxide, a metal–oxide interface is created. The free energy of the interface is given by the Dupré equation:

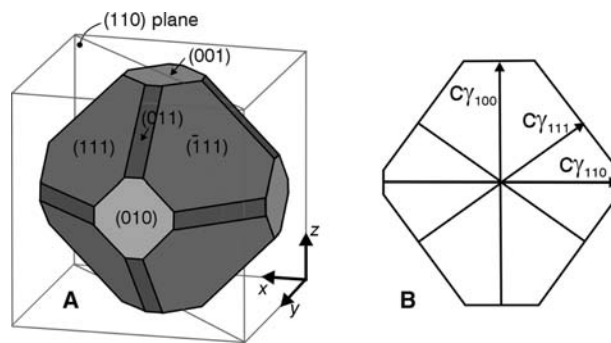

$$\gamma_{\text{int}} = \gamma_{\text{met}} + \gamma_{\text{ox}} - W_{\text{adh}} \quad (5)$$

where  $\gamma_{\text{int}}$  is the interface energy,  $\gamma_{\text{met}}$  and  $\gamma_{\text{ox}}$  the surface free energy of the contact facet of the cluster and the substrate, respectively, and  $W_{\text{adh}}$  the adhesion energy, i.e., the work per unit area needed to separate the cluster and the substrate.

The equilibrium shape of a *supported* cluster can now be found using a modified Wulff construction scheme,<sup>[15]</sup> by replacing the free energy of the surface in contact with the substrate with an effective surface energy  $\gamma^*$ , which is the difference between the interface energy and the surface energy of the oxide:

$$\gamma^* = \gamma_{\text{int}} - \gamma_{\text{ox}} \quad (6)$$

The height  $H$  of the supported cluster, relative to that of a free cluster, thus depends on  $\gamma^*$ . For a cluster residing on a {111} facet (Fig. 4), the cluster will adopt its free-space form on the oxide if  $\gamma^* = \gamma_{111}$ . For smaller

**Fig. 3** The Wulff construction. (A) Cluster displaying three types of facets. (B) Cross section of the cluster along the (110) plane.

**Fig. 4** Cross section of a cluster supported on a {111} facet for a positive (A) and a negative (B) value of the effective surface energy  $\gamma^*$ .  $H$  denotes the height of the cluster.

values of  $\gamma^*$  the cluster gets truncated [Fig. 4A], and for negative values of  $\gamma^*$ , the height of the supported cluster becomes less than half the height of the free cluster, as illustrated in Fig. 4B. An experimental value of the  $\gamma^*$  can be derived from the observed, detailed morphology of the clusters in terms of the cluster surface energies.<sup>[16]</sup> From Eqs. (5) and (6)

$$W_{\text{adh}} = \gamma_{\text{met}} - \gamma^* \quad (7)$$

Again,  $\gamma_{\text{met}}$  denotes the surface free energy of the metal cluster facet in contact with the oxide. The work of adhesion can therefore be derived from experiments, if the surface energies are known.

The Wulff construction is basically a continuum description which does not consider the discrete nature (finite number of atoms) of the clusters, and neglects the formation energy of corner and edge atoms, which play an important role in small clusters. Nevertheless, the theorem has been extremely successful in predicting or rationalizing shapes of metal clusters on oxides.

## TWO CASE STUDIES

A large amount of metal/oxide combinations have been studied and an impressive amount of knowledge has been gained. In the following, focus will be on two different metal/oxide systems which have attracted special attention. The two systems will serve to illustrate fundamental properties, results, considerations, and problems related to research on metal clusters on oxides in general.

### Palladium on $\text{Al}_2\text{O}_3$

Palladium on alumina is an important catalyst for partial or complete oxidation in many catalytic processes. The system has therefore been studied extensively, both in the form of industrial catalysts and as a model system. Most laboratory studies of Pd on alumina have

**Fig. 5** (A) STM image of nanoclusters on  $\text{Al}_2\text{O}_3/\text{NiAl}(110)$ . Note the characteristic hexagonal shape of many clusters. ( $50 \times 50 \text{ nm}^2$ ). (B) Height contours (thin lines) of a single Pd cluster. The thick line indicates the idealized, regular form. ( $15 \times 15 \text{ nm}^2$ ). (C) Ball model of a cluster displaying {100} and {111} facets. (D) Height contours (thin lines) of a Cu cluster, closely resembling a regular hexagon (thick line), ( $9 \times 9 \text{ nm}^2$ ). Source: (B) and (D) are reprinted from Ref.<sup>[17]</sup>, © 2001, with permission from Elsevier.

been carried out on  $\text{Al}_2\text{O}_3$  thin films because of the insulating nature of bulk  $\text{Al}_2\text{O}_3$ . Fig. 5A is an STM image showing the result of Pd evaporation onto a thin  $\text{Al}_2\text{O}_3$  layer formed by oxidation of  $\text{NiAl}(110)$  (cf. Fig. 2B). As expected from surface free energy considerations, Pd grows in the form of 3-D clusters (Volmer–Weber growth). For room temperature, low-coverage deposition of Pd on well-ordered films, the spatial distribution of the clusters is heavily influenced by the intrinsic defect structure of the film with a tendency for the clusters to nucleate at step edges and domain boundaries.

From Fig. 5A it is evident that a large fraction of the clusters are hexagonal in shape. On films with large domains up to 50% of the clusters are hexagonal in shape,<sup>[16]</sup> reflecting the fact that these clusters are crystalline. The remaining clusters have not necessarily adopted their thermodynamical equilibrium form because of incorporated defects, insufficient temperature, etc. Because of the finite size of the STM tip the clusters are imaged as a convolution of the cluster and the tip shapes. This leads to a certain rounding of edges and corners as illustrated in Fig. 5B which displays height contours of a single Pd cluster.<sup>[17]</sup> Based on atomic resolution STM,<sup>[16]</sup> the facets of the cluster can be identified: The top facet is of {111} orientation

while the sides are  $\{111\}$  and  $\{100\}$  facets. For comparison, Fig. 5C shows a ball model of a cluster. As discussed earlier, the general shape of the cluster is governed by the surface and interface energies (modified Wulff construction). The clusters do not display any  $\{110\}$  facet, either because  $\gamma_{110}$  is too large compared to  $\gamma_{100}$  and  $\gamma_{111}$  (cf. Fig. 3B), or because the cluster is too small to develop a genuine  $\{110\}$  facet. Fig. 5D shows the height contours of a Cu cluster formed under similar conditions.<sup>[17]</sup> In this case the shape of the top facet approaches a regular hexagon, illustrating how the surface energies influence the cluster morphology.

The principal objective for dispersing the active metal in a catalyst in the form of nanosized clusters is to increase the surface area. There are, however, several reasons why the dispersion, i.e., the formation of clusters, may influence the reactivity and make it deviate from that of corresponding, extended surfaces. First of all, the number of edge and corner sites will obviously increase dramatically. If such sites are active (see “Gold on  $\text{TiO}_2$ ” section), the dispersion will promote an increase in activity which is easily explained. Secondly, exposure to gases may have different effects on extended surfaces and clusters dispersed on oxides. As an example, exposure of an extended Pd(111) surface to  $\text{O}_2$  is known to result in the formation of a  $(2 \times 2)$  structure, i.e., a structure with a unit cell four times bigger than the substrate unit cell. Exposure of a clean Pd nanocrystal [Fig. 6A] to  $\text{O}_2$  has the same effect in the central portion of the top  $\{111\}$  facet, but an entirely new structure develops along the facet edge, as shown in Fig. 6B.<sup>[18]</sup> It is beyond the scope of this entry to discuss this phenomenon in detail; suffice it to state that the adsorption of gases on nanoclusters may cause reconstructions along facet edges, thereby creating new, possibly catalytically active sites. For very small clusters, the presence of gas may therefore influence the structure of the entire cluster.

The previous example is related to adsorption under static conditions, i.e., at a fixed temperature and in an

unchanging atmosphere of (low pressure) oxygen. What happens to the cluster morphology when the cluster is exposed to gases at a higher pressure and temperature, i.e., under industrial catalytic conditions? An answer was recently found based on an in situ investigation.<sup>[19]</sup> Model catalysts of Cu nanoparticles on ZnO (equivalent to the industrial methanol synthesis catalyst) were imaged with TEM in a high-pressure cell. The Cu nanocrystals were found to undergo dynamic, reversible shape changes in response to changes in the gaseous environment. The changes were found to be caused by adsorbate-induced changes in the surface energies and by changes in the interface energy. To describe and understand the catalytic properties of nanoscale clusters, *dynamic* effects on the nanocrystal morphology must therefore be included.

Dispersion may lead to effects of an even more subtle origin. Consider, for example, the sensitivity to changes in the lattice parameter. Because of the increased importance of the surface stress for smaller clusters, the lattice parameter is expected to decrease for decreasing cluster size.<sup>[20]</sup> Fig. 7 shows an experimental verification obtained for Pd on  $\text{Al}_2\text{O}_3$  on the basis of TEM measurements.<sup>[21]</sup> The smallest clusters (size  $\approx 1.5$  nm) show a 4–5% reduction in lattice parameter. A smaller lattice parameter results in a broadening of the d-band. Compared to the effect of bringing atoms together to form a solid: The atomic levels broaden and become energy bands. The closer the atoms the stronger the broadening. For transition metals with d-bands that are more than half-filled, such as Pd, the broadening results in a downward shift of the d-band center to maintain the degree of filling. According to the d-band model, a shift in the d-band center relative to the Fermi energy will be correlated with a change in binding energy.<sup>[22]</sup> Hence a change in the lattice parameter will influence the reactive properties of the cluster. An indisputable experimental

**Fig. 6** Two atomically resolved STM images ( $2.5 \times 2.5 \text{ nm}^2$ ) of a Pd cluster before (A) and after (B) exposure to  $\text{O}_2$ . The  $(2 \times 2)$  oxygen adlayer in (B) is not imaged by STM, but a severe reordering of the facet edge has taken place.

**Fig. 7** Atomic spacing in Pd clusters on  $\gamma\text{-Al}_2\text{O}_3/\text{NiAl}(110)$  as a function of cluster size. Horizontal bars illustrate the difference in length and width of the clusters whereas the vertical bars are estimated errors. *Source:* From Ref.<sup>[21]</sup>. © 1999, American Chemical Society.

verification of this effect on clusters is still lacking, but changes in the reactivity of a metallic surface induced by a change in lattice parameter has been reported for a (0001)-oriented Ru sample in an area where an edge dislocation intersects the surface.<sup>[23]</sup> On one side of the dislocation the lattice is compressed, and on the other side it is stretched. When analyzing the results of NO dissociation on the surface with STM, a much larger concentration of N atoms appeared at the stretched than at the compressed and the defect-free surface, signaling an enhanced reactivity of the stretched surface in accordance with the d-band model.<sup>[22]</sup>

For tiny (few-atom) clusters, the electronic structure cannot be properly described in a band structure model. Instead the energy levels may be described in a picture based on molecular orbitals. The energy levels, and hence the reactivity, will therefore be very sensitive to the detailed size and shape of the cluster.

In this section a number of concepts which are central in the description of catalytically active metal clusters have been described, whereas the role of the substrate has been neglected, apart from its part in providing a passive, high surface-area matrix (structural promoter) for the dispersed metal clusters. Increasing evidence has been found that the oxide in many cases plays a much more active and decisive role than hitherto expected. References to some aspects of metal-oxide interaction will be made in the next section.

### Gold on TiO<sub>2</sub>

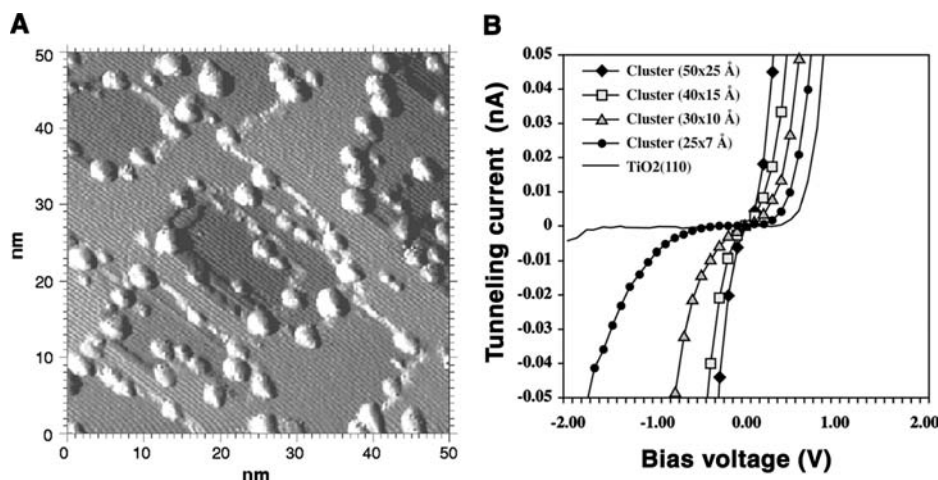

Gold is generally accepted to be the noblest of all the metals because of its electronic structure with a filled 5d band.<sup>[24]</sup> Only little attention has therefore been paid to gold as a potential catalyst. Nevertheless, when gold is highly dispersed on select oxide surfaces in the

form of nanosized clusters, its chemistry changes dramatically and surprisingly a high activity and/or selectivity is exhibited in catalytic processes such as the low-temperature oxidation of CO.<sup>[25]</sup> The observation that the chemical properties of gold depend on the support and in particular on the size of the Au clusters has spurred an intense search for the underlying physical origin.

When Au is evaporated onto a TiO<sub>2</sub> surface (cleaned by Ar ion sputtering and vacuum annealed to  $\approx 1000$  K), the Au atoms form clusters that nucleate at defects. Apart from major defects such as steps, the main nucleation sites are the bridging-oxygen vacancies shown in Fig. 2A.<sup>[26]</sup> A single oxygen vacancy will bind up to three Au atoms and for larger Au clusters, the Au/TiO<sub>2</sub> interface will contain a high density of oxygen vacancies.

Fig. 8A shows an STM image of a 50  $\times$  50-nm area of a TiO<sub>2</sub> (110) surface with a large number of Au clusters (bright protrusions).<sup>[27]</sup> As already mentioned the average cluster size can be varied by adjusting the evaporation flux, temperature, and total dose. By measuring the turnover frequency (TOF), i.e., the number of reactions taking place per Au atom per second, for CO oxidation as a function of the Au cluster size, a clear correlation between the TOF and the cluster diameter was revealed, showing a distinct maximum for a Au cluster diameter of  $\approx 3$  nm.<sup>[27]</sup>

In the search for the origin of this effect, the electronic properties of the Au clusters were investigated with scanning tunneling spectroscopy (STS).<sup>[27]</sup> In this technique, the STM tip is positioned on top of a particular cluster, and the tunnel current  $I$  is recorded as a function of the tunnel voltage  $V$ . The resulting  $I$ - $V$  curves reflect the electronic properties of the clusters and can be correlated with cluster size and geometry, as shown in Fig. 8B. A perfectly metallic cluster on a conducting substrate should display a simple ohmic behavior, i.e., a straight line as  $I$ - $V$  curve. From

**Fig. 8** (A) Constant-current STM image of Au/TiO<sub>2</sub>(110). The total amount of Au corresponds to 0.25 monolayer. (B) Scanning tunneling spectroscopy data acquired for Au clusters of varying sizes on the TiO<sub>2</sub>(110) surface. For reference the STS data of the TiO<sub>2</sub> substrate are also shown. *Source:* From Ref.<sup>[27]</sup>. © 1998, American Association for the Advancement of Science.

Fig. 8B it is evident that the smaller the cluster the stronger the deviation from simple ohmic behavior is observed. When the dimension of the cluster is decreased, a plateau of zero tunnel current develops around zero bias voltage corresponding to the appearance of a band gap between the valence and the conduction band. For comparison, an STS curve for the TiO<sub>2</sub> substrate, having a wider band gap than the Au clusters, is also included in Fig. 8B. These measurements provide a fine illustration of how quantum size effects become important when the dimensions of metal clusters are reduced, but do not by themselves explain the peak in activity for a given cluster size.

To elucidate the mechanism behind the observed activity, the possible role of the substrate must also be considered. It is well known that the support may take part in reactions, for example via spillover effects where reactants may be formed at the metal clusters or the oxide and migrate from one to the other. The active role of an oxide support during CO oxidation over supported Au catalysts has been investigated theoretically and experimentally with conflicting results (see Ref.<sup>[28]</sup> and references therein). To illustrate the complexity of the problem, reference is made to a case study: a theory study based on density functional theory (DFT) calculations.<sup>[29]</sup> MgO rather than TiO<sub>2</sub> was chosen as a substrate because of its structural simplicity and appearance in the experimental literature (Au clusters on MgO have also been shown to be reactive to CO oxidation at RT and even below.)<sup>[30]</sup> The higher reactivity of supported nanometer-sized Au clusters was found to originate from two effects: 1) the oxide acts as a structural promoter, leading to the formation of small Au clusters with low-coordinated Au edge sites that readily bind CO; 2) the proximity of the oxide stabilizes a peroxo-like reaction intermediate CO·O<sub>2</sub>.

It remains to be seen how general such mechanisms are, but the example serves to illustrate how the catalytic process may rely on an intricate interplay between the metal cluster and the oxide, and how challenging it is to sort out the relative importance of different effects.

## CONCLUSION

In this entry, emphasis has been on the synthesis and characterization of metal clusters on relatively flat, extended oxides which mimic real, metal-based catalysts sufficiently well to be exploited as model systems. Based on two case stories, Pd/Al<sub>2</sub>O<sub>3</sub> and Au/TiO<sub>2</sub>, a number of issues relevant for such systems have been introduced and discussed. Many other fascinating applications of metal clusters on oxides may be developed in the near future. Examples can already be found in the literature, such as the fabrication of

single-electron transistors based on contacting Au nanoclusters on SiO<sub>2</sub> with carbon nanotubes.<sup>[31]</sup> While each example is of interest in its own area, the principal importance of metal clusters on oxides is unquestionably still in the field of catalysis.

# Metal Nanoparticle Catalysts

Naoki Toshima

Department of Materials Science and Engineering,  
Tokyo University of Science, Yamaguchi, Japan

## INTRODUCTION

“Metal nanoparticles” receive much attention because of their uniform size and sharp size distribution in nanometers, and because they are easily prepared as a result of recent developments in nanoscience and nanotechnology. In addition, catalysts based on such metal nanoparticles are highly active and selective. They also exhibit a long lifetime for several kinds of chemical reactions. In this entry, a background on the use of metal nanoparticles as catalyst is first briefly discussed. Then, preparation, characterization, structures, and catalyses of metal nanoparticles, especially of bimetallic nanoparticles, are described. The prospects on the use of metal nanoparticles as catalysts<sup>[1–8]</sup> are summarized in the last section.

## METAL NANOPARTICLES AS CATALYSTS

There is a long history since metal has been known to work as a catalyst for various kinds of reactions. The catalytic sites of metals are located on its surface. This means that metal nanoparticles of 1–10-nm size (thus, having a large surface-to-volume ratio) are expected to work as effective catalysts. The surface-to-volume ratio increases with decreasing particle size. In other words, the ratio of surface atoms with respect to all atoms in a particle increases with decreasing particle size. Fig. 1 shows the dependence of the ratio of surface atoms of Au nanoparticles on the radius of nanoparticles, assuming that Au nanoparticles have the same fcc (face-centered cubic) crystalline structure as that of the bulk gold. Fig. 1 shows that the smaller the size, the larger is the ratio. Another characteristic property of the nanoparticles is the quantum size effect. Although bulk metal has a band structure, the electronic energy levels of metal nanoparticles with size of a few nanometers are rather separated as shown in Fig. 2.<sup>[9]</sup> This may have an advantage as a catalyst.

When metal nanoparticles are used as catalysts, it is necessary for the metal nanoparticles to be stabilized under the catalytic reaction conditions. Otherwise, metal nanoparticles can very easily coagulate in solution to form aggregates, which are less effective

as catalysts than the original ones. There are two ways to stabilize metal nanoparticles: One is to immobilize the metal nanoparticles on inorganic supports, resulting in heterogeneous catalysts. The other method is to surround metal nanoparticles with stabilizers, resulting in homogeneous catalysts, or more precisely, homogenized heterogeneous catalysts.

In practical industries, heterogeneous catalysts are often used because they are easy to handle. They can be used in tubular reaction vessels for gaseous reactions in continuous reaction processes, and thus are effective for mass production of conventional chemicals. However, metal nanoparticles often cannot keep their shapes and properties when immobilized on inorganic supports. For example, interactions between metal particles and inorganic supports are often very strong in the supported catalysts. This strong interaction can sometimes increase the stability and activity of catalysts, but in some cases can make the catalytic properties worse.

In contrast, metal nanoparticles in solution, especially those stabilized by polymers, are less affected by the stabilizers than those immobilized on inorganic supports because the interaction between metal nanoparticles and capping polymers is usually very weak in comparison with that between metal nanoparticles and inorganic supports. The structure models of a conventional heterogeneous metal catalyst and a typical metal nanoparticle catalyst are shown in Fig. 3.

In metal nanoparticles stabilized by strong coordination with organic ligand molecules, the story is quite different from those stabilized by polymers. Because the strongly coordinating organic molecules can occupy the surface of metal nanoparticles, the reaction substrates cannot attack the surface of metal nanoparticles. Thus metal nanoparticles strongly coordinated by organic ligands cannot work as effective catalysts.

The advantages of using metal nanoparticles as catalysts are the following:<sup>[1,4]</sup>

1. The size and shape of metal nanoparticles are easily controlled by the preparation conditions.
2. Metal nanoparticles dispersed in solution can be used as catalysts in solution like homogeneous catalysts. Thus the temperature applied to the catalyst is below the boiling point of the solvent.

**Fig. 1** Dependence of the ratio of surface atoms ( $r_s$ ) on the radius ( $r$ ) of gold nanoparticles.

3. Metal nanoparticles dispersing in solution are transparent to light. Thus they can be used as photocatalysts.
4. Metal nanoparticles capped by organic polymers can be functionalized by modifying the organic polymers.
5. It is possible to prepare bimetallic and trimetallic nanoparticles with various compositions and structures. The catalytic activity and selectivity of these metal nanoparticles can be controlled by varying the composition and structure.
6. Metal nanoparticles immobilized on solid supports can be used as catalysts even for the reactions in a gaseous phase.
7. Metal nanoparticles dispersed in solution or immobilized on solid supports are usually more active and selective as catalysts under mild reaction conditions than the conventional industrial catalysts.

The metal nanoparticles dispersed in solution and used as catalysts can be characterized not only by their own structure but also by the structure of the organic layers surrounding them. Both structures provide various functions to the metal nanoparticles used as catalysts.

The structure of a metal nanoparticle capped by an organic layer is shown in Fig. 4. The diameter  $d$  of core

**Fig. 2** Formation of separated energy-levels of metal nanoparticles by a quantum size effect.

**Fig. 3** Schematic illustration of the structures of (A) conventional metal catalyst and (B) metal nanoparticles capped by polymers.

metal nanoparticles can be easily measured by transmission electron microscopy (TEM). The thickness  $\delta$  of the organic layer or the total diameter  $D$  including the organic layer can be measured by various methods depending on the kind of organic layer. In solution, hydrodynamic radius provides  $D/2$ . When the hydrodynamic radius is large enough, it can be measured by a light scattering method. However, when the hydrodynamic radius is small, it can still be measured by a Taylor dispersion method if the size is homogeneous or uniform enough.<sup>[10]</sup> When the organic layer is composed of soluble polymers, the direct measurement of  $D$  is not so easy. The thickness  $\delta$  was proposed to be measured by the amount of polymers adsorbed on the surface of metal nanoparticles.<sup>[11]</sup> Because it is not easy to measure  $D$  in solution, measurement using scanning tunnel microscopy (STM) was performed in the dry state.<sup>[12]</sup>

In solution, the metal nanoparticles interact with each other by weak interaction forces; they form “superstructures,” the size of which can be measured by small-angle X-ray scattering (SAXS).<sup>[13]</sup>

**Fig. 4** Illustration of the metal nanoparticle capped by an organic layer.

**Fig. 5** Formation of metal nanoparticles by a chemical method.

## PREPARATION AND CHARACTERIZATION OF METAL NANOPARTICLES

Metal nanoparticles are defined as metal particles of nanometer size, which have a rather uniform size in the range of 1–10 nm. Metal nanoparticles with rather strict structures are called metal nanoclusters. Metal nanoparticles immobilized on solid supports or dispersed in solution can be used as catalysts.

### Preparation of Metal Nanoparticles Used as Catalysts

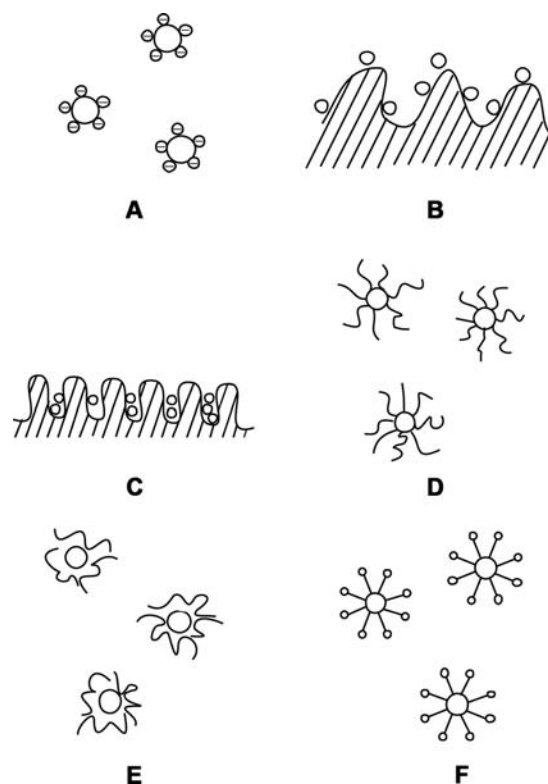

Metal nanoparticles with a rather uniform size can be prepared by both physical and chemical methods. In the physical method, sometimes called the top-down-type method, metal nanoparticles are prepared by decomposition of bulk metal with mechanical force, vaporization, laser abrasion, and so on, which can provide higher energy to bulk metal than the bond energy of metal. In the chemical method, sometimes called a bottom-up-type method, the preparation process starts from reduction of metal ions to metal atoms, which is followed by aggregation resulting in metal nanoparticles Fig. 5. Both physical and chemical methods have their own advantages. However, chemical methods are now considered to be better than physical methods from the viewpoints of reproducibility, homogeneity (e.g., uniformity in size), and mass production.

The production of metal nanoparticles by chemical methods requires some techniques by which coagulation is prevented. For example, electrostatic and steric repulsions among metal nanoparticles are used for this purpose. To prevent coagulation and to keep the dispersity of metal nanoparticles by electrostatic repulsion, electrical charges are provided. Adsorption of ions on the surface of metal nanoparticles is a simple way to acquire such charges Fig. 6A. The typical conventional colloidal dispersions of metal nanoparticles are usually stabilized by this method.

The most satisfying method for stabilization of metal nanoparticles by steric repulsion is the dispersion of metal nanoparticles in solid such as glass. However, in this case, the metal nanoparticles cannot work as catalysts because the substrate molecules cannot attack the surface of metal nanoparticles. Thus adsorption of metal nanoparticles on the surface of inorganic supports or immobilization in porous solids is often used for stabilization of metal nanoparticles by steric repulsion on solids Fig. 6B and C.

For the stabilization of metal nanoparticles in solution by steric repulsion, attachment of organic molecules or organic macromolecules on the surface of metal nanoparticles is easily considered to be a favorite method. An organic molecule with S and/or N atom(s), for example, is used as a ligand, which strongly bonds to metal nanoparticles Fig. 6D. In the case of organic macromolecules, the molecule is strongly attached to the metal nanoparticle because the macromolecule interacts with the surface of a metal nanoparticle at many sites although each interaction may be weak Fig. 6E. Organic molecules with low molecular weight can occasionally act as if they were a macromolecule when the interactions among the organic molecules are strong enough. In micelles and reverse micelles, surfactant molecules aggregate and protect the metal nanoparticles from coagulation Fig. 6F.

One of the simplest and most reproducible methods for preparation of metal nanoparticles is alcohol reduction of precious metal ions in alcohol–water in the presence of water-soluble polymers such as

**Fig. 6** Various metal nanoparticles stabilized by (A) electric charge, (B) inorganic supports, (C) porous solids, (D) organic molecules, (E) soluble macromolecules, and (F) surfactants.

**Fig. 7** Preparation of polymer-capped metal nanoparticle by alcohol reduction.

poly(*N*-vinyl-2-pyrrolidone) (PVP).<sup>[14]</sup> This process is schematically shown in Fig. 7. Thus the precious metal ions form complexes with polymers at first. The metal ions can be reduced by alcohol to produce polymer-metal atom complexes accompanying aldehyde formation from alcohol.

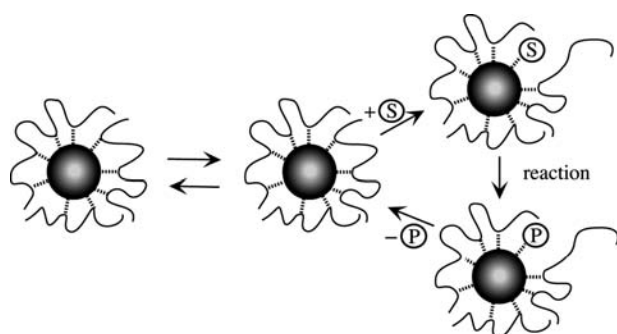

Other chemical reductants, such as hydrazine, molecular hydrogen, glycol, sodium borohydride, etc., can be used instead of alcohol. Energy, such as photoenergy, X-ray,  $\gamma$ -ray, electron beam, microwave, ultrasonic wave, electrolysis, etc., can also be used in solution in the presence of stabilizers to break the bond or reduce the metal ions to 0-valent metal atoms resulting in metal nanoparticles.

Other stabilizers such as organic ligands can be used instead of protective polymers. In general, the presence of strong ligands requires a strong reductant if the reduction is carried out in the presence of stabilizers. Otherwise, stabilizers must be immediately added after the reduction and coagulation of metal atoms to form metal nanoparticles and before the aggregation of metal nanoparticles to form the precipitates.

Metal nanoparticles stabilized by weakly coordinating polymers are considered as the best metal nanoparticle catalyst because substrate molecules can easily

attack the surface of metal nanoparticles and the reaction smoothly occurs as shown in Fig. 8. Because the polymer molecule weakly coordinates with the metal nanoparticle, the substrate molecules can replace the polymer on the surface of metal nanoparticle. When the reaction occurs on the surface and the substrate changes to a product, then the product can easily be removed from the surface because it cannot strongly interact with the metal surface. Upon removal of the product, the parts of the polymer that were left on the metal surface can now interact with the metal surface again and cover the metal nanoparticle. This kind of reversible capping of the polymer on the metal surface cannot occur in organic ligands with low molecular weight, although organic ligands or ionic species play an important role to control the shape of metal nanoparticles.

The metal nanoparticles immobilized on solid supports can be prepared by immobilization of the separately prepared metal nanoparticles on solid supports. Immobilization can be carried out by chemisorption or chemical bond formation between metal nanoparticles and solid supports. The immobilized metal nanoparticles thus prepared work as industrial catalysts for reactions in solution as well as in gaseous phase.

## Characterization of Metal Nanoparticles

Metal nanoparticles can be characterized by a combination of the following methods:<sup>[2,3]</sup>

1. Transmission electron microscopy (TEM). This is the simplest and most reliable method to measure the size and shape of metal nanoparticles. The average size is usually calculated by counting the sizes of about 200 particles. High-resolution TEM (HR-TEM) can provide information not only on the particle size and shape but also on the crystalline structure of metal nanoparticles. When energy dispersive X-ray microanalysis (EDX) is used in

conjunction with TEM, elemental information of metal nanoparticles can be obtained. The localized elemental information is also obtained by electron energy-loss spectroscopy (EELS) in conjunction with energy-filtering TEM (EF-TEM).

2. Ultraviolet and visible absorption spectroscopy (UV/VIS). The color change is a very useful and convenient method to identify the chemical change from the solution of metal ions to the dispersion of metal nanoparticles. The colloidal dispersions of Au, Ag, and Cu (Group 11 elements) have a red to yellow color because of their plasmon absorption, the peak position of which varies depending on the particle size and the extent of coagulation. The plasmon absorption of other metal nanoparticles is located in a UV region and is often difficult to clearly detect.
3. Infrared spectroscopy (IR). The IR spectra can provide information on organic layers surrounding metal nanoparticles. For example, the coordination of poly(*N*-vinyl-2-pyrrolidone) (PVP) onto the surface of metal nanoparticles was revealed by a shift of C=O stretching vibration absorption in the IR spectra. The structure of organic layers and the interaction of organic layers with metal nanoparticles are effective in the catalysis of metal nanoparticles. Thus information given by the IR spectra is very important in some cases. The IR spectra can also be used to understand the surface structure of the metal nanoparticles. The IR spectra of carbon monoxide adsorbed on the surface metal are so often used to identify the element of the surface metal of bimetallic nanoparticles.
4. X-ray diffraction (XRD). The solid structure of metal nanoparticles can be investigated by XRD. For monometallic nanoparticles, XRD can give information on the phase changes depending on the particle size. X-ray diffraction can determine if the bimetallic system is composed of the mixtures of two kinds of monometallic nanoparticles or of single bimetallic nanoparticles in which two elements are included in one particle.
5. X-ray photoelectron spectroscopy (XPS). Photoelectron spectroscopy is used to obtain information on the state of metal, e.g., the oxidation state of metal on the surface. Metal on the surface is often oxidized by air. So the 0-valency of surface metal must be confirmed by using XPS or other methods. When polymers cover the metal nanoparticles, clear XPS spectra of the metal cannot be observed. In this case, the removal of covering polymers from the surface of metal nanoparticles is required. Etching of covering polymers could be useful for this purpose. The polymers can also be removed from the metal nanoparticles by washing the nanoparticles adsorbed on thiol-modified silica supports with a good solvent. The quantitative analysis of XPS spectra of bimetallic nanoparticles can suggest the elements present in the surface region of nanoparticles.
6. Surface enhanced Raman spectroscopy (SERS). The SERS spectra can be obtained in the case of nanoparticles containing Au, Ag, and/or Cu. Quantitative analysis of enhanced Raman spectra can provide information about the adsorbing structures of organic molecules on the metal nanoparticles. Not only monometallic nanoparticles but also bimetallic nanoparticles containing Au, Ag, or Cu can enhance Raman spectra.
7. Scanning probe microscopy (SPM). Scanning probe microscopy techniques such as scanning tunneling microscopy (STM) and atomic force microscopy (AFM) can give information on the total size of metal nanoparticles capped by organic layers and the coagulating structure (superstructure) of capped metal nanoparticles. The superstructure sometimes has an effect on catalysis of capped metal nanoparticles. Although SPM is usually used for observation of dry samples, the superstructure at dry state is often thought to be similar to that in solution.
8. Extended X-ray absorption fine structure (EXAFS). This is one of the most powerful characterization methods to determine the detailed structure of metal nanoparticles, especially bimetallic nanoparticles. Because big synchrotron radiation facilities are now available, the EXAFS technique becomes useful for structure analysis of nanoparticles of precious metals. EXAFS can provide the number of atoms surrounding the X-ray absorbing atom and their interatomic distances involved in the various coordination shells, as well as the electron density. However, to obtain exact information, the sample of metal nanoparticles should be homogeneous, i.e., uniform in size and narrow in size distribution. Because the number of atoms surrounding the X-ray absorbing atom and even their interatomic distances can vary with the size of metal nanoparticles, we succeeded to give a core/shell structure model for Pd/Pt (4:1, mol/mol) bimetallic nanoparticles capped by poly(*N*-vinyl-2-pyrrolidone) (PVP), because they are very homogeneous (monodispersed) and stable.
9. Small-angle X-ray scattering (SAXS). Analysis of SAXS data can give information on

rather long regularity, for example, size of superstructures.

10. Thermogravimetry (TG) and differential thermal analysis (DTA). Thermal analysis (TG and DTA) can give information not only on composition and structure of organic layers but also on the phase transition of metal.
11. Dynamic light scattering (DLS). This method gives the hydrodynamic radius; that is, the size of metal nanoparticles including organic layers.

## STRUCTURE CONTROL OF BIMETALLIC NANOPARTICLES

Bimetallic nanoparticles, in which each particle contains two metal elements, are very important and interesting from the viewpoint of catalysis of metal nanoparticles because catalytic performance is very often affected by the addition of another element to the metal. In addition, the structure of bimetallic nanoparticles is strongly related with the catalytic performance.

Typical structures of bimetallic nanoparticles are illustrated in Fig. 9. These bimetallic nanoparticles have two kinds of metal-metal bonds, i.e., a homobond and a heterobond. If the metal particles are composed of atoms A and B, the homobond is either an A-A bond or a B-B bond, while an A-B bond is a heterobond. If the binding energies of the homobonds are same with that of the heterobond, the random alloy or solid solution should be the thermodynamically most stable structure. If the homobonds are much stronger than the heterobond, no bimetallic particles may be produced but only the mixture of two kinds of monometallic particles will be favorably obtained. However, in practice, there are no such big differences between the two kinds of bonds in precious metals. When heterobonds are preferred over homobonds, a

**Fig. 9** Various structures of bimetallic nanoparticles.

heterobondphilic structure may be obtained.<sup>[15]</sup> The opposite case gives a homobondphilic structure. Hence a core/shell structure, a kind of homobondphilic structure, is obtained as a thermodynamically stable structure. In contrast, an inverted core/shell structure is thermodynamically metastable. Such metastable structures can be constructed by the concept of kinetic control. Thus the structure of bimetallic nanoparticles depends on the kind of a couple of elements used.

## Bimetallic Nanoparticles Composed of a Couple of Platinum-Group Elements

Bimetallic nanoparticles of two kinds of platinum-group elements such as Pt, Pd, Au, etc. can be produced by coreduction of the corresponding metal ions in refluxing alcohol-water in the presence of water-soluble polymer. The coreduction usually gives colloidal dispersions of bimetallic nanoparticles with a core/shell structure, a kind of homobondphilic structure. For example, the solution of  $\text{PdCl}_2$  and  $\text{H}_2\text{PtCl}_6$  in refluxing ethanol-water in the presence of PVP gives colloidal dispersion of Pd/Pt bimetallic nanoparticles with a Pt-core/Pd-shell structures.<sup>[16]</sup> From  $\text{HAuCl}_4$  and  $\text{PdCl}_2$ , Au-core/Pd-shell structured bimetallic nanoparticles were obtained.<sup>[17]</sup>

The easiness of core formation increases in the order of  $\text{Rh} < \text{Pd} < \text{Pt} < \text{Au}$ . Thus Rh is the most easily shell-forming element. The core/shell structure is constructed via the complexes shown in Fig. 9. Two factors control the core/shell structure: 1) redox potential of metal ions; and 2) coordination ability of metal atom to the polymer.<sup>[18]</sup>

The PVP-protected Pd/Pt bimetallic nanoparticles work as a catalyst for partial hydrogenation of 1,3-cyclooctadiene to cyclooctene under mild conditions. The catalytic activity depends on the composition of Pd and Pt. The highest activity can be achieved by the Pd/Pt ratio (4:1, mol/mol) of bimetallic nanoparticles, in which 13 atoms of Pt form a core and 42 atoms of Pd surround the Pt core to form a shell.<sup>[16]</sup>

The mechanism of formation of Pd/Pt bimetallic nanoparticles with a thermodynamically stable Pt-core/Pd-shell structure has been proposed as shown in Fig. 10. In this process, easily reduced Pt(IV) ions are first reduced to produce Pt atoms that form a Pt core. Less easily reduced Pd(II) ions later produce Pd atoms, which deposit on the Pt core to form a Pd shell.

An inverted core/shell structure can be prepared by the so-called sacrificial hydrogen reduction method.<sup>[19]</sup> For example, Pd-core/Pt-shell bimetallic nanoparticles can successfully be prepared by this method. Successive reduction of Pd(II) and Pt(IV) ions cannot produce the inverted core/shell structured bimetallic nanoparticles, because addition of Pt(IV) ions to Pd(0) core

**Fig. 10** Proposed formation mechanism of Pt-core/Pd-shell-structured bimetallic nanoparticles. *Source:* From Ref.<sup>[18]</sup>.

nanoparticles results in redox reaction between them to form Pt(0) nanoparticles and Pd ions. Hence before the addition of Pt(IV) ions, the dispersion of Pd-core nanoparticles is treated with molecular hydrogen, forming hydride-covered Pd nanoparticles. Addition of Pt(IV) ions into the hydride-covered Pd nanoparticles produces Pt atoms, which immediately deposit on Pd cores to form Pd-core/Pt-shell, i.e., inverted core/shell structured bimetallic nanoparticles. This sacrificial hydrogen reduction method is useful for constructing other kinds of core/shell structured bimetallic nanoparticles.

### Bimetallic Nanoparticles Composed of an Iron-Group Element and a Platinum-Group Element

Reduction of ions of an iron-group element (transition metal in the third period) is more difficult than those of a platinum-group element. Nevertheless, ions of an iron-group element can easily be reduced to the corresponding atoms in the coexistence of nanoparticles of a platinum-group element. For example, copper(I) and palladium(II) can be reduced by ethylene glycol at ca. 200°C to produce the dispersions of Cu/Pd bimetallic nanoparticles,<sup>[20]</sup> which are surprisingly stable even

under air. The structure of Cu/Pd bimetallic nanoparticles is analyzed to be a random alloy (solid solution) on the basis of preliminary EXAFS measurements. The precise EXAFS analysis has recently concluded that the Cu/Pd bimetallic nanoparticles thus prepared have a heterobondphilic structure Fig. 11 rather than a random alloy structure.<sup>[15]</sup> The Cu/Pd bimetallic nanoparticles work as catalysts both for hydration of nitriles and hydrogenation of olefins, suggesting that both Cu and Pd atoms are located on the surface of the nanoparticles, because the Cu and Pd are generally known as active catalysts for the former and the latter reaction, respectively. Bimetallic nanoparticles with other combinations such as Cu/Pt, Ni/Pd, Ni/Pt, Fe/Pd, and Fe/Pt can be prepared by the same method.<sup>[21,22]</sup>

### Formation of Bimetallic Nanoparticles by Mixing Two Kinds of Monometallic Nanoparticles; Self-Organization of Metal Nanoparticles

Self-organization is one of the most important concepts in supramolecular science. In the formation of bimetallic nanoparticles from two kinds of metal atoms, the bimetallic structures, such as a core/shell, random alloy, and heterobondphilic structure, are controlled by self-organization in practice.

Another type of self-organization has recently been observed to produce pseudo-core/shell structured bimetallic nanoparticles by mixing two kinds of monometallic nanoparticles in solution.<sup>[23]</sup> Mixing of colloidal dispersions of PVP-protected Ag nanoparticles with those of PVP-protected Rh nanoparticles in solution at room temperature was found to result in a kind of “fusion” to produce colloidal dispersions of Ag/Rh bimetallic nanoparticles with a pseudo-core/shell structure in a few hours Fig. 12. Poly(*N*-vinyl-2-pyrrolidone) is suggested to play an important role for this self-organization. However, the driving force

**Fig. 11** Model structures for Cu/Pd 1:1 (left panel) and Cu/Pd 4:1 (right panel) bimetallic nanoparticles. Big dark balls correspond to Pd. *Source:* From Ref.<sup>[15]</sup>.

**Fig. 12** Formation of pseudo-Ag-core/Rh-shell-structured bimetallic nanoparticles. *Source:* From Ref.<sup>[23]</sup>.

as well as the conditions for this self-organization is not well understood yet.

Nevertheless, Pd/Ag/Rh and Pt/Pd/Rh trimetallic nanoparticles with a triple core/shell structure have recently been successfully prepared by this method.

## CATALYSES OF METAL NANOPARTICLES

Metal nanoparticles are used as catalysts for various kinds of reactions in dispersions or on supports, which are summarized here. Metal nanoparticles stabilized by weakly coordinating polymers are considered to be an effective catalyst, which works as shown in Fig. 8. As for polymer-protected metal nanoparticle catalysts, the catalytic performance, i.e., activity and selectivity, is affected not only by the structures of metal nanoparticles but also by those of the surrounding polymers.

## Reduction

Hydrogenation of C–C multiple bonds is catalyzed by many kinds of precious metal nanoparticles. The

**Fig. 13** Size effect of catalytic activity of PVP-protected Rh nanoparticle catalysts for hydrogenation of internal and vinyl olefins. *Source:* From *Shokubai* **1985**, 27, 488.

activity depends not only on the kind of metal element but also on the size and shape of metal nanoparticles. One of the most significant examples of the size effect is shown for hydrogenation of internal olefins catalyzed by PVP-protected Rh nanoparticle catalysts prepared by an alcohol reduction method Fig. 13.<sup>[1]</sup>

In bimetallic nanometal catalysts, the activity depends on the composition and structure of bimetallic nanoparticles.<sup>[3]</sup> For example, PVP-protected Pd/Pt bimetallic nanoparticles with a core/shell structure show the highest catalytic activity for partial hydrogenation of 1,3-cyclooctadiene to cyclooctene Formula I at a 4:1 atomic ratio of Pd to Pt Fig. 14, in which the Pt core is covered by an atomic layer of Pd.<sup>[16]</sup> This means that the catalytic active site of the metal nanoparticles is located on the surface Pd atoms and that the Pt core adjacent to the Pd has an electronic effect on the surface Pd atoms. In other words, the additional Pt atoms do not have an ensemble effect, but a ligand effect, on the active Pd sites.

The catalytic selectivity of metal nanoparticles can sometimes be controlled by their sizes and shapes. The selectivity of partial hydrogenation of cyclopentadiene catalyzed by PPV-protected Pd nanoparticles rapidly increases when the diameter of Pd nanoparticles is below 2 nm.<sup>[1]</sup>

The selectivity is more often controlled by the organic layer surrounding metal nanoparticles. 10-Undecenoic

**Fig. 14** Dependence of the catalytic activity of PVP-protected Pd/Pt bimetallic nanoparticles for partial hydrogenation of cyclooctadiene to cyclooctene upon the composition of the nanoparticles. *Source:* From *J. Chem. Soc. Faraday Trans.* **1993**, 89, 2537.

**Fig. 15** Schematic illustration of selectivity control of surfactant-protected Pd nanoparticle catalysts for hydrogenation of 2- and 10-undecenoic acid. *Source:* From Ref.<sup>[24]</sup>.

acid is much more easily hydrogenated than 2-undecenoic acid when catalyzed by Pd nanoparticles stabilized by nonionic surfactant molecules.<sup>[24]</sup> This selectivity control is shown in Fig. 15. Polycyclodextrin-covered metal nanoparticles are also effective catalysts for the reaction with high substrate selectivity because the cyclodextrin cavity can recognize the substrate molecule.

Enantioselective hydrogenation can be achieved by using metal nanoparticles capped by chiral stabilizers such as cinchonidine and dihydrocinchoxidine in dispersions and on inorganic supports.<sup>[25]</sup>

The reduction of C=O bond was reported to be catalyzed by Rh nanoparticles. The reduction of nitrobenzene to aniline by hydrogen at room temperature Formula II was catalyzed by PVP-protected Ni/Pd bimetallic nanoparticles, prepared by glycol reduction at 190°C. In nitrobenzene, the atomic ratio Ni/Pd = 1:4 gave the most active catalyst, while in the other substituted nitrobenzene, the ratio was 2:3.

### Visible-Light-Induced Hydrogen Generation

Because metal nanoparticles in dispersions are transparent to visible light, their application to catalyses for photochemical reactions is preferred over conventional solid catalysts. Colloidal dispersions of Pt nanoparticles in water was used for visible-light-induced hydrogen generation in the system of metal nanoparticles/methyl viologen (electron mediator)/trisbipyridineruthenium(II) dichloride (photosensitizer)/ethylenediaminetetraacetic acid disodium salt (electron donor) Formula III.

**Fig. 16** Relationship between hydrogen generation rate and electron transfer rate over various kinds of metal nanoparticle catalysts. *Source:* From Ref.<sup>[26]</sup>.

Various kinds of bimetallic nanoparticles were recently examined as catalysts of the above reaction. It was found that the hydrogen generation rate is proportional to the rate of electron transfer from methyl viologen cation radical to the metal nanoparticles as shown in Fig. 16, and that the bimetallic nanoparticles are more active as a catalyst than the corresponding monometallic nanoparticles.<sup>[26]</sup>

### Oxidation

Oxidation is one of the most general chemical reactions and is often applied to industrial processes. Nevertheless, there are few reports on the application of metal nanoparticle catalysts for oxidation reactions. This is because organic stabilizers are easily oxidized, resulting in their decomposition. Hence development of the stabilizers strong against oxidation is very important.

Oxidation of ethylene to ethylene oxide by molecular oxygen Formula IV is catalyzed by Ag nanoparticles stabilized by poly(sodium acrylate). The reaction proceeds under the pressure of ethylene and oxygen at 170°C.<sup>[27]</sup>

Catalytic oxidation is enhanced by the presence of Cs(I) and Re(VII) ions, which are immobilized on the stabilizer poly(acrylate). The catalytic activity of Ag nanoparticles depends on the protecting polymer. Polyacrylate-protected Ag nanoparticles have much higher activity than PVP-protected ones especially at high temperature. This is probably because of the stronger coordinations of polyacrylate to Ag nanoparticles.

Other examples include oxidation of cyclooctane to cyclooctanone and cyclooctanone by *t*-butyl hydroperoxide (*t*-BHP) catalyzed by Ru nanoparticles in a

biphasic system, and oxidation of D-glucose to D-gluconate by molecular oxygen catalyzed by tetraalkylammonium-stabilized Pd/Pt bimetallic nanoparticles on charcoal.<sup>[28]</sup>

## Hydration

Selective hydration of acrylonitrile, which is catalyzed by copper catalysts, is used for industrial production of acrylamide. The same reaction can proceed by using Cu nanoparticles as catalysts. The colloidal dispersions of PVP-protected Cu nanoparticles were prepared by NaBH<sub>4</sub> reduction of Cu(II) ions and applied to the catalyst for this reaction.<sup>[1]</sup> However, Cu nanoparticles are easily oxidized by the contaminant air and are not stable enough to be repeatedly used. To stabilize Cu nanoparticles, Cu/Pd bimetallic nanoparticles were prepared by coreduction of Cu and Pd ions by glycol at 190°C in the presence of PVP.<sup>[20]</sup> The bimetallic nanoparticles are more stable, and much more active as the catalyst for hydration of acrylonitrile to acrylamide Formula V than the simple Cu monometallic nanoparticles.

## C–C Bond Formation

The C–C bond formation is a useful reaction in organic syntheses and is often catalyzed by homogeneous catalysts of organometallic complexes. Metal nanoparticles have recently been used instead of organometallic complexes as catalysts for C–C bond formation. Because these reactions are catalyzed by ionic species of precious metals in homogeneous catalysts, real active species of these metal nanoparticle catalysts are often considered to be the ionic species produced by oxidation of metal nanoparticles. Further research is required to understand the real reaction mechanism.

Heck reaction, the coupling between aromatic and vinyl carbons Formula VI, was found to be catalyzed by Pd nanoparticles in the presence of base at a rather high temperature.<sup>[29,30]</sup>

Because the reaction requires a rather high temperature, enough stable polymers are preferred as the stabilizer for the metal nanoparticles used as catalysts.

Carbonylation of methanol to directly produce acetic acid Formula VII is catalyzed by a homogeneous Rh catalyst. Poly(*N*-vinyl-2-pyrrolidone)-protected Rh nanoparticles were used as the catalyst of this reaction at 140°C under CO pressure.

Suzuki reaction, which is useful for direct coupling of two different benzene rings Formula VIII, were catalyzed by Pd and Pd/Ni nanoparticles.<sup>[31]</sup> The stability of the PVP-protected Pd nanoparticles was investigated as well.<sup>[32]</sup>

[3 + 2] Cycloaddition reaction between methylene-cyclopropane and methyl acrylate in reflux toluene Formula IX was catalyzed by Ni nanoparticles immobilized on alumina.<sup>[33]</sup>

In these C–C coupling reactions, the catalytic activity of metal nanoparticles is less than the corresponding homogeneous organometallic catalysts. However, metal nanoparticle catalysts have an advantage for repeated usage. For the practical use of metal nanoparticles as catalysts, further investigations of stable protective polymers and of immobilization on inorganic supports as well as of the reaction mechanism will be required.

## CONCLUSION

Catalysts based on metal nanoparticles have recently received much attention because investigations in the field of metal nanoparticles has rapidly developed. Now many techniques have been reported to control the structures of metal nanoparticles, not only the structures of metal parts but also the structure of organic layers surrounding them. By using these techniques, metal nanoparticles can be constructed according to the design.

Metal nanoparticles can be used as catalysts not only in dispersions but also on solid supports. In dispersions, metal nanoparticles can be used as catalysts only for reactions in a solution, while on solid supports they can be used both in solution and in gaseous phase. Thus metal nanoparticles are now applied to catalysts for various kinds of reactions. The number of the reactions for which metal nanoparticles are used as catalysts is going to rapidly increase. In the field of environmental

catalysts, which are the largest in the market of catalysts, conventional catalysts may be replaced by metal nanoparticles designed for this purpose.

# Metal Nanoparticle Ensembles: Collective Optical Properties

Alexander Wei

Department of Chemistry, Purdue University,  
West Lafayette, Indiana, U.S.A.

## INTRODUCTION

Ensembles of gold and silver nanoparticles in the 10- to 100-nm size range exhibit collective electromagnetic properties, which can be tuned according to particle size and interparticle spacing. Self-assembly is a critical enabling mechanism for organizing nanoparticles into ensembles with well-defined lattice structures or geometries, if particle dispersion forces can be adequately controlled. Presented here are several recent theoretical and experimental studies on metal nanoparticle assemblies with novel and technologically appealing optical properties. For example, gold nanoparticles with intense plasmon resonances can be organized into planar arrays or spherical ensembles around dielectric cores, and serve as substrates for surface-enhanced Raman scattering (SERS). Recent theoretical developments indicate that the electromagnetic field factors responsible for such enhancements can be further tuned by adjusting the diameter-spacing ratio, enabling the optimization of metal nanoparticle ensembles for various applications in sensing and nanophotonics.

## SURFACE PLASMONS

Gold and silver nanostructures are well known to exhibit electrodynamic phenomena commonly referred to as surface plasmons (see entry on “Surface Plasmon Spectra of Gold and Silver Nanoparticles”). These are generated by the collective excitation of free electrons in the metal particle, in response to a characteristic electromagnetic frequency. The surface plasmon modes of metal nanostructures have essentially the same function as radio antennas, except that they resonate in the optical and near-infrared (NIR) regions of the electromagnetic spectrum. Surface plasmons can be categorized into two types: localized plasmon resonances, in which incident light is absorbed or scattered by the oscillating electric dipoles within a metal nanoparticle, and surface plasmon polaritons, which propagate along metal surfaces in a waveguide-like fashion until released at some distance from their point of origin (Fig. 1). Localized plasmon resonances generate

electromagnetic field factors, which enhance linear and nonlinear optical effects near the metal surface. The localized plasmonic responses of individual metal nanoparticles are now quite well understood and have been summarized in several recent works.<sup>[1–3]</sup> On the other hand, metal nanoparticle ensembles can support both localized and propagating surface plasmon modes, whose physical relationships are less well defined. Regardless of the complexity of these phenomena, the plasmonic coupling of metal nanostructures with light enhances a broad range of useful optical phenomena, such as resonant light scattering (RLS), surface plasmon resonance (SPR), and SERS, all of which have tremendous potential for ultrasensitive chemical and biomolecular detection and analysis.

The plasmonic responses of coupled metal nanostructures are capable of intensifying local electromagnetic fields by many orders of magnitude. For example, many of the early SERS observations in the late 1970s and early 1980s were performed using kinetically formed aggregates of Ag and Au nanoparticles.<sup>[4]</sup> Interest in SERS has been further stoked by reports of single-molecule SERS spectroscopy,<sup>[5–7]</sup> however, the reproducibility of such activities has been poor. Despite strong evidence that aggregated nanoparticles can generate “hot spots” that produce enormous enhancements in Raman intensities, these vary widely from sample to sample and often disappear after a few days’ aging. The conditions that enable reproducibly high SERS enhancements have yet to be established, and constitute an important challenge in nanomaterials synthesis.

## FABRICATION OF NANOPARTICLE ASSEMBLIES

In the last few years, significant progress has been made in the fabrication and optical characterization of metal nanoparticle assemblies in one, two, and three dimensions. Much of this work has been directed toward the self-assembly and materials properties of nanoparticle assemblies in which the unit particle size is below 10 nm (radius  $R < 5$  nm); these have been

**Fig. 1** Incident light on nanostructured metal surfaces can result in localized (standing) plasmon resonances (A), propagation of surface plasmon waves (B), or a combination of the two (C). Excitation of conduction electrons produces local electromagnetic fields (pink) near the metal surfaces.

reviewed elsewhere.<sup>[8–10]</sup> More recently, several investigations have focused on metal nanoparticle assemblies with unit structures in the 10- to 100-nm range, the central theme of this entry. Both theoretical considerations and experimental investigations of discrete clusters and extended arrays of these midnanometer-sized nanoparticles will be discussed. It will become evident that in addition to particle size, structural parameters such as interparticle distance, lattice geometry, and periodic order also have important roles in the collective optical responses of these ensembles.

### Discrete Clusters of Metal Nanoparticles

Plasmon-resonant nanoparticles can experience significant dipolar coupling when their interparticle separation  $\delta$  is on the order of diameter  $2R$  or less where  $R$  is nanoparticle radius, giving rise to additional plasmon modes. Effective-medium theories such as the Maxwell–Garnett formula, which can accurately describe the plasmon resonance of isolated metal particles below 30 nm, can provide only a limited approximation of the optical responses by coupled nanoparticles.<sup>[11]</sup> These approximations lose their accuracy if  $\delta$  is much less than one particle diameter ( $\delta < 1.5R$ ), at which point evanescent (near-field) coupling becomes significant.

Simulations of discrete  $N$ -particle systems based on generalized Mie theory<sup>[1,12]</sup> or numerical approaches such as discrete dipole approximation<sup>[13,14]</sup> appear to provide more consistent models of coupled metal nanoparticles. These have been used to predict the extinction and absorption cross sections of specific aggregate structures, such as chained particles in linear or bent conformations (Fig. 2). Linear chains of Ag nanoparticles produce longitudinal plasmon resonances at strongly redshifted wavelengths, whereas close-packed aggregates exhibit less pronounced shifts in their collective plasmon resonance frequencies. The optical responses of these  $N$ -particle clusters in fact correlate closely with anisotropic metal particles of similar overall shape, such as nanorods<sup>[15,16]</sup> and nanoprisms.<sup>[13,14,17]</sup>

More recent theoretical treatments have given emphasis to the local electromagnetic fields generated near the metal nanoparticle surfaces, with the objective

of defining regions with the highest field factors (often quantified as a function of  $|E/E_0|$  where  $E$  and  $E_0$  are the plasmon-enhanced and incident electric field intensities) for a given frequency  $\omega$ . This is especially important for surface-enhanced spectroscopies such as SERS, in which signals are amplified as a function of  $G_{\text{EM}} = |E(\omega)/E_0(\omega)|^2 \cdot |E(\omega')/E_0(\omega')|^2$ , where  $G_{\text{EM}}$  is the local Raman enhancement factor and  $\omega$  and  $\omega'$  are the incident and Stokes-shifted frequencies, respectively.<sup>[18]</sup> In the simplest case of a two-sphere system, it is widely agreed that local field factors are greatest when the two particles are almost touching. Xu and coworkers have performed electrodynamic calculations on pairs of Au and Ag particles (10–90 nm) separated by as little as 1 nm, and suggested  $G_{\text{EM}}$  values more than  $10^{11}$  for the best cases.<sup>[19]</sup> These localized enhancements are exquisitely sensitive to interparticle spacing; changes in  $\delta$  by just a few nanometers can cause the local enhancements to drop by several orders of magnitude (Fig. 3). These calculations, in conjunction with experimental studies by the same group,<sup>[7,20]</sup> imply that nanoparticle dimers have potential as substrates for routine single-molecule SERS, given a reliable method for localizing analytes in regions of high field.

### Linear Arrays of Metal Nanoparticles

Linear (1-D) arrays of metal nanoparticles have attracted much interest for their potential to transport energy in an antenna-like fashion and serve as near-field optical waveguides at subwavelength dimensions, with the possibility of integrating nanophotonics with far-field optical devices.<sup>[21]</sup> Theoretical calculations of vectorial energy transport through chains of closely spaced 50-nm Au nanospheres suggest remarkably high levels of transmission at optical resonance, with optimized losses ranging between 10 and 25 dB per micron (Fig. 4).<sup>[22,23]</sup> Several methods for producing nanoparticle 1-D arrays have been reported, including self-assembly on prepatterned surfaces<sup>[24]</sup> and inside of nanoporous templates<sup>[25,26]</sup> as well as by directed assembly using scanning probe microscopy tips.<sup>[21]</sup>

Recent experimental studies on plasmonic 1-D nanoarrays have so far been promising. Proof of concept was established by Krenn and coworkers, who used photon scanning tunneling microscopy to image near-field excitations within Au nanoparticle chains.<sup>[27]</sup> Near-field optical transport in linear arrays of Au nanoparticles and Ag nanorods was also recently demonstrated by Maier et al.<sup>[23,28]</sup> The latter case was shown to support plasmon propagation with losses as

**Fig. 4** Finite-difference time-domain simulation of electric fields (red) localized within a linear array of 50-nm Au particles (blue), with interparticle separations of  $\delta = 75$  nm. *Source:* From Ref.<sup>[23]</sup>.

low as 6 dB per 200 nm, which suggests their feasible integration into all-photonic device architectures.

### Two-Dimensional Arrays of Metal Nanoparticles

Several methods have been employed for arranging metal nanoparticles into periodic and aperiodic two-dimensional (2-D) lattices. Periodically ordered 2-D arrays with relatively large interparticle spacings ( $D/2R = 1.5$  to 5, where center-to-center distance  $D = 2R + \delta$ ) have been fabricated by electron-beam lithography<sup>[29,30]</sup> or by self-assembly on lithographically defined surfaces<sup>[24]</sup> (for some recent examples see Refs. <sup>[31,32]</sup>). Aperiodic 2-D arrays of the same genre have also been produced by self-assembly techniques, mostly by random sequential adsorption onto charged surfaces.<sup>[33–37]</sup> For these cases, the collective optical properties of nanoparticles are dominated by dipolar coupling mechanisms; however, their responses are more complex than predicted by classical dipole–dipole interactions, whose strength varies with  $1/D^3$ . Particles larger than 30 nm can exhibit sizable retardation effects in their dipolar interactions, and this can impact both the wavelength and decay time of their coupled plasmon resonances.<sup>[29,38]</sup> For example, Chumanov et al. observed a remarkable blueshifting and narrowing of extinction maxima in submonolayer films of 100-nm Ag particles as a function of packing density.<sup>[33]</sup> This was later reproduced in lithographically defined Ag nanoparticle 2-D arrays, and reexamined as a function of particle diameter–spacing ratio.<sup>[37]</sup> Recent theoretical analyses by Zhao and coworkers suggest that the blueshifting and narrowing are largely due to radiative dipolar coupling, an electrodynamic term that scales largely with  $1/D$ .<sup>[39]</sup>

Aperiodic 2-D arrays may also provide a practical and straightforward method for preparing SERS substrates.<sup>[34–36]</sup> Submonolayer ensembles of colloidal metal particles can be prepared with packing densities of up to 30% (Fig. 5, left), which is well below the close-packing limit ( $\sim 90\%$ ) but sufficient to produce significant electromagnetic coupling and SERS.<sup>[34–36,40]</sup> Electrostatic self-assembly of Au nanoparticles on spherical submicron particles has also been reported recently;<sup>[41]</sup> in this case, packing densities on the order of 50% can be achieved by increasing the nanoparticles' surface potentials, with a concomitant enhancement in electromagnetic coupling (Fig. 5, right).

2-D nanoparticle arrays with much smaller interparticle spacings ( $D/2R < 1.1$ ) are likely to support strong near-field coupling as well as dipolar coupling, and should be excellent substrates for generating SERS and other surface-enhanced spectroscopies. In principle, such nanoparticle ensembles should also be

**Fig. 5.** Left: planar ensemble of 40-nm Au particles adsorbed onto thiol-functionalized SiO<sub>2</sub>. *Source:* From Ref.<sup>[40]</sup>. © 1995, American Chemical Society. Right: spherical core-shell ensembles of 30-nm particles adsorbed onto amine-functionalized 390-nm SiO<sub>2</sub> particles. *Source:* From Ref.<sup>[41]</sup>. Scale bar = 200 nm in both images.

accessible by thermodynamic self-assembly; however, metal particles in the midnanometer size range experience strong interaction potentials that can promote kinetic aggregation, resulting in poorly defined structures. This can be viewed as a problem in dispersion control: If repulsive interactions can offset particle self-attraction at close range, conditions for thermodynamically controlled self-organization can be achieved. Earlier demonstrations by Schmid et al.<sup>[42]</sup> and by Giersig and Mulvaney<sup>[43,44]</sup> have indicated that colloidal Au particles can be organized into close-packed domains with local 2-D order.

A general method for organizing metal nanoparticles into hexagonal close-packed 2-D arrays has recently been developed by Wei and coworkers, using multivalent macrocyclic surfactants known as resorcinarenes.<sup>[45,46]</sup> These compounds are capable of extracting colloidal Au particles from aqueous suspensions and dispersing them into organic solvents or at air-water interfaces.<sup>[47]</sup> In the latter case, resorcinarene-stabilized nanoparticles as large as 170 nm have been organized into 2-D arrays with excellent local order (Fig. 6). Here the  $D/2R$  ratios are well below 1.1; careful inspection of the TEM images reveals an inverse correlation between array periodicity and interparticle spacing  $\delta$ , most likely due to greater van der Waals attraction with unit particle size.

The periodic 2-D nanoparticle arrays exhibit size-dependent optical properties at visible and NIR

wavelengths. The gold nanoparticle films vary in hue from blue ( $2R = 16$  nm) to a faint gray ( $2R > 70$  nm), the latter being strongly absorptive in the NIR region (Fig. 7). The specular reflectance is also dependent on periodic structure, with maximum reflectance of white light observed for  $2R$  between 40 and 70 nm.<sup>[48]</sup> These variable reflectivities can be attributed to several effects: 1) an angular dependency in attenuated reflection as a function of surface roughness, a well-studied phenomenon in metallic thin films;<sup>[49]</sup> 2) size-dependent optical absorption, with significant absorptivities in the visible region for nanoparticle arrays with periodicities below 40 nm; and 3) size-dependent increases in Mie scattering, a phenomenon that has been characterized for nanoparticles and nanostructured metal surfaces with roughnesses on the order of 40 nm or more.<sup>[1,2,49]</sup>

The 2-D nanoparticle arrays also exhibit size-dependent SERS activities, with excellent levels of signal enhancement in many cases.<sup>[50]</sup> Surface-averaged Raman signals generated from the adsorbed resorcinarenes could be optimized as a function of periodicity and excitation wavelength, with enhancements as high as  $10^7$ . The observed trends are in accord with previous theoretical calculations describing electromagnetic SERS,<sup>[51–54]</sup> and also with SERS studies on disordered metal colloid aggregates.<sup>[55–57]</sup> However, the resorcinarene-stabilized nanoparticle arrays have considerable advantages in reproducibility and stability, and retain essentially all SERS activity more than a year after self-assembly. Additional signal enhancement could be obtained by increasing the solid angle of incidence and collection; the angle-dependent Raman intensities suggest that propagating surface plasmons in the Au nanoparticle films contribute significantly to the SERS effect.

The colloidal Au nanoparticle arrays are capable of detecting exogenous analytes by SERS and thus have potential as spectroscopic chemical sensors.<sup>[50]</sup> Volatile organic compounds adsorbed onto the array surface produce a detectable signal within seconds; removal of the surfactant layer by plasma treatment further increases the arrays' sensitivities and enables the reproducible detection of analytes in aqueous solutions at micromolar concentrations.<sup>[58]</sup> However, recent

**Fig. 6** Self-organized 2-D arrays of resorcinarene-encapsulated Au nanoparticles. Unit particle sizes: (A) 16 nm; (B) 34 nm; (C) 87 nm. *Source:* From Ref.<sup>[45]</sup>. © 2001, American Chemical Society.

theoretical calculations indicate that detection limits can be further lowered by adjusting the interparticle spacing. An incremental change in  $\delta$  delocalizes field intensities but at the same time increases the available sampling space for analyte detection. Recent calculations by Genov et al. indicate that the surface-averaged enhancement factor  $G_R$  (as opposed to the local factor  $G_{EM}$ ) from periodic nanoparticle arrays can be maximized as a function of excitation wavelength at a given value of  $2R/\delta$ , and can surpass that produced by disordered metal–dielectric films by several orders of magnitude (Fig. 8).<sup>[59]</sup>

### 3-D Superlattices of Metal and Metalodielectric Nanoparticles

In addition to enhancing spontaneous emission events such as SERS, metal nanoparticle superlattices may also be capable of blocking electromagnetic radiation at select frequencies, i.e., a photonic band gap. Highly monodisperse particles on the order of an optical wavelength are well known to crystallize into 3-D superlattices, and often produce opalescent Bragg reflections. Colloidal crystals may also exhibit photonic band gaps in the visible to NIR range, and have been highly sought after as a way to manipulate the

flow of light.<sup>[60]</sup> In principle, a photonic band gap can be engineered from nearly any type of material by periodically modulating its dielectric properties. However, lattices with relatively low dielectric contrast are not optimal materials for designing photonic band gaps at optical wavelengths. Periodic metal–dielectric nanostructures are capable of much stronger optical modulation; “inverse-opal” metal-coated colloidal crystals have recently been fabricated and have some promise as photonic band-gap materials.<sup>[61]</sup>

Theoretical studies by Moroz indicate that plasmonic colloidal crystals can support a complete photonic band gap in the visible and even the near-UV range.<sup>[62]</sup> Close-packed, face-centered cubic (FCC) crystals of colloidal Ag particles were calculated to possess tunable band gaps, at frequencies defined by the particle radius and plasma wavelength ( $R/\lambda_p$ ) and with relative gap widths between 5% and 10% as defined by  $(\Delta\omega/\omega_c)$ , the gap width to mid-gap frequency ratio. The photonic band gaps were predicted to be greatest for colloidal crystals with  $R/\lambda_p > 0.9$ ; for Ag, 3-D arrays of large, submicron-sized particles would be needed to produce band gaps for visible wavelengths.

A related study by Zhang et al. suggests that tunable photonic band gaps can also be made using metal-coated, core–shell nanoparticles as 3-D array elements.<sup>[63]</sup> The band gaps of these materials are

**Fig. 8** Left: numerical calculations of surface-averaged field enhancements ( $G_R$ ) from 2-D hexagonal superlattices, with diameter–spacing ratios of 5, 10 and 30, vs. a random metal–dielectric film at the percolation threshold ( $p = p_c$ ). *Source:* From Ref.<sup>[59]</sup>. © 2003, American Chemical Society. Right: local field distribution within a hexagonal lattice produced by  $p$ -polarized light ( $\lambda = 600$  nm,  $2R/\delta = 10$ ).

predicted to be less dependent on long-range order, a critical and challenging issue in the self-assembly of colloidal crystals. Photonic band gaps have been calculated for FCC lattices of SiO<sub>2</sub>/Ag core-shell nanoparticles of different sizes and packing densities: 500/50-nm core-shell particles at 45% packing density are expected to have a robust band gap centered at  $\lambda = 1.5 \mu\text{m}$ , whereas 160/50-nm core-shell particles at 42% packing density are expected to have a band gap across the visible spectrum. Graf and van Blaaderen have recently reported a closely related core-shell colloidal crystal, in which a second dielectric shell has been grown around the metal-coated nanoparticle.<sup>[64]</sup> The outermost SiO<sub>2</sub> shell reduces the van der Waals interactions considerably, and permits their self-organization into colloidal crystals with fractional densities close to that proposed by Zhang et al.<sup>[63]</sup>

## CONCLUSION

In closing, the controlled assembly of metal nanoparticles into well-defined structures can yield novel collective electromagnetic behavior, with excellent potential for function and application. Chemical and bioanalytical nanosensors have already reached a remarkably advanced stage of development, with detection and analysis bordering on the single-molecule limit, and the emerging area of nanophotonics may have long-term impact on telecommunications and device integration.

## ACKNOWLEDGMENTS

The author wishes to thank Beomseok Kim, Steven Tripp, and Bryce Sadtler for their valuable efforts toward the preparation and analysis of the planar and spherical Au nanoparticle arrays, and Dentcho Genov, Andrey Sarychev, and Vladimir Shalaev for related theoretical investigations. Financial support from the National Science Foundation, the National Institutes of Health, and Department of Defense are gratefully acknowledged.

# Metal Nanoparticles Prepared in Supercritical Carbon Dioxide

Harry W. Rollins

Chemistry Department, Idaho National Engineering and Environmental Laboratory,  
Idaho Falls, Idaho, U.S.A.

## INTRODUCTION

The novel optical, electronic, and/or magnetic properties of metal and semiconductor nanoparticles have resulted in extensive research on new methods for their preparation. An ideal preparation method would allow the particle size, size distribution, crystallinity, and particle shape to be easily controlled, and would be applicable to a wide variety of material systems. Numerous preparation methods have been reported, each with its inherent advantages and disadvantages; however, an ideal method has yet to emerge. The most widely applied methods for nanoparticle preparation include the sonochemical reduction of organometallic reagents,<sup>[1,2]</sup> the solvothermal method of Alivisatos,<sup>[3]</sup> reactions in microemulsions,<sup>[4-6]</sup> the polyol method (reduction by alcohols),<sup>[7-9]</sup> and the use of polymer and sol-gel materials as hosts.<sup>[10-13]</sup>

In addition to these methods, there are a variety of methods that take advantage of the unique properties of a supercritical fluid.<sup>[14,15]</sup> Through simple variations of temperature and pressure, the properties of a supercritical fluid can be continuously tuned from gas-like to liquid-like without undergoing a phase change. Nanoparticle preparation methods that utilize supercritical fluids are briefly reviewed below using the following categories: Rapid Expansion of Supercritical Solutions (RESS), Reactive Supercritical Fluid Processing, and Supercritical Fluid Microemulsions. Because of its easily accessible critical temperature and pressure and environmentally benign nature, carbon dioxide is the most widely used supercritical solvent. Supercritical CO<sub>2</sub> is unfortunately a poor solvent for many polar or ionic species, which has impeded its use in the preparation of metal and semiconductor nanoparticles. We have developed a reactive supercritical fluid processing method using supercritical carbon dioxide for the preparation of metal and metal sulfide particles and used it to prepare narrowly distributed nanoparticles of silver (Ag) and silver sulfide (Ag<sub>2</sub>S). The preparation and characterization of these materials and the effects of processing conditions on particle properties is reported.

## NANOPARTICLE PREPARATION METHODS USING SUPERCRITICAL FLUIDS

### Rapid Expansion of Supercritical Solutions

The Rapid Expansion of Supercritical Solutions (RESS) process takes advantage of the pressure dependence of solute solubility in supercritical fluids. In this method, a supercritical solution of the solute is prepared by dissolving the solute in an appropriate solvent and then pressurizing and heating the solution to above its critical point. (Alternatively, the solute can be directly dissolved by the solvent at supercritical conditions.) The supercritical solution is rapidly expanded through a small nozzle or orifice into a region at lower pressure, where the solute is insoluble. The very rapid reduction in pressure results in the precipitation of the solute. The timescale for the precipitation has been estimated to be on the order of 10<sup>-7</sup> sec,<sup>[16]</sup> which results in the homogeneous nucleation and precipitation of the solute. A wide variety of organic, polymeric, and inorganic nanoparticles have been prepared by RESS.<sup>[17-23]</sup> Organic particles prepared using this method typically have a wide particle-size distribution and are in the ~1- $\mu$ m size range. Particle size is highly dependent on solute concentration, with smaller particles being produced at lower concentrations. Ginosar et al.<sup>[24]</sup> reported that the on-line particle-size analysis for the RESS preparation of phenanthrene nanoparticles from carbon dioxide solutions consists of a bimodal distribution of primary nanoparticles and much larger micron-sized aggregates. Processing by RESS using carbon dioxide solutions has primarily been used in the preparation of organic nanoparticles because of the limited solubility of inorganic salts and polymers in CO<sub>2</sub>. Smith, Matson, Petersen, and coworkers<sup>[18,20,25]</sup> have used supercritical water solutions for the RESS preparation of SiO<sub>2</sub> and GeO<sub>2</sub> nanoparticles. Processing of SiO<sub>2</sub> by RESS using a preexpansion temperature of 470°C at 590 bar and an expansion nozzle with an inner diameter of 60  $\mu$ m resulted in the formation of particles with diameters from less than 0.1 to 0.5  $\mu$ m. Variation of the

SiO<sub>2</sub> concentration from 10 to 500 ppm resulted in SiO<sub>2</sub> particles with diameters from less than 0.01 to 0.5 μm, with larger particles being produced at higher SiO<sub>2</sub> concentrations. Variation of the processing conditions has been used to generate thin films of the inorganic material. Supercritical carbon dioxide has been used for the RESS preparation of triiron dodecacarbonyl, dimanganese decacarbonyl, and chromium hexacarbonyl.<sup>[26]</sup> The triiron dodecacarbonyl particles ranged in diameter from 1 to 10 μm.

### Reactive Supercritical Fluid Processing

The RESS process is a precipitation process based on the pressure dependence of solute solubility in supercritical fluids. Unfortunately, metals and metal sulfides are insoluble in most solvents, thus precluding their direct preparation by RESS. Using aqueous solutions of metal salts, the RESS process has been used to prepare metal oxide nanoparticles. Processing of Fe(NO<sub>3</sub>)<sub>3</sub> solutions by RESS using water at 500°C and 100 MPa and orifices with diameters of 50–200 μm resulted in the formation of Fe<sub>2</sub>O<sub>3</sub> nanoparticles with diameters of 20–40 nm.<sup>[27]</sup> Oxidation of metal salts in pressurized water at high temperatures is typically referred to as hydrothermal processing and is a common method in the synthesis of metal oxides. Hydrothermal treatment using batch-type reactions affords little control over the solution temperature and duration of exposure and typically results in the formation of micron-scale particles. Careful control of the reaction conditions has been demonstrated using a flowing system in which the aqueous solution of the metal salt is rapidly mixed with a preheated water stream. Variation of the temperature and flow rate of each stream and the residence time at high temperature can be precisely controlled and limited to short exposure times. Using flowing systems, Poliakoff et al.<sup>[28,29]</sup> were able to prepare nanoparticles of Ce<sub>1-x</sub>Zr<sub>x</sub>O<sub>2</sub> and MFe<sub>2</sub>O<sub>4</sub> (M = Co, Ni, Zn) with particle sizes of ~10 nm. Solutions of metal salts in alcohols have also been processed using high temperatures and pressures to prepare nanoparticles of a variety of metals.<sup>[30,31]</sup>

Sun et al.<sup>[15,32–36]</sup> have developed a reactive supercritical fluid method for the preparation of metal and metal sulfide particles based on the RESS process. In this method, a metal salt is dissolved in a polar solvent, which is then pressurized and heated to supercritical conditions. The supercritical solution is then rapidly expanded through a small nozzle or orifice into a liquid solution containing a second reactant (e.g., reducing agent or sodium sulfide). The method is versatile and can be used with a variety of metal salts, supercritical fluids, and reagents. They have used

this method to prepare nanoparticles of the metals, Ag, Cu, Fe, Ni, and Co, as well as the metal sulfides, CdS, Ag<sub>2</sub>S, and PbS. The particles produced have average diameters of ≤10 nm with particle-size distributions of ~1 nm. Solvents used include methanol, ethanol, acetone, tetrahydrofuran, and ammonia. Particle aggregation is minimized by collecting the sample in liquid solution and can be further prevented through the use of polymer surfactants such as poly(*N*-vinyl-2-pyrrolodone) (PVP).

### Supercritical Fluid Microemulsions

To overcome the limited solubility of polar compounds, particularly metal salts, in carbon dioxide, several researchers have used reverse micelles. Wai et al.<sup>[37,38]</sup> reported the preparation of silver and copper nanoparticles using water-in-CO<sub>2</sub> reverse micelles. Silver and copper salts were dissolved in the aqueous core of reverse micelles formed with sodium bis(2-ethylhexyl) sulfosuccinate (AOT) and the cosurfactant perfluoropolyether phosphate in supercritical carbon dioxide. The cosurfactant perfluoropolyether phosphate is necessary to dissolve the AOT, which is not soluble in carbon dioxide. Addition of a reducing agent to the reverse micelle solutions resulted in the formation of metallic Ag or Cu nanoparticles with 5–15 nm diameters.<sup>[37,38]</sup> AgI, AgBr, and AgCl nanoparticles (3–15 nm) have been prepared by mixing two carbon dioxide microemulsions, one containing AgNO<sub>3</sub> and the other containing NaI, NaBr, or NaCl.<sup>[39]</sup> A fluorinated analog of AOT has been synthesized and used for the preparation of CdS and ZnS nanoparticles by mixing two CO<sub>2</sub> reverse micelle solutions, one containing the metal salt and the other Na<sub>2</sub>S.<sup>[40]</sup> The average diameter was calculated from the band gap and varied from 2.7 to 4.2 nm depending on the water to surfactant ratio. Formation of water-in-CO<sub>2</sub> microemulsions by perfluoropolyether surfactants has been demonstrated<sup>[41–44]</sup> and used to prepare CdS nanoparticles.<sup>[45]</sup> Sun, Atorngitjawat, and Mezziani<sup>[46]</sup> have used perfluoropolyether ammonium carboxylate water-in-CO<sub>2</sub> microemulsions to dissolve AgNO<sub>3</sub>, which was then rapidly expanded into a room temperature solution of sodium borohydride resulting in Ag nanoparticles.

## RESULTS AND DISCUSSION

We have developed a reactive supercritical fluid nanoparticle preparation method based on the RESS process that uses supercritical carbon dioxide as the solvent. In this method, neutral metal salts are dissolved in carbon dioxide using tributyl phosphate

**Fig. 1** Experimental apparatus for the reactive RESS preparation of nanoparticles.

(TBP). The method can be used with a variety of metal salts and can be used for the preparation of both metal and metal sulfide nanoparticles. The particles thus prepared have average diameters of approximately 10 nm, with narrow size distributions. The preparation and characterization of silver and silver sulfide nanoparticles is presented.

### Silver Nanoparticles

The experimental apparatus for the reactive RESS preparation of nanoparticles is shown in Fig. 1. The system consists of an ISCO model 260D syringe pump, a floating piston cylinder (TEMCO model CFT-50-50, 300-cm<sup>3</sup> volume), a high-pressure nitrogen cylinder and regulator, a preheating zone with ~40 ft of 1/16-in. o.d. tubing in an aluminum clamshell, an Omega CN4800 temperature controller with k-type thermocouple in contact with the fluid, a 127- $\mu$ m i.d. by 10-cm-long nozzle, and an expansion chamber. For the preparation of silver nanoparticles, CF<sub>3</sub>SO<sub>3</sub>Ag solution in tributyl phosphate (TBP) was added to the floating piston cylinder, which was filled with liquid CO<sub>2</sub> and pressurized to 2000 psi at room temperature. The amount of CO<sub>2</sub> was gravimetrically determined. The floating piston cylinder was placed on a horizontal platform rocker and allowed to equilibrate for at least 2 hr. The preheating zone was brought to temperature and allowed to equilibrate. A solution of NaBH<sub>4</sub> in ethanol or methanol (150 ml) was immediately prepared before use and was placed in the expansion chamber. The polymer PVP (molecular weight 360,000, ~3.5 mg/mL) was also dissolved in the NaBH<sub>4</sub> alcohol solution to prevent particle aggregation. An excess of sodium borohydride was used for the preparation of all samples ( $[\text{NaBH}_4]/[\text{Ag}^+] = 3\text{--}5$ ). The CF<sub>3</sub>SO<sub>3</sub>Ag solution in CO<sub>2</sub>/TBP was pressurized to 3500 psi using nitrogen on the back side of the piston. The system temperature was equilibrated by flowing CO<sub>2</sub> at 3500 psi for ~5 min. The CO<sub>2</sub> flow was stopped and the CF<sub>3</sub>SO<sub>3</sub>Ag solution flow was initiated and expanded into the NaBH<sub>4</sub> solution.

The NaBH<sub>4</sub> solution immediately turned yellow upon addition of CF<sub>3</sub>SO<sub>3</sub>Ag solution, typical of silver

nanoparticle suspensions. The resulting suspension was then characterized using X-ray diffraction (XRD), transmission electron microscopy (TEM), and UV-Vis absorption spectroscopy. For TEM analysis, a drop of the suspension was placed on a carbon-coated Cu grid, allowed to dry, rinsed with hexane, and then dried in a vacuum oven at 100–120°C overnight to remove residual TBP. For UV-Vis analysis, the samples were diluted to an optical density <1 using 0.2-cm path length cuvettes. For XRD analysis, the sample was dried on a rotary evaporator at up to 80°C. Upon removal of the alcohol, the silver particles and PVP polymer precipitated and the remaining TBP liquid was decanted. The sample was rinsed with hexane and then dried in a vacuum oven. X-ray diffraction patterns for the samples matched the powder diffraction file reference patterns for face-centered cubic silver (04-0783).

Several silver nanoparticle samples were prepared using different expansion temperatures and concentrations of TBP. Transmission electron microscopy analysis and particle-size distributions are shown in Figs. 2–4 for several silver nanoparticle samples.

**Fig. 2** Transmission electron micrograph of silver nanoparticles prepared from supercritical CO<sub>2</sub> solution at 70°C, 3500 psi, with 0.22 wt.% TBP. The particle-size distribution is shown in the inset.

**Fig. 3** Transmission electron micrograph of silver nanoparticles prepared from supercritical CO<sub>2</sub> solution at 110°C, 3500 psi, with 0.24 wt.% TBP. The particle-size distribution is shown in the inset.

Particle diameters and size distributions were determined from the TEM micrographs and are based on a minimum of 200 particles. The samples shown in Figs. 2 and 3 were both prepared using 0.2 wt.% TBP. The sample prepared using a temperature of 70°C has an average particle diameter of 9.9 nm, while the sample prepared at 110°C has an average diameter of 7.4 nm. The particle diameter standard deviation is ~3.5 nm for both samples. Analysis by TEM of a sample prepared using a temperature of 104°C and [TBP]

**Fig. 4** Transmission electron micrograph of silver nanoparticles prepared from supercritical CO<sub>2</sub> solution at 104°C, 3500 psi, with 1.41 wt.% TBP. The particle-size histogram and Gaussian-distribution analysis are shown in the inset.

**Table 1** Properties of silver and silver sulfide nanoparticles prepared by reactive RESS processing using CO<sub>2</sub> solutions

	Temperature (°C)	[TBP] (wt.%)	Diameter (nm)	$\sigma$ (nm)
Silver	70	0.22	9.9	3.4
Silver	110	0.24	7.4	3.5
Silver	104	1.41	12.9	2.2
Silver sulfide	50	0.23	3.1	1.2
Silver sulfide	70	0.23	3.0	1.0
Silver sulfide	110	1.38	7.2	1.8

of 1.41 wt.% has an average diameter of 12.9 nm and a standard deviation of 2.2 nm. Sample preparation conditions and results from TEM analysis are summarized in Table 1. Particle diameter shows a slight dependence on expansion temperature, with smaller particles produced at lower temperature. The particle size and distributions were highly dependent on TBP concentration, with larger, more uniform particles prepared at higher TBP concentrations. The absorption spectra of the 9.9- and 12.9-nm diameter silver nanoparticles are shown in Fig. 5, and both samples exhibit the characteristic surface plasmon absorption band. The 12.9-nm diameter sample is red shifted and broader than the 9.9-nm diameter sample. The absorption maximums are at 406.5 nm (68 nm FWHM) and 399.5 nm (62 nm FWHM) for the 12.9- and 9.9-nm samples, respectively.

### Silver Sulfide Nanoparticles

Silver sulfide nanoparticles were prepared using the reactive RESS processing method. The preparation conditions were the same as those used for the preparation of silver metal nanoparticles except that the expansion chamber contained a methanol solution of

**Fig. 5** Normalized absorption spectra of silver nanoparticles prepared from supercritical CO<sub>2</sub> solutions.

**Fig. 6** Transmission electron micrograph of silver sulfide nanoparticles prepared from supercritical CO<sub>2</sub> solution at 50°C, 3500 psi, with 0.23 wt.% TBP. The particle-size distribution is shown in the inset.

**Fig. 8** Transmission electron micrograph of silver sulfide nanoparticles prepared from supercritical CO<sub>2</sub> solution at 110°C, 3500 psi, with 1.38 wt.% TBP. The particle-size histogram and Gaussian-distribution analysis are shown in the inset.

Na<sub>2</sub>S with PVP. Excess Na<sub>2</sub>S was used in the preparation of all the samples ( $[S^{2-}]/[Ag^+] \approx 7.5$ ). X-ray diffraction analysis of the samples matched the reference pattern for monoclinic Ag<sub>2</sub>S (75-1061). Transmission electron micrographs and particle-size distributions for silver sulfide nanoparticles are shown in Figs. 6–8. Preparation conditions and TEM results are summarized in Table 1. The samples prepared using temperatures of 50°C (Fig. 6) and 70°C (Fig. 7) were both prepared using 0.2 wt.% TBP. The sample prepared using an expansion temperature of 50°C

had an average diameter of  $3.1 \pm 1.2$  nm and the sample prepared using 70°C had an average diameter of  $3.0 \pm 1.0$  nm. The expansion temperature had little, if any, effect on particle size; however, the sample prepared using 50°C had a slightly larger size distribution. Silver sulfide nanoparticles were considerably smaller than silver metal particles prepared using similar conditions. For samples prepared using an expansion temperature of 70°C and 0.2 wt.% TBP, silver nanoparticles were  $9.9 \pm 3.4$  nm, while silver sulfide nanoparticles were  $3.0 \pm 1.0$  nm. Silver sulfide nanoparticles prepared using an expansion temperature of 110°C and 1.38 wt.% TBP had an average diameter of  $7.2 \pm 1.8$  nm (Fig. 8). Particle size and size distribution are larger for the silver sulfide sample prepared using higher TBP concentration. The UV–Vis–NIR

**Fig. 7** Transmission electron micrograph of silver sulfide nanoparticles prepared from supercritical CO<sub>2</sub> solution at 70°C, 3500 psi, with 0.23 wt.% TBP. The particle-size distribution is shown in the inset.

**Fig. 9** Absorption spectra of silver sulfide nanoparticles prepared from supercritical CO<sub>2</sub> solutions.

absorption spectra of the silver sulfide nanoparticle suspensions are shown in Fig. 9. The samples with average diameters of  $\sim 3$  nm have an absorption onset at  $\sim 950$  nm, while the sample with an average diameter of 7.2 nm has an absorption onset at  $\sim 1250$  nm. This is consistent with a shift in band gap (and absorption onset) to higher energies with decreasing particle size for semiconductor nanoparticles.

## CONCLUSION

Silver and silver sulfide nanoparticles with average diameters  $\sim 10$  nm with narrow size distributions have been prepared using a reactive supercritical fluid processing method. In this method, a neutral metal salt is dissolved in  $\text{CO}_2$  using tributyl phosphate. The supercritical solution of the metal salt is rapidly expanded into a liquid solution containing a second reactant, resulting in the formation of metal or metal sulfide nanoparticles. The nanoparticles have been characterized by powder X-ray diffraction, transmission electron microscopy, and absorption spectroscopy. The particle size and size distribution depend on preparation conditions, most notably on TBP concentration.

## INTRODUCTION

Nanotechnology is a catchword that evokes excitement in researchers and captures the imagination of laymen. The excitement in the research community stems from the fact that theoretically predicted variations in the physical properties of solid objects as their dimensions approach a few nanometers ( $1\text{ nm} = 10^{-9}\text{ m}$ )—viz. lowering of melting point, Coulomb charging, novel magnetic, optical phenomena, etc.—have been verified experimentally.<sup>[1–4]</sup> This experimental verification has been possible because of rapid strides made over the last two decades, both in techniques for synthesis and in tools for characterization of individual nanoscale objects. These advances have also opened up a vast array of potential technological applications and have occurred just as the limits of photolithography-based solid-state technology are being reached. Coupled with the revolutionary impact of solid-state electronic devices on our lives, advances in synthesis, manipulation, and characterization of nanomaterials have made nanotechnology—and in particular nanoelectronics—a cynosure of public interest.

There are two alternative approaches for fabricating nanoelectronic devices: the “top–down” and the “bottom–up” approaches. The top–down approach is similar to current photolithographic techniques used to produce microelectronic devices. It consists of “chiseling” nanometer-scale features in bulk materials. Using such techniques as e-beam lithography and x-ray phase shift lithography, this approach can now produce nanoscale features ( $<50\text{ nm}$ ) and has the decided advantage of being compatible with current microelectronic processing methods and design concepts. However, this approach suffers from two important drawbacks: 1) processing costs rise exponentially as feature size decreases; and 2) the surfaces and interfaces produced by this approach exhibit atomic-scale imperfections, which critically degrade device performance as feature size approaches nanometer dimensions. The bottom–up approach consists of “building” the device or circuit by assembling it from

preformed nanoscale “bricks.” Bottom–up processing, involving the serial manipulation of nanoscale objects, is technologically impractical. However, it is often possible to induce nanoscale objects to assemble themselves into desired structures. It is such biologically inspired self-assembly which holds the greatest promise.

There are a number of interesting nanoelectronic building blocks, viz. metal nanocrystals and nanowires (both magnetic and non-magnetic), semiconductor nanocrystals and nanowires, and carbon nanotubes. In this entry, we focus solely on non-magnetic metal nanocrystals. Two characteristics of metal nanoparticles are critical for assessing their usefulness in nanoelectronic applications: 1) the ease with which bare metal particles cold weld on contact to form hard aggregates; and 2) the tendency of metal particles to oxidize in an atmospheric environment especially in the presence of water molecules. The first characteristic means that the surface of a metal nanoparticle must be passivated by attachment of a monolayer of capping ligands or surfactant molecules before any attempt is made to assemble these particles into a uniform nanostructure. We will refer to such encapsulated particles as molecularly protected nanoparticles (MPNs). The second characteristic means that only noble metals such as Au and Ag will form nanoparticles that are not rapidly oxidized when exposed to an atmospheric environment. Linear alkanethiol molecules readily react in solution with both Au and Ag nanoparticles to form stable MPNs. These MPNs can be manipulated as stable physical species in a variety of organic solvents. The ability to manipulate Au and Ag MPNs in organic liquids, to synthesize macroscopic quantities of these particles with diameters in the 2–20 nm range, and to control the interparticle spacing in arrays of these particles by changing the length of the alkanethiol molecules coating the metal core make Au and Ag MPNs ideal building blocks for the self-assembly of nanoelectronic devices. To date, most studies of metal MPNs are of Au nanoparticles encapsulated by an alkanethiol monolayer.

## ELECTRONIC APPLICATIONS OF METAL NANOPARTICLES

The simplest metal nanoparticle-based electronic material is fabricated by suspending Au MPNs in an organic solvent such as toluene, casting or spraying this suspension on a solid substrate, and allowing the solvent to evaporate. The nanoparticles agglomerate as the solvent evaporates to form a loosely aggregated solid. If the original suspension is dilute and care is taken to allow the solvent to evaporate slowly, small 3-D superlattice domains or “ordered MPN crystals” form as the suspension becomes supersaturated; however, in general, the solid phase that forms is amorphous. The closest interparticle spacing in the solid is determined by the length of the alkanethiol molecules encapsulating the Au particles. Because this spacing is on the order of a nanometer, these amorphous solids are weak electrical conductors in which electrons tunnel through the organic layers separating the Au particles and hop from particle to particle. Snow and Wohltjen<sup>[5]</sup> have measured the electrical conductivity of amorphous films of Au MPNs as a function of the ratio of the diameter of the gold core to the length of the alkanethiol encapsulant. They measured electrical conductivities ranging from  $10^{-6}$  to  $10^{-12}$  ( $\Omega \text{ cm}$ )<sup>-1</sup> and found that the conductivity at a given temperature increases as this ratio is increased. They have also shown that, when such an MPN solid is exposed to volatile organic vapors, its electrical conductivity is a function of the partial pressure of the organic molecule.<sup>[6]</sup> This effect is most probably because of the absorption of the organic molecule into the alkanethiol layer surrounding the gold nanoparticles. Quantum tunneling varies exponentially with distance, and a small swelling of this layer results in a large variation in tunnel resistance. Thus even as simple a structure as an amorphous solid of Au MPNs constitutes an interesting electronic material, and a film of this nanostructured material can act as a chemiresistive sensor. Unfortunately, films of alkanethiol-coated Au nanoparticles are not strongly species-selective.<sup>[6]</sup> However, adding different chemical functionalities to

the ligand shell around the Au particles may be a way to increase the chemselectivity of the film.

Amorphous films of Au MPNs can also be used to fabricate low-resistance electrical conductors on flexible substrates. Low-resistance conductors are important components of high- $Q$  inductors, capacitors, tuned circuits, and interconnects. An inexpensive method for fabricating such conductors on flexible substrates is critical for the development of ultralow-cost microelectronic systems such as radiofrequency identification tags. Using a dense suspension of Au MPNs in a volatile organic liquid, it is possible to print micron-thick lines via either ink jet or silk screen techniques on a substrate. If the Au particle diameter and the alkanethiol encapsulant are optimized, these low-conductivity Au MPN lines can be converted into high-conductivity Au lines. This transformation is made possible by the low melting temperature and low shear resistance of Au nanoparticles.<sup>[2,7,8]</sup> It is accomplished either by thermally annealing the lines at a relatively low temperature ( $<150^\circ\text{C}$ ),<sup>[9]</sup> or by exposing them to laser radiation.<sup>[10]</sup>

Although the electrical conduction behavior of an amorphous film of Au MPNs has technological potential, placing a single Au MPN between two electrodes provides a much richer range of electronic behavior. In this configuration (Fig. 1), the nanoparticle is able to suppress all electrical conduction at low-bias voltages. This phenomenon is called “Coulomb blockade.” Coulomb blockade occurs when the electrostatic energy increase caused by adding a single electron on a capacitively coupled metal island is much larger than the thermal energy of the electrons:

$$e^2/2C \gg k_B T \quad (1)$$

where  $e$  is the charge on an electron,  $C$  is the effective capacitance of the metal island,  $k_B$  is the Boltzmann constant, and  $T$  is the absolute temperature of the metal island. In the case of metal MPNs, the capacitance  $C$  is directly proportional to the radius of the metal nanoparticle. For room temperature operation,

**Fig. 1** (A) Schematic representation and equivalent circuit of nanostructure consisting of a single metal MPN placed between two electrodes. (B) Ideal  $I$ - $V$  curve for this nanostructure illustrating Coulomb blockade at low bias and Coulomb staircase as bias is increased.

Eq. 1 is satisfied when the particle diameter is less than approximately 2–3 nm. Larger particles are able to suppress all electron transport only if their temperature is lowered. For Coulomb blockade to be observed, the tunneling resistance ( $R$ ) to and from the metal island must also be much greater than the resistance quantum ( $R_Q$ ):

$$R \gg R_Q \quad (2)$$

where  $R_Q = h/2e^2$  ( $\sim 12.9 \times 10^3 \Omega$ ), with  $h$  being the Planck's constant.

When both Eqs. 1 and 2 are satisfied, the  $I$ - $V$  curve for an asymmetric junction  $\{R_R \gg R_L \text{ or } R_L \gg R_R\}$  shows characteristic steps in the current, called "Coulomb staircase" (Fig. 1). The asymmetry in the resistance means that the flow of electrons is controlled either at the right or left tunnel junction, and so electrons tend to accumulate on the metal island. Because of the electrostatic energy associated with the charging of the island, an additional electron is not added at steady state until this excess energy is compensated for by increasing the external bias. Both Coulomb blockade and Coulomb staircase phenomena have been experimentally verified at room temperature using an Au MPN.<sup>[3,11]</sup> In this experiment, a scanning tunneling microscope (STM) was used to measure the  $I$ - $V$  characteristics of a vertical nanostructure, fabricated by depositing a single 2-nm-diameter gold particle on a gold substrate that had been coated with a self-assembled monolayer (SAM) of a double-ended thiol molecule.

The structure shown in Fig. 1 is the simplest example of a large class of nanoelectronic logic and data storage devices that are based on the controllable transfer of single electrons between small conducting islands separated by tunnel barriers.<sup>[12]</sup> For example, Tucker<sup>[13]</sup> proposed a nanoscale field effect transistor (FET) based on modulating the voltage range of the Coulomb blockade by applying an asymmetric bias on a conducting island transverse to the direction of

current propagation. Fabrication of such a single electron tunneling-field effect transistor (SET-FET), using metal nanoparticles, requires the ability to place 1-D chains of metal MPNs on an insulating substrate with variable interparticle spacing and the ability to address a nanoparticle having a diameter of  $\sim 2$  nm from three directions. At present, there does not appear to be any way to self-assemble such a device. Although, in principle, any SET architecture can be constructed using metal MPNs, the technical difficulties involved in self-assembling complex SET circuits that can operate at room temperature seem overwhelming.

Roychowdhury, Janes, Bandyopadhyay<sup>[14]</sup> have suggested a logic architecture (Fig. 2) involving metal MPNs that does not require room temperature Coulomb blockade for its operation. This architecture consists of a uniform 2-D array of Au MPNs with input and output addressing along the edges of the array. The nanoparticles are coupled through electron tunneling barriers both to each other and to a semiconductor substrate that is a resonant tunneling diode (RTD) structure. The computation is performed by allowing the array to relax to its ground state, which depends on the Coulomb interactions of adjacent islands for a particular set of input voltages. This 2-D array architecture is compatible with the self-assembly and microcontact printing techniques described later in the present entry, and recent reports on the formation of 8-nm-wide metallic lines<sup>[15]</sup> and addressable cantilever arrays<sup>[16]</sup> suggest that edge addressing issues and even readout of the charge state of individual nanoparticles may be tractable.

The weak interaction forces that exist between metal MPNs, although ideal for promoting self-assembly from solution, are not strong enough to produce 1-D, 2-D, or 3-D arrays that are structurally robust. Thus it is often necessary to strengthen the self-assembled structures formed by Au MPNs. This can be accomplished by displacing the monofunctional alkanethiol molecules coating the particles with difunctional molecules that bind the particles to each other or to the substrate. Both dithiol molecules and diisonitrile

**Fig. 2** Schematic of nanoelectronic architecture proposed by Roychowdhury et al. for Boolean logic. Nanostructure consists of an ordered 2-D array of Au MPNs linked to a RTD substrate. *Source:* From Ref.<sup>[14]</sup>. ©IEEE, 1997.

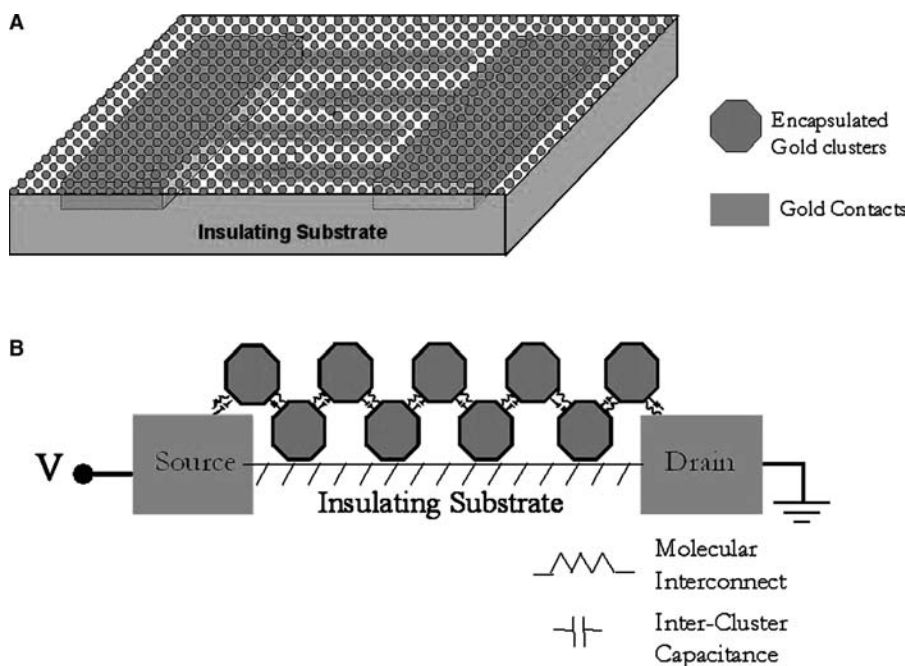

molecules are able to displace monothiol molecules from Au.<sup>[17,18]</sup> Attaching conjugated molecules having distributed electronic states in the gap between adjacent metal nanoparticles in an array, or between a metal nanoparticle and a substrate, is also an attractive way to self-assemble another kind of electronic nanostructure. The metal–molecule–metal bridge that is established in this manner is the focus of the emerging field of molecular electronics.<sup>[19,20]</sup> The diode structure shown in Fig. 1 can now be thought of as being replaced by one in which the conjugated linking molecule takes the place of the Au MPN. To date, experimental measurements of electron transport through such metal–molecule–metal structures have been attempted either by introducing a “nano” gap between two metal electrodes and adsorbing the desired organic molecules on the electrodes, or by STM manipulation of metal atoms and a single organic molecule on a substrate. An elegant example of this latter type of experiment is reported in the recent paper by Nazin, Qiu, and Ho<sup>[21]</sup> Although interesting electronic behavior has been demonstrated,<sup>[22]</sup> the problem of how to self-assemble logic or memory circuits is still unsolved. A fruitful approach to this problem may be to self-assemble molecular electronic devices using “linked arrays” of metal MPNs.

Au MPNs have been used to fabricate lateral structures that are linked by conjugated molecules. Andres et al.<sup>[17]</sup> fabricated a linked monolayer of Au nanoparticles in the gap between lithographically defined electrodes by first self-assembling a uniform superlattice array of Au MPNs and then by replacing the alkanethiol molecules coating the Au particles with

difunctional conjugated molecules. They measured electron transport in this monolayer film. Datta et al.<sup>[23]</sup> have proposed the use of quasi-1-D conductive ribbons of linked metal nanoparticles, which they term “molecular ribbons,” as interconnects for semiconductor devices. It is difficult to fabricate linked monolayer films that are free of defects when the length of the linking molecule does not closely match the spacing in the original MPN array. One way to solve this problem is to fabricate a linked bilayer film, such as that shown in Fig. 3.<sup>[24]</sup> This bilayer consists of two monolayers of Au MPNs with a molecular interconnect covalently linking the two layers. This nanostructure has been proposed as the basis of a novel chemiresistive sensor.<sup>[24]</sup> It is hypothesized that target molecules that ligate with the linking molecules will shift the electronic energy levels of the linking molecules, thereby changing the tunnel resistance between the two layers and the electrical conductivity of the film. If this hypothesis is confirmed, this scheme would provide a generic method for fabricating chemiselective sensing elements.

Au MPNs have also been used to construct linked vertical structures. They have been utilized as nanoscale contacts on a semiconductor substrate<sup>[25]</sup> and as nanoscale switches on top of redox molecules.<sup>[26]</sup> Such linked vertical structures represent an attractive paradigm for molecular electronics-based devices.

Metal MPNs are also being studied for hybrid microelectronic applications such as floating gate memory cells and multiple tunnel junction devices.<sup>[27,28]</sup> Metal nanoparticles provide an attractive choice for these applications because of the abundance

**Fig. 3** Schematic representation of a chemiresistive sensor element proposed by Santhanam. (A) Plane view and (B) cross-sectional view. This bilayer forms the channel of an electrical diode. *Source:* From Ref.<sup>[24]</sup>.

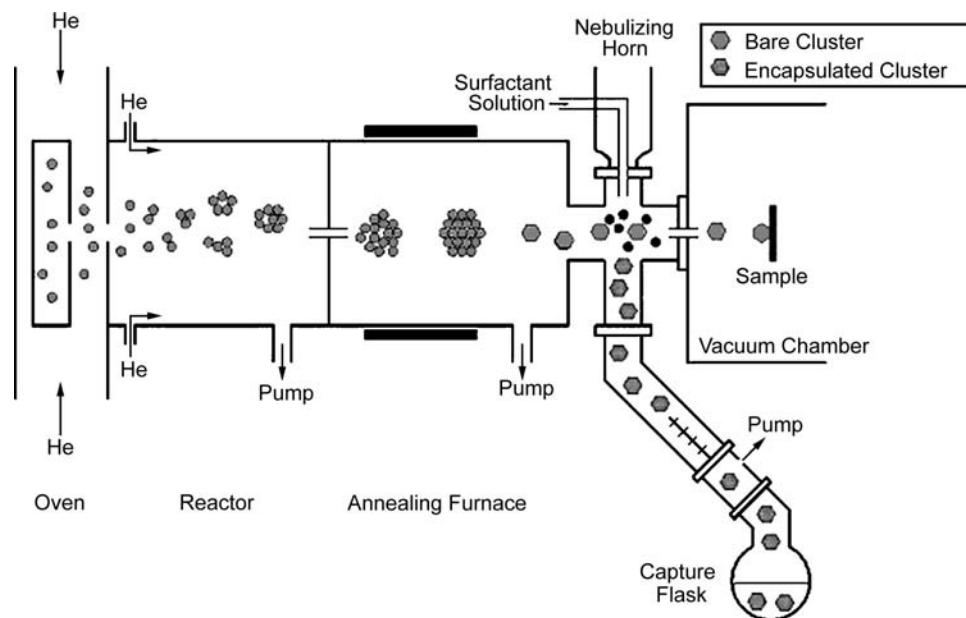

of electrons near the Fermi level and the ability to tune their work function by changing the metal.

## MPN SYNTHESIS

Metal MPNs can be synthesized either in the gas phase or in liquid solution. In either case, the essential requirement for synthesizing particles with a narrow size distribution is to initiate a temporally discrete homogeneous nucleation event followed by a slow growth regime, and to prevent particle aggregation. An apparatus for gas-phase synthesis of metal nanoparticles is shown schematically in Fig. 4.<sup>[29,30]</sup> Metal atoms, evaporated from a single crucible or a series of crucibles located in a resistively heated oven, are entrained in helium and induced to condense by mixing the hot flow from the oven with a room temperature stream of helium. Controlling conditions in the oven and helium flows controls the mean particle size. The particles are thermally annealed in the gas phase by passing the aerosol mixture through a tube furnace. They are scrubbed from the gas phase by contact with a mist of organic solvent containing surfactant molecules and collected as a stable colloidal suspension. The reactor shown in Fig. 4 also has provision for expanding a portion of the aerosol stream into a vacuum chamber to form a particle beam. Potential advantages of gas-phase synthesis are: 1) the ability to synthesize extremely small particles and to vary

the mean particle size over a wide range; 2) the ability to produce pure metal particles, which may then be encapsulated with a wide variety of surfactants; 3) the ability to produce mixed metal particles even when the constituent metals are immiscible at room temperature; and 4) the ability to thermally anneal metal particles before encapsulating them with an organic surfactant.

Solution-based techniques for the synthesis of metal nanoparticles are based on the reduction of positively charged metal ions or ion complexes in solution usually in the presence of a capping ligand to arrest particle growth at a desired size. The major advantage of solution synthesis is the simplicity of the required equipment. The major disadvantage is the need for removal of excess reactants and for isolation of the particles as pure MPNs. In the case of Au particles, encapsulation by alkanethiols simplifies the isolation and purification steps greatly. A general technique for solution synthesis of nanoparticles with a controlled size and a narrow size distribution is to isolate small volumes of aqueous solution in which particle growth takes place by means of nonionic inverse micelles.<sup>[31,32]</sup> However, two homogeneous solution methods are more commonly used for the production of Au MPNs. The first method is reported by Brust et al.<sup>[33]</sup> This is a two-phase (water–toluene) reduction of  $\text{AuCl}_4^-$  by sodium borohydride in the presence of an alkanethiol. The Au ions are transferred to the toluene phase using tetraoctylammonium bromide,

**Fig. 4** Schematic representation of an aerosol reactor used to produce metal MPNs with a narrow size distribution. Metal atoms are condensed in a helium flow to form bare metal clusters (nanoparticles). The aerosol containing the nanoparticles then passes through an annealing furnace, after which the particles are encapsulated with an appropriate surfactant molecule and captured as a colloidal suspension.

where they are simultaneously reduced by borohydride and capped by the alkanethiol. Once encapsulated Au particles have formed, they are precipitated from the toluene solution by the addition of a polar solvent, and then washed, dried, and resuspended in a non-polar solvent such as toluene, hexane, or chloroform. The second method is reported by Giersig and Mulvaney.<sup>[34]</sup> This method makes use of the classical method of Turkevich, Stevenson, and Hillier<sup>[35]</sup> which produces charge-stabilized Au particles by reduction of  $\text{AuCl}_4^-$  in water using trisodium citrate as the reducing agent. An alkanethiol dissolved in tetrahydrofuran (THF) is then added to this aqueous solution, causing encapsulation of the Au particles and their gradual flocculation. The capped Au particles can be extracted into cyclohexane. They are precipitated from cyclohexane by the addition of a polar solvent, and then washed, dried, and resuspended in a nonpolar solvent. Au MPNs produced by the Giersig method retain a residual charge before they are extracted into cyclohexane and can be deposited on a conducting substrate by electrophoresis.<sup>[34]</sup> After they have been washed, dried, and resuspended in a nonpolar solvent, there does not seem to be any difference between Au MPNs produced by the two methods; however, the Brust method appears to be more suitable for the synthesis of smaller particles (<5 nm) and the Giersig method appears to be more suitable for the synthesis of larger particles (>5 nm).

The standard deviation of the diameter distribution of particles synthesized by either the Brust method or the Giersig method is about 10%. The size distribution can be narrowed by fractional crystallization.<sup>[36]</sup> This involves selective precipitation of the particles in a solvent mixture containing a good solvent and a poor solvent such as toluene/acetone. Whetten et al.<sup>[37]</sup> have used selective precipitation in the presence of excess alkanethiol surfactants to refine the size distribution of Au MPNs synthesized by the Brust method. Starting with Au MPNs having a mean diameter in the 1- to 2-nm range, they were able to prepare monodispersed samples having a fixed number of gold atoms. Stoeva et al.<sup>[38]</sup> have found that it is possible to refine both the size distribution and faceting of Au MPNs simply by heating a concentrated suspension of the particles in a process they have termed “digestive ripening.”

Au MPNs produced by solution synthesis are compact, nearly spherical particles with a narrow size distribution that can be improved by size-selective precipitation; however, the gold cores are not necessarily faceted single crystals. Whetten et al.<sup>[37]</sup> report that in the 1.5- to 3.5-nm range, Au MPNs synthesized by the Brust method have faceted gold cores that are primarily single crystals with a face-centered cubic (FCC) lattice and a lattice constant close to the bulk gold value of 0.409 nm. High-resolution transmission

electron microscopy (HRTEM) analysis of Au MPNs that were synthesized by the Giersig method with diameters in the 5- to 20-nm range reveals that these particles are primarily polycrystalline.<sup>[39]</sup> This is also true for Au MPNs with diameters greater than a few nanometers that are synthesized by gas-phase condensation, unless they are thermally annealed by heating them above their melting temperature and then allowing them to recrystallize in the gas phase. Then they become predominately single crystals or singly twinned crystals with an FCC lattice and a lattice constant of 0.409 nm.<sup>[24,39]</sup>

The ultimate Au MPN as far as controlled size and crystal structure are concerned is the triphosphine ligand-protected 55-gold-atom particle synthesized by Schmid et al.<sup>[40]</sup> almost two decades ago. These particles have an icosahedral geometry and exhibit Coulomb blockade behavior at room temperature. They played an important role in establishing the quantum size behavior of metal MPNs and in suggesting possible electronic applications of encapsulated metal nanoparticles.<sup>[41,42]</sup> However, the complex synthesis of these particles, which requires anaerobic conditions and diborane as a reducing agent, and the difficulty of replacing the triphosphine ligands with other ligands have led to these particles being studied much less than alkanethiol-encapsulated Au particles. A more convenient synthesis technique and schemes for utilizing exchange reactions to modify the characteristics of these particles have been reported.<sup>[43]</sup>

Because of their simplicity and flexibility, the solution-based synthesis routes of Brust et al.<sup>[33]</sup> and Giersig and Mulvaney<sup>[34]</sup> are currently the methods of choice for preparing Au MPNs for electronic applications. Similar solution-based methods are available for preparing semiconductor and magnetic metal MPNs.<sup>[36,44]</sup> Methods utilizing safer solvents and biosynthetic routes are being explored to address environmental concerns.<sup>[45,46]</sup>

## FABRICATION OF ORDERED MPN ARRAYS

The ability to assemble nanometer-scale metal islands or particles into ordered arrays is a prerequisite for the successful fabrication of nanoscale electronic devices based on these building blocks. In what follows, we focus on self-assembly methods involving metal MPNs. “Top-down” approaches using resist-based lithographic patterning will not be discussed at all. However, two methods that do not make use of metal MPNs are worth mentioning. The first technique is to self-assemble an ordered monolayer of polystyrene or silica spheres on a substrate and thermally evaporate metal atoms onto this colloidal mask. This results in nanometer-scale metal deposits forming on

the areas of the substrate not masked by the colloidal spheres.<sup>[47]</sup> The second technique involves synthesis of metal nanoparticles inside structures formed using diblock polymers.<sup>[48,49]</sup> The major drawbacks of both of these schemes are that the metal islands or particles have largely uncontrolled shapes and typically have interparticle spacings much larger than molecular dimensions. Because of the ease by which Au nanoparticles can be thermally annealed, the first of these drawbacks may not be severe in the case of Au. Nevertheless, the large interparticle spacings make it difficult to see how electronic circuits can be fabricated using these methods. Self-assembly of MPNs that have been preselected as to size, shape, and surface chemistry into ordered arrays seems to be the most promising approach for fabricating nanoscale electronic devices.

### 3-D Arrays

Starting with metal MPNs that have a narrow size distribution, it is relatively easy to produce ordered 3-D arrays or superlattices, in which the MPNs take the place of atoms in conventional crystals. Ordered 3-D arrays are formed by supporting a drop of the colloidal nanoparticle suspension on a flat surface and slowly evaporating the solvent. Encapsulated metal nanoparticles typically self-assemble into an FCC or HCP superlattice.<sup>[38,50]</sup> Faceted, single-crystal Au MPNs often adopt preferred orientations in both 2-D and 3-D arrays in which the (111) atomic planes of each Au particle align parallel to the (111) atomic planes of all the other Au particles and to the surface of the supporting substrate.<sup>[38,39]</sup>

### 2-D Arrays

Uniform, close-packed monolayers of MPNs are an essential component of many proposed nanoelectronic

devices. There are several techniques for fabricating nanoparticle monolayers by self-assembly. These fall into three categories: 1) field-enhanced or molecular interaction-induced deposition from a colloidal solution of MPNs onto a solid substrate; 2) drop casting or spin coating of a suspension of MPNs onto a solid substrate and allowing of the solvent to evaporate; and 3) spreading of a suspension of hydrophobic MPNs in an organic solvent on a water surface, allowing of the solvent to evaporate, and transferring of the floating MPN film to a solid substrate.

Giersig and Mulvaney<sup>[34]</sup> employed electrophoretic deposition at field strengths of 1 V/cm to deposit a monolayer of Au MPNs on a carbon film-coated TEM grid. The monolayer was polycrystalline with small hexagonal close-packed domains. When the nanoparticles were deposited without an electric field, no ordering was observed. The adsorption of MPNs from solution onto functionalized surfaces has also been used to form nanoparticle monolayers. In this case, the substrate is coated with a “tether” molecule having a strong affinity for the particles. The substrate is immersed in a colloidal solution of MPNs, removed after a period of time, and rinsed to remove unbound particles. The MPN monolayer formed in this manner is amorphous and is seldom dense (Fig. 5A).<sup>[51,52]</sup> This approach can also be used to form multilayers if, after the deposition of each monolayer, the monofunctional molecule encapsulating the particles is replaced by a difunctional molecule such as a dithiol. The major drawback of these methods for electronic applications is the lack of long-range order in the particle film.

The simplest method of forming a monolayer of MPNs is to spread a thin film of a colloidal suspension containing the particles either by drop casting or spin coating on a substrate that is wet by the solvent, and to allow the solvent to evaporate.<sup>[17]</sup> As the solvent evaporates, small monolayer islands form on the substrate. These islands result from the breakup of the

**Fig. 5** Examples of nanoparticle monolayers self-assembled by three different methods. (A) Scanning electron microscopy (SEM) micrograph of a monolayer formed by adsorption of the particles onto a substrate coated with a bifunctional tether molecule. (B) SEM micrograph of a monolayer produced by compression of nanoparticle rafts on a Langmuir trough. (C) TEM micrograph of a monolayer formed by drop casting a colloidal suspension of nanoparticles on a carbon film-coated TEM grid. *Source:* From Ref.<sup>[51]</sup>. ©ACS, 2000. From Ref.<sup>[56]</sup>. ©AIP, 2001.

liquid film because of dewetting as the film thickness approaches molecular dimensions. The monolayer islands are dense and consist of small hexagonal close-packed domains (Fig. 5C). An important parameter for optimizing the size and degree of order in these monolayer domains is the rate of evaporation of the solvent. However, the key to forming large ordered regions are the uniformity and smoothness of the substrate.<sup>[53]</sup> Surface nonuniformities arrest the lateral mobility of the nanoparticles and result in microscopic voids and grain boundaries in the particle film.

A liquid/liquid interface, because of its inherent uniformity in the lateral direction and non-uniformity in the vertical direction, provides an ideal surface for self-assembling 2-D arrays of nanoparticles. Usually the self-assembly process is carried out by casting an organic suspension containing nanoparticles, which are encapsulated by a hydrophobic molecule, on a water surface and by allowing the solvent to evaporate. The number of nanoparticles spread on the water surface is taken to be smaller than the number needed to form a dense monolayer. When the organic solvent evaporates, discrete monolayer rafts of nanoparticles form on the water surface. These monolayer domains are often well-ordered but cover only a fraction of the surface area. A dense monolayer is obtained by decreasing the area available to the particle rafts using a Langmuir trough.<sup>[54–56]</sup> As the area of the trough is decreased, the monolayer rafts collide with each other and coalesce. Without an organic solvent present, the monolayer domains typically exhibit solidlike behavior and resist deformation. Collier et al.<sup>[57]</sup> were able to make use of the rigid behavior of a nanoparticle film supported on a water surface to carefully compress a film of Ag MPNs and to measure a reversible insulator-to-metal transition as the film was compressed and the tunneling distance between adjacent particles was decreased. Unfortunately, this rigid behavior often results in microscopic voids (Fig. 5B) and multilayer domains in monolayers assembled using a Langmuir trough.<sup>[56]</sup>

Schmid and Beyer<sup>[58]</sup> have proposed an intriguing variation on the classical technique. They introduce an amphiphilic molecule that has a strong affinity for the nanoparticles to assist in the formation of an ordered particle monolayer. They first self-assemble a

layer of these molecules at an organic / water interface. When nanoparticles are introduced to the system, they adsorb on the amphiphilic layer and assemble into monolayer sheets or ribbons, depending on the experimental conditions.

Santhanam et al.<sup>[59]</sup> have also proposed a modification of the classical technique. They are able to self-assemble uniform, ordered 2-D arrays of Au MPNs on a water surface by controlling the nucleation and growth of the particle monolayer. This is accomplished by designing a cell that establishes a “concave” lens of colloidal solution on the water surface (Fig. 6). As the solvent evaporates, the organic layer thins fastest at the center of the cell and, at some point, a monolayer array of MPNs nucleates at this spot. The periphery of this 2-D array is defined by a circular contact line. As more solvent evaporates, additional MPNs deposit at the edge of the particle monolayer, and the contact line moves steadily outward. The advantage of this technique is that new particles are added to the growing monolayer in the presence of solvent molecules. This ensures enough particle mobility to largely eliminate microscopic holes and grain boundaries, and promotes the formation of a close-packed crystalline monolayer. Figure 7 shows a photograph of a film of 5-nm-diameter Au MPNs that was self-assembled on a water surface using this technique. The different hue seen near the edge of the cell arises from the increased curvature of the water interface at the cell wall, which leads to contact line instabilities. This results in alternating bands of multilayer regions surrounding the uniform monolayer region in the center of the cell. Figure 7 also shows TEM micrographs of samples of this Au MPN film taken near the center and the edge of the cell. These images clearly illustrate the long-range translational ordering of the monolayer that forms in the center of the cell and the nature of the multilayer bands that form at the edge of the cell. A bilayer film can be produced on the water surface simply by increasing the concentration of the particles in the initial colloidal solution.

Once a high-quality monolayer of MPNs is self-assembled on the water surface, if it is to be used for constructing an electronic device, it must be transferred to a solid substrate. This transfer has been accomplished by either dipping the substrate through the

**Fig. 6** Schematic illustration of the process proposed by Santhanam et al. for self-assembly of a uniform close-packed monolayer of metal MPNs by controlling the nucleation and growth of the monolayer film on a water surface. *Source:* From Ref.<sup>[59]</sup>. ©ACS, 2003.

**Fig. 7** Photograph of a film of 5-nm-diameter Au MPNs that were self-assembled on a water surface using the method of Santhanam et al. The two inserts are TEM micrographs of samples of this nanoparticle film that were transferred to carbon film-coated TEM grids. The upper insert is taken from the central portion of the film, which is a uniform close-packed monolayer with a diameter of approximately 1 cm. The lower insert is taken from the outer edge of the film and shows one of the multilayer bands that form near the wall of the cell. *Source:* From Ref.<sup>[59]</sup>. ©ACS, 2003.

water surface and slowly withdrawing it [Langmuir–Blodgett (LB) method], or by holding the substrate parallel to the water surface and touching it to the nanoparticle film [Langmuir–Schaefer (LS) method]. Although Santhanam et al.<sup>[59]</sup> found the LS method preferable, it proved unsatisfactory when the substrate was large and/or hydrophilic. As a result, they developed a two-step transfer process. First, using the LS method, the nanoparticle film is transferred from the water surface to a polydimethylsiloxane (PDMS) pad. After carefully wicking off any water drops that adhere to the transferred nanoparticle film, the PDMS pad is then pressed conformally onto the desired substrate. This technique is analogous to conventional microcontact printing,<sup>[60]</sup> with the nanoparticle monolayer taking the place of the molecular ink. This two-step printing technique facilitates the formation of MPN films with a controlled number of layers. This

can be achieved either by repeating the process for a desired number of cycles and printing the monolayers one on top of the other, or by picking up the monolayers successively onto the same elastomeric pad and then using a single printing step. The use of a PDMS stamp also allows the formation of patterned monolayer and multilayer arrays of MPNs by using an appropriately structured elastomeric pad.<sup>[24,61]</sup> Fig. 8 shows TEM images at three different magnifications of a bilayer film of 5-nm-diameter Au MPNs that has been patterned into a series of micron-scale lines and printed on a  $\text{Si}_3\text{N}_4$  substrate.<sup>[24,61]</sup>

### 1-D Arrays

The ability to form 1-D arrays or thin ribbons of metal MPNs is important in the context of using linked metal

**Fig. 8** TEM micrographs of a bilayer film of 5-nm-diameter Au MPNs that were deposited as a pattern of parallel lines on a silicon nitride substrate using the two-step process proposed by Santhanam et al. The low-magnification micrograph on the left shows the lines printed on the substrate. The higher-magnification micrograph in the center shows the relatively sharp edge of one of the lines. The highest-magnification micrograph on the right shows the dense close-packed nanostructure of the film at the edge of one of the lines. (From Ref.<sup>[61]</sup>. ©ACS, 2003.)

MPNs as interconnects. However, because metal MPNs are nearly spherical in shape, this is a difficult pattern to produce by self-assembly and can be accomplished only with the help of appropriate templates to direct the self-assembly process. For example, carbon nanotubes, long-chain polymers, and DNA strands can be decorated with MPNs to produce quasi-1-D chains, and MPNs can be assembled inside a nanotube or adsorbed on a thin line fabricated on a substrate. Hornyak et al.<sup>[62]</sup> have synthesized nanoporous alumina membranes with controlled pore size and narrow pore size distribution, and used the pores as a template to form quasi-1-D chains of Au MPNs. A colloidal solution of the particles was drawn by means of a vacuum into the pores. On evaporation of the solvent, some of the pores were found to be filled with MPN chains. Gleich, Chi, and Fuchs<sup>[63]</sup> made use of the wetting instability of a monolayer transferred onto a solid substrate to produce channels on the order of 200 nm in width and were able to form quasi-1-D chains of MPNs by drop casting a colloidal solution onto this template. Quasi-1-D arrays or ribbons of MPNs have also been prepared by patterning a 2-D monolayer of MPNs using e-beam lithography.<sup>[64]</sup> In principle, the PDMS stamping technique described in “2-D Arrays” could be extended to produce nanometer-scale ribbons of metal MPNs using an appropriate master to mold the PDMS stamp. The technique of Melosh et al.,<sup>[15]</sup> which makes use of selective etching of a GaAs/AlGaAs superlattice to generate thin parallel trenches, could possibly be used as the master, or a master could be generated using e-beam lithography and PMMA resist.

## CONCLUSION

Au MPNs are attractive building blocks for fabricating nanoelectronic devices by self-assembly. The synthesis of Au MPNs with a mean diameter in the 2- to 20-nm range, with a narrow size distribution, and with a monolayer coating of alkanethiol molecules is, by now, a standard procedure. The assembly of these particles to form chemiresistive films and low-resistivity printable conductors is well established. Recent results describing the self-assembly of high-quality monolayer films of Au MPNs on a water surface and the discovery that these films can be transferred as patterned close-packed arrays onto any reasonably flat substrate have opened up a wide range of potential nanoelectronic applications. What remains is the need to establish methods to reproducibly link these ordered arrays of alkanethiol-encapsulated gold particles with conjugated organic molecules to form nanometer-scale interconnects and molecular electronic circuits.

# Metal Nanostructures: Synthesis Controlled by Photoexcitation

Kei Murakoshi  
Yoshihiro Nakato

*Department of Chemistry, Osaka University, Osaka, Japan*

## INTRODUCTION

The current interest in the structural control of metal and semiconductor materials in the nanoscale region has been rapidly promoted in terms of construction of ultrasensitive and low-energy-consumption devices.<sup>[1]</sup> Recently developed nanodevice technologies using scanning probe microscopy have allowed us to construct ultrasmall structures on an atomic scale.<sup>[2]</sup> However, this method is not adaptable to mass production because it is too slow, especially for sizes of more than a few nanometers. This situation, together with the limitation of the size control to about a hundred nanometers for conventional photolithographic techniques, clearly indicates that the creation of nanodevices sized between a few nanometers and tens of nanometers remains an undeveloped aspect of the present nanotechnology (Fig. 1). Thus we should develop methods of effective and high-speed construction of desirable nanostructure in this size region.

To solve the problem, we have proposed the idea of applying localized photoexcitation at metal nanostructures for the structural controls. Generally, metal nanoparticles such as Au, Ag, and Cu show characteristic surface plasmon absorption in the visible–near-infrared wavelength region (Fig. 2).<sup>[3,4]</sup> The electric field induced by excited surface plasmons is highly localized, and the direction of its polarization can be controlled by changing the wavelength and polarization of illumination light. Thus if the localized field can be utilized to induce electrochemical reactions, such as metal dissolution and deposition, the effect can be applied to change and control the metal nanostructures (Fig. 3).

## OVERVIEW

There have been numerous reports on structural changes of metal nanoparticles under photoillumination,<sup>[5,6]</sup> unfortunately, most of them describe fragmentation and structural deformation of the particles. There are

few reports concerning structural control in a nanometer region by photoillumination. Generally, it is known that the quantum efficiency of photoelectrochemical reactions at metals is extremely low because of the very short lifetime of photoexcited electrons or holes in the system. But it should be noted that there are several interesting examples to prove the possibility of the plasmon-mediated photoinduced electron transfer phenomenon in photoemission experiments using roughened metal electrodes.<sup>[7–11]</sup> For example, Fedurco et al.<sup>[7]</sup> reported that increments in photocurrent reduced carbon dioxide in solution at roughened Ag electrode. The quantum yield of the photocurrent exhibited a sharp maximum at the peak wavelength of surface plasmon of Ag electrode. The results suggest that plasmon-mediated photoinduced electron transfer at metal electrode may be possible if an appropriate electron acceptor/donor exists at the interface. Metal deposition and dissolution could be involved in the reactions for the structural control.

In this review, we summarize our recent developments to control metal nanostructures via photoillumination. After brief summaries of the research, the possibilities of future applications will be discussed.

## PHOTOINDUCED ANISOTROPIC AGGLOMERATION OF GOLD NANOPARTICLES IN SOLUTION AND ON Au(111) SINGLE CRYSTAL SURFACE

One of the promising ways to construct well-organized periodic nanostructures is the use of self-assembling processes of colloidal crystal agglomeration.<sup>[12–16]</sup> When the surface charge of inorganic nanoparticles with a narrow size distribution are carefully controlled in the course of the preparations, the nanoparticles form agglomerates with a highly ordered superstructure. Examples of well-ordered colloidal particles composed of nanosized metal and semiconductor crystals have been reported. If one can control the interaction

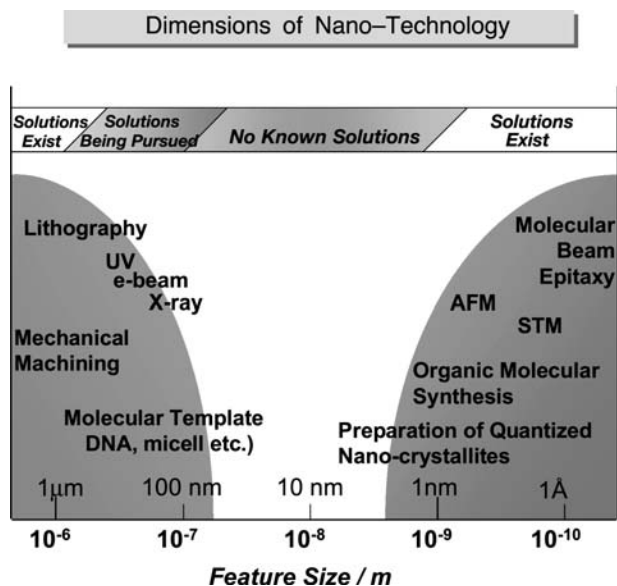

Fig. 1 Dimensions of nanotechnology.

between particles, desirable periodic superstructures and anisotropies can be introduced into the nanosized colloidal crystals. To demonstrate the possibility of combining photoexcitation for this aim, we investigated anisotropic agglomeration of gold nanoparticles (diameters ca. 6 nm) modified with organic thiols by

photoillumination with monochromatic light in aqueous media.<sup>[17]</sup>

Fig. 4 shows time-dependent spectral changes of gold nanoparticles after adding a surface-modifying reagent, thionicotinamide (TNA), in the dark and under illumination. In Fig. 4A and B, the initial spectrum with a single absorption peak at 520 nm in the dark is accompanied by evolution of an absorption band at wavelengths longer than 700 nm. After ca. 300 sec, the spectrum demonstrated double peaks at 520 and 720 nm. These changes can be attributed to agglomeration of gold nanoparticles by surface modification with the added reagent. The two absorption maxima of 520 and 720 nm can be attributed to the excitation of the transverse and longitudinal modes of surface plasmons in anisotropic agglomerates, respectively.<sup>[3,4]</sup> The modifying reagent should be bound on the gold surface via strongly interacting groups of thiol and/or amide.<sup>[18]</sup> The formation of such binding is expected to reduce or diminish anionic surface charges on the gold nanoparticles, leading to an increase in van der Waals attractive forces among the surface-modified gold nanoparticles, and hence resulting in agglomeration. Fig. 4(C)–(F) shows the effect of photoillumination on agglomeration of the gold nanoparticles. Under illumination at 830 nm, agglomeration was slightly accelerated. The evolution of the new absorption band above 700 nm became faster than that in the dark, showing the saturation in about 200 sec after the addition of TNA. In the case of 530-nm illumination, such acceleration of agglomeration was also observed, and further became faster than the illumination at 830 nm. The evolution of the new band above 700 nm reached saturation in about 180 sec. For the illumination at 830 and 530 nm, the absorption intensities also decreased after the saturation. The decreases reflect further aggregation and precipitation of the nanoparticles in solution. This result indicates that photoillumination accelerates the agglomeration of gold nanoparticles depending on the wavelength of the illumination light.

The above-presented photoinduced agglomeration reflects the change in the interaction between the gold nanoparticles by surface plasmon excitation.

**Fig. 4** Time-dependent absorption spectra of an aqueous solution containing gold nanoparticles modified with thionicotinamide. Measurements were performed 120 times at intervals of 10 sec, (A) in the dark, (C) under illumination at 830 nm, and (E) under illumination at 530 nm. Contour plots of time-dependent absorption spectra of the same systems, (B) in the dark, (D) under illumination at 830 nm, and (F) under illumination at 530 nm.

The interaction between colloidal particles was described by the total interaction potential consisting of an attractive van der Waals potential and a repulsive electrostatic potential in the DLOV theory.<sup>[19]</sup> The former potential contains a constant term determined by material- and geometry-dependent dispersion of coupled surface plasma oscillation frequencies. It was suggested that photoexcitation of the oscillations induces additional attractive forces via electromagnetic multipolar interactions. The results of the photoinduced agglomeration shown here should also be attributed to the photoinduced increase in the attractive force between the gold nanoparticles via surface plasmon excitation by illumination at 830 and 530 nm (Fig. 5). The wavelength dependence, i.e., slightly higher acceleration of agglomeration as well as earlier start of precipitation by 530-nm illumination than those by 830-nm illumination, may suggest another contribution of photoexcitation than the expected one. Illumination at 530 nm is known to cause not only plasmon excitation but also interband excitation of the gold nanoparticles, leading to photochemical reactions.<sup>[6]</sup> The relatively higher-energy excitation often results in destruction of the particles via electron ejection from them, fragmentation, and fusion. On the other hand, illumination at 830 nm under the present condition does not seem to cause structural deformation of individual particles. Furthermore, the excitation of the longitudinal mode at 830 nm is expected to induce anisotropic polarization along the long axis of the anisotropic agglomeration. Although the present results on the wavelength dependence of photoinduced agglomeration suggest that the 530-nm illumination is more effective in speed, it seems that the illumination at 830 nm is a more suitable perturbation to cause anisotropic agglomeration via plasmon excitation without any degradation of the gold nanoparticles.

The behavior of adsorption of the gold nanoparticles on Au(111) surfaces under photoillumination

**Fig. 5** Agglomeration process of the gold nano-particles in solution.

was also investigated. Surface modified gold nanoparticles are adsorbed on Au(111) surface. We reported that their agglomerates on the Au(111) surface, prepared by immersion of the surface in the solution of gold nanoparticles, formed dot-interconnected lines of gold particles with a single particle width.<sup>[20]</sup> When the immersion conditions, such as the concentration of the gold nanoparticles and the immersion time, were changed, the coverage of the nanoparticles on the surface could be altered. Fig. 6 shows scanning tunneling microscopic (STM) images of the gold nanoparticles on the Au(111) surfaces prepared under 830-nm light illumination with different magnifications for different places. The images clearly show that each line of arrays is composed of the gold nanoparticles with the diameter of ca. 6 nm. Fig. 6(B) shows that the linear arrayed structure of the gold nanoparticles is formed on a typical structure of steps and terraces of the Au(111) surface with a monoatomic height at step edges crossing at 60° with each other, suggesting that the coverage of the nanoparticles should be a monolayer. It is also seen that the aligned arrays are parallel to the direction of one of the steps [Fig. 6(C)]. Although some vacancies or pits of the nanoparticles are observed, the alignment of the gold nanoparticles is not affected by such imperfections. It should be noted that this linearly arrayed structure was not observed at the surface prepared under dark or under illumination at 530 nm.<sup>[17]</sup>

As shown before, the photoillumination should cause an additional attractive interaction between the gold nanoparticles. The excitation at a long wavelength of 830 nm corresponds to the excitation of the longitudinal mode of surface plasmons in the anisotropic gold agglomerates, which propagates in the long-axis direction. The selective excitation of this mode is expected to cause an anisotropic electric field, leading to agglomeration in one specific direction. Isotropic excitation at 530 nm will not be able to induce such an anisotropic field, leading to random adsorption of nanoparticles. In addition, relatively strong excitation at 530 nm caused the destruction of the nanoparticles as observed in the solution experiments.

In this section, we have shown the promoting effect of photoillumination on agglomeration of surface-modified gold nanoparticles. The additional interactions between the particles were induced by photoillumination, and were controlled by changing the wavelength of illuminating light. In the case of adsorption onto the Au(111) surface, the illumination also affected the adsorption structure. The illumination at 830 nm led to the formation of a closed-packed and linearly arrayed superstructure on the surface. The results imply that photoillumination can be applied to control the superstructure of colloidal metal nanoparticles.

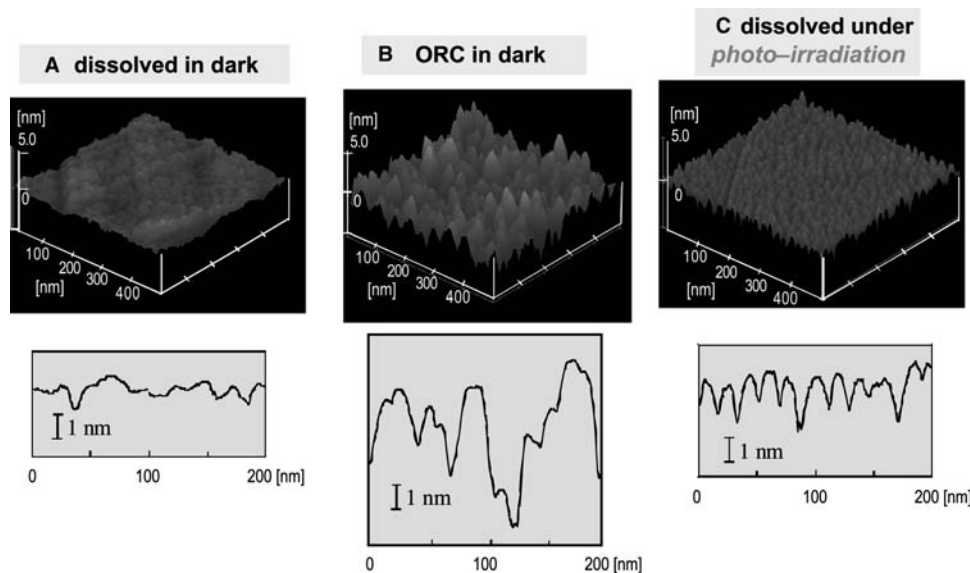

**Fig. 6** Scanning tunneling microscopic images of linear arrayed structures of gold nanoparticles adsorbed on a Au(111) surface prepared under illumination at 830 nm.

### NANOSCALE STRUCTURAL CHARACTERISTICS OF PHOTODISSOLVED Au(111) SINGLE CRYSTALLINE SURFACE

We investigated the effect of photoillumination on electrochemical dissolution of a gold electrode in KCl electrolyte. Structural changes in the surface morphology of metal electrodes by photoillumination have been recognized, especially in the field of surface-enhanced Raman scattering (SERS) spectroscopy.<sup>[21–23]</sup> Enhancement factors of the scattering signal are very sensitive to the surface microscopic morphology.<sup>[24–26]</sup> There are several reports on the change in SERS enhancement factors by photoillumination during electrochemical roughening in halide solutions.<sup>[21–23]</sup> The difference in the scattering intensity may reflect the structural characteristics of the surface prepared under the illumination. Thus the dissolution of metal electrode under photoillumination is expected to give some characteristic features, which differ from the

surfaces prepared under the dark. In this section, the structure of the photoilluminated electrode surface was characterized by STM. Comparison between the electrodes prepared under darkness and photoillumination conditions shows the effect of photoexcitation of metal on the electrochemical reaction.<sup>[27]</sup>

Several surface structures of Au(111) surface prepared by electrochemical dissolution were shown in Fig. 7. Under the dark conditions, it was found that the change of the surface structure was observed when the potential became more positive than 0.6 V vs. an Ag/AgCl reference electrode. Fig. 7A shows STM images of the surface after the positive polarization at 1.0 V under the dark. Formation of a random-valley structure at the terrace was shown in the image. Potential cycling between oxidation and reduction potentials (−0.1 and 1.0 V) resulted in a further roughened surface, consisting of spherical particles with the diameter of 20–30 nm as shown in Fig. 7B. The surfaces prepared in the dark had neither flat parts

**Fig. 7** Scanning tunneling microscopic images and vertical sectional views of Au(111) surface kept at (A) 1.0 V for 5 sec under darkness, (B) −0.1 V for 5 sec after positive polarization at 1.0 V for 5 sec under darkness, and (C) 0 V for 5 sec under photoillumination; observed area was 500 × 500 nm.

nor residual step lines. Fig. 7(C) exhibits a photodissolved surface formed at a relatively negative potential of 0 V. The image shows that structural changes can be caused at much more negative potentials under the photoillumination than that in the dark. As the structural characteristics, homogeneous islands approximately 15 nm in size were found on the surface. The height of the islands was quite uniform, and the trace of the step edge was seen as a well-aligned dot-line structure of the islands. Comparison of the vertical sectional view of the surface to the surfaces prepared under the dark condition (Fig. 7A,B) shows that the size of the islands and the depth of the valleys are uniform.

Photoillumination of metal surfaces excites electrons and holes, and thus could induce electron transfer reactions if electron donors/acceptors exist at the interface. In the present system, a gold electrode dissolves via oxidation of gold forming  $\text{AuCl}_4^-$  when a sufficiently positive potential ( $>0.8$  V) is applied. Photoexcitation at 830 nm can generate excited holes with energy of 1.49 eV relative to the Fermi level, leading to the oxidative dissolution of the surface at a more negative potential. In addition to this effect of the potential, there were interesting structural characteristics observed at the dissolution under the dark. As shown in Fig. 7C, the island structure had a relatively narrow size distribution. Theoretical calculation of the electric field, taking into consideration strong electromagnetic coupling on the metal surface, predicted the creation of a very localized plasmon mode at the valley of the periodic superstructure.<sup>[28,29]</sup> Calculation results show that the strongest electric field is highly localized at the bottom of the valley between the particles. Thus, in the present case, after the formation of these randomly distributed valleys, some of them, whose separation distance is the same as the period of the photoexcited field induced by 830-nm light illumination, are selectively excited and form a localized field at the bottom of the valleys. Such a localized field could induce localized photodissolution of the metal via resonant electronic excitation. Formation of the periodic structure by photoillumination may be explained by the selective dissolution caused by a periodic electromagnetic field on the surface.

Scanning tunneling microscopic images proved that dissolution of the gold electrode was accelerated by photoillumination. At the surface prepared under the illumination, the size distribution of the islands was relatively small, and the heights of the islands were uniform. The selective dissolution caused by a periodic electromagnetic field on the surface may contribute to the formation of such uniform structure. The present results imply that the photoillumination can be applied to control the structure of metals in the size around 10 nm via photodissolution.

## PHOTOINDUCED SINGLE METAL-DOT DEPOSITION ONTO METAL SURFACE

Photoinduced electron transfer reactions via plasmon excitation have been reported in several roughened metal electrode systems.<sup>[7-11]</sup> For further developments as a novel method of nanostructural control in the size between a few nanometers and tens of nanometers, coupling the phenomenon with an electrochemical scanning tunneling microscope (EC-STM) system could prove interesting.<sup>[30,31]</sup> Several attempts have been reported on using photoirradiation for the tunneling gap of STM systems for nanostructure fabrication.<sup>[32-38]</sup> Although some of these studies succeeded in the preparation of nanostructures on solid surfaces, several problems still remain. When light is irradiated in the STM gap, thermal expansion of the tip and the sample substrates is observed as the most prominent effect.<sup>[32-34,36,39-49]</sup> This contribution is difficult to control, and often changes the distance of the gap leading to the deformation of the prepared structures. Thus it is important to identify the conditions that minimize the thermal expansion. Appropriate potential control of the electrodes in EC-STM systems is expected to improve the reaction efficiency of the photoinduced metal deposition.<sup>[50]</sup>

In this section, the effect of the photoirradiation on the gap between the Au(111) surface and the tip of the electrochemical STM was shown. Relatively weak light ( $100 \text{ mW/cm}^2$ ) was irradiated in the gap in the present experiment. During the irradiation for 10 msec, the position of the tip was fixed at the central part of the observed area under the constant tunneling current mode. After the irradiation, the tip was again scanned to obtain the surface image. This relatively weak light irradiation in the gap between the tip and the surface of the Au(111) electrode, whose potential was maintained at 0.4 V vs. Ag/AgCl in aqueous solution containing 0.1 M  $\text{CuSO}_4$ , resulted in the formation of a small island structure on the Au(111) surface in the vicinity of the tip (Fig. 8). The island structure was formed on the surface just below the tip only when the light was irradiated at the point of the gap. The island was dissolved when the potential of the electrode was maintained at 0.6 V, indicating that the island is a photodeposited Cu dot. This fact indicates that a Cu metal nanodot can be prepared by the photoirradiation of an atomically smooth surface of a metal electrode in the vicinity of the metal tip. The position of the dot can be controlled by changing the position of the metal tip of the electrochemical STM.

In this system, the contribution of the plasmon mode was successfully applied to construct a single metal-dot structure on the smooth Au(111) surface in the vicinity of the thin metal tip. Ukraintsev and Yates<sup>[40]</sup> proposed the possibility that the tip can work

**Fig. 8** Electrochemical scanning tunneling microscope image of Cu nanodot on Au(111) single crystalline electrodes prepared by photoirradiation with power of  $100 \text{ mW/cm}^2$  for 10 msec.

as a conical antenna or a waveguide for the light under irradiation. Thus it is expected that the enhanced field was induced by photoirradiation in the gap between the smooth metal surface.<sup>[35,51–53]</sup> The field can induce the highly localized excitation of electrons at that point, leading to position-selective metal deposition onto the electrode surface, in the vicinity of the tip. As a result, a dot 15 nm in size and 1 nm in height was prepared on the Au(111) surface (Fig. 8). The fact that the preparation of the dot was achieved under relatively weak light irradiation proves the effective antenna effect of the tip in localizing the excitation. The method of position-selective photodeposition may be applied as a novel method to construct three-dimensional metal nanostructures on the solid surface.

### PHOTOINDUCED STRUCTURAL CHANGES OF SILVER NANOPARTICLES ON GLASS SUBSTRATE IN SOLUTION UNDER AN ELECTRIC FIELD

In the field of structural control of metal nanoparticles, several important topics remain unresolved. One of these areas involves the application of an external electric field for structural control. It is desirable to achieve control of metal nanostructures on surfaces of insulating materials, as metal nanostructures constructed for use as conducting materials. In this case, structural control of metals must be conducted via electrochemical dissolution and deposition without donation of charge from the substrate electrode. Numerous reports exist, describing sophisticated techniques pertaining to construction of metal nanostructures on electrodes of conducting materials,<sup>[54–56]</sup> as well as photoinduced

structural changes of dispersed metal nanoclusters in solution. However, little documentation occurs with respect to induction of the electrochemical reaction of metal dissolution/deposition to control the metal nanostructure adsorbed on insulating materials, in the absence of an external electric circuit.<sup>[57,58]</sup> Investigation of the combined effects of an external electric field and photoillumination is expected to give useful information on the structural control of metal nanostructures on insulating materials. The investigation shown here clarified the effect of photoirradiation of Ag nanoparticles adsorbed on a glass substrate under an electric field in solution.<sup>[59,60]</sup>

Application of an electric field to the Ag nanoparticles on glass immersed in solution was conducted employing a two-electrode cell (Fig. 9). Ag nanoparticles on a glass plate were prepared by the method of sputter deposition. The size of the hemispherical islands was approximately 20 nm in diameter (Fig. 10). The absorption spectrum of the film showed a plasmon absorption peak at 480 nm in air (Fig. 10). The absorption spectra of the Ag nanoparticles changed as a result of photoirradiation under an external electric field in water. Fig. 11 shows the time-dependent changes in the absorption spectra of the Ag nanoparticles on the glass plate during photoirradiation at various intensities (0.06, 0.26, and  $0.90 \text{ mW/cm}^2$ ) under applying an electric field of  $20 \text{ V/cm}$ . Absorption around the spectral peak wavelength (approximately 500 nm) decreased as a result of photoirradiation. Slight changes in the absorption were observed in the wavelength region below 420 nm.

The rate of the changes linearly increased as the intensity of the irradiated light increased. Fig. 12 displays the dependence of photoirradiation intensity on the change in the absorption of the nanoparticles.

**Fig. 9** Schematic presentation of experimental setup and two-electrode cell.

**Fig. 10** Absorption spectrum (top) and an atomic force microscopic image (bottom) of evaporated Ag nanoparticles on a glass substrate.

**Fig. 11** Time-dependent absorption spectral change of the evaporated gold nanoparticles on a glass substrate in pure water during irradiation at  $0.06 \text{ mW/cm}^2$  (A),  $0.26 \text{ mW/cm}^2$  (B), and  $0.90 \text{ mW/cm}^2$  (C). Applied electric field was  $20 \text{ V/cm}$ . Measurements were performed nine times at intervals of 15 sec.

The increase in the level of the changes was nearly linear with increasing intensity of irradiation. The effect of the applied electric field is also presented as the difference in the slope of the intensity dependence. The slope of an applied electric field of  $20 \text{ V/cm}$  was greater than twice that observed in the absence of an applied field. These results prove that photoirradiation induces dissolution of Ag particles even under relatively weak light irradiation in the range of  $\text{mW/cm}^2$ ; moreover, the findings indicate that photodissolution accelerates upon application of an external electric field in solution. It should be noted that dissolution

**Fig. 12** Dependence of irradiation power on the absorption change at 500 nm of the gold film observed in the absence of an electric field (solid line) and upon application of an external electric field (20 V/cm) (broken line) for 120 sec.

caused by application of an electric field alone without photoirradiation was minor, compared with the case involving the combination of an electric field and irradiation. Only slight incremental intrinsic dissolution of nanoparticles was evident upon application of an electric field in solution under darkness.

The synergetic effect of the weak light and the electric field was also detected in the structural changes. Fig. 13 displays AFM images of as-prepared Ag nanoparticles and those following treatment with light only, and with light and the electric field. The treatments with light only resulted in slight decreases in

the number of Ag nanoparticles without apparent size changes in the particles. On the other hand, the combined perturbations led to significant changes in particle size. The original size of approximately 20 nm in the prepared samples increased to 50–100 nm following polarization under irradiation. The particles were interconnected, forming anisotropic shapes. These changes in the size of the nanoparticles were more apparent when the irradiated light intensity became stronger (Fig. 13). This observed structural change suggests that photoirradiation under an external electric field induces deposition of Ag to specific particles as well as dissolution. This dissolution of the particles leads to an increase of the interparticle distance. The spectral blue shift shown in Fig. 3 seems to reflect this decrease in the interaction between the particles rather than the change in the size of the nanoparticles.

The effect of photoirradiation with respect to acceleration of dissolution under an electric field may be considered as follows. In comparison to the relatively large-sized metal particles, the present electric polarization of Ag nanoparticles approximately 20 nm in size should be much smaller, and would be on the order of  $10^{-5}$  V. Although this polarization appears to be insufficient to induce an electrochemical reaction, photoirradiation may assist the increase in polarization of the nanoparticles via photoexcitation. When resonant electronic excitation of nanoparticles is induced via plasmon excitation, the resultant polarization corresponding to several electron volts can generate electrochemical reactions such as metal dissolution and deposition (Fig. 14).

**Fig. 13** Atomic microscopic images of the evaporated Ag nanoparticles on a glass substrate, as-deposited, following only irradiation, and following irradiation and an electric field. Dimensions are indicated on the images.

Fig. 14 Proposed mechanism of the photoinduced structural change under an external electric field in solution.

In the present system, possible electrochemical reactions in a single particle during the initial stage may include the oxidation reaction of Ag metal dissolution, the reductive reaction of hydrogen evolution, dissolved oxygen, and/or native oxide partially covering the surface of the Ag nanoparticle.<sup>[61]</sup> As the reaction proceeds, a Ag<sup>+</sup> ion is likely to be generated by dissolution, and diffuse to the neighboring particles. When a Ag<sup>+</sup> ion arrives at a neighboring particle, Ag deposition could occur as a dominant reductive reaction at the particles, leading to changes in the size of the Ag nanoparticles. The applied electric field can assist the migration of the Ag<sup>+</sup> ions; consequently, the electric field accelerates the present reactions.

The results shown here proved that photoirradiation of metal nanoparticles under polarization by an external electric field accelerates structural changes in Ag nanoparticles. The reaction can be attributed to the highly localized electrochemical reactions of metal dissolution/deposition on the surface of the Ag nanoparticles. This phenomenon can be utilized for structural control of Ag nanoparticles adsorbed on the surface of an insulating material, circumventing the need for an external electric circuit.

glutamic acid

Fig. 15 Time-dependent SERS signals from the Ag on Au film during application of an external electric field. Measurements were performed at 20-sec intervals (from bottom to top). Two spectra at the top were at 420 and 480 sec after applying field.

#### CHANGES IN NEAR-INFRARED OPTICAL RESPONSE OF METAL THIN FILM ON GLASS SUBSTRATE BY ELECTRIC POLARIZATION IN SOLUTION

The technique of applying an external electric field to metal nanostructures could be used to control the optical properties of metal thin films on glass. One of the promising applications of metal nanostructures is their use as substrates for single molecular detection employing surface-enhanced Raman scattering

**Fig. 16** Surface structures of the Ag on Au film before and after the application of an external electric field.

(SERS).<sup>[62–65]</sup> The phenomenon utilizes localized electromagnetic fields at the metal nanostructure under photoirradiation. Although the SERS enhancement has often included visible excitation because of its very sensitive resonance condition, the importance of near-infrared (NIR) excitation has also been recognized because of the advantages associated with non-fluorescence properties and lower damage in photosensitive target molecules.<sup>[66,67]</sup> Recently, theoretical calculations proved that the effective electromagnetic enhancement via near-infrared excitation would be possible if some appropriate metal nanostructures were constructed.<sup>[29]</sup> Recent efforts have focused on preparation of the NIR-SERS active substrates using well-controlled structural units.<sup>[25,68]</sup> Although several sophisticated methods were successful with respect to generation of fully reproducible NIR-SERS activity, the preparations were often complicated because of the need for specialized synthetic or preparative techniques. Furthermore, additional tuning for optimized NIR-SERS activity is rather difficult following the preparation. Thus novel facile and controllable techniques to prepare NIR-SERS active substrates should be developed.<sup>[69]</sup>

Near-infrared SERS activity of the Ag on Au film on glass substrate under electric polarization was evaluated in aqueous solution containing 1 mM glutamic acid. Spectra were obtained in situ from the near-infrared laser Raman microscope system with excitation wavelength of 780 nm.<sup>[70]</sup> Intensity of the SERS significantly increased upon application of an external electric field to the film (Fig. 15). The empirical signal enhancement factor, which was determined from the peak integration ratio of the SERS vibration at  $1400\text{ cm}^{-1}$  to the unenhanced signal from the solution of a defined sample concentration, was found to be greater than  $10^7$ . The value is comparable to the recently reported value of the near-infrared SERS from carefully prepared gold nanoparticle superstructures possessing a precisely controlled periodic structure.<sup>[71,72]</sup> Strong enhancement of greater than  $10^7$  in the present systems could be attributable to the small

particle structure characterized by diameters of approximately 10–20 nm on the Ag on Au film.

In this investigation, the NIR-SERS activity of an Ag on Au thin film was controlled via application of an external field to the metal thin films on an insulating substrate in solution. We found a novel application of an external electric field to the control of metal nanostructures on an insulating material in solution. As the result of the structural change of the Ag on Au thin film, significant enhancement of the near-infrared Raman scattering of amino acid molecules in solution was achieved (Fig. 16). The method is an extremely facile and effective technique in terms of control of NIR optical properties of such thin metal films on an insulating material in solution. Moreover, this procedure should be applied in the preparation of substrates displaying optimized NIR-SERS activity for various highly sensitive molecular sensors.

## CONCLUSIONS AND FUTURE PERSPECTIVE

We have demonstrated that selective excitation of a specific surface plasmon mode of metal nanostructures can be employed as a perturbation for effective structural control. Useful effects on the particle interaction and highly localized electrochemical reaction were found in several nanostructured metal systems. The phenomena can be applied as a novel method to control metal nanostructures in the size region between a few nanometers and a hundred nanometers. As for the use of the method in future technologies, further optimization is required, utilizing the specificities of the wavelength and the polarization of the light for finer-size tuning at the metal nanostructures. Control in the contribution of the heat caused by photoillumination is also important for more precise structural control in the nanometer-size region. Despite these still unsolved issues, the structural control via localized photoexcitation should be one of the promising approaches to construct nanostructures in a size

region, which remains underdeveloped in the present nanotechnology.

## ACKNOWLEDGMENTS

We would like to thank our collaborators, Messrs. T. Kitamura, H. Tanaka, Y. Sawai, and M. Suzuki, and Dr. J. Li in Osaka University, who, together with the authors, performed most of the work presented here. Grateful acknowledgment is also made to Dr. K. Ajito, NTT Basic Research Laboratories, for stimulating discussion and his contribution for in situ confocal near-infrared Raman measurements. This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology, Japan.

## INTRODUCTION

This entry summarizes several approaches to the large-scale synthesis of metal nanostructures with various well-defined shapes by controlling the chemistry in solutions. The strategies include preferential adsorption of capping reagents on different crystallographic planes, use of self-assembled surfactant molecules as templates, control over the plasmonic excitation, and template-engaged replacement reaction. The as-synthesized nanostructures have well-controlled shapes and exhibit unique properties compared to their bulk material. They are promising candidates for applications in a range of fields that include optoelectronics, photonics, sensing, clinical diagnostics, catalysis, and energy storage/conversion.

## MOTIVATION FOR CONTROLLING THE SHAPE

Studies on metal nanoparticles have a long history since Faraday first observed the remarkable change of color associated with the size variation of gold colloids.<sup>[1]</sup> In addition to color tuning, properties of metal nanostructures have been extensively studied during the last two decades because of their promising uses in photography,<sup>[2]</sup> catalysis,<sup>[3]</sup> photonics,<sup>[4]</sup> electronics,<sup>[5]</sup> optoelectronics,<sup>[6]</sup> information storage,<sup>[7]</sup> chemical and biological sensing,<sup>[8,9]</sup> surface-enhanced Raman scattering (SERS),<sup>[10–12]</sup> clinic diagnosis,<sup>[13]</sup> and cancer therapy.<sup>[14]</sup> The performances of metal nanostructures in the aforementioned applications can be tailored by their chemical composition, size, shape, crystallinity, and structure (solid vs. hollow) because the intrinsic properties of a metal nanostructure are sensitive to any one of these parameters. The number of references in this multidisciplinary field

has increased dramatically and comprehensive reviews covering various aspects of the field have been published in recent years.<sup>[15–22]</sup> The first edition of this Encyclopedia includes overviews on “Nanocrystals Synthesized in Colloidal Self-Assemblies” and “Metal Nanostructures Synthesized by Photoexcitation.” However, this entry focuses on as much as possible a wider array of chemically synthetic approaches and how these techniques apply to the preparation of metal nanostructures with well-defined shapes and hollow interiors.

Controlling the shape of a metal nanostructure has been proven a powerful handle to fine-tune its properties. For example, the optical responses (e.g., surface plasmon resonance or SPR, and fluorescence) of gold or silver nanorods have been demonstrated to be highly sensitive to their aspect ratios.<sup>[15]</sup> Theoretic studies have suggested that the number of absorption peaks and effective spectral ranges for SERS are strongly dependent upon the exact morphology displayed by metal nanostructures.<sup>[23]</sup> With regard to catalysis, cubic platinum nanoparticles with their surfaces bound by  $\{1\ 0\ 0\}$  facets prefer to adsorb hydrogen molecules while carbon monoxide tends to strongly bond on the  $\{2\ 1\ 0\}$  facets of buckyball-shaped platinum nanoparticles.<sup>[24]</sup> Most recently, El-Sayed and Narayanan have comparatively studied the catalytic activity of platinum nanoparticles with different shapes (e.g., tetrahedron, cube, and quasi-sphere) toward the reaction between hexacyanoferrate (III) ions and thiosulfate ions in colloidal solution, and concluded that the activation energy decreased with the increase of percentage of surface atoms located on the corners and edges.<sup>[25]</sup> In case of magnetic property, the arrayed Ni nanowires with diameter of  $\sim 30$  nm that were prepared using the porous alumina membranes showed much enhanced coercivities, as high as 680 Oersteds, in comparison with bulk Ni (only

tens of Oersteds) and remnant magnetization up to 90%.<sup>[26]</sup> When metal nanostructures are developed into hollow ones, they can offer some advantages over their solid counterparts in making composites in terms of lighter weight, saving of material, and reduction of cost.<sup>[27]</sup> In particular, hollow nanostructures made of metals are intriguing to synthesize and study because they exhibit super tuning ability compared to their solid counterparts in surface plasmon resonance and catalytic activities. For example, Pd nanoshells have recently been demonstrated as an effective, recoverable catalyst for the Suzuki coupling reactions,<sup>[28]</sup> while solid Pd nanoparticles usually lose their catalytic activities after once cycle of operation.<sup>[29]</sup>

## OVERVIEW OF SYNTHETIC APPROACHES FOR CONTROLLING THE SHAPE

The fundamental and technological importance of metal nanoparticles with well-defined shapes has triggered the development of practical approaches that could produce nanostructures with desirable morphologies in large quantities. In principle, a metal can be generated by reducing its corresponding salt(s) with chemicals having relatively low redox potentials (e.g.,  $\text{NaBH}_4$ ,  $\text{H}_2$ , citric acid, and alcohols) and/or radicals generated from radiolysis of solvents or gases.<sup>[30,31]</sup> Pyrolysis of organometallic precursor is also an effective way to produce versatile metals in organic media.<sup>[32]</sup> This entry provides a brief overview of several solution-phase (which is referred to as “soft” medium) approaches that have been demonstrated for synthesizing metal nanostructures with well-defined shapes rather than spheres. It is further divided into four sections according to the properties of confinements that are used to direct the growth of metal nanocrystals. The first section explicitly discusses that the preferential adsorption of capping species (e.g., polymeric molecules and ions) onto different crystallographic planes can kinetically control the growth rates along different axes, resulting in various morphologies. The second section compares various metal structures synthesized by mediation of the self-assembled surfactant molecules (e.g., cetyltrimethylammonium bromide or CTAB, and sodium bis(2-ethylhexyl) sulfosuccinate or AOT). The third section represents that the plasmonic excitation induces the anisotropic transformation of metal nanoparticles into planar nanoprisms or nanodisks. The fourth section assesses the potential of template-engaged replacement reaction in synthesizing metal nanostructures with hollow interiors and complex multi-layered configurations. Finally, the entry is concluded with personal perspectives to the way in which this field is developing.

## PREFERENTIAL ADSORPTION OF CAPPING AGENTS

It is well known that the capping agents can protect metal nanoparticles from aggregating and are used to obtain well-dispersed sols of metal colloids. The capability of capping reagents in growing metal nanoparticles with selective shapes has been recognized in the last few years. To this end, the common sense is that the molecules could preferentially adsorb onto different crystallographic faces and mediate the relative growth rate along different crystal axes, resulting in the formation of nanoparticles with various shapes.<sup>[33,34]</sup>

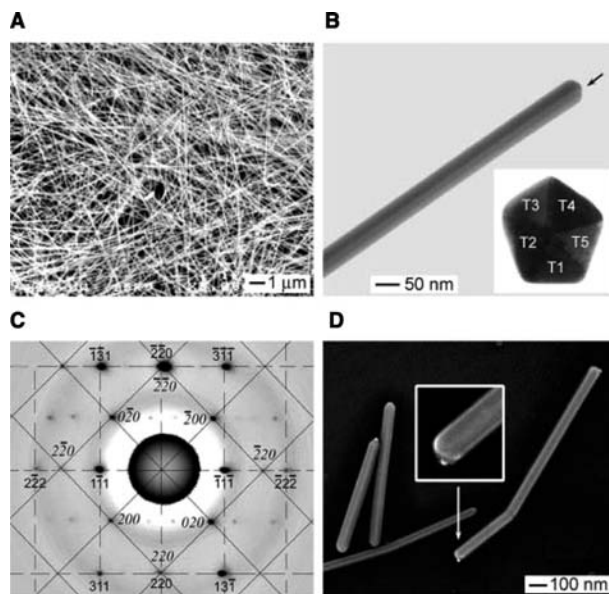

With sharing this view, Sun and Xia developed a modified polyol process<sup>[35]</sup> involving poly(vinyl pyrrolidone) (PVP) that has been demonstrated a practical approach to synthesize nanowires (or nanorods) and nanocubes of silver.<sup>[36–38]</sup> In the synthesis, silver atoms are generated by reducing silver nitrate with ethylene glycol (which serves as both solvent and reducing agent) at elevated temperatures. The resultant atoms spontaneously assemble into small nanocrystals with different shapes and crystallinities depending on the reaction conditions (Fig. 1). We refer to this evolution process as the nucleation stage. These nanocrystals could serve as seeds for further addition of silver atoms (referred to as the growth stage). Although the exact function of PVP in the nucleation stage is still to be elucidated, it is believed that the preferential adsorption of PVP molecules to  $\{1\ 0\ 0\}$  facet of silver plays a critical role in growing one seed into larger structure. The shape of resultant nanoparticles is a

**Fig. 1** Schematic illustration on the formation of silver nanowires (or nanorods) and nanocubes via the PVP-modulated polyol process. The planes marked in gray with light and deep tones represent the facets bounded by  $\{1\ 1\ 1\}$  and  $\{1\ 0\ 0\}$  crystallographic planes, respectively. The twinned  $\{1\ 1\ 1\}$  planes and boundaries are filled in black color. “PVP/Ag” denotes the ratio between the amount of PVP (in terms of repeating unit) and silver nitrate.

manifestation of the crystallinity and morphology of the seed (see Fig. 1). For instance, multiple-twinned particles (MTPs) with the decahedral shape are produced when no PVP is introduced at the nucleation stage. Such a seed is comprised of five slightly deformed tetrahedrons by twinning their adjacent  $\{1\ 1\ 1\}$  faces. The seeds with fivefold symmetry would evolve into uniform nanowires characterized by pentagonal cross-section when their growth is assisted with PVP. In this case, the deposition of silver atoms on the twin boundaries leads to the uniaxial elongation of an MTP into a rod-shaped nanostructure under the confinement of twin planes (marked in black in Fig. 1). Meanwhile, the growth of rods in lateral directions is highly passivated by PVP through the strong co-ordination bonding between PVP and the side surfaces (exposing  $\{1\ 0\ 0\}$  facets). In comparison, the 10 end surfaces terminated with  $\{1\ 1\ 1\}$  facets retain high activity in attracting silver atoms because they are loosely covered by PVP. When a proper amount of PVP is added during nucleation, for example, when the molar ratio of the repeating unit of PVP to silver ions is between 1.5 and 2.0, single crystalline cubooctahedrons are formed. The passivation of  $\{1\ 0\ 0\}$  facets by PVP causes a much higher growth rate of  $\{1\ 1\ 1\}$  facets than that of  $\{1\ 0\ 0\}$  facets, and leads to the formation of nanocubes exposing only  $\{1\ 0\ 0\}$  facets.

The characterization results of silver nanowires and nanocubes were consistent with the evolution mechanism sketched in Fig. 1. Fig. 2A shows a typical SEM image of the as-obtained silver nanowires with diameter of 50–60 nm and lengths up to 50  $\mu\text{m}$ , indicating the abundant quantity that could be routinely achieved using this synthetic approach. Their cross-sections were directly observed from microtomed slices, which were prepared by cutting the nanowires embedded in cured epoxy. As shown in the inset of Fig. 2B, the nanowires exhibited a pentagonal profile with the fivefold contrast originated from the twinned boundaries. The stark contrast across each twin plane confirmed that each silver nanowire contained five single crystalline subunits (labeled as T1, T2, T3, T4, and T5). These subunits were equivalent and each had an untwinned side surface that tended to lie against the surface of TEM grid during sample preparation. As a result, the TEM image always displayed a straight twin boundary in the middle of a nanowire (as indicated by the arrow in Fig. 2B). Fig. 2C displays the selected-area electron diffraction (SAED) pattern recorded from the silver nanowire shown in Fig. 2B by aligning the electron beam perpendicular to the side surface of subunit T1. This pattern confirmed the formation of multitwinned crystalline structures.<sup>[39]</sup> Analysis of this pattern indicated that the side surfaces of each nanowire were terminated by  $\{1\ 0\ 0\}$  facets. The reactivity of the side surfaces and ends of as-prepared silver

**Fig. 2** (A) An SEM image taken from the silver nanowires randomly assembled on a silicon substrate. (B) A TEM image recorded from the end of an individual nanowire showing the existence of a twin plane along the longitudinal axis (as indicated by the arrow). The inset in (B) is a TEM image of the cross-section of a Ag nanowire indicating that each wire had a fivefold twinned structure characterized by five single crystalline subunits (marked as T1, T2, T3, T4, and T5). (C) A selected-area electron diffraction pattern taken from an individual nanowire by directing the electron beam perpendicular to one of its five side surfaces. It corresponds to a superposition of square  $[0\ 0\ 1]$  (marked with italic characters, corresponding to T1) and rectangular  $[1\ \bar{1}\ \bar{2}]$  (marked with regular characters, corresponding to T3 and T4) zone patterns of face-centered cubic silver, together with the double diffraction reflections. The  $(2\ 2\ 0)$  and  $(2\ \bar{2}\ 0)$  reflections for these two zone patterns resulted in the same diffraction spots. (D) SEM image of several short silver nanowires after they had exchanged their PVP capping molecules with 1,12-dodecanedithiol (50 nM), and reacted with gold nanoparticles for 10 hr. The bright dots at the ends of the nanowires represent gold nanoparticles that had been attached through the dithiol linkage. Silver nanorods with relatively low aspect ratios were selected for this study in order to show both ends of each nanorod in the same image. The final concentration of  $\text{AgNO}_3$  and PVP ( $M_w \approx 55,000$ , calculated in terms of the repeating unit) were 0.027 and 0.05 M, respectively. The reaction temperature was  $160^\circ\text{C}$  and the reaction time was 60 min.<sup>[37]</sup>

nanowires was studied using the ligand-exchange experiment.<sup>[38]</sup> In a typical operation, gold nanoparticles were added to the dispersion of silver nanowires after they had been incubated in a very dilute solution of 1,12-dodecanedithiol. Fig. 2D shows the result, indicating that only the ends of each wire could adsorb gold nanoparticles. This observation implied that the interaction between PVP and the side surfaces of silver

nanowires was too strong to be replaced with the dithiol molecules when the concentration of dithiol was sufficiently low. In contrast, because the interaction between PVP and the ends of each nanowire was much weaker, the ends remained highly reactive for continuous addition of silver atoms during the growth stage.

Fig. 3A shows a typical SEM image of as-synthesized silver nanocubes with a mean edge length of 175 nm. The inset is the SEM image taken by tilting the sample stage of 20°, which clearly reveals that all the faces of each cube were smooth. The inset in Fig. 3B shows the electron diffraction pattern obtained by directing the electron beam perpendicular to one of the square faces of a cube. The square symmetry of the spots indicates that each silver nanocube was a single crystal bounded by {1 0 0} facets. Silver nanocubes with different sizes could be easily obtained by controlling the growth time. Fig. 3B shows a TEM image of the product obtained by shortening the growth time from 45 (the corresponding product as shown in Fig. 3A) to 14 min; the edge length decreased to 95 nm. The observation implied that the growth rate of all faces was almost the same once the cubic shape was formed. Thus, the further growth only increased its size without significant morphological change due to the equivalence of the six faces of each cube.

In contrast to the polyol process, silver nanoplates with triangular shapes can be obtained when ethylene glycol is replaced with *N,N*-dimethyl formamide (DMF). Liz-Marzán and Pastoriza-Santos have successfully synthesized silver nanoprisms by refluxing a DMF solution of silver nitrate (0.22 mol/L) in the presence of PVP (0.4 mmol/L).<sup>[40]</sup> The dependence of

morphology of silver nanostructures on solvent implies that the solvent molecules might compete with PVP molecules for preferential adsorption because both ethylene glycol and DMF have atoms (O for ethylene glycol and N for DMF) with lone electron pairs that could fill the empty orbitals of silver atoms to form co-ordination bonds. The synergetic adsorption of PVP and solvent molecules is similar to the synthesis of Co nanocrystals via pyrolysis of  $\text{Co}_2(\text{CO})_8$  in *o*-dichlorobenzene, a solvent having negligible interaction with Co.<sup>[41]</sup> In this system, the surfactant mixture of trioctylphosphine oxide (TOPO) and oleic acid was used to modulate the relative growth rates of different crystal facets. In addition to organic molecules, inorganic anions (e.g., halogenide and hydroxide) have also been found to dramatically change the shapes of metal nanostructures.<sup>[42,43]</sup> Pileni and coworkers systematically studied the effects of different anions on the shape of Cu nanoparticles synthesized from the  $\text{Cu}(\text{AOT})_2$ -isooctane-water system.<sup>[42]</sup> The addition of  $\text{Cl}^-$  led to the formation of Cu nanorods with high aspect ratios. Nanocubes became the dominated products by replacing  $\text{Cl}^-$  with  $\text{Br}^-$  and the size of nanocubes decreased significantly with addition of  $\text{F}^-$ . The preferential adsorption of capping reagents could enable us to synthesize metal nanoparticles with well-controlled shapes (for example, nanorods, nanowires, nanocubes, and nanoprisms) and in large quantities. However, the success systems are limited to only a few metals (e.g., Ag, Pt, Cu, Co, Fe<sup>[44]</sup>), and how the capping reagents work is still elusive.

## SELF-ASSEMBLED SURFACTANT MOLECULES

Surfactant molecules with polar hydrophilic heads and hydrophobic hydrocarbon chains tend to self-assemble into mesophase structures with various constructions when they are added to water. As shown in Fig. 4, cetyltrimethylammonium bromide (CTAB) could self-associate to different aggregates, depending on the pH value of medium. Weakly basic environment leads to the formation of rod-like micelles with double layers (process A), while planar lamellar phase is generated in strongly basic solution (process D). These assemblies provide a class of “soft” templates for synthesizing metal nanostructures with controlled shapes. Murphy and coworkers<sup>[45,46]</sup> have reported a seed-mediated route to the synthesis of metal nanorods with controllable aspect ratios in the presence of rod-like micelles. In this synthesis, small gold or silver nanoparticles stabilized with citrate ions were used as seeds. When a metal salt (e.g.,  $\text{HAuCl}_4$  or  $\text{AgNO}_3$ ), a weak reducing agent (e.g., ascorbic acid), and a base solution (e.g., NaOH) with relatively low concentration were mixed

**Fig. 3** (A) SEM image of silver nanocubes obtained by growing silver nanocrystals via the polyol process for 45 min. The inset gives the high-magnification SEM image of the same sample taken at a tilting angle of 20°. (B) TEM image of the silver nanocubes obtained by shortening the growth time to 14 min. The inset shows diffraction pattern recorded by aligning the electron beam perpendicular to one of the square faces of an individual cube. The final concentration of  $\text{AgNO}_3$  and PVP were 0.068 and 0.10 M, respectively. The reaction temperature was 160°C.<sup>[36]</sup>

**Fig. 4** Depiction of metal nanostructures with various shapes formed by templating against self-assembled CTAB molecules in aqueous medium. (A) Formation of rod-like micellar phase; (B) reduction of metal ions which are encapsulated within the micellar cylinder; (C) removal of surfactant with appropriate solvents to collect pure nanorods or nanowires; (D) formation of planar lamellar mesophase; (E) generation of truncated triangular plates by templating against the lamellar phase; (F) aging of truncated triangular plates with formation of circular disks; (G) continuous aging of circular disks leading to the formation of spheres; (H) formation of armed structures (e.g., monopod, bipod, and tripod gold nanocrystals) by using the truncated triangular nanoplates of silver as seeds.

with the seeds, the seeds served as nucleation sites for the growth of nanorods within the confined micellar phase (see, process B). The lateral dimensions and aspect ratios of these one-dimensional (1D) nanostructures could be controlled by varying the concentration of seeds. Gold nanorods with more repeatable and higher quality could be obtained if the (CTAB)-capped seeds were used instead of citrate-capped ones.<sup>[47]</sup> Pure nanorods could be collected by removing the surfactant molecules after the reaction has completed (process C). The formation of rod-like structures was found to be independent of the reducing means. For example, Yang and coworkers and Esumi and coworkers<sup>[48,49]</sup> have prepared gold nanorods via the photochemical reactions induced by UV irradiation in the presence of rod-like CTAB micelles. Fourier-transform infrared spectroscopy (FTIR) and thermal gravimetric analysis (TGA) have been employed to study the structure of surfactant layers on the resultant gold nanorods.<sup>[50,51]</sup> The results indicated that CTAB adsorbed to the side surface of gold nanorods in a bilayer fashion, with the trimethylammonium headgroup of the inside monolayer of CTAB facing the gold surface. Chen and Carroll have demonstrated that the same approach could extend to synthesize truncated triangular silver nanoplates by increasing the pH value of reaction solution.<sup>[52]</sup> The TEM images of the closely stacked nanoplates revealed that the facial surfaces of

each nanoplate were covered with a monolayer of CTAB, consistent with the formation of a planar lamellar phase (processes D and E). The monolayer-protected silver nanoplates were not stable. The aging of triangular plates (with  $D_{3h}$  symmetry) at 40°C could transform them into various shapes with higher symmetries, such as circular disks (with  $C_{\infty,h}$  symmetry) and spheres (with  $C_s$  symmetry) (see processes F and G).<sup>[53]</sup> Most recently, these authors have successfully prepared gold nanocrystals with shapes of monopod, bipod, and tripod by using the as-synthesized silver nanoplates as seeds (process H).<sup>[54]</sup>

Another surfactant system used to successfully synthesize metal nanoparticles with various shapes was based on the reverse micelles formed in mixtures of sulfosuccinate (AOT), isooctane, and water.<sup>[55–57]</sup> In this case, the shape of surfactant assemblies was mainly determined by the ratio ( $w$ ) between water and surfactant. For examples, Pileni and coworkers have synthesized Cu nanorods by templating against the interconnected cylinders of AOT assembled at  $w = 10$ . When the value of  $w$  was increased to 20, supra-aggregates of AOT were formed, leading to the generation of Cu nanocrystals with various shapes, including MTPs and triangular plates. Metal nanoparticles could be synthesized in large quantities by using this kind of “soft” templates, albeit it is difficult and tedious to prepare micellar phase with controlled

morphologies as well as to remove the surfactant layers attached on the surface of metal nanostructures.

### CONTROLLED PLASMONIC EXCITATION

Plasmonic excitation has been suggested to provide the driving force that guides anisotropic growth of nanoparticles made of noble metals that exhibit strong surface plasmons.<sup>[58–62]</sup> Mirkin and coworkers<sup>[58,59]</sup> pioneered this approach to synthesize silver triangular nanoprisms with well-controlled size and monodispersity. In their synthesis, spherical silver nanoparticles with small size of 4.8–8.0 nm were firstly prepared by reducing silver nitrate with NaBH<sub>4</sub> in the presence of trisodium citrate and bis(*p*-sulfonatophenyl) phenylphosphine dehydrate dipotassium (BSPP). The resultant colloidal solution was transferred to transparent vessels and placed under the irradiation of light. The light fragmented silver nanospheres into much smaller clusters along with the formation of small silver nanoprisms. When subject to continuous illumination, the nanoprisms acted as seeds and grew until all the nanospheres had been consumed. If a lamp with monochromatic output (e.g., 550 nm) was used, the ultimate product contained bimodal silver nanoprisms with edge lengths around 70 and 150 nm, respectively. Each large prism was proposed to originate from four small ones through an edge-selective particle fusion mechanism.<sup>[58]</sup> In this case, the light wavelength (i.e., 550 nm) correlated to the dipole plasmon band (i.e., 640 nm) of silver nanoprisms with edge length of 70 nm. When a secondary beam with wavelength at either 340 or 450 nm was selected to excite the quadrupole plasmon (out-of-plane or in-plane mode) of the nanoprisms, the particle fusion process was inhibited, leading to the formation of nanoprisms with uniform size. Once the secondary beam was fixed to excite the quadrupole plasmon, the average edge length of the monodisperse nanoprisms correlated well with the wavelength of the primary excitation. Larger particles with in-plane dipole plasmon band located at longer wavelengths could be produced by increasing the wavelength of primary excitation. No matter which kind of silver source (small silver nanospheres vs. silver ions) was used, the plasmonic excitation could generate silver nanoprisms with shape and size related to the properties of exciting light.<sup>[60]</sup> Although this approach works only on the preparation of silver nanoprisms at the moment, it might be able to generate various morphologies of silver as well as other plasmonic metals when the role of light is thoroughly explored. The interested reader can find more details on the use of photoexcitation for structural control of metal nanoparticle assemblies in another review entry of the first edition of this Encyclopedia.

### TEMPLATE-ENGAGED REPLACEMENT REACTION

Galvanic replacement reaction has been demonstrated as a versatile and effective means for preparing metal nanostructures (e.g., thin films) by consuming the more reactive component.<sup>[63,64]</sup> Xia and coworkers have recently exploited the replacement reactions between silver nanostructures and desired metal salts that enable one to prepare metal nanostructures with hollow interiors.<sup>[65–71]</sup> For example, nanoboxes made of Au/Ag alloy could be synthesized by reacting silver nanocubes with aqueous chloroauric acid (HAuCl<sub>4</sub>) solution:

Fig. 5A summarizes the major steps involved in the galvanic replacement process that is performed at 100°C.<sup>[65]</sup> When the HAuCl<sub>4</sub> solution was mixed with the dispersion of silver nanocubes bounded by {1 0 0} facets (see a typical SEM image shown in Fig. 5B), the replacement reaction started from the sites with relatively high surface energies. The elemental gold generated from the replacement reaction tended to deposit on the surface of each template because their crystalline structures (both gold and silver are face-centered cubic) and lattice constants (4.0786 and 4.0862 Å for gold and silver, respectively) matched well. If the concentration of HAuCl<sub>4</sub> was high enough, the dissolution of silver could be continued until the whole silver template was completely consumed, leading to the formation of a box-like structure with uniform and homogeneous walls (Fig. 5C). The surface smoothness of each nanobox could be attributed to the Ostwald ripening process occurring at elevated temperature. The TEM image taken from a microtomed nanobox (inset of Fig. 5C) confirmed the formation of a void interior. Along with the replacement reaction, alloying also occurred between the deposited gold layer and the underlying silver surface because the interdiffusion rates of silver and gold atoms are relatively high at 100°C.

Silver atoms in the cubic boxes made of Au/Ag alloy (Fig. 5C) could be selectively removed when more HAuCl<sub>4</sub> was added to the reaction system. In this so-called *dealloying process*, numerous lattice vacancies would be formed because only one gold atom can be generated at the expense of three silver atoms, according to the stoichiometric relationship shown in Eq. (1). These lattice vacancies could be released via Ostwald ripening along with reconstruction of the morphology of the nanoboxes. As a result, each corner of the box became truncated to form new faces bounded by

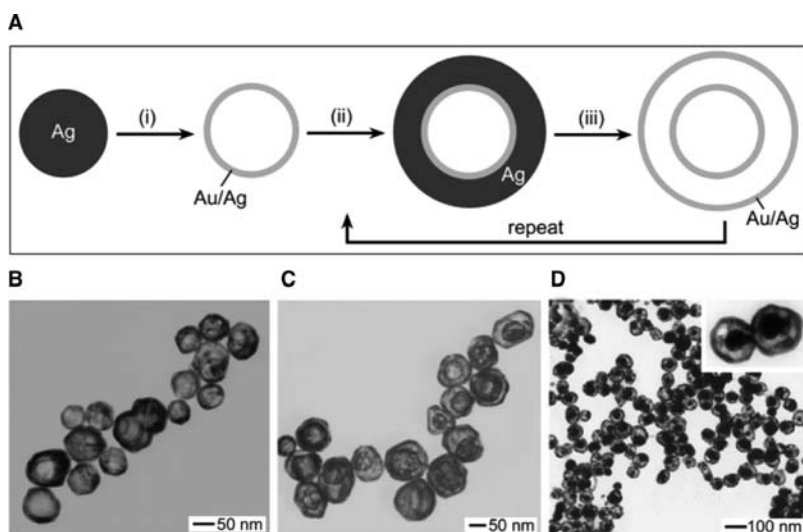

**Fig. 5** (A) Summarization on the typical morphologies involved in the galvanic replacement reaction between a silver nanocube and an aqueous  $\text{HAuCl}_4$  solution. The major steps include following: (i) formation of a cubic nanobox with a uniform, smooth, homogeneous wall composed of Au/Ag alloy; (ii) dealloying of Au/Ag alloyed wall along with morphological reconstruction, resulting in the formation of a truncated nanobox of Au/Ag alloy; and (iii) continuation of dealloying, together with the formation of pores in the wall. The cross-sectional views correspond to the plane along dashed lines. (B–E) SEM images were taken from silver nanocubes (B) before and (C–E) after they had reacted with different volumes of 1 mM  $\text{HAuCl}_4$  solution: (C) 0.5, (D) 1.0, and (E) 2.0 ml.<sup>[65]</sup>

{1 1 1} crystallographic plane (step ii of Fig. 5A). Fig. 5D shows a typical SEM image of such truncated nanoboxes, and each of them was bounded by eight triangular faces and six octagonal ones. The inset shows the SEM image of a truncated nanobox sitting on the silicon substrate against its triangular faces, indicating that the newly formed triangular faces were also flat. Further dealloying could generate more lattice vacancies, and the Ostwald ripening process could not reconstruct the box and form a seamless box with ultrathin walls because such structures were not stable at  $100^\circ\text{C}$ . To this end, the lattice vacancies coalesced into pinholes in the wall (step iii of Fig. 5A). Fig. 5E shows a typical SEM image of such porous nanoboxes with cubic morphology. It is conclusive that the

template-engaged replacement reaction between silver nanocubes and  $\text{HAuCl}_4$  has the capability to generate hollow nanoboxes of Au/Ag alloys with various walls: cubic and seamless walls, truncated cubic and seamless walls, and truncated cubic and porous walls.

The template-engaged replacement reaction can be extended to silver templates with other shapes and crystallinities, such as polycrystalline spheres and multiple-twined wires. Fig. 6B shows a TEM image of Au/Ag alloyed nanoshells obtained by reacting the silver nanospheres of  $\sim 75$  nm in diameter with  $\text{HAuCl}_4$  in aqueous medium (step i of Fig. 6A). The surface of resultant Au/Ag alloyed nanoshell could be coated with a conformal, thin layer of pure Ag via an electroless plating process (step ii of Fig. 6A).

**Fig. 6** (A) Depiction of the procedure for synthesizing multiple-walled nanoshells composed of Au/Ag alloys: (i, iii) galvanic replacement reaction between Ag and  $\text{HAuCl}_4$  and alloying between Ag and Au; (ii) electroless deposition of pure silver on the surface of Au/Ag alloy shell. (B, C) Typical TEM images of Au/Ag alloy nanoshells that contained single (B), and double (C) walls, respectively. (D) TEM image of rattle-like nanostructures that were composed of solid Au/Ag alloyed nanoparticles encapsulated within Au/Ag alloyed nanoshells.<sup>[68]</sup>

When the replacement reaction was repeated one more time, a concentric Au/Ag alloyed layer with slightly larger dimension would be formed, and a double-walled Au/Ag nanoshell was finally obtained (step iii of Fig. 6A). Nanoshells with more than two walls could be readily prepared by repeating steps ii and iii.<sup>[68]</sup> Fig. 6C shows a TEM image taken from the bilayered nanoshells of Au/Ag alloys. It was believed that the inner shells were movable in the liquid medium because they could be located at the bottom of the outer shells as well as the top ceilings and/or other positions during the drying of sample. The spacing between outer and inner shells was determined by the thickness of silver layers deposited in the electroless plating process. If the Au/Ag alloyed nanoshells were replaced with solid Au/Ag alloyed nanoparticles to undergo the electroless plating of Ag and replacement reaction, nanorattles consisting of movable solid cores and hollow shells (both are made of Au/Ag alloys) could be prepared. Fig. 6D shows a typical TEM image of nanorattles that were prepared by using Au/Ag alloyed nanoparticles with diameter of  $\sim 30$  nm as templates. The average diameter of the outer shells was  $\sim 70$  nm, which was consistent with the thickness of silver layers deposited via electroless process. Statistical analysis over several hundred particles indicated that the yield of such nanorattles could be as high as 95% in each run of synthesis.

The approach which combines replacement reaction and electroless deposition could also enable us to prepare coaxial Au/Ag nanotubes with multiple layers by templating against silver nanowires.<sup>[71]</sup> Fig. 7A shows an SEM image of double-walled nanotubes consisting of Au/Ag alloys after they had been subjected to strong sonication. The inset of Fig. 7A clearly displays that each tube was composed of two coaxial sheaths characterized by a pentagonal cross-section similar to that of the silver template. If precursors rather than  $\text{HAuCl}_4$  were applied in the second round of replacement reaction, double-walled nanotubes made

of hybrid components could be generated. Fig. 7B gives an SEM image of the product obtained by reacting the Ag-coated Au/Ag nanotubes with aqueous  $\text{Pd}(\text{NO}_3)_2$  solution. In this sample, the inner and outer walls of each tube were constructed from Au/Ag and Pd/Ag alloys, respectively. The broken nanotube clearly shows that the side surfaces of Pd/Ag alloy tube (i.e., the outer wall) were rougher than those of Au/Ag alloy tube (i.e., the inner wall). The surface roughness could be attributed to the polycrystallinity of Pd/Ag sheath caused by the lattice mismatch between Pd and Ag ( $\sim 4.8\%$ ).

It is believed that the template-engaged replacement reaction could be easily extended to produce hollow nanostructures with numerous compositions because nanostructures made of many metals other than silver have been synthesized through various approaches. For example, hollow nanoshells composed of Pt nanoparticles with size of  $\sim 2$  nm had been prepared by reacting the Co nanoparticles with  $\text{H}_2\text{PtCl}_6$  in the nitrogen-saturated aqueous medium.<sup>[72]</sup> Different from the solid Pt nanoparticles with roughly the same size as that of nanoshells, nanoshells had relatively larger surface area, resulting in the increase of catalytic activity towards the electrochemical oxidation of methanol in acid solution.

## CONCLUSIONS

We have briefly discussed four classes of confinements that have been used to direct the anisotropic growth of metal nanostructures: 1) preferential adsorption of capping reagents onto different crystallographic planes; 2) self-assembled surfactant molecules; 3) controlled plasmonic excitation; and 4) template-engaged replacement reaction. Each method has been successful in preparing nanostructures consisting of specific components and having specific shapes. A comprehensive understanding of the complex chemical and physical processes involved in the synthetic strategies is still necessary to extend the present approaches to synthesize metal nanostructures with a broader number of shapes and compositions. The properties of a metal nanostructure have been suggested to be highly dependent on its shape and/or construction, but the novel properties associated with well-defined morphologies are still to be explored in order to improve its performance in the existing applications as well as to find new applications. In addition to systematic studies on the properties of the as-synthesized metal nanostructures, effective methods are sought for assembling individual nanostructures into ordered architectures (or superlattices) that might provide functional platforms in various applications such as chemical and

**Fig. 7** Metal nanotubes with double-layered walls: (A) both the inner and outer walls were composed of Au/Ag alloys; (B) the inner wall of each nanotube was made of Au/Ag alloy and the outer one was made of Pd/Ag alloy.<sup>[71]</sup>

biological sensing. For instance, Mirkin and coworkers have demonstrated that the oligonucleotide-modified gold nanoparticles could be selectively bonded to an arrayed substrate modified by the complementary oligonucleotide strand. This strategy has the ability to detect DNA with high sensitivity similar to that obtained from fluorophore-probe technique.<sup>[73]</sup> The recent results demonstrated by Yang and coworkers suggested that Langmuir–Blodgett (LB) process was a powerful technique to assemble 1D metal nanostructures (e.g., silver nanowires) into monolayered film with aligned orientation.<sup>[74]</sup> Such LB films of silver nanowires served as a kind of excellent substrate for SERS of 2,4-dinitrotoluene, the most common nitroaromatic component sought in detection of buried landmines and other explosives. There are still infinite opportunities to develop processes for synthesizing metal nanostructures and assembling them into ordered functional architectures. However, one who is working on metal nanostructures should take great caution because the particles with sizes on the nanometer scale have been proven pulmonary toxic.<sup>[75]</sup>

## ACKNOWLEDGMENT

The research on the synthesis of silver nanostructures with various shapes and template-engaged replacement reaction between silver templates and HAuCl<sub>4</sub> aqueous solutions had been supported in part by a Career Award from the NSF (DMR-9983893), an AFOSR-DURINT subcontract from SUNY-Buffalo, a DARPA-DURINT subcontract from Harvard University, and a David and Lucile Packard Foundation which were assigned to the Xia's group at the University of Washington.

# Metal–Oxide Interfaces: Design via Control of Defect Density

A. Bogicevic

Ford Motor Company, Dearborn, Michigan, U.S.A.

## INTRODUCTION

Ever since metals and ceramics were first joined together, mankind has striven to control this bond to enable the development of new and superior composite products. Transistors, catalytic converters, light bulbs, jet engine turbines, cutting tools, and dental implants are but a few examples of every day products that depend on the integrity of metal–ceramic interfaces. Further technology development is, in an increasing number of applications, rapidly reaching a point where precise atomic-level control of the composite interface is required. This is already a reality in the ever-shrinking world of microelectronics components, where device performance relies on metal–oxide junctions, often only a few atomic layers thick, and in emerging fields such as nano-fabricated catalysts and nano-electromechanical systems.

The ability to control the formation and stability of composite interfaces can be generally viewed as requiring two critical components: an adequate understanding of what factors determine interface formation and integrity, and the actual means to manipulate the interface using that insight. Atomic defects and impurities are well known to strongly influence interface formation and can, these days, be relatively well controlled experimentally. However, the poor understanding of *how* such defects affect individual metal–oxide systems currently represents a major obstacle for using defect control to one's advantage in tailoring interfaces. The large variations in system behavior with respect to any given defect situation indicate the complexity of the problem. This intricacy is ultimately rooted in the quantum mechanical nature of nano-sized components, which, in itself, can lead to the emergence of new properties, e.g., the onset of catalytic ignition of normally inert metals.<sup>[1]</sup> Therefore, first-principles parameter-free atomistic calculations are a useful complement to well-controlled experiments for shedding some light on this problem. Substantial progress has been made lately on both theoretical and

experimental ends, and this article highlights some of these developments with regard to simple point defects. While the focus here falls on applications involving thin metal films and dispersed metal particles on metal oxides, certain generalizations can be made for other materials, as well as the inverse situation encompassing the growth of oxides on metals.

In the following, a brief overview of metal–oxide bonding is given from a theorist's perspective, as an introduction to the important concepts of adhesion, wetting, and nucleation and growth processes. A natural division is made into thermodynamic and kinetic aspects of interface control, and the discussion then shifts to the role of common point defects and the prospects of defect-mediated control of metal–oxide interfaces.

## METAL–OXIDE INTERFACE

The nature and strength of the bond between a metal and an oxide varies, often sensitively, with the constituent materials and their preparation, e.g., surface morphology, metal coverage, gas phase atmosphere, etc. A number of different adhesion mechanisms have been reported, including weak van der Waals dispersion forces between induced surface dipoles, electrostatic polarization binding, and strong ionic and covalent bonding (the latter being more directional).<sup>[2–5]</sup> Several reviews on the general science of metal–oxide interfaces have been recently published. Recommended background literature includes the excellent reviews on the surface science of metal oxides by Henrich and Cox,<sup>[6]</sup> and on metal–oxide interfaces by Finnis<sup>[2]</sup> and by Campbell.<sup>[7]</sup>

Single metal atoms tend to form relatively strong chemical bonds to most oxide surfaces.<sup>[2,4,5]</sup> This is mainly the result of a severe under-coordination of the metal atom (compared to its favored bulk state), which is therefore reactive with the surface. These ionic or covalent metal–oxide bonds are correspondingly

**Fig. 1** Low coverage metal–oxide bond lengths ( $d_{01}$ ) and metal adsorption energies ( $E_a$ ) for various metal atoms deposited on thin alumina films. The dashed line separates  $4d$  elements and the Group IB coinage metals. Note how the metal–oxide bond lengths ( $d_{01}$ ) increase down and to the left in the periodic table as the metal cation radii increase, with an attendant weakening of the adsorption energy. Note also the exception to this bond length–bond strength relation for the Ru–Nb–Y series, which is attributable to multiple ionization for Nb and Y (cf. Ru–Pd–Ag that are all singly ionized).

quite short, normally around 1–2 Å.<sup>[4,5,8,9]</sup> Typical bond strengths range from 1 to several eV, and are normally referred to as adsorption or desorption energies—defined as the energy required to remove a metal atom to the vacuum level. The metal–oxide bonds tend to further strengthen at various oxide surface defects, e.g., anion/cation vacancies, which can trap and immobilize diffusing metal atoms (as discussed in detail below). Figure 1 illustrates how the adsorbate–substrate bonds shorten and strengthen on ultrathin ( $\approx 5$  Å) alumina films as the adsorbate radius decreases (see Ref.<sup>[5]</sup>). For ionic adsorbate–substrate bonds, the metal atoms normally occupy the electrostatically favored position at low coverages,<sup>[3–5,9]</sup> although this rule of thumb weakens with oxide covalency. Strong chemical bonds tend to introduce new states in the band gap of the oxide, and one often finds a moderate to strong net spin polarization on the metal atom.<sup>[9]</sup>

As the metal coverage increases, metal–metal bonds are strengthened at the expense of weakened metal–oxide bonds. At some point, the very nature of the interfacial bond can change, and several theoretical studies have suggested simple polarization binding<sup>[10,11]</sup> as the origin of metal–oxide cohesion at coverages near and above 1 monolayer (ML).<sup>[5]</sup> This image interaction-based binding is considerably weaker than the ionic and covalent bonds typically found at low coverages. Fig. 2 illustrates the polarization binding found in a number of metal–oxide systems at the atomic level. The transition to increased metal coverage is marked by a lengthening of the metal–oxide bonds, typically by about 1 Å or more,<sup>[5,9]</sup> accompanied by a substantially weakened metal–oxide bond.

This is illustrated in Fig. 3 for single-layer ML thick metal films atop an ultrathin alumina substrate. The exact coverage at which metallic states appear depends on several factors, but has been estimated to be about 2/3 ML in certain systems.<sup>[5]</sup>

As the metal film or particle grows thicker, its cohesion to the oxide decreases only slightly in the case of polarization binding, and stabilizes already at about 2 ML.<sup>[5]</sup> This is a simple consequence of the image interaction bonding, which is to first order independent of the metal film thickness. The interface structure can change at any time during the film formation, as

**Fig. 2** Charge density difference plot that illustrates how single-layer Nb, Ru, and Pd metal films adhere to a thin alumina support by means of polarization binding atop the oxide anions (see Ref.<sup>[5]</sup> for details). Solid lines indicate charge accumulation, dashed lines charge depletion, and the position of the topmost oxygen ions and the adsorbate atoms is indicated with (six) filled dots. As one moves to the right in the periodic table (PT),  $d$ -shell filling increases, there is more charge rehybridization, and less of the ionic core exposed, resulting in weakened metal–oxide bonds. Note the counterpolarization of the oxygen ions in the top layer of the oxide, which thus actively participate to some degree in the bond formation.

**Fig. 3** High coverage adhesion energies and film-oxide separations for various metal films deposited on ultrathin alumina films. The trends are similar to those at low coverage (cf. Fig. 1), which is largely attributable to atomic size arguments here as well, although the far-left elements again behave anomalously because of the rehybridization illustrated in Fig. 2.

existing bonds are broken and new ones are formed. During initial film formation, this tends to happen because of improving metal coordination. For example, Pt clusters on MgO(100) occupy initially both anion and cation sites to maximize their coordination, but spread out to anion sites only as the cluster becomes larger and starts forming a metal film.<sup>[9]</sup> In other circumstances, it is the variation in elastic strain energy within the growing metal film that leads to change of interface structure, as reported in a systematic study of metal film growth atop thin alumina films.<sup>[5]</sup> Here it was found that elastically soft single-layer films preferred a buckled adsorption atop cations, while at 2 ML and above, all metal films preferred unrumpled atop anion adsorption because of the accumulated strain energy penalty.<sup>[5]</sup> Overlayer strain is also often relieved through misfit dislocations, which can already appear at a few ML film thickness, leaving behind epitaxial interface domains.

### Adhesion and Wetting (Thermodynamics)

Thermodynamic analyses constitute a good starting point for assessing interface morphology and stability [kinetics are discussed in the section “Nucleation and Growth (Kinetics)”]. The work of adhesion  $W_{ad}$  describes the reversible free-energy change for cleaving an interface to produce surfaces in equilibrium with their environments. It is defined by the Dupré equation as

$$W_{ad} = \sigma_m + \sigma_o - \gamma_{mo} \quad (1)$$

where the three terms on the right-hand side of Eq. (1) denote the surface energies of the metal and the oxide,

and their mutual interface energy.<sup>a</sup> The work of adhesion is directly correlated to the degree to which a metal will wet an oxide, with the contact angle  $\theta$  given by

$$\cos \theta = \frac{\sigma_o - \gamma_{mo}}{\sigma_m} \quad (2)$$

The smaller the contact angle  $\theta$ , the greater the wettability of the oxide by the metal, as illustrated in Fig. 4.

In some applications, good wetting that results in a uniform metal film atop the oxide is desired (e.g., metal-oxide electronic junctions), while in other situations one instead strives to decrease the wetting to improve metal particle dispersion (e.g., catalysis applications). High oxide surface energies and low metal surface energies thus favor wetting of an oxide by the metal, as does increasing the interface energy.<sup>b</sup>

At this moment, it is useful to make a note about theoretical adhesion studies between metals and oxides. If one starts from unrealistic surfaces (e.g., non-stoichiometric oxides), which may not spontaneously reconstruct because of constraints, artificially strong interface energies will be computed because such surfaces are unstable and therefore very reactive. This is

<sup>a</sup>The work of adhesion is closely related to the work of separation  $W_{sep}$ , which is a fundamental interfacial quantity that establishes the minimum work needed to cleave a metal-oxide interface into two free surfaces. A detailed discussion on this topic is given in Ref.<sup>[2]</sup>.

<sup>b</sup>The sign conventions differ in the literature, so some caution must be taken when comparing the three relevant energies. While a higher surface free energy is typically associated with an energetic penalty, a higher interface energy is often taken to mean more energetically favored.

**Fig. 4** Schematic illustration of how the contact angle  $\theta$  is determined by surface/interface energies, and how wetting increases with a smaller contact angle. Non-wetting occurs for  $\theta > 90^\circ$ , wetting for  $<90^\circ$ , and perfect wetting or spreading for  $\theta = 0^\circ$ .

particularly important for oxide surfaces, and the simple recipe for avoiding such misconstructions is to ensure that the surface free energies are realistic, if not in agreement with experiment. The alternative is to include the energetic penalty of altering a realistic oxide into a reactive state by taking into account the displaced oxide material in the energetic balance.

### Nucleation and Growth (Kinetics)

Metal–oxide interfaces are, in a number of applications, manufactured through controlled growth of one component atop the other. The most common growth modes in epitaxial growth are layer-by-layer Frank–Van der Merwe (FV) growth, three-dimensional Volmer–Weber (VW) growth, and the Stranski–Krastanov (SK) growth mode that transitions from FV to VW growth after a few initial layers (Fig. 5). The two-dimensional FV growth mode corresponds to complete wetting, and is expected on thermodynamic grounds for systems in which  $\sigma_o - \gamma_{mo} > \sigma_m$ . Correspondingly, three-dimensional VW growth is expected for the opposite scenario where  $\sigma_o - \gamma_{mo} < \sigma_m$ , and the intermediate 2-D–3-D SK mode for situations in which  $\sigma_o - \gamma_{mo} \simeq \sigma_m$ .

These types of free-energy analyses outline the thermodynamic limits of achievable interface morphologies. In reality, it can be technically quite difficult to realize the desired interface properties within these limits. In addition, there is frequently a need to also join non-wetting materials. The fact that epitaxial growth is a highly non-equilibrium process is part of the problem with achieving thermodynamically stable interfaces, but also enables joining nominally non-wetting materials. This kind of interface manipulation

**Fig. 5** Schematic illustration of three common epitaxial growth modes. The SK growth mode starts out in a layer-by-layer FV fashion, and later transitions to a 3-D VW-type growth.

is enabled by kinetic control of the microscopic pathways that the system undergoes as one material is grown atop the other.

Mean-field nucleation theory provides a suitable mathematical framework for understanding the role that different atomic diffusion and reaction processes play in determining film morphology. As atoms arrive on the surface from the gas phase, they diffuse and meet to form the smallest stable island nuclei, e.g., dimers. As more atoms are deposited, the further growth of these nuclei competes with the formation of new nuclei. At the saturation density of stable nuclei, any further deposition leads exclusively to island growth. The mean-field assumption that the monomer density in between islands is homogeneous facilitates a simple analytical solution to the time evolution of island densities.

As an example illustrating the important concepts of a critical nucleus size and its relation to atomic processes that can be manipulated via defect density, the simple case of 2-D nucleation and growth with stable dimers is considered next. The rate equations for the density of single atoms  $n_1$  and stable metal islands  $n_x$  then read,<sup>[12]</sup>

$$\frac{dn_1}{dt} = F - 2\tau_1 D n_1^2 - \tau_x D n_1 n_x - \phi_x F (F t - n_1) - 2\phi_1 F n_1 \quad (3)$$

$$\frac{dn_x}{dt} = \tau_1 D n_1^2 + \phi F n_1 - 2n_x (F - dn_1/dt) \quad (4)$$

where the subscript  $x$  denotes the number of atoms in the island,  $\tau$  represents the capture rates,  $D$  is the

adatom diffusivity,  $F$  is the influx rate of atoms,  $t$  is the time, and  $\phi$  relates to direct impingement on existing islands. Incorporating the standard Arrhenius relation for thermally activated processes within transition state theory,  $\nu = \nu_0 \exp - E/k_B T$ , where  $\nu$  represents the process rate,  $\nu_0$  the vibrational prefactor,  $k_B$  the Boltzmann factor, and  $E$  the activation energy of the process, and using the approximate mean free path relation  $l \simeq (D/F)^{1/6}$ , one arrives at the general island density expression for 2-D islands in the complete condensation regime,

$$n_x = \eta(\theta, i) \left( \frac{D}{F} \right)^{-\chi} \exp \left( \frac{E_i}{(i+2)k_B T} \right) \quad (5)$$

with the scaling exponent  $\chi$  given by

$$\chi = \frac{i}{i+2} \quad (6)$$

and where  $\theta$  denotes the coverage and  $\eta$  represents a universal scaling function of the coverage  $\theta$ . The *critical* island size  $i$  represents the number of atoms in the smallest stable nucleus minus one, and  $E_i$  its binding energy ( $E_1 = 0$ ). From Eqs. (5) and (6), it is evident that these last two parameters, in particular, strongly affect the island density, which is the primary means to kinetic control of growth morphology. This is the primary subject of the remainder of this entry.

## ROLE OF DEFECTS

There are essentially two approaches to tailoring metal-oxide interfaces: manipulation of thermodynamic energies and manipulation of growth kinetics. In the first case, one strives to adjust the interface energy or the surface energies of the constituents, while the second approach encompasses adjusting the nucleation and growth kinetics. Point defects in particular were repeatedly shown to strongly influence or control both interface formation and interface stability<sup>[13-16]</sup> as well as the chemical reactivity of thus formed overlayers.<sup>[1,6,7,10,17-19]</sup> Even in well-controlled ultrahigh vacuum environments, relatively modest defect densities on the order of  $10^{12} \text{ cm}^{-2}$  (roughly 1 defect per 1000 surface atoms) have been known to dominate the nucleation and growth process of interface formation.<sup>[14,16]</sup> For example, it was recently shown that even low  $10^{-11}$  mbar pressure chambers allowed for low-level impurities to completely change the growth mode of Pt(111) from flat films (FW) to 3-D dispersed particles (VW).<sup>[20]</sup>

The presence of point defects is often noted indirectly, e.g., via sample coloration, or by the way the metal island density varies in growth experiments

(see below). Sometimes, it is discrepancies with other studies that eventually lead to the realization of defect-affected systems. In the Pt example above, new experiments prompted by variances with first-principles calculations revealed that 0.001 ML of adsorbed CO was responsible for the unexpected 3-D growth.<sup>[20]</sup> In other examples, hydroxyl groups from dissociated water were identified as nucleation centers in several metal-oxide systems,<sup>[21-24]</sup> as confirmed by first-principles theoretical calculations.<sup>[8,23]</sup> The mechanism by which hydroxyls tend to nucleate metal islands on oxides is discussed in some detail in Refs.<sup>[8,23,24]</sup> Other defects that have been commonly held responsible for affecting metal-oxide interface formation are hydrogen, carbon, sulphur, and other contaminants, as well as intrinsic oxide point defects such as oxide vacancies.

A common misconception in the literature is that the trapping ability of a defect is also a signature of its propensity to preferentially nucleate metal islands. If one ignores the interaction between the trapped atom and the sea of diffusing adatoms, there is actually *no* net effect whatsoever on the nucleation and growth process. All that would happen upon the trapping is that the population of diffusing adatoms and the availability of surface sites would decrease by the number of trapped atoms. In essence, this would be equivalent to considering a smaller portion of the growth area, resulting in no net perturbation.

Clearly then, at the very heart of nucleation and growth lies the interaction between metal adatoms, and its manipulation is grounded in the modification of these interactions. A defect will preferentially nucleate metal islands if, and only if, it stabilizes the metal-metal bond(s) of the cluster compared with the same cluster on the defect-free surface. Specifically, the defect must enhance the binding energy of the smallest stable cluster, henceforth referred to as the *core* cluster. The core cluster is what the critical cluster, introduced earlier, becomes upon the addition of a single atom. Thus, one distinguishes between unstable, critical, core, and stable clusters, which contain  $n < n_i$ ,  $n_i$ ,  $n_i + 1$ , and  $n > n_i + 1$  atoms, respectively, with  $i$  representing the critical cluster size.

It is evident from these arguments alone that the concept of critical and core clusters are central in any growth process, and that the trapping energy of clusters smaller than the core cluster are not (single atoms included). This is also reflected in the nucleation theory expressions for the island density, which carry an exponential dependence of the core cluster binding energy [cf. Eq. (5)]. Depending on the metal-oxide system and the overall growth conditions, the core cluster can consist of a dimer, trimer, tetramer, or even larger aggregates. In many instances, dimers (pairs of atoms) constitute the core cluster ( $i = 1$ ). In this case, the

appropriate quantity entering Eq. (5) is the dimer binding energy  $E_b$ , which is defined with respect to two infinitely separated adatoms. A good indication of whether a defect may preferentially nucleate metal islands for  $i = 1$ , is to thus consider whether it enhances  $E_b$ . For a discussion of how cluster mobility enters the picture, and the conditions under which larger clusters than dimers may become critical, the reader is referred to the excellent review of nucleation and aggregation by Brune.<sup>[12]</sup>

At this point, it is important to realize that, in some cases, even significant changes in core cluster binding energies brought about by defects can be absolutely irrelevant for the nucleation and growth process. The relevance of defect-mediated changes in the binding energy of the core nucleus depends on the degree of perturbation and on the relevant growth conditions. For example, a change in  $E_b$  of, say, 1 eV on top of an already strong dimer bond of several eVs will barely perturb the nucleation process under most growth conditions—once two atoms meet, they will stick together for a sufficiently long time to nucleate an island irrespective of the actual dimer binding energy. Conversely, the same change of 1 eV in a system with relatively weak dimer bonds of an eV or less will have a tremendous effect under the same growth conditions. Clearly, the relevant measure here is to consider the relative change the defect brings about in the core cluster binding energy compared with its absolute value on the pristine surface, and to view that perturbation in light of the growth conditions (e.g., temperature and flux), cf. Eq. (5).

## NUCLEATION AT OXIDE VACANCIES

The role of intrinsic oxide point defects in metal–oxide interface formation remains quite controversial. It has been suggested in several studies that surface anion vacancies serve as nucleation centers for metal islands by trapping metal adatoms, thereby strongly affecting the growth kinetics and consequent growth modes.<sup>[16,27–29]</sup> A number of theoretical first-principles studies have shown that both single metal atoms and metal films bind stronger, in the former case much stronger, to oxide surfaces containing intrinsic defects such as oxygen vacancies.<sup>[8,9,27,28,30–32]</sup> Oxygen vacancies in particular were suggested as the most likely candidate for nucleating metal islands.<sup>[16,30]</sup> However, there is, to this date, no direct experimental or theoretical evidence to support this supposition. Direct experimental verification remains elusive, not least because of the inherent difficulty in atomically resolving insulating oxide surfaces. Instead, indications of defect-controlled nucleation and growth often comes from noting that the metal island density  $n_x$  stays constant

over a wide range of deposition temperatures  $T$  and/or deposition fluxes  $F$ ,<sup>[15,16]</sup> cf. Eq. (5). Theoretical studies, while supporting the trapping model, have not adequately addressed the issue of nucleation, which involves the buildup of metal–metal bonds on the oxide surface. The first theoretical study to actually do so suggested that oxygen vacancies on MgO(100) do not preferentially nucleate Pt islands, contrary to prevailing speculations.<sup>[8]</sup> Subsequent studies of a number of other systems lend further support to these initial findings, and provide a physical explanation to why highly reactive vacancies do not necessarily nucleate metal islands.<sup>[9]</sup> In the following, these arguments are recounted and elaborated on to explain why the ability of oxygen vacancies (and other defects) to trap individual atoms is, in general, not a good indication of their propensity to preferentially nucleate metal islands.

Anion and cation vacancies can both exist in several charge states in most oxides. The  $F_s$  surface anion vacancy results from the removal of an oxygen atom, and contains two electrons that are weakly trapped by the electrostatic Madelung potential. These electrons give rise to electronic surface states, which at a sufficient (bulk) density of vacancies can often be seen by the naked eye through coloration of the oxide. The  $F_s$  center (the  $F$  stems from the German *Farbe* for color) can be viewed as a core-less oxygen ion, although a much more reactive one at that. In the case of divalent oxides, one can construe two additional types of anion vacancies, the singly charged paramagnetic  $F_s^+$  center and the doubly charged  $F_s^{2+}$  center, where one or both of the color center electrons are absent. The  $F_s$  center is typically the most stable of these anion vacancies,<sup>[25,26]</sup> and also the most well studied one. The generalization to oxides of other valency, and to the corresponding cation vacancies is analogous.

## Trapping of Individual Adatoms

The first thing to keep in mind when considering oxide vacancies is that they are undoubtedly more reactive than most, if not all, other sites on the otherwise pristine oxide surface. Their reactivity can be appreciated by considering the energetic penalty of creating the defects. The anion vacancy formation energy ( $F_s$  center) for MgO(100) is a huge 13.5 eV, which is a rather representative value for other oxides as well (the corresponding cation formation energy is reportedly 13.1 eV).<sup>[8]</sup> Therefore, it is not very surprising that both anion and cation vacancies are extremely reactive and will trap and immobilize nearly any metal (or non-metal) atom that comes near. The natural abundance of surface vacancies in thermodynamic

**Fig. 6** Adsorption energies  $E_a$  at regular sites (atop anions) on MgO(100) and at  $F_s$  centers at 1/36 ML coverage for a string of 4d and 5d metal elements across the periodic table, as computed within generalized gradient approximation of density functional theory (DFT-GGA). The main point of this figure is to illustrate the considerable strengthening of the metal–oxide bond at the oxygen vacancy, with the only exception Nb being due to its large size preventing sufficient penetration of the vacancy.<sup>c</sup> Source: From Ref.<sup>[9]</sup>.

equilibrium is obviously quite low because of their large formation energy. However, intentional creation of oxide vacancies can be accomplished using a variety of experimental techniques, including ultraviolet (UV) irradiation in reducing atmospheres, ion beam sputtering, and doping with aliovalent cations.<sup>[33,34]</sup>

The trapping ability of neutral oxygen vacancies is illustrated in Fig. 6, which shows the adsorption energy of individual metal atoms at regular sites (atop anions) and at  $F_s$  centers on MgO(100) (where they sit deeply inside the vacancy).<sup>[9]</sup> The adsorption energies increase substantially at the  $F_s$  defect compared with the surface in all cases except Nb, which is too large to fill the vacancy.<sup>c</sup> The color center electrons are largely transferred to the trapped metal atoms, which assume a negative charge. Similar results have been noted in several other systems,<sup>[8,9,27,28,30–32,35]</sup> several of which have also suggested that the trapped metal atoms develop a significantly enhanced activity toward other adsorbates.

### Impact on Cluster Stability

To assess whether there is a preference for metal islands to nucleate at oxide vacancies, it is thus appropriate to compare the dimer binding energies at the vacancy and on the defect-free surface. The dimer binding energy at the vacancy is defined with respect to one atom trapped in the vacancy and the other infinitely far apart on the defect-free surface. For details

about adsorption geometries of dimers, the reader is referred to Ref.<sup>[9]</sup>.

Fig. 7 displays the dimer binding energy for a variety of metal dimers at regular sites and at  $F_s$  centers on MgO(100).<sup>[9]</sup> The dimer binding on the pristine surface is noted to increase to the left in the periodic table. This trend follows that of the bulk cohesive energy of these metals, and can be well understood by simple  $d$ -shell filling arguments: the strongest metal–metal bonds occur for half-filled  $d$ -shells, and so as the anti-bonding  $d$ -states become increasingly more occupied to the right of Nb, the bond strength decreases accordingly. Silver and gold both behave somewhat anomalously in this regard, a well-known fallacy of the  $d$ -shell model in alloy theory involving these elements.

Fig. 7 further shows that the dimer binding trend at the  $F_s$  vacancy is quite similar to that on the defect-free surface, and that, in several cases, the adatom–adatom bond is actually weakened at the defect. More importantly, it is evident from a comparison between Figs. 6 and 7 that there is no apparent relation between how well vacancies stabilize atoms (universally) vs. how they affect dimer bonds (quite varied). These results lend tangible support to the main conclusion of the previous section—that it is inappropriate to deduce a defect’s ability to nucleate islands based solely on how strongly it traps individual atoms.

A good part of these observations can be understood by simple bond-order and  $d$ -shell filling arguments. Bond-order and rebonding considerations state that the stronger one of the dimer atoms interacts with a third party, the weaker its bond becomes to its partner adatom, as noted in Fig. 7. The fact that the dimer binding trend at and away from vacancies is the same originates from the  $d$ -shell filling arguments outlined above. However, depending on the amount

<sup>c</sup>Atoms too large to sufficiently fill the vacancy may not bind as strongly because of the exponentially decaying Madelung field away from the surface.

**Fig. 7** Dimer binding energies  $E_b$  on the defect-free terrace of MgO(100) and at  $F_s$  centers at 1/18 ML coverage for various 4d and 5d metal elements, as computed within DFT-GGA. Source: From Ref.<sup>[9]</sup>.

of charge transfer to the dimer, one would expect a shift in the maximum, to the left in the periodic table for  $F_s$  vacancies. The reasoning here is as follows. As a second atom joins an already trapped atom at the  $F_s$  vacancy, electron density from the color center electrons is shared between the two atoms. This is evident from a lengthening of the adatom–adatom bond, by the dimer tilt angles being toward neighboring oxide cations, and from charge density analyses.<sup>[9]</sup> In Group VIII elements, this adds to antibonding levels because the  $d$ -shells are overfull, thereby weakening the adatom–adatom bonds. In contrast, the opposite happens to the far left in the periodic table (Nb and beyond), where added electron density to the underfilled  $d$ -shell strengthens the dimer bond. In the extreme case of complete transfer of the two color center electrons, one would therefore expect the maximum adatom–adatom binding to be shifted by one element to the left in the periodic table. The noble metals bind only weakly to the oxide, and their dimers are less prone to interact with the  $F_s$  defects. This results in a weak perturbation of the dimer bond due to lesser charge exchange, as attested by the dimer bond strengths being quite near gas phase values (e.g., 1.7 eV for Ag).<sup>[36]</sup>

As mentioned previously, changes in core cluster energies resulting from defects may or may not be relevant, depending on the magnitude of both relative and absolute energies, as well as the growth conditions, cf. Eq. (5). A closer examination of Fig. 7 suggests that  $F_s$  vacancies on MgO are unlikely to significantly affect the nucleation kinetics of, e.g., Nb, Ru, Ag, and Au, while Pd, Pt, and possibly also Ir, should be considerably more sensitive to such defects.

While  $d$ -shell filling arguments seem to provide a useful perspective on metal nucleation at defects, there are a number of other factors that likewise influence the core cluster binding energy. The size of the metal

atom has already been mentioned, as it affects its trapping and amount of charge transfer to the atom and subsequent clusters. The degree of covalency is another factor which varies depending on the type of metal bonding, e.g.,  $s$ - $p$  and  $s$ - $d_\sigma$  bonding, and which affects the ability to form multidirectional bonds<sup>[37]</sup> For large enough clusters, the ability to relieve mismatch strain becomes energetically competitive and is clearly affected by adsorption geometry. In addition, the  $d$ -shell filling arguments become less indicative as the cluster becomes bigger and the charge is shared over more atoms. Studies of how larger clusters are affected by  $F_s$  vacancies are reported elsewhere.<sup>[9]</sup>

## CONCLUSION

This entry emphasizes the need of a microscopic understanding of nucleation kinetics and adhesion energetics to facilitate defect-mediated engineering of metal–oxide interfaces. For example, it is shown via straightforward nucleation theory analyses that single-atom trapping is, by default, not a good indicator of a defect’s ability to preferentially nucleate metal islands as it omits the crucial aspect of metal–metal bond formation. The principal conclusions in this regard can be summarized as:

1. Defects affect metal–oxide interfaces by changing the nucleation kinetics, by modifying adhesion and thereby wetting energetics, or both.
2. To assess whether a defect serves as a preferential nucleation center, it is not sufficient to consider only single atom trapping. A better measure is how well the defect stabilizes the binding energy of the core cluster.

- The stabilization of the core cluster must be viewed in light of both the absolute core cluster binding energy and the growth conditions to assess its impact on nucleation dynamics.

The neutral oxygen vacancy defect, whose much-debated role as potential nucleation center remains a controversial topic, is considered in some detail within the nucleation theory framework. A series of first-principles calculations very clearly shows the disconnect between single-atom trapping and core cluster stabilization at  $F_s$  centers on magnesia. These calculations further demonstrate considerable variations in cluster formation energies depending on metal species, which is interpreted by using  $d$ -shell filling arguments. The computed energies suggest that, in several cases,  $F_s$  centers on magnesia do not, in fact, stabilize island formation. While nucleation theory and chemical arguments provide a reasonably well-grounded basis for interpreting the role of defects in metal–oxide interface formation, more studies are needed for quantitative predictions and generality assessments. In particular, it would be interesting to extend these studies to other metal–oxide systems, and to quantify the formation barriers for dimers at and away from defects where charge transfer to/from the adsorbates may play an important role. In addition, more studies are needed to assess whether defects that destabilize initial cluster formation may actually increase the monomer density between the defect sites, and thereby promote nucleation away from the defects. More studies are also needed to provide a better understanding of cluster geometries, to which the energetics underpinning all nucleation arguments are extremely sensitive.

# Metal Oxide Nanoparticles

Ryan M. Richards

Department of Chemistry, International University of Bremen, Bremen, Germany

## INTRODUCTION

Metal oxides include materials with a wide range of properties and applications. When the size of these materials is brought down to the nanometer regime, a number of size-dependent properties arise primarily as a result of surface chemistry. This field of nanoscience is facilitated by the fact that many of the systems of interest have been extensively studied in the bulk form and therefore provide ready comparisons with the nanoparticulate systems.

The insulating oxides are made up of the metals from the left and right sides of the periodic table. Typical examples of insulating oxides include MgO, CaO, Al<sub>2</sub>O<sub>3</sub>, and SiO<sub>2</sub>. The oxides of the metals in the middle of the periodic table (Sc to Zn) make up the semiconducting or metallic oxides. Typical examples include ZnO, TiO<sub>2</sub>, NiO, Fe<sub>2</sub>O<sub>3</sub>, and Cr<sub>2</sub>O<sub>3</sub>. Additionally, the transition metal oxides, which include the oxides of Ru, Mo, W, Pt, V, and so forth, are of particular interest for applications in catalysis, sensor materials, and other potential applications.

## OVERVIEW

The surface chemistry effects result from the large number of atoms at the surface of nanoscale materials. In spherical nanoparticles, for example, at a size of 3 nm, 50% of the atoms or ions are on the surface, allowing the possibility of manipulation of bulk properties by surface effects and allowing near stoichiometric chemical reaction.<sup>[1]</sup> When strong chemical bonding is present, delocalization can vary with size; this, in turn, can lead to different chemical and physical properties.<sup>[2]</sup>

Because of the refractory nature of most of the metal oxides, the formation of the ultrasmall particles is facilitated.<sup>[2]</sup> The highly ionic nature of some materials, especially MgO, Al<sub>2</sub>O<sub>3</sub>, ZrO<sub>2</sub>, and TiO<sub>2</sub>, allows the formation of many stable defect sites, including edges, corners, and anion/cation vacancies. In choosing materials for study, MgO and CaO were found to be attractive because they are highly ionic and have high melting points, and it would be expected that samples of very small particle size might be stable and isolable.

Furthermore, reactive surface sites on these oxides have been extensively studied, especially for MgO crystals and powders.

It should also be noted that materials prepared via aerogel methods have very low densities, can be translucent or transparent, have low thermal conductivities, and have unusual acoustic properties. They have found various applications, including as detectors for radiation, superinsulators, solar concentrators, coatings, glass precursors, catalysts, insecticides, and destructive adsorbents. It has been shown that nanoparticles of ceramic materials (which includes some metal oxides) can be compressed at relatively low temperatures into solids that possess better flexibility and malleability than traditional ceramics.<sup>[2]</sup> It should also be noted that nanoparticles of crystalline substances have about 10<sup>19</sup> interfaces/cm<sup>3</sup> and range in surface area up to 800 m<sup>2</sup>/g. Upon compaction, but without growing the nanocrystals, solids with multitudinous grain boundaries are formed. In the case of TiO<sub>2</sub>,<sup>[3]</sup> solid samples are obtained that undergo plastic deformation at room temperature, presumably by diffusional creep. It has been proposed that further work in the area of consolidated nanophase materials may lead to ceramics with increased flexibility, less brittleness, and perhaps greater strength.<sup>[2]</sup> It may also be possible to form materials with a large fraction of atoms at grain boundaries, perhaps in arrangements that are unique. Additionally, it may be possible to produce binary materials of normally immiscible compounds or elements.

The very high surface areas of nanoscale particles gives rise to a number of defect sites. There have been numerous studies of their surfaces in an attempt to clarify the type of defect sites that can exist.<sup>[4–7]</sup> The most common defects are coordinatively unsaturated ions due to planes, edges, corners, anion/cation vacancies, and electron excess centers. Such sites are often attributed as the active sites for many useful and interesting reactions, including methane activation,<sup>[8]</sup> D<sub>2</sub>-CH exchange,<sup>[9]</sup> CO oligomerization,<sup>[10–12]</sup> oxygen exchange in CO<sub>2</sub>,<sup>[13]</sup> and H<sub>2</sub>O.<sup>[14]</sup>

## STRUCTURE AND BONDING

Determining the exact nature of structure and bonding in nanomaterials is particularly difficult because,

generally, these materials are made of very small crystallites or are amorphous. Recent advances in crystallography for powders and crystals employing X-ray, electron, and neutron diffraction have provided insight into the structures of metal oxides. Metal oxides crystallize in a variety of structures, and bonding in these materials can range from ionic ( $\text{MgO}$ ,  $\text{Fe}_{1-x}\text{O}$ ) to metallic ( $\text{TiO}$ ,  $\text{ReO}_3$ ).<sup>[15]</sup>

An understanding of not only the crystal structure and bonding, but also the local microstructures, which result from defects, is necessary to understand the structure of complex transition metal oxides. Of course, on the nanoparticulate scale, the number of defects due to edges, corners, centers, and other surface imperfections is greatly enhanced by the large surface area (Fig. 1). The pursuit of an understanding of the structure/property relationship is integral to the understanding of the unique properties observed on the nanoscale.

In bulk structures, five types of crystals can be defined based on bonding considerations: covalent, ionic, metallic, molecular (van der Waals), and hydrogen bonded. These structures are also present on the nanoscale; however, one must also consider the number of atoms at the surface when examining the structure of nanoscale materials. Ionic crystals are formed when highly electronegative and highly electropositive elements are combined in a lattice. It has been found that the ionic model is a poor approximation for crystals containing large anions and small cations (e.g., oxides and sulfides), where the covalent contribution to bonding becomes significant.<sup>[15]</sup> van der Waals interactions play a crucial role in many transition metal

oxides, especially those with layered structures. In many oxide hydrates or hydroxy oxides, hydrogen bonding also contributes to the cohesive energy. In most transition metal oxides, the bonding is only partly ionic; however, there are several examples that are primarily ionic such as  $\text{MgO}$  and  $\text{CaO}$ . In other words, there is a considerable overlap between the orbitals of the cations and anions. Many transition metal oxides also exhibit metallic properties.

Inorganic compounds of the formula  $\text{AB}$  can have the rock salt (B1), CsCl (B2), Zn blend (B3), Wurzite (B4), or NiAs (B8) structure.<sup>[16]</sup> Alkaline earth metal oxides, such as  $\text{MgO}$  and monoxides of 3d transition metals, as well as Lanthanides and Actinides, such as  $\text{TiO}$ ,  $\text{NiO}$ ,  $\text{EuO}$ , and  $\text{NpO}$ , exhibit the rock salt structure with the 6:6 octahedral coordination.

## Defects

Because of the number of atoms at the surface and the limited number of atoms within the lattice, the chemistry and bonding of oxide nanoparticles is greatly affected by the defect sites present. Point defects in crystals, such as vacancies and interstitials described by Schottky and Frenkel, account for the transport properties of ionic solids.<sup>[16]</sup> However, it appears that the point defect model is valid only when the defect concentration (or the deviation from stoichiometry) is extremely small. The defects that occur in the ionic solids are grouped into the following classes: point, linear, planar, and volumetric defects. Point defects are a result of the absence of one of the constituent atoms (or ions) on the lattice sites, or their presence in interstitial positions. Foreign atoms or ions present in the lattice represent another type of point defect. Point defects cause displacements on neighboring atoms or ions because of polarization in the surrounding region. A cationic vacancy in an ionic solid will have an electronegative charge, causing displacements of neighboring anions.<sup>[15]</sup> The energy of formation of a point defect mainly depends on the atomic arrangement in the immediate neighborhood of the corresponding to rows of atoms that do not possess the right coordination. Boundaries between small crystallites (grain boundaries), stacking faults, crystallographic shear planes, twin boundaries, and antiphase boundaries are planar defects. Three-dimensional volumetric defects are a result of segregating point defects.

The common point defects in ionic solids are Schottky pairs (pairs of cation and anion vacancies) and Frenkel defects (cation or anion interstitial plus a vacancy).<sup>[16]</sup> When there is a large concentration of Schottky pairs, the measured pycnometric density of the solid is considerably lower than the density calculated from the X-ray unit cell dimensions (e.g.,

**Fig. 1** A representation of the various defects present on metal oxides. *Source:* From Ref.<sup>[162]</sup>.

$\text{VO}_x$ ).<sup>[15]</sup> Creation of defects is generally an endothermic process. Thus the formation energies of vacancies in ionic solids are generally 2 eV or more. Therefore, the intrinsic defect concentration in these solids is extremely low even at high temperatures.<sup>[15]</sup>

The surface of a crystal constitutes a planar, 2-D defect. The environment of atoms or ions on the surface of a crystal is considerably different from that in the bulk. In polycrystalline materials, there are grain boundaries between the particles. The interface between two solid phases is an important factor in determining the course of reactions, crystal growth, and so on. An interface may be coherent, incoherent, or semicoherent. It is coherent when the interface matches perfectly between the contact planes of two solid planes. Epitaxial growth occurs when there is considerable mismatch (semicoherent interface).

In close packed solids, one also often encounters stacking faults. For example, in a solid with cubic close packing, ABC ABC ABC, there can be a fault such as ABC AB ABC. Other types of planar defects include tilt boundary (array of periodically space of edge dislocations), twist boundary (array of screw dislocations), twin boundary (a layer with mirror plane symmetry with respect to the rotation of one part of the crystal, on a specific plane, with respect to another, and anti-phase boundary across which the sublattice occupation becomes interchanged).

The radius of the oxide anion (1.44 Å) given by Shannon and Prewitt is larger than most cations.<sup>[15]</sup> However, in crystals, the ionic radii correspond to free ions and not ions. The anions in crystals are subjected to a positive Madelung potential, which gives rise to a contraction of the charge cloud, while cations are subjected to negative potential causing an opposite effect.<sup>[15]</sup>

Generally, phase purity is hard to achieve, especially for phases containing more than one cation.<sup>[17]</sup> Often, phase segregation occurs, and so the particles are a mixture of other possible phases derivable from the precursors.

## SYNTHESIS

One of the areas of fundamental importance to the understanding and development of nanoscale materials, is the development of synthetic methods that allows the scientist control over such parameters as particle size, shape, and size distributions. While considerable progress has taken place in recent years, one of the major challenges to scientists is the development of a “synthetic toolbox,” which would afford access to size and shape control of structures on the nanoscale and conversely allow scientists to study the effects these parameters impart to the chemical and physical properties of the nanoparticles.

The syntheses of nanoscale particles are generally grouped into two broad categories: “bottom up” and “top down.” Those materials prepared from atomic precursors that come together to form clusters, and subsequently nanoparticles are referred to as “bottom up” preparations. Conversely, when the nanoscale is reached by physically tearing down larger building blocks, the process is referred to as “top down.”

“Bottom up” preparation methods are of primary interest to chemists and materials scientists because the fundamental building blocks are atoms. Gaining control over the way these fundamental building blocks come together and form particles are among the most sought-after goals of synthetic chemists. Therefore these methods will be the focus of this section. Interest in “bottom up” approaches to nanoscale oxides and other materials is clearly indicated by the number of reports and reviews on this subject.<sup>[18–34]</sup> Indeed, there are numerous “bottom up” approaches to the preparation of nanoscale materials and metal oxides are no exception. Generally, the preparations can be divided into two basic categories: physical and chemical. Several physical aerosol methods were reported for the synthesis of nano-size particles of oxide materials. These include gas condensation techniques,<sup>[35–41]</sup> spray pyrolysis,<sup>[39,42–48]</sup> thermochemical decomposition of metal–organic precursors in flame reactors,<sup>[41,49–51]</sup> and other aerosol processes named after the energy sources applied to provide the high temperatures during gas–particle conversion. The most common and widely used “bottom up” wet chemical method for the preparation of nanoscale oxides has been the sol–gel process. Other wet chemistry methods including novel microemulsion techniques, oxidation of metal colloids, and precipitation from solutions have also been used.

The methods of sample preparation are naturally the determining factors in producing different morphologies.<sup>[1]</sup> For example, burning Mg in  $\text{O}_2$  (MgO smoke) yields 40–80 nm cubes and hexagonal plates, while thermal decomposition of  $\text{Mg}(\text{OH})_2$ ,  $\text{MgCO}_3$ , and especially  $\text{Mg}(\text{NO}_3)_2$  yields irregular shapes often exhibiting hexagonal platelets. Surface areas can range from  $10 \text{ m}^2/\text{g}$  (MgO smoke) to  $250 \text{ m}^2/\text{g}$  for  $\text{Mg}(\text{OH})_2$  thermal decomposition, but surface areas of about  $150 \text{ m}^2/\text{g}$  are typical. In the case of calcium oxide, surface areas can range from 1 to  $100 \text{ m}^2/\text{g}$  when prepared by analogous methods, but typically about  $50 \text{ m}^2/\text{g}$  is typical.

## Physical/Aerosol Methods

### Vapor condensation methods

Gas condensation techniques to produce nanoparticles directly from a supersaturated vapor of metals are

among the earliest methods for producing nanoparticles. They generally involve two steps: first, a metallic nanophase powder is condensed under inert convection gas after a supersaturated vapor of the metal is obtained inside a chamber. A high pressure of inert gas is usually needed to achieve supersaturation, then the powder is oxidized by allowing oxygen into the chamber. This postoxidation is a critical step and very often it becomes necessary for this process is to be performed slowly. Because of the large exothermic reaction, particles heat up for short times (usually less than 1 sec) to temperatures as high as 1000°C, resulting in their agglomeration into large particles by rapid diffusion processes. A subsequent annealing process at higher temperature is often required to complete the oxidation. For further information on these processes, please see Refs.<sup>[52–57]</sup>

Supersaturated vapor has been achieved by many different vaporization methods. The most common techniques include thermal evaporation,<sup>[57–65]</sup> sputtering,<sup>[35,39,66,67]</sup> and laser methods.<sup>[36,41]</sup>

Gas condensation methods to prepare nanoparticles directly from supersaturated vapor have many advantages over other techniques including: versatility, ease in performance and analysis, and high-purity products. They can also be employed to produce films and coatings. In spite of the success of these methods, the drawback lies in the high production cost because of low yields and the difficulty in scaling-up. Heating techniques have other disadvantages that include the possibility of reactions between the metal vapors and the heating source materials. Furthermore, the operating temperature is limited by the choice of the source material, and because of that, they cannot be used to make a wide variety of materials. For further discussion on supersaturation, particle nucleation and growth, and the transport and collection of the particles, see Ref.<sup>[54]</sup>.

### Spray pyrolysis

Spray pyrolysis is another useful method for the synthesis of high-purity homogeneous oxide powders.<sup>[39,42–48]</sup> This technique has been known by several other names including solution aerosol thermolysis,<sup>[45]</sup> evaporative decomposition of solutions,<sup>[46]</sup> plasma vaporization of solutions,<sup>[47]</sup> and aerosol decomposition.<sup>[48]</sup> The starting materials in this process are chemical precursors, usually appropriate salts, in solution, sol, or suspension form. The process involves the generation of aerosol droplets by nebulizing or “atomization” of the starting solution, sol, or suspension. The generated droplets undergo evaporation and solute condensation within the droplet, drying, thermolysis of the precipitate particle at higher temperature to form a microporous particle, and finally, sintering to form a dense particle.

Aqueous solutions are usually used because of their low cost, safety, and the availability of a wide range of water-soluble salts. Metal chloride and nitrate salts are commonly used as precursors because of their high solubility. Precursors that have low solubility or those which may induce impurities, such as acetates that lead to carbon in the products, are not preferred.<sup>[43,46]</sup> For further details on atomization techniques, refer to Refs.<sup>[39,43–46]</sup>

During the transformation of the aerosol droplets into particles, different processes are involved including solvent evaporation, precipitation of dissolved precursor, and thermolysis of precipitated particles. One advantage to this process is that all of these processes take place in one step. Other advantages include the production of high-purity nano-size particles, the homogeneity of the particles as a result of the homogeneity of the original solution, the fact that each droplet/particle undergoes the same reaction conditions, and no subsequent milling is necessary. Disadvantages of spray pyrolysis include the large amounts of necessary solvents and the difficulty in scaling up the production. The use of large amounts of nonaqueous solvents increases production expenses because of the high cost of pure solvents and the need for proper disposal.

### Combustion methods

The combustion synthesis technique consists of bringing a saturated aqueous solution of the desired metals salts and suitable organic fuel to boil, until the mixture ignites a self-sustaining and rather fast combustion reaction takes off, resulting in a dry, usually crystalline, fine oxide powder. By simple calcination, the metal nitrates can, of course, be decomposed into melt oxides upon heating to or above the phase transformation temperature.

Flame processes have been widely used to synthesize nanosize powders of oxide materials. In this process, chemical precursors are vaporized and then oxidized in a combustion process using a fuel/oxidant mixture such as propane/oxygen or methane/air.<sup>[49]</sup> It combines the rapid thermal decomposition of a precursor/carrier gas stream in a reduced pressure environment with themophoretically driven deposition of the rapidly condensed product particles on a cold substrate.<sup>[51]</sup> The flame usually provides a high temperature (1200–3000 K), which promotes rapid gas-phase chemical reactions.<sup>[41]</sup> Several types of flame reactors have been used in research settings and have produced numerous types of nanoscale metal oxides.<sup>[41,49–51,68–73]</sup>

### Mechanochemical synthesis

Mechanochemical synthesis involves the mechanical activation of solid state displacement reactions. This process has been successfully used recently to make

nanoparticles of a number of materials including ceramics, such as  $\text{Al}_2\text{O}_3$  and  $\text{ZrO}_2$ .<sup>[74–79]</sup> It involves the milling of precursor powders (usually a salt and a metal oxide) to form a nanoscale composite structure of the starting materials, which react during milling and subsequent heating, if necessary, to form a mixture of dispersed nanocrystals of the desired oxide within a soluble salt matrix.

## Chemical Methods

### Sol–Gel technique

Sol–gel techniques have long been known for the preparations of metal oxides and have been described in several books and reviews.<sup>[18–25,27–34]</sup> The process is typically used to prepare metal oxides via the hydrolysis of metal reactive precursors, usually alkoxides in an alcoholic solution, resulting in the corresponding hydroxide. Condensation of the hydroxide molecules by giving off water leads to the formation of a network of metal hydroxide. When all hydroxide species are linked in one network-like structure, gelation is achieved and a dense porous gel is obtained. The gel is a polymer of a three-dimensional skeleton surrounding interconnected pores. Removal of the solvents and appropriate drying of the gel results in an ultrafine powder of the metal hydroxide. Further heat treatment of the hydroxide leads to the corresponding ultrafine powder of the metal oxide. Because the process starts with a nanosized unit, and undergoes reactions on the nanometer scale, it results in nanometer materials.

The chemical and physical properties of the final product are primarily determined by the hydrolysis and drying steps. Hydrolysis of metal alkoxides ( $\text{M}(\text{OR})_z$ ) involve nucleophilic reactions with water as follows:

The mechanism of this reaction involves the addition of a negatively charged  $\text{HO}^{\delta-}$  group to the positively charged metal center ( $\text{M}^{\delta+}$ ). The positively charged proton is then transferred to an alkoxy group followed by the removal of  $\text{ROH}$ . Condensation occurs when the hydroxide molecules bind together as they release water molecules and a gel/network of the hydroxide is obtained, as demonstrated below.

The rates at which hydrolysis and condensation take place are important parameters affecting the properties of the final product. Slower and more controlled hydrolysis typically leads to smaller particle sizes and

more unique properties. Hydrolysis and condensation rates depend on the electronegativity of the metal atom, the alkoxy group, solvent system, and the molecular structure of the metal alkoxide. Those metals with higher electronegativities undergo hydrolysis more slowly than those with lower electronegativities. For example, the hydrolysis rate of  $\text{Ti}(\text{OEt})_4$  is about 5 orders of magnitude greater than that of  $\text{Si}(\text{OEt})_4$ . Hence the gelation times of silicon alkoxides are much longer (on the order of days) than those of titanium alkoxides (seconds or minutes).<sup>[43]</sup> The sensitivity of metal alkoxides toward hydrolysis decreases as the OR group size increases. Smaller OR groups lead to higher reactivity of the corresponding alkoxide toward water and, in some cases, results in uncontrolled precipitation of the hydroxide.

Because alcohol interchange reactions are possible, the choice of solvents in sol–gel processes is very important. As an example, when silica gel was prepared from  $\text{Si}(\text{OMe})_4$  and heated to  $600^\circ\text{C}$ , and when ethanol was used as a solvent, the surface area was  $300\text{ m}^2/\text{g}$  with mean pore diameter of  $29\text{ \AA}$ . However, when methanol was used, the surface area dropped to  $170\text{ m}^2/\text{g}$  and the mean pore diameter increased to  $36\text{ \AA}$ .<sup>[20]</sup>

The rate of hydrolysis also becomes slower as the coordination number around the metal center in the alkoxide increases. Therefore alkoxides that tend to form oligomers usually show slower rates of hydrolysis, and hence, are easier to control and handle. *n*-Butoxide ( $\text{O}-n\text{-Bu}$ ) is often preferred as a precursor to different oxides including  $\text{TiO}_2$  and  $\text{Al}_2\text{O}_3$  because it is the largest alkoxy group that does not prevent oligomerization.<sup>[21]</sup>

Careful handling in dry atmospheres is required to avoid rapid hydrolysis and uncontrolled precipitation because most metal alkoxides are highly reactive toward water. For alkoxides with low rates of hydrolysis, acid or base catalysts can be used to enhance the process. The relatively negative alkoxides are protonated by acids creating a better leaving group and eliminating the need for proton transfer in the transition state. Alternatively, bases provide better nucleophiles ( $\text{OH}^-$ ) for hydrolysis; however, deprotonation of metal hydroxide groups enhances their condensation rates.

Developments in the areas of solvent removal and drying facilitated the production of nanoscale metal oxides with novel properties. When drying is achieved by evaporation under normal conditions, the gel network shrinks as a result of capillary pressure that occurs and the hydroxide product obtained is referred to as xerogel. However, if supercritical drying is applied by using a high-pressure autoclave reactor at temperatures higher than the critical temperatures of solvents, less shrinkage of the gel network occurs as there is no capillary pressure and no liquid–vapor interface, which allows the pore structure to remain largely intact. The hydroxide product obtained in this manner is referred

**Fig. 2** TEM micrograph of the nanostructure of CP MgO. Note that, here, there is no porosity and all of the nanocrystals have agglomerated together. *Source:* From Ref.<sup>[113]</sup>.

**Fig. 3** TEM micrograph of the nanostructure of AP MgO (supercritical solvent removal). Here the porosity is formed by the interconnected cubic nanocrystals of MgO. *Source:* From Ref.<sup>[113]</sup>.

to as an aerogel. Aerogel powders usually demonstrate higher porosities and larger surface areas compared to analogous xerogel powders. Aerogel processing has been very useful in producing highly divided powders of different metal oxides<sup>[18,26,80]</sup> (Figs. 2 and 3).

Sol-gel processes have several advantages over other techniques for the synthesis of nanoscale metal oxides. Because the process begins with a relatively homogeneous mixture, the resulting product is a uniform ultrafine porous powder. Furthermore, sol-gel processing has the advantage in that it can also be scaled up to accommodate industrial-scale production (personal Contact with Nantek Inc., Manhattan, KS, June 1999).

Numerous metal oxide nanoparticles were produced by making some modifications to the traditional aerogel method. One modification involved the addition of large amounts of aromatic hydrocarbons to the alcohol-methoxide solutions before hydrolysis and alcogel formation. This was carried out to further reduce the surface tension of the solvent mix and to facilitate solvent removal during the alcogel-aerogel transformation.<sup>[1,18,81]</sup> The resulting nanoparticles exhibited higher surface areas, smaller crystallite sizes, and more porosity for samples of MgO, CaO, TiO<sub>2</sub>, and ZrO<sub>2</sub> [these samples are often referred to as aerogel preparation (AP) samples for aerogel or autoclave preparation].<sup>[17,82]</sup>

#### Reverse microemulsions/micelles method

The reverse micelle approach is one of the recent promising routes to nanocrystalline materials. Several recent studies have shown that this approach is a potential candidate to synthesize nanocrystalline metal oxide powders with well-defined and controlled properties.<sup>[83-90]</sup> By carefully controlling reaction parameters, this technique affords a great deal of control over the particle size and shape.

Surfactants dissolved in organic solvents form spheroidal aggregates called reverse micelles. In the presence of water, the polar head groups of the surfactant molecules organize themselves around small water droplets, small water pools (~100 Å), leading to dispersion of the aqueous phase in the continuous oil phase as shown in Fig. 4.<sup>[91-93]</sup>

Reverse micelles are used to prepare nanoparticles by using a water solution of reactive precursors that can be converted to insoluble nanoparticles. Nanoparticle synthesis inside the micelles can be achieved by different methods including hydrolysis of reactive precursors, such as alkoxides, and precipitation reactions of metal salts.<sup>[84,85]</sup> Solvent removal and subsequent calcination leads to the final product. A variety of surfactants can be used in these processes such as, pentadecaoxyethylene nonylphenylether (TNP-35),<sup>[85]</sup>

Fig. 4 Schematic representation of (A) micelle and (B) inverse micelle.

decaoxyethylene nonylphenyl ether (TNT-10),<sup>[85]</sup> poly(oxyethylene)<sub>5</sub> nonyl phenol ether (NP5),<sup>[90]</sup> and many others that are commercially available. Several parameters, such as the concentration of the reactive precursor in the micelle and the weight percentage of the aqueous phase in the microemulsion, affect the properties, including particle size, particle size distribution, agglomerate size, and phases of the final oxide powders. There are several advantages to using this method—the preparation of very small particles and the ability to control the particle size. Disadvantages include low production yields and the need to use large amount of liquids.

#### Low-temperature wet-chemical synthesis; precipitation from solutions

One of the conventional methods to prepare nanoparticles of metal oxide ceramics is the precipitation method.<sup>[94–96]</sup> This process involves dissolving a salt precursor, usually chloride, oxychloride, or nitrate, such as  $\text{AlCl}_3$  to make  $\text{Al}_2\text{O}_3$ ,  $\text{Y}(\text{NO}_3)_3$  to make  $\text{Y}_2\text{O}_3$ , and  $\text{ZrCl}_2$  to make  $\text{ZrO}_2$ . The corresponding metal hydroxides usually form and precipitate in water by adding a base solution such as sodium hydroxide or ammonium hydroxide solution. The resulting chloride

salts, i.e.,  $\text{NaCl}$  or  $\text{NH}_4\text{Cl}$ , are then washed away and the hydroxide is calcined after filtration and washing to obtain the final oxide powder. This method is useful in preparing composites of different oxides by coprecipitation of the corresponding hydroxides in the same solution. One of the disadvantages of this method is the difficulty to control the particle size and size distribution. Very often, fast (uncontrolled) precipitation takes place resulting in large particles.

#### Colloidal methods

Some nanostructured metal oxides can also be prepared through the oxidation of metal colloids. Nanosized (i.e., 3–5 nm) colloidal  $\text{Fe}(0)$ ,  $\text{Co}(0)$ , and  $\text{Ni}(0)$  particles are very oxophilic both in solution and in powder form, and cannot be redispersed after exposition to air. However, the precisely controlled, stoichiometric addition of argon-diluted air to an organic solution of a 3-nm  $\text{Fe}(0)$ -sol stabilized by  $\text{N}(\text{octyl})_4\text{Br}^-$  leads to a rusty-brown solution of colloidal  $\text{Fe}^{3+}$  oxide, which can be isolated and redissolved, e.g., in THF.<sup>[97]</sup> Colloidal  $\text{CoO}$  nanoparticles have also been prepared by air oxidation of  $\text{N}(\text{octyl})_4\text{Br}^-$  stabilized  $\text{Co}(0)$  particles<sup>[98]</sup> (Fig. 5).

Fig. 5 Schematic representation of the oxidation of tetraalkylammonium stabilized colloids. Source: From Ref.<sup>[97]</sup>.

Particles prepared via the colloidal approach are also easily supported to form heterogeneous catalysts. It was shown that air oxidation at room temperature leads to surface passivation. Consequently, the resulting particles show a composite structure with a metallic core surrounded by an oxide surface layer.<sup>[99]</sup> Recently, a new process for the manufacture of a water-soluble PtO<sub>2</sub> colloid has been developed, which is significant because of its use as a water-soluble “Adams catalyst.”<sup>[100,101]</sup> Colloidal PtO<sub>2</sub> stabilized by carbo- or sulfobetaines, respectively, were prepared by simple hydrolysis/condensation of metal salts under basic aqueous conditions in the presence of the surfactants. This method was further exploited to give bi- and trimetallic colloidal metal oxides used as precursors for fuel cell catalysts, e.g., colloidal Pt/RuO<sub>x</sub> and Pt/Ru/WO<sub>x</sub>.<sup>[102]</sup>

## SPECIFIC PROPERTIES AND APPLICATIONS

As previously mentioned, the properties of nanoparticles are usually size-dependent. When prepared in nanometer size particles, materials exhibit unique chemical and physical properties that are remarkably different than those of the corresponding bulk materials. The study of physical and chemical properties of nanoparticles is of great interest as a way to explore the gradual transition from atomic or molecular to condensed matter systems.

As the size of a particle decreases, the percentage of atoms residing on the surface increases. As an example, a study on different samples of MgO nanoparticles has revealed that for particles ~4 nm in diameter, ~30% of the atoms are surface atoms.<sup>[18]</sup> Naturally, surface atoms/ions are expected to be more reactive than their bulk counterparts as a result of coordinative unsaturation. Because of this and the fact that the surface-to-volume ratio is large, it is not unusual to see unique behavior and characteristics for nanoparticles. This particle size effect is a characteristic of different nanomaterials including metal oxides.

In this section, we will briefly discuss some selected properties of nanophase metal oxides showing significant size dependence.

### Chemical Properties: Acid/Base Behavior of Metal Oxide Surfaces

Metal oxides are often hard acids or bases (e.g., MgO, Al<sub>2</sub>O<sub>3</sub>), so they possess sites capable of catalyzing acid/base chemistry. Several insulating oxides and oxide composites were found to be potential catalysts for a variety of important reactions as a result of their surface basicity or acidity.<sup>[103–107]</sup> Some selected

reactions typical to metal oxides include dehydration of alcohols, cracking of hydrocarbons, isomerization of olefins and paraffins, dehydrohalogenations, alkylations, and esterifications.

Acidity and basicity vary from one metal oxide to another. Several metal oxides exhibit surface basic behavior, such as MgO, CaO, and SrO, while others are considered to be acidic solids that possess more and stronger acidic sites on their surfaces, such as Al<sub>2</sub>O<sub>3</sub>. Acid/base behavior and the presence of several types of deficiencies in the lattice and on the surface are two major driving forces for surface reactivity of metal oxides. When metal oxides are prepared in nanostructures, the percentage of coordinatively unsaturated ions, especially on edges and corners, increases significantly. Consequently, surface chemistry effects, which are barely noticeable in large particle systems, become overwhelming in nanoparticle systems. These effects are demonstrated by enhanced surface reactivities and catalytic potentials possessed by many nanoparticle systems of metal oxides.<sup>[108–112]</sup>

Two of the most intensively studied nanoparticulate systems of the metal oxides are MgO and CaO. Two types of nanocrystalline oxides have been prepared and thoroughly studied; a “conventional preparation” (CP), and an “aerogel preparation” (AP).<sup>[1,17,18,81]</sup> Nanocrystalline MgO prepared by a modified aerogel procedure (AP), yields a fine, white powder of 400–500 m<sup>2</sup>/g and 4 nm average crystallite size. High-resolution transmission electron microscope (TEM) imaging of a single crystallite indicated a polyhedral structure suggesting the presence of high surface concentrations of edge/corner sites, and various exposed crystal planes (such as 002, 001, 111).<sup>[113]</sup> Conversely, the conventional preparation (CP) yields particles with surface areas of 150–200 m<sup>2</sup>/g and 8 nm average crystallites.

If intrinsic surface chemistry differences due to size are to be uncovered, consider that in bulk MgO the effective ionic charges are close to +2, whereas the MgO molecule is much more covalent with effective charges close to +1.<sup>[1]</sup> Lower coordination surface ions such as Mg<sub>3c</sub><sup>2+</sup>, Mg<sub>4c</sub><sup>2+</sup>, O<sub>3c</sub><sup>2-</sup>, and O<sub>4c</sub><sup>2-</sup> are expected to have effective charges between +1 and +2. Surface sites on crystalline and powdered MgO have been probed by theoretical as well as experimental efforts. Ab Initio calculations with H<sub>2</sub> have been used to probe perfect crystal surfaces and various defect sites. On the perfect (100) MgO surface, H<sub>2</sub> has a small adsorption energy and does not dissociate. However, temperature programmed desorption methods have shown that polycrystalline samples do dissociate H<sub>2</sub>, probably on O<sub>3c</sub>–Mg<sub>3c</sub> sites. These sites are apparently very active for heterolytic H<sub>2</sub> dissociation. The microfaceted (111) surface of MgO is

particularly reactive, and steps, kinks, and point defects (ion vacancies and substitutions) are also important. Indeed, the unique catalytic properties of defective MgO surfaces also depend on a plethora of unusual coordination sites.

There have also been studies of the Lewis acid and base sites of metal oxide nanoparticles using a variety of techniques. For example, through the use of probe molecules, electron spin resonance (ESR) was used to quantify the Lewis acid and base site on AP-MgO.<sup>[114]</sup> Surprisingly, AP MgO was found to possess both types of Lewis sites, which is very interesting because MgO is not typically associated with acid catalysis, and it is believed that this is the first observation of this type of Lewis acid activity on MgO.<sup>[115]</sup>

### Catalytic properties of transition metal oxides

The development of nanoscale transition metal oxides has been of importance to several applications, especially in catalysis. Transition metal oxides that are electrically conductive are of fundamental importance to catalysis and, in particular, to fuel cells. Ion and electron transfer reactions required for these applications require high surface area materials with defective or charged surfaces.<sup>[116]</sup> Water-soluble PtO<sub>2</sub> (i.e., a colloidal “Adams catalyst”) has been applied in the immobilized form for the reductive amination of benzaldehyde by *n*-propylamine.<sup>[100,101]</sup> The selectivity in favor of the desired monobenzylated product was found to be >99% and the immobilized PtO<sub>2</sub> was found to be 4–5 times more active than the commercial Adams catalysts. The PtO<sub>2</sub> colloid was also effective in the hydrogenation of carbonyl compounds, or of olefins in solution or in immobilized form.

The most active and CO-tolerant fuel cell catalysts [direct methanol fuel cell (DMFC) and proton exchange membrane fuel cell (PEMFC)] have been shown to contain oxides and hydrous oxides of Pt and Ru. Recent studies have revealed that practical Pt–Ru blacks are not single phase materials, but are instead bulk mixtures of Pt metal, Pt hydrous oxides, and hydrous and dehydrated RuO. A proposed mechanism for the increased CO tolerance is that Pt-adsorbed CO is removed via an oxygen transfer step from electrogenerated Ru–OH because Ru(0) transfers oxygen more effectively than Pt(0). Additionally, recent studies have suggested that the presence of metal oxides (in particular, Ru, Sn, and Mo) in electrocatalysts working with a carbon containing feed show improved CO tolerance.<sup>[117,118]</sup> It is generally accepted that this is a result of the oxide interacting with the CO-poisoned metal (usually Pt) and oxidizing the CO to CO<sub>2</sub>. Because these metal oxides are

composed of metals with high oxidation potentials, the hydrous oxides are readily regenerated by water in the feed.

Furthermore, by combining Pt/Ru alloy catalysts with transition metal oxides (WO<sub>x</sub>, MoO<sub>x</sub>, VO<sub>x</sub>) improved DMFC catalysts have been produced. Electrochemical results demonstrated that the introduction of the oxides leads to an improvement of the catalytic activity toward methanol oxidation.<sup>[119]</sup> The addition of a transition metal oxide to the PtRu catalyst led to a decrease in the methanol oxidation and surface oxide formation with the most effective being VO<sub>x</sub>.

Ruthenium oxide, in particular, has been the subject of numerous investigations because of the numerous chemical and electrical applications it can be used for. Ruthenium oxide also catalyzes the Fischer Tropsch methanation of CO<sub>2</sub>, and selectively hydrogenates benzene and its derivatives to cyclohexane and relevant cycloalkenes.<sup>[120]</sup> Solid state nuclear magnetic resonance (NMR) investigations of hydrous ruthenium oxide prepared using LiOH have demonstrated that the mobility of water molecules and their interaction with ruthenium oxides play an important role in proton charge density.<sup>[121]</sup>

RuO<sub>2</sub>–TiO<sub>2</sub> aerogels have been prepared and the redistribution of electrical properties on the nanoscale have been studied. It was found that the electrical (electronic and protonic) transport properties of the bulk RuO<sub>2</sub>–TiO<sub>2</sub> are redistributed when synthesized as an aerogel. Electron transport dominates the characteristics of the dense form, while protonic transport of the hydrous oxide surfaces governs the electrical properties of the aerogel.<sup>[122]</sup> Anhydrous RuO<sub>2</sub> is also used as a thick film resistor but the hydrous oxide is preferred in electrocatalysis.<sup>[123]</sup> RuO<sub>2</sub> electrodes are generally prepared by the thermal decomposition of RuCl<sub>3</sub> · yH<sub>2</sub>O,<sup>[124]</sup> which produces hydrous materials that are more correctly described as RuO<sub>x</sub> · yH<sub>2</sub>O or RuO<sub>x</sub>H<sub>y</sub>.

### Adsorptive Properties

Compared to their conventionally prepared and commercial counterparts, nanoparticles of several metal oxides exhibit a significantly enhanced ability to chemically adsorb and dissociate a variety of organic

molecules on their surfaces. One of the great promises that nanoparticles of metal oxides hold in chemical applications is their remarkable ability to chemically adsorb a wide variety of molecules, especially organic molecules that are of concern as environmental hazards.

Several oxides have shown promise in this field including MgO, CaO, Al<sub>2</sub>O<sub>3</sub>, SiO<sub>2</sub>, and ZnO. A wide range of molecules including chlorinated hydrocarbons, phosphorous compounds, alcohols, aldehydes, ketones, and amines were found to strongly adsorb and chemically decompose on the surfaces of these oxides.<sup>[125–133]</sup> Details and examples on this subject are discussed in the literature.<sup>[1,134]</sup>

It has been proposed that as particles become smaller in size, they may take on different morphologies, which may alter their surface chemistry and adsorption properties in addition to increasing the surface area and porosities.<sup>[135]</sup> One of the most intriguing observations was that nanocrystals prepared by the altered aerogel approach have exhibited higher surface chemical reactivities than more conventionally prepared samples (precipitation of hydroxides followed by vacuum dehydration, herein referred to as CP samples).<sup>[135]</sup> For example, in the reaction of  $2\text{CaO} + \text{CCl}_4 \rightarrow 2\text{CaCl}_2 + \text{CO}_2$ , AP (aerogel prepared) samples demonstrated reaction efficiencies twice those of CP samples and 30 times higher than commercial samples.<sup>[1,136]</sup> For the adsorption of SO<sub>2</sub>, AP MgO adsorbed three times as much as CP MgO/nm<sup>2</sup>.<sup>[137,138]</sup> For the destructive adsorption of CH<sub>3</sub>(CH<sub>3</sub>O)<sub>2</sub>PO, the reaction efficiency was four times higher for AP MgO than CP MgO, and 50 times higher than for CM MgO.<sup>[139]</sup> This high reactivity observed at both room temperature and high temperatures observed for numerous reactions demonstrates that this is not an effect of higher surface area alone. Nanoparticles (especially the AP samples) have been shown to possess a much greater number of defect sites per unit surface area, which are believed to be responsible for the observed chemistry.

### Physical/Mechanical Properties

Many physical properties of nanoscale metal oxides are also size-dependent. Most of the physical properties are dominated by those of the surface, which differ from the bulk because of the different bonding geometries present in nanoscale materials. Several systems of nano-phase oxides have exhibited quite interesting and potentially useful mechanical properties, which creates the necessity for much more work on exploring their physical properties.

#### Improved sintering and hardness properties

Unique consolidation and compaction properties have been observed in ceramics produced from nanophase

powders. Ceramic is processed from nanophase powders by first compacting a powder composed of individual ceramic particles (usually less than 50 nm in size) into a raw shape (often called a green body), then it is heated at elevated temperatures. Densification occurs as a result of diffusion of vacancies out of pores (to grain boundaries) leading to sample shrinkage, which is referred to as pressureless sintering. Fortunately, nanophase powders were found to compact as easily as their analogous submicron particles. Samples have to be sintered at the lowest temperature possible for a time sufficient to remove the residual porosity and establish coherent grain boundaries to avoid particle size growth. Successful sintering enhances the hardness of materials. However, if, hardness decreases with sintering, only grain growth is occurring.<sup>[54]</sup>

Experimental evidence has demonstrated that nanophase powders densify at faster rates than commercial (submicron) particles. The slow densification of commercial samples is a result of their larger grain and pore sizes. It has also been found that faster densification rates allow achieving a given density at smaller grain sizes, before serious growth takes place. As a result of their small particle and pore sizes, nanocrystalline powders sinter to much greater densities than their conventional analogs at the same temperature. This also demonstrates that nanocrystalline powders, as compared to conventional powders, reach the same density at much lower temperatures, which eliminates the need for very high temperatures.<sup>[54,133,140–142]</sup>

Nonuniform heating where the outside layers of the particles densifies into a hard impervious shell, which constrains the inside of the sample from normal shrinking leading to some cracking as a result of strain incompatibility, is one disadvantage that can occur with fast densification. This problem can be avoided by several ways. The most efficient way is to heat the samples slowly to reduce the shrinkage in the outer shell while heat is transported to the inner regions.<sup>[143]</sup> Additionally, high-density nanostructured oxide systems including Y<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub> and ZrO<sub>2</sub> have been achieved via pressure-assisted sintering, and it has been shown that applying some pressure during sintering can increase the densification rate and suppress the particle growth.<sup>[144,145]</sup>

#### Reduced brittleness and enhanced ductility and superplasticity

The ability of some polycrystalline materials to undergo extensive tensile deformation without necking or fracture is referred to as superplasticity and ductility. Theoretical and experimental results provide evidence for the possibility that, traditionally, brittle materials can be ductilized by reducing their particle and grain sizes. Brittle ceramics can be superplastically

deformed at modest temperatures and then heat-treated at higher temperatures for high-temperature strengthening when made from nanocrystalline precursors. The great interest in this property stems from the fact that brittle fracture is a technical barrier in the use of ceramics in load-bearing applications. This interest in the superplasticity of oxide materials has been growing after it was experimentally demonstrated in 1986 that yttria-stabilized tetragonal zirconia polycrystals could be elongated by over 100% in tension.<sup>[145,146]</sup> Similar behavior was later demonstrated by other nanophase ceramic systems involving  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$ , and  $\text{ZnO}$ .<sup>[147–155]</sup>

One important use of superplasticity in ceramics is diffusion bonding, where two ceramic parts are pressed together at moderate temperatures and pressures to form a seamless bond through diffusion and grain growth across the interface. Diffusion bonds form more easily in nanocrystalline ceramics than in larger-grained ceramics as a result of both the enhanced plastic flow of nanocrystalline ceramics and the larger number of grain boundaries they provide for diffusional flux across the interface.<sup>[156,157]</sup>

Other properties of ceramics that are size-dependent include electrical and optical properties. An increase in the electrical resistance and dielectric constant was observed for nanophase ceramic materials as a result of their small particle sizes.<sup>[158,159]</sup> An effect on optical properties of ceramic materials was also found because of their nanometer particle sizes. As an example, nanoparticles of  $\text{TiO}_2$  were found to become a more efficient ultraviolet (UV) absorber.<sup>[160]</sup> In conclusion, nanophase ceramic powders and metal oxides hold great promise for better materials with unique desired properties and potential applications as compared to their large-grained counterparts.

#### Additional selected size dependent properties

Lead zirconate–titanate (PZT), a solution of ferroelectric  $\text{PbTiO}_3$  ( $T_c = 490^\circ\text{C}$ ) and antiferroelectric  $\text{PbZrO}_3$  ( $T_c = 230^\circ\text{C}$ ), belongs to the ferroelectric family of perovskite structure with a general formula of  $\text{ABO}_3$  (where A = mono or divalent, and B = tri to hexavalent ions).<sup>[158]</sup> Nanoscale PZT particles (25 nm) were synthesized by using an in situ method. Powder X-ray diffraction (XRD) studies of these particles found the sample X-ray amorphous and produced single phase PZT after heating at  $500^\circ\text{C}$ .

Nanophase powders of  $\text{Y}_x\text{Zr}_{1-x}\text{O}_{2-x/2}$  have been prepared from a mixture of commercially available  $\text{ZrO}_2$  and  $\text{Y}_2\text{O}_3$  powders.<sup>[161]</sup> It was found that, depending on the starting powder mixture composition, the yttrium content in the nanophases can be controlled and the tetragonal or cubic phases can be obtained. Tetragonal or a mixture of tetragonal and

cubic were observed for low yttria content (3.5% mol yttria), and cubic for higher yttria contents (19, 54, and 76% mol yttria). These powders were found to have a most probable grain radius of about 10–12 nm and the grains appear as isolated unstrained single crystals with polyhedral shapes. The grain shapes appeared to be polyhedral and not very anisotropic. Lattice fringes were parallel to the surfaces demonstrating that (100) and (111) faces dominate.

## CONCLUSION

Nanoscale metal oxides are of considerable importance to both the fundamental understanding of size-dependent properties and numerous applications. While, in many cases, a basic understanding of the bonding and structure present in these systems has been determined, there is still a great deal of work to be carried out. Additionally, the methods for the preparation of oxide systems is a continually evolving area of science. Ultimately, developments in the areas of synthesis, instrumentation, and modeling will aid scientists as we try to gain an understanding of the relationships between physical, electronic, and chemical properties.

Developing a “tool box” of synthetic methods, which would afford scientists the possibility to put atoms together into nanomaterials with predetermined shapes and sizes, is an ongoing effort among preparative chemists. Another ongoing effort is the search for relationships between these shapes and sizes, and the chemical and electronic properties observed. As rapid advances take place in these areas, we will begin to see the potential of nanoscience begin to realize its potential. Metal oxides should be at the forefront of these advances in nanoscience because of their stability and the amount of information that has been gathered about their bulk counterparts through the years.

# Metal Oxide Nanoribbons and Carbon Nanotubes: Modeling

Amitesh Maiti

Materials Science, Accelrys Inc., San Diego, California, U.S.A.

## INTRODUCTION

Nanotechnology<sup>[1–5]</sup> continues to be a rapidly emerging field in which new ideas are being born and discoveries are being made at a breathtaking pace. New materials systems with novel properties are being designed or invented at an incredible rate in laboratories throughout the world. Of nanosystems, two of the most intensely studied are carbon nanotubes (CNTs)<sup>[6,7]</sup> and metal–oxide nanoribbons.<sup>[8]</sup> CNTs have been a popular area of research for more than a decade because of the promise of a host of commercial applications, while metal–oxide nanoribbons, particularly those synthesized from inexpensive SnO<sub>2</sub> and ZnO, have been a materials system of great current interest because of their potential applications as chemical sensors for pollutant gas species and biomolecules. The well-characterized atomic structures of both these systems, as well as their high degree of structural purity, allow accurate computer modeling and *in silico* property prediction. In the following, we illustrate some of the modern techniques of molecular modeling to study technologically important applications such as displays, electromechanical sensing, and chemical sensing.

## ROLE OF MOLECULAR MODELING

As with any new technology, Nanotechnology has many challenges to overcome, typically associated with our control and precision at the nanoscale. Some of the challenges include: device integration (interconnect failure, addressability issues), growth and synthesis (difficulty in size-dispersion control, requirement of novel assembly techniques, presence of structural defects), contact resistance (necessity of atomic-level structural precision at junctions), functionalization (challenges with chemical inertness), and doping (non-uniformity of dopant levels). Molecular modeling is a great approach in surmounting some of the above obstacles because it often provides deeper insight into the system properties as a function of size/shape, structural defects, added functional groups, and system

surroundings. Often, the whole nanosystem/device can be modeled in full atomistic detail on the computer, and its properties studied with a level of precision not possible experimentally. The growing success of density functional theory (DFT),<sup>[9]</sup> availability of accurate interatomic potentials (force fields),<sup>[10]</sup> development of Green's function-based electronic transport codes,<sup>[11]</sup> and deployment of sophisticated graphics user interface (GUI) have all led to the emergence of molecular modeling as a powerful tool in Nanotechnology research. Molecular modeling applications to nanomaterials are too numerous to mention here, and we can only point to the literature for further reference.<sup>[12–17]</sup>

## CARBON NANOTUBES (CNTs)

### Atomic and Electronic Structure

A CNT can be geometrically thought of as a graphite sheet rolled into a seamless cylinder. A necessary condition for the cylinder to be seamless is that, upon rolling, a graphite lattice point ( $n_1, n_2$ ) coincides with the origin (0,0). Thus if  $a_1$  and  $a_2$  are the two lattice vectors of graphite, the CNT circumference is equal to the length of the vector ( $n_1 a_1 + n_2 a_2$ ), while the CNT chiral angle  $\theta$  is defined as the angle between vectors ( $n_1 a_1 + n_2 a_2$ ) and  $a_1$ . With the choice of lattice vectors as in Fig. 1A, the chiral angle and diameter of a CNT are given respectively by the formulas:

$$\theta = (\tan^{-1}[\sqrt{3}n_2/(2n_1 + n_2)]), \text{ and} \quad (1)$$

$$d = a\sqrt{(n_1^2 + n_1n_2 + n_2^2)}/\pi \quad (2)$$

where  $a = |a_1| = |a_2| \sim 2.45 \text{ \AA}$  is the lattice constant of graphite. The CNT diameter and chirality, and therefore its atomic geometry, are completely specified by the two integers ( $n_1, n_2$ ), which are referred to as the chiral indices of the CNT. Because of the symmetry of the graphite lattice, a nanotube of any arbitrary chirality can be defined in the range  $n_1 \geq n_2 \geq 0$  and  $n_1 > 0$ , which implies that the chiral angle  $\theta$  for all

**Fig. 1** Carbon nanotube (CNT) basics. (A) A graphite sheet with lattice vectors  $a_1$ ,  $a_2$ . A few lattice points are indicated, as is the chiral angle  $\theta$  for a (3,1) CNT. Dotted and dashed lines are drawn along circumferences of armchair and zigzag tubes, respectively; (B) a (5,5) armchair tube; (C) a (9,0) zigzag tube.

CNTs lies between  $0^\circ$  and  $30^\circ$ . CNTs with the extreme chiral angles of  $0^\circ$  and  $30^\circ$  have special names: a CNT with  $\theta = 0$  (i.e.,  $n_2 = 0$ ) is called *zigzag*, while a CNT with  $\theta = 30^\circ$  ( $n_1 = n_2$ ) is called *armchair*. The names armchair and zigzag simply reflect the shape of the open edges of these CNTs (Fig. 1B,C). CNTs with any other chiral angles (i.e.,  $0 < \theta < 30^\circ$ ) are called *chiral*.

Armchair and zigzag CNTs possess short periodic repeat lengths along the nanotube axis, the repeat length being only  $a$  ( $\sim 2.45 \text{ \AA}$ ) for armchair tubes and  $\sqrt{3} a$  ( $\sim 4.24 \text{ \AA}$ ) for zigzag tubes. On the other hand, chiral CNTs can possess very long periodic repeat lengths depending on the ratio of its chiral indices. Thus electronic structure calculations, especially those employing first-principles Quantum Mechanics (QM) with periodic boundary conditions, are rarely performed on chiral tubes. However, this does not turn out to be a serious limitation. Because a CNT is just a rolled-up graphite sheet, one can obtain a good approximation to the CNT electronic structure simply by applying an appropriate boundary condition to the electronic structure of a graphite sheet, with a small perturbation resulting from the finite cylindrical *curvature* of the CNT surface. The boundary condition for a CNT with chiral indices  $(n_1, n_2)$  corresponds to the coincidence of the  $(n_1, n_2)$  lattice point of graphite with the origin  $(0,0)$ . It has been known for some time that a single sheet of graphite (also known as graphene) is neither a semiconductor nor a metal, but a semi-metal<sup>[18]</sup> (i.e., a zero-bandgap semiconductor). This peculiarity implies that the electronic states of graphene are very sensitive to additional boundary conditions that a CNT mandates. Taking into account small effects due to curvature, such boundary conditions lead to the important result<sup>[19–24]</sup> that: all *armchair* tubes are metallic; CNTs with  $n_1 - n_2 = 3n$  ( $n = \text{any positive}$

integer), which includes the  $(3n,0)$  *zigzag* tubes as a special class, are quasimetallic (small bandgap  $\sim 10 \text{ meV}$  or less, arising from curvature effects); and CNTs with  $n_1 - n_2 \neq 3n$  are semiconducting, with a bandgap decreasing as  $1/d$  as a function of tube diameter  $d$  (thereby converging to the zero bandgap of graphite in the limit  $d \rightarrow \infty$ ). Experimental measurements are often unable to make the distinction between metallic and quasimetallic tubes because of the presence of contact resistance and thermal effects. Thus, for simplicity, experimentalists often classify CNTs as either metallic or semiconducting, and we follow the same convention in the discussion below.

### Synthesis Methods, Properties, Potential Applications

CNTs were originally discovered by Sumio Iijima in 1991<sup>[25]</sup> in the soot produced by an arc discharge between graphite electrodes in a helium atmosphere. The original tubes<sup>[25–27]</sup> were multiwalled, i.e., they consisted of several concentric cylinders with successive layers separated by a distance approximately equal to the interlayer spacing of graphite. Subsequently, single-walled CNTs were synthesized in the same arc-discharge apparatus with the addition of transition-metal catalysts.<sup>[28,29]</sup> Presently, high-quality multiwalled and single-walled CNTs can be grown in well-defined directions via chemical vapor deposition (CVD),<sup>[30]</sup> while high-yield of single-walled CNTs can be obtained by several techniques, including: arc discharge of Ni–Y catalyzed graphite electrodes,<sup>[31]</sup> laser ablation of Ni–Co catalyzed graphite targets,<sup>[32]</sup> and vapor-phase pyrolysis of CO and  $\text{Fe}(\text{CO})_5$ <sup>[33]</sup> (the so-called HiPCO process).

Over the last decade, CNTs have become one of the hottest research areas in all of science and engineering because of a number of fascinating properties:

- Depending on their chiral indices, they can behave like metals or semiconductors, as discussed in the section “Atomic and Electronic Structure.”
- Single- or multiwalled CNTs are exceptionally strong, could possess a Young’s modulus as high as 1.2 TPa, six times the modulus of steel.
- CNTs are elastic to the highest degree, and do not display plasticity behavior even under large deformation including stretching, bending, or twisting.
- Metallic CNT are one-dimensional quantum conductors where electrons travel ballistically: there is no heat dissipation along the length of the CNT. All dissipation occurs at the contacts.
- CNTs can have huge aspect ratio (i.e., length-to-diameter ratio), as large as  $10^5$ . Therefore, field emission of electrons can be induced from the tip of long metallic CNTs in the presence of moderate electric fields.
- Depending on its chiral indices, metallic CNTs can undergo metal-to-semiconductor transition under small tensile or torsional strain. This effect is discussed in more detail in this section.
- With a magnetic field parallel to its axis, a CNT can exhibit the Aharonov–Bohm effect.
- Atoms/molecules can be enclosed inside a CNT.
- A CNT can be doped both p-type and (to a lesser degree) n-type.

All of the above properties come with the promise of a host of commercial applications,<sup>[34,35]</sup> including: field emission-based flat panel displays,<sup>[36–42]</sup> novel semiconducting devices and robust metallic interconnects in microelectronics,<sup>[43,44]</sup> hydrogen storage devices,<sup>[45]</sup> structural reinforcement agents,<sup>[46]</sup> chemical sensors,<sup>[47–49]</sup> electromechanical sensors,<sup>[47,50]</sup> nano-probes,<sup>[51]</sup> and nanotweezers.<sup>[52]</sup>

### Molecular Modeling of CNTs

Ever since they were discovered, CNTs have provided a fertile ground for theoretical simulations and analysis. In fact, the prediction of the dependence of CNT’s electronic structure on its chirality<sup>[19–21]</sup> came within just a few months of the experimental discovery.<sup>[25]</sup> Since then, there have been a huge number of theoretical investigations<sup>[14–16,53–55]</sup> of growth mechanisms, structure and energetics of topological defects, mechanical and electrical response to various kinds physical perturbation, field emission from tips of metallic CNTs, electronic effects of doping and gas adsorption, chemical reactivity, interaction with polymers,

capillary effects, CNT–metal contacts, H and Li storage, thermal conductivity, and encapsulation of organic as well as inorganic material. Computational approaches used in the above work include solving diffusion equations, QM simulations (DFT, tight binding, and semiempirical methods), classical molecular dynamics, kinetic Monte Carlo, genetic algorithms, and Green’s function-based electronic transport theory. The following two sections illustrate the use of some of the above techniques to explore two application areas of CNTs: 1) field-emission displays; and 2) nano-electromechanical sensors.

### CNT-Based displays: effect of adsorbates

Synthesis of CNTs with length-to-width ratio as large as  $10^5$ , as well as advanced fabrication methods for generating self-aligned or patterned nanotube films on glass<sup>[56]</sup> or silicon<sup>[40]</sup> substrates have pushed CNT-based flat-panel displays to the brink of commercial reality.<sup>[57–59]</sup> One major challenge to overcome is to reduce the threshold field, defined as the electric field necessary to induce a current of  $1 \text{ mA/cm}^2$ . One way to achieve this is to introduce adsorbates that might effectively lower the ionization potential (IP) and facilitate the extraction of electrons. An important experimental work in this regard was performed at Motorola,<sup>[60]</sup> which studied changes in field emission behavior in the presence of various gases, i.e., CO, CO<sub>2</sub>, H<sub>2</sub>, and water vapor. Adsorbed water was found to significantly enhance the emission current, while the other residual gases did not have any noticeable impact. Water also appeared to be present at the CNT tip up to very high temperatures ( $\sim 900 \text{ K}$ ), and field-emission current was more enhanced at higher partial pressures of water.

To understand the difference between H<sub>2</sub> and water on the field-emission properties of CNTs, first-principles electronic structure calculations were carried out on a (5,5) armchair tube, with a hemispherical tip represented by the half of a C<sub>60</sub> molecule. A uniform external field  $E_{\text{FE}}$ , directed toward the tube from above, was chosen to represent the electric field close to the tube tip under field emission conditions. Because the actual field close to the tip is radial rather than uniform,<sup>[61]</sup> the uniform field representation is appropriate only if the tube stem in the simulation is confined to the same size as the tube diameter. For this reason, a short stem of three atomic layers (30 atoms) was used. A more realistic field around the tip could perhaps be simulated via a large number of point charges situated at some distance from the tip. Such an effort was not undertaken for two reasons: 1) in all flat panel display designs, the field emission occurs not from isolated tubes, but from a film of closely spaced nearly

aligned tubes, with the resulting E-field more closely resembling a uniform field above the tip assembly; 2) the essential chemistry that drives the effect of adsorbates on field emission behavior can be extracted from calculations by using a uniform field, as illustrated below. For all calculations, a magnitude of  $E_{FE} = 1 \text{ V/\AA}$  was used as a ballpark figure, around which field emission is known to occur for these systems. Difference in electronegativities between H and C introduces an artificial dipole moment in the CNT if the dangling C atoms at the stem end are H-saturated. The C atoms at the stem end were therefore left unsaturated. In addition, these C atoms were fixed during the simulation to mimic the presence of a long stem in actual experiments. Structures of the CNT with or without adsorbates were optimized by using the DFT code DMol<sup>3</sup>,<sup>[62]</sup> in which the electronic wave functions are expanded as a linear combination of atom-centered basis functions defined on a numerical grid. The present calculations explicitly considered all electrons in the system (i.e., core electrons were included), with wave functions expanded in the double numeric polarized (DNP) basis set,<sup>[63]</sup> and the exchange-correlation part of the electron–electron interactions represented by the gradient-corrected Perdew–Burke–Ernzerhof (PBE) functional.<sup>[64]</sup> The main results from this study<sup>[65]</sup> can be summarized as follows:

1. A single H<sub>2</sub> molecule can either lie “flat” or “upright” on the CNT (Fig. 2A,B). A single water molecule adsorbs in such a way that its plane symmetrically cuts the CNT into two equal halves. The two H atoms are symmetrically equidistant from the tip, and could be

**Fig. 2** Optimized structures for adsorbates on a CNT tip in zero electric field: (A) H<sub>2</sub> (flat); (B) H<sub>2</sub> upright; (C) a single “down” water; (D) a cluster of five water molecules; (E) view of (D) from top.

either closer or further from the surface as compared to the O atom. We call these configurations “down” (Fig. 2C) and “up” water, respectively.

2. In zero electric field, none of the adsorbates show any significant binding to the CNT tip. The H<sub>2</sub> has less than 0.1 kcal/mol binding in either configuration, while a single water has  $\sim 0.7$  kcal/mol binding.
3. At a tip field of  $1 \text{ V/\AA}$ , the binding energies change significantly. Thus H<sub>2</sub> has a binding energy of 1.1 and 3.5 eV, in the flat and the upright configurations, respectively, while the “down” water has a binding energy of  $\sim 20$  kcal/mol, which is of the order of a chemical bond. The “up” water becomes unstable in the presence of a finite electric field at the CNT and spontaneously flips into a “down” water. Therefore “up” water is not considered further in the discussion below.
4. Because water molecules can form clusters through H bonding, it was also important to consider the structure and adsorption energy of a cluster of water molecules on the CNT tip. Because of the fivefold symmetry of the (5,5) CNT (with a C<sub>60</sub> half cap) about its axis, it was easy to determine the global minimum for a cluster of five water molecules. In the minimum energy structure, the five water molecules form a “crown” on the top of the CNT (Fig. 2D,E). Each water molecule in this crown is tilted with respect to the ideal “down” water configuration for a single water molecule. However, the resulting loss in interaction energy with the CNT tip is almost exactly recovered from the gain in H bonding to the nearest neighbor waters.
5. The adsorbate atoms in all cases are at a distance of 3 Å or more from the CNT surface. This strongly suggests that they are being physisorbed. This is supported by an analysis of charge density in the region between the adsorbate and the CNT tip, which is less than  $0.004 \text{ e/\AA}^3$ . Even at a field as large  $1 \text{ V/\AA}$ , the changes to the adsorbate and CNT structures are small. In particular, the distance between the adsorbate and the CNT changes by less than 0.07 Å, and the bond lengths change by less than 0.01 Å. The most significant geometrical change is in the H–O–H angle in water, which decreases from 103.7° in zero field to 98° on the tube tip at  $E_{FE} = 1 \text{ V/\AA}$ . Such a change in angle leads to only a 0.02 a.u. increase in the dipole moment of water.
6. An analysis of the various interaction energies and the dipole moments of the CNT as well as

the adsorbates yield the following picture: in the absence of an electric field, the CNT has a very small dipole moment. This small dipole has only negligible interaction with any of the adsorbates. However, under field-emission conditions, large E-field at the CNT tip induces a significant dipole moment. This dipole interacts with the dipole of the adsorbates. Water molecules having a large intrinsic dipole moment interacts strongly, while H<sub>2</sub> molecules have only a small field-induced dipole, and therefore a much weaker interaction.

- Finally, the highest occupied molecular orbital (HOMO) for the isolated CNT, one water molecule on CNT, and five water molecules on the CNT were analyzed (Fig. 3). The HOMO essentially remains confined to the CNT tip, and its shape does not significantly change because of the presence of the adsorbates. However, when the ionization potential (IP) is computed, it is found to be 0.1 and 0.6 eV lower for the one water and five water cases, respectively, compared to the adsorbate-free CNT. This also perfectly correlates to the instability of the HOMO orbital. Thus electrostatic interactions from the adsorbates make the HOMO level in the CNT more unstable, with a corresponding decrease in the IP, thereby lowering the operating voltage for field emission.

Table 1 displays computed IP of a (5,5) CNT tip (same as in Fig. 2) for a number of potential adsorbates,<sup>[66]</sup> including water. It is clear that as the lowering of IP becomes more pronounced, the larger the dipole moment of the adsorbate becomes. This work calls for further experiments on polar adsorbates to optimize the performance of CNT-based field-emission displays. It would also be interesting to compute *I-V* characteristics due to field emission from CNT tips<sup>[67]</sup> in the presence of adsorbates.

**Fig. 3** Highest occupied molecular orbital (HOMO) for: isolated CNT; CNT + 1 adsorbed water; and CNT + 5 adsorbed water. Although the position and shape of the HOMO is not significantly affected by the adsorbates, the energy level and ionization potential change markedly.

**Table 1** IP of a (5,5) CNT for various molecules physisorbed on its tip

Adsorbate	Dipole moment (Debye)	Ionization potential (eV)
H <sub>2</sub>	0.0	6.40
HCl	1.0	6.36
H <sub>2</sub> O	2.0	6.30
HCN	3.0	6.20
LiH	5.9	6.12

### CNT-based nano-electromechanical sensors

Interest in the application of carbon nanotubes as electromechanical sensors received a significant boost from the pioneering experiment of Tomblor et al.,<sup>[50]</sup> in which the middle part of the segment of a metallic CNT suspended over a trench was pushed with an Atomic Force Microscope (AFM) tip. Beyond a deformation angle of  $\sim 13^\circ$ , the electrical conductance of the tube dropped by more than 2 orders of magnitude. The effect was found to be completely reversible, i.e., through repeated cycles of AFM deformation and tip removal, the electrical conductance displayed a cyclical variation with constant amplitude. An interesting explanation was put forward by O(N) tight-binding calculations,<sup>[68]</sup> which show that beyond a critical deformation several C atoms close to the AFM tip become sp<sup>3</sup>-coordinated. This leads to the tying up of  $\pi$  electrons into localized  $\sigma$  states, which would explain the large drop in electrical conductance.

Considering the significance of the above result, it was important to carry out an independent investigation using first-principles QM. Unfortunately, the smallest models required to simulate the AFM deformation of a CNT typically involve a few thousand atoms, which makes first-principles QM simulations unfeasible. This necessitated a combination of first-principles DFT and classical molecular mechanics. Bond reconstruction, if any, is likely to occur only in the highly deformed, non-straight part of the tube close to the AFM tip. For such atoms ( $\sim 100$ – $150$  atoms including AFM-tip atoms), a DFT-based QM description was used, while the long and essentially straight part away from the middle was described accurately by using the Universal Forcefield (UFF),<sup>[69]</sup> which was previously used in CNT simulations.<sup>[70]</sup>

Because of known differences in the electronic response of zigzag and armchair tubes to mechanical deformation, the simulations were performed on a (12,0) zigzag and a (6,6) armchair tube, each consisting of 2400 atoms. The AFM tip was modeled by a 6-layer deep, 15-atom Li needle normal to the (100) direction, terminating in an atomically sharp tip. To simulate AFM tip deformation, the Li needle was initially

aimed at the center of a hexagon on the bottom side of the middle part of the tube. The Li needle tip was then displaced by an amount  $\delta$  toward the tube along the needle axis, resulting in a deformation angle  $\theta = \tan^{-1}(2\delta/l)$ ,  $l$  being the unstretched length of the tube. At each end of the tube, a contact region defined by a unit cell plus one atomic ring (a total of 36 and 60 atoms for the armchair and the zigzag tube, respectively) was then fixed, and the whole tube relaxed with the UFF, while constraining the needle atoms as well. The contact region atoms were fixed to simulate an ideal undeformed semiinfinite carbon nanotube lead, and to ensure that all possible contact modes are coupled to the deformed part of the tube. Following the UFF relaxation, a cluster of 132 C atoms for the (6,6) tube, and a cluster of 144 C atoms for the (12,0) tube were cut out from the middle of the tubes. These clusters, referred to below as the *QM clusters* (plus the 15 Li-tip atoms in tip deformation simulations) were further relaxed with Accelrys' DFT code DMol<sup>3</sup>,<sup>[62,63,71–73]</sup> with the end atoms of the cluster plus the Li-tip atoms fixed at their respective classical positions. To cut down on CPU requirements, the DFT calculations were performed by using the Harris functional<sup>[74,75]</sup> and the local exchange-correlation potential due to Vosko, Wilk, and Nusair.<sup>[76]</sup>

Fig. 4 displays the tip-deformed QM cluster for (6,6) and (12,0) tubes at the highest deformation angle of 25° considered in these simulations. Even under such large deformations, there is no indication of sp<sup>3</sup> bonding, and the structure was very similar to what was observed for a (5,5) tube in a previous work.<sup>[77]</sup> The absence of sp<sup>3</sup> coordination is inferred based on an analysis of nearest-neighbor distances of the atoms

**Fig. 4** DMol<sup>3</sup>-relaxed Li-tip-deformed QM clusters for: (A) the (6,6) armchair (132 C atoms); and (B) the (12,0) zigzag (144 C atoms), in side views. The deformation angle is 25° for both tubes. Panels (C) and (D) are the respective views along the tube length, with the Li tip hidden for clarity.

with the highest displacements, i.e., the ones closest to the Li tip. *Although, for each of these atoms, the three nearest neighbor C–C bonds are stretched to between 1.45 and 1.75 Å, the distance of the fourth neighbor, required to induce sp<sup>3</sup> coordination is greater than 2.2 Å for all tubes in our simulations.*

Following the structural relaxation of the CNTs, the transmission and conductance were computed using the recursive Green's function formalism.<sup>[11,78]</sup> A nearest-neighbor sp<sup>3</sup> tight-binding Hamiltonian in a non-orthogonal basis was chosen, and ideal semiinfinite contacts assumed at both ends. The parameterization scheme explicitly accounts for the effects of strain in the system through a bond length dependence of the Hamiltonian and the overlap matrices  $\mathbf{H}_{ij}$  and  $\mathbf{S}_{ij}$ .<sup>[79]</sup> First, the retarded Green's function  $G^R$  of the whole CNT was determined by solving the following equation:

$$(E \cdot \mathbf{S}_{ij} - \mathbf{H}_{ij} - \Sigma_{L,ij} - \Sigma_{R,ij})G^{R,jk} = \delta_i^k \quad (3)$$

where  $\Sigma_{L,R}$  are the retarded self-energies of the left and the right semiinfinite contacts. The transmission at each energy was then obtained<sup>[80]</sup> from the equation:

$$T(E) = G^{R,ij}\Gamma_{L,jk}G^{A,kl}\Gamma_{R,li} \quad (4)$$

where  $\Gamma_{L,R} = i(\Sigma_{L,R}^R - \Sigma_{L,R}^A)$  are the couplings to the left and right leads. Finally, the total conductance of the tube was computed by using Landauer–Büttiker formula:

$$G = \frac{2e^2}{h} \int_{-\infty}^{\infty} T(E) \left( -\frac{\partial f_0}{\partial E} \right) dE \quad (5)$$

where  $f_0(E)$  is the Fermi–Dirac function. In Eqs. (3) and (4), summation over the repeating roman indices is implied. The lower and upper indices denote the covariant and contravariant components of a tensor.

The simulations (Fig. 5) indicate that the conductance remains essentially constant for the (6,6) armchair tube up to deformation as large as 25°. However, for the (12,0) zigzag tube, the conductance

**Fig. 5** Computed conductance (in Siemens) of AFM-deformed (6,6) and (12,0) CNTs as a function of deformation angle  $\theta$  (in degrees).

drops significantly, by 2 orders of magnitude at  $20^\circ$  and 4 orders of magnitude at  $\theta = 25^\circ$ . Because  $sp^3$  coordination could be ruled out, what could be the cause for such a large conductance drop in the experiment of Ref.<sup>[50]</sup> as well as for the metallic zigzag tube in Fig. 5? Also, why did the armchair tube display no significant drop in conductance even up to large angles of deformation?

A simple explanation emerges if one zooms out from the middle of the tube and looks at the profile of the whole tube under AFM deformation. One immediately discovers an overall stretching of the tube under AFM deformation, as indicated schematically in Fig. 6. Fig. 7 compares drop in conductance in the (12,0) tube subjected to: 1) AFM deformation; and 2) uniform stretching. Such comparison makes it clear that tensile strain is the main reason behind the conductance drop in an AFM-deformed metallic zigzag tube. It was also verified that the (6,6) armchair tube does not undergo any significant conductance drop upon stretching.<sup>[81]</sup>

To explain the differences in conductance drops of the armchair (6,6) and the zigzag (12,0) tubes as a function of strain, it helps to revisit the literature where a considerable amount of theoretical work already exists.<sup>[82–86]</sup> An important result<sup>[86]</sup> is that the *rate of change* of bandgap as a function of strain depends on the CNT chiral angle  $\theta$ , more precisely as proportional to  $\cos(3\theta)$ . Thus stretched armchair tubes ( $\theta = 30^\circ$ ) do not open any bandgap, and always remain metallic. On the other hand, a metallic (3n,0) zigzag tube ( $\theta = 0$ ) can open a bandgap of  $\sim 100$  meV when stretched by only 1%. This bandgap increases linearly with strain, thus transforming the CNT into a semiconductor at a strain of only a few percent. In general, all metallic tubes with  $n_1 - n_2 = 3n$  will undergo the above metal-to-semiconductor transition, the effect being the most pronounced in metallic zigzag tubes. An experiment such as that in Ref.<sup>[50]</sup> is thus expected to show a decrease in conductance upon AFM deformation for all CNTs except the armchair

**Fig. 6** Schematic diagram representing deformation with an AFM tip. The tip-deformed tube undergoes a tensile strain. The deformation angle  $\theta$  is related to the tip displacement ( $\delta$ ) and non-deformed tube length ( $l$ ) by  $\theta = \tan^{-1}(2\delta/l)$ .

**Fig. 7** Conductance of an AFM tip-deformed (12,0) tube compared to the same tube under a uniform stretch. Actual angles of tip deformation are indicated. The % strain for the AFM-deformed tube is computed from the average C–C bond stretch in the middle of the straight portion of the tube. The inset shows transmission in the vicinity of the Fermi surface (energy = 0) for a uniform strain of 10% and a tip-deformation angle of  $25^\circ$ , compared to the non-deformed tube.

tubes. Researchers are also beginning to explore the electromechanical response of a squashed CNT,<sup>[87,88]</sup> where  $sp^3$  coordination is a possibility.

In addition to the above results for metallic CNTs, theory also predicts that for semiconducting tubes ( $n_1 - n_2 \neq 3n$ ), the bandgap can either increase (for  $n_1 - n_2 = 3n - 2$ ) or decrease (for  $n_1 - n_2 = 3n - 1$ ) with strain. These results have recently prompted more detailed experiments on a set of metallic and semiconducting CNTs deformed with an AFM tip,<sup>[89]</sup> as well as on CNTs under experimental tensile stretch.<sup>[90]</sup> Commercial applications from such work could lead to novel pressure sensors, transducers, amplifiers, and logic devices.<sup>[91]</sup>

## NANOWIRES AND NANORIBBONS

In spite of tremendous advances in carbon nanotube research, there remain a number of practical difficulties hindering many applications. Cheap mass production remains one of the biggest hurdles. Other technological challenges involve controlling CNT chirality, isolating/separating CNTs from bundles, alignment in nanocomposites, and so on. Chemical inertness of the CNT poses big problems in functionalization, sensor applications, and adhesion to structural materials. The above deficiencies have prompted researchers to explore other types of one-dimensional nanostructures. These efforts have recently led to the synthesis

of *nanowires* and *nanoribbons*. Nanowires are typically solid (i.e., not hollow) cylindrical objects with a nearly uniform diameter of a few tens of nanometers or less. So far, most nanowires<sup>[1]</sup> have been synthesized from standard semiconductors: Si, Ge, GaAs, GaP, GaN, InAs, InP, ZnS, ZnSe, CdS, CdSe, and mixed compounds. Semiconducting nanowires have great potential in electronic and optoelectronic applications at the nanoscale. In addition, conducting nanowires made of transition and noble metals, silicides ( $\text{ErSi}_2$ ), and polymeric materials have also been investigated in connection with interconnect applications.

Nanoribbons are a close cousin of the nanowires. As the name suggests, they possess a uniform rectangular cross-section with well-defined crystal structure, exposed planes, and growth direction (Figs. 8 and 9). So far, nanoribbons have primarily been synthesized from the oxides of metals and semiconductors. In particular,  $\text{SnO}_2$  and  $\text{ZnO}$ <sup>[92–94]</sup> nanoribbons have been materials systems of great current interest because of their potential applications as catalysts, in optoelectronic devices, and as chemical sensors for pollutant gas species and biomolecules.<sup>[95–97]</sup> Although they grow to tens of microns long, the nanoribbons are remarkably single-crystalline and essentially free of dislocations. Thus they provide an ideal model for the systematic study of electrical, thermal, optical, and transport processes in one-dimensional semiconducting nanostructures, and their response to various external process conditions.

### $\text{SnO}_2$ Nanoribbons: A Brief Introduction

$\text{SnO}_2$  nanoribbons are usually synthesized by evaporating  $\text{SnO}$  or  $\text{SnO}_2$  powder at high temperature, followed by deposition on an alumina substrate in the

**Fig. 8** TEM bright-field image of  $\text{SnO}_2$  nanoribbons displaying strain contrast induced by bending of the ribbons. Each nanoribbon is single-crystalline without any dislocations. *Source:* From Ref.<sup>[93]</sup>.

**Fig. 9** Schematic diagram of a  $\text{SnO}_2$  nanoribbon, showing typical dimensions, exposed planes, and growth direction.

downstream of an Ar gas flow.<sup>[92]</sup> Field-emission scanning electron microscopy (FE-SEM) and transmission electron microscopy (TEM) revealed that the ribbons: 1) possess a highly crystalline rutile structure; 2) grow tens of microns long in the  $\langle 10\bar{1} \rangle$  direction; 3) display a uniform quasirectangular cross-section perpendicular to the growth direction; and 4) present the  $(10\bar{1})$  and  $(010)$  rutile planes as surface facets along the growth axis, with dimensions ranging from 80 to 120 nm by 10 to 30 nm (Fig. 9). Rutile  $\text{SnO}_2$  is a wide bandgap (3.6 eV) n-doped semiconductor, with the intrinsic carrier density determined by the deviation from stoichiometry, primarily in the form of oxygen vacancies.<sup>[98]</sup>

### $\text{SnO}_2$ Nanoribbons as Chemical Sensors

Recent experiments with  $\text{SnO}_2$  nanoribbons<sup>[99]</sup> indicate that these are highly effective in detecting even very small amounts of harmful gases such as  $\text{NO}_2$ . Upon adsorption of these gases, the electrical conductance of the sample decreases by more than 1 order of magnitude. More interestingly, it is possible to remove the adsorbates by shining UV light, and the electrical conductance is completely restored to its original value. Such single-crystalline sensing elements have several advantages over conventional thin-film oxide sensors: low operating temperatures, no ill-defined coarse grain boundaries, and high active surface-to-volume ratio.

Electron-withdrawing groups such as  $\text{NO}_2$  and  $\text{O}_2$  are expected to deplete the conduction electron population in the nanoribbon, thereby leading to a decrease in electrical conductance. To investigate this, first-principles DFT calculations of the adsorption process of  $\text{NO}_2$ ,  $\text{O}_2$ , and  $\text{CO}$  on the exposed  $(10\bar{1})$  and  $(010)$  surfaces, as well as the edge atoms of a  $\text{SnO}_2$  nanoribbon, were carried out. The DFT code used was DMol<sup>3</sup><sup>[62,63,71–73]</sup> with the same basis set, parameter settings, and exchange-correlation functional as in the section “Atomic and Electronic Structure.” Nanoribbon surfaces were represented in periodic supercells (Figs. 10 and 11), and accurate Brillouin zone

**Fig. 10** Simulation supercells representing exposed surfaces of a  $\text{SnO}_2$  nanoribbon: (A)  $(10\bar{1})$  surface; (B)  $(010)$  surface. Surface atoms are shown in ball representation. White (larger) balls and black (smaller) balls represent Sn and O atoms, respectively.  $\text{Sn}^1$  and  $\text{Sn}^2$  are neighboring Sn atoms connected with a bridging O.

integration was performed by careful sampling of  $k$ -points chosen according to the Monkhorst–Pack scheme,<sup>[100]</sup> with a  $k$ -point spacing of  $0.1 \text{ \AA}^{-1}$ . To estimate charge transfer to adatoms, the partial charge on each atom was computed by using the Mulliken population analysis.<sup>[101]</sup>

In bulk rutile  $\text{SnO}_2$ , the Sn atoms are octahedrally coordinated with six O neighbors, while each O atom is a threefold bridge between neighboring Sn centers. At both  $(10\bar{1})$  and  $(010)$  surfaces, the Sn atoms lose an O neighbor, thereby becoming fivefold coordinated (Fig. 10A,B). The surface O atoms become

**Fig. 11** Simulation supercells representing  $\text{SnO}_2$  nanoribbon edges. For clarity, the periodic cell is not shown, and the interior atoms are represented by polyhedra. The edge (Sn) atoms are shown in ball representation.

twofold-coordinated bridges connecting neighboring surface Sn atoms (Fig. 10A,B). Both surfaces were represented by three layers of Sn, each layer being sandwiched between two O layers. The bottom  $\text{SnO}_2$  layer was fixed to simulate the presence of several bulk-like layers in the actual sample. To reduce interaction with periodic images, the surface unit cell was doubled in the direction of the smaller surface lattice constant, and a vacuum of  $15 \text{ \AA}$  was placed normal to the surface. To simulate nanoribbon edges [i.e., lines of intersection of  $(10\bar{1})$  and  $(010)$  planes], a structure similar to that in Fig. 11 was embedded in a periodic supercell with the smallest repeat period ( $5.71 \text{ \AA}$ ) along the length of the ribbon, and a vacuum of  $15 \text{ \AA}$  normal to both the  $(10\bar{1})$  surface ( $y$ -axis) and the  $(010)$  surface ( $x$ -axis). At the nanoribbon edges, the Sn atoms can be either threefold- or fourfold-coordinated (Fig. 11).

Details of the results on binding energy and charge transfer are discussed elsewhere.<sup>[102]</sup> Important results are summarized below:

1. All adsorbate structures involve one or more bonds to surface Sn atoms. The binding energy on different surfaces and edges increases in the sequence  $(010) < (10\bar{1}) < 3\text{-fold edge} < 4\text{-fold edge}$ .
2.  $\text{NO}_2$  adsorption displays a very rich chemistry because it can either form a single bond to a surface Sn, or can adsorb in the bidentate form through two single bonds to neighboring Sn atoms. The doubly bonded  $\text{NO}_2$  is 2–3 kcal/mol more stable than the single-bonded  $\text{NO}_2$ , and the binding energies are in general 4–5 kcal/mol higher on the  $(10\bar{1})$  surface than on the  $(010)$ . Activation barrier between the doubly bonded and single-bonded structures is expected to be low, which should make the  $\text{NO}_2$  species mobile on the exposed faces by performing a series of random walk steps along well-defined rows of Sn atoms on the surface.
3. When two  $\text{NO}_2$  molecules meet on the surface, either through random walk as described above, or through the incidence of a second  $\text{NO}_2$  from the gas phase in the vicinity of an already chemisorbed  $\text{NO}_2$ , there is a transfer of an O atom from one  $\text{NO}_2$  to the other, thus converting it to a surface  $\text{NO}_3$  species. The net disproportionation reaction  $\text{NO}_2 + \text{NO}_2 \rightarrow \text{NO}_3 + \text{NO}$  is well known in chemistry. The bidentate  $\text{NO}_3$  group has a substantially higher binding energy, especially on the  $(10\bar{1})$  surface, and should not, therefore, be mobile. The resulting NO species is only weakly bound to the surface and should desorb easily. Synchrotron measurements using X-ray absorption near-edge spectroscopy (XANES) have recently confirmed the

abundance of  $\text{NO}_3$  species on the nanoribbon surface following  $\text{NO}_2$  adsorption (Fig. 12).<sup>[102]</sup>

4. A CO likes to adsorb in the following manner: the C forms two single bonds to the surface—one with a surface Sn and another with a bridging O, while the O of the CO forms a double bond to the C and sticks out of the surface. This way, the C atoms attains its preferred 4-valency and the O has its bivalency satisfied.
5. On a defect-free surface (i.e., surface with no O vacancies), the  $\text{O}_2$  molecules can only weakly physisorb. In this configuration, there is no charge transfer to the  $\text{O}_2$ , and therefore a nanoribbon surface without surface O vacancies should be insensitive to atmospheric oxygen. However, at surface O-vacancy sites, the  $\text{O}_2$  molecule has a strongly bound chemisorbed structure in the form of a peroxide bridge.
6. Both  $\text{NO}_3$  groups and chemisorbed  $\text{O}_2$  (at O-vacancy sites) accept significant amount of

**Fig. 12** N K-edge XANES spectra acquired after exposing nanoribbons of  $\text{SnO}_2$  to  $\text{NO}_2$  at 300 K. Traces “A” and “B” correspond to two different nanoribbon samples, respectively. Included in the figure are the corresponding spectra for  $\text{KNO}_2$  and  $\text{KNO}_3$ . Source: The assignment of the features in these spectra is discussed in Refs.<sup>[103,104]</sup>

electronic charge from the surface. Therefore such adsorbates should lead to the lowering of electrical conductance of the sample. On the other hand, CO donates a moderate amount of electrons to the surface, and is therefore expected to increase the electrical conductance. All these results are consistent with direct experimental measurements of sample conductance.<sup>[96,99,105]</sup> Charge transfer between molecular species (donor or acceptor alike) and the nanoribbon surface could thus serve as a general mechanism for ultrasensitive chemical and biological sensing by using single-crystalline semiconductor nanowires.

## INTRODUCTION

It is now widely recognized that the fundamental properties of materials strongly depend on the size of crystallites, especially if they are in the nanometer regime. Most of the physical, optical, and electronic properties of a bulk solid vary when the crystallites are in the nanoscale regime. If the grain size can be maintained at nanoscale dimensions, this creates major opportunities to design advanced materials with enhanced properties.

The emerging nanometals industry encompasses nanoparticles, nanolayers, thin films, nanofibers, and bulk nano-structured metals and alloys. This entry focuses on metal nanoparticles, their properties and uses, with special emphasis on those manufactured by the electroexplosion of metal wire (EEW), a process that is the most commercialized and has produced the greatest diversity of metal nanopowders.

Nanometals are in the process of becoming one of the major feedstocks for a host of emerging technologies and industries. The body of knowledge on nanosize particles has grown throughout the latter part of the twentieth century as various processes for producing them were developed. With the exception of precious metals, most of the focus has been on ceramics and non-metallic materials. More recently, there has been an increasing interest in other metallic nanoparticles. Handling them is problematic because they are highly reactive and difficult to produce, handle, and ship.

Nanosize precious metals have already had a long history of development and use as catalysts and in photography because of their chemical stability in water and air. Precious metal catalysts in a ceramic matrix, as in automotive catalysts, or dispersed homogeneously in media have had a profound affect on industrial processes. The increasing availability of other nanosize metals should lead to a plethora of new applications from composites to chemicals.

## NANOMETAL PROCESSES

There are over a dozen companies that are currently developing processes for nano metal particles, but only a few companies routinely manufacture and supply them. Production quantities are currently limited to only grams or a few kilograms but some companies claim they are building facilities to produce tens to hundreds of kilograms per day. As a result of the small quantities, the prices range from several hundred to a few thousand dollars per kilogram. Most companies do not stock nano metal powders but will produce them on a custom basis.

The manufacturing processes for micron-scale powders, such as water atomization, are generally not adaptable to nanometer size metal powders, mostly because the powders would be oxidized in the environment in which they are produced. The methods currently being developed for nanosize particles include the following:

- **Ball milling**—This method is capable of milling brittle materials to nanometer size, but fails for ductile metals such as copper unless milling is performed at cryogenic temperatures. Milling produces non-spherical particles with a broad particle size range. Dry milling of the more reactive metals can result in their contamination by air but wet milling under an organic fluid can protect the powder. Dry milling in an inert atmosphere is more complex and expensive.
- **Precipitation from aqueous solution**—Such processes are limited to precious metals because most other nanosize powders will react with water, causing surface contamination and, in the case of reactive metals, rapid and sometimes violent reaction. Metals that are precipitated from aqueous solutions generally tend to be porous and highly agglomerated. For example, silver particles can be

produced<sup>[1]</sup> via the reduction of acidic silver salt solutions using aldehydes in the presence of silica sol, but the powder is highly agglomerated. The silica is subsequently hydrolyzed in caustic, and aided by a surfactant, it is separated from the agglomerated silver powder. Bonet et al.<sup>[2]</sup> describe a method for producing deagglomerated precious metal particles smaller than 10 nm by heating a mixture of precious metal salts with hot (~150°C) ethylene glycol using polyvinylpyrrolidone (PVP) to minimize agglomeration.

- Organometallic synthesis in solution—This method employs the use of kinetically controlled reactions of organometallic precursors usually in non-aqueous solvents to product metal nanoparticles. The process can also utilize redox chemistry to reduce an inorganic precursor. The advantage of this process is that monodisperse populations of small (<50 nm) particles is possible, and the disadvantage is that Schlenk-type techniques may be necessary.
- Evaporation/condensation under vacuum—Vacuum-driven thermal evaporation is limited to low-boiling-point metals such as aluminum and copper. Higher-boiling-point materials can be evaporated by e-beam or laser heating, but the capital and operating costs of such processes are high, favoring the development of processes that operate at or near ambient pressure.
- Evaporation/condensation of the metal in an inert gas environment—Because most of the nanometals will react with oxygen or nitrogen to form oxides and nitrides, such processes require an inert gas cover. Generally, argon is used because of its lower cost compared to helium. Higher energy or impulse heating, such as laser bombardment or electric discharge, can attain higher temperatures and volatilize higher boiling metals compared to slower heating, e.g., via resistance heating of a crucible containing the molten metal. Ablation is well suited to refractory materials especially when employing laser-based heating. This has been performed both with excimer and CO<sub>2</sub> lasers for a variety of high melting materials. Once evaporated, the metal nucleates in the cold inert gas and coalesces to larger particles during transport to the collector. Eifert and Gunther<sup>[3]</sup> describe a pilot-scale reactor using a cryogenically cooled condenser with a scraper to remove product from the condenser. Other collection approaches involve an electrostatic filter and cyclone separators.
- Thermal decomposition of a salt or organometallic precursor in a flame or plasma—Axelbaum, Rosen, and Dufaux<sup>[4]</sup> produced nanosize metal particles submerged in a sodium chloride shell by flame reaction of a metal salt such as titanium tetrachloride with sodium vapor in argon. The NaCl

encapsulate is removed from the particles by both washing and subsequent sublimation at 800°C. There is potential for ionic contamination of the product, as well as sintering that could occur during sublimation of the salt.

- The electroexploded wire (EEW) process—The EEW process is a physical process converting wire into nano particles in the absence of any chemical reaction that could contaminate the product. It is capable of producing a wide spectrum of nanopowders including high and low boiling metals as well as complex alloys. The EEW process has a very long history. In 1773, Edward Nairne applied an electrical pulse to a wire, causing it to explode in air to form aerosols of metal oxide. The EEW phenomenon also occurs at the moment of burnout of an incandescent filament, when a thinned filament is explosively converted to aerosolized powders in the burned out bulb, producing a momentary brilliant flash. The EEW principal is also used in exploding bridge wire (EBW) explosive detonators. There was a considerable amount of research carried out on EBWs in the 1940s and 1950s, showing that the pulse duration is only a few microseconds long and reach temperatures higher than 15,000 K are reached at the moment of explosion.

In the 1970s and 1980s, institutes of the Russian Academy of Sciences located in Tomsk, Siberia, invested considerable effort in developing the EEW process. Their innovation included adaptation of the process within an inert gas chamber and an effective mechanism for feeding wire from an internal spool to an electrode. Prior to 1995, most of their emphasis was for producing nano aluminum for energetics and nano copper for use in lubricating oil.

In 1994, Argonide Corporation was founded to commercialize EEW nanopowders. In 1997, a cooperative research and development agreement (CRADA) between the Department of Energy (DOE) and Argonide funded these Russian groups to further develop the process. Funds were also provided to the National Renewable Energy and Los Alamos National Laboratories for characterization of the nano powders. With the exception of a 2-year halt during 1998–1999, the program continues to the present. The focus of this joint effort is on process improvement and applications development.

EEW powders can be produced from any metal that is available as ductile wire. Kilogram quantities have been produced with aluminum, copper, nickel, tin, indium, zinc, titanium, tungsten, niobium, tantalum, and silver and gram quantities with gold, palladium, and platinum. The alloys that have been produced include stainless steel, Hastelloy, and nickel–titanium.

Fig. 1 Electroexplosion machine.

Fig. 1 shows an EEW machine, where the main reactor is seen in the upper center. The chamber and associated piping include either one or two cyclone separators (one is visible under the main chamber). A reel of wire is enclosed in the right side of the chamber and is then fed through an electrically insulated baffle. When the wire contacts a strike plate located in the center of the chamber, the circuit is closed causing a large pulse ( $10^2$ – $10^3$  J in 1  $\mu$ sec) to flow through the wire, creating a plasma. A very strong field is formed that contains the plasma during the microsecond pulse. When the vapor pressure of the metal exceeds the ability of the field to contain the plasma, there is an interruption in current flow, and containment by the field is lost, allowing clusters of metal atoms to be projected at supersonic speed through the argon. The metal clusters are less than about 10 nm, but coalescence occurs as flowing argon (at 2–3 atm) transports the clusters to a cyclone separator, where the now agglomerated particles are collected. At this point, further growth and coalescence is frozen, producing spherical particles with an average particle size of 40–150 nm, depending on the wire size, exploding regime, and freezing point of the metal. X-ray diffraction shows the powders to be relatively pure elemental metal.

Several hundred grams of powder per hour are produced in a single exploder with the rate proportional to the specific gravity of the metal. The energy density introduced in an exploding wire is one of the most important parameters in the process. Pulse energy is optimized by balancing the energy input with the diameter of the wire to produce electrical energy equivalent to the sublimation energy of the metal. With the current power supplies, the best trade-off between the particle size and production rate is achieved by using

0.3-mm diameter wire and results in nanopowders with an average size of 100 nm. Smaller particles (down to about 50 nm average particle size) are produced by substantial reduction in wire diameter, but at the cost of reduced throughput of metal powders. Below a critical energy density, no explosion will occur and the wire is evaporated leading to coarser particles.

Particle size can also be reduced by a higher rate of electrical explosions and by reducing the overpressure of inert gas. Low levels of active gases, such as nitrogen and oxygen, if added to the argon in the reactor, often result in reduced particle size without much contamination of the metal. The apparent mechanism is the formation of fine oxide coatings such as aluminum oxide on aluminum, inhibiting coalescence of the metal particles. Excessive oxygen will result in the production of nanosize metal oxides such as ( $\gamma$ ) aluminum and titanium oxides, with particle size about 30–50 nm in diameter.

Powder is collected in the separators until they contain about 1 kg. The collector is frequently emptied into a collection drum. The EEW process is scalable, and a newer reactor design increases the throughput of the reactor and minimizes downtime. In the newer device, the explosion frequency has been increased from about 0.5 to 3 Hz, as recirculation of the argon gas is increased. A feed-through system was developed so that a large spool of wire can be fed into the reactor without opening the chamber and interrupting the process. Also, the arrangement and length of the piping was altered to improve sedimentation, particularly of occasional large particles that are produced by the conventional process.

The EEW process is limited to particles with average sizes less than about 300 nm. Particles as small as 20 nm

have been made in experimental quantities. Virtually all the metals produced by this process are combustible, and several of them, such as aluminum, iron, titanium, and zirconium, are either pyrophoric or nearly so. The powders are collected and protected from oxidation by the argon in the reactor. The more reactive powders are transferred to liquid hydrocarbon. In the case of Alex<sup>®</sup> nanoaluminum, the particles are passivated by adding dry air before removing it from the chamber and are then packaged as a dry powder.

All EEW powders are handled and shipped as hazardous (combustible) metal powder. Alex<sup>®</sup> is the nanometal made in the greatest quantity, followed by nickel, copper, tungsten, stainless steel, silver, and zinc. While Ni, Cu, and W may oxidize when exposed to air, they are relatively well behaved compared to dry iron, stainless steel, or titanium powders. The preferred method of packaging dry metal powders is in glass ampoules, and they are offered in quantities of at least 100 g net weight of powder.

The principal advantages of the EEW process are:

1. As with gas condensation techniques, contamination by chemical reactants or by reaction with solvents is avoided.
2. Spherical particles are ordinarily produced.
3. As compared to other high-temperature processes, virtually all of the electrical energy in the EEW process is directly converted to heat. There is little opportunity for convection or

radiation heat loss during the very rapid ( $\sim 1 \mu\text{sec}$ ) pulse.

4. Alloys can be converted to nanopowder with no measurable segregation as compared to evaporative processes, where the composition of the particles will vary.
5. The process operates with pressurized inert gas, simplifying the weight and cost of the reactor and piping.

Alloys are produced on a custom basis, so long as the fine wire is either commercially available in a continuous filament or can be produced with sufficient ductility to be fed into the wire feed mechanism without breakage.

## PHYSICAL AND CHEMICAL PROPERTIES

Table 1 summarizes the surface area and crystallographic character of several EEW powders including aluminum oxide ( $\gamma$  phase) and aluminum nitride. As with other nano powders, the principal difference in the physical and chemical properties of nanometals results from their greater surface area as compared to fine (micron) size particles. The surface area is inversely proportional to the square of the diameter of the particle, so a 100-nm spherical particle has a surface 1000 times greater than a 10- $\mu\text{m}$  particle. This creates opportunity for creating materials with new and useful

**Table 1** Electroexploded nanopowders and their characteristics

Powder	Particle size distribution function	Average particle size [nm]	Metal content [%]	Surface area [ $\text{m}^2/\text{g}$ ]	Particle morphology	Crystalline defects
Al	Normal-logarithmic	80–150	Passivated $\geq 92$	8–18	Spherical	Numerous defects
Al	Normal Gaussian	30–50	Depends on particle size distribution	20–48	Crystallites	No information
Cu	Normal logarithmic	100–150	passivated $\geq 90$ non-passivated $\geq 96$	5–8	Spherical	Numerous defects
Cu	Normal Gaussian	30–50	passivated $\geq 90$ non-passivated $\geq 96$	$\sim 12$	Crystallite faces	Small amount of defects
Ni	Normal logarithmic	80–100	passivated $\geq 95$ non-passivated $\approx 99$	4.5–6	Spherical	Numerous defects
Ni	Normal Gaussian	30–50	passivated $\geq 95$ non-passivated $\approx 99$	$\sim 7.5$	Crystallite faces	Small amount of defects
Zn	Normal logarithmic	100–200	passivated $\geq 90$	4.1–6	Spherical	Numerous defects
$\gamma\text{-Al}_2\text{O}_3$	Normal Gaussian	30–50	Not applicable	20–45	Spherical	Small amount of defects
AlN	Normal Gaussian	50–60	Not applicable	$\sim 36$	Crystallite faces	Small amount of defects

**Fig. 2** Field emission electron microscopic view of Alex<sup>®</sup> (50,000 $\times$ ).

properties, but also poses difficulty in handling, shipping, and storage.

A scanning electron microscopy photo of Alex<sup>®</sup> nanopowder is seen in Fig. 2. Surface area [Brunauer–Emmett–Teller (BET)] measurement is generally a good surrogate for determining average particle size because EEW powders are mostly spherical, fully dense, and smooth. The surface area of Alex<sup>®</sup> with 100 nm average particle size ranges from about 10 to 20 m<sup>2</sup>/g. Fig. 3 shows a sector of an Alex<sup>®</sup> particle with a passivation coating about 2.5–3 nm thick. X-ray powder diffraction shows these particles are primarily metallic aluminum, while the coating is principally aluminum oxide with minor amounts of nitride and an oxynitride. The amount of active aluminum for a 100-nm size average particle is approximately 88–90 wt.%. The oxide content rises with diminishing particle size, as the 3-nm oxide layer comprises an increasingly greater mass.

The thermal properties [differential thermal analysis (DTA)] of Alex<sup>®</sup> powder when heated in air, oxygen, and nitrogen was compared<sup>[5]</sup> to that of micron size aluminum. Alex<sup>®</sup> powder reacts rapidly with these gases, producing very sharp exotherms that occur well below the melting point (660°C) of aluminum, while 20- $\mu$ m-size aluminum does not react until about 1000°C.

An organic coating has been developed for many of the nanometals and is being used for coating aluminum and other reactive nanometals. The coating (called L-Alex<sup>®</sup>) is based on the reaction of a carboxylic acid (palmitic) acid with the aluminum powder rather than

coating it with oxide. The resistance of L-Alex<sup>®</sup> to moisture attack during accelerated aging was compared<sup>[6]</sup> to oxide-coated Alex<sup>®</sup> and to a 17- $\mu$ m-size aluminum powder (Cap45a). The test involved exposure of a thin layer of the aluminum particles in a dish within a temperature humidity chamber. Each day, a sample of each powder was removed and titrated for residual aluminum metal. The powder in the dish was mixed daily to expose fresh surface. Aging was performed at several temperatures and humidity levels from room temperature and dry conditions to a maximum of 60°C/75% relative humidity (RH). Fig. 4 shows a 20% and 70% aluminum metal loss, respectively, in the case of Cap45a and Alex<sup>®</sup> powders, but the L-Alex<sup>®</sup> showed little aluminum loss throughout the 40-day test exposure. The study also showed that bayerite (Al(OH)<sub>3</sub>) is the major product of hydrolysis rather than Al<sub>2</sub>O<sub>3</sub>. Degradation of the Cap45a powder ceased after day 12 when exposed to harsher conditions as a result of the buildup of a layer of bayerite.

Melting point is one of the properties that can be altered by reducing particle size down into the nanometer range. Fig. 5 shows the melting point of gold<sup>[7]</sup> as a function of particle size. Melting point reduction is not really significant until the particle size is less than about 10 nm.

EEW powders have crystal defects, faults, and twins caused by rapid quenching during the process. Fig. 6 shows a high-resolution transmission electron microscope (TEM) view of EEW nickel showing twins and polytwins. The clusters are propelled by electroexplosion

**Fig. 3** High-resolution (400,000 $\times$ ) transmission electron microscope of alumina layer on the surface of spherical Alex<sup>®</sup> particle.

at 2 km/sec through the cold argon, which results in a quenching rate of about  $10^8$  °C/sec. The disorder in the EEW aluminum crystal extends into the oxide outer layer, causing the powders to be physically metastable and more chemically reactive. Fig. 7 is a DTA of EEW silver showing an exotherm at about 220°C, far below the melting point (960°C) of silver. The internal energy is estimated to be about 40% of the heat of fusion. When alloy wire is electroexploded, the very high quench rates often produces non-equilibrium phases. For example, EEW 300-stainless steel can be heterogeneous, containing not only the expected austenite phase, but also alpha iron, nickel, and others components in the Fe–Ni–Cr phase diagram.

## APPLICATIONS

Nanomaterials and nanotechnology are currently receiving major attention and publicity as a future market. While certain ceramic nanopowders have reached commercial status, nano metals are still in the research stage and sales average about 1 kg per order. Prices are hundreds of dollars per kilogram, and while substantial reductions in cost are anticipated, nanopowders will always be more expensive than conventional size powders. In addition, they bear higher shipping and handling costs. Therefore the focus of nanopowder suppliers is on applications, in which there is high value added by the nanosize

**Fig. 4** Aluminum powder accelerated aging in 60°C/75% RH air.

Fig. 5 Melting point of gold particles as a function of particle size.

particles. Target markets include energetics, microelectronics, metallurgical coatings, biotechnology, and niche powder metallurgy applications.

### Energetics

Aluminum is a highly energetic combustion fuel, particularly on a volumetric basis. For more than a century, it has been used as an additive in energetic compositions such as thermite, in explosives and pyrotechnics, and more recently, in rocket propellants. Because of its high surface area, nano aluminum provides a number of advantages over conventional aluminum powder, particularly with respect to burning rate. Fig. 8 shows that substituting Alex<sup>®</sup> for a conventional micron size

(~20  $\mu\text{m}$ ) aluminum in a mixture with ammonium perchlorate can increase the burning rate about 20 times.<sup>[8]</sup> Nano aluminum also ignites more rapidly. When combusted in an air shock tube, Alex<sup>®</sup> has an ignition delay of only 3  $\mu\text{sec}$  compared to 600  $\mu\text{sec}$  for 3- $\mu\text{m}$  diameter aluminum powder.

### Rocket Propellants

Rapid burning increases the thrust and speed of a rocket engine, and higher thrust is desired in many advanced missile systems. Several researchers<sup>[8-10]</sup> have noted a doubling of burning rate when Alex<sup>®</sup> is substituted for micron size aluminum in conventional solid rocket propellants such as Al/ammonium perchlorate/hydroxy-terminated isobutylene binder (Al/AP/HTPB). The rapid burning is attributed to the smaller particle size and (much) larger surface area. A model developed for aluminum particle combustion in a rocket engine predicts that nano aluminum would burn very rapidly. This model<sup>[11]</sup> describes the life of the burning particle as proportional to the square of the particle diameter. Experimental data shows that a 5- $\mu\text{m}$  aluminum particle survives for about 4 msec in a rocket engine. Extrapolation of the  $d^2$  model down to a 100-nm diameter predicts that the particle would be consumed in about 600 nsec, about 4 orders of magnitude shorter than the micron-size particle. High-speed photography of a burning propellant surface confirms that a nano aluminum particle is completely consumed at the surface of the burning grain rather than being propelled into the burning flow stream as in the case of the micron size aluminum.

Fig. 6 Crystallographic defects in EEW nickel.

Fig. 7 DTA of EEW silver particles. Source: Los Alamos National Laboratory.

A faster burning grain is also more efficient because combustion is complete within the engine rather than in the exhaust stream of the rocket. The hybrid rocket engine would also benefit from nano aluminum as a fuel ingredient. The classic hybrid uses liquid oxygen with a rubber base binder (HTPB) grain that contains either no oxidizer, or just enough to react with the HTPB so as to be a gas generator. Pyrolysis of the rubber creates low-molecular-weight organic molecules that are forced into the engine and then react with liquid oxygen. If aluminum is added to a solid fuel such as HTPB, there is a theoretical increase in rocket performance, but unfortunately micron size aluminum does not burn effectively in such a hybrid. However, Chiavarinni et al.<sup>[12]</sup> found that adding 10 wt.% Alex<sup>®</sup> to an HTPB slab increased the regression rate by 70% and also resulted in smoother burning compared to the pure HTPB slab.

Aluminum, if gelled into kerosene, increases the volumetric energy density of the liquid rocket fuel. Unfortunately, micron size aluminum does not burn efficiently when immersed in kerosene; however, nano aluminum

Fig. 8 Burning rate of aluminum/ammonium perchlorate powder mixes.

additive is completely combusted.<sup>[13]</sup> The higher temperatures created by combustion of nano aluminum also accelerates the combustion of the kerosene.

## Explosives

Reshetov, Shneider, and Yavorovski<sup>[14]</sup> were the first to notice that nano aluminum influences the detonation velocity of high explosives. When less than 30 wt.%, nano aluminum is added to hexamethyl-3-nitroamine (HMX) (Fig. 9), detonation velocity (VoD) decreased from 5400 to 4700 m/sec, about equivalent to that of explosives when micron size aluminum is added to HMX. However, beyond 30 wt.%, there is a rapid rise in VoD to 7000 m/sec. Even where the VoD is not affected, the force of the detonation is enhanced by the rapid reaction of the nano aluminum with the gases generated behind the detonation wave.

The affect of nano aluminum on enhanced detonation was demonstrated experimentally in the United States and Europe, and several organizations are studying Alex<sup>®</sup>'s use in explosives. When incorporated into ammonium dinitramide, Alex<sup>®</sup> was shown<sup>[15]</sup> to increase VoD from 4380 m/sec for a 97% dinitramide (balance Viton binder) to 5070 m/sec (73:24:3 ADN/Alex<sup>®</sup>/Viton). Identical loading of conventional aluminum had a detrimental effect on VoD. Similarly, detonation tube experiments comparing type 40XD flake aluminum and Alex<sup>®</sup> in N<sub>2</sub> gas dispersed lactose/Al/ammonium perchlorate compositions showed VoD enhancements for Alex<sup>®</sup> over the flake grade at four different Al concentrations.<sup>[16]</sup> Most recently, a collaborative program between Australian (DMSO-Adelaide) and Canadian (DREV) laboratories has

Fig. 9 Detonation velocity as a function of aluminum in HMX explosive.

demonstrated a beneficial enhancement for both VoD and brisance for a number of trinitrotoluene (TNT)-based tritonal and H-6 derivatives containing Alex<sup>®</sup>.<sup>[17]</sup> VoD enhancements of 200–300 m/sec and improvements in brisance of up to 27% were observed in a number of tritonal charges when conventional aluminum grades were substituted for Alex<sup>®</sup>.

### Gun Propellants

When Alex<sup>®</sup> is added to gun propellants, the burning rate was nearly doubled as compared to high caloric conventional double-base propellants.<sup>[18]</sup> Simultaneously, the pressure exponent of Vieille's burning law decreases from more than 0.8 for double base propellant to 0.66, resulting in more stable burning. Such aluminized gun propellants would be useful as a burning rate accelerator, as an igniter in high-pressure rocket propulsion, and as a booster.

### Miscellaneous Pyrotechnics

Metal/oxide pyrotechnic heat sources (thermite) are enhanced with faster burning nanosize aluminum. Mixtures of nano size aluminum and nano MoO<sub>3</sub> powder results in a very fast burning material. The reaction rate can be altered to develop energy release rates spanning the range between conventional explosives and conventional thermites. Such mixtures have application in advanced munitions, pyrotechnics, detonators, and primers.

### Self-Heating Synthesis (SHS)

Refractory compounds or alloys may be synthesized by direct reaction using the heat generated by metal/metal reaction or as in thermite, where a metal reduces an inorganic compound. Table 2<sup>[19]</sup> shows several reactions in which EEW powders were used to form intermetallic alloys. At 200°C, a pellet of EEW copper and micron zinc powder can react within a second producing light and forming brass. Pressed pellets of

Alex<sup>®</sup> and amorphous boron, when heated to 500°C and ignited by a hot wire, immediately forms aluminum diboride, while ordinary aluminum and boron would have to be heated above 1000°C for several hours to form the diboride. Nickel aluminide and alloys of aluminum with tungsten, iron, nickel, or molybdenum were produced at much lower temperatures and at shorter times than could be achieved by reacting micron size powders.

### Electrically Conductive Inks and Pastes

The goal of shrinking circuits and increasing functionality has resulted in a continuing search for new and improved processes in electronic packaging. Metal powders such as copper, gold, nickel, tin, and solder are formed into pastes and used for electronic interconnects. Copper pastes are used in the production of hybrid multi-chip module (MCM) circuits. The pastes are printed on ceramics such as aluminum oxide and more recently aluminum nitride to produce highly dense, thick film circuits. Nanosize powders provide a flatter surface topology and more precise edge definition and line spacing that would be attainable as compared to conventionally sized powders. Precise patterning ensures lower cross-talk between adjacent conductor lines. While such better edge definition is not attainable in silk screening patterns because of resolution limits of the process, newer patterning methods such as photo-patterned thick film processes could benefit from the smaller features of nanosize particles.

Metal-filled polymers also play an important role in microelectronics, including electrically conductive adhesives, polymers for shielding from radiofrequency radiation, and in magnetic polymeric layers. In most cases, high aspect ratio fibers and flakes are used because of the greater opportunity for conductor/conductor contact within the composite. Nano metal powders offer an advantage in increased electronic conductivity because of an increase in the number of point-to-point contacts. The authors developed silver-filled polyurethane and epoxy adhesives having

**Table 2** Alloying reactions in EEW pressed pellets

Metal 1	Metal 2	Reaction method	Product/comments
EEW Cu	Coarse Zn—30%	hot wire at 25°C	Brass verified by XRD
EEW Al	Amorphous B	hot wire at 500°C	AlB <sub>2</sub> produced
EEW Al	Coarse Ni	hot wire at 25°C	Al–Ni alloy principal phase
EEW Al	Coarse Fe	hot wire at 25°C	FeAl, FeAl <sub>3</sub> and Fe <sub>2</sub> Al <sub>5</sub>
EEW Al	EEW W (60 wt %)	self-ignited at 300°C	WAl <sub>4</sub> and WAl <sub>5</sub>
EEW Al	Coarse Mo	no reaction	
EEW Al	EEW Mo	self-ignited at 300°C	Al <sub>12</sub> Mo, Al <sub>5</sub> Mo and Al <sub>4</sub> Mo

an electronic conductivity of  $1 \times 10^{-5}$  and  $2 \times 10^{-6} \Omega\text{m}$ , respectively, which are improvements over silver flake-filled polymers. The conductivity of the composite is enhanced by agglomerated particles that are particularly prevalent in EEW silver.

## Nanostructures

Over the last few years, there have been extensive studies on nanostructures, with an expectation that they will form superplastic or ultrahigh strength, tough materials. Smaller grains result in greater strength, generally following the classic Hall–Petch relation, at least for grain sizes 50 nm and larger. Extrapolations forecast 2–7 times higher hardness and 2–3 times the tensile strength as compared to parts produced from conventional powders. Furthermore, the boundaries formed in a nanocrystalline structure tend to have higher ductility. Thus in contrast to most methods of strengthening metals, nanostructures have the potential dual benefit of increasing strength while also maintaining or increasing ductility.

There is a dilemma in that smaller grain size of a nano powder based compact recrystallize and grow at lower temperature, countering efforts to form nanostructures. Consolidation methods, such as equal channel angular extrusion (ECAE), that do not rely on much heating can densify the compact to greater than 99% while minimizing grain growth.

The breadth of potential applications for nanostructured metals and alloys is considerable. The higher tensile strength and fatigue strength, and even the enhanced ductility that have been reported in nanostructured metals can impact any application in which strength or strength-to-weight ratios are critical properties. Transportation, aerospace, sports products, implantable medical components, and chemical and food processing applications appear promising.

## Low-Temperature Sintering

The onset of sintering occurs substantially lower in temperature with nanosize particles. Eifert et al.<sup>[20]</sup> achieved a decrease in the onset of sintering of tantalum from about 1800 to 900°C when the particle size is reduced from 2  $\mu\text{m}$  to 50 nm. The onset of sintering of 40 nm iron powder is as low as 370 K, approximately 21% of the melting point as compared to  $\sim 900$  K, or 50% of melting for 2- $\mu\text{m}$ -size iron powder.<sup>[21,22]</sup> The challenge of the nanoparticulate approach is that the pores are readily formed in nano sinters at low temperatures, and they tend to slow full densification unless there is some strain induced in the porous compact to prevent the stabilization of larger pores.

## MISCELLANEOUS APPLICATIONS

Wear-resistant and microelectronic coatings can be formed from slurries of nanopowders. For example, the authors bonded a pattern of copper particles to glass by laser irradiation of a dried nanopowder paste deposited by silkscreen. The laser melted the individual particles to form circular disks approximately 1  $\mu\text{m}$  in diameter in a line pattern with resolution of approximately 5  $\mu\text{m}$ . The particles then provided a seed layer for the electroless deposition of additional copper to form a circuit pattern.

Selective laser sintering of metal powders is used for the computerized 3-D design and production of rapid tooling. Nanopowders are likely to be superior to conventional powders in that they sinter more readily and produce parts with tighter tolerance because of their smaller particle size.

Nanosize nickel–titanium alloys are being evaluated as source materials for producing memory alloy components.

Sintered metal disks are used in industrial filtration because of their capability to operate at elevated temperature and in corrosive environments. Disks produced from nanopowders would result in smaller pore size and would be more effective in filtering submicron particles.

A new class of heat transfer fluids is being developed where nanocrystalline particles are being suspended in liquids such as water or oil.<sup>[23]</sup> Copper oxide (5 vol.%) suspended in water results in an improvement in thermal conductivity of almost 60% as compared to water without nanoparticles. Direct evaporation of copper nanoparticles into pump oil results in similar improvements in thermal conductivity compared to oxide-in-water systems, but more importantly, requires far smaller concentrations of dispersed nanocrystalline powder.

Gold and other spheres are being considered for use as carriers of pharmaceutical and therapeutic agents through the blood stream to target organs. Colloidal gold particles have also been exploited in several bioanalytical methods, including a proposed DNA detection method.<sup>[24]</sup>

Iron powder, if injected into underground water plumes, will destroy trace halogenated solvents. “Iron walls,” which are permeable reactive barriers injected into the plumes, containing zerovalent iron, intercepts halogen-saturated solvents causing their dechlorination. For chlorinated ethenes [perchloroethylene (PCE) and trichloroethylene (TCE)], the products are mostly fully dechlorinated although some chlorinated alkanes yield partial dechlorination products that may still be a pollution problem. There have now been many feasibility studies, pilot tests, small- to medium-scale demonstration projects, and full-scale applications performed by numerous groups.

The authors have found that nano-iron is far more effective in converting perchlorethylene to dichlorethylene than micron size iron. Also, nano iron has potential for the conversion of trace As [+3] to As [+5] so that it could be filtered from drinking water.

Nanosize particles interact differently with the electromagnetic energy spectrum than do micron size particles. For instance, solid particles, with sizes substantially below  $<1/20$  of the wavelength of light are transparent so that the film can be strengthened by adding inorganic particles without affecting transparency.

Nanosize metallic silver is being considered as a biocide for water purification and in medical formulations.

Nanosize copper is used as an additive in lubricating oils and sold in Russia. Tarasov et al.<sup>[25]</sup> showed that adding 0.5% nano copper to lubricating oil reduces friction in rubbing surfaces, particularly when under high load as in heavy-duty engines, thereby extending their life. The lubricating mechanism is believed to be the deposition of nano copper particles onto the surfaces of a hot friction pair, producing a softer metal surface on the aggravated surface. Such mixtures may prove to be superior to existing lubricants such as those containing Teflon particles.

Nanosize metal particles also have potential as precursors for the synthesis of a wide variety of inorganic compounds such as oxides with complex stoichiometry and with unique sizes, shapes, and reactivities. Furthermore, they have potential as precursors in the direct synthesis of metal organic compounds.

## SAFETY, HANDLING, AND SHIPPING CONSIDERATIONS

Nano-metal powders are regarded as hazardous materials, particularly with respect to shipping regulations. Department of Transportation and International Air Transport Authority (IATA) require the user to test and categorize such powders relative to the combustion hazard prior to shipment. Should testing under the protocol show the powders to be pyrophoric in air, then shipment on passenger aircraft is disallowed. United Parcel Service and other carriers will not handle pyrophoric materials. The powders may be passivated by oxidizing their surface as in the case of nano aluminum, coating with an organic as in the case of L-Alex<sup>®</sup>, or immersion in a compatible liquid such as a hydrocarbon.

Working safety is also an issue with nano metal powders. Caution must be exercised to minimize the danger of untoward ignition and burning. Efforts should be directed to minimize the possibility of static ignition, *particularly when there is an oxidant mixed in with the powder*. Such oxidants include metal oxides and other oxidizing salts and halogenated organic

liquids and solids. For instance, magnesium or aluminum mixed with Teflon powder is a highly reactive pyrotechnic. Users should study Material Safety Data Sheets (MSDS) before using nano metals. High efficiency particulate air (HEPA)-type respiratory filters should be used in operations where there is an opportunity for encountering nanoparticulate dust.

An issue common to most forms of nano metal powders is packaging to assure purity. Glass ampoules are superior to packaging in plastic containers, although ampoules would still not be acceptable under Department of Transportation (DOT) or IATA rules if the powder is pyrophoric. In this case, the powders have to be submerged in liquid hydrocarbon and sealed to prevent the ingress of air to minimize contamination.

## CONCLUSION

The burgeoning field of nanotechnology is forecast to have an economic impact as great as biotechnology or microelectronics. Nano powders including nano metals are likely to be key source materials in this new industry. The EEW process is one of several methods being commercialized for manufacturing nano metal powders. EEW powders are readily produced from any metal or alloy that can be produced in the form of fine metal wire including elemental metals such as aluminum and copper, refractory metals such as titanium, tantalum, and tungsten, and alloys such as stainless steel and nickel-titanium.

Applications for nano metals include energetics such as rocket propellants, explosives and pyrotechnics, in self-heating synthesis of inorganic compounds and alloys, in high-strength nano structured metals, electrically conducting inks for microcircuits and in advanced capacitors, in environmental remediation, as carriers for bioactive and medical therapeutics, and in wear-resistant coatings. Most of the sales of nano powders are for small quantities to researchers investigating new properties with potential applications not discernable at this writing, but which are likely to add to the potential growth of this subindustry.

## ACKNOWLEDGMENTS

We are grateful for the support of the Department of Energy and its Incentives for Prevention of Proliferation (IPP) under the cooperative agreement. We are also grateful to the U.S. Industrial Coalition of Washington, DC, which has collaborated in the funding efforts.

We also appreciate the efforts of the team at the National Renewable Energy Laboratory including Ms. Tanya Rivkin, Mr. Alexander Miedaner, and Calvin Curtis as well as Dr. Joel Katz of Los Alamos

National Laboratory who contributed their time in characterizing the powders.

Lastly, we want to thank the many Russian scientists and engineers that contributed their knowledge and effort in developing the EEW technology and in manufacturing the powders.

# Metallic Nanopowders: Rocket Propulsion

Leonid Kaledin

Frederick Tepper

Argonide Corporation, Sanford, Florida, U.S.A.

## INTRODUCTION

Active metal powders are extensively used as fuels in most solid rocket propellants because of the high energy produced during their combustion. The specific impulse ( $I_{sp}$ ) of the rocket engine is proportional to  $(T_c/M)^{1/2}$ , where  $T_c$  is chamber temperature and  $M$  is molecular weight of combustion products. Thus the best propellants are those that produce the highest combustion temperature and the smallest possible molecular weight of the combustion products. Therefore the best oxidizers are fluorine and oxygen and the best fuels are lithium, beryllium, boron, aluminum, and magnesium. Lithium is extremely reactive and beryllium is extremely toxic so these are impractical in rocket applications. That leaves boron, aluminum, and magnesium powders as primary candidates.

Aluminum is a major ingredient in solid rocket fuels, often combined in a rubbery binder along with particles of oxidizer. When burning aluminum in solid propellants, the energy utilized can be diminished because the droplets agglomerate, producing larger droplets and slower combustion that can occur too late (after the nozzle) to be effective. The agglomerates, although partially oxidized, often slag up on the internal surfaces of the engine, reducing combustion efficiency and weighing down the vehicle.

As with solid propellants, adding aluminum to liquid fuels would also provide a theoretical advantage in higher volumetric energy density, but the metal must be uniformly dispersed and remain so in the hydrocarbon. As with solid propellants, aluminum combustion must be rapid enough so that it is consumed within the rocket engine. The most effective means of achieving complete combustion is to use powders with particle sizes at least an order of magnitude or two smaller than the metal powder ordinarily used in solid propellants. This entry focuses on Alex<sup>®</sup> nanosize aluminum particles manufactured by the electroexplosion of metal wire (“EEW”) and its use in liquid and solid rocket propellants.

## BACKGROUND

### Metal Powders for Solid Rocket Engines

Boron has been considered for many years as a candidate solid rocket fuel as it has a high energy content on both a gravimetric ( $I_{sp}$ ) and volumetric (density  $I_{sp}$ ) basis. In practice it has been difficult to realize these advantages as the combustion is severely hindered by a layer of oxide layer ( $B_2O_3$ ) on the particle surface and boron's vapor pressure is too low to escape the droplet, limiting the gas-phase oxidation to a much slower heterogeneous surface reaction.<sup>[1-3]</sup>

Aluminum has always been recognized as a highly energetic reactant for solid rocket fuels and one that can be more practically applied than boron. Because its specific gravity is high ( $2.7\text{ g/cm}^3$ ) relative to organic fuels, it is particularly advantageous for increasing density specific impulse, thereby reducing the size and therefore the weight of the rocket. It is generally used with ammonium perchlorate (AP) as a solid oxidizer and the two solid phases are held together with a rubber base binder such as hydroxy-terminated polybutadiene (HTPB) resin. Aluminum and its oxides are non-toxic and non-polluting. While AP has been the oxidizer of choice, it is a groundwater pollutant and it also produces large quantities of hydrogen chloride in rocket exhaust. Newer and more energetic oxidizers such as ammonium dinitramide (ADN) are being considered, primarily because they do not produce halogens in the exhaust. Also, there are efforts to replace HTPB with more energetic binders such as glycidyl azide polymer (GAP).

### Metal Powders for Liquid Rocket Engines

When burning aluminum in solid propellants, the delivered performance is affected because it agglomerates while molten. Duterque<sup>[4]</sup> collected the ash of aluminum from a solid propellant burn and found that it contained a significant amount of unburned aluminum. Despite this deficiency, aluminum is quite attractive

and it is used widely in solid propellants, particularly as the aluminum oxide particle reduces or suppresses combustion instability by damping of combustion waves.<sup>[5]</sup>

Dispersing metal particles as a gel in liquid propellants have been studied analytically and experimentally for more than 69 years<sup>[6]</sup> because of the higher specific impulse afforded by adding active metals such as aluminum. NASA<sup>[7-13]</sup> studied its use into gelled RP-1 (kerosene) for bi-propellant liquid propellant systems. It has also been considered as an additive to liquid hydrogen<sup>[14]</sup> because it would thicken the hydrogen, increasing safety in the event of leakage. Palaszewski and Rapp<sup>[11]</sup> suggest that given the suitable rheological tailoring, metallized propellants offer tremendous safety advantages. Design studies conducted for NASA missions show that aluminized gelled RP-1 with liquid oxygen can deliver rocket engine efficiencies that are comparable to that of traditional liquid propellants. Palaszewski and Rapp<sup>[11]</sup> discuss how using O<sub>2</sub>/RP-1/Al gel propellants as a replacement for the liquid rocket booster in the space shuttle boosters results in shorter boosters for the same payload size due to the increased propellant density. This in turn has the potential to deliver a higher payload mass over its solid counterpart. Fig. 1 shows the volumetric energy density calculated using the Propellant Evaluation Program (PEP) code<sup>[15]</sup> for aluminized RP-1 and ethanol fluids and compares these two fuels with nitrogen tetroxide/hydrazine, a highly energetic bi-propellant but one that is toxic and environmentally unfriendly. The computed energy available increases consistently with increasing aluminum content.

Unfortunately, conventional aluminum powder, when burning in liquid hydrocarbon fuel, also

agglomerates as in the case of solid propellants, reducing delivered specific impulse ( $I_{sp}$ ). Wong and Turns<sup>[16]</sup> noted significant Al agglomeration in burning JP-10 resulting in inefficient combustion. And as in the case of solid propellant engines using aluminum, this agglomeration would result in unburned combustion products deposited on engine walls.

### Metal Powders in Liquid Monopropellants

In the late 1950s and early 1960s, Atlantic Research studied the combustion of Arcogel, a gel of aluminum powder, ammonium perchlorate with dioctyl adipate as a liquid carrier. They found that such mixtures had adequate (6 months) shelf life and good stability under high acceleration loading and vibration. Arcogel was extensively characterized and found to be non-detonable and insensitive to ignition. They also conducted small motor tests. However, they found the viscosity to be unacceptably high at low temperatures ( $-55^{\circ}\text{C}$ ). In the early 1990s, this work was continued,<sup>[17]</sup> evaluating nitrated ester/AP/Al, hydrogen peroxide/Al, and HN/water/Al gels. All were found to have limited promise because of their sensitivity to premature ignition or detonation.

### Environmental Issues

Regulatory environmental requirements are forcing new choices for rocket propellant ingredients. For instance, ammonium perchlorate (AP), the oxidizer of choice for solid propellants, is falling out of favor because hydrogen chloride is a significant combustion

Fig. 1 Theoretical density specific impulse (vacuum, 100:1 expansion ratio) of aluminized bi-propellants.

product. Toxicological constraints are also affecting the choice of liquid propellants. For instance, hydrazine, which is extensively used, is very toxic, as is nitrogen tetroxide. Threshold limit value (TLV) concentrations for hydrazine are fractions of a part per million, often below the limits of detection (LOD) of continuous monitoring instruments. Those working with this fluid often have to wear completely encapsulated suits. In addition to AP, there are two other inorganic oxidizers that have potential for solid propellants—ammonium nitrate (AN) and ammonium dinitramide. Another oxidizer being developed in the Netherlands is hydrazinium nitroformate (HNF).

Fluids such as ethanol<sup>[18,19]</sup> and methanol<sup>[20]</sup> are being considered as non-toxic options in bi-propellant system. Boeing<sup>[21,22]</sup> reported on the hazardous and costly operations associated with monomethyl hydrazine (MMH) and nitrogen tetroxide propellants related to the Space Shuttle Orbiter OMS/RCS system which culminated in NASA's selection of ethanol/LOX as the bi-propellant. They designed such a propellant system and projected improvements in vehicle weight, complexity, and operational cost. They believe that the design solutions are applicable to other space-based cryogenic propulsion and power generation systems. Aluminizing these non-toxic fuels could substantially enhance propellant energy density without causing any environmental or toxic concerns.

Effect utilization of aluminum's combustion energy in propellants resolves a number of problems—improved performance, particularly on a volumetric basis, and achieving that with no penalty as a pollutant or a toxin.

## NANOMETAL POWDER FUELS

Many of the difficulties related to inefficient burning of aluminum powder in solid (as well as liquid) propellants could be ameliorated if the particle size of the powder were small enough. Nanosize aluminum was first prepared in the early 1970s by Russian scientists in Siberia,<sup>[23]</sup> who formed the powder by electroexploding metal wires (EEW). The EEW method is described in a separate entry of this Encyclopedia. Most of the Russian work was focused on producing nanosize aluminum for its potential use as a metal additive for rocket propellant fuel.

Electroexploding metal wire aluminum powder (Alex<sup>®</sup>) consists of spherical particles that are fully dense and about 100 nm in size. Because they are so active, during collection they form hard agglomerates. Because these particles are potentially pyrophoric, the final step in the manufacturing process involves controlled oxidation with dry air to form a passivating layer approximately 3 nm thick. Oxygen analysis shows

the coating to be about 92–95% aluminum (between about 85% and 89% as oxide). X-ray diffraction shows the crystallites to be essentially aluminum, while the coating has been found<sup>[24]</sup> to be principally aluminum oxide, with some aluminum nitride and some aluminum oxy-nitride. The passivation step is controllable and thinner passivation layers are readily obtained, but the U.S. Department of Transportation (DOT) and International Air Transport Association (IATA) prevent air shipment of pyrophoric materials, so sufficient coverage is necessary to assure no pyrophoricity.

When ignited in air Alex<sup>®</sup> appears to have two separate ignition steps. The first occurs at lower temperatures (400–500°C) and a second where the powder burns white hot. Mench et al.<sup>[25]</sup> studied the thermal behavior of Alex<sup>®</sup> powder and compared it to micron-size aluminum. Their data show that Alex<sup>®</sup> powder has very sharp exotherms when heated in air, oxygen, or nitrogen. These occur well below the melting point (660°C) of aluminum, while 20- $\mu$ m-size aluminum does not react with oxygen or air until about 1000°C.

A coated version of nano-aluminum (L-Alex<sup>®</sup>) is based on the replacement of the oxide coating by reaction with palmitic acid to form a monomolecular layer of palmitate. This version was tested by boiling the coated Alex<sup>®</sup> in water for an hour and the resulting coating appears to protect the metal, while ordinary Alex<sup>®</sup> would have reacted within minutes. Accelerated aging testing showed<sup>[26]</sup> L-Alex<sup>®</sup> to be superior in moisture and oxidation resistance to conventional Alex<sup>®</sup>.

## Alex<sup>®</sup> as an Additive to Solid Propellants

Ivanov and Tepper<sup>[23]</sup> reported a 10- to 20-fold increase in burning rate if air-passivated Alex<sup>®</sup> was substituted for ordinary propellant grade aluminum when mixed with ammonium perchlorate powder (no binder). Sigman and co-workers<sup>[27]</sup> also reported that the burning rate of Alex<sup>®</sup> with AP (again no binder) was 10 times greater than with other micron-size aluminum powders. Chiaverini et al.<sup>[28]</sup> reported that Alex<sup>®</sup> when added to HTPB binder produced a substantial increase in the burning rate in oxygen.

The agglomeration of aluminum droplets has been studied by Simonenko and Zarko<sup>[29]</sup> who noted that there was a growth in aluminum oxide particles collected from the combustion products of a solid propellant grain as compared to that of the original particle size of the aluminum. They also noted that there was a substantial amount of aluminum left within the residual products they collected. In a separate study Glotov, Zarko, Beckstead<sup>[30]</sup> noted that the replacement of commercial aluminum by Alex<sup>®</sup> in quantities as small as 8 wt.% increases burning rate and decreases agglomerate size as well as increases

the amount of oxidation. For example, total replacement of commercial aluminum by Alex<sup>®</sup> increases combustion efficiency to 99.2% as compared to 94.28% for coarse aluminum.

There have been considerable studies and modeling of the combustion of aluminum in a solid rocket engine. The Brooks and Beckstead model<sup>[31]</sup> estimates that the life of the particle is proportional to the particle size raised to the power of  $n$  with nominal values of approximately 1.5 to 1.8.<sup>[32]</sup> The life of a 35- $\mu\text{m}$  particle is about 6 msec. Extrapolating the Brooks and Beckstead equation for the burning time of a 100-nm-size particle (Alex<sup>®</sup>) results in a lifetime of only approximately 160 and 920 nsec, respectively, for  $n = 1.8$  and  $n = 1.5$ .

Experimental observations support the very short life computed for combustion of an Alex<sup>®</sup> particle that had originated from a solid propellant. Wang et al.<sup>[33]</sup> found that when Alex particles are flash-heated to the boiling point, 2740 K, in the presence of a nitrocellulose (NC) oxidizer, the energy release occurs in  $\sim 5$  nsec even much faster than predicted by the Brooks and Beckstead model. Ivanov and Tepper<sup>[23]</sup> noted from high-speed cinematographic photographs of a burning propellant that the combustion of Alex<sup>®</sup> is complete at the burning surface, while micron-size aluminum is known to burn throughout the throat and often past the nozzle.

### Alex<sup>®</sup> as an Additive to Hybrid Propellants

The classic hybrid technology uses LOX with an HTPB grain that contains either no oxidizer, or just enough to react with the HTPB so as to be a gas generator. This creates low molecular weight organics that are forced into the engine and then react with the liquid oxidizer. The hybrid fuel technology offers a number of advantages including the ability to throttle the engine in real time, stop and start and shift from combustion with on-board oxidizers to air. Should the mission require rapid launching, then the hybrid with storable oxidizers offers advantages over cryogenic fuels. Also, the grain case is smaller and much lighter without the heavy inorganic oxidizer that is in conventional solid propellants. Hybrid solid propellants are much easier, safer, and less costly to manufacture because the oxidizer is not combined into the grain. Also, there are fewer corrosion problems as the fuel is solid. These advantages would be very useful in a rocket-based combined-cycle (RBCC) engine.<sup>[34]</sup>

Hybrid problems include the fact that the distance of the flame to the burning surface is an order of magnitude larger than with solid propellant. This makes heat transfer an order of magnitude smaller and consequently the regression rate is an order of magnitude smaller. Because the main flow is rather

**Table 1** Specific impulse of aluminized HTPB resins with liquid oxygen (LOX)

Fuel			$I_{sp}$ (vacuum) <sup>a</sup> , sec	$I_{sp}^{\text{density}}$ , sec g/cm <sup>3</sup>
Metal	Carrier	Oxidizer		
0% Al	100% HTPB	LOX	371	392
25% Al	75% HTPB	LOX	376	423
50% Al	50% HTPB	LOX	370	458
	Hydrazine	N <sub>2</sub> O <sub>4</sub>	362	442

<sup>a</sup>At chamber pressure of 6.895 MPa (1000 psia) and expansion ratio of 100:1.

stratified, the mixing process and therefore the combustion can be incomplete. To achieve complete mixing and combustion of oxidizer and fuel, an aft combustion chamber is added to the hybrid motor.

However, many of these problems can be ameliorated by adding Alex<sup>®</sup>. Chiaverini et al.<sup>[28]</sup> added 10 wt.% Alex<sup>®</sup> to an HTPB slab and found an increase of 70% in the regression rate. They also noted much smoother burning in the case of Alex<sup>®</sup>-loaded HTPB. Table 1 shows how using Alex<sup>®</sup> increases the specific impulse and density-specific impulse of a hybrid and compares it to NTO/Hydrazine.

### Alex<sup>®</sup> as an Additive to Liquid Propellants

Palaszewski and Powell,<sup>[35]</sup> in some theoretical computations, demonstrated that 0-, 5-, and 55-wt.% aluminum loaded into RP-1 gel propellants provide benefits over neat RP-1. The 0-wt.% loading is attractive when safety over traditional RP-1 (ungelled) is desired and the 5-wt.% loading gave the maximum theoretical specific impulse. The 55-wt.% loading was chosen based on the fact that a liquid-based booster with O<sub>2</sub>/RP-1/Al could conform to the volume constraints of the current solid rocket booster even with potential two-phase flow losses taken into account. Palaszewski and Zakany<sup>[7,9]</sup> did some combustion experiments with these three mixes using micron-size aluminum for the 5% and 55% loadings. While relatively good performance was obtained, the engine efficiencies were not sufficient for NASA missions.

### Mechanisms of Combustion of Gelled Aluminized Propellants

The combustion of a heterogeneous two-phase gel of liquid fuel and aluminum particles is essentially a two-step process. The first step is the combustion of the liquid droplet, which involves boiling of the liquid. A vapor blanket of fuel exists around the two-phase droplet and the flame zone is at some distance beyond

the liquid–gas interface, protecting the aluminum from oxidation. At the temperatures and pressures that exist in the rocket engine, the aluminum will be molten. Aluminum combustion would be delayed until the hydrocarbon is burned away, and during that interval the micron-size aluminum droplets could coalesce. The smaller the hydrocarbon droplet the less time there is for the aluminum to agglomerate. The second step in the process involves the combustion of the now dry aluminum droplet. The mechanisms associated with this second step would be very similar to that occurring had the particles been generated from a solid propellant grain such as Al/organic binder/solid inorganic oxidizer. A nanosize aluminum particle would therefore be expected to have a life less than a microsecond, several orders of magnitude shorter than if micron-size aluminum had been dispersed into the kerosene.

### Development and Formulation of Aluminized Gels

The authors were sponsored by NASA to evaluate the benefits of using Alex<sup>®</sup> in lieu of micron-size aluminum powder as a dispersed phase in RP-1.<sup>[36]</sup> Wetting and gelling agents were used as additives to aid in homogenization and providing dynamic stability. Fumed silica (Cab-O-Sil<sup>®</sup> grade M5) was used as a gellant and the stability of the gel was determined by centrifugation for 1 hr at 1300 rpm. It was found that when Alex<sup>®</sup> loading was greater than about 25 wt.%, fumed silica was unnecessary as the powder acts as a pseudo-gellant. A 30 wt.% Alex<sup>®</sup> in RP-1 gel was found to be dynamically stable when stored for 2 years at room temperature. A non-anionic surfactant, specifically

Tween-85 (polyoxyethylene sorbitan trioleate), was used because it was more effective as a wetting and dispersing agent for the aluminum particles than anionic and cationic surfactants.

The viscosity of the gelled formulations was then measured so as to determine the practicality of pumping the mixture and spraying it into a combustion chamber. Spray characteristics of a given gas–liquid injector are a function of the liquid surface tension and the gas and liquid velocities, densities, and viscosities.<sup>[37]</sup> Liquid propellants typically have viscosities near 1 mPa sec and have Newtonian-type flow behavior.

Green, Rapp, Roncace<sup>[37]</sup> reported absolute viscosity value of 1.89 mPa sec for RP-1. This value remains constant in a wide range of applied shear rates from 1 to 100,000 sec<sup>-1</sup>. Gelled propellants typically have viscosity in the range of 20 to 50 mPa sec at the shear rates in the range of 10<sup>5</sup> to 10<sup>6</sup> sec<sup>-1</sup> that are typically encountered in engine injectors.<sup>[38]</sup> This is within the range of the pumping systems currently used in rocket engines. As the viscosity of a gelled fuel is a function of variables other than temperature (e.g., shear rate and temporal rheological effects such as thixotropy and gel relaxation time), the rheology is non-Newtonian, and viscometry is reported as “apparent” viscosity at a specific shear rate.

Fig. 2 shows the viscosity of Alexgel fluids and compares them with the viscosity measurements of Rapp<sup>[39]</sup> for micron-size aluminum/fumed silica/RP-1 gel permitting extrapolation to strains characteristic of the injector. Note the reduced viscosity when a surfactant is added to a 30% Alex<sup>®</sup>/RP-1. A power law rheological model ( $\tau = K \cdot \dot{\gamma}^n$ , where  $\tau$  is a shear stress,  $\dot{\gamma}$  is a shear rate,  $n$  is effective flow behavior index, and  $K$  is a constant of effective consistency) can be applied to

Fig. 2 Apparent viscosity of aluminized fuels.

model flow behavior. In general, power law is applicable to model flow behavior of pseudo-plastic fluids with zero yield point. Gelled fuels evaluated in Refs.<sup>[7,9,39]</sup>, and<sup>[40]</sup> have very small yield values ranging from 0.03 to 22 Pa. These yield points are greatly exceeded in injector fluid flow, so their contributions are negligible. By extrapolation of viscosity data to high shear rates using a power law rheological model to the large shear rates encountered in engine injectors, the gels have viscosity near kerosene and therefore within the capability of the pumping systems currently used in rocket engines.

### Ignition Delay Measurements

Fig. 3 is a stainless steel combustion bomb<sup>[41]</sup> used to measure ignition delay of kerosene and its aluminized versions. The injection port is water cooled to keep the gel (or neat RP-1) at ambient temperature. Fuel temperatures are monitored by a thermocouple at the nozzle close to the tip. The bomb, containing an oxidizing gas of known pressure, is preheated to a defined temperature. Using a piston powered by high-pressure argon, approximately  $0.3\text{ cm}^3$  of fuel is injected into the bomb and it auto-ignites at temperatures above about  $400^\circ\text{C}$ . An internal transducer measures pressure rise due to combustion. The time is measured from the first movement of the piston forcing the fluid into the chamber until there is a

rapid rise of pressure. Generally, the pressure rise due to combustion is 2–4 times the original pressure, depending upon whether the gas is air or oxygen. The inner length of the bomb is 10 cm, which is the maximum length of the spray pattern. The transit time of the spray to the farthest end of the internal space is approximately 25 msec. At lower temperatures where reaction was slow, the spray would deposit on the inner walls, and the ignition delay extended out to hundreds of milliseconds. This appears to be characteristic of the time for auto-ignition of the gel as a film on the wall of the chamber rather than during the spray interval.

### Combustion of Metallized RP-1

Fig. 4 shows chemical ignition delay times of neat RP-1, gelled RP-1, and aluminized gelled RP-1 in hot oxygen<sup>[40]</sup> at a fixed pressure at 0.8 MPa and at four different test temperatures ( $410^\circ\text{C}$ ,  $460^\circ\text{C}$ ,  $520^\circ\text{C}$ , and  $580^\circ\text{C}$ ). Gelled RP-1 was used as a control rather than neat RP-1, to attain equivalent viscosity and permit comparison of the combustion of control vs. the aluminized fluids under similar spray patterns as predicted by the power law model. The gelled RP-1 (6.5-wt.% silica) had a viscosity at high shear rates equivalent to 30% Alex<sup>®</sup>/RP-1. The data in Fig. 4 indicate that the 30-wt.% Alexgel ignites faster than gelled RP-1, but about equivalent to that of pure kerosene.

Fig. 3 Device for measuring ignition delay times of gels.

Fig. 4 Average ignition delay in hot oxygen vs. temperature.

However, a surfactant when added to the 30-wt.% Alexgel reduces ignition delay below that of pure RP-1 kerosene (compare curve 1 and curve 2), demonstrating that Alex<sup>®</sup> acts as combustion accelerant for kerosene. Estimations based on the power law model indicate that apparent viscosity of this gel is comparable to that of RP-1 at injector shear rates ( $6.3 \cdot 10^4 \text{ sec}^{-1}$ ). Gels produced from 5- $\mu\text{m}$  aluminum did not show any reduction in ignition delay.

Similar experiments were repeated except in air<sup>[40]</sup> rather than oxygen, and at an initial air pressure of 1.1 MPa. Four different fuels were examined: gelled RP-1, 25-wt.% Alexgel, neat RP-1, and 30-wt.% L-Alex<sup>®</sup>/2-wt.% Tween-85/RP-1 fuel. Tests were performed at four different temperatures (430°C, 550°C,

580°C, and 600°C). The data in Fig. 5 indicate that 25-wt.% Alexgel (curve 3) ignites faster by approximately 30% than gelled RP-1 (curve 4). Curve 1 shows that the L-Alex<sup>®</sup> version ignites faster by factor of 2–3 than neat RP-1 (curve 2). As it was noted earlier, these two fluids have similar fluidity at high shear rates, confirming that L-Alex<sup>®</sup> is even more superior as a combustion accelerant than Alex<sup>®</sup> in an air environment.

### “Combustion” in Nitrogen

Alex<sup>®</sup> is known to react rapidly with gaseous nitrogen and this is supported by the DTA data of Mench

Fig. 5 Average ignition delay of different fuels in air vs. temperature.

et al.<sup>[25]</sup> This characteristic would be of benefit in air-breathing engines, permitting incipient combustion to occur and support these engines when they are starved for air. Alex<sup>®</sup>/RP-1 gels (55-wt.% Al) were sprayed into pure nitrogen at 750°C showing incipient combustion, but substantially slower than in air or oxygen. Nevertheless, the energy generated by this reaction can contribute to heat generation, while minimizing the opportunity for flame-out in air-breathing engines such as RBCC systems.

### Small Rocket Engine Tests

The combustion performance of Alexgels was measured in a small rocket engine by Mordosky et al.<sup>[42]</sup> The objective was to measure flame temperature, specific impulse, and  $c^*$  combustion efficiency (defined as  $P_c A_t / dm / dt$ ).<sup>[43]</sup>

In order to compare rocket test results obtained from different test engines, it is beneficial to have exactly the same fuel and oxidizer compositions as well as approximately the same operational conditions. The small rocket engine constructed by Mordosky et al.<sup>[42]</sup> was 30.5 cm long with an internal diameter of 12.0 cm. Combustion of Alexgels was done in gaseous oxygen. The aluminum loadings (Table 2) were the same, but there were some variations in the surfactant and gellant. Table 3 shows average values of adjusted  $c^*$  efficiency of the Penn State fuels as compared to the work of Palaszewski and Zakany.<sup>[7,9]</sup> They show that:

- i. The 5-wt.% Alex<sup>®</sup>/RP-1 gel burns more efficiently as compared to 5-wt.%Al/RP-1 gel using coarse aluminum.
- ii. The 55-wt.% Alex<sup>®</sup>/RP-1 gel burns more efficiently as compared to 55-wt.%Al/RP-1 gel.
- iii. The 5-wt.% Alex<sup>®</sup>/RP-1 gel burns with the same efficiency as neat RP-1, although the viscosity of the neat RP-1 is very much lower than that of gelled RP-1 or Alex<sup>®</sup>-loaded gels.

These data show that the combustion of the nano aluminum overcomes the deficiency of a larger droplet spray pattern associated with higher viscosity of the Alexgels. They also measured the aluminum oxide that is produced during combustion and found it to be submicron in size.

## APPLICATIONS OF ALEXGELS

### Hydrocarbon-Based Liquid Rocket Engines

Combustion bomb testing reinforced by small rocket engine tests shows that Alex<sup>®</sup> nano aluminum powder provides improvement in volumetric energy density over pure kerosene while micron-size aluminum burns inefficiently when dispersed in hydrocarbon. Another benefit is the reduction of metal slagging on the walls of the rocket engine.

### Hydrocarbon-Based RBCC Systems

Cryogenic hydrogen is being considered for RBCC engines. However, maintaining this cryogenic fuel over long duration flights, such as its use for re-entry, is problematic. Should hydrocarbon fuel be considered for RBCC engines, then adding Alex<sup>®</sup> would provide the same potential benefits as its use in hypersonics, i.e., flame stability and increased output in the air augmented mode, while providing increases in volumetric  $I_{sp}$  in the rocket mode as well.

### Pulse Detonation Engines

Another possible use for aluminizing kerosene is in pulse detonation engines (PDEs). The detonation of kerosene in air has yet to be demonstrated. The potential for reducing ignition delay into the submillisecond regime by adding Alex<sup>®</sup> is almost certain. Further reductions of particle size, enhanced by finer sprays as well as organic layered aluminum such as the

**Table 2** Compositions of the RP-1/Alex<sup>®</sup> gel propellants tested at Penn State

Metal loading weight percentage	Liquid fuel (RP-1)	Metal powder (Alex)	Gellant (SiO <sub>2</sub> )	Surfactant (Tween-85)
0 wt.%	95%	0%	5%	0%
5 wt.%	90%	5%	5%	0%
10 wt.%	86%	10%	4%	0%
30 wt.%	68.2%	30%	1.3%	0.5%
55 wt.%	43.3%	55%	0.4%	1.3%

**Table 3** Average values of normalized  $c_{avg}^*$  efficiency of NASA gels to the Penn State gels

Gel formulation	$c_{avg}^*$ (Alex <sup>®</sup> )	$c_{avg}^*$ (coarse Al, adjusted)	$c^*$ Ratio of nano/coarse aluminum [ $c_{avg}^*$ (Alex <sup>®</sup> )/ $c_{avg}^*$ (Al, adjusted)]
Neat RP-1	–	88.9 ± 1.8	–
5 wt.%	88.3 ± 1.7	78.1 ± 2.4	1.132 ± 0.036
55 wt.%	83.0 ± 2.2	77.8 ± 2.4	1.07 ± 0.04

L-Alex<sup>®</sup>, could result in overcoming the difficulty in detonating kerosene.

## Liquid Hydrogen Engines

Adding aluminum to cryogenic hydrogen to form gels has been suggested by Starkovich, Adams, and Palaszewski<sup>[14]</sup> as a means to increase volumetric energy density and at the same time increase the containment of a liquid hydrogen leak. Such benefits could also be useful for a liquid hydrogen RBCC engine, where Alex<sup>®</sup> could also serve to increase flame stability during the air cycle.

## CONCLUSION

Gels of Alex<sup>®</sup> in RP-1 are dynamically stable at least over the short term and matched the viscosity of coarse aluminum gelled into RP-1 (Fig. 2). Ignition delays of nano-aluminized gels were always shorter than gelled RP-1 (equivalent viscosity) as well as neat RP-1, which has lower viscosity. Alex<sup>®</sup> acts as a combustion accelerant for RP-1, and probably other kerosenes as well. An organic coated version of Alex<sup>®</sup> (L-Alex<sup>®</sup>) was developed and found to have ignition delays in air lower than RP-1 by a factor of 2–3. These findings are relevant to advanced rocket combined cycle engines, hypersonic (scramjet) engines, and perhaps pulse detonation engines. Coarse aluminum is not a combustion accelerant for RP-1 in oxygen.

Rocket engine testing at Penn State showed that the 5-wt.% and 55-wt.% Alexgels burn *substantially* more efficiently than coarse aluminum. The 5-wt.% Alex<sup>®</sup>/RP-1 gel burns with the same efficiency as neat RP-1, although the viscosity of the neat RP-1 is very much lower than that of gelled RP-1 or micron-size aluminized gels. Apparently, the kinetics of combustion of the nano aluminum overcomes the larger droplets of the spray caused by higher viscosity.

The overall conclusion is that loading Alex<sup>®</sup> into RP-1 improved its combustion kinetics and efficiency as compared to neat RP-1, and better than published values for micron-size aluminum gels. Moreover,

Alex<sup>®</sup> additions would result in improving the combustion of kerosene in air-breathing engines.

## ACKNOWLEDGMENTS

We appreciate the support of NASA Glenn Research Center under Contract No. NAS 3-99117, under the guidance of Brian Palaszewski, technical representative.

## INTRODUCTION

Nanosize metal clusters occupy a position between the molecular and solid state and, because of the dominant role of their abundant surface area, provide a unique way to learn how metal-metal bonding, cluster shape, and packing are affected by ligands bound to the cluster surface. Such studies may give insights into complex issues in catalysis, such as selectivity of binding of substrates to vertex, edge, or face sites on a metal cluster, and how such binding affects the intermetal bond distances, essentially causing a surface reconstruction, mass redistribution, or shape change. Studies of the 3-D interface structure of nanosize metal clusters should yield information quite different from the extensive literature describing ligand interactions with extended, 2-D metal surfaces. Because clusters more closely resemble practical heterogeneous catalysts (e.g., hydrodesulfurization process, hydrogenation process), important new scientific and technical insights may be gained by their study.

The formation of metal colloids or clusters by the controlled reduction, nucleation, and growth from metal salts in aqueous solution has been investigated for over a century. In the case of gold colloids, the earliest scientific investigations were undertaken by Michael Faraday<sup>[1]</sup> and spanned over a decade. Human interest in the colors of such colloidal systems dates back to the Roman times, as pointed out by Kreibitz and Vollmer<sup>[2]</sup> in their excellent review of the optical properties of metal clusters. An example cited therein is a Roman goblet from the fourth century in the British Museum whose fame is attributed to the shining colors generated by a composition of Ag and Au clusters. The purple colors of colloidal Au and Cu dispersions are thought to be the origin of the association of purple with royal colors.

## OVERVIEW

The earliest methods of colloidal synthesis (e.g., Faraday method) rely on the chemical reduction of metal salts in aqueous solution. The remarkable

stability of these ancient wine-red sols was a result of charge stabilization via adsorbed citrate ions. In sealed vials, samples prepared by Faraday in the mid-1850s can be still be viewed in the Cavendish museum in Cambridge—a true testament to solution stability.

Only very recently have scientists developed non-aqueous methods of colloidal synthesis requiring steric, not charge, stabilization. An early example of this approach, which ultimately led to the development of magnetic particles for recording purposes, was that of Hoon et al.<sup>[3]</sup> They produced Co colloids (now called nanoclusters, nanocrystals, or nanoparticulates) in the 1–100 nm range by thermolysis of  $\text{Co}_2(\text{CO})_8$  in the presence of dispersant polymers. This seminal work provided the basis of nearly all subsequent methods for production of colloids from metallorganic precursors using high  $T$  decomposition. Other reports of base metal colloidal synthesis via thermal decomposition in the presence of surfactants or polymers soon followed.<sup>[4,5]</sup> With the advent of exotic organometallic precursors, even binary semiconductors could be produced by this approach.<sup>[6]</sup>

Although organometallic precursors are the basis of many current approaches to cluster synthesis in non-aqueous, low-dielectric constant solvents, there are several drawbacks to this approach. The toxicity, air sensitivity, cost, and unwanted by-products (e.g., metallic films) prevented the widespread adoption of such methods outside the chemical community.

Methods of systematic control of cluster size in organometallic decomposition routes are still lacking. Nevertheless, in certain cases, remarkable monodispersity can be achieved. One of the earliest and best-known examples of monodisperse metal cluster growth from atomic precursors in solution was the synthesis by Schmid<sup>[7]</sup> of  $\text{Au}(N = 55)$  clusters by diborane reduction of  $\text{Au}(\text{PPh}_3)\text{Cl}$  in benzene or methylene chloride. Fifty-five atoms of a metal corresponds to the closing of the second atomic shell of a  $\text{Au}(N = 13)$  cluster core with 42 Au atoms with a dozen  $\text{PPh}_3$  molecules weakly ligated to the faces of the inorganic core. Consequently, the role of the ligand used to sterically stabilize inorganic nanoclusters in a solvent was discovered to be critical in determining

the eventual structure and stable size of a given nanocluster. By a continuation of this growth process, Schmid has extended the range of sizes available to many thousands of atoms, utilizing a synthesis reminiscent of polymeric growth—one generation providing the “seeds” for the next.<sup>[8]</sup> His approach has also been extended to other metals such as Pd and Pt. However, the yields from each growth generation are low so, as in organic synthesis, the overall yield can be quite small for larger clusters. Also, the weak binding of the PPh<sub>3</sub> group means that the long-term stability (e.g., longer than a few days) of such clusters is severely compromised.

It would be very nice to have a general nanocluster chemical synthesis, which combines the advantages of low toxicity/cost precursors, and high yield of traditional aqueous-based colloidal chemistry with the size dispersion control and chemical versatility of organometallic methods. Possibly with this goal in mind, Boutonnet, Kizling, and Stenius<sup>[9]</sup> first used aqueous pools of water found in oil—continuous microemulsions to solubilize simple, ionic, metal salts of Au, Pd, Pt, and Rh, followed by chemical reduction using hydrazine or hydrogen gas to produce metal clusters dispersed in oils. Such new nanomaterials were later shown to have good catalytic activity for hydrogenation.<sup>[10]</sup>

A serious limitation of using water containing microemulsions as microscopic reactors for metal colloid formation was the limited types of reducing agents permitted (basically hydrazine or aqueous NaBH<sub>4</sub>), as well as the inherent polydispersity of microemulsions, which produced a fairly broad size dispersion in the final product. This limitation was overcome by the surprising discovery that ionic metal salts could be directly solubilized in a variety of newly discovered inverse micelle systems.<sup>[11–13]</sup> The most useful of these systems were reported in a series of papers and a patent, and form the basis of the most versatile method for the formation of nanoclusters, both semiconductor and metallic, in the 1–10 nm regime.<sup>[14–16]</sup> The complete absence of water and air in these systems allowed the use of very strong, even pyrophoric, reductants such as LiAlH<sub>4</sub> [in tetrahydrofuran (THF)] for the first time and permitted even exotic nanocrystalline species such as Si and Ge to be made by low-*T* chemical synthesis for the first time.<sup>[17–20]</sup> In addition, the well-defined interface and monodispersity inherent to inverse micelle systems resulted in narrow cluster size distributions.

Meanwhile, physicists were taking a different approach to cluster synthesis, based on their expertise in high-vacuum, molecular beam techniques coupled with the use of mass spectrometers for mass selection and analysis. An excellent example of the results that emerged from such endeavors is that of de Heer and coworkers, who utilized a supersonic expansion of an

atomic cluster source into a vacuum in the presence of an inert gas to create cluster beams.<sup>[21]</sup> Using a mass spectrometer they, and others,<sup>[22]</sup> discovered that certain masses of clusters were produced in relatively large abundance. These “magic” sizes corresponded to the closing of atomic shells, analogous to stable nuclear shells from nuclear chemistry,<sup>[23]</sup> or the electronic shells forming the basis of chemical bonding and the periodic table. Alkali metal clusters, in particular, were discovered to be well described by simple “jellium” models and their optical properties were investigated. Other interesting phenomena emerged from these studies, including the discovery of enhanced magnetic moments in small clusters of Co, Fe, and Ni compared to their bulk counterparts.<sup>[24]</sup>

The ability to compare the size-dependent physical properties (e.g., absorbance, PL, magnetic behavior, melting point, chemical reactivity) of clusters prepared by beam methods and those prepared by solution techniques is complicated by the very important role of the interface, also known as the embedding media effect.<sup>[2]</sup> “Naked” clusters in a vacuum have very different optoelectronic properties compared to those coordinated to a solvent or a ligand. Importantly, clusters in solution, in order to be perfectly dispersed, require tightly binding ligands to prevent association or “clumping” in solution, so one can never consider very small inorganic nanoclusters (1–3 nm) without also understanding their organic interface or “shell.” Even in a vacuum, a naked cluster has unsatisfied bonding at its surface, which probably requires some sort of structural “reconstruction” to minimize its energy, and this has not been taken into account in even the most refined theories of cluster structure. Thus, there is considerable controversy among theorists regarding the actual equilibrium shape of a cluster for a given number of atoms. In short, we have a long way to go before understanding the size- and interface-dependent properties of nanoclusters. Scientists may expect to be fruitfully employed in this enterprise for many years to come.

In this entry, we cannot possibly do justice to the enormous literature in the area of metallic nanoclusters or quantum dots. Accordingly, we primarily focus on metallic Q-dots of Au and Ag, which historically provided the earliest fascination with dispersed colloidal materials. In fact, the beautiful colors of colloidal sols, which differed so significantly from their bulk counterparts and organic dyes, influenced their medieval uses in stained glass, goblets, etc. Their synthetic preparation was a well-guarded alchemic secret. It is probably not surprising that the majority of scientific investigations of the optical properties of metal clusters have focused on the few metals with visible absorbance. This restricts studies to the alkalis and noble metals (Au, Ag, Cu). This is because strong collective

oscillations (plasmon resonances) require quasi-free electrons, as well as weak damping of these oscillations in the visible regime [i.e., the imaginary part of the dielectric constant  $\varepsilon(\omega)$  must be small]. A further preference for studies of Au and Ag colloids occurs because of their remarkable long-term stabilities in aqueous solutions under ambient conditions and their interesting size- and shape-dependent optical properties, which can often be described by the Mie theory<sup>[25]</sup> of electromagnetic scattering. In this review, we emphasize the important role of synthesis methods, advanced characterization tools for both feedback and understanding of size/optical properties, and formation of arrays of these dots. We discuss both alloys and core-shell nanoparticles of these materials. Only briefly discussed will be the magnetic and catalytic properties of nanoclusters.

## EXPERIMENTAL

### Nanocluster Synthetic methods

#### Inverse micelle method

The inverse micelle synthesis has been extensively described in a series of papers<sup>[11,13–20,26–28]</sup> and patent.<sup>[12]</sup> A key difference of this method from either liquid or gas atomic aggregation processes (e.g., high- $T$  thermal decomposition of organometallics) is that the cluster-cluster aggregation process, whose kinetically determined structures inevitably result in power-law or log normal cluster size distributions, is fundamentally altered by the microheterogeneous environment of the droplet-like inverse micelles. Because the ionic metal salt precursor is only soluble inside the micelle at typical precursor metal salt concentration of 0.01–0.1 M and surfactant concentrations of ~5–10 wt.% (~0.2 M), there are only about 1–4 precursor ions/micelle. Thus, growth to the final observed sizes of  $N = 10$ –10000 atoms must occur via micellar diffusion, micelle collision, temporary interface fusion, and atomic interchange. The micelle interior volume roughly determines the maximum size of the small atomic clusters, which may interchange during the growth or aggregation step of the synthesis. This cluster growth rate is set by the diffusion rate of the micelles, which is ~2 orders of magnitude slower than would occur in a continuous liquid phase (i.e., Schmid approach, gas-phase aggregation, etc.). So the opportunity for structural adjustments to atomic positions during atomic exchange and growth is enhanced, possibly favoring thermodynamic stabilities over metastable (e.g., disordered) cluster structures. For this reason, we have never observed disordered, and rarely<sup>[29]</sup> non-equilibrium nanoclusters as the final product

regardless of the melting point of the corresponding bulk material.

Our approach has changed only in minor ways since our first description of metal nanocluster synthesis in 1989.<sup>[11]</sup> The most significant change is the use of strongly binding surfactants, thiols, to passivate the surface during or after the chemical reduction, which allowed us to employ liquid chromatographic analysis of the nanocluster size and size dispersion.<sup>[30]</sup> When thiols are added prereduction, they can significantly alter the final nanocluster size, because they inhibit the cluster growth more strongly than the non-ionic and cationic surfactants we typically use to solubilize ionic gold, silver, or platinum salts in inverse micelles. However, the use of alkyl thiols as passivating agents presents other issues, which we have recently discussed—certain alkyl thiols act as etchants, reducing the size of the as-synthesized clusters.<sup>[31]</sup> They also fail to bind as effectively to larger (e.g.,  $D_c > 4$  nm) ( $D_c =$  inorganic core diameter) Au clusters compared to smaller ones (e.g.,  $D_c < 2$ –3 nm). The thiols, although present in much lesser amounts than the surfactants used to form the inverse micelles, compete very effectively for binding sites on the growing nanocluster surface. Because of their strong binding properties, thiol passivating agents also permit purification and removal of ionic byproducts and most of the surfactant micelles used to solubilize the metal salt precursors. The stabilization of the nanocluster surface by a strongly binding ligand is critical to the variety of purification approaches we have described.<sup>[30]</sup>

Numerous other papers describing Au nanocluster synthesis using so-called phase transfer catalysts (i.e., cationic surfactants)<sup>[32,33]</sup> have been published. There are some misconceptions about the role of the cationic surfactants used in this synthetic approach. The first is that the typical recipe requires water to first dissolve the salt (typically  $\text{HAuCl}_4$  or  $\text{NaAuCl}_4$ ) and then requires this aqueous salt solution to be brought into contact with an immiscible toluene solution containing a cationic surfactant [usually tetraoctylammonium bromide (TOAB)]. One needs to ask why only certain cationic surfactants will actually solubilize the gold salt into the organic phase? The reason is that very hydrophobic, long-alkyl chain surfactants are required to ensure both the formation of spherical micelles in the organic (toluene) phase and the total exclusion of water from that phase. Because such cationic surfactants spontaneously form inverse micelles in toluene, as was discovered several years ago by neutron scattering, they are capable of directly solubilizing a wide variety of metal salts without the use of water. We have described such an inverse micelle synthesis in Ref.<sup>[13]</sup> and in our original patent,<sup>[12]</sup> using didodecyldimethyl ammonium bromide (DDAB) in toluene. One can also use linear alkane solvents with these surfactants, but

geometric considerations in the tail group packing often require a cosurfactant such as hexanol be added to “fill in the gaps” in the micellar surfactant droplet interface with linear alkanes.

With this general understanding of the role of the cationic surfactant as a micelle forming agent, which can directly solubilize a variety of metal salts, water need not be introduced into the system, thus allowing the use of strong reducing agents such as  $\text{LiBH}_4$  in tetrahydrofuran (THF), or  $\text{LiAlH}_4$  in THF or toluene. These reducing agents are generally superior to  $\text{NaBH}_4$  in water, which must be used to reduce  $\text{HAuCl}_4$  in two-phase systems. Even if one chooses to use  $\text{NaBH}_4$  as a reductant, because  $\text{NaBH}_4$  in neutral aqueous solution is unstable with respect to hydrolysis, only highly alkaline solutions ( $\sim 4 \text{ NaOH}:\text{NaBH}_4$ ) should be used to effect reductions. Such caustic reducing solutions are quite stable and are actually sold by Aldrich as stock  $\sim 4.4 \text{ M NaBH}_4$  in  $\sim 14 \text{ M NaOH}$  solutions, and can be diluted into water, as desired.

In the case of gold or silver, the precursor metal salts are so easily reduced that the use of alkaline  $\text{NaBH}_4$  in water as we described in our early work is quite acceptable. However, this reducing agent is somewhat ineffective for the reduction of Pt or Pd salts, and is completely ineffective for formation of metallic Fe, Ni, Co, Si, or Ge. Instead, in the case of Fe, Ni, or Co, the corresponding metal boride will form.

### Metathesis method

In this cluster formation method, a chemical reduction of an organic soluble metal–organic precursor is used to produced metal clusters. This can be carried out in a coordinating or non-coordinating solvent, or some combination thereof. Alternatively, a surface-active (but not micelle forming) species such as dodecanthiol (C12SH) or tri-*n*-octylphosphine (TOP) may be added to prevent run-away growth during the chemical reduction. The best example of this approach is the one described by Schmid, and exemplified by the reaction that produces  $\text{Au}(N = 55)$  clusters. We refer the reader to his excellent review on this subject for further details.<sup>[8]</sup>

Another approach to the production of metal clusters in solution relies on the high-*T* reduction of organometallic precursors by glycols in coordinating solvents such as diphenyl ether. This “poly-ol” method was recently refined to produce base metal clusters of a variety of sizes of Co, Fe, and Ni. Generally, empirically chosen surfactants are used to stabilize the growing nanocluster. A review of this approach appeared recently.<sup>[34]</sup> Briefly, the nanocluster size is increased by increasing the amount of precursor and/or decreasing the amount of surfactant. There is usually some unwanted metallic film formation and/

or incomplete reduction so the yield is not 100%, and the method requires high boiling point solvents as the reduction typically takes place between 200 and 300°C. Some of these solvents may not allow solubilization of all the available components (metal–organic, poly-ol, stabilizer), so a fair amount of empirical variation is required before achieving an optimal synthesis.

### Thermal decomposition method

In this method, which is the oldest approach for non-aqueous synthesis of metallic Q-dots, a thermally labile, oil soluble, metal–organic precursor is thermally decomposed in the presence of a surfactant-like stabilizer, typically a block copolymer.<sup>[3]</sup> Under the proper conditions, fairly monodisperse colloids can result. However, the method is typically only used for base-metal nanocluster synthesis (Co, Fe, Ni) because an available thermally unstable metallorganic is required [e.g.,  $\text{Fe}(\text{CO})_5$ ,  $\text{Co}_2(\text{CO})_8$ ,  $\text{Ni}(\text{CO})_4$ ]. As these compounds are very air-sensitive and either mildly or severely toxic, all handling must be carried out in either a glove box, or by Schlenk-line methods. Additionally, because of the rapid growth rate compared to chemical reduction methods, the final clusters are highly defective, requiring significant annealing to produce high-quality samples. This means the final material properties (e.g., saturated magnetic response) are typically only a small fraction of that found in the corresponding bulk materials.<sup>[3–5]</sup>

### Nanocluster Characterization

#### Size exclusion chromatography (SEC)

We use a commercial Waters corporation autosampler, solvent pump, degasser, and detectors together with commercially available polystyrene microgel columns (Polymer Laboratories) with controlled pore sizes to separate and analyze organically passivated metal nanoclusters. The alkyl organic shell on the metal surface prevents specific chemical interaction with the hydrophobic column material. A single-channel output of an in-line photodiode array (PDA) detector at a particular wavelength near the classical plasmon resonance, ( $\sim 520 \text{ nm}$  for Au,  $\sim 400 \text{ nm}$  for Ag) was used as described in previous papers<sup>[30,35]</sup> to obtain the peak apex elution time and peak width, which together yield the average cluster size and size dispersion. A conductivity detector and refractive index (RI) detector were also used to demonstrate that the eluting metal clusters had no charge and were separated from the non-absorbing chemicals (surfactant micelles, salt byproducts, etc.) used in the synthesis. A chromatogram showing the separation  $D_c = 2 \text{ nm}$

Au nanoclusters from the solvents and surfactants used to produce them is illustrated in Fig. 1, taken from Ref.<sup>[30]</sup>.

The use of SEC to obtain cluster sizes and size distributions was explained in detail in a recent paper.<sup>[30]</sup> In that work, we demonstrated that the elution time  $t_e$  for a properly passivated Au nanocluster sample with a hydrodynamic diameter  $D_h$  obeyed the relation,  $\log D_h \sim t_e$ , allowing one to obtain a metal core diameter after subtraction of the thickness of the organic passivating layer. This thickness was determined by taking a sample with a single core size as determined by transmission electron microscopy (TEM) and adding a series of alkyl thiols, designated herein as CkSH, with chain lengths  $k$  of  $6 < k < 16$ , to the toluene mobile phase, and obtaining  $D_h$  from  $t_e$  and subtracting the known TEM core size. Fig. 2 shows an example of this size separation capability for a single core size,  $D_c = 2.0$  nm and  $k = 6, 10,$  and  $14$ . It illustrates that clusters with different total hydrodynamic sizes due to organic shell differences may be separated by using SEC.

The organic passivating shell thicknesses agree well with values calculated from known C–C bond lengths in linear alkanes and confirmed by SEC. A best fit to a series of linear alkanes and polystyrene polymer standards gave  $D_h$  (nm) =  $608 \exp(-0.62525t_e \text{ (min)})$  for the PL1000 column used in that reference. This relation was valid for  $1 \text{ nm} < D_h < 10 \text{ nm}$ . Columns are available with larger pore sizes, which extend this range to larger values. For further information, the reader should consult the excellent book by Yau Kitland, and Bly<sup>[37]</sup>

In the case of other nanoclusters such as Si, Ge, Co, Ni, and Fe, or semiconductors such as CdS, CdSe, FeS<sub>2</sub>, and MoS<sub>2</sub>, tetrahydrofuran (THF) or acetonitrile (ACN) appears to be the best mobile phase choice. It is highly recommended to use inhibited THF to

**Fig. 1** Chromatographic separation of capped Au nanoclusters stabilized using c12SH and containing the non-ionic surfactant c12e5. A PL500 column and a toluene mobile phase were used.

**Fig. 2** Effect of capping agents on the hydrodynamic diameter of Au nanoclusters. The HPLC chromatogram of Au nanoclusters with three alkyl thiols, CkSH,  $k = 6, 10, 14$ , added after reduction. The absorbance at 520 nm [ $A(520 \text{ nm})$ ] from the PDA vs. elution time is shown. The SEC column used was a Polymer Labs PL1000 and the mobile phase was toluene at 1 mL/min flow rate. Source: From Ref.<sup>[30]</sup>.

minimize oxidation as a result of peroxide formation. This is especially true if fraction collection of purified nanoclusters is desired. In our case, automatic vacuum removal of all gases occurs prior to the pump and injection system, so air-sensitive nanomaterials can be easily analyzed or fraction collected without degradation. In addition, an in-line filter and short “guard” column of the same column material is used to prevent retention time changes with age and/or injection of “bad” samples. With such an elaborate system (and many ruined columns during the learning process!), we can reproduce the retention time (i.e.,  $D_h$ ) of high-quality, stable nanocluster samples to within the instrument resolution of 0.01–0.02 min over periods exceeding 1 year. This corresponds to a size resolution (see Fig. 3) of  $\sim 1 \text{ \AA}$ ! Additionally, shape information is incorporated into the retention time, as we can achieve near baseline separation of C60 from C70 on a typical PL500 column, although these fullerenes differ in hydrodynamic size by only  $\sim 1 \text{ \AA}$ . Fig. 3 illustrates this point.

As we have discussed,<sup>[30,37]</sup> increasing the total pore volume for a pure SEC elution mechanism increases the resolving power of the separation. Preparative columns with diameters of 25.4 mm are available (i.e.,  $\sim 10\times$  the pore volume) that can separate clusters differing in size by only  $\sim 2\%$ . With such columns, large amounts (10–100 mg) of nanoclusters can be injected and fraction collected with great size selectivity ( $\sim 1$ – $2 \text{ \AA}$  separation). We have developed a custom-designed, anaerobic, automated fraction collection system which we will describe in future work.

**Fig. 3** Chromatogram instrumental linewidth for samples of decane (C10), C60, and C70 run on a PL500 column in toluene. *Source:* From Ref.<sup>[30]</sup>.

There is an inherent elution peak width at half-height associated with the chromatography column itself even for monodisperse molecules such as octane (Fig. 3).<sup>[30]</sup> Unlike reverse-phase chromatography columns, for SEC columns the instrumental band-broadening does not depend on elution time, but simply on the average size of the microgel particles used to pack the column. For example, the high-resolution columns used in previous studies were packed with porous 5- $\mu\text{m}$  particles and had significantly narrower inherent band-broadening than less expensive columns packed with 10- $\mu\text{m}$  particles of the same material. This column band-broadening is experimentally determined by using a known monodisperse sample and the same column used for study of the unknown samples. Using decane C10, we found  $\Delta t_{1/2} = 0.25\text{--}0.27$  min while we found  $\Delta t_{1/2} = 0.40$  min for purified (99.9%, Strem Chemicals) buckyballs, C60 and C70.<sup>[30]</sup> From shape considerations, the latter standard seems more appropriate to compare to our spherical nanocluster samples. Any cluster elution peak whose width exceeds this value implies some polydispersity in the sample provided the sample does not have specific chemical interactions with the column. In fact, as shown in our previous work, reproduced in Fig. 4, our best metal cluster samples have  $\Delta t_{1/2} = 0.30\text{--}0.35$  min, slightly narrower than the best available C60, so there is some uncertainty ( $\sim 0.05$  min) as to which value best represents the inherent column broadening. Roughly speaking, the subpopulations of such a polydisperse sample with elution times lying outside  $t_e \pm 0.4/2$  will be separated from the clusters represented by the signal at the apex of the peak and contain additional spectral information. The optical spectra obtained from the size-selected population eluting at the peak apex represents

**Fig. 4** Size distribution of Au clusters is as narrow as buckyballs. Normalized absorbance chromatogram from PDA detector ( $A/A_{\text{max}}$ ) for C12SH-stabilized Au nanoclusters and 99.9% C60. HPLC conditions were a PL500 column using toluene as the mobile phase flowing at 1 mL/min. The C60 elution time has been shifted to coincide with that of the Au nanoclusters for ease of comparison. *Source:* From Ref.<sup>[30]</sup>.

a single size to within the  $\pm 2 \text{ \AA}$  resolution for our column. This resolution of  $\pm 2 \text{ \AA}$  may be increased by increasing the total pore volume of the column by adding an identical column in series.

Typically, a 10- $\mu\text{l}$  amount of  $\sim 0.01$  M nanocluster solution is injected from a crimp top vial using our Water's model 717 autoinjector and sampling loop. The total experimental time is 15 min, so complete size and optical analysis of 20 samples under automated control is quite feasible in a day. The retention time at the peak apex elution is measured by using the absorbance obtained from a chosen wavelength element of a 1024-channel, on-line, photodiode array (PDA), absorbance detector. The mobile-phase background absorbance, although not significant in the region of interest for most metal nanoclusters, is automatically removed. Organic chemicals (e.g., solvents, surfactants) that do not absorb at mobile-phase-transparent wavelengths, are detected by using an on-line differential refractometer (Water's model 410).

#### Transmission electron microscopy (TEM, HRTEM)

About 2  $\mu\text{l}$  of the purified  $\sim 0.01$  M solution of nanoclusters was deposited on a holey carbon grid, under which a porous filter paper was placed to quickly wick the solvent away to minimize cluster pile up on the grid. For core sizes larger than  $D_C \sim 2$  nm high-resolution TEM (HRTEM) was used to confirm the metal core size to an uncertainty of one lattice constant ( $\pm 2 \text{ \AA}$ ). However, in this size range, this

**Fig. 5** HRTEM of a region of a holey carbon grid on which a drop of sample Au,  $D = 1.8(2)$  nm was allowed to dry. Source: From Ref.<sup>[30]</sup>.

measurement uncertainty is as large as the SEC resolution, even assuming a perfectly monodisperse sample with all the clusters in an identical focal plane on the holey carbon grid and identical nanocrystal orientation.

Nanocrystal orientation is very important for small crystals. For example, if a randomly oriented distribution of monodisperse icosohedral Au crystals is examined with  $d\langle 111 \rangle = 2.1$  nm and  $d\langle 100 \rangle = 2.7$  nm, one obtains the number average  $D_c(\text{TEM}) \sim 2.4 \pm .3$  nm, but this is not a result of size dispersity. In addition, with the smallest clusters, especially Ag, there are e-beam cluster “melting” artifacts that make absolute size measurements difficult because the boundary with the grid becomes less sharp, in addition to causing some cluster fusion where their surfaces touch. For these reasons, size determination by high-resolution SEC, complemented by HRTEM, has major advantages. Fig. 5 shows an HRTEM of Au,  $D_c = 1.8$  nm particles, showing the atomic lattice fringes from this HPLC-purified sample, and illustrates the effects of crystallographic orientation and focal plane effects on the apparent cross-sectional diameter of this nearly monodisperse sample.

#### Absorbance spectra

The absorbance spectra of passivated metal nanoclusters was obtained by using an on-line photodiode array PDA with an adjustable bandwidth and wavelength

range. For the purpose of the studies reported in this review, the bandwidth was either 2.4 or 4.8 nm, and a wavelength range of 290–795 nm was used. Complete absorbance spectra were collected every 2 sec during the chromatography. A Cary 2300 ultraviolet (UV)–visible spectrometer was also used to verify selected results from the PDA. Both spectrometers were calibrated by using a holmium filter.

Because a typical cluster elution linewidth is about 0.3–0.4 min, between 10 and 15 complete spectra were available as a function of elution time (i.e., size). Thus, in addition to the information concerning how the absorbance spectra changes with cluster size at the peak of the elution, we also can determine the spectral homogeneity of an elution peak. A spectrally pure or homogeneous elution peak corresponds to one in which there is no variation in the absorbance spectral shape within the peak. Size or shape polydispersity would lead to size-dependent optical absorption spectra within the elution peak.

#### Synthesis Optimization with SEC Feedback

Perfecting the methods of inorganic nanocluster synthesis requires rapid, quantitative feedback concerning final cluster size, shape, optical properties, and their relationship to the myriad synthetic variables, which can affect the average cluster size and size distribution. A good analogy is with advances in organic synthesis which have been facilitated greatly by the advent of modern analysis methods, such as Fourier-transform infrared (FTIR), gas chromatography/mass spectrometry (GC/MS), liquid chromatography (LC)/PDA, nuclear magnetic resonance (NMR), etc. Without such feedback, the synthetic chemist is very much in the dark with respect to whether changes in synthetic protocol are making things better or worse. Another example comes from the application of liquid chromatography/mass spectrometry (LC/MS) and capillary gel electrophoresis approaches to DNA and protein analysis which, along with polymerase chain reaction (PCR) amplification, essentially enabled the rapid sequencing of the human genome. Unfortunately, carrying such analytic methods directly over into the field of inorganic nanocluster synthesis is not always straightforward. Perhaps, this is the reason for the limited number of nanomaterials that humans know how to synthesize in a predictable manner—the best examples being transition metal nanoclusters as pioneered by my group, and II–VI semiconductors (mainly CdSe) as pioneered by Murray, Bawendi, Alivisatos, and Brus.<sup>[6,38–40]</sup> These materials were explicitly chosen because they have clearly identifiable, size-dependent visible colors (absorbance) that allows rapid feedback regarding size and monodispersity.

For example, in the case of CdSe, size changes as small as 1–2 Å result in clear differences in the absorbance edge. In the case of nanosize Au or Ag, one can perceive, even with the naked eye, color changes corresponding to ~2–4 Å in size, and using an absorbance spectrometer, 1–2 Å size differences.

## RESULTS AND DISCUSSION

Our recognition of the dearth of rapid analysis techniques for inorganic nanomaterials led us to try to adapt some modern analytical methods to understand size/optical property relationships in both semiconductors and nanometals. These techniques include in situ elemental analysis of purified cluster solutions using X-ray fluorescence (XRF), which is very useful for composite nanoclusters, and size-exclusion liquid chromatography, which has recently become our most useful tool, supplanting even TEM in both size precision and utility. We now illustrate the power of these new analysis methods in improving nanocluster synthesis with several examples from our previous work.

### Nanocluster/Ligand Binding Studies

We have recognized for many years that at least four important factors control the final size of nanoclusters synthesized in inverse micelles:

1. The micelle size,
2. The binding strength of the surfactant micelle used,
3. The amount of precursor salt used in the synthesis,
4. The strength of the reducing agent used.

Variables 3) and 4) influence the final cluster size even in the absence of micelles as, e.g., in metathesis methods using metal–organic precursors in the presence of coordinating ligands. Perhaps, not surprisingly, increasing the concentration of metal salt precursor increases the final cluster size, while increasing the rate of reduction by using a stronger reducing agent decreases the cluster size. Also, increasing the strength of the binding of the micelle-forming surfactant decreases the final cluster size if all other variables remain fixed. However, it is very difficult to predict, a priori, which surfactants will bind most strongly to which metals, nor how much change in final size will be achieved by changing the precursor concentration or reducing strength.

By measuring the total amount of clusters eluting from a given column/mobile phase using measurement of the elution area at a given wavelength with and

without the column, one can study the competition for the organic ligand between the high surface area column and the high surface area nanoclusters. It is found that, for Au nanoclusters, thiol exchange does not occur on the time scale of the chromatography experiment (~15 min) even in the presence of an overwhelming amount of a different CkSH in the mobile phase [i.e., the clusters elute at the time expected for the chain length (thickness) of the alkyl thiol], while for Ag nanoclusters, complete exchange occurs under these conditions. Thus, Ag nanoclusters bind alkyl thiols significantly more weakly than Au. Pt, Pd, and Rh nanoclusters do not exchange thiols during the chromatography like Ag, but still have slightly more weak binding than in the case of Au clusters of the same size, as indicated by fewer (<100%) eluting clusters.<sup>[30]</sup>

One can learn about ligand metal cluster binding, so critical to catalysis, by examining the relative amount of clusters eluting from a column with a mobile phase of pure toluene. In this case, the column attempts to separate the ligand from the cluster. Failure to do so results in complete elution of the clusters, as judged from ratio of the area under the elution peak compared to the no-column case. In Fig. 6, one observes that the relative areas decrease with  $k$  for  $k = 6, 10,$  and  $14$ , indicating shorter chain thiols bind less strongly than longer ones.<sup>[30]</sup>

These types of subtle binding effects are nearly impossible to study by other methods. In fact, the organic ligand cannot be seen in TEM so its length

**Fig. 6** Effect of capping agent size on the hydrodynamic diameter of Au nanoclusters. HPLC chromatogram of Au nanoclusters with three alkyl thiols, CkSH,  $k = 6, 10, 14$ , added after reduction. The absorbance at 520 nm [ $A(520\text{nm})$ ] from the PDA vs. elution time is shown. The SEC column used was a Polymer Labs PL1000 and the mobile phase was toluene at 1 mL/min flow rate. Source: From Ref.<sup>[30]</sup>.

can only be indirectly inferred from the intercluster gap. An interesting prediction from our SEC ligand/cluster binding studies is that, under vacuum as in an electron microscope, only longer chain thiols will be able to retain their ligands, preventing cluster coalescence and allowing the formation of hexagonal or cubic quantum dot arrays (QDAs). This is indeed the case as we have shown in previous work on QDAs.<sup>[41,42]</sup> Another prediction based upon our SEC work is that Ag nanoclusters will more readily desorb even long chain alkyl thiol ligands under vacuum and so, the longevity of QDAs of Ag under TEM is significantly decreased relative to Au. Also, electron beam melting effects are more severe in QDAs of Ag than of Au although the melting temperatures of the two materials are very similar. As expected, QDAs of alkyl thiol ligated Pt, Pd, and Rh are more robust than Ag under vacuum.

A somewhat surprising observation common to all metal Qdots, which we have studied, is that monodentate ligands such as alkyl thiols, alkyl sulfides, and primary amines bind increasingly less effectively as the size of the nanocluster increases. In fact, for  $D_c > 10$  nm, one finds that displacement of a polydentate ligand such as a non-ionic alkylated polyethylene oxide by a more strongly binding alkyl thiol will result in complete irreversible aggregation of a Au or Ag nanocluster solution! Thus, one needs to develop more advanced polydentate ligands for larger nanoclusters.

Intuition often fails when choosing an appropriate multidentate ligand for a given metal Qdot. For example, we have found that alkyl chain disulfides aggregate these larger clusters, which surprised us greatly. This observation probably indicates that the hypothesis that alkyl thiolates form disulfides on nanocrystalline gold is wrong. Fortunately, non-ionic block copolymers, such as were employed in the first synthesis of Co via high- $T$  decomposition,<sup>[5]</sup> are obvious choices and, if selected appropriately, they stabilize a very broad range of transition and base metal Qdots extremely effectively. However, they do not allow efficient SEC analysis of the stabilized large nanoclusters as most columns are too effective at pulling them off the cluster surface, and such bulky stabilizers may prevent deposition of additional atoms to form core-shell particles, so they are not a panacea. Thus we are still searching for the most effective steric ligands for SEC analysis of large,  $D_c > 10$  nm nanoclusters.

### SEC Studies of Synthetic Variables

Traditionally, TEM or X-ray diffraction (XRD) was used to infer the nanocluster particle size. In the case of the former, between a few dozen particles to a few hundred are measured from a “chosen” area of the

grid and tediously counted. Many “representative” areas of the grid must be chosen by the microscopist, requiring significant expertise and time. To obtain a detailed analysis of even a single sample in a day’s time requires a dedicated graduate student or postdoctorate individual—highly motivated by the possibility of a permanent job! Considering that a skilled synthetic inorganic chemist can easily make a dozen samples in the same period of time, one can see where the roadblock to synthetic progress occurs.

Other traditional surface science methods of analysis often prove inadequate as well. For example, in XRD characterization of size, the first maximum in the low-angle diffraction pattern can be used to obtain the average interparticle spacing (assuming either hexagonal or cubic packing). Unfortunately, the interparticle gap depends on the organic ligand and its degree of interdigitization, so this method of core size determination is not ideal, although it is applicable to the smallest clusters with  $D_c < 2$  nm, and has been used with good precision for very monodisperse clusters.<sup>[43]</sup>

As we have extensive experience with small-angle neutron scattering (SANS), X-ray scattering (SAXS), and dynamic light scattering (DLS), I initially believed these methods would prove very useful for size and size dispersion analysis.<sup>[44]</sup> However, in the case of metal Qdots and DLS using visible light, the very strong absorbance and concomitant weak scattering requires very low nanocluster concentrations so that the signal-to-noise (S/N) ratio is exceptionally low for clusters with  $D_c < 4$  nm. This technical difficulty has precluded our routine use of this method. In the case of SANS, the scattering length density difference between solvent and typical metal Qdots is very low, again giving low S/N and long data collection times. SAXS is the best approach with respect to S/N from metallic Qdots, but typically requires an intense tunable (synchrotron) X-ray source, to avoid large (e.g., 24 hr) data collection times.<sup>[44]</sup> Thus until we had developed SEC for nanoclusters, our synthetic feedback was poor.

To illustrate the speed, precision, and high information content of SEC size/optical property analysis, we now review some selected cases of using SEC to determine the effect of variation of synthetic parameters on metal Qdot synthesis. We refer the reader to the results of a recently submitted manuscript for further examples.<sup>[31]</sup> First, we fix the solvent, metal precursor concentration, reductant, and inverse micelle surfactant, and examine the effect of alkyl thiol concentration on the final cluster size. Fig. 7 shows the SEC chromatograms from Au nanoclusters synthesized with various amounts of added C12SH from 0.0 to 0.03 M. As expected, having more of the tightly binding alkyl thiol restricts the growth more strongly.

**Fig. 7** Effect of C12SH concentration on the final nanocluster size and size distribution of Au nanoclusters made by  $\text{NaBH}_4$  reduction of a two-component TOAB/toluene inverse micelle system with  $[\text{Au}] = 0.01 \text{ M}$ . The column is a PL1000 type and the mobile phase is toluene with C12SH added at 0.01 M. The SEC core sizes assume a core-size-independent 2.4-nm total organic shell, and are indicated above each curve. *Source:* From Ref.<sup>[31]</sup>.

The linewidths observed (size dispersions) only vary slightly once the thiol concentration exceeds 0.01 M. (The Au/C12SH ratio is 1:1 for this case.) In fact, once the Au/CkSH ratio exceeds 1.0, the samples are nearly monodisperse. It is noteworthy that although TEM easily gives the size of the largest cluster made with no alkyl thiol present, Au #511, as  $D_c \sim 3.8 \text{ nm}$ , the other three samples all appear to be around  $D_c \sim 1.8 \pm .2 \text{ nm}$  using HRTEM because identification of the cluster/substrate boundary combined with orientation effects obscure the true size differences, which SEC clearly demonstrates. ( $2 \text{ \AA}$  is one lattice fringe and thus is the inherent measurement uncertainty for a perfectly monodisperse sample.) Also noteworthy is that this information was obtained in 15 min/chromatogram by using only  $10 \mu\text{l}$  of a 0.01 M Au cluster sample! On this particular day, the effect of over 12 different synthetic variables were determined by SEC.

We obtain the complete absorbance spectra from our PDA array throughout the peak elution (every 2 sec, which corresponds to a size discrimination of only 1–2 Å). The spectra obtained at the peak apex represent the absorbance of the majority of the nanoclusters. The spectra normalized at a common value, 500 nm, are shown in Fig. 8 for each sample. One observes the characteristic blue shift of the plasmon, which we first identified in Ref.<sup>[13]</sup> and confirmed using SEC in a recent paper.<sup>[36]</sup> As the size decreases from  $\sim 2.0$  to 1.6 nm, additional non-classical features appear in the absorbance as a result of the discrete density of states of a gold cluster. For example,  $D_c = 1.6 \text{ nm}$  corresponds very closely to the magic,

**Fig. 8** Absorbance at the elution peak of each of the chromatograms of Fig. 7, illustrating the blue shift and plasmon broadening with decreasing size. All the clusters are in toluene, which is also the mobile phase. *Source:* From Ref.<sup>[31]</sup>.

two fully closed shells icosahedra with  $N = 55$  having  $D_c = 1.5\text{--}1.6 \text{ nm}$  first synthesized and identified by Schmid.<sup>[7]</sup> Recently, Whetten has also identified this magic size using MALDI TOF mass spectroscopy.<sup>[45,46]</sup> The features of this smallest  $\sim 9 \text{ kDa}$  cluster fraction correspond closely to the spectra of Au #538 shown in Fig. 8. The enhancement of both the UV and near-infrared (NIR) absorbance is characteristic of the quantum confinement effects in ultrasmall metallic Qdots<sup>a</sup> and corresponds to the absorbance features which are observed in semiconductor Qdots.<sup>[6,47]</sup>

Both Au and Ag possess strongly size-dependent optical absorbance in the quantum confinement regime,  $D_c < 5 \text{ nm}$ , which allows us to assay the size homogeneity of the elution peaks of Fig. 7 by examining the “spectral homogeneity” of the peak. Measuring the uniformity of the spectral shapes of an eluting component is a commonly used approach to look for possible coelution of inhomogeneous species even with simple chemicals.<sup>[37]</sup> We have extended its use to Au, Ag, and Cu nanoclusters. In the case of metallic Qdots of Au or Ag, spectral inhomogeneity could arise from either size or shape effects. In fact, we find that only the largest component, Au  $D_c = 3.8 \text{ nm}$ , made without C12SH present during the synthesis, possesses any significant spectral inhomogeneity, as demonstrated by the spectra obtained at the peak apex time,  $t = 7.36 \text{ min}$ , and at the half-width at half maximum positions,  $t = 7.16$  and

<sup>a</sup>Quantum size effects are a result of the discrete nature of the electronic levels as a cluster is built up from atoms. The level splitting ( $\Delta E$  is roughly given by  $\Delta E \sim E_f/N$ , where  $E_f$  is the Fermi level of the metal and  $N$  is the number of atoms in the cluster. If  $E_f \sim 5 \text{ eV}$ , eV, then ( $\Delta E \sim 50 \text{ meV}$  for a 100-atom cluster. At room temperature, one might see these effects for Au at  $N \sim 400$  or  $d \sim 3 \text{ nm}$ .

$t = 7.56$  min (Fig. 9). The total variation of the plasmon position even for this sample is incredibly small, as the bandwidth of the detector was set to  $\pm 4.8$  nm for these experiments. However, it is certainly real and corresponds to size inhomogeneity of  $\sim \pm 0.5$  nm. Samples made with alkyl thiol present during the reduction have elution linewidths and spectral homogeneities consistent with complete monodispersity—a tribute to both the inverse micelle method and the role of alkyl thiols as etchants to narrow the size distribution.<sup>[31,45]</sup>

What is the role of inverse micelle type and solvent on the final cluster size? Both of these issues were the subject of a recent publication.<sup>[31]</sup> In that work, it was demonstrated that even in the presence of a strongly binding thiol, the size and/or strength of the micellar binding to the encapsulated precursor salt had a significant effect on the final size and size distribution. Fig. 10 shows the cluster size distribution obtained without deconvolution of the instrumental linewidth for nonionic, three types of cationic surfactant, and an anionic surfactant. In each case, the solvent was held constant, toluene, as was the reductant,  $\text{LiAlH}_4$ .

As was noted in the original reference, the structure and binding properties of the inverse micelle used is a competitive factor with the binding of the alkyl thiol surfactant. For example, the presence of the significantly weaker binding tetrahexylammonium chloride (THAC) results in much larger clusters than do bromide head group cationics didodecyldimethylammonium bromide (DDAB) or tetraoctylammonium bromide (TOAB). Didodecyldimethylammonium bromide has a smaller micelle interior volume and one could rationalize the smaller final cluster size compared to TOAB by this factor.

**Fig. 9** Elution peak spectral homogeneity of the sample Au,  $D_c = 3.8$  nm, with the broadest size distribution (linewidth) shows the population to be mildly inhomogeneous in size, but with only a spread of plasmon positions from 496 to 511 nm, a size dispersion of about  $\pm 0.5$  nm. *Source:* Previously unpublished work.

**Fig. 10** Plot of the Au core size  $D_c = D_h - 2.4$  obtained by assuming the previously measured total shell thickness of 2.4 nm, vs. normalized detector response at 520 nm (relative number of particles). The surfactants used in the synthesis are indicated. *Source:* From Ref.<sup>[31]</sup>.

A most surprising result was the formation of a bimodal population distribution from inverse micelles of the nonionic surfactant C12E5 in toluene, whereas only a narrow dispersion, monomodal distribution is produced when alkanes are used as the oil continuous phase, as has been reported previously.<sup>[35,36]</sup> This illustrates that the packing of the surfactant molecules into a droplet-like interface, and the lability of this interface is strongly affected by the interaction of the surfactant alkyl chains with the oil used.

Finally, one might wonder about the role of precursor salt concentration on the final size and size distribution in the inverse micelle synthesis. To study this we used a single cationic surfactant two component micelle system (TOPB/tol), where TOPB = tetraoctylphosphonium bromide and a fixed  $[\text{metal}]/[\text{surfactant}]$  ratio. As the  $[\text{HAuCl}_4]$  was varied from 0.01 to 0.1 M, no discernible change in size from  $D_c \sim 1.9$  nm was observed, nor did the size distribution alter as monitored by elution peak linewidth. This is in strong contrast to metastatic reduction reactions of organometallics in coordinating organic solvents, where an increase in  $[\text{precursor metal-organic}]$  leads to systematically greater final sizes with concomitant increases in size dispersion. For example, in the case of Fe(II) reduction in a coordinating solvent, an increase in size from  $D_c \sim 2.0$  to 14 nm occurs over the same concentration range. This illustrates the fundamentally different mechanism operating in the inverse micelle case.

### Optical Properties of Au, Ag, and Au/Ag Core-Shell Nanocrystals

In the proceeding section, we touched on the very interesting optical properties of Au, which exhibits a

non-classical (i.e., not explained by the Mie theory of electromagnetic scattering from metal colloids), blue shift and damping of the plasmon absorbance peak with decreasing size.

In Fig. 11, we show the absorbance chromatograms of several samples of Au nanocluster samples all stabilized with dodecanthiol to ensure a nearly constant shell thickness and interface environment. The peak heights have all been normalized to allow easy comparison of the elution shapes and widths. The elution peaks have *not* been deconvoluted with the instrumental band broadening. The size, as determined from the peak apex elution time, is given in Table 2. A constant shell thickness of  $2.4 \pm 0.1$  nm, as determined previously,<sup>[30]</sup> was used for all samples to obtain the metal core size.

The corresponding optical spectra for each sample at the peak of its elution are shown in Fig. 12. The spectra are normalized so that absorbance = 1.0 at 500 nm in each case. From this figure, we obtain the size-dependent blue shift and broadening of the optical plasmon as a function of size. This information is contained in Table 2.

The data from Fig. 12 and Table 2 demonstrate that, as the size decreases into the quantum size regime, a very rapid broadening and blue shift of the absorbance occurs between  $D_c = 3.0$  nm and  $D_c = 1.3$  nm. The classical Mie theory assumes no size dependence to the complex dielectric constant  $\epsilon(\omega)$  and so predicts that the optical plasmon for spherical Au clusters will blue shift with decreasing size until a size of  $D_c \sim 10$  nm is reached, at which point no further changes from the predicted peak position of 530 nm

**Fig. 11** Normalized absorbance chromatograms of several differently sized Au nanocluster samples. *Source:* From Ref.<sup>[36]</sup>.

**Fig. 12** Normalized peak elution spectra from Fig. 11 demonstrate the effect of decreasing Au nanoclusters size (increasing elution time) on the optical absorbance in the visible. *Source:* From Ref.<sup>[36]</sup>.

(in toluene) or half-width should occur. Thus all the spectra shown in Fig. 12 are non-classical in character, exhibiting significant blue shifts and broadening compared to the Mie prediction. The effects of cluster size are usually accounted for by assuming that  $\epsilon(\omega)$  is size-dependent. This allows classical effects, such as increased electron scattering at the metal–dielectric interface, to be empirically incorporated into the theory, as well as quantum size effects (QSE) and the effect of chemical interface damping. Although all these effects are predicted to increase the linewidth, just as what has been observed in the present experiments, as well as the majority of experiments on embedded clusters, a prediction of the direction of the peak shift is much more problematic.<sup>[2]</sup>

The absorbance spectra in Fig. 12 have been normalized at a common wavelength, 500 nm, to allow easy comparison of the peak shapes. (See Table 1 for sample synthesis conditions and other details. Note that the sample number has nothing to do with the number of atoms in a cluster, which can only be approximately estimated even with TOF-MS.) Both the UV and, to a lesser extent, the NIR absorbance are enhanced as the cluster size decreases. We have also noted the development of new features in the absorbance profile of the smallest  $D_c = 1.7$  and  $D_c = 1.3$  nm clusters.<sup>[31,36]</sup> More recent work by others has confirmed this trend, which is attributed to the appearance of molecule-like density of states in small metal clusters.<sup>[45,46]</sup>

Ag213	AgNO <sub>3</sub> (0.01 M)	TOPB (0.12 M)	Toluene	NaBH <sub>4</sub> (0.02 M)	N.A.

Surfactant abbreviations are: AOT = *bis*(2-ethylhexyl) sulfosuccinate sodium salt, C12E5 = penta-ethyleneglycol-mono-*n*-dodecyl ether, DDAB = didodecyldimethylammonium bromide, TOAB = tetraoctylammonium bromide, TOAC = tetraoctylammonium chloride; reductants prepared in anhydrous tetrahydrofuran (THF) as 1–2 M solutions, SuperH = LiB(C<sub>2</sub>H<sub>5</sub>)<sub>3</sub>H, LS-SelBH = LiB(CH(CH<sub>3</sub>)CH(CH<sub>3</sub>)<sub>2</sub>)<sub>3</sub>H; LSeAlH = LiAl[OC(CH<sub>3</sub>)<sub>3</sub>]<sub>3</sub>H, final concentrations are indicated in table.

One does not need separate, completely monodisperse samples to determine the optical absorbance behavior of metal nanoclusters as a function of size, because the SEC process will separate clusters with very small differences in size  $\sim \pm 2 \text{ \AA}$  and the PDA detector will provide the spectra corresponding to these sizes. The information obtained on samples exhibiting size polydispersity is very consistent with that

obtained from the peak apex spectra of the individual samples of Table 2, demonstrating the consistency of the SEC size analysis. For example, in Table 2, we show that Au693bp has a peak retention time of 7.5 min corresponding to an average size of 2.9 nm and a plasmon peak at 501 nm. This is within the experimental uncertainty of the data of Fig. 12 corresponding to a size of 2.8 nm and having a plasmon

**Table 2** Size-dependent optical properties of Au and Ag nanoclusters

Sample name	$t_e$ (min)	$D_{\text{core}}$ (nm, SEC)	$D_{\text{core}}$ (nm, TEM)	$\lambda_p$ (nm)	$\Delta\lambda_{1/2}$ (nm)

$\Delta\lambda_{1/2}$  (nm) = Half-width at half maximum determined on long wavelength side of asymmetrical plasmon peak.

peak at 496 nm because the spectra bandwidth was set at 2.4 nm. The size-selected cluster population of Au #511b, which elutes near the half-maximum at  $t = 7.14$  min, corresponds to a SEC size of 4.2 nm and has identical spectra to that at the peak apex of Au #690bp.

In a recently submitted paper, we demonstrate a synthesis based upon the seminal work of G. Schmid,<sup>[7]</sup> which illustrates the selection and optical characterization abilities of HRSEC for strongly polydisperse samples.<sup>[31]</sup> In that paper, we illustrated the effects of the emergence of a discrete, “molecule-like” density of states in Au “molecules” specifically, Au( $N = 13$ ), the smallest closed shell atomic configuration. Such molecular species had been previously shown by us<sup>[48]</sup> and subsequently by others<sup>[45,46]</sup> to have both visible and NIR photoluminescence (PL), which is a startling result! This relatively strong PL ( $\sim 10^{-4}$  Q.E.) can come from both s-to-d interband transitions (visible PL), or intra-d-band transitions (NIR and IR PL). Such unexpected optoelectronic properties illustrate the reason why very small nanoclusters are so interesting.

### Ag nanoclusters

We next examine the size dependence of the optical absorbance of Ag nanoclusters grown in inverse micelles and stabilized with the identical alkyl thiol (C12SH) used in our Au cluster studies. A strong motivation for this complementary study is the important difference in the optics of Au and Ag clusters arising from the different energies of the interband (filled d shell to conduction sp band) transition onsets in the two metals. The close proximity of the interband transition to the plasmon energy in Au (it lies to the red of the plasmon energy) is the reason why energy damping (peak broadening) is so much greater for Au clusters than for Ag, where the interband transition energy onset lies significantly to the blue of the conduction band plasmon. This makes a determination of the size dependence of the linewidth for small Au clusters difficult (i.e., the peak simply disappears). It also leads to a pronounced asymmetry to the peak shape.

There has been a matter of significant controversy regarding the direction of the plasmon absorbance energy shift with cluster size in the quantum size region. Depending on details and relative weights assigned to the various theoretical factors, one can “predict” either a blue or a red shift with decreasing size. We had demonstrated a blue shift in the case of monodisperse, spherical nanoclusters of gold, and this is the general consensus based on dozens of papers in this field. However, the case of Ag is not as well established, and both red and blue shifts have been reported. We were considerably surprised when SEC and on-line

optical characterization of our inverse micelle prepared Ag nanoclusters showed a clear red shift with decreasing size. The magnitude of this shift was truly astounding compared to gold. In the smallest clusters we studied, the damping of the very sharp and relatively symmetrical absorbance plasmon of Ag completely disappears—the first such observation in nanosize Ag. Fig. 13 shows the effect of size decreases on the position of the optical absorbance of Ag nanoclusters.

The main feature of the optical absorbance of nearly free-electron metals such as Cu, Au, or Ag is a condensation of the conduction electron oscillator strength into a narrow frequency band of plasmon polariton excitations, which are caused by the particle surface—the plasmon resonance. If the dielectric function for a metal cluster does not depend on its size, little or no variation in the position of energy maximum of the plasmon absorbance profile is predicted to occur below a size of 10 nm. So, for particles smaller than this size, as Kreibig and Genzel have pointed out,<sup>[49]</sup> the absorbance band shape only changes with size if intrinsic particle effects are important. It has been established by numerous experiments that, for sizes less than  $\sim 5$  nm,  $n(\omega, R) \sim 1/R$ .<sup>[2]</sup> This is, of course, just the surface-to-volume ratio.

Both classical effects [such as electron scattering at the metal/dielectric interface and quantum size effects (QSE)] become important at sizes below  $\sim 5$  nm. The latter effects, in particular, should become important when the level spacing near the Fermi level exceeds

**Fig. 13** SEC separation and on-line characterization of Ag nanocluster solutions in toluene show the strong red-shift and extreme damping of the plasmon with decreasing size. See Table 1 for synthesis details and other information. Source: From Ref.<sup>[36]</sup>

the available thermal energy. This will occur at about 400 atoms of Au, or a size of about 2.5 nm, assuming the nanoclusters to have the density of the bulk material.<sup>a</sup> It turns out that both classical effects, such as the reduced free path of the electron and QSE effects, both predict a  $1/R$  dependence to the resonance linewidth, so an observation of a  $1/R$  behavior to the resonant linewidth does not, by itself, demonstrate a QSE. However, the emerging weak features in the spectra of our smallest clusters probably do indicate the onset of discrete bands, which is a true QSE.

A further complication in the interpretation of experimental observations in either classical (electron scattering) or quantum confinement (continuous bands becoming discrete) behavior occurs in the case of metals such as Au and Cu, in which the onset frequency of the interband transitions from d-type orbitals to the sp-type conduction band is close to the plasmon energy. In this case, there are major changes in the resonance energy just because of the importance of these transitions. For example, in the case of both Cu and Ag, the free-electron (Druid model) Mie theory predicts a resonance of  $\sim 9.2$  eV in a vacuum ( $\epsilon_m = 1$ ); however, the contribution of the 4d core electrons to the susceptibility shifts this to the experimental value of  $\sim 3.8$  eV for Ag but  $\sim 2$  eV for Cu! It may be that the different directions of the plasmon energy shift we have established for Au and Ag with the same passivating layer, embedded in an identical media, toluene, are a result of the relatively greater importance of the interband transitions in Au compared to Ag. For a more extensive discussion of our findings for nanosize Au and Ag, we refer the reader to Ref.<sup>[36]</sup> and the monograph by Vollmer and Kreibitz,<sup>[2]</sup> which is the definitive modern work on this subject.

The Ag samples whose spectra were shown in Fig. 13 are all coated with an identical ligand, C12SH, which gives keeps the clusters from aggregating even when deposited onto a holey carbon grid and inserted into the high vacuum of an electron microscope. Fig. 14 shows a TEM of Ag #205 illustrating the ready formation of arrays which we have termed quantum dot arrays—the next subject of this review.

We summarize our findings concerning the size-dependent optical properties of Au and Ag as follows. For both Au and Ag clusters in the size range  $D_c = 8$  to  $d = 1.5$  nm, the plasmon linewidth broadens following a  $1/R$  linewidth size dependence, whose slope

**Fig. 14** TEM of Ag #205,  $D_c = 4.0 \pm 0.5$  nm nanoclusters with a plasmon peak at 440 nm in toluene.

is greatest for Au. The peak asymmetry in the plasmon band shape is greatest for Au and increases with decreasing size for both Au and Ag clusters. The plasmon peak energy blue shifts with decreasing size for Au clusters, while in the case of Ag nanoclusters a red shift is observed.

### Core–Shell Particles and Alloys of Au and Ag

There are many scientific reasons to investigate core–shell or alloy nanoclusters. For example, even monolayer shell coverages can shift the Fermi level,  $E_f$ , via e-donation/acceptance by huge amounts (e.g.,  $\sim 20$ – $30\%$  donation/atom blue shifts  $E_f$  by  $\sim 1$  eV!). In the case of metals with dissimilar electron affinities, interface structures may form, which are similar to doping-induced depletion zones in bulk semiconductor materials. This effect may be a basis for metal rectification or spatial charge separation and thus of importance to nanocluster photocatalysis.<sup>[50,51]</sup> In view of the very interesting physics of such core–shell structures and the possibility of “reconstruction” occurring as the result of a heteroatomic deposition process, this area of nanometals should be very fecund and deserving of future investigation.

The coinage metals Au and Ag are a nearly an ideal system to study the effects of size and composition on the optical properties of nanoparticles because they have identical covalent radii, have simple fcc cubic lattice structures, and are miscible in all proportions. (However, this also means that diffraction-based methods such as TEM are not very useful for determining their structures.) One may pose a myriad of questions—some of which may even be theoretically treated—albeit, within the confines of classical electromagnetic Mie theory. For example, for fixed

<sup>a</sup>Quantum size effects are a result of the discrete nature of the electronic levels as a cluster is built up from atoms. The level splitting ( $\Delta E$  is roughly given by  $\Delta E \sim E_f/N$ , where  $E_f$  is the Fermi level of the metal and  $N$  is the number of atoms in the cluster. If  $E_f \sim 5$  eV, eV, then ( $\Delta E \sim 50$  meV for a 100-atom cluster. At room temperature, one might see these effects for Au at  $N \sim 400$  or  $d \sim 3$  nm.

composition and size, how does the order of deposition Au/Ag vs. Ag/Au (core-shell) affect the optical spectra? For equivalent atomic compositions and size, does a random nanocluster alloy of Au and Ag differ optically from the corresponding core-shell cluster? For a fixed total size, how does composition affect the optical absorbance?

First, a brief remark on the synthesis of core-shell vs. alloy nanometals. To make alloy-type materials, a chosen ratio of precursor salts (typically  $\text{NaAuCl}_4$  and  $\text{AgNO}_3$ ) are dissolved in a suitable inverse micelle solution. A reducing agent is then added to effect core-reduction. The agent chosen should approximately have the same reduction kinetics to avoid prenucleation of one material over the other, which would result in a core-shell type structure. By using an extremely aggressive reduction such as  $\text{LiAlH}_4$ , both metals undergo instantaneous reduction provided aggressive mixing is utilized.

To make core-shell structures, a simple variation on our newly developed solution epitaxial growth, which will be reported in a future work,<sup>[52]</sup> is employed. Specifically, a given seed nanocrystal, say  $D_c = 1.8$  nm Au, is purified via SEC or precipitation methods, and a metal organic precursor solution is slowly coinjected along with the reductant, typically  $\text{NaBH}_4$ , via a syringe pump. A slow injection rate, typically 1–2 mL/hr is used, to ensure hetero- vs. homogeneous nucleation of the growth solution. A key aspect is the choice of a suitable surface active agent as well as the organometallic atom source. In general, one wishes to avoid the use of micelle-forming surfactants because these may act as nucleation centers for homoatomic clusters from the feedstock. For Au/Ag and Ag/Ag core-shell nanocrystals, small amounts of long-chain alkyl thiols work quite well and allow facile SEC analysis to be performed.

### Effect of Alloying on Ligand Binding

Size exclusion chromatography can be used to determine the relative binding of ligands of a given size and metal type as mentioned earlier in this review. We demonstrated that no thiol exchange occurs for  $\text{C}_k\text{SH}$ ,  $k = 6, 10, 14$ , in the case of Au nanoclusters, when an overwhelming amount of  $\text{C}_{12}\text{SH}$  is in the mobile phase. In contrast, Ag nanoclusters with the identical thiols on their surface completely exchanged with the  $\text{C}_{12}\text{SH}$  in the mobile phase during the chromatography as evidenced by a common elution time in all cases, which corresponds to a shell of  $\text{C}_{12}\text{SH}$  (the core size is fixed in both cases). One must remove the completing thiol from the mobile phase and use a pure toluene eluant to observe the effect of various organic shell thicknesses on the elution time.

What is the effect of alloying or formation of a core-shell structure on the thiol binding behavior? We find that 1:1 (atomic ratio) alloys of a common core size,  $D_c \sim 2.0$  nm, elute at distinct times, which correspond to the organic shell thickness as shown in Fig. 15. So the effect of alloying Ag with Au is to prevent ligand exchange. At least two rationalizations of this observation are possible. The change in interatomic coordination and bonding distance in a spherical cluster alloy of Au/Ag affects the thiol metal binding strength, or, more likely, having Au sites at the surface of the metal alloy nanocluster allows the thiol to preferentially bind to these sites. In either case, our alloy AuAg binding results have obvious ramifications for issues in catalysis, where it is empirically known that even small amounts of metal atoms in a majority phase (e.g., Co in  $\text{MoS}_2$  hydrodesulfurization catalysts) has a profound effect on the catalytic activity by affecting the Mo substrate binding strength.

Despite the differences in total hydrodynamic size observed in Fig. 15 as a result of the alkyl chain length differences, the optical spectra of each 1:1 Au/Ag alloy nanocluster are indistinguishable, as demonstrated by the elution peak apex absorbance spectra shown in Fig. 16. For similar-sized nanoparticles of pure Ag, the plasmon would occur at 460 nm, while there would be no discernible plasmon peak as a result of damping effects in a pure Au sample of this size. So the effect of alloying on the optical properties of small noble metal nanoclusters is dramatic and constitutes the clearest evidence of a significant composition change from the corresponding pure metal Qdots of equivalent size.

Suppose we grow a 1:1 nanocrystal alloy of a smaller size. Which direction will the plasmon energy shift? If the cluster were pure Ag, a red-shift would be expected, while for pure Au, a blue shift is the norm.

**Fig. 15** Effect of organic shell on the total hydrodynamic size of Au/Ag alloy nanoclusters formed by core-reduction of the precursor salts in inverse micelles. *Source:* Unpublished data.

**Fig. 16** The peak apex absorbance spectra of a  $D_c = 2.4$  nm 1:1 Au/Ag alloy. *Source:* Unpublished data.

The results are shown in Fig. 17. The peak apex absorbance spectra of a 1:1 Au/Ag alloy blue shifts with decreasing size, so the Au component dominates its optical behavior. As expected, an increased damping of the plasmon occurs with decreasing size occurs; however, a distinct absorbance maximum is still observed even for  $D_c = 1.8$  nm clusters, apparently because of the silver component, a truly remarkable decrease in the dissipation of the electron plasmon oscillations! A complete theoretical explanation of the alloy behavior in the quantum size regime will prove most challenging, considering that even the extent of damping (peak broadening) and energy shift cannot be predicted currently for pure metal Qdots.

To impress upon the reader how distinct the optical absorbance behavior of the  $D_c = 1.8$  nm alloy Qdots are from the pure nanometals of the same size, coated with the identical organic thiol we show in Fig. 18 the spectra from such dots, obtained at the peak apex of the chromatograms.

**Fig. 17** The peak apex absorbance spectra of a  $D_c = 2.4$  and 1.8 nm 1:1 Au/Ag alloy. *Source:* Unpublished data.

**Fig. 18** The peak apex absorbance spectra of  $D_c \sim 1.9$  nm pure metal nanoclusters. Compare with the spectra of Fig. 17. *Source:* Unpublished data.

As one might anticipate, Au/Ag and Ag/Au nanocrystals of the same size have very distinct optical absorbance signatures, which can be easily seen with the naked eye. Consider first the growth of Ag onto a purified seed solution of Au,  $D_c = 6.8$  nm, as shown in Fig. 19. The relatively large seed nanocrystals have a distinct absorbance peak at around 520 nm in benzene, which gives them a wine red color. As Ag is slowly deposited onto their surface the absorbance blue shifts, in the direction one would expect for Ag clusters, the peak becomes more symmetrical and narrows with increasing amounts of Ag deposition. In short, the Ag shell component begins to dominate the optical properties.

Fig. 20 shows the case of growth of a Au shell onto a  $D_c = 2.5$  nm Ag nanocluster seed. The relatively sharp and symmetrical resonance of the Ag homoatomic cluster broadens and red shifts as Au is

**Fig. 19** Optical absorbance for a series of Au/Ag nanoclusters starting from a  $D_c = 6.8$  nm Au nanocrystal. The atomic ratios of Au/Ag are indicated in the figure. *Source:* Unpublished data.

**Fig. 20** Optical absorbance for a series of Ag/Au nanoclusters starting from a  $D_c = 2.5$  nm Ag nanocrystal. The atomic ratios of Au/Ag are indicated in the figure.

deposited. The 1:1 ratio case is worth comparing to the 1:1 alloy of approximately the same size from Fig. 17. One notes that the alloy has both sharper and more red shifted ( $\lambda_{\max} \sim 508$  nm) compared to the core-shell spectra of Fig. 20. One observes also that the 1:2 Ag/Au nanocluster has not red shifted to the extent one would predict for a pure Au cluster of the same size, but exhibits considerably more dissipation (line broadening) and red-shift than expected for a corresponding homoatomic Ag nanocluster of equivalent size.

There is a considerable literature discussing thermal decomposition routes to the formation of base metal colloids, which has been recently reviewed.<sup>[34]</sup> These methods are based on the decomposition of metal carbonyls in the presence of a surfactant or polymer in a relatively high boiling point solvent such as xylene or triethyl benzene. In general, these methods are only effective in producing larger nanoclusters with  $D_c > 4-5$  nm with considerable nanocrystalline defects and polydispersity. Recent refinements in these methods have significantly improved on the polydispersity but, unfortunately, because of the rapid nature of the decomposition, significant defects are inevitable and are reflected in the poor magnetic response compared to the bulk counterparts (e.g.,  $\sim 0.2$  of  $M_{\text{sat}}$  for  $D_c \sim 6$  nm hcp Co).

What is very interesting is that different structural phases of these nanoclusters may be produced depending on the synthetic approach. We gave the first example of this in a paper describing the effect of surfactant on the formation of either  $\alpha$ -Fe (bcc phase) or  $\gamma$ -Fe (high  $T$ , fcc phase) using the inverse micelle process.<sup>[53]</sup> Later work by Sun and Murray<sup>[54]</sup> showed an even more surprising result for Co, which, when reduced by Superhydride at high  $T$ , produced the  $\varepsilon$ -Co phase, a complex 20-atom/unit cell structure related to  $\beta$ -Mn. These Co nanoparticles could be

converted to the hcp phase by annealing at  $>300^\circ\text{C}$ . However,  $\varepsilon$ -Co nanocrystalline Co showed significantly lower magnetic response than hcp Co of the same size.

### Base Metal Nanoclusters—Co, Fe, and Ni

A puzzle is the observation that, even in the case of directly synthesized nanocrystalline hcp Co, as the size reached the lower size limit of high- $T$  methods,  $D_c \sim 3$  nm, a saturation magnetism of only 8 emu/g was observed, about 5% of the bulk value.<sup>[34]</sup> Even for the largest  $D_c \sim 11$  nm Co clusters, a value of only about 60% of the bulk was observed. Likewise, the value of  $\sim 60\%$  is about what is the best achieved for nanocrystalline  $\alpha$ -Fe. Is the lowered magnetic response attributable to the surface, nanocrystalline defects, spin canting effects, or inadvertent formation of an oxide layer? Although lower density oxide is evident in TEMs of these nanomaterials, its thickness is probably not sufficient to explain the lowered magnetic response, so a likely explanation is poor spin exchange coupling as a result of nanocrystalline defects and/or spin canting near the surface.

By contrast, using the inverse micelle approach, which entails significantly lower nanocrystalline growth rates, we have recently observed saturation magnetism for  $D_c \sim 1.8$  nm Co nanoclusters slightly greater than bulk values. This implies full contribution of all the spins to the magnetism, including those at the cluster surface. This is a somewhat unexpected result and seems to depend very sensitively on the chemical nature of the surfactant used to grow the nanoclusters, as well as the time allowed for structural “reconstruction” of the as-synthesized cluster surface. Details will be presented elsewhere.<sup>[56]</sup> However, our results are consistent with previous observations of very small Co, Fe, and Ni nanoclusters made in cluster beams in vacuum and studied by magnetic deflection combined with mass selection.<sup>[24]</sup> The fact that magnetic clusters can be grown in solution with high magnetic response and no hysteresis (i.e., they a superparamagnetic at all  $T$ ) bodes well for potential applications requiring no energy dissipation [transformers and other high radio frequency (RF) inductors].

### Formation and Analysis of Quantum Dot Arrays

Hexagonal or cubic packed “rafts” or arrays of quasi-monodisperse spherical colloids [quantum dots arrays (QDAs)] can readily form on various types of substrates upon drying from the liquid phase. Many factors including the initial cluster concentration, the drying rate, the type and physical size of organic ligand “shell,” and the cluster core size itself affect the quality of the final cluster film. Just as in bulk crystallization,

defects and voids may be introduced if the drying rate is too rapid, trapping colloids in metastable positions. I highly recommend observing the drying of micron-size polystyrene spheres in water on a glass slide under a microscope to understand the role of various factors in the state of the final colloidal film. It is amazing to watch the spheres flow into the drying front and then find the best packing position (usually hexagonal) for themselves. Sometimes, a sphere will not remain mobile long enough to position itself in the ideal position. Subsequently, this point defect will propagate through the rest of the drying front creating a line defect. In other rare cases, a dumbbell-shaped dimer of two spheres will approach the drying front and, because of its strong intersphere interaction, cannot fit into the proper position in the lattice. Minority spheres of the wrong size and or shape will often be excluded from the lattice, a spontaneous form of size segregation. All of these factors are important on the nanoscale as well although we do not have the ability to observe the dynamics of lattice formation, only the final structures.

Au nanocluster superlattices were first reported in a 1993 entry by Giersig and Mulvaney,<sup>[56]</sup> who used a modified classical Faraday synthesis in water to produce ~14-nm diameter clusters. Because these samples were charged-stabilized with citrate ions, they were able to employ electrophoretic deposition to form monolayer arrays. Because of the small size of the citrate ion, the gap between particles was fixed and small at ~1 nm.

In 1994, Brust et al.<sup>[57]</sup> used an inverse micelle process in the presence of alkane thiols to make QDAs of 8-nm Au particles that were cross-linked with a bifunctional dithiol. Robert Whetten's group at Georgia Tech was the first to demonstrate the formation of QDAs with relatively small Au nanoparticles produced by using the inverse micelle technique with large amounts of thiol present during the reduction to severely limit the cluster growth. They also showed 3-D superlattices of significant (~1–10  $\mu\text{m}$ ) size.<sup>[58]</sup> Later work by Heath and coworkers utilizing inverse micelle techniques produced highly polydisperse dedecanthiol capped Au clusters which still formed ordered arrays in which they noted that size exclusion of smaller clusters occurred spontaneously during the drying process.<sup>[59]</sup>

In 2000, we reported the first quantitative studies of the effect of particle size and the organic capping thickness on the spacing and degree of ordering in Au QDAs.<sup>[41]</sup> These studies were enabled by the development of the first detailed digital image analysis methods for metallic nanocluster QDAs. Later, we reported similar studies on Pt QDAs, which had not been made previously.<sup>[42]</sup> We will summarize highlights of those entries now.

First, the formation and, in particular, the domain size of QDAs depend on many experimental factors. The successful formation of superlattices depends on the proper choice of oil, surface passivant, metal ligand binding strength, ligand chain length or structure, substrate type, and rate of drying.

Consider, for example, the effect of metal ligand binding strength on QDA stability. We have demonstrated via SEC that alkyl thiols bind considerably more strongly to Au and Pt nanoclusters of a fixed size than they do to Ag. This is reflected in the stability under TEM vacuum conditions of Au arrays compared to Ag ones. Although both initially form large, highly ordered hexagonal domains as observed in TEM, Ag QDAs rapidly (<1 day) deteriorate as a result of alkyl thiol desorption followed by cluster fusion or sintering.

We have also shown using SEC that the alkyl chain length affects the binding affinity of metallic Qdots for thiol surfactants. We find that longer chain length thiols bind more strongly, for example, to Au nanoclusters. TEM studies of QDAs, as a function of alkyl chain length  $k$ , confirm that short chain,  $k < 8$  thiols, fail to form large ordered domains. What is more surprising is that an optimal value,  $k = 10\text{--}14$ , is observed, with worse array formation despite stronger binding affinity for  $k = 16$ . Perhaps this is attributable to the observation that alkane ligands interdigitate and facilitate the QDA formation, and  $k = 16$  is approaching the length at which this process is still efficient.

The rate of drying and concentration of the initial cluster solution is also important in determining the structure of the final QDA. The effects here are a little more obvious, namely, faster drying and lower initial concentration favors the formation of monolayers of hexagonally or square packed Qdots, while higher concentrations and slower drying (less-volatile solvents) favors cluster pile-up and formation of bilayers and 3-D crystals on the substrate. In fact, 3-D crystals of Ag form so readily upon slow drying from solution that they can be observed on the glass surfaces of vials with inadequately sealed lids. Naturally, such molecular crystals dissolve readily into organic solvents.

Finally, we found that use of substrates such as Teflon was more effective than glass for the formation of large (~10–100  $\mu\text{m}$ ), supracrystals. See Fig. 21 is shown below. The triangular facets or crystal habit adopted by these QDA superlattices seems to depend on the nanocrystal core size, but this is a very complex issue (see Fig. 21). Graphite proved to be too porous for good QDA crystal superlattice formation, and holey carbon TEM grids, which are also relatively porous were more effective for the formation of either mono- or bilayer QDAs. However, these general observations are also particular to the metal type, with Ag

**Fig. 21** Optical micrograph of QDA 3-D superlattices made of Au nanocrystals with  $D_c \sim 4.6$  nm. *Source:* From Ref.<sup>[41]</sup>.

almost always showing both mono- and multilayer formation using holey carbon grids. One important technical point is that, for hydrophilic substrates such as glass, inert grease (Krytox) should be used to contain the non-wetting oil.

The nanocrystal size-dependent habit adopted by 3-D QDAs is amusingly illustrated in Fig. 22, for

**Fig. 22** A tri-foil crystal motif is observed in an optical micrograph of  $D_c = 4.0$  Pt nanocrystals. It is reminiscent of a well-known Japanese corporate logo (although no funding was provided to influence this fortuitous observation). *Source:* From Ref.<sup>[42]</sup>.

**Fig. 23** An optical micrograph of Pt QDAs formed by very small ( $D_c = 2.5$  nm) nanocrystals with slightly irregular shapes shows that crystal habit depends on the nanocrystal core size. *Source:* From Ref.<sup>[42]</sup>.

$D_c = 4.0$  nm Pt nanocrystals.<sup>[42]</sup> The “Mitsubishi” motif exhibited by these crystals is in marked contrast to that exhibited by smaller,  $D_c = 2.5$  nm crystals in Fig. 23. In both cases, dodecanthiol was used to passivate the surface, decane was used as the solvent, and an identical Pt concentration and substrate was used.

On larger-length scales still the QDAs of Fig. 21 form dendritic films, Fig. 24, of “cluster matter,” whose complex optical and electrical behavior was the subject of a fairly recent paper and is discussed in Kreibig and Vollmer’s monograph.<sup>[2]</sup> These dendritic films were shown to sinter into a metallic film with high optical reflectivity and electrical conductivity at low temperatures ( $\sim 200^\circ\text{C}$ ).<sup>[60]</sup>

Finally, it should be mentioned that, depending on growth conditions, many other crystal habits were observed, including large ( $\sim 1\text{--}10\ \mu\text{m}$ ) hexagonal motifs. The conditions that favor one habit over another are just as complex and difficult to understand as that of macrocrystalline growth from supersaturated solutions,

**Fig. 24** Optical micrograph at low magnification of the triangular Au QDAs shown in Fig. 21. *Source:* From Ref.<sup>[41]</sup>.

and growing QDAs of large size and high perfection is very much an art. An obvious goal would be to obtain crystals of sufficient size to perform single-crystal XRD and determine each atomic position in each identical nanocrystal to atomic resolution. This may well be possible in the future. It would answer some currently unknowable issues with respect to surface structure in nanocrystals with major impact on the design of nanometal catalysts, nanophosphors, etc.

### TEM image analysis

The qualitative observations of the preceding section can be augmented in the case of QDA monolayers by employing automated digital image analysis of large areas of TEM grids. Consider the TEM of Fig. 25. We first determine the center-of-mass position, and average size of all acceptable (i.e., non overlapping) nanocrystals in the image. These are then replaced with digital, color-coded balls of the same size, and the particle coordinates can be subsequently used to calculate both the 2-D and radial-averaged,  $g(r)$ , correlation functions. The latter is the Fourier transform of  $S(q)$ , the scattering structure factor which would be obtained from, for example, small-angle X-ray scattering (SAXS)<sup>[44]</sup> or neutron scattering (SANS). Balls that are sufficiently out of register with neighboring balls (e.g., in a hexagonal lattice) are then assigned colors that identify the coherent domains (analogous to the peak linewidth in SAXS). Fig. 26 shows the result of such assignments.

With the available domain and nanocrystal position information, one can then rotate each domain by the correct amount to obtain a coherent domain for the entire region (balls which fail to belong to any of

**Fig. 26** The digitized ball file containing the center-of-mass coordinates of the nanocrystals and whose ball color codes for the domain of a given ball is shown. *Source:* From Ref.<sup>[41]</sup>.

the domains are eliminated for simplicity). The resulting rotated 2-D correlation function is shown in Fig. 27. One easily observes the hexagonal symmetry of the QDA in this figure, and the very high degree of long-range order.

A radial average can then be performed to obtain  $g(r)$  and the average interparticle spacing. This is shown in Fig. 28. The hexagonal symmetry of the lattice is reflected in the splitting of the second peak, which is harder to observe when the domains are incoherent (i.e., not rotated). The average interparticle spacing and the gap can be very precisely determined from such analysis. This allowed us to perform a very precise

**Fig. 25** A monolayer of  $D_c = 4.6$  nm Au clusters that forms 3-D crystals as shown in Fig. 21. *Source:* From Ref.<sup>[41]</sup>.

**Fig. 27** Rotated 2-D pair correlation function from Fig. 26. *Source:* From Ref.<sup>[41]</sup>.

determination of the effect of alkyl chain length (organic shell thickness) on the interparticle spacing in Au and Pt QDAs for the first time. We reported a change of  $\sim 1.2 \text{ \AA}/\text{carbon}$  for alkyl chains C $_k$  with  $6 < k < 14$ , in the case of Au and  $1.4 \text{ \AA}/\text{carbon}$  in the case of Pt QDAs. For comparison, SEC determination of the organic shell thickness in Au alkylthiolate nanoconjugates found an increase of  $2.4 \text{ \AA}/2 \text{ carbon}$  atoms in the shell thickness in toluene—a very good agreement. It is important to note that substantial interdigitation of the alkyl groups is always observed

**Fig. 29** Pt QDA bilayer with the clusters deposited onto the low-energy trigonal sites above the first monolayer. *Source: Unpublished data.*

**Fig. 30** Pt Qdot bilayer has the second layer of clusters deposited onto twofold symmetry sites. *Source: Unpublished data.*

in the case of Au, Ag, Pt, and Pd QDAs, and plays an important role in the formation of the arrays. In the case of surfactants that do not easily pack or are too short, QDA formation is very rare. Also, for particles smaller than  $\sim 2.5 \text{ nm}$ , long-range order is rarely observed and the particles prefer to disperse randomly on the grid.

The symmetry of a monolayer lattice obtained from a given nanocluster solution is typically hexagonal; however, in the same preparation on the same grid, we have also observed and reported square lattice packings, so the symmetry cannot be solely dependent on organic layer thickness, nanocluster metal type, nor solvent because these are all identical. It does indicate that these two lattice types are of very similar energy.

Similarly, unexpected packing can occur in bilayers, as demonstrated by Figs. 29 and 30. In Fig. 29, a Pt PDA bilayer we observe the “expected” low-energy trigonal (threefold) locations of the second layer above the “holes” in the first hexagonal layer. But in other Pt QDA, Fig. 30, we observed that clusters in the second layer occupy the twofold sites.

### Nanocluster Matter and Nanotechnology

Cluster matter is obviously significantly more complex to study and understand than dilute solutions of individual Qdots acting independently. However, it does present some intriguing technological possibilities. Consider, for example, the effect of nanocrystal diameter and particle spacing on the effective dielectric constant of a fcc (or hexagonal) QDA. Fig. 31 shows that as the ratio of  $D_c/\text{gap}$  increases, the dielectric constant can become very large. This has implications for energy

**Fig. 31** The calculated dielectric constant of an fcc QDA superlattice increases dramatically with core diameter/gap ratio. *Source:* From Ref.<sup>[41]</sup>.

storage in capacitors because cluster matter may not suffer the same problems with increased dielectric breakdown as those known for bulk powders. We discuss the reasons for these difference in Ref.<sup>[41]</sup>

Another area in which metallic nanoclusters are likely to have a significant impact in the future is in heterogeneous catalysis. As examples, we cite our work on nanosize Fe and FeS<sub>2</sub> as coal hydrogenation and hydrogenolysis catalysts, where the nanoclusters are directly deposited onto the coal powder, which acts both as a support and a substrate.<sup>[61,62]</sup> The coal is broken down under high-pressure H<sub>2</sub> into liquids, which may serve as either chemical feedstocks for advanced engineering materials or as fuels in energy production. A very significant amount of the chemical products are aromatic or naphthalenic in structure, a very desirable starting point for many engineering polymers and plastics.

We have also investigated nanosize MoS<sub>2</sub> as a photocatalyst demonstrating a size-dependent photooxidation of both phenol<sup>[50]</sup> and pentachlorophenol.<sup>[51]</sup> The latter is a major environmental contaminant as it has been widely employed as a fungicide and herbicide for wood preservation. As MoS<sub>2</sub> has a two-dimensional graphite-like structure with the catalytically active Mo sites at the “edge” of the cluster, making this material nanosize vastly increases its potential catalytic activity. Already, it is the most useful fuel hydrodesulfurization catalyst known. (This is the critical first step in crude refining, in which heteroatom compounds are removed to avoid poisoning subsequent expensive transition metal catalysts.) One would anticipate that nanosize MoS<sub>2</sub> would be even more effective (perhaps at lower temperature and H<sub>2</sub> pressures).

We have examined nanosize Pd, Pt, and Rh deposited on high surface area, commercially available supports such as alumina and carbon and found that not only can milder *T* and *P* conditions be utilized for hydrogenation, but that the product distribution (selectivity) can be tuned by nanocluster size and metal type. In fact, we have discovered that Pd nanoclusters on carbon can actually be more effective than more expensive Rh in the hydrogenation of pyrene. This is not true of commercially available Pd and Rh catalysts, and indicates the almost limitless possibilities in this largely unexplored area of nanotechnology.

## CONCLUSION

In this review, we discussed chemical preparation methods for the synthesis of metallic quantum dots, emphasizing the important role of surface active agents for the control of the average cluster size and size dispersion. Inverse micelle synthesis in non-polar oils using readily available, inexpensive ionic metal salts encapsulated in their interior is the most versatile method for metallic Qdot synthesis. We demonstrated the use of liquid chromatography for cluster size analysis and the role such rapid feedback plays in synthesis development. We demonstrated that special, thermodynamically stable cluster sizes are formed in the size regime  $D_c < 3$  nm, that the binding strengths of ligands to metal nanoclusters is stronger for Au than Ag, and that the length of the thiolate itself affects the binding affinity. We noted that short chain length alkyl thiolates may act as etchants to narrow the size distribution with time, and that, in general, an evolution of the cluster size distribution does occur, its rate being correlated with the bulk melting *T* of the material (i.e., slower evolution for Pt than for Au or Ag).

We next reviewed the size-dependent optical properties of Au and Ag nanoclusters, optical properties of core-shell particles, and the unexpected visible and NIR photoluminescence from molecular sized nanometals. A blue shift of the plasmon resonance was observed for nanosize Au, while the opposite behavior was found for Ag and attributed the greater role of inter-d-band transitions in Au than in the case of Ag. We reported the emergence of distinct molecule-like absorbance features in Au clusters approaching 1 nm in dimension. The optical properties of core-shell particles of equivalent size and atomic composition were shown to depend on whether Ag or Au was in the interior and were further shown to depend on whether an alloy or a true core-shell type structure was synthesized.

We next discussed the various synthetic approaches and resulting magnetic properties of the base itinerant metals, Co, Fe, and Ni. We discussed the possible

reasons for the heretofore low magnetic response of nanocrystals of these materials and also discussed soon-to-be published work on ultrasmall,  $D_c = 1.4$  and  $1.9$  nm Co nanocrystals exhibiting greater-than-bulk magnetic response. Possible reasons connected with surface magnetism and surface reconstruction in nanocrystals were given as explanations of our observations. We also discussed the synthesis of non-equilibrium crystal structures of nanoparticles of Fe and Co.

We next discussed the formation of QDAs of nanocrystals of Au, Pt, and Pd outlining the important parameters controlling the degree of order and whether mono-, bi-, or multilayer QDAs form. In particular, we reviewed novel digital-image analysis methods for obtaining the average domain size, interparticle spacing, and extent of long-range order in TEM images of QDAs. We noted that bilayers may exhibit either the predicted low-energy, threefold coordination or a twofold coordination in the second layer. We also commented that either hexagonal or square packing of nanocrystals can occur in the same sample on the same substrate.

We concluded our review with a discussion of the relationship between Qdots and nanotechnology. The ability to control the size, shape, and interface structure of Qdots is critical to their application in nanotechnology as new magnetic, dielectric, optical, and catalytic materials. As one example, we discussed the effect of core size to interparticle ratio on the dielectric constant and pointed out that one may expect nanosize clusters to eliminate some of the dielectric breakdown issues found in macroscopic materials, allowing significant increases in energy storage in capacitors. We particularly emphasized catalytic applications because we feel these may yield the most spectacular improvements on conventional technology. Two examples, the direct conversion of coal to chemicals and fuels using Fe and  $\text{FeS}_2$ , and solar-driven photocatalysis using  $\text{MoS}_2$  were given.

In any review, one must be quite selective in the topics covered. But we hope to have given the reader a good overview of the reasons for the large scientific interest in nanomaterials and nanotechnology, as well as the tools which are currently being developed to further these fields. Essentially, scientists are redoing all of materials research on a length scale in which interface is dominant. Thus these endeavors are likely to continue for many years and yield many unexpected observations.

## ACKNOWLEDGMENTS

This work was supported by the Division of Materials Sciences, Office of Basic Energy Sciences of the US Department of Energy under contract DE-AC04-

94AL8500. Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed-Martin Company, for the Department of Energy. The author would like to acknowledge the support of many collaborators over the years, especially my technical assistants, Edward Vernon, Sharon Craft, Judy Odinek, and James Mikkaelson. I would also like to recognize the fine TEM, XRD, and SAD work of Paula Provencio and my long-time friend and collaborator James Martin.

# Metallomacrocyclic Selective Ion Receptors

Kay Severin

Institut de Chimie Moléculaire et Biologique, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

## INTRODUCTION

Macrocyclic compounds, which are able to selectively bind ions, have received considerable attention because of applications in the fields of sensing, catalysis, and ion-transport, among others. Traditionally, covalent bonds are used for the construction of the macrocyclic framework. However, a drawback of this approach is that quite often, the synthesis is time-consuming and expensive. In the following, a unique class of receptors is described. These receptors are formed by self-assembly of three organometallic subunits and have a diameter of approximately 1 nm. They show an outstanding affinity and selectivity for lithium and sodium salts. This characteristic was used to construct specific chemosensors for lithium and fluoride ions, and to stabilize and characterize unusual molecules such as LiF.

## SELF-ASSEMBLY OF ORGANOMETALLIC HALF-SANDWICH COMPLEXES

Half-sandwich complexes of the general formula  $[(\pi\text{-ligand})\text{MCl}_2]_2 [(\pi\text{-ligand})\text{M}] = (\text{arene})\text{Ru}, \text{Cp}^*\text{Rh}, \text{Cp}^*\text{Ir}$  are common starting materials in organometallic synthesis and catalysis (Fig. 1). They are either commercially available or accessible via one-step synthetic procedures. In the solid state, they are not sensitive toward air and moisture, which facilitates the handling. The organic  $\pi$ -ligands are relatively inert toward substitution reactions. Consequently, they generally act as spectator ligands. On the other hand, the chloro ligands can be easily substituted with other neutral or anionic ligands.

The availability of three facial coordination sites can be utilized for self-assembly processes: upon addition of suited tridentate ligands, polynuclear complexes are obtained (Fig. 2). So far, macrocycles with two,<sup>[1–3]</sup> three (see below), four,<sup>[4–6]</sup> and six<sup>[7]</sup> metal fragments have been isolated and characterized. Generally, the compounds are formed in excellent yields. The number  $n$ , as well as the overall geometry, strongly depends on the nature of the bridging ligand.

In self-assembly reactions, there is a general bias toward the generation of aggregates with a small number of subunits due to reasons of entropy. On the other hand, the coordinate vectors of the ligand and the metal have to be matched, which may exclude the formation of very small assemblies such as dimers ( $n = 2$ ). For the combination of half-sandwich complexes with rigid tridentate ligands, the most common structural motif are trimers ( $n = 3$ ). First examples of such compounds were reported by Fish,<sup>[8]</sup> Annen et al.,<sup>[5]</sup> Korn and Sheldrick,<sup>[9]</sup> Beck et al.,<sup>[10,11]</sup> and Carmona et al.,<sup>[12]</sup> who used nucleobase derivatives and  $\alpha$ -amino acidates as bridging ligands. Structurally related compounds were subsequently reported by Yamanari et al.<sup>[13,14]</sup> In all cases, mono-anionic ligands were employed, which results in a charge of +3 for the trimeric assembly. As a consequence, an enhanced solubility in polar solvents such as methanol and water is observed but also a severely reduced affinity for cationic guest molecules. To obtain neutral macrocycles, our group has utilized *dianionic* tridentate ligands to bridge the half-sandwich complexes. After initial investigations using 3,4-dihydropyridine derivatives,<sup>[15]</sup> we have focused on the 2,3-dihydropyridine ligand. Upon addition of base, the chloro ligands of  $[(\pi\text{-ligand})\text{MCl}_2]_2$  undergo a substitution reaction to give the corresponding trimeric macrocycles in excellent yield (Fig. 3). The reaction can be performed with  $(\text{arene})\text{Ru}^{\text{II}}$  complexes (arene =  $\text{C}_6\text{H}_6$ ,  $p\text{-MeC}_6\text{H}_4\text{Pr}$ ,  $\text{C}_6\text{H}_3\text{Et}_3$ ,  $\text{C}_6\text{Me}_6$ ,  $\text{C}_6\text{H}_5\text{CO}_2\text{Et}$ ),<sup>[16–18]</sup> with  $\text{Cp}^*\text{Rh}^{\text{III}}$  complexes<sup>[17]</sup> and with  $\text{Cp}^*\text{Ir}^{\text{III}}$  complexes,<sup>[19]</sup> respectively. The solubility of the resulting compounds depends on the nature of the  $\pi$ -ligand: whereas the  $(\text{benzene})\text{Ru}$  complex displays a low solubility in organic solvents, such as dichloromethane, the  $(p\text{-MeC}_6\text{H}_4\text{Pr})\text{Ru}$ ,  $(\text{C}_6\text{H}_3\text{Et}_3)\text{Ru}$ ,  $\text{Cp}^*\text{Rh}$ , and  $\text{Cp}^*\text{Ir}$  complexes are well soluble in common organic solvents such as benzene and toluene.

The structures of the resulting macrocycles have been extensively studied by single crystal X-ray analysis.<sup>[16–19]</sup> In all cases, a pseudo- $C_3$ -symmetric geometry is observed. The tetrahedral metal fragments are connected via the pyridine N-atom and the two O-atoms of the pyridonate ligand. On average, the metal atoms

**Fig. 1** Chloro-bridged half-sandwich complexes of  $\text{Ru}^{\text{II}}$ ,  $\text{Rh}^{\text{III}}$ , and  $\text{Ir}^{\text{III}}$  as versatile starting materials for the construction of macrocyclic complexes.

are 0.54 nm apart from each other; the diameter of the complexes depends on the nature of the  $\pi$ -ligand and is approximately 1 nm. In Fig. 4, the structures of two representative macrocycles in the crystal are depicted.

The metal centers in these complexes are chiral and have the same absolute configuration. Because there is no chiral induction present during the synthesis, the macrocycles are obtained as a racemic mixture. Other isomers cannot be detected, indicating that the self-assembly process is completely diastereoselective. In solution, the complexes are configurationally stable on the nuclear magnetic resonance (NMR) time scale as evidenced by the observation of separate signals for the diastereotopic groups of the (*p*- $\text{MeC}_6\text{H}_4\text{Pr}$ )Ru complex ( $\text{CD}_3\text{OD}$  or  $\text{CDCl}_3$ ).

## METALLAMACROCYCLIC RECEPTORS FOR ION-PAIRS

### Selective Complexation of Lithium and Sodium Salts

Metallacrown complexes are analogues of crown ethers, in which metal atoms constitute an integral part of the macrocyclic framework. Compounds of this kind were first reported in 1989 by Pecoraro et al.<sup>[20,21]</sup> At present, metallacrown complexes with ring sizes between 9 and 30 atoms are known.<sup>[22]</sup> Similar to their organic counterparts, metallacrowns can selectively bind metal ions with high affinity. The trinuclear complexes depicted in Fig. 3 represent analogues of 12-crown-3. When investigated for their ability to bind alkali metal ions, it was found that the complexes display a very high affinity for lithium and sodium salts (Fig. 5).

The  $\text{Li}^+$  and  $\text{Na}^+$  adducts can be distinguished from the free receptors by  $^1\text{H}$  NMR: a significant downfield shift is observed for the signals for the bridging ligands as well as for the signals of the  $\pi$ -ligands. Because the exchange of the alkali guest is slow on the NMR time scale, quantitative information about adduct formation can be obtained by integration of the corresponding  $^1\text{H}$  NMR signals. Therefore, NMR spectroscopy can be used to investigate the affinity, the binding kinetics, and the selectivity of the 12-metallacrown-3 complexes.

To evaluate the affinity of the receptor  $[(p\text{-MeC}_6\text{H}_4\text{Pr})\text{Ru}(\text{C}_5\text{H}_3\text{NO}_2)]_3$  (**1**) for  $\text{LiCl}$  and  $\text{NaCl}$ , competition experiments with various organic ionophores were carried out.<sup>[16]</sup> These experiments showed that in chloroform, the binding affinity of **1** toward these salts is significantly higher than that of crown ethers (Fig. 6). A real competition situation, in which both the free receptor **1** and the adduct **1**·MCl can be detected, is only observed if extremely good ionophores, such as 2,1,1-cryptand, are employed as competing receptors.

**Fig. 4** Ball and stick representation of the molecular structure of macrocyclic (benzene)Ru and Cp\*Ir complexes in the crystal. The hydrogen atoms are omitted for clarity.

To obtain more information about the binding kinetics, the time course of the reaction between the receptor **1** (11.4 mM) and a twofold excess of LiCl was investigated (Fig. 7).<sup>[23]</sup> Quantitative adduct formation is observed after approximately 2 days. This result confirms that the affinity of the receptor **1** for LiCl is very high, but also that the complexation reaction is unusually slow. Using a computational analysis, an apparent second-order rate constants of  $k_f = 1.6 \pm 0.3 \times 10^{-3} \text{ M}^{-1} \text{ sec}^{-1}$  was calculated. This value is very low compared to what has been measured for other ionophores. A formation rate constant of  $k_f = 4.8 \times 10^5 \text{ M}^{-1} \text{ sec}^{-1}$ , for example, has been determined for the Li<sup>+</sup>-specific [2,1,1]-cryptand.<sup>[24]</sup>

The selectivity of the metallacrown complexes strongly depends on the nature of the  $\pi$ -ligand. Whereas the (C<sub>6</sub>H<sub>6</sub>)Ru, (*p*-MeC<sub>6</sub>H<sub>4</sub>Pr)Ru and (C<sub>6</sub>H<sub>5</sub>CO<sub>2</sub>Et)Ru complexes bind both Li<sup>+</sup> and Na<sup>+</sup> salts, the (C<sub>6</sub>H<sub>3</sub>Et<sub>3</sub>)Ru, (C<sub>6</sub>Me<sub>6</sub>)Ru, Cp\*Rh, and Cp\*Ir complexes are specific for Li<sup>+</sup> salts. None of the receptors are able to bind K<sup>+</sup> salts. This pronounced selectivity for small cations is a result of the steric requirements of the  $\pi$ -ligands. A view along the pseudo-C<sub>3</sub> symmetry axis of the Li<sup>+</sup> and Na<sup>+</sup> adducts of receptor [(C<sub>6</sub>H<sub>6</sub>)Ru(C<sub>5</sub>H<sub>3</sub>NO<sub>2</sub>)<sub>3</sub>] (**2**) nicely illustrates the close encapsulation of the cations by the

benzene ligands of the receptor (Fig. 8). Given the rigidity of the host complex, it is evident that larger cations than Na<sup>+</sup> are not able to bind to the three adjacent O-atoms, which constitute the binding site.

Ionophores with high selectivity for Li<sup>+</sup> ions are of general interest because of potential applications as chemosensors. In this context, the ruthenium complex [(C<sub>6</sub>H<sub>5</sub>CO<sub>2</sub>Et)Ru(C<sub>5</sub>H<sub>3</sub>NO<sub>2</sub>)<sub>3</sub>] (**3**) displayed the most promising characteristics of all investigated receptors. Although this macrocycle is able to bind Na<sup>+</sup> ions, it shows an outstanding affinity and selectivity for Li<sup>+</sup> salts.<sup>[18]</sup> This is demonstrated by the following experiment: if an aqueous solution containing LiCl (0.05 M) and a large excess of NaCl, KCl, CsCl, CaCl<sub>2</sub>, and MgCl<sub>2</sub> (1.00 M each) is shaken with a chloroform solution of complex **3**, the exclusive and quantitative extraction of LiCl is observed (Fig. 9). This is remarkable because a) the extraction of LiCl from water is in principle a very difficult thing to accomplish due to the high enthalpy of hydration and b) the nearly perfect selectivity for Li<sup>+</sup>. Overall, the affinity and

**Fig. 5** Selective complexation of lithium and sodium salts by 12-metallacrown-3 complexes.

**Fig. 6** Competition experiment between receptor **1** and 18-crown-6: the 12-metallacrown-3 complex **1** has a significantly higher affinity for NaCl.

**Fig. 7** Time course of the reaction between the receptor **1** (11.4 mM) and LiCl (22.8 mM) in CD<sub>3</sub>OD to give the corresponding adduct **1** · LiCl (◆).

selectivity of complex **3** is comparable to the best receptors for Li<sup>+</sup> that have been reported so far.

Several MX (M<sup>+</sup> = Li<sup>+</sup>, Na<sup>+</sup>; X<sup>-</sup> = Cl<sup>-</sup>, Br<sup>-</sup>, I<sup>-</sup>) adducts have been characterized crystallographically. In all cases, the salt is bound as an ion pair with the alkali metal ion being coordinated to the three oxygen atoms of the metallacrown complexes (Fig. 10). The anion, which is tightly bound to the respective cation, is situated in close proximity to the  $\pi$ -ligands. The resulting tetrahedral coordination geometry is commonly found for LiX complexes but rarely found for NaX complexes. The unusually low coordination number results in Na–X bond length, which are among the shortest reported so far (e.g., Na–Cl = 253 pm for the NaCl complex of **1**).<sup>[17]</sup>

**Fig. 8** Space filling representation of the structures of **2** · LiCl (left) and **2** · NaCl (right) in the crystal (the Cl<sup>-</sup> anions are not depicted). Salts with larger cations such as KCl do not coordinate to **2** because they are efficiently blocked by the arene  $\pi$ -ligands, which encapsulate the binding site.

### Electronic Effects in 12-Metallacrown-3 Complexes

There are several effects that contribute to the exceptionally high affinity of 12-metallacrown-3 complexes for Li<sup>+</sup> and Na<sup>+</sup> salts in organic solvents: 1) The receptors are very rigid and the three O-donor atoms are ideally preorganized to bind small cations; 2) The salts are bound as an ion pair; 3) The energetic costs for the desolvation of the donor atoms are very small because

**Fig. 9** Selective extraction of LiCl from water containing a large excess of NaCl, KCl, CsCl, CaCl<sub>2</sub>, and MgCl<sub>2</sub>.

**Fig. 10** Ball and stick representation of the molecular structure of  $2 \cdot \text{NaBr}$  in the crystal. The hydrogen atoms are omitted for clarity.

the binding site is well shielded by the  $\pi$ -ligands. A fourth contribution is based on the peculiar electronic situation of metallacrown complexes. It is known that metal–oxygen bonds can be very polar, even in complexes of the late transition metals.<sup>[25]</sup> A computational study has revealed that the Ru–O bonds of receptor **2** are likewise highly polarized with a partial negative charge of  $-0.88$  for the oxygen atoms (Fig. 11).<sup>[23]</sup> For the organic counterpart 12-crown-3, on the other hand, significantly lower values were calculated ( $-0.59$ ). Because the O-donor atoms of the metallacrown complex are ideally preorganized, the increased negative charge is an important contribution to the high affinity for cationic guests. This result is of general importance because it points to an intrinsic advantage of metallacrown complexes: a highly polarized binding site.

To further address the question on how electronic effects influence the host–guest chemistry of 12-metallacrown-3 complexes, the derivative **4** having chloro-substituents at the bridging pyridonate ligands was synthesized (Fig. 12). The electron-withdrawing groups were expected to slightly reduce the partial negative charge on the O-donor atoms in *para* position. It was shown that this rather conservative

**Fig. 11** The highly polarized Ru–O bonds in 12-metallacrown-3 complexes favor the binding of cationic guest molecules for electrostatic reasons.

**Fig. 12** A 12-metallacrown-3 complex with chloro-substituents (**4**) displays a significantly lower binding constant for LiCl (values determined in  $\text{CD}_3\text{OD}/\text{D}_2\text{O}$ , 5:1).

change reduces the affinity of the receptor **4** for LiCl and NaCl by approximately 2 orders of magnitude, although only very small structural differences were observed.<sup>[23]</sup>

### Redox-Responsive Receptors

For applications in the field of sensing, it is necessary to transduce the binding of the analyte in some kind of signal output. Because of the sensitivity and accuracy of the measurement, electrochemical methods have found considerable attention in this context. Over the past years, many redox-responsive macrocycles have been synthesized to electrochemically recognize small ions.<sup>[26]</sup> Especially appealing are compounds with a responsive or signaling unit being an integral part of the receptor itself.

In the case of 12-metallacrown-3 complexes, electrochemical methods turned out to be ideally suited for the detection of lithium and sodium salts. The free receptor **1** is oxidized at a potential of  $+583$  mV when measured against a Ag/AgCl reference electrode. Upon addition of LiCl or NaCl, the metallamacrocycle is significantly more difficult to oxidize with a peak potential of  $940$  mV ( $1 \cdot \text{LiCl}$ ) and  $900$  mV ( $1 \cdot \text{NaCl}$ ), respectively.<sup>[17]</sup> A similar shift toward anodic potential is found for the other 12-metallacrown-3 complexes. The differences are large compared to what is observed for other redox-responsive ionophores such as ferrocene containing crown ethers,<sup>[26]</sup> and, in principle, sufficient to build an amperometric molecular sensor device.

The detection of guest molecules with 12-metallacrown-3 complexes can even be performed without employing electrochemical methods. That fact that the host–guest complexes are more difficult to oxidize was used to develop a colorimetric test: if the oxidation agent 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) is added to a solution of the

**Fig. 13** The different redox-potential of the free receptor **1** and the adduct **1**·LiCl can be used to detect lithium ions with a simple color test.

free receptor **1**, the originally yellow solution immediately turns dark brown because DDQ oxidizes the ruthenium complex. However, in the presence of LiCl, no reaction and thus no color change occurs (Fig. 13). A similar behavior is observed for the NaCl adduct. It is thus possible to detect lithium and sodium salts with a simple and fast color test.

### Stabilization of Unusual Molecules

Although hundreds of alkali metal halide complexes have been synthesized and structurally characterized,<sup>[27]</sup> complexes of molecular LiF are virtually unknown. There are some reports about compounds with Li···F contacts but here, the fluoride atom is either covalently bound to other atoms (e.g., in PF<sub>6</sub><sup>-</sup> salts) or coordinatively bound to very strong Lewis acids (e.g., to Ti<sup>4+</sup>).<sup>a</sup> The difficulty to stabilize complexes of molecular LiF is a result of the very high lattice energy of this salt. Consequently, the crystalline form represents a thermodynamic trap. A similar situation is found for the less common salt LiFHF containing the interesting FHF<sup>-</sup> anion.<sup>[29]</sup>

Our strategy to obtain complexes of these salts was to generate them in situ in the presence of the macrocyclic host. For this purpose, we first synthesized LiBF<sub>4</sub> adducts of the 12-metallacrown-3 complexes. The weakly bonded BF<sub>4</sub><sup>-</sup> anion was then exchanged with F<sup>-</sup> or FHF<sup>-</sup> in a salt metathesis reaction using potassium or tetraethylammonium salts (Fig. 14). After extraction with benzene to remove the KBF<sub>4</sub> or NEt<sub>4</sub>BF<sub>4</sub> biproducts, the LiF and LiFHF complexes were obtained in pure form.<sup>[30]</sup>

The physical properties of these encapsulated lithium salts were of special interest. In solution, the complexes were studied by heteronuclear NMR spectroscopy.<sup>[30]</sup> The first thing to point out is the strong scalar coupling between <sup>7</sup>Li and the adjacent <sup>19</sup>F atom observed for all complexes (90–103 Hz). The hydrogen bond of the FHF<sup>-</sup> anion was shown to be highly asymmetric: the value of <sup>1</sup>J<sub>HF</sub> of the distal fluorine

<sup>a</sup>For a cluster with the formula [(Cp\*TiF<sub>3</sub>)<sub>4</sub>(LiF)], see Ref.<sup>[28]</sup>.

**Fig. 14** General strategy for the synthesis of LiF complexes by anion metathesis.

atom is large compared to that of the free FHF<sup>-</sup> anion, and coupling to the proximal fluorine atom was not observed. Therefore, an adequate description of the LiFHF complexes is a LiF complex hydrogen-bonded to a HF molecule (LiF···HF).

Several LiF and LiFHF complexes were examined by single crystal X-ray crystallography.<sup>[19,30]</sup> As what was found for other MX adducts, the lithium cation is bound to the three oxygen donor-atoms of the macrocyclic receptor with the fourth coordination site being occupied by the F<sup>-</sup> or FHF<sup>-</sup> anion (Fig. 15). The complexes show Li–F bond length between 176 and 181 pm. These values are among the shortest Li···F distances reported so far, highlighting the unique situation of molecular LiF and LiFHF inside the macrocyclic hosts.

The successful stabilization of LiF and LiFHF prompted us to investigate whether 12-metallacrown-3 complexes could capture unusual sodium salts. Similar to LiF, Na<sub>2</sub>SiF<sub>6</sub> displays a very low solubility in common solvents because of the high thermodynamic stability of the crystalline form. Thus it is not surprising that complexes of molecular Na<sub>2</sub>SiF<sub>6</sub> had not been described so far. The strategy to synthesize such a complex was related to that of the LiF complexes: a tetrafluoroborate adduct, **1**·NaBF<sub>4</sub>, was used as the starting material. Upon reaction with (NEt<sub>4</sub>)<sub>2</sub>SiF<sub>6</sub>, rapid anion exchange occurs and the dimeric complex

**Fig. 15** Ball and stick representation of the molecular structure of [Cp\*Ir(C<sub>5</sub>H<sub>3</sub>NO<sub>2</sub>)<sub>3</sub>]·LiFHF (left) and [Cp\*Rh(C<sub>5</sub>H<sub>3</sub>NO<sub>2</sub>)<sub>3</sub>]·LiF (right) in the crystal. The hydrogen atoms and the methyl groups of the Cp\* π-ligands are not shown for clarity.

$1 \cdot \text{Na}_2\text{SiF}_6 \cdot 1$  is obtained. The molecular structure in the crystal shows that two metallacrown complexes encapsulate the ion-paired  $\text{Na}(\mu\text{-F})_3\text{Si}(\mu\text{-F})_3\text{Na}$  guest molecule (Fig. 16).

In solution, two sets of signals are observed by  $^1\text{H}$ NMR spectroscopy, the relative ratio of which is 7:3. They correspond to the two diastereoisomers formed upon dimerization of the chiral hosts. The deviation from the statistical distribution shows that there is chiral recognition between the metallacrown complexes.

### Selective Complexation of Fluoride

Because the organometallic metallacrown complexes show a pronounced preference for the complexation of ion-pairs, they can also be used as specific receptors for anions. In particular, it is possible to use the  $\text{LiBF}_4$  adduct of the  $\text{Cp}^*\text{Ir}$  receptor  $[\text{Cp}^*\text{Ir}(\text{C}_5\text{H}_3\text{NO}_2)]_3$  (**4**) to construct a selective chemosensor for the fluoride anion.<sup>[19]</sup> As a result of the steric requirements of the large  $\text{Cp}^*$   $\pi$ -ligands, the lithium ion inside receptor **4** is well shielded. As a consequence, most anions (such as the  $\text{BF}_4^-$  counter ion) are efficiently blocked and  $\text{LiX}$  ion-pairs are not formed in solution. However, the small fluoride anion is able to enter the binding site and coordinate to the lithium ion (Fig. 17). The selective formation of  $\text{LiF}$  ion-pairs is further enhanced by the intrinsic affinity of  $\text{Li}^+$  to  $\text{F}^-$ .

The success of this approach was evidenced by the following NMR competition experiment: A mixture of  $\text{NBu}_4\text{X}$  ( $\text{X}^- = \text{Cl}^-, \text{Br}^-, \text{I}^-, \text{NO}_3^-$ ) and  $\text{NBu}_4\text{F}$  was added to a solution of complex **4**· $\text{LiBF}_4$  (receptor/ $\text{X}^-/\text{F}^- = 1:100:2$ ). In spite of the large excess of the competing anions  $\text{X}^-$ , the exclusive formation of **4**· $\text{LiF}$  was observed by NMR spectroscopy

**Fig. 16** Stabilization of molecular  $\text{Na}_2\text{SiF}_6$  by encapsulation with two metallacrown complexes **1**. The ball-and-stick representation is based on the structure in the crystal. The hydrogen atoms and the side chains of the  $\pi$ -ligands are not shown for clarity.

**Fig. 17** A lithium ion coordinated to a metallamacrocyclic host can act as a specific binding site for the fluoride anion. The space filling model of the  $\text{LiF}$  adduct of receptor **4** in the crystal (right) shows the close encapsulation of the fluoride anion by the  $\text{Cp}^*$   $\pi$ -ligands.

in all cases.<sup>[19]</sup> This indicates that the fluoride- $\text{X}^-$  selectivity is higher than 1000:1.

The presence of fluoride anions can also be detected by electrochemical methods. For **4**· $\text{LiBF}_4$ , the peak potential for the first oxidation is observed at  $890(\pm 3)$  mV when measured against a  $\text{Ag}/\text{AgCl}$  reference electrode.<sup>[19]</sup> Upon addition of five equivalents of  $\text{NBu}_4\text{F}$ , the complex is significantly easier to oxidize ( $\Delta E = -203$  mV). This can be explained by the reduced electron-withdrawing character of the ion-paired  $\text{LiF}$  guest as compared to the solvated lithium ion. In agreement with the NMR studies, only small changes are observed upon addition of other anions, such as  $\text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{NO}_3^-$ ,  $\text{HSO}_4^-$ , or  $\text{ClO}_4^-$  ( $\Delta E < 24$  mV). Similar results are obtained in solutions containing methanol in contrast to many other fluoride receptors, which have little or no affinity for  $\text{F}^-$  in protic solvents.

### CONCLUSION

Trinuclear metallamacrocycles of the general formula  $[(\pi\text{-ligand})\text{M}(\text{C}_5\text{H}_3\text{NO}_2)]_3$  [ $(\pi\text{-ligand})\text{M} = (\text{arene})\text{Ru}, \text{Cp}^*\text{Rh}, \text{Cp}^*\text{Ir}$ ] can easily be obtained via self-assembly by using commercially available starting materials. These nanometer-sized complexes are extremely good receptors for lithium and sodium salts with affinities and selectivities comparable to the best ionophores described so far. The possibility to vary the metal fragment was shown to be essential for the development of a chemosensor for lithium ions. Electronic effects are likewise important: subtle changes of the bridging ligand have a pronounced effect on the affinity for guest molecules. For the future design of metallacrown complexes, electronic effects should thus be considered as a powerful tool to modulate the binding affinities. A unique feature of the metallacrown complexes described in this article is the fact that the lithium and sodium salts are bound as an ion pair. As a result, it was not only possible to isolate unusual molecules

such as LiF and LiFHF but also to construct a highly specific chemosensor for the fluoride anion. It appears likely that the synthetic concept described here can be expanded to construct other 12-metallacrown-3 complexes with exciting new properties. Research along these lines is currently being pursued in our laboratory.

## ACKNOWLEDGMENTS

I am grateful to the following coworkers who have carried most of the experiments described in this overview: M.-L. Lehaire (syntheses), Z. Grote (syntheses), R. Scopelliti (X-ray analyzes), H. Piotrowski (X-ray analyses). The work was supported by the Swiss National Science Foundation.

## INTRODUCTION

The area of nanotribology has advanced greatly in the past 17 years with the introduction of scanned probe microscopies<sup>[1]</sup> for the characterization of surface properties.<sup>[2–9]</sup> The ability to probe the details of structure, friction, and adhesion on a local atomic/molecular scale affords a definitive approach for understanding the mechanisms of wear at the most fundamental level. Muscovite mica, a layered aluminosilicate in the form of  $\text{KAl}_2(\text{Si}_3\text{AlO}_{10})(\text{OH})_2$ , has been a suitable standard for atomic force microscopy (AFM)<sup>[1]</sup> investigations of the atomic scale relationship between friction,<sup>[10–26]</sup> adhesion,<sup>[10,13,14,16,23,25,27–31]</sup> and wear<sup>[14–16,23,32,33]</sup> due to the ability to readily generate large areas of atomically smooth surface. The rich solution chemistry of mica, attributed to the Brønsted acid sites  $[\text{Si}-\text{O}(\text{H})-\text{Al}]$  within the basal (001) plane and its alternating sheet structure, combine with the vast atomically flat surface areas created when cleaved, to give a model substrate for examining a variety of phenomena. These include studies of double layer forces,<sup>[28,30,34–40]</sup> van der Waals forces,<sup>[38,41–43]</sup> ion binding and mobility,<sup>[35,44–46]</sup> monitoring the recoil tracks of alpha particles,<sup>[17,47]</sup> the characteristics of polymers at interfaces,<sup>[38,48,49]</sup> and ordering of discrete water layers.<sup>[38,43,50]</sup>

This review will be limited to a discussion on the wear of mica surfaces, with instructive comparisons drawn to other systems. The overall scope and outline of the chapter is detailed as follows.

As the area of nanotribology is too vast for us to cover in this review,<sup>[5,51,52]</sup> we shall endeavor to provide a perspective on studies as related to the mica surface, with a focus on direct observations of charge nucleation and defect formation, further limited to scanned probe microscopy studies. Relevant oxide and inorganic systems that have exhibited behavior paralleling that of mica will also be discussed. We will first begin with a description of the structure and chemistry of the mica surface followed by an overview of the scanned probe methodologies employed in the

investigation of nanotribological properties of mica surfaces. This includes the operating principles of the atomic force microscope (AFM), lateral force (or friction) measurements by AFM, as well as adhesion measurements. Moreover, as one wishes often to quantify such details we will also describe methodologies used to calibrate the signals retrieved from such experiments and then provide a brief description of a standardized approach for the measurement of wear at surfaces, whereby the details of the tip contact area will be explicitly taken into consideration when evaluating the number of scans needed to induce wear at an interface. After describing these approaches, we will then focus on the wear of the mica surface, including the impact of water, and functionalization of the mica surface with alkylsilanes.

## MICA SURFACES

The outermost mica surface typically exposes a hexagonally arrayed pattern of oxygen atoms, with a periodicity of 0.52 nm (Fig. 1A). Mica is comprised of a layered aluminosilicate structure with a periodicity of 1.0 nm normal to the (001) crystal basal plane (Fig. 1B), which is defined by a repeating boundary layer of  $\text{K}^+$ .<sup>[53,54]</sup> The  $\text{K}^+$  ions electrostatically bind the sheets together and act to neutralize the net negative charge associated with the partial substitution of Si with Al (on average one out of every four). It is at these boundaries that cleavage is preferred and is where shearing of the layers most readily occurs. Under aqueous conditions of low electrolyte concentrations, the outermost  $\text{K}^+$  layers are solvated into solution and exchanged with  $\text{H}^+$ .<sup>[19,30,34–36,44,46]</sup> This ready displacement has hindered direct imaging of the  $\text{K}^+$  terminated mica surface. The surface of mica may also be readily functionalized by a range of chemistries. Some of the most popular involve the organization of self-assembled monolayers of triethoxy- or trichloro-derivitized alkylsilanes, which can form densely packed structures on mica.<sup>[20,55–65]</sup> This provides

**Fig. 1** (A) Pictorial representation of the mica (001) cleavage plane showing the 0.52-nm lattice periodicity. (B) Repeating layered structure of mica along the *c* axis with interlayer distances referenced to the basal plane.

a means of investigating lubricant layers as protective barriers for the minimization of friction and wear.

To date, most surface wear studies have focused on the evaluation of surface structure before and after wear,<sup>[15,33,66–71]</sup> thus missing the key stage of the nucleation of defects that ultimately results in the gross structural changes observed. Although some studies have investigated the time evolution of wear using scanned probes,<sup>[14,16,72–77]</sup> the different approaches presented can make it difficult to compare experiments from different laboratories, and a more standardized approach is required. This is in part because of the typically large contact area between the AFM tip and the surface being worn, which frequently exceeds the area density of defects nucleated. Thus, an averaging over the contact renders the low population of defects “invisible” to the probe tip until gross wear has occurred.

Investigations of the wear of oxide surfaces such as mica and silica have unique difficulties when probing wear at the atomic level, which are associated with the chemical complexity of the surfaces, especially in the presence of water<sup>[71,78–87]</sup> where the surface charge density is highly pH dependent.<sup>[66,79–81,88,89]</sup> A recent demonstration by Maw et al. illustrates the incongruous

wear behavior that exists for ceramics in solution (pH = 7).<sup>[32]</sup> Specifically, they found that a Si<sub>3</sub>N<sub>4</sub> tip exhibited pronounced wear after being rastered against a quartz substrate for 25 scans at ~120 nN of force. However, under similar conditions the Si<sub>3</sub>N<sub>4</sub> tip exhibited little wear when the surface was mica. Here the disparity has been attributed to the relevant population of silanol (Si–OH) groups that can form bonds between the tip and substrate, which facilitates removal of tip materials. As the basal plane of mica possesses a Brønsted acid site, because of the 1 in 4 substitution of Si for Al, it is expected that the ionization potential of the surface is largely controlled by this site (at least at lower pH's), and therefore the chemically active Si–O<sup>−</sup> or M–OH should be in minute quantities.<sup>[40,46,65,90]</sup> Because the isoelectric point (IEP) of quartz is between pH 2 and 3, it is apparent that at pH 7 a significant number of Si–O<sup>−</sup> and Si–OH groups are available for condensation at the tip–quartz contact.<sup>[78]</sup> The influence of such tribochemically active species in initiating surface degradation is evident and illustrates the necessity to account for this when choosing material pairs for a given application, i.e., the chemistries should be complementary. This certainly applies to device applications such as microelectromechanical systems (MEMS) where interfacial chemical forces can readily dominate the moving contacts within the device.<sup>[70,91–96]</sup>

The organization of the water molecules<sup>[38,43,50]</sup> and counterions<sup>[19]</sup> immediately at the oxide surface may also impact the evolution of surface defects. Studies of the influence of water on the wear of oxide surfaces show a critical dependence on the amount of water present<sup>[14]</sup> and, in the case of solvation of the surface, the local pH of the surrounding water environment. Much of the wear processes present at oxides can be attributed to the catalytic activity of water (more appropriately the OH<sup>−</sup> ion) on the metal–oxygen and silicon–oxygen bonds present on such surfaces, the details of which have been investigated for many years.

## SCANNED PROBE METHODOLOGIES

### Atomic Force Microscopy: General Methodology

In atomic force microscopy, a sharp tip with a radius of curvature ranging between 10 and 50 nm is scanned over a surface using a piezoelectric translator to control the position of the tip relative to the sample. The forces acting between the tip and sample (these can be van der Waals, electrostatic, or magnetic in nature) act to attract or repel the tip to or from the surface, which in turn alters the bending of the lever to which the tip is attached. In most conventional AFMs, lever

deflections are detected by reflecting a laser beam off the back of the cantilever onto a quadrant photodiode. The photodiode signals are split to allow detection of the normal or torsional motions of the cantilever–tip assembly (Fig. 2). These motions can in turn (when appropriately calibrated, as discussed later) be translated into the normal and lateral forces acting between the tip and surface. The AFM can be operated in several imaging modes, including contact, non-contact/tapping, amplitude, and phase-modulated force or frictional force imaging. For nanotribological studies, contact and frictional force imaging modes are the most frequently used.

In contact mode the tip is brought in contact with the surface until the lever experiences a fixed amount of deflection. Assuming that this amount of deflection stays within a linear limit, then a Hooke's law response can be assumed. If the lever spring constant is known (see below) then the amount of deflection can be converted into the force applied between the tip and surface. During imaging, a feedback loop is then used to maintain a fixed amount of lever deflection (constant normal force) by repeatedly moving the piezoelectric translators up and/or down, hence following the topography of the surface. The lateral force signals are concomitantly acquired with the topographic images allowing for correlations to be drawn between the two. The lateral force signal is an excellent indicator of changes in local chemistry even when obvious topographic differences are not present. For example, the spatial organization of films consisting of both hydrophobic and hydrophilic end-groups, which have the same thickness and appear uniform in topography,

**Fig. 2** Schematic of an atomic force microscope. In this configuration, the tip is scanned over a fixed sample. The cantilever–tip assembly is mounted on a piezoelectric translator, which controls the tip position over the surface. In contact mode, the tip is pressed against the surface until a fixed set point force is reached ( $F_0$ ). The deflection of the lever is detected by a quadrant photodiode from which the normal force ( $F_z$ ) and torsional (frictional) force ( $F_f$ ) may be measured. As the tip is scanned over the surface a feedback loop raises and lowers the tip depending on whether the normal force is larger than or less than the set point force to maintain a constant force.

can be easily distinguished in the frictional images [Fig. 3A (2–3)].

### Lateral Force (Friction and Shear) Measurements

Eventhough qualitative lateral force, or frictional response, can be readily obtained by AFM, quantifying frictional forces can be a daunting task. This is due to the difficulties associated with calibration of the lateral spring constants for AFM cantilevers (see below). Here we briefly discuss the type of information, which may be obtained from lateral force or shear force measurements. In lateral force measurements, friction is assessed using a friction loop. The friction loop is generated from the forward and reverse scans plotting the lateral force data vs. distance (Fig. 3B). Initially, the tip sticks to the surface and the torsional force on the lever increases without the sliding motion of the tip. Once the static friction has been overcome, then the tip will begin to slide over the surface and the sliding friction may be determined (Fig. 3B). The shear modulus of the surface may also be measured using this same basic approach. To evaluate the shear modulus, the tip is oscillated in the scan direction and the slope of the friction force ( $F_f$ ) vs. distance signal is measured prior to sliding. This slope value contains the combined stiffness of the tip–sample contact [Eq. (1)] from which the shear modulus of the surface may be determined.

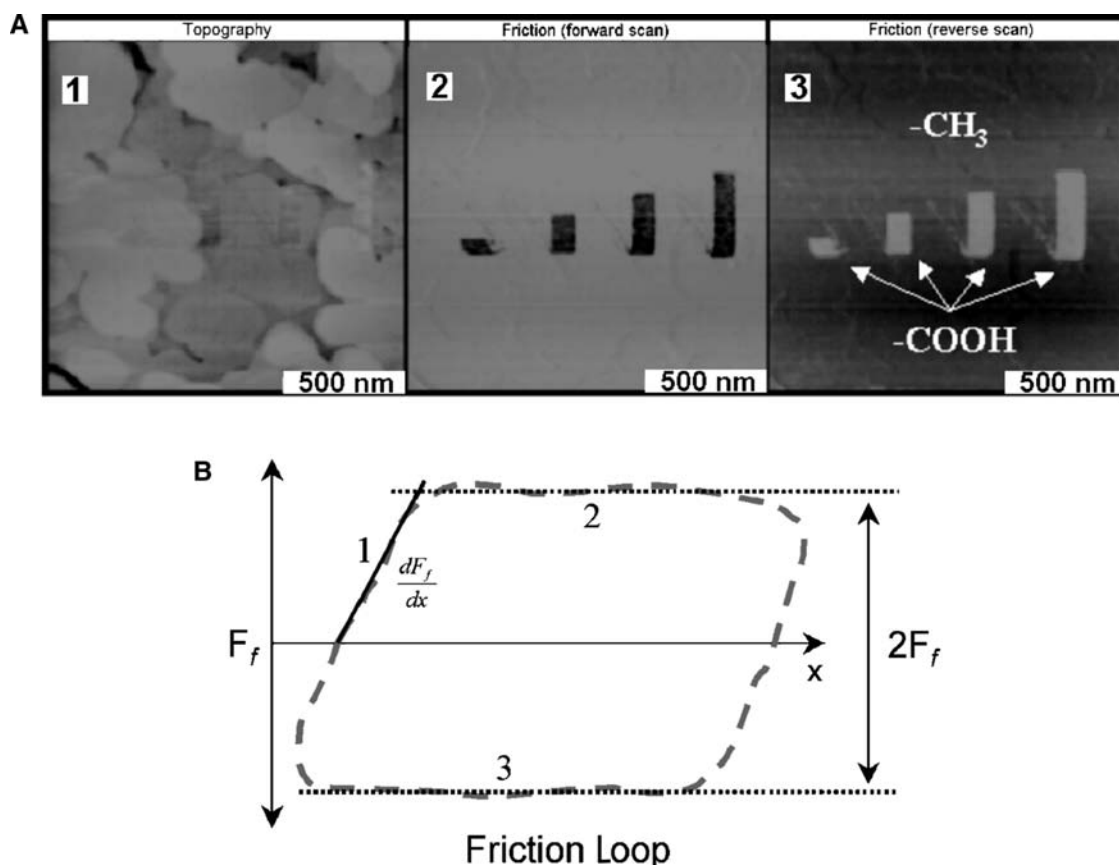

$$\frac{dF_f}{dx} = k_{\text{total}} = \left( \frac{1}{k_{\text{lever}}} + \frac{1}{k_{\text{contact}}} \right)^{-1} \quad (1)$$

A significant advantage of this measurement is that the details of the tip size ultimately fall out of the calculation, removing a potential source of error. The reader is directed to the literature for a more complete description of lateral stiffness measurements.<sup>[97]</sup>

## MAKING QUANTITATIVE MEASUREMENTS

### Calibration of AFM Cantilevers

AFM cantilevers can be bought from numerous sources and most frequently come as V-shaped or rectangular springboard-shaped levers. The levers are generally made from silicon and silicon nitride. Coatings are often applied to enhance the reflectivity of the laser beam. The reflective coating, however, can add strain to the levers when used in vacuum because of heating. The average lever spring constants provided by the manufacturer are often inaccurate and quantitative measurements should not be based on these

**Fig. 3** (A) Topographic (1) and forward and reverse friction images (2, 3) of mercaptoundecanoic acid grafted into a dodecanethiol self-assembled monolayer on Au. Whereas the topographic image shows almost no height contrast in the image because of the near equivalent heights of the two materials, the friction images clearly show the “chemical” contrast of the  $-\text{COOH}$  terminated regions vs. the  $-\text{CH}_3$  terminated regions. (B) Schematic of a friction loop. Initially the tip sticks to the surface (1) until the static friction between the tip and surface is overcome. The tip then enters a sliding friction regime (2). As the scan is reversed, the signal in the photodetector becomes negative (3) and a reverse trace is produced. The “frictional” force is the average of the forward and reverse friction traces. The stiffness of the contact may be deduced from the slope of the friction loop ( $dF_f/dx$ ) before sliding.

values. Therefore, each lever should be independently calibrated, preferably via an in situ methodology.

The determination of lever force constants is less demanding for a rectangular cantilever beam,<sup>[98]</sup> but it still requires non-trivial details of the lever’s dimensions and physical constants, e.g., modulus and Poisson ratio. These details become more difficult to define for metal-coated levers, as the coating significantly modifies the lever’s elastic properties. For a rectangular beam of length  $L$ , width  $w$ , thickness  $t$ , Young’s modulus  $E$ , the stiffness  $k$  is given by:

$$k_{\text{lever}} = \frac{Ewt^3}{4L^3} \quad (2)$$

Errors inherent to the determination of the spring constant come from difficulties in accurately measuring (by SEM) the thickness of the lever. In addition, for chemical vapor deposited silicon nitride levers,

variations in  $E$  can also occur. If a bulk value for  $E$  is used, the thickness can be determined by measuring the resonance frequency of the cantilever.<sup>[99]</sup> However, this method works only for uncoated monolithic cantilevers.<sup>[100]</sup> The formulae for the spring constants for V-shaped levers are much more complicated.<sup>[101]</sup> Uncoated, single-crystal silicon cantilevers are perhaps the best choice for which the force constant can be reliably determined by using Eq. (2) and the resonance frequency.<sup>[102]</sup>

A range of methods for the calibration of the normal<sup>[99–114]</sup> and torsional (lateral) force constants<sup>[101,105,110,115,116]</sup> of AFM cantilevers have been described. A recent method proposed by Sader, Chon, and Mulvaney appears to be reliable and simple to perform for rectangular levers.<sup>[107]</sup> It relies on measuring the resonance frequency and the quality factor of the cantilever in air. Use of the hydrodynamic function relates the damping of the lever resonance by air to the

quality factor, and the dependence of  $E$  and  $t$  are eliminated from the resulting formula for the force constant.

### Probe Tip Characterization

A problem of quite a different nature is an accurate measurement of the AFM tip shape and composition. With respect to tip geometry, continuum mechanics requires a priori knowledge of the probe shape, mechanical properties, and physical dimensions in order for the models to be properly applied.<sup>[117,118]</sup> Carpick et al. illustrated this point rather succinctly in an instructive set of experiments with non-parabolic Pt tips on a mica substrate in ultrahigh vacuum (UHV).<sup>[12]</sup>

There are several in situ methods to characterize the tip shape, where an AFM topographic image is used to deconvolute the tip and sample geometry.<sup>[119–121]</sup> Separation of the tip and sample contributions by contact imaging of known, or at least sharp, sample features allows determination of the tip.<sup>[104,105,120–131]</sup> Ex situ tip imaging by electron microscopy has also been performed.<sup>[103]</sup> Some of these measurements have revealed that a number of microfabricated cantilevers possess double tips and other unsuitable tip structures.<sup>[122,125,130,131]</sup> This demonstrates the importance of tip characterization in nanotribological measurements. Thin film coatings applied to the microfabricated levers can provide robust, smooth, and even conductive coatings.<sup>[132,133]</sup> Further work in this direction would be useful in providing a wider array of dependable tip structures and materials.

Detailed control of tip chemistry is still a difficulty of scan probe studies with commonly used tips (e.g., silicon nitride) possessing a variable stoichiometry.<sup>[89,112,134]</sup> Coating with inert metals (such as Au or Pt) or functionalization with alkylsilanes or alkanethiols is often useful; however, one must be aware of the “chemical” compatibility and how this can translate into “anomalous” wear behavior.<sup>[32]</sup> The chemical composition of the tip is equally important, but is also challenging to determine or control. Qian, Xiao, and Wen have shown that the AFM tip is readily chemically modified when scanned in contact with various materials,<sup>[25]</sup> even tips that have been coated with self-assembled monolayers to control their chemistry. They recommend “running in” the tip with a standard sample to give reproducible results. The stresses that take place in a nanocontact can be very large, and so modification of both the chemistry and structure of the tip is an important consideration.

### Adhesion Measurements

When quantifying adhesion and interfacial energies from AFM measurements, often the contact mechanics

model developed by Johnson, Kendall, and Roberts (JKR)<sup>[118,135]</sup> is used to analyze adhesion data from force–distance spectroscopy. Determination of the most appropriate continuum mechanics model to use, however, requires consideration of the range of forces and the materials operative at the contact. The JKR model is often applied to highly adhesive, compliant contacts, whereas the Derjauin–Müller–Toporov (DMT) model relates to stiff, weakly adhering contacts.<sup>[117,136]</sup> Attention has been given to identifying which model is most appropriate and therefore best describes the contact for a given material pair; the reader is directed to the references for the complete treatments.<sup>[135–138]</sup> The application of such models to AFM force of adhesion measurements ( $F_{adh}$ ) enables the number of interacting species (and consequently the average “unit” interaction force or energy) to be derived from the estimated contact area and the average molecular packing density. Using the JKR model, one can see that the  $F_{adh}$  (AFM pull-off force) is related to the work of adhesion,  $W_{adh}$ , and the reduced radius,  $R$ , of the tip–surface contact:

$$F_{adh} = -\frac{3}{2}\pi RW_{adh} \quad (3)$$

The work of adhesion, a formalism of Dupré from 1869, is a combination of the tip–surface ( $\gamma_{ts}$ ), tip–solvent ( $\gamma_{tl}$ ), and surface–solvent ( $\gamma_{sl}$ ) interfacial energies ( $W_{adh} = \gamma_{sl} + \gamma_{tl} - \gamma_{ts}$ ). For tip–surface combinations that have the same chemical composition, the surface energy may be estimated directly from the adhesion measurement ( $W_{adh} = 2\gamma_{sl}$ ) because  $\gamma_{sl} = \gamma_{tl}$ , with  $\gamma_{ts} = 0$ . Furthermore, the effective contact radius at separation,  $r_s$ , from the JKR model is given as:

$$r_s = \left( \frac{3\pi W_{adh} R^2}{2K} \right)^{1/3} \quad (4)$$

where  $K$  is the reduced elastic modulus of the tip and surface. Using the contact area at separation and the assumed packing density of the molecules at the surfaces in contact, an estimate of the adhesion force or interaction energy on a per molecule basis can be made.

The accuracy of the interfacial energies and per molecule values obtained with this approach must be carefully evaluated, as several sources of error exist in the various elements of the calculation. These include imprecise knowledge of the contact, including the tip radius, packing densities of molecular monolayers on the modified surfaces, as well as unknown elastic properties of the contact. Such properties are typically assumed to be dominated by those of the underlying substrate, and the bulk values of the surface and/or tip materials (Au, Si, mica,  $Si_3N_4$ ,

SiO<sub>2</sub>) are often used in these calculations.<sup>[59–61,139]</sup> Moreover, as mentioned earlier, if the molecular packing densities of the monolayers being evaluated are not known (as is frequently the case with a typical AFM tip), then estimations must be used.

### Watching Wear with the AFM (How Many Scans Does It Take?)

Atomic force microscopy tips, acting as single asperities, have proven indispensable in actively mediating the transition of a substrate surface from its native state to the defect nucleation regime (rupture of terminating surface bonds) and finally to the molecular-fragment abstraction (gross wear) regime.<sup>[14,73–77,140–142]</sup> Unifying empirical evidence pertaining to the intimate details of defect nucleation is essential to properly aid the current effort of wear map modeling on the micro- and macroscopic scales, situations with multiple asperity contacts, and a multitude of wear mechanisms operating in concert.<sup>[51,143]</sup> To ease comparison of data compiled from numerous research facilities within the field, guidelines outlining the optimal experimental protocol for an SPM study are desirable. Recent developments in modeling tip-activated dissolution of calcite and brushite by Dickinson et al. has given impressive results and holds promise for evaluating other “model” systems.<sup>[74–77]</sup> Salmeron and Kopta have recently used a model, similar to the one adopted by Dickinson et al., in their studies of tip induced mica surface degradation under low vacuum with variable humidity.<sup>[14]</sup> In this work, the objective was to evaluate the critical defect density necessary for the onset of gross surface degradation (abstraction of the surface terminating SiO<sub>3</sub> molecular fragments). The progressive layer removal illustrated the fidelity of inducing defects; however, linear regression analysis obtained a collected physical constant ( $B_0$ ) that was appreciably higher than anticipated. This could be attributed to scan overlap, which can lead to significant additional history of unintentional wear on the surface.

Here we outline a strategy for conducting wear trials with AFM, based on the Hertzian theory of *elastic* contacts,<sup>[144]</sup> to account for the degree of scan overlap in AFM wear trials, and arrive at an interesting *contact radius–line step* (CRLS) relationship.<sup>[145]</sup> This approach is intended to 1) account for additional scan history that line-scan overlap imparts to a surface and to experimentally quantify the impact of this overlap on the propagation of defects; 2) eliminate the systematic error in reported scan history (experimental number of scans,  $N_{\text{scans}}^{\text{Exp}}$ ) for wear trials performed with line-scan overlap; and 3) examine previous load ( $F_z$ ) and frequency ( $N_{\text{scans}}^{\text{Exp}}$ ) studies to reevaluate activation parameters for defect nucleation. Furthermore, the

extent of wear can be predicted with application of CRLS analysis for *paired* overlap and non-overlap wear trials, giving a unique perspective of the fundamental kinetics and thermodynamics of defect nucleation and growth.

### Contact Radius–Line Step Analysis

A brief description of CRLS analysis follows with a focus on its application rather than on the details of its derivation. A comprehensive discussion of CRLS model and experiments is described elsewhere.<sup>[145]</sup> First, consider the general case of obtaining an AFM micrograph or performing a wear trial. In either instance, one of many parameters set during image acquisition is the image resolution (res), the number of lines scanned per image. Typically, it is adjustable within the range of 8–1024 lines/image, depending on the design specifications of the microscope used. Although it is not generally thought of as an adjustable parameter for use in experimentation, it is readily illustrated that res can play an important role when assessing the number of scans required to induce wear. Its importance arises because res dictates the magnitude of the line step (LS), i.e., the distance the tip moves in the slow scan ( $L_{\text{sscan}}$ ) direction after each forward–reverse trace. Fig. 4 illustrates the inverse relationship between LS and res for the specified slow scan lengths ( $L_{\text{sscan}}$ ). Before we show how LS ties into defect production, we introduce the Hertzian definition of the contact radius ( $a$ ) as defined for an AFM tip compressed against flat elastic body without adhesion [Eqs. (5) and (6)].<sup>[118]</sup>

$$a = \left( \frac{3RF_z}{4\varepsilon} \right)^{1/3} \quad (5)$$

with

$$\varepsilon = \left( \frac{1 - \nu_1^2}{E_1} + \frac{1 - \nu_2^2}{E_2} \right)^{-1} \quad (6)$$

Here  $R$ ,  $F_z$ , and  $\varepsilon$  are the tip radius of curvature, the applied normal force, and the combined elastic modulus given in terms of the individual tip and substrate Poisson ratios ( $\nu_i$ ) and Young's moduli ( $E_i$ ). It is apparent that at a typical res of 256 lines/image, the LS is <4 nm for all  $L_{\text{sscan}}$  below  $\sim 1 \mu\text{m}$  in length. Thus, unless  $a \leq 2 \text{ nm}$ , overlap from successive scans will occur, and shows that avoidance of scan overlap and its effects are difficult to realize when probing regions with nanoscopic dimensions.

If we make the assertion that ideal scanning conditions for assessing wear as a function of the number of scans requires imaging conditions with no scan

Fig. 4 Inverse relationship between image line step (LS) and image resolution (res) for several slow scan lengths  $L_{scan}$ . The dashed line and accompanying shaded region illustrate the occurrence of scan overlap during AFM imaging for contacts with a contact radius  $a \geq 2$  nm. For wear trials this implies that scan overlap will systematically contribute unaccounted attempts to defect production.

overlap, it is recognized that the line step (LS) must be greater than or equal to the contact diameter. Using the Hertz definition of  $a$  and the condition that ideal AFM wear trials have  $LS = 2a$ , the ideal ratio of contact radius to line step (CRLS) is 0.5. Furthermore, line-scan overlap is avoided (neglecting drift) when CRLS is  $\leq 1/2$ . This further implies that an ideal AFM wear trial, with  $LS = 2a$ , will have an ideal slow scan length,  $L_{scan}^{CRLS}$ , given by Eq. (7). Expression (7) reveals an important relationship between the AFM scanning parameters,  $L_{scan}^{CRLS}$  and res, and the applied normal load. A  $L_{scan}^{CRLS}$  vs.  $F_z$  plot is especially useful for conducting internally consistent load ( $F_z$ )-dependent studies.

$$L_{scan}^{CRLS} = 2a \times res = res \times \left(\frac{6RF_z}{\epsilon}\right)^{1/3} \quad (7)$$

We have used the term “ideal” quite ambiguously to describe  $L_{scan}^{CRLS}$ , the most appropriate scan size for defect generation. It is expected and empirically validated that the generated defects will be more uniformly (relative to overlapping trials) distributed over the wear area before the advent of other varieties of defects. This allows for the design of experiments to probe these low-density species (typically <1 defect within the tip-sample contact).<sup>[14]</sup>

To evaluate the effects of scan overlap we must account for the additional history overlap imparts to the surface; achieved by estimating a scan correction

( $scan_{cor}$ ) for overlapping studies. The  $scan_{cor}$  determines the additional number of scans contributed by overlap to the contact history and therefore can be used to estimate the number of scan cycles required to achieve an equivalent degree of wear, under identical loads, without scan overlap. The  $scan_{cor}$  is arrived at naturally by association to the force of overlap within overlapping contacts. The Hertz model defines the pressure distribution  $p(r)$  in terms of  $r$ , the distance from the center of contact via Eq. (8).<sup>[144]</sup>

$$\begin{aligned} F_z &= \int_0^{2\pi} \int_0^a p(r) r dr d\theta \\ &= \frac{1.5F_z}{\pi a^2} \int_0^{2\pi} \int_0^a \left(1 - \frac{r^2}{a^2}\right)^{1/2} r dr d\theta \\ &= \frac{2p_0\pi a^2}{3} \end{aligned} \quad (8)$$

Here  $p_0$  is the maximum Hertz pressure within the contact. Once the boundary of the overlapping area is defined (Fig. 5), the force of overlap can be calculated. The  $scan_{cor}$  is collectively calculated in terms of  $F_{ovlp}^{Total}$ , the total force within all successive overlapping contact areas.  $F_{ovlp}^{Total}$  is formulated from a geometric breakdown of overlapping circles of radii  $a$  (Fig. 5) and leads to the three integrals in Eq. (9), which have been converted to Cartesian coordinates. The  $(F_z \times res)$  term normalizes each experimental scan and the functions A, B, and C are given in Fig. 5.

$$\begin{aligned} scan_{cor} &= 1 \\ &+ \frac{2 \times \sum_{m_1}^{m_i} \{res - m_y\} \left(\frac{1.5F_z}{\pi a^2}\right) \left[ \int_0^{a \sin(\theta)} \int_0^{\sqrt{a^2-x^2}} p(x,y) dy dx - \int_A^{a \sin(\theta)} \int_0^B p(x,y) dy dx + \int_0^C \int_0^{-B} p(x,y) dy dx \right]}{res \times F_z} \end{aligned} \quad (9)$$

**Fig. 5** Geometry of overlapping scans according to Hertzian contact mechanics theory.

The center-to-center distance ( $\Delta_y$ ) along the slow scan axis for successive scans is referenced to the first scan line ( $n_0 = 0$ ) and is known a priori;  $n_y$  is a positive integer corresponding to the  $n$ th line step from  $n_0$

as shown in Fig. 6. The series is truncated at  $n_i$  ( $n_i = 2a/LS$ ) because overlap does not exist for the  $i$ th successive scan where  $\Delta_i \geq 2a$ . For simplicity, the summation is redefined in terms of  $m_y$  having an integer range of  $[m_1, m_i]$  with  $m_i = n_{i-1}$  because the 1 in Eq. (9) accounts for  $n_0$ . For the interested reader, more details on the theoretical workup can be found in Ref.<sup>[145]</sup>. We can now utilize the general, material independent result [ $scan_{cor}$  given in Eq. (10)] to explore how CRLS analysis is applied to previous wear trials with mica.

$$scan_{cor}(\theta, m_y) = 1 + \sum_{\theta(m_1)}^{\theta(m_i)} \left[ \frac{res - m_y}{res} \right] \times \left( 1.011 \exp \frac{-(\theta - 92.83)^2}{34.67^2} \right) \quad (10)$$

Completing the correction simply requires multiplying the experimental number of scans containing overlap ( $N_{scans}^{Exp}$ ) with  $scan_{cor}$  ( $scan_{cor} \times N_{scans}^{Exp} = N_{scans}^{Cor}$ ). Importantly, CRLS can be tested directly because it can predict wear for “paired” trials. In such circumstances, an experimental trial with overlap is taken as the primary trial from which the CRLS prediction and the secondary non-overlapping experiments are based. Experimentally, the secondary trials are conducted at a Hertz mean pressure ( $p_m$ ) equivalent to the primary run over a region with  $L_{sscans}^{CRLS}$  defined by Eq. (7). Therefore, the non-overlapping secondary wear trials

**Fig. 6** Definition of elements used for  $scan_{cor}$  analysis of sequential raster lines.

consist of  $N_{\text{scans}}^{\text{cor}}$  over a  $(L_{\text{sscans}}^{\text{CRLS}} \times L_{\text{fscan}})$  nm<sup>2</sup> region. The surface damage from both instances can be evaluated and compared with  $F_{\text{adh}}$  measurements, topography, and frictional force microscopy. In theory, the two wear experiments have “identical” scan history within this Hertzian approximation. Deviations from CRLS behavior are expected, however, because the tenets of elastic contact mechanics do not include inelastic energy dissipation pathways natural to a wearing contact. Numerical and experimental results clearly demonstrate that the systematic error attributed to scan overlap is considerable and affects fundamental wear processes acting at the tip–surface contact.<sup>[145]</sup> Work is currently under way to establish the relationship between scan overlap and defect nucleation and growth.

## WEAR OF MICA SURFACES

There have been many theoretical and experimental studies on wear of oxides and the generation and propagation of defects within condensed matter. Here we shall describe a few examples of crystalline systems within the context of tip induced defect nucleation and wear of mica surfaces in solution. The examples will focus on studies of defect nucleation that have revealed the prototypical behavior of what is to be expected (and what is detectable with AFM) of a surface reconstructing under the influence of an AFM tip. At the most fundamental level of defect nucleation, this includes *terminal* surface bond rupture for covalent systems as well as removal of ions from ionic surfaces.

### Native Mica Surfaces

Now we will briefly describe adhesion and wear of mica surfaces using silicon-nitride-based AFM tips. The complete experimental details are described elsewhere.<sup>[142]</sup> In these studies, oxidized and hydroxylated silicon nitride tips were used.<sup>[102,122]</sup> Under these conditions, the silicon nitride tip chemistry then varies with pH similar to that of silica,<sup>[146]</sup> where a neutral silanol-covered surface exists at the isoelectric point between pH 2 and 3, with a gradual surface charge increase via the formation of an anionic surface species with increasing pH ( $\sim 0.004\text{--}2$  charges/nm<sup>2</sup>) over the range of pH 3–10.<sup>[66,78]</sup> In aqueous solution, the adhesive force ( $F_{\text{adh}}$ ) vs. pH for native mica with an oxidized and hydroxylated silicon nitride tip is shown in Fig. 7. This pH dependence on adhesion is similar to that found for silica surfaces under the same conditions, with a shift in peak adhesion from pH  $\sim 4.5$ , for silica/silica, to pH  $\sim 6$  for the silica/mica interaction.<sup>[66]</sup> Based on this profile, alterations

**Fig. 7** Mean  $F_{\text{adh}}$  vs. pH for muscovite mica with a  $\text{Si}_3\text{N}_4$  tip. Error bars correspond to the first standard deviation from the  $>180$  force distance curves collected for each point.

in adhesion, friction, and topography under various loads for three pH ranges (pH 2–3, 5–6, and  $>8$ ) can be assessed and related to the interfacial chemistry.

Typical of silicates, for the highest pH conditions (pH  $\geq 8$ ), the mica surface undergoes rapid wear.<sup>[78–81,85]</sup> Even under low loads (Hertz mean pressure,  $p_m \sim 1.2$  GPa) wear scars 0.22 nm in depth are formed. With additional scans ( $>10$ ) wear scars of 1.0 nm or more are rapidly formed (Fig. 8). Upon removal of a single repeat layer (1.0-nm-deep feature), the friction in the wear scar is equivalent to that of the contiguous unworn mica surface, indicating that we have progressed from the outermost oxygen-terminated layer to the next chemically equivalent repeat layer. This is a general observation for mica wear at any pH and has also been observed by Salmeron et al. under humid conditions.<sup>[14,16]</sup> Comparison of the threshold forces for removal of the  $\text{SiO}_3/\text{AlO}_3$  tetrahedral layer, i.e., generating 0.22-nm wear scars, illustrates the tribochemical influence hydroxide ions have on hydrolysis of surface bonds. Table 1 summarizes the threshold pressures and the ab initio calculated activation energies ( $E_a$ ) for water, acid, and base-catalyzed Si–O–M hydrolysis.<sup>[147,148]</sup> Once the  $\text{MO}_3$  (M=Si or Al) basal fragment is removed, the underlying aluminate (gibbsite) layer is exposed and should carry a net positive charge for pH  $\leq 10$ .<sup>[149,150]</sup> This is another “model” property of mica and the details on how this affects the tip–sample contact during friction imaging can be found in Ref.<sup>[142]</sup>

Conducting wear trials at pH 5 under lower loads ( $p_m \sim 0.74$  GPa; ca.  $\frac{1}{2} p_{\text{thresh}}$ ), the surface friction in the imaged region is observed to *decline* (Fig. 9A) relative to the unworn surface, before any noticeable wear (topographical) on the nanometer scale. This decrease in friction can be attributed to the accumulation

**Fig. 8** Topographic AFM images of a worn mica surface at pH 8 and the corresponding line trace across the surfaces showing both 1.0- and 0.22-nm wear regions.

of negative surface charge both on the tip and at the imaged surface through  $\text{OH}^-$  insertion into strained Al–O–Si and Si–O–Si bonds, yielding surface anions, such as siloxy ( $\text{Si-O}^-$ ) groups.<sup>[83,86]</sup> Analysis of the

**Table 1** Threshold pressures for mica wear under solution conditions, and ab initio calculated activation energies ( $E_a$ ) for acid-, base-, and  $\text{H}_2\text{O}$ -catalyzed hydrolysis

Conditions	$p_{\text{thresh}}^{[148]}$ (GPa)	Hydrolysis activation energy ( $E_a$ , kcal/mol)
Mica wear pH 3	2.1	–
Mica wear pH 5	1.5	–
Mica wear pH 8	1.2	–
Si–O–Si (OH catalyzed)	–	2–8 <sup>[148]</sup>
Si–O–Al ( $\text{H}^+$ catalyzed)	–	16 <sup>[147]</sup>
Si–O–Si ( $\text{H}^+$ catalyzed)	–	24 <sup>[147]</sup>
Si–O–Al ( $\text{H}_2\text{O}$ catalyzed)	–	26 <sup>[147]</sup>
Si–O–Si ( $\text{H}_2\text{O}$ catalyzed)	–	29 <sup>[147,160]</sup>

Threshold pressures ( $p_{\text{thresh}}$ ) were calculated with Hertz continuum mechanics theory.  $p_{\text{thresh}}$  corresponds to the gross deformation (abstraction) regime that is defined by removal of  $\text{SiO}_3$  and  $\text{AlO}_3$  basal tetrahedral units.

surface topography reveals a discernible increase by  $\sim 0.05$  nm (Fig. 9B), which is near the noise-level limit of  $\pm 0.03$  nm. This height increase would be consistent with capping of the surface dangling bonds by  $\text{OH}^-$  and  $\text{H}^+$  as the bonds are ruptured. Adhesion measurements, as summarized in Table 2, within the native and worn (“induced”) region show a marked shift to lower adhesive forces for the worn surface, which is expected for the proposed repulsive tip–sample interaction.

Although not a common observation, several groups have reported surface charging with little to no topography changes during wear experiments. Using the nanoscale Kelvin probe, capable of measuring variations in surface potential (work function mapping), DeVecchio and Bhushan have observed electron-deficient regions within the “zero-wear” regime for single-crystal aluminum under ambient conditions ( $\text{RH } 45 \pm 5\%$ ).<sup>[73]</sup> The topography and potential maps are given in Fig. 10 and illustrate the charging effect before catastrophic failure of the

**Fig. 9** Friction (A) and topography (B) cursor profiles of the native and worn mica surface following defect nucleation (charging) of a  $(400 \times 400) \text{ nm}^2$  region under pH 5 conditions. The friction and topography profiles, respectively, indicate that the worn surface has become *negatively* charged and has *expanded* in height by  $\sim 0.05$  nm with respect to the unworn (neighboring) mica surface.

**Table 2** Tribological properties of mica and halide crystals

Specimen	Anion radius (nm)	Native periodic (nm)	Reconstructed periodicity (nm)	Nucleation height (nm)	$F_{adh}^{Induced}/F_{adh}^{Native}$	$F_f^{Induced}/F_f^{Native}$
Mica <sup>a</sup>	–	0.52 <sup>b</sup>	0.3	$\leq 0.05 \pm 0.03$	0.38–0.75 <sup>c</sup>	0.74–1 <sup>c</sup>
KF <sup>d</sup>	0.136	0.378	–	$0.2 \pm 0.03$	0.98	2.3
KCl <sup>d</sup>	0.181	0.445	–	$0.04 \pm 0.02$	0.93	1.79
KBr <sup>d</sup>	0.195	0.467	–	$< 0.02$	0.94	1.24

<sup>a</sup>From Refs.<sup>[142]</sup> and <sup>[145]</sup> with topography, friction, and adhesion data corresponding to the defect nucleation regime.

<sup>b</sup>For micas (001) crystal plane;  $F_{adh}^{Induced}/F_{adh}^{Native}$  is the ratio of force of adhesion measurements within the wear-induced region to the native surface;  $F_f^{Induced}/F_f^{Native}$  is the force of friction ratio of measurements within the wear-induced region to the native surface.

<sup>c</sup>Depends strongly on pH and the extent of surface charging.

<sup>d</sup>From Ref.<sup>[141]</sup>.

surface.<sup>[73]</sup> While studying the frictional properties of halide crystals (KF, KCl, and KBr) in UHV, Carpick et al. observed the evolution of “mysterious” high-friction regions for all crystal surfaces on AFM imaging. Table 2 provides a summary of the tribological properties of mica and the halide crystals. An interesting characteristic of the halide systems is that for KBr the increased friction was not accompanied with a change in topography; however, topographic contrast on the order of 0.2 nm was found to simultaneously occur for the KF crystal. It is believed that “defects” are triggered by the AFM contact; however, it is not clear why localization of the high-friction regions occurs and why the high- and low-friction regions have nearly identical adhesive forces. Further experiments are needed to address these questions and will be valuable contributions toward bridging simulation and experiment.<sup>[151–153]</sup>

**Fig. 10** Topography (left) and surface potential (right) micrographs of single-crystal aluminum postwear trial under low loads. Although very little topographic contrast is present, the surface potential detects an electron deficient domain (bright central region) corresponding to the nucleation regime, i.e., pregress deformation of the surface. Source: From Ref.<sup>[73]</sup>.

For mica, under pH 5–6 imaging conditions, the tip induced surface charges have a temporal stability between 10 and 45 min, depending on the number of subsequent scans. Lattice-resolved images within a charged region, even with negligible topographic and friction contrast, portray a transforming mica lattice with two lattice constants. One periodicity corresponds to the native surface (0.52 nm) whereas the other corresponds to the defective, reconstructed surface (0.3 nm). This transition has been monitored in situ by scanning at a load  $\sim 75\%$  of the threshold force for SiO<sub>3</sub> abstraction. Exemplary friction micrographs of an in situ reconstruction, at pH 5 and under a load of 9 nN ( $p_m$  of 1.25 GPa), are given in Fig. 11. The progression from the 0.52- to the 0.3-nm periodicity (Fig. 11) provides explicit evidence as well as a characteristic structure of the metastable “nucleation” wear regime before the advent of gross deformation. An additional benefit of this in situ reconstruction is the ability to observe the transition regime, where a mixed population of the two discrete surface species are observed.<sup>[142]</sup> Such information may find applications in calculating the kinetic parameters of the reconstructing surface.

The lattice-resolved reconstruction clarifies that the change in the observed structure at the outermost surface is due to scission of the surface Si–O–Si and Al–O–Si bonds, along with the concomitant insertion of OH<sup>−</sup> and H<sup>+</sup> to terminate the surface. Appearance of the 0.3-nm lattice is intriguing, however, because AFM only gives a characteristic periodicity. The origin is difficult to assign unequivocally, although a simple geometric argument correlates well with AFM results.<sup>[142]</sup> There are interesting corollaries to work on high-silica zeolites,<sup>[83]</sup> silica,<sup>[154]</sup> cristobalite,<sup>[155]</sup> and kaolinite<sup>[156]</sup> that lend support to our current interpretation of the reconstruction; that is, hydrogen bonding is contributing significantly to the stability of the reconstructed surface.<sup>[156]</sup> For instance, Koller et al. have examined the siloxy–silanol (SiO<sup>−</sup> ··· HOSi) defect interaction in high-silica zeolites and found that

**Fig. 11** Frictional force images of in situ tribochemical surface reconstruction of the native mica lattice from a 0.52- (left) to a 0.3-nm (right) periodicity under the local stress of an AFM tip. The 2-D FFT inserts clearly illustrate the lattice reconstruction. This progression occurs over several scans and leaves no wear of the surface.

six-member rings are able to form stable conformations with multiple defects.<sup>[83]</sup>

For the lowest pH conditions ( $\text{pH} < 3$ ), wear of the surface is inhibited even though the surface is still immersed in water. In fact, the surface shows no wear under *identical loads* with over 8 times the number of scans required for wear at pH 5–6. Clearly, this is because of insufficient amounts of  $\text{OH}^-$  in the water to catalyze the Si–O–Si or Al–O–Si bond scission needed to initiate wear. Only after the load is increased to 23 nN ( $p_m \sim 2.1$  GPa) is any noticeable wear observed (in the limit of 10 scans). Interestingly the threshold force of  $\sim 70$ – $80$  nN ( $p_m \sim 2.25$  GPa), previously determined by Kopta and Salmeron with monolayer coverage of water on mica, is consistent with the range of our determinations in acidic solutions.<sup>[14]</sup>

Comparing the surface wear at pH 3, 5–6, and 8 (Table 1) shows that load (the local stress field) plays a more significant role under conditions where the  $\text{OH}^-$  concentrations are the lowest. Again, this is justified by the necessity to strain the bridging oxygen bonds more and induce cleavage in the absence of  $\text{OH}^-$  mediated bond scission. The critical load for this transition must then be linked with the minimum stress needed to facilitate bond scission in the presence of a particular  $\text{OH}^-$  concentration.

A brief comparison of mica wear<sup>[14,16,142,145]</sup> to the tip induced dissolution of calcite is instructive because there are distinct differences between these two systems. Dickinson, et al.<sup>[74–77]</sup> have elegantly explored calcite and brushite dissolution in supersaturated solutions with AFM. They have found strong correlations between theoretical and experimentally determined activated volumes and realistic activation energies using a relatively straightforward model. Application

of a similar model to mica has had some difficulties with agreement between empirically fitted material constants and their “known” values.<sup>[14]</sup> There is a fundamental difference between mica and calcite that may be limiting the model’s success. The basal mica plane is a covalent network of bridging oxygen bonds, which require scission in order for defect nucleation to occur. On the other hand, the nucleating stage for calcite (an ionic crystal) involves the displacement of individual surface ions into solution (separating ion pairs). As demonstrated by Dickinson, calcite wear does not exhibit a critical load where dissolution suddenly begins (Fig. 12). This is in stark contrast to mica, where in UHV and under  $3 \leq \text{pH} \leq 8$  conditions, a critical threshold pressure is observed, thus indicating that mechanical stress accounts for a significant portion of the energy required to cleave the surface bonds, and comparisons between the two systems should be conducted with caution, especially relating to adaptation of models.

### Mica Surfaces Functionalized with Alkylsilanes

There have been few frictional studies of modified mica surfaces by AFM. Alkylsilanes in the form of triethoxy- or trichlorosilanes can form mono- and multilayers on the mica surface. The formation of monolayers of alkylsilanes on mica and silicon surfaces has been heavily investigated especially for use as potential lubricant and protectant films in MEMS devices.<sup>[92,93,96,157,158]</sup> Unlike reactions of alkylsilanes on hydroxylated silicon surfaces, alkylsilane monolayers on mica do not form covalent bonds to the substrate, but rather become organized via an interconnected network of –Si–O–Si– linkages between

### Wear Track Growth Rate vs Contact Force During Repeated Linear Scanning

**Fig. 12** AFM scanning induced wear track growth of calcite as a function of applied load. Notice the absence of a critical load for dissolution, indicating the growth is reaction limited. This is unlike mica, which exhibits a threshold force in the abstraction regime for removal of  $\text{SiO}_3$  molecular fragments. *Source:* From Ref.<sup>[77]</sup>.

nearest neighbors. This produces monolayers with relatively lower packing densities as compared to other alkane-based SAMS such as alkanethiols on Au.<sup>[159]</sup> A key difficulty in the formation of alkylsilane monolayers is the precise control over the amount of water present during film formation. Sufficient water is required to carry out the condensation reactions on the surface for monolayer formation without inducing the production of micelles among unreacted alkylsilanes. Long-range ordered structures are in general not observed for alkylsilane films on mica surfaces.

Wear of the mica surface is inhibited by the presence of an alkylsilane film. The friction response of the surface, however, is highly dependent on the amount of water present in the environment during wear. The presence of water above 50% relative humidity rapidly increases the friction as a function of load, much as it does for the native mica surface as described above.<sup>[61]</sup> This impact of water on the frictional properties of the nominally hydrophobic coated surface clearly shows

that defects within the films can provide sufficient access of water to the underlying surface–film interface to catalyze film breakdown even under relatively low loads ( $\sim 10$  nN) as compared to the wear of the native surface ( $\sim 75$  nN).

## CONCLUSION

The area of nanotribology of oxides and the probing of defect nucleation at the atomic level by AFM is just beginning. Continuing developments in AFM technology via enhanced non-contact methodologies is advancing the ability of the AFM to probe even single atomic defects at crystal surfaces on non-conducting substrates. In this entry we have described how detailed control of the imaging environment and of the chemistry at the tip and sample surfaces can allow for atomic-level details of defect nucleation to be assessed and probed in situ before the onset of gross wear. This has permitted examination of tribochemically and mechanically enhanced wear processes of mica to be explored. We have also outlined a methodology for assessing the scan history dependence on wear of surfaces. Many avenues of oxide wear and charge nucleation at surfaces are unexplored and deserve attention, including the impact of temperature on wear at the nanoscale.

# Micro- and Mesoporous Nanomaterials: Catalytic Properties

Johannes A. Lercher

Andreas Jentys

*Institut für Technische Chemie, Technische Universität München, Garching, Germany*

## INTRODUCTION

Micro- and mesoporous materials are unique materials having found widespread use as solid catalysts or catalyst components in areas ranging from petroleum refining to the synthesis of intermediates and fine chemicals. The reasons for the widespread use are related to the possibility to tailor the concentration and nature of catalytically active sites and their immediate environment, which allows controlling the nature of catalytically active sites and the access of molecules to these sites. Such strict control of access is only found in enzymes and similar biological catalysts, but has the inherent disadvantage that it restricts the size of molecules to be converted.

The materials are also special, because they may be nanostructured with respect to the pore diameters<sup>[1]</sup> and with respect to the overall size of the particles.<sup>[2,3]</sup> This may induce interesting properties, which are hardly explored at present. Nearly all solids with a high specific surface area contain micro- and mesopores, most of them being irregular arrays of void space defined by coalescing primary particles and voids generated upon the transformation of material precursors to the final material. The present entry will only discuss materials with regular pore structure, either being fully crystalline (zeotype materials) or showing at least significant long-range ordering (mesoporous materials).

## OVERVIEW

The pores of micro- and mesoporous materials range from a few tenths of a nanometer to pores with diameters of more than 10 nm.<sup>[4]</sup> The confinement of that surface represents the inverse of effects sometimes observed with solid materials of nanoscopic dimensions. As the largest fraction of the atoms in nanoparticles consists of surface atoms, the properties of nanomaterials are, among other effects, determined by the surface free energy and termination effects. In contrast, in crystalline microporous materials all atoms and, hence, also the pores are part of the crystalline structure.

This leads to the high thermal stability such porous materials have,<sup>[5]</sup> while solid nanoparticles tend to

reduce their free surface energy by coalescing and growing into larger entities. The stability originates from the thermodynamic stabilization by periodicity,<sup>[6]</sup> which indicates in consequence that the stabilization decreases with the size of the coherent domains.

Micro- and mesoporous materials act as catalysts by offering new reaction pathways via binding at least one of the reacting partners to an active site and/or increasing the concentration of reactants in a fraction of the total reaction volume. Thus, in addition to the nature of the solid material, three main processes have to be qualitatively and quantitatively described for understanding catalysis, i.e., the transport to and from the catalytically active sites (leading, for example, to shifts in the selectivity), the sorption and desorption at the active site (including preferential sorption and the relation between sorption in the pores and localized adsorption) and finally the transformation of the reacting molecules in the surface chemical reactions. All three processes may be distinctly different in micro- and mesoporous materials compared to processes at open surfaces, as the size of the molecules approaches the size of the material pores. The complexity of these problems receives only a sketchy treatment in this entry. The description will be primarily confined to microporous materials, because of their industrial importance. Whenever possible, reference will be made to more in-depth reviews on particular properties of the materials discussed.

## STRUCTURAL AND CHEMICAL PROPERTIES OF MICRO- AND MESOPOROUS MATERIALS

Crystalline microporous materials are characterized by structurally well-defined voids, whose diameters exceed typical atomic dimensions. The fact that a molecule has to be able to access these pores puts a lower limit to the pore diameter of approximately 0.25 nm. If these voids are below 2 nm in diameter the material is called microporous, above mesoporous (with an upper limit of approximately 50 nm). It should be noted that in mesoporous materials the pores are also periodically arranged; however, the confining material is typically amorphous.

**Fig. 1** Examples for zeolite building blocks and one-, two-, and three-dimensional zeolite structures (T atoms are shown in orange, O atoms in red).

The crystalline materials may be of an inorganic or organic nature. Typical examples are zeolites and related tectosilicates for the inorganic materials<sup>[7]</sup> or cyclodextrine-type materials<sup>[8–10]</sup> and metal–organic frameworks.<sup>[11–13]</sup> Throughout this review, zeotypes (zeolites or aluminum phosphates) will be used as the examples to describe the interactions and catalytic actions. However, when the varying chemistry of the framework materials is kept in mind, the results can be extended to wide variations with respect to metal oxides/phosphates/sulfides or to (metal) organic entities.<sup>[14]</sup>

Common to zeolites and related materials is the principle of structures built by corner sharing  $\text{TO}_4$  tetrahedra or in some cases octahedra. T indicates the tetrahedrally coordinated cations such as  $\text{Si}^{4+}$  and  $\text{Al}^{3+}$  for zeolites or  $\text{Al}^{3+}$  and  $\text{P}^{5+}$  for aluminophosphates. These building blocks form a three-dimensional structure including a one-, two-, or three-dimensional pore network (see Fig. 1 for examples of zeolite building blocks and one-, two-, and three-dimensional zeolite structures). In some materials larger cages are formed at the intersections of the pores. Currently, about 140 framework types are known. To each framework type a three-letter code (Framework-Type Code) is assigned by the Structure Commission of the International Zeolite Association.<sup>[15]</sup> The framework type of a zeolite describes the connectivity of the framework tetrahedral atoms in the highest possible symmetry without reference to chemical composition and, therefore, defines the topology of the material with respect to size and shape of the pore openings, the dimensionality of the channels system, the volume and arrangement of the cages, and the type of cation sites available.<sup>[16]</sup>

Crystalline molecular sieves are often characterized by their smallest pore opening named after the number of T-atoms in the rings defining the size of the pore. A comparison between the diameters of the pore

openings and the size of typical reactant molecules is given in Fig. 2. Small pore zeolites, such as Zeolite A (LTA), Sodalite (SOD), and Zeolite P have pores build-up by 8-membered rings (8 MR pores). Medium pore zeolites, such as ZSM-5 (MFI), have minimum pore openings defined by 10-membered rings, while the pore openings of large pore zeolites, e.g., Zeolite Y (FAU), Mordenite (MOR), and Beta (BEA), are defined by 12-membered ring pores. Materials with pores of a larger minimum diameter are called ultra-large pores materials with 20 T-atom pores being the accepted upper limit. The materials with the largest pores are VPI-5 (18-MR pores)<sup>[17]</sup> and JDF-20 (20 MR pores).<sup>[18]</sup> Note that both materials are aluminophosphates. For siliceous materials UDT-1 (14-MR

**Fig. 2** Comparison between the diameters of the pore openings and the size of typical reactant molecules.

**Fig. 3** Possibilities of tailoring the zeolite by replacing framework  $\text{Si}^{4+}$  or  $\text{Al}^{3+}$  with different cations, i.e.,  $\text{P}^{5+}$ .

pore)<sup>[19]</sup> and CIT-5 (14 MR pores)<sup>[20]</sup> were among the materials with the largest pore sizes described.

The chemical composition determines the specific properties of microporous molecular sieves. Purely siliceous or aluminum phosphate molecular sieves are chemically inert. Chemical functionality and charge is introduced into such frameworks by substitution of cations with valences differing on the average from the value of four. Thus  $\text{Al}^{3+}$  as a T-atom in a silicate framework causes a negative framework charge, which has to be balanced by a proton (forming a hydroxy group, Brønsted acid site) or by a metal cation (forming a Lewis acid site).<sup>[21–23]</sup> The bare, negatively charged tetrahedron is the corresponding base anion. The differences in the charge of these tetrahedra determine the theoretically highest concentration of acid and base sites of the material. The possibilities of tailoring molecular sieves by replacing framework  $\text{Si}^{4+}$  or  $\text{Al}^{3+}$  with different cations, such as  $\text{P}^{5+}$ , are schematically shown in Fig. 3. Note that only cation exchange molecular sieves appear existing. For detailed information the reader is referred to excellent reviews.<sup>[16,24,25]</sup>

The chemical composition of the framework determines the polarity of the lattice and, in consequence, the acid–base properties of the material.<sup>[21,26–28]</sup> Because of the instability of Al–O–Al bonds (proximity of two positively charged atoms), only half of all silicon atoms can be replaced by aluminum in materials based on silica (lowest Si/Al ratio possible of 1). This has been expressed in the Loewenstein rule.<sup>[29]</sup> Consequently, each Al–O tetrahedron is surrounded by four Si–O tetrahedra. Adjacent Al–O tetrahedra are referred to as next nearest neighbors (NNN). Various models, reviewed by Barthomeuf,<sup>[27]</sup> relate the acid strength of Brønsted sites to the concentration of NNN Al atoms. The strongest acid sites are observed in the absence of NNN Al–O tetrahedra. The site strength decreases as the concentration of NNN

Al–O tetrahedra increases. Thus, in addition to long-range effects of the chemical composition, experiments and theoretical calculations<sup>[30]</sup> show that short-range effects influence the strength of acid sites. Additionally, more subtle factors such as the crystal structure leading to various angles between the tetrahedra (T–O–T bonding angle) and the nature of the metal cations at exchange sites can influence the strength of acid sites.<sup>[28,31,32]</sup>

Adjusting the combination of chemical composition, (partial) cation exchange, and the molecular sieve structure can lead to a wide variety of chemical properties. Depending upon the charge on the metal cation/proton and the oxygen, the acidic or basic properties of the molecular sieves will dominate and, consequently, the materials will act as a solid acid or base.<sup>[33]</sup>

Acid/base sites generated by substitution in crystalline materials are generally more stable than sites in mesoporous materials with amorphous walls, because the latter material does not face constraints in the relaxation of bonds.<sup>[34,35]</sup> In contrast to the crystalline materials, mesoporous materials have pores generated by the condensation of (X-ray amorphous) oxides<sup>[36]</sup> around medium and high molecular weight surfactants.<sup>[37]</sup> After forming a coherent structure, the surfactants are removed and the regular void structure with pore diameters between 20 and 100 nm remains. The large pores possess many hydroxyl groups,<sup>[38]</sup> which are well suitable for anchoring functional groups or metal–organic complexes.<sup>[39]</sup> The most prominent members of the family are the MCM41S-type materials (e.g., MCM-41, MCM-48) with hexagonally or cubic structures<sup>[40]</sup> and materials such as SBA15 synthesized using non-ionic triblock copolymers.<sup>[41,42]</sup> For postsynthetic modifications these materials are frequently used in their pure silica form.<sup>[43–45]</sup> Recently, mesoporous materials have been synthesized with fractions of crystalline materials as building blocks as part of the wall structure<sup>[46]</sup> or as delaminated and pillared zeolite entities.<sup>[47,48]</sup> These materials are able to combine the local structure of crystalline molecular sieve materials and, hence, the presence of stable and strong Brønsted acid sites with the accessibility for large molecules. The best examples for this are related to delaminated structures of MWW- or FER-type materials. When oxide pillars are used to stabilize the delaminated layers, widely differing chemical functions can be combined in one material, i.e., acidic and basic sites or acidic and redox sites.<sup>[49]</sup>

## FUNCTIONAL PROPERTIES

### Brønsted Acid Sites

As described above the strength of Brønsted acid sites varies markedly with the local and overall environment,

i.e., the chemical composition and the structure of the zeolite.<sup>[27,28]</sup> While the lengths of Al–O and Si–O bonds and the corresponding Al–O–Si and Si–O–Si angles<sup>[34]</sup> exert a subtle influence, the strongest sites are found in the absence of Al NNN atoms. For these materials Brønsted acid sites appear to be identical in strength and catalytic activity. This has been shown for protolytic cracking of *n*-hexane<sup>[50]</sup> and the isomerization of *m*-xylene<sup>[51]</sup> both being monomolecular reactions under the chosen reaction conditions. For *n*-hexane and *n*-hexene cracking this equivalency was shown also for materials with varying aluminum concentration.<sup>[50]</sup>

### Lewis Acid Sites

Lewis acid sites are electron pair acceptor sites formed by accessible metal cations stemming from lattice defects, oxide nanoparticles formed by lattice degradation, and cation exchange. The strength of Lewis acid sites is proportional to the ratio between the charge of the metal cation and its size,<sup>[52]</sup> but it can be reduced by limited accessibility (inability to assume minimum bond distance). Lewis acid sites formed by metal cation exchange are weak to moderately strong, because many of the exchangeable cations have a low electronegativity (e.g., alkali or alkali earth metals) or are relatively large (e.g., La<sup>3+</sup>). Together with the adjacent framework oxygen atoms they act as Lewis acid/base pair and may polarize bonds in reacting molecules.

Lewis acid sites originating from lattice defects or by degradations of the lattice are part of alumina or silica/alumina nanoparticles formed by the extraction of aluminum from the lattice (Fig. 4), which can be charged or neutral.<sup>[53,54]</sup> Al<sup>3+</sup> exists in octahedral and tetrahedral coordination and will have stronger Lewis acid sites than exchangeable metal cations.<sup>[26]</sup> The extra-framework alumina species (EFAL) are typically extracted from the zeolite lattice by steam treatment at higher temperatures and either block active sites by substituting for exchangeable cations, enhance the acidity by interacting with a Brønsted acid site, or block the access to micropores by forming voluminous oligomeric species.<sup>[55–58]</sup>

**Fig. 4** Hydrothermal extraction of aluminum from the zeolite lattice.

A third type of Lewis acid site has been recently described as Al<sup>3+</sup> reversibly and partially extracted from the lattice using a base molecule such as ammonia.<sup>[59,60]</sup> The Al<sup>3+</sup> cation assumes an octahedral coordination under such conditions. The reversibility is broken, however, once Al–O–Al bonds are formed, i.e., when the aluminum oxide species are completely detached from the lattice. Detailed information on such sites is not available, but it can be speculated that the drastic enhancement of catalytic activity for acid-catalyzed hydrocarbon conversion after mild steaming is associated with such reversible detached Lewis acid sites.<sup>[61]</sup>

It should be noted here that the interaction of the Lewis acid sites with electron pair donor molecules is very strong. The presence of the acid–base pairs allows polarizing molecules, which can potentially enhance their reactivity.<sup>[62,63]</sup> Lewis acid sites also act as hydride or anion receptors in a variety of reactions. Their presence seems also to stimulate dehydrogenation of alkanes to some degree.

### Basic Sites

Basic sites are proton accepting or electron pair donating oxygen atoms of the lattice. The strength is proportional to the negative charge on the oxygen. To a first approximation, this negative charge can be estimated with the help of the intermediate electronegativity using the Sanderson electronegativity principle<sup>[64]</sup> or the electronegativity equalization method (EEM).<sup>[30]</sup> It varies inversely to the intermediate electronegativity, i.e., materials with lower intermediate electronegativity and higher polarity show higher base strength.<sup>[65,66]</sup> The oxygen 1s binding energy can be used to confirm this trend experimentally.<sup>[67]</sup> Like the acid strength discussed above the base strength of the oxygen atoms in the lattice also depends subtly on T–O–T bond angles and on the local chemical environment (e.g., oxygen atoms in AlO<sub>4</sub> tetrahedra are more basic than in SiO<sub>4</sub> tetrahedra).<sup>[22,68]</sup> Additionally, the type of cation influences the polarity of the lattice.<sup>[69]</sup> Even when all cation exchange sites are exchanged with alkali cations, the overall chemical composition allows for the SiO<sub>2</sub>-based materials only

a weak base strength. Stronger base sites are therefore linked to clusters of alkaline or alkali-earth oxide hydroxides in the zeolite pores.<sup>[70,71]</sup> Very strong basic sites can be created by supporting metallic sodium in the zeolite pores,<sup>[25]</sup> which interact with framework oxygen atoms or react with trace humidity. Loading zeolites with alkali metal oxides utilizes the microporous material primarily as support.<sup>[72]</sup> Such materials show high activity in typical base-catalyzed reactions such as alcohol dehydrogenation or toluene side chain alkylation.<sup>[73]</sup> However, the low rates of base-catalyzed reactions make the materials always very susceptible to traces of catalytically more active protons, which then dramatically change the chemical reactivity.<sup>[73]</sup>

### Redox Sites

Redox sites can be introduced into micro- and mesoporous materials by isomorphous substitution of metal ions into framework positions, ion exchange with metal cations, and grafting metal complexes onto the surface of (mesoporous) molecular sieves. All three options lead to materials with unique properties that may be tailored for specific uses. While the first approach comes closest to mimicking enzyme catalysis, the ion exchanged materials are excellent redox catalysts for gas-phase reactions in environmental applications and the third group brings the wide variety of the metal-organic chemistry to mesoporous materials. For excellent reviews on the materials, see Refs.<sup>[43,74-77]</sup>

Examples for the first group of materials include Ti-silicalite (TS1-1),<sup>[78-80]</sup> vanadium silicates with MFI and MEL structure,<sup>[81]</sup> iron-containing MFI zeolites,<sup>[82]</sup> and Co and Cr incorporated into the framework of aluminum phosphate with AFI and AEL structure.<sup>[83]</sup> The uniqueness of these materials lies in the fact that isolated, identical, and stable sites are formed in a matrix that allows the proper adsorption of the reactants and provides sufficient space for the chemical transformations (with steric constraints of the molecular sieve directing the reaction). Most importantly, however, the materials can be tailored to have the proper hydrophobic/hydrophilic properties.<sup>[84]</sup>

Ti-silicalite (TS1-1) is an excellent catalyst for the oxidation of small molecules with H<sub>2</sub>O<sub>2</sub> and was the first commercially used zeolite-based partial oxidation catalyst. Experimental<sup>[78-80]</sup> and theoretical studies<sup>[85,86]</sup> suggest that the active sites in TS-1 are isolated and uniformly distributed Ti(IV) atoms in tetrahedral coordination, where each Ti(IV) is separated from other titanyl groups by at least two Si-O tetrahedra. The isolation of the Ti<sup>4+</sup> centers is required to obtain high selectivities (low rate of H<sub>2</sub>O<sub>2</sub> decomposition). Next to incorporation into the MFI or MEL structure, incorporation of Ti has also been reported,

e.g., for BEA (Ti-Beta), MTW (Ti-ZSM-12), and MWW (Ti-MCM-22).<sup>[87-89]</sup>

Transition metal cation exchanged materials have seen enormous interest as potential materials for reduction of NO<sub>x</sub> with hydrocarbons.<sup>[77,90-92]</sup> Most of the materials investigated are based on the MFI structure, and Cu, Co, and Fe are the most studied materials.<sup>[93]</sup> Such materials cannot be used in liquid-phase reactions as the metal cations at exchange places would be leached. Iron containing ZSM-5 materials are especially remarkable as their catalytic activity differs markedly from that of bulk Fe<sub>2</sub>O<sub>3</sub>.<sup>[82]</sup> Fe-ZSM-5 is unable to activate O<sub>2</sub>, but shows high activity for the decomposition of N<sub>2</sub>O<sup>[94]</sup> and utilizes the oxygen for selective gas-phase oxidation steps. Similar to the microporous Fe-ZSM-5, mesoporous iron-containing silicas with MCM-41-type structure<sup>[95,96]</sup> can be used to oxidize large hydrocarbons to oxygenates with N<sub>2</sub>O.

### UNDERSTANDING SIZE AND SHAPE OF MICRO- AND MESOPORES

In an ideal crystal the position of the atoms in the lattice and as a consequence also the void space between them are well defined. Thus in principle the pores can be assessed by experimental structure determining methods such as X-ray diffraction.<sup>[97,98]</sup> Practical problems are associated with the fact that the materials are not ideal frameworks and contain lattice defects and larger irregular void spaces (mesopores). Moreover, the accessible pore volume is defined by the van der Waals radii of the lattice oxygen atoms and of the sorbed molecules, both being flexible and temperature dependent.<sup>[99]</sup> Basically, understanding the pore volume and pore accessibility is based on five principal methods, including (high-resolution) transmission electron microscopy and tomographic methods,<sup>[100-102]</sup> adsorption of small inert molecules,<sup>[103]</sup> <sup>129</sup>Xe NMR spectroscopy,<sup>[104]</sup> adsorption of probe molecules of various sizes, and<sup>[105]</sup> lately on computer modeling the accessible pore space.<sup>[106]</sup> Typically, the combination of methods is mandatory to describe the properties of micro- and mesoporous nanomaterials.<sup>[107,108]</sup>

The complexity is seen in a comparison of the computer modeling of *n*-hexane, benzene, and 1,3-diethylbenzene adsorption in a zeolite with the MOR structure (Fig. 5) and the corresponding experimental

**Fig. 5** Accessible pore volume of mordenite for *n*-hexane and benzene and 1,3-diethylbenzene.

**Fig. 6** Adsorption of (A) *n*-octane, (B) benzene, (C) pyridine, and (D)  $\text{NH}_3$  on (E) H/MOR.

sorption experiment (Fig. 6). Unequivocally, the simulation presented in Fig. 5 shows that molecules with kinetic diameters larger than the pore diameter are excluded from accessing the pores (1,3-diethylbenzene). Computer modeling shows *n*-hexane may access also side pockets in this material, while benzene is unable to do so. Experiments show in contrast that neither molecule can approach sites in the side pockets. This indicates that very subtle changes in the interactions (linear amines access the side pockets) may lead to drastic changes in the sorption properties.

### TRANSPORT OF MOLECULES IN AND INTO MICRO- AND MESOPORES

Transport of molecules follows in the most cases configurational diffusion and in limited cases Knudsen diffusion for the largest pores. The mathematical principles and the methods to measure diffusion processes in microporous materials are excellently summarized in Ref.<sup>[109]</sup>. Configurational diffusion involves the transport of molecules between places of relatively long residence time (sorption sites) by hopping<sup>[110,111]</sup> between the pronounced sorption minima. The activation energies may be significant, as for each movement bonds have to be broken and energy maxima have to be overcome. The similarity of the minimum kinetic diameter of the diffusing molecule and the pore diameter makes it impossible or difficult for molecules to pass each other in the pore network. The resulting sequentially ordered transport of the molecules has been described as single-file diffusion<sup>[112,113]</sup> and is important to describe separation and catalysis in materials with one channel.<sup>[114,115]</sup>

Differences between the mobility of molecules at equilibrium or during forced movement through the pores can be substantial.<sup>[17,51,109]</sup> Significant slowdown of the transport process is induced by the crystal boundaries,<sup>[116,117]</sup> leading to faster transport through single crystal than polycrystalline H-ZSM-5.<sup>[118]</sup> This has been related recently to a weakly sorbed precursor state that allows adsorption of the aromatic molecules at the outer surface of the microporous particle and a subsequent entering into the pore system after arbitrary movement on the outer surface.<sup>[119]</sup>

### SORPTION IN MICRO- AND MESOPOROUS MATERIALS

Many of the unique properties of the microporous materials as sorbents and catalysts result from the proximity of the molecule to the surrounding wall. As a consequence, the molecules interact with the framework oxygen atoms by undirected short-range dispersion forces (physisorption), which can dominate over specific directed interactions for weakly polar and larger molecules. Such situations have been well demonstrated for alkanes in molecular sieves. Adsorption of more polar compounds may also include polar, field-dipole, and field gradient-quadrupole contributions to the interaction.

Adsorption of an alkane (as an example) in H-ZSM-5 has two energetic components of interaction, one related to the directed binding to hydroxy groups and another that results from the London dispersion forces.<sup>[120]</sup> The direct interaction results from a dipole-induced hydrogen-bridge of alkane hydrogens. To partition between these two groups of interactions, it is useful to compare microporous materials with and without Brønsted acid sites. The dependence of the heat of sorption of *n*-alkanes on their chain length is

**Fig. 7** Heat of sorption of *n*-alkanes on (□) H-ZSM-5, (■) ZSM-5 (siliceous), (○) H-Y, and (●) Y (siliceous).

shown in Fig. 7 for two groups of molecular sieves, i.e., materials of MFI and FAU structure with and without strong Brønsted acid sites. The initial heat of sorption increases linearly with the chain length for ZSM-5 and zeolite Y.<sup>[105,121]</sup> However, the increment in the heat of sorption per carbon atom is larger for the medium pore ZSM-5 material compared to the large pore zeolite Y. Also, the modest contribution of polarization by strong Brønsted acid sites ( $7\text{--}10\text{ kJ mol}^{-1}$ ) is higher for ZSM-5 indicating higher acid strength. Overall, it can be concluded that the interaction between the alkane and the zeolite is governed by physisorption.

The sorption in the pores reduces the degrees of freedom (translatory and configurational) for the sorbed molecules (decrease of their entropy). Stronger bonding leads to a more pronounced reduction of the sorbate entropy. With increasing chain length of the alkane (increasing heat of sorption), indeed, also the entropy in the sorbed state decreases sympathetically. For a given heat of adsorption, the loss of entropy decreases with the pore size of the molecular sieve.<sup>[121]</sup> The slope of the resulting linear correlation between entropy and enthalpy can be used for unknown materials as characteristic value for the available pore diameter. Entropy plays also a significant role in ordering and sorbing molecules that can only partly access the pore system.<sup>[122]</sup>

Molecular sieves containing alumina are hydrophilic and are used as drying agents. However, in the pure silica form materials with the same structure and micropores interact very weakly with polar compounds (are hydrophobic). For practical measures a comparison of the sorption capacity for *n*-hexane and water has been introduced as hydrophobicity index.<sup>[123]</sup> The reason for this weak interaction lies in the low polarity of the pure silica lattice, which does not tend to form hydrogen bonds with polar molecules such as water or alcohols.<sup>[124]</sup> This is especially important for small molecules (water, ammonia, methanol, methylamine, etc.) that show a less pronounced interaction via dispersion forces than large molecules.

## CATALYSIS IN THE CONFINEMENT OF MICRO- AND MESOPORES

The dominating chemical functions, i.e., acid, base, or redox, determine the surface chemistry and the way reactions are catalyzed. The confinement of the pores does not lead to completely new chemistry, but the proximity of the lattice and the reacting molecules may stabilize some transition states similar to situations found in liquid phase or enzyme catalysis. It is impossible to review the wide variety of chemical reactions reported for microporous and mesoporous

materials. Therefore, we will limit the review to those special situations, where the molecular sieves show special properties. For more general overviews the reader is referred to Refs.<sup>[7,125–131]</sup>

One of the most striking observations is the strong adsorption of even apolar molecules and the resulting high catalytic activity. This is most prominently seen in the conversion of light alkanes on various zeolites and mesoporous materials. At a particular temperature the rate of alkane cracking increases exponentially with the size of the alkane. This is not related to an easier breaking of the C–C bond (the true energies of activation are identical for all molecules) but is caused by the exponential increase of the adsorption equilibrium constant with the size of the molecule.<sup>[132,133]</sup> As the strength of adsorption is also related to the pore size, materials with larger pores adsorb fewer molecules at a given partial pressure. Indeed, the rate of *n*-alkane cracking is about an order of magnitude slower with materials of the FAU structure than with H-ZSM-5. The energy of activation, however, is identical for both reactants. The rates for cracking are even smaller for acidic mesoporous materials. As a consequence it is possible to selectively crack a heavy fraction of alkanes in the presence of light alkanes by choosing a large pore acidic material.

The variation of the chemical composition can be used to subtly influence the selectivity. It has been recognized for example that zeolites with higher concentration aluminum substituted into the lattice show appreciable hydride transfer activity, which not only maintains the cracking chain reactions, but also shifts the product distribution between olefins and aromatic molecules.<sup>[134]</sup> Now it could be shown with the reverse reaction, i.e., the alkylation of *iso*-butane with *n*-butene, that hydride transfer increases with the aluminum concentration over a much wider range of chemical indicating that a less strongly acidic material has the higher tendency to hydride transfer. This is surprising as it shows that the stability of the new bond between the carbon atom and the lattice oxygen is more important than the polarity of the C–O bond in the alkoxy group.<sup>[135,136]</sup>

While hydride transfer is important for hydrocarbon activation at low temperatures, deprotonation reactions by strong bases such as ammonia may help to release highly polar species such as alkylammonium compounds. Alkylammonium ions are generated by the reaction of ammonium ions with methanol, but are unable to leave the zeolite pores, because of their high base strength.<sup>[137]</sup> Scheme 1 shows that in the initial step an ammonium ion is formed, which donates a proton to the alcohol leading to an alkylammonium ion and water as a leaving group. Alkyl transfer reactions or adsorption-assisted desorption is necessary to allow the decomposition of the alkylammonium

**Scheme 1** Acid-catalyzed methylamine synthesis.

ion and the desorption of alkylamines, while another ammonium ion is formed. The zeolite also binds the alkylammonium ions very strongly, but activates the alkyl groups on the other hand so that they can also react with strongly nucleophilic reactants.

The changes in the chemical composition can be used to modify the relative concentration of reactants in the pores by varying the polarity of the lattice and the strength of interaction with polar and apolar molecules. A nice academic example for that effect is reported by Namba et al.,<sup>[138]</sup> who studied the direct esterification of acetic acid with *n*-, *iso*-, and *tert*-butyl alcohol on different zeolites. The poisoning of the acid sites by water formed in the process was significantly weaker with the more hydrophobic high-Si/Al-ratio ZSM-5 catalysts. Materials with a low tendency to sorb polar compounds are therefore excellent catalysts for the synthesis and transformation of highly polar products.<sup>[139]</sup>

The weak interaction with water is also the main reason for the successful use of H<sub>2</sub>O<sub>2</sub> with Ti-silicalite materials. A significant concentration of water in the pores under reaction conditions would lead to the hydrolysis of, for example, epoxide groups formed from the reaction with olefinic molecules (Scheme 2). It should be noted that such subtle differences in the strength of interaction can be used to optimize polar and basic molecular sieves in order to adjust the ratio of methanol and toluene adsorbed in the pores of alkali exchanged zeolites during the side chain alkylation of toluene. In contrast to the well-tailored zeolites, the conversion over basic layered compounds such as hydrotalcites indicates that improper ratios between toluene and methanol lead to inactive catalysts.<sup>[140]</sup>

While there has been limited direct evidence, some results also suggest that it should be possible to use the polarization by the zeolite pores to activate molecules. Evidence includes the modification of the optical properties of sorbed naphthalene<sup>[141]</sup> and the variations in the cracking activity in aluminum phosphate molecular sieves because of local field gradients.<sup>[142]</sup>

**Scheme 2** Epoxidation and hydrolysis.

The most pronounced and important effect in micro- and mesoporous materials, however, relates to its shape selectivity. It can be induced by limitations of the access of some of the reactants to the pore system (reactant selectivity), the limitation in the diffusion of some of the products out of the pores (product selectivity), and constraints in forming certain transition states (transition state selectivity) (see Scheme 3 for a comparison of the types of shape selectivity).<sup>[125,143–145]</sup>

Reactant selectivity occurs when the access of certain reactant molecules to the intercrystalline void space of the zeolite is suppressed on the basis of the diameter, while other (less bulky) molecules can enter and react. The first example of reactant shape selectivity was reported by Weisz and Frillette<sup>[146]</sup> for the dehydration of an *n*-butanol/*iso*-butanol mixture over LTA-type zeolites. Because of its larger minimum kinetic diameter *iso*-butanol is excluded from entering the zeolite pores, while *n*-butanol is easily dehydrated to butene. This demonstrates that the pores are able to realize a well-defined cutoff point with respect to the minimum kinetic diameter of the reacting molecules. This principle of size exclusion is frequently used in hydrocarbon processing to remove linear hydrocarbons from a mixture of hydrocarbons (e.g., selectofining).

Product selectivity is the result of the differences between the diffusivities of the reaction products in the pores of the zeolite. A typical example is the

**Scheme 3** Schematic representation of the three types of shape selectivity.

isomerization of alkylaromatics. Note that the diffusion constant of *p*-xylene in chemically modified ZSM-5 zeolites is about  $10^3$  times higher than that of *m*-xylene.<sup>[51,147]</sup> Therefore *p*-xylene will diffuse quickly out of the pores of the zeolite to the gas phase, while the more bulky product (*o*- and *m*-xylene) will undergo secondary isomerization reactions. As this type of shape selectivity results from the differences in the diffusivities it depends on the pore size but also on the crystal size of the zeolite particles.

Transition state shape selectivity occurs when the configuration of a potential transition state is spatially constrained compared to other transition states and therefore only certain reaction pathways are possible. *m*-Xylene isomerization is a well-documented example. It is interesting to note for this reactant that it diffuses slower through the pore channels of H-ZSM-5 than both reaction products, *o*-xylene and *p*-xylene. None of the products is adsorbed in a measurable degree during reaction. The *p*-xylene position is preferably formed as the transition state is smaller and, hence, entropically preferred. This is also confirmed kinetically by the temperature independence of the preference to *p*-xylene.<sup>[51]</sup>

Recently, it has also been shown that selectivity can be induced by the spacing between pore mouths of zeolites, although this has been strongly debated in relation to the hydroisomerization of alkanes.<sup>[148,149]</sup>

It has been shown that product patterns could be explained by invoking only the acid sites at the entrance of small pore materials such as erionite, ZSM-22, and Theta-1. The isomer distribution suggests that branching of *n*-alkanes occurs in approximately the distance between two pore openings.

## CONCLUSION

Crystalline nanostructured microporous and, to a lesser extent, mesoporous materials are broadly available providing a unique environment that allows to tailor the local reaction to an extent that is otherwise seen only in enzymes. This progress was and is based on the gradually developing understanding of chemical and physical processes and the material properties involved in the catalytic reactions. Rapidly advancing experimental capabilities and the progress in theoretical chemistry aided the speed of development greatly. The steric and chemical control of the environment of the active sites, the mobility of the reactants and products, and the interplay between these processes are understood at a level that makes it possible to design materials for specific purposes. The realization of controlled size and morphology of the microporous materials, the synthesis of stable larger pore materials, and the generation of well-defined outer surfaces and delaminated structures are three of the major challenges to be overcome. The introduction of chiral centers into the structure and the combination of organic and inorganic entities are other challenges that will see breakthroughs in the future.

## INTRODUCTION

In many aspects, colloidal particles suspended in a liquid behave like large idealized atoms that exhibit liquid, glass, and crystal phases similar to those observed in atomic systems.<sup>[1–6]</sup> Phase transitions in colloidal systems have been intensively studied over the last decade not only because of the theoretical interest for addressing fundamental questions about the nature of liquids, crystals, and glasses, but also for many practical applications of colloids.<sup>[7–11]</sup> In recent years, colloidal dispersions have been used extensively for the fabrication of nanostructured materials such as photonic crystals, catalysts, membranes, and ceramics, and for device applications.<sup>[11–16]</sup> Current uses of colloidal particles as the building blocks of materials rely mostly on empirical approaches. Meanwhile, present knowledge on the structural and thermodynamic properties of colloidal dispersions is primarily based on an effective one-component model (OCM) where colloidal particles are represented by hard spheres and all remaining components in the dispersion, including solvent molecules, small ions, and polymers, are represented as a continuous medium.<sup>[17–23]</sup> Although the OCM approach is attractive because of its simplicity, application to practical systems is often limited by incomplete understanding of colloidal forces.<sup>[24–28]</sup>

Amid numerous conventional colloids, aqueous dispersions of poly-*N*-isopropylacrylamide (PNIPAM) microgel particles, first synthesized by Pelton and Chibante<sup>[29]</sup> in 1986, are of special interest for studying phase transitions and for the fabrication of colloid-based advanced materials.<sup>[30–36]</sup> Nearly monodispersed PNIPAM particles can now be routinely prepared in a wide range of colloidal sizes (50 nm up to 1  $\mu$ m) and with a variety of physiochemical characterizations.<sup>[35,37]</sup> Because the size of PNIPAM particles is

temperature-sensitive,<sup>[38]</sup> crystallization at different colloidal volume fractions can be conveniently measured by varying temperatures. By tuning the preparation conditions and the composition of the aqueous solution, the interaction potential between microgel particles can vary from star-polymer-like to hard-sphere-like potential for short-range repulsion, from electrostatically neutral to highly ionizable for long-range electrostatic interactions, and from essentially no attraction to strong attraction for van der Waals forces.<sup>[36,39]</sup> Furthermore, steric repulsion can be introduced by grafting polymers on the surface of PNIPAM particles.<sup>[40]</sup> The versatility in interaction potential makes PNIPAM microgel particles attractive for studying a broad variety of interesting phenomena in colloidal systems.<sup>[32,41–44]</sup> Although the practical values of PNIPAM particles have been long recognized, most previous studies on the physiochemical properties of PNIPAM dispersions have focused on particle preparations, swelling, rheology, and light (neutron) scattering measurements.<sup>[35,36,45–47]</sup> Little work has been reported on the relationship between the temperature-dependent interparticle potential and the phase behavior of PNIPAM dispersions. Unlike that in a conventional colloidal system, the interparticle potential in aqueous dispersions of PNIPAM microgel particles is sensitive to temperature changes. Consequently, the phase diagram of PNIPAM dispersions may be noticeably different from those for ordinary colloids where, in most cases, the interparticle potential is essentially invariant with temperature.

In this chapter, we report our recent investigations on the colloidal forces and phase behavior of neutral PNIPAM particles dispersed in pure water.<sup>[48–50]</sup> We will first discuss thermodynamic methods for the characterization of colloidal forces based on dynamic and static light scattering measurements. The analytical expression of colloidal forces allows us to construct a

theoretical phase diagram that can be compared with that obtained from spectroscopic measurements. In particular, we will illustrate how the volume transition of PNIPAM particles affects the interaction potential and determines a novel phase diagram that has not been observed in conventional colloids. Finally, we discuss briefly the kinetics of crystallization in an aqueous dispersion of PNIPAM particles.

### COLLOIDAL FORCES BETWEEN MICROGEL PARTICLES

Qualitatively, the pair potential between neutral microgel particles includes a short-range repulsion that is similar to the interaction between two polymer-coated surfaces, and a longer-ranged van der Waals-like attraction that arises from the difference in the Hamaker constants of the particle and the solvent.<sup>[51,52]</sup> To obtain a quantitative expression for the interparticle potential that covers a broad range of temperature, we assume that the interaction potential can be represented by a Sutherland-like function that includes a hard-sphere repulsion and a van der Waals attraction. A similar potential was used Senff and Richtering<sup>[43,53]</sup> for representing the phase behavior and rheological properties of PNIPAM microgel dispersions. Fig. 1 shows that the relative zero shear viscosity of PNIPAM dispersion can be approximately

**Fig. 1** Relative zero shear viscosity at different temperatures vs. the effective volume fraction. The line represents the master curve of hard-sphere suspensions. *Source:* From Refs.<sup>[43,53]</sup>.

represented by that for hard spheres. Besides, as shown later, the kinetics of microgel crystallization also resembles that for hard spheres.

The variation of microgel diameter as a function of temperature is related to the swelling of microgel particles. The classical theory of gel swelling, proposed many years ago by Flory,<sup>[54]</sup> asserts uniform distributions of polymer segments and crosslinking points throughout the polymer network. However, recent experiments based on nuclear magnetic resonance (NMR) and light scattering investigations suggest the heterogeneous nature of PNIPAM particles.<sup>[51,55]</sup> To take into account the heterogeneity, we use an empirical modification of the Flory–Rehner theory proposed by Hino and Prausnitz.<sup>[56]</sup> This theory has been applied successfully to describing the volume transitions of bulk PNIPAM gels. Because the physics for the volume transition is irrelevant to the particle size as long as the surface effect is unimportant, and because the effect of the osmotic pressure of dispersion on the swelling of an individual particle is negligible,<sup>[42]</sup> we assume that the same thermodynamic model for bulk polymer gels is also applicable to microgel particles.

According to the modified Flory–Rehner theory,<sup>[56]</sup> the polymer volume fraction within the particle  $\phi$  is determined from:

$$\ln(1 - \phi) + \phi + \chi\phi^2 + \frac{\phi_0}{m} \times \left[ \left(\frac{\phi}{\phi_0}\right)^{1/3} - \left(\frac{\phi}{\phi_0}\right)^{5/3} + \left(\frac{\phi}{2\phi_0}\right) \right] = 0 \quad (1)$$

where  $m$  is the average number of segments between two neighboring crosslinking points in the microgel network, and  $\phi_0$  is the polymer volume fraction in the reference state where the conformation of network chains is closest to that of unperturbed Gaussian chains. Approximately,  $\phi_0$  is equal to the volume fraction of polymers within the microgel particles at the condition of preparation. The Flory polymer–solvent energy parameter  $\chi$  is given empirically as a function of temperature  $T$  and polymer volume fraction  $\phi$ :<sup>[56]</sup>

$$\chi = \frac{3}{1 - 0.65\phi} \times \left[ 2 \ln \left( \frac{5001}{1 + 5000 \exp(2458.867/T)} \right) - \frac{4566.468}{T} \right] \quad (2)$$

At a given temperature, Eq. (1) can be solved to find the polymer volume fraction  $\phi$  from which the diameter of PNIPAM particles ( $\sigma$ ) is calculated:

$$\frac{\sigma}{\sigma_0} = \left(\frac{\phi_0}{\phi}\right)^{1/3} \quad (3)$$

where  $\sigma_0$  is the particle diameter at the reference state. In this work, we fit the average chain length  $m$  and the volume fraction of polymer  $\phi_0$  at the reference state to the diameters of microgel particles obtained from static and dynamic light scattering measurements. Because the osmotic pressure of microgel dispersion is small in comparison to the gel swelling pressure, the microgel particle concentration has a negligible effect on the chemical potential of water. As a result, the size of microgel particles should be insensitive to the overall concentration of colloidal dispersions.

The van der Waals attraction beyond the hard-sphere diameter may be represented by a power law potential:

$$u_A(r) = -\frac{H}{r^n} \quad (4)$$

where  $H$  is the Hamaker constant. We assume that  $n = 8$  in considering that the range of attraction between colloidal particles (relative to the particle size) is shorter than that between atomic molecules. The calculated results are not sensitive to a small change in  $n$  if the Hamaker constant is obtained by fitting to osmotic second virial coefficients from static light scattering experiments. Because the interparticle attraction arises from the dispersion forces between polymeric segments from different particles, the Hamaker constant of microgel particles is approximately given by:<sup>[57]</sup>

$$H \propto \rho_m^2 \quad (5)$$

where  $\rho_m$  represents the number density of polymeric groups within each particle. The proportionality constant in Eq. (5) is independent of temperature and polymeric group density  $\rho_m$ . Following Eqs. (4) and (5), we obtain the attractive potential because of the van der Waals forces:

$$\frac{u_A(r)}{kT} = -k_A \left(\frac{T_0}{T}\right) \left(\frac{\sigma_0}{\sigma}\right)^{6+n} \left(\frac{\sigma}{r}\right)^n \quad (6)$$

where  $k_A$  is a dimensionless constant, and  $T_0$  is the reference temperature that is introduced for the purpose of dimensionality. In Eq. (6), the parameters  $T_0$ ,  $\sigma_0$ , and  $k_A$  are temperature-independent and they can be obtained by fitting to osmotic second virial coefficients from static light scattering measurements. An osmotic second virial coefficient in a colloidal dispersion is defined as:

$$B_2 = 2\pi \int_0^\infty [1 - e^{-u(r)/kT}] r^2 dr \quad (7)$$

where  $r$  stands for the center-to-center distance between colloidal particles,  $k$  is the Boltzmann constant, and  $u(r)$  is the interparticle potential.

The particle size and the osmotic second virial coefficients of microgel dispersions can be conveniently measured using static and dynamic light scattering. To correlate the radius of PNIPAM gel particles as a function of temperature, we combine the radius of gyration  $R_g$  with the hydrodynamic radius  $R_H$  from static and dynamic light scattering measurements, respectively. By assuming that the microgel particles are homogeneous spheres, we define the effective radius:

$$R = (\sqrt{5/3}R_g + R_H)/2 \quad (8)$$

This effective radius is introduced to represent the excluded volume of microgel particles as required in phase equilibrium calculations. Fig. 2 presents the radius of microgel particles near the volume transition temperature (approximately at 34.3°C). The error bars give the difference between the hydrodynamic radius and that calculated from the radius of gyration. The solid line is calculated by using the modified Flory–Rehner theory [Eqs. (1–3)]. In the calculation of the particle radius, the polymer fraction at the condition of preparation  $\phi_0 = 0.0884$ , the average number of segments between two neighboring crosslinking points  $m = 34$ , and the particle radius at the preparation condition  $R_0 = 125.8$  nm are obtained by fitting to the experimental data. These model parameters are in good agreement with experiments.

Fig. 3 presents the reduced osmotic second virial coefficients ( $B_2/B_2^{\text{HS}}$ ) for PNIPAM microgel particles dispersed in water. Here the open circles are data

**Fig. 2** Radius of PNIPAM particles vs. temperature. The points are averages from dynamic and static light scattering measurements with the error bars showing the differences between the two. The line is calculated from [Eqs. (1–3)].

**Fig. 3** The reduced osmotic second virial coefficients ( $B_2/B_2^{HS}$ ) for PNIPAM particles dispersed in pure water. Points are from static light scattering and the line is calculated from Eq. (7) normalized by the second virial coefficient  $B_2^{HS} = (2\pi/3)\sigma^3$  for the corresponding hard spheres.

points from static light scattering measurements and the line is calculated using Eqs. (6) and (7), with the molecular weight  $M_W = 1.73 \times 10^7$  g/mol and the proportionality constant  $k_A = 6.43 \times 10^{-5}$  obtained by fitting to the experimental data. The hard-sphere second virial coefficient is related to the particle diameter  $\sigma$  by  $B_2^{HS} = (2\pi/3)\sigma^3$ . A positive osmotic second virial coefficient means that the overall interparticle potential is repulsive; otherwise, it is attractive. Fig. 3 indicates that below the volume transition temperature, the PNIPAM particles behave essentially like hard spheres. In this case, the microgel particles are in the swollen state and they contain up to 97% of water by volume. As a result, the van der Waals attraction between colloidal particles is negligible because of the close match in the Hamaker constants of the particle and the water. The reduced osmotic second virial coefficient exhibits a sharp change at the volume transition temperature, beyond which it turns to negative, indicating an increase in the van der Waals attraction as the particles collapse. Fig. 3 suggests that with temperature-dependent size and energy parameters, the Sutherland-type function captures the essential features of the interaction potential between microgel particles.

Because the number density of polymeric segments within each particle is closely related to the particle size, we expect that the attraction between microgel particles is highly temperature-sensitive. Fig. 4 shows the reduced energy parameter  $\varepsilon/(kT)$  near the volume transition temperature as obtained by correlation with the osmotic second virial coefficients from experiments. Experimental values for this parameter are

**Fig. 4** The reduced energy parameter ( $\varepsilon/kT$ ) for interparticle potential between PNIPAM particles near the volume transition temperature.

not included because it is difficult to make a direct (or indirect) measurement of the reduced energy parameter. But the credibility of calculated results is implied in the comparison of osmotic second virial coefficients, as shown in Fig. 3. Remarkably, the energy parameter increases by over six orders of magnitude as temperature changes from 24°C to 36°C, with the sharpest increase at the volume transition temperature of 34°C.

## THERMODYNAMIC MODELS FOR PHASE EQUILIBRIUM CALCULATIONS

To calculate the phase diagram, we need to have the thermodynamic models for both fluid and crystalline phases, as well as the structure of the crystal. It has been shown before by small-angle neutron scattering measurements that even at low crosslinker concentrations, aqueous dispersions of PNIPAM microgel particles crystallize like hard-sphere liquids.<sup>[42]</sup> Fig. 5 indicates that the structure factor of the colloidal crystal is well represented by that for a face centered cubic (fcc) structure. Therefore it is reasonable to assume that hard spheres provide a good reference system for representing the thermodynamic properties of microgel dispersions. Because the van der Waals attraction between microgel particles is short-ranged compared to the particle size, a first-order perturbation theory is appropriate for both phases. The higher-order terms are insignificant when the perturbation potential is short-ranged.<sup>[58]</sup>

**Fig. 5** (A) Neutron scattering profile for a dilute microgel dispersion. (B) Scattering profile for a colloidal crystal of microgel particles. (C) Structure factor of the crystal. The Bragg peaks are interpreted according to the fcc lattice. Source: From Ref.<sup>[42]</sup>.

The Helmholtz energy of the fluid phase includes a hard-sphere contribution that is given by the Carnahan–Starling equation of state, and a perturbation that takes into account the van der Waals attraction. In dimensionless units, the Helmholtz energy is given by:

$$\frac{F}{NkT} = \ln(\eta) - 1 + \frac{4\eta - 3\eta^2}{(1 - \eta)^2} + 12\eta \int_1^{\infty} x^2 g_F^{\text{HS}}(x) \frac{u_A(x)}{kT} dx \quad (9)$$

where  $N$  represents the total number of particles,  $\eta = \pi\rho\sigma^3/6$  is the particle packing fraction,  $\rho$  is the particle number density, and  $g_F^{\text{HS}}(r)$  is the hard-sphere radial distribution function. For convenience, we correlate the integral in Eq. (9) as a function of particle packing fraction using the radial distribution function  $g_F^{\text{HS}}(r)$  obtained from the Percus–Yevick equation:<sup>[59]</sup>

$$I_F(\eta) \equiv \int_1^{\infty} x^{-6} g^{\text{HS}}(x) dx = 0.027224\eta^2 + 0.1642\eta + 0.2007 \quad (10)$$

The quadric form as given in Eq. (10) is applicable to the reduced density  $\rho\sigma^3 < 0.6$ . Replacement of the

integral in Eq. (9) with  $I_F(\eta)$  gives:

$$\frac{F}{NkT} = \ln(\eta) - 1 + \frac{4\eta - 3\eta^2}{(1 - \eta)^2} - 12\eta I_F(\eta) \varepsilon^* \quad (11)$$

where:

$$\varepsilon^* = \frac{\varepsilon}{kT} = k_A \left( \frac{T_0}{T} \right) \left( \frac{\sigma_0}{\sigma} \right)^{6+n} \quad (12)$$

Other thermodynamic properties can be derived from Eq. (11) following standard thermodynamic relations.

To describe the thermodynamic properties of the solid phase, we follow a perturbation approach similar to that for the fluid phase. The Helmholtz energy includes a contribution from the reference hard-sphere crystal and a perturbation taking into account the van der Waals attraction:

$$\frac{F}{NkT} = \frac{F^{\text{HS}}}{NkT} + 12\eta \int_1^{\infty} x^2 g_S^{\text{HS}}(x) \frac{u_A(x)}{kT} dx \quad (13)$$

where  $g_S^{\text{HS}}(r)$  is the radial distribution function of the hard-sphere solid. As in a hard-sphere system, an aqueous dispersion of PNIPAM microgel particles forms a face centered cubic lattice in the solid phase even when the particles are at low crosslinking density (“softer” particles).<sup>[42]</sup>

According to an improved cell theory,<sup>[60]</sup> the Helmholtz energy of the hard-sphere solid is given by:

$$\frac{F^{\text{HS}}}{NkT} = - \ln \left[ \frac{8}{\sqrt{2}} \left( (\rho/\rho_0)^{1/3} - 1 \right) \right] \quad (14)$$

Compared with the original cell model proposed many years ago by Lennard-Jones and Devonshire,<sup>[61]</sup> the improved cell model introduces a factor of 8, taking into account the fact that the neighboring particles share partially the free space. Unlike the original cell model, the modified cell model provides accurate freezing and melting densities for the fluid–solid transition of uniform hard spheres. The hard-sphere radial distribution function  $g_S^{\text{HS}}(r)$  can be calculated using a modified Gaussian model for density distributions.<sup>[49]</sup> Using the radial distribution function  $g_S^{\text{HS}}(r)$  for the hard-sphere solids, we numerically integrate the perturbation term in Eq. (13). The final expression for the Helmholtz energy of the solid phase is given by:

$$\frac{F}{NkT} = - \ln \left[ \frac{8}{\sqrt{2}} \left( (\rho/\rho_0)^{1/3} - 1 \right) \right] - 12\eta I_S(\rho) \varepsilon^* \quad (15)$$

where:

$$I_S(\rho) \equiv \int_1^\infty x^{-6} g_S^{HS}(x) dx = 0.451\rho^2 - 0.5253\rho + 0.5514 \quad (16)$$

Eq. (16) is applicable for the solid phase with the reduced density  $0.95 < \rho\sigma^3 < 1.27$ .

### EQUILIBRIUM PHASE DIAGRAM

Once we have an expression for the Helmholtz energy, the chemical potential  $\mu$  and the osmotic pressure  $P$  can be derived following standard thermodynamic relations:

$$\mu = \left( \frac{\partial F}{\partial N} \right)_{T,V} \quad (17)$$

$$P = - \left( \frac{\partial F}{\partial V} \right)_{T,N} \quad (18)$$

where “V” stands for the total volume. A fluid–fluid coexistence curve is obtained from the criteria of phase equilibrium:

$$\mu^\alpha = \mu^\beta \quad (19)$$

$$P^\alpha = P^\beta \quad (20)$$

where “ $\alpha$ ” and “ $\beta$ ” designate two distinguishable fluid phases. To calculate the pressure and the chemical potential in the fluid phase, the Helmholtz energy is given by Eq. (11). For each temperature, we solve for equilibrium densities  $\rho^\alpha$  and  $\rho^\beta$  using Eqs. (19) and (20). If no solution is found, the temperature is above the critical temperature for fluid–fluid equilibrium; in this case, there is only one fluid phase.

For fluid–solid equilibrium, we also use Eqs. (19) and (20). But now, for phase  $\alpha$ , we use Eq. (11) for the liquid-phase Helmholtz energy, whereas we use Eq. (15) for the solid-phase Helmholtz energy for phase  $\beta$ . Again, we search for densities  $\rho^\alpha$  and  $\rho^\beta$  that satisfy both equations of phase equilibrium [i.e., Eqs. (19) and (20)].

To calibrate the thermodynamic models proposed in this work, we first consider the phase behavior of a Yukawa system that is often used to represent colloidal dispersions with weak attractive interactions. Fig. 6 compares the fluid–solid as well as metastable fluid–fluid coexistence curves from simulation<sup>[62]</sup> and from the perturbation theory. The agreement is satisfactory except near the critical point of the fluid–fluid equilibrium where the long-range fluctuations become

**Fig. 6** The phase diagram of a typical colloidal system with weak attractive forces. The points are from simulation data for Yukawa potential. Source: From Ref.<sup>[62]</sup>. The lines are from the theory.

significant. An improved prediction in this region can be achieved by applying the renormalization group theory.<sup>[63]</sup> Fig. 6 indicates that at high temperature, the system is dominated by short-range repulsion and it exhibits freezing transition similar to that for hard spheres, whereas at low temperature, freezing occurs at dilute conditions and is separated by a metastable liquid–liquid equilibrium.

**Fig. 7** The phase diagram of aqueous dispersions of PNIPAM particles determined from turbidity measurements (symbols) and from the thermodynamic perturbation theory with an empirical correction of temperature (lines). The filled and open circles represent the melting and the second phase separation temperatures, respectively.

Fig. 7 shows the calculated phase diagram of PNIPAM microgel dispersion using the first-order perturbation theories for fluid and solid phases. Also shown in this figure are results determined from a UV-VIS spectrometer. In this calculation, the calculated temperature is rescaled empirically by  $T' = T(15/R_g)^{0.005}$  to match the experimental results quantitatively. The discrepancy is probably because of the slight size difference ( $\sim 2$  nm) between the microgel samples used in light scattering and in phase diagram measurements. Nevertheless, the theory and the experiment agree, at least semiquantitatively.

The phase diagram shown in Fig. 7 differs drastically from that of a conventional colloidal dispersion, or that of a colloid polymer mixture.<sup>[64]</sup> Below the volume transition temperature, the coexistence phases at the freezing and melting points have close particle densities, similar to that observed in a hard-sphere system. However, above the volume transition temperature, fluid–solid transition spans over a wide gap of particle concentrations. At high temperature, the fluid phase at the freezing point is highly dilute, whereas the solid phase at the melting point is highly concentrated. Interestingly, this phase diagram indicates that the microgel dispersion can freeze at temperatures both above and below the gel volume transition temperature. For instance, according to this phase diagram, a microgel dispersion with 7 g/L particle concentration is in the fluid state at 34.5°C; it becomes a solid of similar density when the temperature drops to about 34°C, and the dispersion will be separated into a dilute solution and a solid of much higher density (about 17 g/L) at about 35.3°C. The dashed line in Fig. 7 shows a metastable fluid–fluid coexistence curve with a low critical solution temperature. This coexistence curve is reminiscent of that for an aqueous solution of uncrosslinked PNIPAM polymer. Because of strong hydrogen bonding with water molecules from CO and NH groups, PNIPAM can be dissolved in water at low temperature. In this case, the isopropyl groups along the PNIPAM chain are caged by water molecules. When the temperature is increased, the cages of water molecules are partially melted, resulting in entropy increases. As a result, on increase of the temperature, the hydrophobic attraction caused by the isopropyl groups and the polymer backbone become more important and the solubility of PNIPAM in water drops.

## KINETICS OF CRYSTALLIZATION

As shown in Fig. 3, light scattering measurements indicate that when the particles are in the swollen state, the osmotic second virial coefficients of PNIPAM microgel dispersions are essentially the same as those for hard

spheres. The nucleation kinetics confirms further that the swollen PNIPAM particles behavior like hard spheres. We find that the kinetics of microgel crystallization can be represented quantitatively by the classical nucleation theory (CNT).

The classical theory of nucleation and crystal growth has been adapted by Russel<sup>[65]</sup> to hard-sphere colloids, and extended and evaluated numerically by Ackerson and Schatzel.<sup>[66]</sup> According to the CNT,<sup>[67]</sup> the crystal nucleation rate per unit volume  $I$  depends exponentially on the Gibbs energy barrier in the formation of a critical nucleus  $\Delta G_{\text{crit}}$ :

$$I = \zeta \exp(-\Delta G_{\text{crit}}/k_B T) \quad (21)$$

where the kinetic prefactor  $\zeta$  is usually expressed as  $A\phi^{5/3}(1 - \phi/\phi_g)^{2.6}$ , where  $A$  is a constant independent of the particle volume fraction  $\phi$ , and  $\phi_g$  is the glass transition concentration. The critical Gibbs energy of nucleation is related to the difference in the chemical potentials of the solution and the crystal  $\Delta\mu$ , the solution–solid interfacial tension  $\gamma$ , and the number density of the crystalline phase  $\rho_s$ :

$$\Delta G_{\text{crit}} = \frac{16\pi}{3} \frac{\gamma^3}{[\rho_s \Delta\mu]^2} \quad (22)$$

Fig. 8 The nucleation rates per unit volume as a function of the particle volume fraction in an aqueous dispersion of PNIPAM microgel particles and in various hard-sphere systems. The solid line is calculated from CNT with the prefactor  $A$  and the fluid–solid interfacial tension  $\gamma$  as adjustable parameters. The dashed line is the prediction of the CNT using  $A$  and  $\gamma$  from Monte Carlo simulation.

In most applications of the CNT to analyze crystal nucleation experiments, the parameter  $A$  in the kinetic prefactor and the interfacial tension are treated as adjustable variables.

In Fig. 8, we compare the rate of nucleation per unit volume in the microgel dispersion investigated in this work with previous studies for hard-sphere-like colloids.<sup>[7,68–70]</sup> Also shown in Fig. 8 are calculated results from CNT using  $A$  and  $\gamma$  as adjustable parameters, as well as the predictions of CNT with the kinetic prefactor and the fluid–solid interfacial tension obtained from Monte Carlo simulations.<sup>[71]</sup> In these calculations, the chemical potentials of the fluid and solid phases are calculated from Eqs. (11) and (15). Fig. 8 indicates that although the rate of nucleation for microgel dispersions is close to previous investigations on well-established hard-sphere-like colloids and it agrees well with CNT using  $\log_{10}(A) = -5.96$  and  $\gamma/k_B T = 0.45$ , it significantly deviates from simulation results for hard spheres. Similar observations have been reported by Schatzel and Ackerson for crystallization kinetics in a model hard-sphere system consisting of polymethyl methacrylate particles coated with a thin layer of hydroxystearic acid suspended in a mixture of decalin and tetralin.<sup>[68]</sup>

## CONCLUSION

The volume transition of PNIPAM particles significantly affects the interaction potential and determines a novel phase diagram that has not been observed in conventional colloids. Because both particle size and attractive potential depend on temperature, PNIPAM aqueous dispersion exhibits phase transitions at a fixed particle density by either increasing or decreasing temperature. At low temperature, freezing occurs at large particle volume fractions, similar to that in a hard-sphere system; whereas at high temperature, the freezing occurs at low particle concentration, driven by the strong van der Waals attraction caused by the collapsed microgel particles. Although the kinetics of nucleation in PNIPAM microgel dispersions is similar to that for hard-sphere-like colloids, it deviates significantly from the prediction of the CNT using the kinetic prefactor and the fluid–solid interfacial tension obtained from recent simulations for the crystal nucleation of hard spheres.

In many aspects, the phase behavior of colloidal dispersions reassembles that for simple fluids. However, a noticeable difference is that unlike the vapor–liquid equilibrium of a simple fluid, the equilibrium between a dilute and a concentrated colloidal dispersion is often metastable. Although that difference, arising from the short-ranged solvent-mediated attraction between colloidal particles, is now well-documented, not much

attention has been given to other features that are unique in colloidal systems. Temperature-dependent potential, as shown in this work, is special in colloidal systems. Because the interparticle potential is strongly temperature-dependent, the phase behavior of PNIPAM dispersions differs remarkably from that for simple fluids or for conventional colloids. In future work, it might be interesting to investigate other features that are special to colloidal dispersions, including the multibody effect on the phase behavior and dissimilarity of interparticle potentials in different phases.

## INTRODUCTION

Carbon dioxide (CO<sub>2</sub>), when heated and pressurized above its critical temperature (31°C) and pressure (7.377 MPa), is identified as being in a fourth, supercritical state with properties intermediate between liquid and gas (Table 1). At the critical point, the interface of CO<sub>2</sub> liquid and vapor starts to vanish (Fig. 1). Supercritical CO<sub>2</sub> (scCO<sub>2</sub>) has liquid-like densities providing good solvent capability, gas-like viscosities, and diffusivities to benefit mass transport, and a non-hazardous nature for the environment. Because of these properties and other advantages of CO<sub>2</sub> over organic solvents such as low surface tension and low cost,<sup>[1]</sup> scCO<sub>2</sub> has received increasing industrial<sup>[2]</sup> and research<sup>[1]</sup> attention in a variety of processes such as extraction,<sup>[3,4]</sup> cleaning,<sup>[5,6]</sup> polymer synthesis,<sup>[7,8]</sup> and more recently microelectronics processing.<sup>[9,10]</sup> CO<sub>2</sub> has been proposed to serve as an energy-efficient and environmentally benign solvent platform.<sup>[11]</sup> The real-time monitoring of the time-dependent mass change is crucial to understanding, characterizing, designing, and controlling the aforementioned processes. However, this monitoring presents a number of challenges because of the difficulty in applying various detection methods under high-pressure conditions.

In this entry, two microweighing techniques in scCO<sub>2</sub>, gravimetric and piezoelectric, are reviewed. A comparison is made between two representatives of these techniques: the magnetic suspension balance (gravimetric) and the quartz crystal microbalance (QCM, piezoelectric). The QCM theory in high-pressure fluids is briefly introduced, followed by a summary of recent research which includes 1) the experimental verification of QCM theory; 2) the scCO<sub>2</sub> adsorption on metal surfaces; and 3) the dissolution of polymer films for applications in scCO<sub>2</sub>-based lithography processes. Finally, the application of QCM in absorption, solubility, and other surface-specific processes in scCO<sub>2</sub> will be reviewed to highlight the versatility of the QCM technique.

## MICROWEIGHING TECHNIQUES: GRAVIMETRIC AND PIEZOELECTRIC

Many important physical and chemical processes can be monitored by observing the associated mass changes. Currently, two microweighing techniques, gravimetric and piezoelectric, have been widely used as an analytical tool for research and applied applications. Gravimetric microbalances are the most direct technique to measure mass variations at the microgram level. However, in a number of cases, most conventional gravimetric microbalances such as spring, beam, and torsional balances are not designed for the operation under extreme conditions. The extreme conditions are usually defined as conditions of high pressures (>1450 psi), viscous fluids, and/or high temperatures. In order to adapt the conventional gravimetric balances to work under extreme pressures, some researchers<sup>[12,13]</sup> have designed a high-pressure container to include both the microbalance and the sample. This not only greatly increases the system expenses, structural complexity, and operational difficulties, but also sacrifices the capability under high temperatures (>125°C) because of the microbalance working conditions. Jwayyed, Humayun, and Tomaska<sup>[13]</sup> modified a commercial high-pressure microbalance (Cahn C-1000 balance) by redesigning the container (nipple shape with 30 cm o.d. and 25 cm height) for use in scCO<sub>2</sub>. They were only able to extend the pressure limit from 1600 to 3000 psi.

In recent years, some researchers<sup>[14,15]</sup> have been able to design a unique balance, a magnetic suspension balance (MSB), for mass measurements under extreme conditions (>3000 psi). The MSB takes advantage of the principle of magnetic coupling to isolate the balance from the sample that is contained in a small pressure cell (Fig. 2), while maintaining most features of the traditional microbalances. Using this magnetic suspension coupling, the measured force is transmitted from the pressure cell to the microbalance that is located in the ambient environment. Such novel design eliminates the large container, enables the capability of mass determinations under extreme conditions, and

**Table 1** Physical properties of gas, liquid, and supercritical fluid (order of magnitude)

	Density (g/cm <sup>3</sup> )	Diffusivity (cm <sup>2</sup> /sec)	Viscosity (g/cm/sec)
Gas	1 × 10 <sup>-3</sup>	1 × 10 <sup>-1</sup>	1 × 10 <sup>-4</sup>
Liquid	1.0	5 × 10 <sup>-6</sup>	1 × 10 <sup>-2</sup>

makes realistic applications of gravimetric techniques in CO<sub>2</sub>-based processes. The MSB has primarily been applied to determine the adsorption/absorption and diffusivity of scCO<sub>2</sub> in addition to other solutes on/in bulk solid materials under static conditions.<sup>[16–22]</sup> Applications of MSB for other chemical processes and applications under dynamic (flowing) conditions are rarely found in the literature.

Piezoelectric quartz crystal resonators take advantage of the electric polarization that occurs when the crystal is subjected to a mechanical stress.<sup>[23]</sup> Several different devices operate using the piezoelectric technique according to the modes of electromechanical coupling, such as modes of thickness shear, face shear, and surface acoustic wave.<sup>[24]</sup> The AT-cut thickness-shear mode resonator, commonly referred to QCM, is the most widely used piezoelectric mass sensor.<sup>[25]</sup> The QCM consists of a thin quartz disk with two metal electrodes plated on its two opposite surfaces (Fig. 3). The QCM is a powerful microweighing tool for detecting in situ the mass changes to the ng/cm<sup>2</sup> level of

sensitivity. In the last decade, there has been increased application of the QCM for studies of a wide range of chemical processes and chemistries on surfaces and in thin films.<sup>[23–29]</sup> There are few difficulties for QCM applications under extreme conditions, because of the rigidity and chemical inertness of the quartz crystals and the elimination of any connection except the supply of electricity. Rigid electrical leads are commonly used to hold the crystal in place and excite the sensor that is contained in the pressure cell (Fig. 4). The QCM has been applied to many scCO<sub>2</sub>-based processes and chemistries in bulk phases or at surface films; they will be summarized later in the following sections.

Table 2 summarizes a comparison of the performance of MSB with QCM for the microweighing in scCO<sub>2</sub>. As can be seen, the QCM is a more powerful and versatile microweighing tool in scCO<sub>2</sub> than the MSB, mainly owing to its low cost, conceptual simplicity, high mass sensitivity, wide range of applications, rapid time response, and miniature and simple construction. In particular, the nanogram-level sensitivity enables the QCM as a possible technique that can be utilized to study interfacial processes related to nanotechnologies and nanomaterials.

### QUARTZ CRYSTAL MICROBALANCE THEORY IN HIGH-PRESSURE FLUIDS

#### Fundamentals

As the QCM is piezoelectric, an external electrical potential applied across the electrodes produces internal mechanical stress. This stress induces an acoustic wave that propagates through the crystal and meets minimum impedance when the thickness of the crystal is a multiple of a half wavelength of the acoustic wave. A resonant oscillation is achieved by including the crystal into an oscillation circuit in which the electric and the mechanical oscillation are close to the fundamental frequency (*F*<sub>0</sub>) of the crystal.<sup>[25,26]</sup>

When a crystal is immersed in a fluid, any frequency shift from its fundamental value (*F*<sub>0</sub>) in vacuum can be observed because of contributions from 1) mass sorption or desorption from the crystal surface; 2) pressure; 3) density and viscosity of the fluid surrounding the crystal; and 4) surface roughness of the crystal. The following expression has been established to describe changes in the crystal frequency, Δ*F*, due to the aforementioned effects.<sup>[30]</sup>

$$\Delta F = F - F_0 = \Delta F_m + \Delta F_P + \Delta F_\eta + \Delta F_r \tag{1}$$

where *F* is the measured frequency of quartz, Δ*F*<sub>m</sub> relates to mass loading, Δ*F*<sub>P</sub> is dependent on pressure,

**Fig. 1** Phase diagram for CO<sub>2</sub> with constant density lines (dot lines, g/cm<sup>3</sup>). Above the critical point (31°C and 1070 psi), the vapor–liquid equilibrium (VLE) boundary vanishes, and the supercritical state is observed. The dash lines do not represent a boundary, but for the convenience to distinguish different states of CO<sub>2</sub>.

Fig. 2 A typical magnetic suspension balance (MSB). Source: From Ref.<sup>[21]</sup>.

$\Delta F_\eta$  changes with density and viscosity, and  $\Delta F_r$  is a function of surface roughness.

According to the well-known Sauerbrey equation,<sup>[31]</sup>  $\Delta F_m$  is directly proportional to the mass loading on the crystal:

$$\Delta F_m = -2nF_0^2 \Delta m / (\mu_q \rho_q)^{1/2} = -C_m \Delta m \quad (2)$$

where  $\mu_q$  is the shear modulus of quartz,  $\rho_q$  is the density of the crystal,  $\Delta m$  is the film mass per real surface

area,  $n$  is the number of faces of the crystal exposed, and  $C_m$  is the mass sensitivity of QCM, which is a function of the characteristic properties ( $F_0$ ,  $\mu_q$ , and  $\rho_q$ ) of the quartz crystal. Eq. (2) applies only if the adsorbed mass is much less than the mass of the crystal and it assumes this mass is firmly attached to the surface; hence the material moves together with the crystal. Such conditions are assumed to be fulfilled in cases of coated solid films and self-assembled monolayers.

The pressure dependence of frequency,  $\Delta F_p$ , increases with increasing pressure linearly, as shown by Stockbridge<sup>[32]</sup> for gases up to 15 psi. Susse<sup>[33]</sup> described a similar relationship for liquids up to  $1.5 \times 10^4$  psi. Thus  $\Delta F_p$  can be written as:

$$\Delta F_p = F_0 \alpha P = C_p P \quad (3)$$

where  $\alpha$  is the proportionality constant and  $C_p$  is the pressure sensitivity of QCM crystal, both of which are independent of the type of fluid in contact with the crystal.

The viscosity and density contribution,  $\Delta F_\eta$ , describes the interaction of the vibrating crystal with a Newtonian viscous fluid. The interaction leads to an additional loading of the crystal, causing a decrease in frequency.  $\Delta F_\eta$  is expressed to be proportional to the square root of the product of viscosity and density of the surrounding fluid:<sup>[32,34,35]</sup>

$$\Delta F_\eta = -0.5 C_m (\pi F_0)^{-1/2} (\rho_f \eta_f)^{1/2} \quad (4)$$

where  $\rho_f$  and  $\eta_f$  are the absolute density and viscosity of the fluid, respectively.

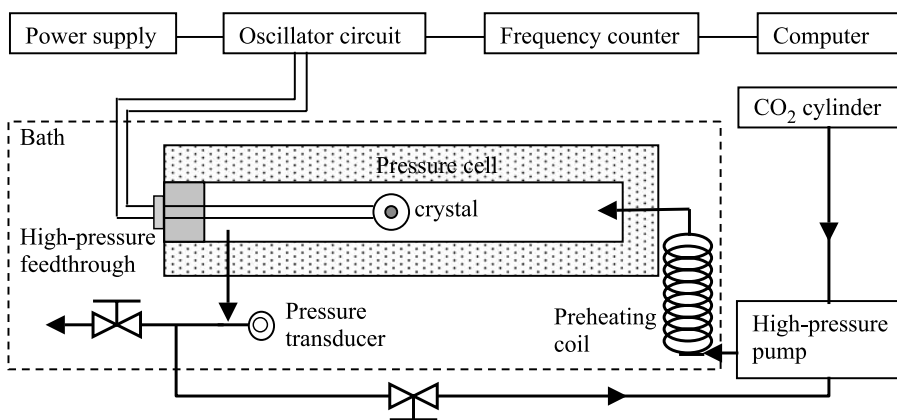

Fig. 3 Schematic view of a piezoelectric QCM crystal (only one side shown). A typical 5-MHz QCM from International Crystal Manufacturing consists of a thin quartz crystal (0.85 cm diameter) sputtered with a metal electrode (0.35 cm diameter) on each side. Both sides should be exposed to  $scCO_2$  because of high pressure.

**Fig. 4** Schematic view of an experimental setup of QCM measurement system in scCO<sub>2</sub>. Source: From Ref.<sup>[50]</sup>.

**Roughness Effect**

A common feature of the approaches to QCM theory as reviewed by Thompson et al.<sup>[27]</sup> is the neglect of microscopic properties of interfaces and surface roughness.<sup>[36]</sup> This leads to deviations of most experimental frequency shift data from the predictions by these approaches. Buttry and Ward<sup>[23]</sup> and Schumacher, Borges, and Kanazawa<sup>[37]</sup> observed that up to 80% of the observed frequency shifts for a crystal in contact with a liquid could be attributed to roughness effects.

As the microscopic properties of crystal–fluid interfaces change with the surface morphology, a predictive analytical expression for the roughness contribution to frequency,  $\Delta F_r$ , is not available. Urbakh and Dalkhin<sup>[36,38,39]</sup> formulated a model for surface roughness, assuming that a rough surface can be characterized by the average height ( $h$ ), lateral length ( $a$ ), and distance ( $l$ ) between the inhomogeneities of the surface (Fig. 5). They incorporated this model into a framework of perturbation theory<sup>[36,38]</sup> and derived a general

relationship for  $\Delta F_r$  as:

$$\Delta F_r = -0.5C_m(\pi F_0)^{-1/2}(\rho_f \eta_f)^{1/2} \Psi(a/\delta, a/l, h/a) \tag{5}$$

where  $\Psi$  is a scaling function, related to three dimensionless factors,  $a/\delta$ ,  $a/L$ , and  $h/a$ ;  $\delta$  is the decay length of fluid velocities,

$$\delta = [\eta_f/(\pi F_0 \rho_f)]^{1/2} \tag{6}$$

In particular, if one assumes a slowly varying roughness ( $h/a \ll 1$  and  $h/\delta \ll 1$ ) for the crystal surface with a limit of  $a/\delta \ll 1$  or  $a/\delta \gg 1$ , the scaling function  $\Psi$  is proportional to the ratio  $a/\delta$ .<sup>[36]</sup> Reformulating Eq. (5) yields:

$$\Delta F_r = -0.5C_m C_r \rho_f \tag{7}$$

where  $C_r = \Psi \delta$  is defined as the frequency–roughness correlation factor. This factor is only a function of sur-

**Table 2** Comparison of two microweighing methods

Characteristics	Gravimetric: MSB <sup>[21]</sup>	Piezoelectric: QCM <sup>[24]</sup>
Mass sensitivity	$10^{-5}$ – $10^{-6}$ g <sup>13</sup>	$<10^{-9}$ g
Time resolution of response	$5 \times 10^{-2}$ sec <sup>13</sup> (need fine damping control system)	$<10^{-3}$ sec
Measuring variables	Gravity	Frequency and/or impedance
Calculations	Simple	Simple
Construction	Complex, especially the designing of the magnetic coupling and fine damping control system	Very simple
Size	Medium size when comparing with the QCM	Miniature size (0.5–2.5 cm diameter)
Calibration	Required to correct buoyancy	Not necessary <sup>25</sup>
Cost	Expensive	Cheap ( $<\$30$ a QCM crystal) <sup>a</sup>
Operation conditions	Mainly static; <sup>13</sup> extreme conditions	Both static and dynamic; extreme conditions
Applications	Mainly for processes and chemistries in bulk phases	For processes and chemistries both in bulk phases and at thin films

<sup>a</sup>Price information was obtained from International Crystal Manufacturing.

**Fig. 5** Two types of ideal surface roughness. (A) Slightly rough,  $h/\delta \ll 1$ ; (B) strongly rough,  $h/\delta \gg 1$ . Source: From Ref.<sup>[40]</sup>.

face roughness ( $h$  and  $a$ ), provided that the assumptions above are fully established. Otherwise,  $C_r$  should be additionally viewed as a weak function of  $\delta$ .

**EXPERIMENTAL EXAMINATION OF QUARTZ CRYSTAL MICROBALANCE THEORY AND ADSORPTION OF CO<sub>2</sub> ON METAL SURFACES**

As the frequency of a QCM crystal exposed to a high-pressure fluid is affected by different factors, it is critical to accurately separate out each influencing factor. Experimental verification of QCM theory enables the calculation of the actual mass change on the crystal surface. The investigation of CO<sub>2</sub> adsorption on metal electrodes of blank crystals is a required initial step for the successful use of the QCM technique to investigate the chemical and physical properties of surface films in scCO<sub>2</sub>.

**Separation of Contributions to Frequency**

As the microscopic properties of crystal–fluid interfaces complicate the QCM frequency behavior, a unique strategy<sup>[40]</sup> to verify the QCM theory in scCO<sub>2</sub> is to experimentally establish a relationship between the microscopic properties of crystal surfaces and frequency shifts. In a study reported here, the surface roughness of QCM crystals (three gold and three silver 5-MHz crystals; Table 3) was characterized using an AFM technique. Three groups of QCM experiments were performed on the six crystals to separate the following different contributions to QCM frequency:  $\Delta F_p$ ,  $\Delta F_m$ ,  $\Delta F_\eta$ , and  $\Delta F_r$ . The first set of experiments performed on Ag-polished and Ag-rough crystals utilized helium, the lightest inert gas considered nonabsorbing ( $\Delta F_m = 0$ ) on metals, to determine  $\Delta F_p$  and  $\Delta F_\eta$ . To evaluate the roughness contribution of frequency,  $\Delta F_r$ , the second set of experiments utilized N<sub>2</sub>, another nonabsorbing gas on the metal surfaces at room temperatures (i.e.,  $\Delta F_m$  negligibly small). The last group of experiments was conducted using low-density gaseous CO<sub>2</sub> ( $< 0.2 \text{ g cm}^{-3}$ ), an adsorbing gas at room temperatures, to test the adsorbed masses of CO<sub>2</sub> on the metal surfaces.

The first set of experiments in helium indicated that the frequency shifts of the smoothest silver crystal (Ag-polished) could be accurately predicted with the QCM theory for pressure and viscosity (Eqs. (3) and (4)) by neglecting the roughness effect. However, for the roughest silver crystal (Ag-rough), about 10% of the total frequency shifts could not be theoretically predicted with Eqs. (3) and (4). The variations in the prediction were attributed to the roughness effect. This is consistent with the experimental findings by Tsionsky et al.<sup>[30]</sup> who investigated frequency shifts of gold and nickel crystals in He, H<sub>2</sub>, Ar, and N<sub>2</sub>.

**Table 3** Some characteristic properties of six different QCM crystals

Crystals	RMS roughness <sup>a</sup> (10 <sup>-7</sup> cm)	$H$ (10 <sup>-7</sup> cm)	$a$ (10 <sup>-7</sup> cm)	$l$ (10 <sup>-7</sup> cm)	$C_r$ (10 <sup>-5</sup> cm) <sup>b</sup>	
					Eq. (8a)	Eq. (8b)
Ag-polished	3.7	12	180	190	1.32(1–2.65 $\rho_f$ )	0.398 + 4.96 × 10 <sup>4</sup> $\delta$
Ag-unpolished	26	85	1410	2180	1.79(1–3.48 $\rho_f$ )	0.322 + 7.44 × 10 <sup>4</sup> $\delta$
Ag-rough <sup>c</sup>	647	1030	–	–	7.28(1–1.27 $\rho_f$ )	5.16 + 1.05 × 10 <sup>5</sup> $\delta$
Au-polished	2.8	8	110	120	1.37(1–2.23 $\rho_f$ )	0.595 + 4.10 × 10 <sup>4</sup> $\delta$
Au-unpolished	115	210	1370	2120	3.22(1–2.37 $\rho_f$ )	1.41 + 9.17 × 10 <sup>4</sup> $\delta$
Au-rough <sup>3</sup>	681	1090	–	–	6.88(1–1.51 $\rho_f$ )	3.99 + 1.63 × 10 <sup>5</sup> $\delta$

<sup>a</sup>The rms roughness is defined as the root mean square (or standard deviation) of the  $Z$  values within a given AFM image area with respect to the average  $Z$  value.

<sup>b</sup>The units for  $\rho_f$  and  $\delta$  are g/cm<sup>3</sup> and cm, respectively.

<sup>c</sup>Lack of data for  $a$  and  $l$  because of no apparent periodic inhomogeneities in the AFM images of the strongly rough crystals.

Source: From Ref.<sup>[40]</sup>.

The second set of experiments in nitrogen showed that the roughness effect had a significant influence on the frequency even for the smoothest silver and gold crystals. The experimental roughness contribution,  $\Delta F_r$ , was calculated by subtracting theoretical  $\Delta F_p$  and  $\Delta F_\eta$  from the experimental  $\Delta F$  (Eq. (1)). The resulting  $\Delta F_r$  was plotted as a function of theoretical  $N_2$  density; the corresponding frequency shift corrected in this manner was found to be a nearly linear function of density, indicating the precision of the theoretical expression of  $\Delta F_r$  (Eq. (7)). Therefore the frequency-roughness correlation factor,  $C_r$ , can be obtained by correlating  $\Delta F_r$  with the  $N_2$  density ( $\rho_f$ ) or the decay length ( $\delta$ ), using Eqs. (8a) and (8b),

$$C_r = a_1(1 + b_1\rho_f) \tag{8a}$$

$$C_r = a_2 + b_2\delta \tag{8b}$$

where  $a$  and  $b$  are the constants assumed to be independent of the type of fluid. The values of  $a$  and  $b$  for each crystal are also shown in Table 3. Eqs. (8a) and (8b) represent accurate predictions of  $C_r$  with most correlation coefficients better than 0.999. Eq. (8a) is only applicable to gases because of the neglect of the influence of viscosity, while Eq. (8a) is suitable for dense gases ( $\rho_f > 0.2 \text{ g/cm}^3$ ) and liquids.<sup>[40]</sup>  $C_r$  was found to be dependent primarily on the rms roughness of crystals and, to a lesser degree, on  $a$  and  $l$ .<sup>[40]</sup>

In the last group of experiments, the frequency shifts ( $\Delta F$ ) of all six crystals in gaseous  $CO_2$  (pressure <1000 psi) were measured to evaluate the amount of  $CO_2$  adsorbed on the metal surfaces. The  $CO_2$  adsorption was calculated from  $\Delta F_m$  that was obtained by subtracting the theoretical  $\Delta F_p$ ,  $\Delta F_\eta$ , and  $\Delta F_r$  from  $\Delta F$ , using Eqs. (1) to (4), (7), and (8a). As can be seen (Fig. 6), all six crystals with different surface roughness values adsorbed similar amounts of gaseous  $CO_2$  per real surface area, which agrees well with the adsorption theory. This is additional evidence of the accuracy of the reformulated QCM theory by including the roughness contribution. It also implies that the  $a$  and  $b$  values obtained in  $N_2$  are independent of the type of fluid.

### Adsorption of Supercritical $CO_2$ on Metal Surfaces

Several researchers have determined the mechanisms of adsorption of  $scCO_2$  on metal surfaces. Otake et al.<sup>[41]</sup> determined the mass of  $CO_2$  adsorbed onto rough silver QCM electrodes at  $40^\circ C$  and at pressures up to 5800 psi. They concluded that  $scCO_2$  mass adsorption on metal surfaces could approach values as high as  $25 \mu\text{g/cm}^2$ . Guigard et al.<sup>[42]</sup> evaluated the

**Fig. 6** Adsorption of gaseous  $CO_2$  on silver and gold surfaces at  $40^\circ C$ , using the  $C_r$  values calculated with Eq. (8b). Source: From Ref.<sup>[40]</sup>.

adsorption of  $CO_2$  on rough gold electrodes at  $40^\circ C$  and  $45^\circ C$  and at pressures up to 1500 psi. They found the similar maximum amount of  $CO_2$  adsorption as by Otake et al. However, these researchers all neglected the roughness contribution to frequency in the calculation. In order to fully account for the roughness contribution, the Wu research group examined in greater detail the  $scCO_2$  adsorption on metal surfaces.<sup>[40]</sup>

The frequency shifts of Ag-polished and Ag-rough crystals (Fig. 7) in  $scCO_2$  were measured to evaluate

**Fig. 7** Frequency shift of Ag-polished and Ag-rough crystals in  $scCO_2$  at  $40^\circ C$  as a function of pressure. Source: From Ref.<sup>[40]</sup>.

the amount of CO<sub>2</sub> adsorbed on the surfaces (Fig. 8). The calculation procedure is the same as in the gaseous CO<sub>2</sub>. As the CO<sub>2</sub> density and the amount of adsorbed CO<sub>2</sub> increase with increasing pressure, the holes and valleys between the inhomogeneities on the crystal surface are gradually filled (Fig. 8, inset), which causes a gradual decrease of surface roughness.<sup>[36]</sup> Therefore  $C_r$  was corrected for the overestimation of the roughness contribution,<sup>[40]</sup>

$$C_r = (a_2 + b_2\delta)\xi/\xi_0 \quad (8c)$$

where  $\xi$  and  $\xi_0$  are the roughness in centimeters of the original substrate surface and the modified surface by the adsorbed molecules, respectively.  $\xi$  is a function of thickness (or mass) of adsorbed molecular layers. Analysis showed that it was appropriate to predict scCO<sub>2</sub> adsorption on the Ag-polished crystal by neglecting the roughness contribution ( $C_r = 0$  or  $\xi = 0$ ), when the density was larger than 0.4 g cm<sup>-3</sup> (Fig. 8). This was because the quantity (2.4 μg/cm<sup>2</sup>) of CO<sub>2</sub> mass absorbed at the density of 0.4 g cm<sup>-3</sup> could smooth the surface of Ag-polished crystal.<sup>[40]</sup> For the Ag-rough crystal, calculation showed that the two limits of  $\xi/\xi_0 = 1.0$  and 0.75 could fit the adsorption data of the Ag-polished crystal well in the regions of low and high densities (<0.4 and >0.7 g/cm<sup>3</sup>; Fig. 8). It was concluded that the use of rough QCM crystals (rms roughness >10 nm) required careful attention in scCO<sub>2</sub> adsorption studies, because of

**Fig. 8** Adsorption of scCO<sub>2</sub> at 40°C on Ag-polished and Ag-rough QCM crystals. The inset on the upper right corner demonstrates how the adsorbed mass may alter the surface morphology. *Source:* From Ref.<sup>[40]</sup>.

the variation of  $C_r$ .<sup>[40]</sup> Only very smooth QCM crystals (several nanometers or less) are capable of accurately determining the adsorption of scCO<sub>2</sub> on the metal surfaces without considering the surface roughness contribution. The adsorption of scCO<sub>2</sub> on the silver and gold surfaces at 40°C ranges to 3.6 μg/cm<sup>2</sup>, but not up to 25 μg/cm<sup>2</sup> as determined by Otake et al.<sup>[41]</sup> and Guigard et al.<sup>[42]</sup> who used very rough crystals and neglected the roughness contribution.

## APPLICATIONS OF QUARTZ CRYSTAL MICROBALANCE FOR DISSOLUTION STUDY OF POLYMER FILMS IN SUPERCRITICAL CO<sub>2</sub>

Polymer dissolution (or polymer desorption) in solvents is an important phenomena in polymer science and engineering. Applications of polymer dissolution or desorption are found in several areas such as microlithography, controlled drug delivery, and plastics recycling.<sup>[43]</sup> For example, the successful implementation of a microlithography process requires technical information on the dissolution of photoresist polymer films in specific solvents during 1) the development of the resist images and 2) the stripping of the remaining films after the lithography process.<sup>[44]</sup> Hinsberg, Willson, and Kanazawa<sup>[45,46]</sup> and Ito<sup>[47]</sup> applied the QCM techniques to determine the dissolution rate of novolac and poly(4-hydroxystyrene) films in aqueous developer solutions at atmospheric pressure. Mueller et al.<sup>[48]</sup> have used the QCM to investigate the diffusivity of casting organic solvents in photoresist films for the evaluation of the influence of the solvents on the polymer dissolution behavior. These researchers demonstrated that the QCM technique was a particular attractive tool for the evaluation of the dissolution of polymer films in organic and aqueous solutions.

The dissolution kinetics of polymer films in scCO<sub>2</sub> provides useful technical information for the development of scCO<sub>2</sub>-based interfacial processes that require excellent control of surface properties (e.g., thickness and morphology) at the micro- and nanometer scales. The recently proposed surface processing of microelectronics in scCO<sub>2</sub><sup>[9]</sup> is a typical field that requires information on polymer film dissolution. However, a search of the literature in this specific area revealed that there have been a very limited number of studies on the polymer dissolution kinetics in scCO<sub>2</sub> by the use of QCM technique. To date, the number of dissolution studies of polymer films in scCO<sub>2</sub> by other online techniques, e.g., interferometry,<sup>[49]</sup> is also limited. This is probably due to the lack of various detection techniques at extreme conditions and to the situation of such scCO<sub>2</sub>-based processes being in the stages of early development. Nevertheless, Wu and

Grant<sup>[50]</sup> have utilized the QCM for the evaluation of polymer film dissolution in  $scCO_2$ .

Based on the availability and applicability of the reformulated QCM theory in  $scCO_2$ , the dissolution study of polymer films in  $scCO_2$  was achieved utilizing the experimental high-pressure QCM apparatus (Fig. 4). Fig. 9 represents a typical experimental run using a Si-polished QCM crystal to evaluate the dissolution kinetics of poly(FOMA-r-THPMA) films (low MW polymer) at 60°C and 2400 psi. The fundamental frequency ( $F_0$ ; Fig. 9) of the blank crystal was determined in vacuum ( $P = 0$  psi). The crystal was removed from the vessel and the polymer film was cast onto the crystal by dip-coating in an 8 wt.% polymer-trifluorotoluene solution. After drying the film in vacuum for 30 min the stable frequency ( $F_1$ ; Fig. 9) of the coated crystal was measured. The total polymer mass ( $m_0$ ) coated on the crystal corresponded to the frequency difference of ( $F_1 - F_0$ ).  $CO_2$  was gradually pumped into the vessel via steep changes in pressure

(see abrupt steep changes in frequency curve in Fig. 9) and the frequency data ( $F_{2,i}, i = 1$  to 4) were continually recorded. As the polymer was insoluble at pressures lower than 1700 psi at 60°C, this set of frequency data at elevated pressures were used to evaluate the swelling (or  $CO_2$  absorption) of film and  $CO_2$  diffusivity in the polymer film. After the frequency of the crystal became stable at the last step change in pressure ( $P = 1520$  psi), the  $CO_2$  pressure was instantaneously raised to the required experimental pressure (2400 psi) by adding more  $CO_2$  into the vessel. The QCM frequency went through a minimum value ( $F_3$ ) and increased rapidly, indicating the removal of polymer film from the crystal surface. The minimum frequency is the point at which  $CO_2$  absorption (film swelling) and film dissolution are balanced. Therefore in the example presented here, the dissolution of polymer film in  $scCO_2$  consists of two steps: 1) absorption-dominating and 2) dissolution-dominating. After the polymer film dissolved in  $scCO_2$  at 2400 psi and 60°C for 10 min, the  $CO_2$  in the vessel was rapidly released and the QCM frequency ( $F_5$ ) was measured again in vacuum. The remaining polymer film was removed by dissolution in pure trifluorotoluene (TFT), and excess TFT was dried off in vacuum. The original fundamental frequency ( $F_6 = F_0$ ) of the crystal was recovered, indicating complete polymer removal. On the polymer dissolution graph, the line from  $F_3$  to  $F_4$  represents the dissolution curve that can be used to evaluate the kinetics. Wu and Grant<sup>[50]</sup> have evaluated the dissolution kinetics of poly(FOMA-r-THPMA) films under the conditions that will be required for static film-developing and stripping in the microelectronics processing. Studies are currently underway to evaluate the dissolution kinetics of polymer films in a flowing  $scCO_2$  environment.

Symbol	$\Delta F$	Note
$m_0$	$F_1 - F_0$	Polymer mass initially coated
$m_1$	$F_5 - F_1$	Polymer mass removed
$m_1'$	$F_4 - F_3$	Mass change during dissolution
$m_2$	$F_6 - F_5$	Polymer mass not removed during dissolution
—	$F_{2,i} - F_1$	$CO_2$ adsorption during step-pressurizing
—	$F_5 - F_4$	$CO_2$ desorption during the release of $CO_2$

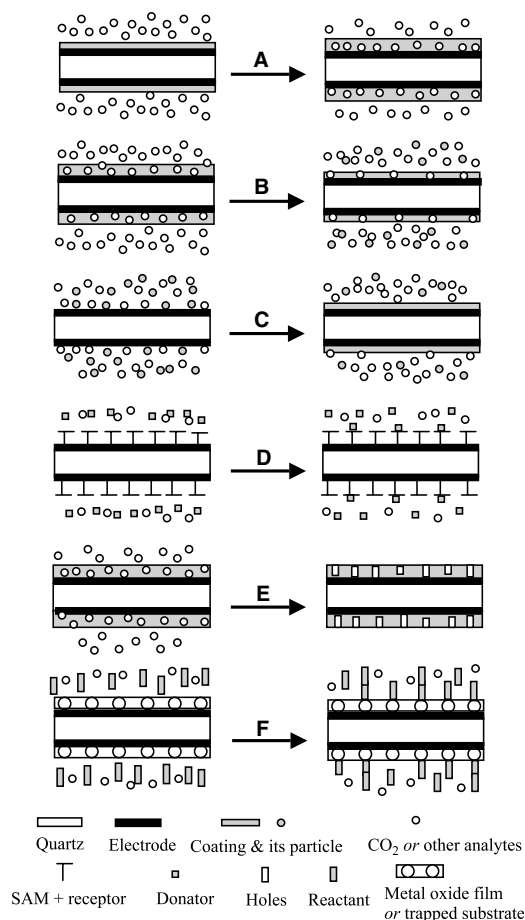

**Fig. 9** A typical experimental QCM determination for the dissolution of poly(FOMA-r-THPMA) film in  $scCO_2$  at 2400 psi and 60°C under static conditions. Detailed explanation in the text. Source: From Ref.<sup>[50]</sup>.

### ADDITIONAL QUARTZ CRYSTAL MICROBALANCE APPLICATIONS IN SUPERCRITICAL $CO_2$

#### Absorption of Supercritical $CO_2$ and Other Analytes in Solid Films

The absorption and solubility of  $scCO_2$  or other analytes in solid films are important properties that can be used to understand many  $scCO_2$ -based processes and chemistries. The swelling of polymer films in  $scCO_2$  is a typical example of absorption processes. The QCM determination of absorption is realized by modification of the QCM surface with a coating that can interact with a desired analyte in a way that the mass and thickness of the coating are increased (Fig. 10A). To date, researchers<sup>[51-53]</sup> have successfully used the QCM technique to investigate the absorption

**Fig. 10** Schematic representations of some typical  $\text{scCO}_2$ -based processes or chemistries that can be investigated using the QCM. (A) Absorption or molecular recognition; (B) cleaning, developing, stripping, drying, dissolution, or solubility in  $\text{scCO}_2$ ; (C) deposition; (D) molecular recognition; (E) foaming; (F) surface reaction, or polymerization.

of  $\text{scCO}_2$  in polymers at elevated pressures with high performance. There are a limited number of QCM studies on the absorption of an analyte other than  $\text{CO}_2$  into a solid film, where both the analyte and the solid film are contained in a  $\text{scCO}_2$  environment.

Interestingly, based on the QCM, some dual techniques have been developed to measure other absorption-relevant physical properties. Hattori et al.<sup>[54,55]</sup> combined vapor-liquid partition chromatography with a piezoelectric QCM to measure vapor-liquid equilibrium (VLE) ratios of benzene and toluene at an infinite dilution state in a  $\text{scCO}_2$ -poly(vinyl acetate) system. The QCM indicated the solubility of organic solutes in the polymer phase while the chromatography analyzed the concentrations of solutes in the  $\text{scCO}_2$  phase. Good VLE data were obtained with this dual technique. Nakamura et al.<sup>[56]</sup> reported the determination of adsorption isotherms of  $\text{scCO}_2$  on several proteins and polysaccharides by a combination of two different

microbalances, gravimetric and piezoelectric. The QCM was used to measure the absorption of  $\text{CO}_2$  into the proteins and polysaccharides; the absolute adsorption could be accurately calculated from the gravimetric data by subtracting the absorption contribution.

### Precision Cleaning and Dissolution Using Supercritical $\text{CO}_2$

The QCM determination in cleaning and dissolution processes typically involves the partial or complete removal of a film or coating from the QCM surface by a liquid, gas, or a fluid in the supercritical state (Fig. 10B). Precision cleaning and precision decontamination can be defined as processes that result in a surface contaminant level of less than  $10 \mu\text{g}/\text{cm}^2$ .<sup>[57]</sup> However, most precision cleaning processes require a contaminant level of less than  $1 \mu\text{g}/\text{cm}^2$ .<sup>[58]</sup> A majority of recently developed  $\text{scCO}_2$ -based precision cleaning processes are found in the microelectronic industry. Some typical examples are 1) the decontamination of micromechanical devices;<sup>[59]</sup> 2) the initial removal of impurities such as organic soils and fingerprints from silicon wafers; 3) the stripping of resists from metallized silicon surfaces without damaging thin metallization patterns;<sup>[60]</sup> and 4) the direct development of resist films.<sup>[10,61]</sup> More recently, the  $\text{scCO}_2$ -drying of organic or aqueous rinse liquids from micro-electro-mechanical systems (MEMS) or other silicon structures were proposed to prevent the collapse of the fine features on the surfaces.<sup>[62,63]</sup> The QCM is capable of monitoring the mass changes in all these  $\text{CO}_2$ -based precision-cleaning processes at the nanogram scale.

### Solubility of Chemicals in Supercritical $\text{CO}_2$

A thermodynamic property that is essential to any application of supercritical fluids is chemical solubility. The application of the QCM in the determination of solubility (Fig. 10B) is, in principle, very close to the approach used for cleaning and dissolution studies. A critical difference is the amount of time required for the attainment of phase equilibrium. The QCM method is ideally suited for solutes that exhibit low solubility, or for measurements conducted at low  $\text{scCO}_2$  densities, a condition in which many solutes have low solubility. This is because the QCM theory (Eq. (2)) is considered accurate provided the mass of a coating does not exceed 2% of the crystal mass.<sup>[23]</sup> Guigard et al.<sup>[42]</sup> have applied the QCM technique to determine the solubilities of two metal chelates, bis(acetylacetonato) copper and bis(thenoyltrifluoroacetonato) copper, in  $\text{scCO}_2$  and described the methodology in detail. They found that the solubilities measured by the QCM were in excellent agreement with the four

sets of literature values obtained using other techniques, with a standard deviation of 25%.<sup>[42]</sup> This level of discrepancy is actually encouraging because of the extreme low solubility values on the order of  $10^{-5}$  mole fraction. Besides metal chelates, the QCM method can be extended to determine the solubilities of natural products (e.g., herbal medicines), photoresists, polymers, fats, biomaterials, and many other chemicals of interest for CO<sub>2</sub>-based processes. This is especially true in cases in which the traditional detection methodologies (e.g., spectroscopic techniques) are limited due to either their low sensitivity or the complexity of the associated apparatuses under extreme pressure conditions.

### Molecular Recognition in Supercritical CO<sub>2</sub>

Molecular recognition is of interest for biological processes because most biomolecules show selectivity and specificity when interacting with other species. This particular microweighing methodology involves either directly coating host molecules (insoluble in scCO<sub>2</sub>) on the surface of a QCM crystal (Fig. 10A) or modifying the surface with a self-assembled monolayer (SAM) (Fig. 10D). The SAM can be formed using thiols or other chain-like molecules that have two active groups at the two ends of the chain. The -SH group of the thiol or one end of the chain-like molecule is attached to the QCM surface, while the -OH group or the other end is grafted with the receptor molecule. When guest or donor molecules are supplied into the vessel together with CO<sub>2</sub>, they are bonded to the host or receptor molecules via molecular interactions, resulting in a mass increase of the coating. Naito et al.<sup>[64,65]</sup> successfully demonstrated two examples of molecular recognitions in scCO<sub>2</sub> using the QCM technique. In the first system, ethyl acetate and ethanol were selectively bound to anthracene-bis(resorcinol)tetraol that was coated on the crystal surfaces. In the second situation, nucleobases such as 9-ethyladenine and 2-pyrrolidone were recognized at different extents by thymine that was immobilized on the thiol-modified QCM surfaces. The equilibrium constants and the associated kinetics of molecular binding were easily obtained by the use of the QCM technique.

### Evaluation of Deposition in Supercritical CO<sub>2</sub>

Chemicals either previously dissolved in the scCO<sub>2</sub> phase or produced via reactions of other CO<sub>2</sub>-soluble chemicals may deposit onto surfaces, due to solubility variations with temperature and pressure or the insoluble characteristics. The dynamic mass of deposited surface films can be detected in situ using the QCM method (Fig. 10C). For example, the QCM technique can be directly used to evaluate the deposition of

metals (e.g., copper and nickel) on silicon wafers.<sup>[66]</sup> The metals were generated via the hydrogen reduction of organometallic compounds that are dissolved in a scCO<sub>2</sub> carrier. This deposition process was named as chemical fluid deposition (CFD), and the deposition of metals on pattern features less than 100 nm wide has been demonstrated using such CFD technique.<sup>[66]</sup>

### Polymer Foaming in Supercritical CO<sub>2</sub>

In recent years, scCO<sub>2</sub>-based polymer foaming has been of particular importance in the production of low dielectric films in electronics manufacturing and tissue engineering scaffolds for biological purposes.<sup>[67]</sup> Upon removal of the scCO<sub>2</sub> phase, the absorbed CO<sub>2</sub> is released from swollen polymer networks, resulting in free-standing porous foams. The foams have cell diameters of less than 1 μm and the process accomplishes density reductions of 97% relative to the parent polymers.<sup>[68]</sup> Quartz crystal microbalance can act as a useful tool for detecting the dynamic mass changes associated with such foaming processes (Fig. 10E). The dynamic mass changes can be correlated with the structure and morphology of the foams by evaluation using microscopic techniques, such as SEM and AFM. The combination of the QCM microweighing with the microscopic techniques can provide a comprehensive understanding of the foaming processes.

### Surface Reactions in Supercritical CO<sub>2</sub>

Reactions or polymerizations on metal oxide surfaces or other surfaces immobilized with active groups can be followed by detecting the mass increase on the surfaces with the QCM technique (Fig. 10F). When treated with acids, the metal oxide surfaces provide OH active groups to promote immobilization. The silylation of native oxide silicon surfaces in the preparation of coating for hydrophobic photoresists<sup>[69]</sup> is a typical example of surface reactions in scCO<sub>2</sub>. Supercritical CO<sub>2</sub> has been utilized as a carrier of silane reagents, thereby reducing the consumption of chemicals and improving the rate of surface coverage.

### CONCLUSION

Two techniques, MSB and QCM, have been developed primarily as microweighing tools for wide use under extreme conditions. In the literature, the MSB has been utilized mainly for the determination of adsorption/absorption and diffusivity of scCO<sub>2</sub> in bulk polymers under static conditions. When compared to the MSB technique, the QCM has found a wider range of applications for many scCO<sub>2</sub>-based static or

dynamic processes both in the bulk phase and at the surface film. This is primarily because of the intrinsic attributes of the QCM approach, such as the nanogram-level mass sensitivity, millisecond-level time resolution, miniature and simple construction, and low cost. The QCM can be successfully developed into a submicroweighing tool in  $\text{scCO}_2$  by the careful examination of the QCM theory in high-pressure fluids. Although the QCM has applications in various  $\text{CO}_2$ -based processes and chemistries, such as dissolution, solubility, adsorption/absorption, and molecular recognition, the reported efforts and application areas in the literature are limited to date. It is evident from the progress reviewed in this entry that the QCM demonstrates great potential for use in  $\text{scCO}_2$ .

Because  $\text{scCO}_2$  is a “green” solvent, it is expected that the use of this solvent in nanoscale processing will increase significantly in the next few decades. The complete scope of the QCM in actual nanoscale processing has not been realized either. Hence the QCM will serve as an excellent analytical tool for developmental studies on emerging nanotechnologies and nanomaterials.

## ACKNOWLEDGMENTS

This material is based upon work supported in part by the Science and Technology Center of the National Science Foundation under Agreement No. CHE-9876674. We acknowledge the DeSimone group at the University of North Carolina, Chapel Hill (UNC), the Carbonell group and Kenan Center at the NC State University for technical assistance and facility utilization. Finally, we acknowledge Professor Scott Wallen and Michael Hurrey at UNC for their contributions in AFM experiments.

## INTRODUCTION

The term “electrokinetics” means the combined effects of motion and electrical phenomena. However, the term “electrokinetic properties” carry a wider connotation including zeta potential ( $\zeta$ ), the structure of electrical double layer (EDL), surface potential, and isoelectric point (iep) phenomena. The electrokinetic properties of a substance, inorganic or organic, are used to explain the mechanism of dispersion and agglomeration in a liquid phase and to identify the adsorption mechanisms of ions or molecules at a solid–liquid interface. Therefore they play an important role in a spectrum of applications including ceramics, food, mining, paper, medicine, water and wastewater treatment, emulsions, biochemistry, and detergents. In this entry, the type and significance of electrokinetic properties of mineral nanoparticles, the mechanism of particle–particle interactions in liquid systems, and the applications of electrokinetic phenomena are presented.

## DESCRIPTION OF ELECTROKINETIC PROPERTIES OF MINERAL PARTICLES

### Origin of Surface Charge

Each mineral particle in a liquid whether colloidal ( $<1\ \mu\text{m}$ ) or nanoparticle ( $<100\ \text{nm}$ ) carries electrokinetic charges depending on the properties of liquid phase such as pH and ionic strength.<sup>[1–3]</sup> The surface charge of minerals can originate as a result of a number of mechanisms discussed below.

### Dissociation of surface groups

In most solid minerals, dissociable functional surface groups such as carboxyl ( $-\text{COOH}$ ) and hydroxyl ( $-\text{OH}$ ) are present. These groups may be ionizable depending on the solution pH; a surface is

charged either negatively at high pHs or positively at low pHs.

For metal oxides and hydroxides: (see Eq. (1) below)

where M represents a metal cation at the surface.

For coal representing a typical hydrophobic mineral where R represents a hydrocarbon compound constituting the coal structure (see Eq. (2) below).

Consequently, for simple metal oxides and hydroxides, e.g.,  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3$ , and  $\text{AlOOH}$ , complex metal oxides including clay minerals<sup>[4–6]</sup> and some hydrophobic minerals, e.g., coal,<sup>[7]</sup>  $\text{H}^+$ , and  $\text{OH}^-$  ions are considered as the potential determining ions (pdis) (see “[Potential Determining, Indifferent, and Specifically Adsorbed Ions](#)” section).

### Preferential dissolution of lattice ions

This type of charging mechanism is generally developed in aqueous solutions with some soluble ionic solids, viz.,  $\text{AgI}$ ,  $\text{CaCO}_3$ ,  $\text{BaSO}_4$ , and  $\text{CaF}_2$  as a result of the preferential release of certain constituent lattice ions from the solid into liquid phase as a result of hydration and lattice energies.<sup>[8]</sup> The concentrations of these ions at equilibrium state are dictated by the solubility product of the solid.<sup>[9]</sup> For  $\text{AgI}$  particles, for instance, the amount of  $\text{Ag}^+$  ions released into water from the particle surface at  $25^\circ\text{C}$  is more than that of  $\text{I}^-$  ions. Therefore the surface of  $\text{AgI}$  particle remains negatively charged. Thus the constituent lattice ions for these minerals are considered as the pdis.

### Preferential adsorption of ions from solution

This mechanism is most commonly observed and results from the differences in the affinity of two phases for some ions. Some specific ions (see “[Potential Determining, Indifferent, and Specifically Adsorbed Ions](#)” section) can strongly adsorb on a solid surface and charge the particle, or, vice versa, a charged particle can become noncharged through such adsorption, e.g., adsorption of  $H^+$  and  $OH^-$  on oxide minerals (Eqs. (3) and (4) in the case of  $SiO_2$ ),  $Ag^+$  and  $I^-$  adsorption on silver iodide particles, and  $Al^{3+}$  and  $HDTMA^+$  (hexadecyltrimethylammonium) adsorption on clinoptilolite.<sup>[10]</sup> It should be noted that especially for  $H^+$  and  $OH^-$  ions, it is difficult to distinguish whether the charging of a particle is generated from the adsorption or dissociation of these ions (see below).<sup>[2]</sup>

### Isomorphic substitutions

Almost all clay and zeolite minerals that are generally characterized as aluminum silicates exhibit negative charges in water, which results from the substitutions within the crystal lattice of  $Al^{3+}$  for  $Si^{4+}$  or  $Mg^{2+}$  for  $Al^{3+}$ .<sup>[11–14]</sup> Consequently, negative charges are developed in the lattice to compensate the so-called exchangeable cations, i.e.,  $Na^+$ ,  $K^+$ , and  $Ca^{2+}$  entering the crystal structure. When such minerals come in contact with water, some of these cations can easily dissociate, leading to negatively charged surfaces.

### Accumulation and transfer of electrons

Besides ion transfer, as explained above, electron transfer is also possible between solid and liquid phases depending on differences in the electron affinities of the two phases. Also, some molecules of dipole character may be oriented at the solid–liquid interface leading to charged surfaces,<sup>[2,3]</sup> this is mostly observed at the metal–solution interface.

### Electrical Double Layer and Double-Layer Models

When a mineral particle is immersed in a liquid, a surface charge will be developed through one of the mechanisms discussed above. Let us imagine a

negatively charged solid particle in an electrolyte solution; while the oppositely charged counterions will congregate in the vicinity of the particle, coions having the same sign with that of the particle will be repelled from the surface as a result of electrostatic interactions. Thus a charged surface layer (layer 1) and an ionic layer (layer 2) all the way to the bulk water constitute the electrical double layer with a thickness usually ranging from a few angstroms to a few hundred angstroms. To examine the structure of EDL, different models have been proposed.<sup>[3,15]</sup> These models are introduced below.

### Helmholtz compact layer model

The earliest model of the EDL, in which a rigid layer away from the surface in solution consists of oppositely charged ions, was proposed in 1879 by Helmholtz.<sup>[16]</sup> Also, the surface charge of particle is equal to that of rigid layer. Because this model ignores the disrupting effect of thermal agitation, it is unreasonable. This model is known as a molecular condenser model owing to its similarity to a parallel plate condenser.<sup>[1]</sup> Using the law of distribution of EDL, the potential  $\psi$  (V) across the double layer for this capacitor is

$$\psi = \sigma d / \epsilon \epsilon_0 \quad (5)$$

where  $\sigma$  is the charge density per unit area of a plate ( $C/m^2$ ),  $\epsilon$  (dimensionless) is the dielectric constant of the medium, and  $\epsilon_0$  is the permittivity of free space ( $8.854 \times 10^{-12} C^2/Jm$ ).

### Gouy–Chapman diffuse double-layer model

This is independently known as the Gouy–Chapman model. They expressed that, in addition to the electrostatic attraction of counterions to the charged surface, some of them tend to diffuse toward the bulk solution because of their thermal motion. Note that the EDL theory can be developed for different solid geometries such as flat plate, sphere, and cylinder. Because most studies for organic and inorganic solids in liquids assume the flat plate geometry,<sup>[17,18]</sup> here we also consider the flat plate to simplify the structure of EDL. The theory of Gouy–Chapman is based on the two fundamental equations: Poisson and Boltzmann.<sup>[16]</sup> The Poisson equation (Eq. (6)) for a flat surface given below is related to the potential distribution of an electric charge relative to the distance from the surface in a medium.

$$d^2\psi/dx^2 = \psi_{(x)} = -\rho_{(x)}/\epsilon\epsilon_0 \quad (6)$$

where  $\psi_{(x)}$  is the double-layer potential (V) at a point located a distance  $x$  from the surface,  $\rho_{(x)}$  is the

charge density per unit volume (C/m<sup>3</sup>) at the same point.

The Boltzmann equation is given by

$$n_i = n_i^0 \exp(-z_i e \psi / kT) \tag{7}$$

where  $n_i$  is the number of ions of type  $i$  per unit volume near the surface or in diffuse layer,  $n_i^0$  is the number of ions of type  $i$  per unit volume in the bulk solution,  $z_i$  is the valence number of  $i$  including its sign,  $e$  is the electronic charge ( $1.602 \times 10^{-19}$  C),  $k$  is the Boltzmann constant ( $1.381 \times 10^{-23}$  J/K), and  $T$  is the absolute temperature (K). The term  $z_i e \psi$  signifies the electrostatic (or coulombic) work required to bring the ion,  $i$ , from the bulk of the solution (where  $x \rightarrow \infty$  and  $\psi_0 = 0$ ) to a position where the potential is  $\psi$ .

The volume charge density near the surface is

$$\rho = \sum e z_i n_i = \sum e z_i n_i^0 \exp(-z_i e \psi / kT) \tag{8}$$

Substituting Eq. (8) into Eq. (6) yields the Poisson-Boltzmann equation (Eq. (9)).

$$d^2 \psi / dx^2 = (-1 / \epsilon \epsilon_0) \sum e z_i n_i^0 \exp(-z_i e \psi / kT) \tag{9}$$

Eq. (9) shows a non-linear differential equation without an explicit general solution but can be analytically solved by the Debye-Huckel approximation provided that  $z_i e \psi < kT$ , i.e., the potential ( $\psi$ )  $< 25.7 / z_i$  mV throughout the EDL. Thus Eq. (9) is converted to the following form<sup>[16]</sup>

$$d^2 \psi / dx^2 = \kappa^2 \psi \tag{10}$$

where  $\kappa$  is known as the Debye-Huckel parameter with a unit of reciprocal length (m<sup>-1</sup>) and given by

$$\kappa = \left[ \frac{e^2 \sum n_i^0 z_i^2}{\epsilon \epsilon_0 kT} \right]^{1/2} \tag{11}$$

For water at 25°C, Eq. (11) becomes

$$\kappa = 3.288 I^{1/2} \tag{12}$$

where  $I$  is the ionic strength ( $I = \frac{1}{2} \sum c_i z_i^2$ ) of the solution and  $c_i$  is the concentration of an ion,  $i$  in mol/L, and  $z_i$  is the valence number of  $i$ . Note that the inverse of  $\kappa$ ,  $1/\kappa$ , is a very important term in the stability of colloidal particles and is called as “the electrical double-layer thickness.” When the distance from surface reaches the value of  $1/\kappa$ , the double-layer (DL) potential ( $\psi$ ) equals  $\psi_0/e$  ( $e = 2.7182$ ). Eq. (12) clearly shows that the double-layer thickness is basically dependent on the ion concentration and the valency of the ion. An increase in both parameters results in

a decrease in double-layer thickness and potential as shown in Fig. 1.

For surface potentials ( $\psi_0$ )  $< 25$  mV, the solution of Eq. (10) yields<sup>[3]</sup>

$$\psi = \psi_0 \exp(-\kappa x) \tag{13}$$

where  $x$  is the distance from surface and  $\kappa$  is the Debye-Huckel parameter. For high surface potentials, i.e.,  $z_i e \psi > kT$ , the exact solution of Eq. (9) is required. The solution given by Gouy (1910) and Chapman (1913), for the case of a symmetrical electrolyte ( $z_{i+} = -z_{i-} = z$ , such as NaCl, CaSO<sub>4</sub>; and  $n_{i+}^0 = n_{i-}^0 = n^0$ ) and some mathematical manipulations, becomes<sup>[16]</sup>

$$\tanh(z e \psi / kT) = \tanh(z e \psi_0 / kT) \exp(-\kappa x) \tag{14}$$

or

$$\gamma = \gamma_0 \exp(-\kappa x)$$

where  $\gamma = \tanh(z e \psi / 4kT)$  and  $\gamma_0 = \tanh(z e \psi_0 / 4kT)$ .

Evidently, although Eq. (14) is relatively more complex than Eq. (13), it has wider applicability. The surface

**Fig. 1** Variation of electrical double-layer thickness with electrolyte concentration. Source: From Ref.<sup>[16]</sup>.

charge density ( $\sigma_0$ ) of a particle in a liquid is given elsewhere.<sup>[3]</sup>

### Stern–Grahame model

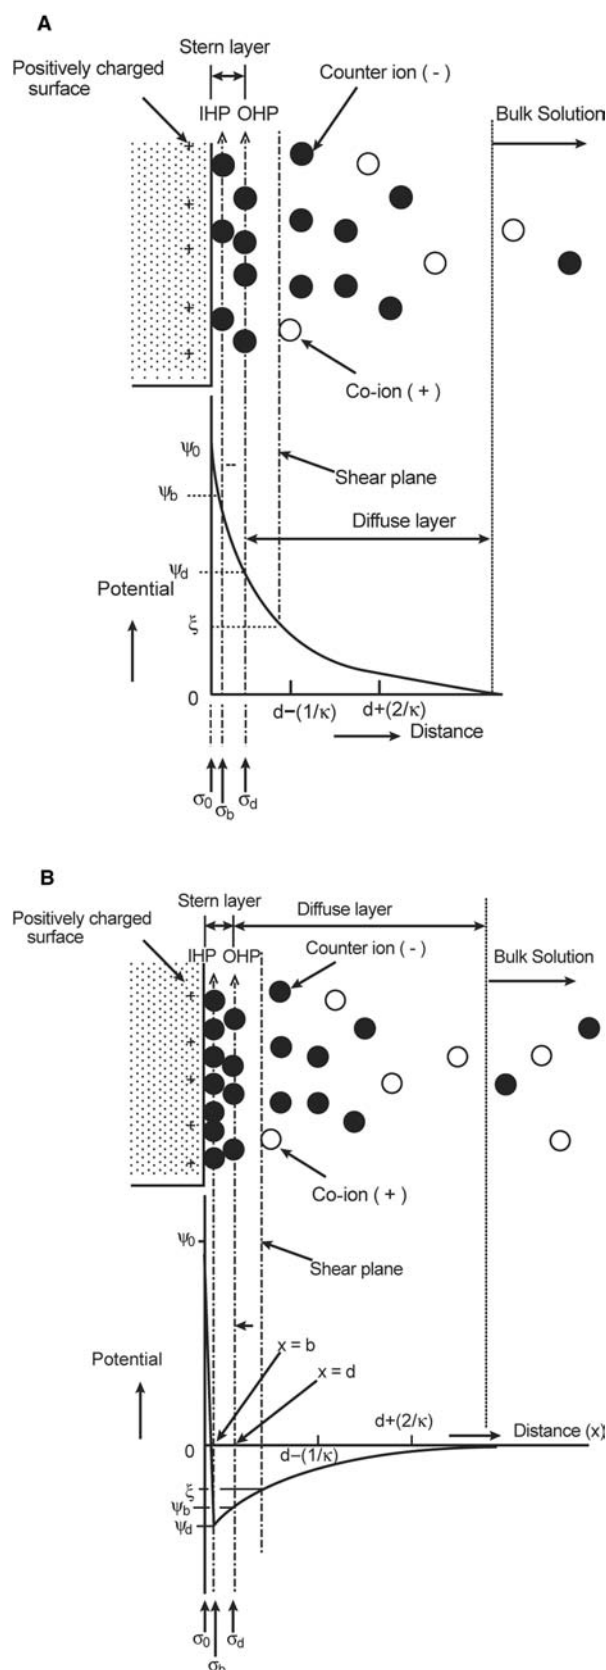

The Gouy–Chapman model of EDL includes some unrealistic cases. For example, the ions are assumed as point charges and any specific effects related to the ion size are neglected. Therefore the adsorption densities on the solid surface calculated for moderate surface potentials and ionic strength values are so high that they are physically impossible. Also, the solvent is assumed to have continuous properties everywhere in solution; however, its properties such as the dielectric constant and the viscosity may be different in the EDL and the bulk solution.

Stern (1924)<sup>[19]</sup> modified the Gouy–Chapman model with an adsorbed layer of ions of thickness  $d$ , which is usually considered as 0.3–0.5 nm. This layer, assumed to be held fixed at the surface, is called the Stern layer. Thus the ion distribution in solution around the charged particle is divided into two parts: the Stern layer, which is the identical form in the Helmholtz model and consists of specifically adsorbed ions, and the diffuse (or Gouy) layer. The double layer in Fig. 2 essentially shows three layers, i.e., the layer of charged solid surface, the Stern layer, and the diffuse layer, but in the literature the commonly used term is “double layer.” Also, there is a shear plane in the diffuse layer at which the double layer potential ( $\psi$ ) is called the zeta ( $\xi$ ) potential.

Grahame<sup>[19]</sup> further divided the Stern layer into two parts: inner Helmholtz plane (IHP) and outer Helmholtz plane (OHP) (Fig. 2A,B). At the  $b$  plane, there are specifically adsorbed unhydrated ions known as the IHP, while that of the closest approach to the more weakly adsorbed hydrated ions at  $d$  is known as the OHP, the onset of the diffuse layer. This model, known as the Stern–Grahame model, is usually represented with low amounts of specifically adsorbed ions (Fig. 2A) while the modified version (Fig. 2B) incorporates the specifically adsorbed ions. In the former, the sign of particle surface cannot be reversed, but it is possible in the latter. The potential distribution in the diffuse layer for a symmetrical electrolyte (Eq. (14)) can be rewritten as;

$$\tanh(ze\psi/4kT) = \tanh(ze\psi_d/4kT) \times \exp[-\kappa(x - d)] \quad (15)$$

Note that, in the case of electrolyte concentrations less than 0.1 M, the zeta ( $\xi$ ) potential can be used instead of  $\psi_d$ . The composition of the double layer is usually inferred from a comparison between  $\sigma_0$  and  $\sigma_d$  or  $\psi_0$  and  $\psi_d$ , then computed by some model. The following

**Fig. 2** The Stern–Grahame model represented by (A) by low concentration of specifically adsorbed ions and (B) by higher concentration of the specifically adsorbed ions.

equation has a reasonably wide applicability if the amount of specifically adsorbed ions is low.

$$(\theta/1 - \theta) = (c_i/55.5) \times \exp[-(z_i e \psi_b + \Phi)/kT] \quad (16)$$

where  $\theta = \sigma_b/\sigma_0$  ( $0 \leq \theta \leq 1$ ),  $\sigma_b$  and  $\sigma_0$  are charge densities at the IHP and at the surface (in  $C/cm^2$ ), and  $\Phi$  stands for the specific adsorption free energy in units of  $kT$  and  $\psi_b$  is the potential at the IHP,  $c_i$  is the bulk concentration of ion  $i$  (mol/L). Eq. (16) is an extension of the familiar Langmuir equation.<sup>[2]</sup>

### Potential Determining, Indifferent, and Specifically Adsorbed Ions

Potential determining ions (pdi) are the major ions responsible for the establishment of the surface charge of particle.<sup>[3]</sup> Their activities in the liquid play a crucial role in the generation of potential difference across a solid-liquid interface. They are also able to reverse the sign of  $\zeta_p$  of the solid. As a simple recipe, for a cation to be the pdi, it must make the surface more positive upon increasing the cation concentration. Similarly, for an anion to be the pdi, it must impart the surface more negative charges with increasing anion concentration. While the pdi for ionic solids such as AgI, BaSO<sub>4</sub>, and CaCO<sub>3</sub>, etc. are the lattice constituent ions, i.e., Ag<sup>+</sup>, I<sup>-</sup>, Ba<sup>2+</sup>, SO<sub>4</sub><sup>2-</sup>, Ca<sup>2+</sup>, CO<sub>3</sub><sup>2-</sup>, H<sup>+</sup> and OH<sup>-</sup> ions are for metal oxides and hydroxides, silicate or clay minerals, some hydrophobic minerals (e.g., coal), and some synthetic polymers with sulfate groups.<sup>[1,3,5,6]</sup> Fig. 3 clearly shows the difference in

the behavior of a positively charged alumina surface toward (a) pdi: H<sup>+</sup> and OH<sup>-</sup>; (b) the indifferent ions Cl<sup>-</sup>, and NO<sub>3</sub><sup>-</sup>, Na<sup>+</sup>, and Ba<sup>2+</sup>; and (c) the specifically adsorbed ions SO<sub>4</sub><sup>2-</sup> and S<sub>2</sub>O<sub>3</sub><sup>2-</sup>. For metal oxides, for example, the surface potential is determined by the activities of pdis and expressed by Nernst-like equation

$$\psi_0 = (RT/F) \ln(a_{H^+}/a_{H^+}^0) \quad (17)$$

where  $F$  is the Faraday constant,  $a_{H^+}$  is the activity of H<sup>+</sup>, and  $a_{H^+}^0$  refers to the point of zero charge (pzc). The operational formula for aqueous solutions at 25°C is  $\psi_0 = 0.059 \text{ V (pH}^0 - \text{pH)}$ , where  $\text{pH}^0$  refers to the pzc.<sup>[19]</sup> For AgI, Eq. (17) can be written as

$$\psi_0 = (RT/F) \ln(a_{Ag^+}/a_{Ag^+}^0) \quad (18)$$

Indifferent ions are those that cannot specifically adsorb in the Stern layer of the EDL and unable to reverse the sign of surface charge of the particle but only compress the electrical double layer. For example, monovalent ions such as Na<sup>+</sup> and Cl<sup>-</sup> are indifferent ions for colemanite,<sup>[21]</sup> and Na<sup>+</sup>, Cl<sup>-</sup>, NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup>, CaOH<sup>+</sup>, MgOH<sup>+</sup>, Al(OH)<sup>+</sup>, and Al(OH)<sup>2+</sup> are indifferent ions for clinoptilolite (natural zeolite).<sup>[10]</sup> Indifferent ions, which usually decrease the double-layer thickness ( $1/\kappa$ ), are used in electrokinetic studies to determine the point of zero charge (pzc) or isoelectric point (iep) of minerals (Fig. 3).

Specifically adsorbed ions possess special affinity for the solid surface through coulombic and non-coulombic forces. These noncoulombic forces may be chemical in nature, i.e., involving some degree of

**Fig. 3** Zeta potential profile of a positively charged alumina surface in the presence of various ions. *Source:* From Ref.<sup>[3]</sup>.

covalent bonding with surface atoms or be more physical, e.g., van der Waals forces between the ion and the surface or between the hydrocarbon chains of surfactant ions adsorbed.<sup>[3]</sup>

### Isoelectric Point and/or Point of Zero Charge

Although the isoelectric point (iep) and the point of zero charge (pzc) are identical by definition, there are some differences between them. The iep or pzc of some typical minerals are given in Table 1. While the pzc denotes the state in which the net surface charge of the solid is zero, the iep describes the condition at which the potential at the shear plane, i.e., the zp obtained from electrokinetic measurements is zero; the iep and pzc are the same in the absence of the specific adsorption. But the pzc of a mineral need not coincide with the iep in most cases as seen in Table 1.

The iep of a mineral is directly obtained by electrokinetic measurements (see “Potential Determining, Indifferent, and Specifically Adsorbed Ions” section) against pH, usually in the presence of indifferent electrolytes (or ions) of various molarities seen in Fig. 4. This figure indicates that 1)  $\text{KNO}_3$  is an indifferent electrolyte for this system and 2) the iep in this case is the same as the pzc. The pzc is experimentally determined usually by potentiometric titration method of the adsorbed pdi.<sup>[40]</sup> For example, for oxides, hydroxides, and silicates, the surface charge density at pzc,  $\sigma_0$ , can be expressed as

$$\sigma_0 = F(\Gamma_{\text{H}^+} - \Gamma_{\text{OH}^-}) = 0 \quad (19)$$

where  $\Gamma_{\text{H}^+}$ , and  $\Gamma_{\text{OH}^-}$  are analytical surface excess for  $\text{H}^+$  and  $\text{OH}^-$  ions, respectively. Here it must be noted that iep and pzc of minerals depend on the heterogeneity of mineral surface and pretreatments of minerals such as leaching, washing, and ultrasonic scrubbing.<sup>[11,23,30,41]</sup> Interestingly, the iep of particularly semisoluble salt-type minerals has been found to vary with the solids concentration.<sup>[21]</sup>

### Zeta Potential (zp)

Zeta ( $\xi$ ) potential is an intrinsic property of a mineral particle in a liquid. It determines the strength of the EDL repulsive forces between particles and identifies the stability of a colloidal system. The zp is known as the measurable surface potential of a particle, viz., the potential at the shear plane. There is no direct experimental method for determining both the surface potential ( $\psi_0$ ) and Stern layer potential ( $\psi_d$ ).<sup>[3]</sup> So far, the exact position of the shear plane within the diffuse layer of the EDL could not be determined, but it is assumed that the position of the shear plane is very

close to the outer Helmholtz plane (OHP).<sup>[1]</sup> The  $\xi$  potential is fairly close to the Stern potential,  $\psi_d$ , in magnitude, and definitely less than the potential at surface,  $\psi_0$ .

## METHODS OF ZETA POTENTIAL MEASUREMENTS

Electrokinetic measurements using electrophoresis, electroosmosis, streaming potential, and sedimentation potential can be interpreted to yield a quantity known zeta or electrokinetic potential.<sup>[3,42]</sup> Of these four techniques, the electrophoresis is perhaps the best known and most commonly used technique to measure the zp of minerals. While the electrophoresis technique with modifications is extended for the measurement of very fine particles such as nanoparticles (<100 nm) and colloidal particles (<1  $\mu\text{m}$ ), other techniques are usually employed for larger particles. The size of mineral particles is independent of the charge and only identifies the measurement technique.

### Electrophoresis

When a charged mineral particle in a conducting liquid is applied an electrical field, it moves toward the oppositely charged electrode (relative to its charge). This is called electrophoresis. The method is based on the mobility ( $U$ ) of the particle under the applied electrical field ( $E$ ). The electrophoretic mobility of the particle represents the velocity ( $\nu$ ) per unit electric field ( $E$ ) and is given by

$$\begin{aligned} U \text{ (mobility)} &= \text{speed/electric field} = \nu/E \\ &= (\text{m/sec.})/(\text{V/m}) \end{aligned} \quad (20)$$

The mobility of particle is converted to the zp by the Henry equation

$$U = (\xi\epsilon/1.5\eta)f(\kappa a) \quad (21)$$

where  $\xi$  is the zeta potential,  $\epsilon$  is the dielectric constant of the medium relative to the vacuum,  $\eta$  is the viscosity of the medium,  $f(\kappa a)$  is the corrector factor depending on the product of  $\kappa$  (Debye–Huckel parameter), and  $a$  is the particle radius. For very small particles in dilute solution where the thickness of the DL ( $1/\kappa$ ) is large,  $\kappa a \ll 1$  and  $f(\kappa a) = 1$  (Huckel equation). For large particles in more concentrated solution,  $\kappa a \gg 1$  and  $1/\kappa$  is small, and  $f(\kappa a) = 1.5$  (Smoluchowski equation).<sup>[7]</sup>

If the particles are invisible, as in the case of some protein molecules, they are tracked by the Tiselius technique.<sup>[3,42]</sup> However, for particles of about 0.5  $\mu\text{m}$  in diameter or larger, direct observation is possible

**Table 1** iep and pzc of some typical natural and synthetic minerals

They were mixed in an autoclave, and were calcined afterward at 500°C.

using an optic microscope illuminated with a strong light source. An ultramicroscope is useful for particles down to 0.1 μm. An electrical field is applied on the cell consisting of two electrodes and the movement of

mineral particles dispersed in a conducting liquid is observed. Thus the rate of movement of particles moving toward the opposite electrode is observed under an optical microscope using a light beam lamp.

**Fig. 4** Determination of the iep by electrokinetic measurements against pH in the presence of indifferent electrolytes of various molarities. *Source:* From Ref.<sup>[39]</sup>.

Particle velocity is measured by timing individual particles on a microscope grid as they move from the start to the finish line. Ten to twenty particles are usually tracked with each traverse taking 3–15 sec. Thus the electrophoretic mobility of the particle is determined and then converted to the  $z_p$  using the Smoluchowski equation.

Electrokinetic measurements of nanoparticles can be performed by the Laser Doppler Electrophoresis method (LDE), the Phase Analysis Light Scattering Techniques (PALS), Tiselius technique, the Rotating Prism and Rotating Grating, and zone electrophoresis methods.<sup>[42,43]</sup> The LDE and PALS techniques can provide  $z_p$  or electrokinetic measurements of many millions of nanoparticles in a few seconds. The LDE is based on the mixing of scattered light from a sample of a suspension of colloidal particles moving in an electric field, with light directly from the source. The scattered light is frequency-shifted by the Doppler effect, and optical mixing of this with the “unshifted” reference beam light leads to a beating at a frequency dependent on the speed of the particles. The limitation of this method arises from the small displacement of the particles because of a low mobility. This problem can be somewhat overcome with the Phase Analysis Light Scattering Technique (PALS). In this technique, phase modulation is applied so that the Doppler frequency of zero mobility particle is equal to the modulation frequency  $\omega_0$ . It is possible then to measure the deviation of the actual frequency, present in the scattered light, by performing a phase comparison of the

detected signal with the imposed modulator frequency. If the mobility is truly zero, the relative phase of the two will be constant: If a small mobility is present, the relative phase will be shifted, and a small phase shift can be detected by a phase comparator.<sup>[43]</sup> At high ionic strengths where the conventional zeta meters fail to function, the PALS technique is becoming useful.

## Electroosmosis

This method is based on the measurement of liquid in a capillary (or in a system of capillaries such as a porous plug of compressed solid particles) under an applied electric field. When electric field or potential gradient,  $E$ , is applied via the working electrodes on the system, the electrolytes flow in response to the field and drag the liquid along with them. This movement of liquid can be conveniently observed by measuring the movement of a small bubble in the capillary, converting it to the flow rate from which the flow rate the  $z_p$  of the solid may be calculated using the following equation.<sup>[9]</sup>

$$\xi = 4\pi\eta\lambda V_e/\epsilon i \quad (22)$$

where  $V_e$  is the electroosmosis velocity of the liquid,  $i$  is the electric current passing through the capillary,  $\eta$  is the viscosity of the liquid,  $\epsilon$  is dielectric constant of the liquid, and  $\lambda$  is the specific conductance of the liquid.

## Streaming Potential

Streaming potential method may be considered as the converse of the electroosmosis. Here the electric field instead of the liquid velocity is measured. When a liquid is forced to flow through a capillary tube or porous plug by applying pressure, a potential difference is developed. This potential difference is called the streaming potential. The  $z_p$  of the solid (constituting the porous plug) from streaming potential data is given by the following Helmholtz–Smoluchowski equation (Eq. (23)).<sup>[19]</sup>

$$\xi = 4\pi\eta\lambda E_s/\epsilon P \quad (23)$$

where  $E_s$  is the streaming potential and  $P$  is the pressure applied for streaming the liquid. This equation is valid under the conditions where the flow is linear and the pore diameter is much greater than the value of  $1/\kappa$ .<sup>[3,9]</sup>

## Sedimentation Potential

This technique may be regarded as the converse of the electrophoresis method. When a particle in a liquid

settles through a suspending medium under the gravitational forces, it produces an electric field  $E$ . This electric field is measured by inserting reversible electrode probes at two different heights in the column of settling particles and then  $E = \Delta\phi/L$ , where  $\Delta\phi$  is the potential difference and  $L$  is the separation between the electrodes. The  $E$  value may be used to calculate the  $z_p$ , provided that the particle surface is nonconducting, the particles are of uniform size, and  $\kappa a \gg 1$ .<sup>[3,9]</sup>

$$E = (\xi\epsilon a^3/3\eta\lambda)(m_1 - m_2)ng \quad (24)$$

where  $a$  is the radius of the particle,  $m_1$  and  $m_2$  are the densities of particle and liquid respectively,  $n$  is the number of solid particles in a unit volume, and  $g$  is the gravitational constant.

## INTERACTION MECHANISMS BETWEEN MINERAL PARTICLES

### DLVO Theory and the Interaction Energy Curves

The DLVO (Derjaguin and Landau, 1941;<sup>[44]</sup> Verwey and Overbeek, 1948<sup>[45]</sup>) theory explains the stability of colloidal systems including nanosized particles considering the total potential energy of interaction between colloidal particles depending on the distance between them. The total or net interaction energy is equal to the summation of the EDL interaction energy ( $V_{ER}$ ) and the van der Walls interaction energy ( $V_{VA}$ ) and given as

$$V_T = V_{ER} + V_{VA} \quad (25)$$

The EDL interaction energy between two colloidal particles in an electrolyte solution results from the overlapping of their diffuse layers; that is, it results from an osmotic pressure of counterions in repulsive character when the two particles have the same sign of charge. But, when they are opposite in charge, the DL interaction energy becomes attractive in character. The van der Walls interaction energy ( $V_{VA}$ ) between the particles arises from the London–van der Walls forces. If the two particles are identical, the van der Walls interaction is always negative (attractive) but in the case of different particles, this may change depending on the Hamaker constant of the particles and the medium.<sup>[15,46]</sup>

For two spherical colloidal particles of equal size, which usually appear in most colloidal systems, the total interaction energy using the DLVO theory is

described provided that  $a \gg H$  as follows<sup>[15]</sup>

$$V_T = 32\pi\epsilon\epsilon_0 a(kT/ze)^2 \chi^2 \exp(-\kappa H) - (Aa/12H) \quad (26)$$

where  $a$  is the radius of colloidal particles,  $H$  is the shortest distance between them,  $A$  is the effective Hamaker constant depending on the Hamaker constants of the particles and the medium,  $\kappa$  is the Debye–Huckel parameter, and  $\chi$  is given by

$$\chi = \tanh(ze\xi/4kT) \quad (27)$$

Indeed, the right hand of Eq. (27) is identical with the term  $\tanh(ze\psi_d/4kT)$  in Eq. (15), only the zeta ( $\xi$ ) potential instead of  $\psi_d$  is used. In Eq. (26), the first term denotes the EDL repulsion energy ( $V_{ER}$ ) and the second term the van der Walls attraction energy ( $V_{VA}$ ). Note that here  $\xi$  is used as an effective surface potential of the particles. If  $V_T$ ,  $V_{ER}$ , and  $V_{VA}$  are plotted as a function of the distance ( $H$ ), the characteristic curves such as those in Fig. 5 are obtained. Here the  $V_T$  value at each distance is obtained by the summation of the  $V_{ER}$  and  $V_{VA}$  values; that is, the smaller energy is subtracted from the larger energy. If repulsive, the net value is plotted above; if attractive, the net value is plotted below. The  $V_T$  curve is then formed. As seen in Fig. 5, both repulsive and attractive interactions become weaker as the separation distance increases. At sufficiently large distances, the particles exert no influence on each other.

If the colloidal particles are very close, the van der Walls attractive forces take over with a resultant negative energy of interaction leading to the coagulation of particles. At contact state, the total interaction energy is known as the primary minimum. There is also another negative attraction energy usually beyond 3 nm known as the aggregation region or the secondary minimum.<sup>[46]</sup> But the coagulation in this region is not stable and reversible with respect to the case in the primary minimum.<sup>[9,47]</sup> Rheological properties such as thixotropy are closely related to coagulation at the secondary minimum.

If the particles are further away, van der Walls attraction forces sharply decrease because of the large exponent of inverse distance, and the EDL repulsion forces take over with an energy barrier occurring between the particles. If aggregation is required, the height of the energy barrier shown in Fig. 5 should be lowered or removed. Conversely, for a good dispersion, the height of the energy barrier must be enlarged. These two cases can be realized by changing the EDL repulsive forces, as it is perhaps impossible to change the van der Walls forces.

**Fig. 5** Repulsive and attractive forces as a function of distance of separation.

Now we can ask this question, how can we change the EDL repulsive forces? This is possible by changing the  $z_p$  of particles through changing parameters such as the type and concentration of electrolyte and solution pH. For example, for negatively charged colloidal silica particles in distilled water at 0,  $-14$ , and  $-30$  mV, the photomicrographs of the colloidal silica particles taken by Rosental<sup>[3]</sup> are given in Fig. 6A, B, and C, respectively. The total interaction energy ( $V_T$ ) curves are assumed to correspond to the cases in Fig. 6A, B, and C, respectively. As seen in Fig. 6A, silica particles with a  $z_p$  value of  $-30$  mV exhibit dispersion and the height of the energy barrier is considerably high. When KCl is added into water, the  $z_p$  of silica particles comes down to the  $-14$  mV (Fig. 6B) as a result of the double-layer compression with a resultant decrease in repulsive energy and in turn in the height of the energy barrier. Consequently, in this system, sometimes the van der Waals attractive forces may become dominant depending on the kinetic conditions and/or the existence of the non-DLVO forces such as hydration, hydrophobic forces, and steric forces. When a trivalent electrolyte,  $AlCl_3$ , is added into system, the  $z_p$  comes down to zero, which is called the isoelectric point (Fig. 6C), owing to the charge neutralization on the silica surface; the height of the energy barrier disappears and the van der Waals attractive forces become dominant in the system.<sup>[49]</sup> Accordingly, the colloidal particles come in contact and coagulate (Fig. 6C).

At the point where the energy barrier just disappears:

$$dV_T/dH = 0 \text{ and } V_T = 0 \quad (28)$$

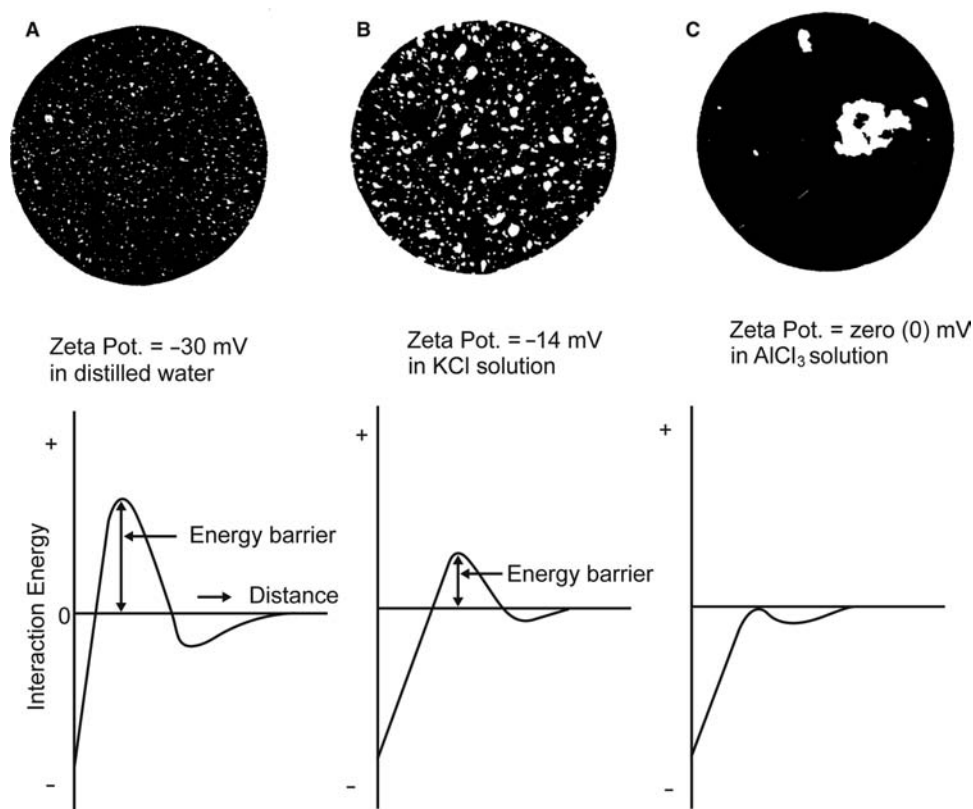

Applying these conditions to Eq. (26) results in an expression for the critical coagulation (or flocculation) concentration,  $C_c$ , for a symmetrical ( $z_+ = -z_-$ ,  $z$  is the valence number of electrolyte, e.g., NaCl) electrolyte as follows:

$$C_c = K(P^4/A^2z^6) \quad (29)$$

where  $K$  is a constant that depends only on the properties of the dispersion medium and  $A$  is the effective Hamaker constant. When the  $z_p$  is very high, the term  $P$  approaches unity and the critical concentration becomes inversely proportional to the sixth power of the valency,  $z$ . This dependence of  $C_c$  on  $1/z^6$ , known as the Schultz–Hardy rule, is consistent with the DLVO theory. For instance, if coagulation occurs at 1 M with a 1:1 electrolyte, it will occur at  $1/2^6$  ( $\cong 0.016$ ) M with a 2:2 electrolyte, and at  $1/3^6$  ( $\cong 0.0014$ ) M with a 3:3 electrolyte.

## APPLICATIONS OF ZETA POTENTIAL AND ELECTROPHORETIC MOBILITY

As mentioned earlier, the  $z_p$  is a good indicator to explain the stability mechanisms of different colloidal

**Fig. 6** Total energy of interaction curves for silica particles and their corresponding coagulation behavior. *Source:* From Ref.<sup>[48]</sup>.

and emulsion systems, and the adsorption mechanism between any organic or inorganic species at any solid–liquid interface. The term stability, when applied to colloidal dispersions, is a relative term intended to express the resistance of the dispersion to change. In any colloidal system, colloidal particles may have different z<sub>p</sub> values depending on the conditions, i.e., solution pH, existence of electrolyte, type, and concentration. The z<sub>p</sub> is used mainly in the following areas as an indicator of the dispersion and coagulation of colloidal systems. Therefore it has a wide spectrum of applications, some of which will be briefly mentioned.

The preparation of a well-dispersed clay–water colloidal system in the slip casting molding method requires the z<sub>p</sub> of clay particles be sufficiently high to provide repulsion between the particles so that a dense packing with strong material is produced.<sup>[50]</sup> In the purification of municipal water and cleaning up of industrial wastes, it is usually necessary to remove solids from dilute suspension. The key to effective colloid removal is the reduction of z<sub>p</sub> of the colloidal particles to zero by adjusting solution pH, and type and concentration of electrolyte.<sup>[11,51]</sup>

The pigments in paint, consisting of fine particles or nanoparticles, colored or colorless solid particles, must be dispersed readily to maintain a stable dispersion.

The z<sub>p</sub> value of pigments in a solvent plays an important role in maintaining a good dispersion.<sup>[52]</sup> The pharmaceutical industry often prepares their product by suspending colloidal particles or nanoparticles of the drug uniformly throughout a liquid vehicle. A successful suspension remains stable and enjoys a long shelf life. This is often achieved by producing a stable dispersion that settles very slowly at maximum z<sub>p</sub>. Suspensions of paper stocks containing fine particles including filler or pigments are generally regarded as colloidal systems. If fine particles are agglomerated, they will attach to the fiber, leading to better drainage and improvement in total retention at a z<sub>p</sub> value of 0 mV.<sup>[53]</sup> The EDL repulsive forces and z<sub>p</sub> values between colloidal latex particles defining a sol of polymer particles such as polystyrene latex<sup>[50]</sup> have a decisive role in the preparation of monodisperse latex.<sup>[54,55]</sup>

The z<sub>p</sub> measurements are used to determine the optimum conditions for the stability of emulsions. In most emulsion systems such as cream in cosmetic industry (oil in water or water in oil emulsions), mayonnaise in food industry (solid in liquid emulsion), and toothpaste in pharmaceutical industry (solid in liquid emulsion), the stability is achieved through a good control of z<sub>p</sub>.<sup>[56]</sup> The z<sub>p</sub> values of fiber materials are used in the characterization of fiber materials such as carbon, polyethylene, cotton, and polyester in

liquids and identifying the adsorption capacity of different organic dye molecules.<sup>[42]</sup>

Flotation is a technique widely used in mining industry to separate valuable minerals from their ores or to separate the valuable minerals from each other. Finely ground minerals in water are coupled with an appropriate collector chemical and then floated with air bubbles. The  $z_p$  is used to select appropriate collector, elaborate the method of collector adsorption on minerals, and examine activation mechanism of minerals.<sup>[7,8,55]</sup>

Electrophoretic deposition is an important technique directly used to produce a thin or thick coating on a conducting base.<sup>[50,57]</sup> In this technique, charged particles migrate to an electrode of opposite charge under the influence of an electric field. Untirusting paint coatings on metal surfaces, composite coatings, production of superconductors,<sup>[48]</sup> and photocopying by electrodeposition<sup>[58]</sup> are further examples of this kind. Differences in electrophoretic mobilities of some proteins induce their separation in biological systems.<sup>[19,40,42,47,52–54,58–61]</sup> Similarly, analysis of the blood cells can reveal illness through electrophoretic mobility; a mobility of  $-1.1 \mu\text{m sec}^{-1}/\text{V cm}^{-1}$  is reported for fresh human red cells in blood at pH 7.4.<sup>[60]</sup> In addition, the intravascular coagulation diseases of human can be indirectly controlled by  $z_p$ .<sup>[48]</sup> Bacterial action is also governed by electrical potential.<sup>[62]</sup>

Detergency is the ability to remove dirt such as soil and oil adhering to fiber. The dirt removal from fabric by detergent is explained by the heterocoagulation theory including the EDL repulsion and van der Waals attraction energy between two different materials, fabric and dirt.<sup>[59,61]</sup> Soil used for agricultural purposes contains an appreciable fraction of colloidal material composed of both lyophobic and lyophilic colloids. When soil is treated with water, the soil must be kept in a flocculated state to impart porosity, a suitable medium for good plant growth; this condition is provided by adding some electrolyte into water. The permeability of oil-producing sandstones is governed by the clay particles present in sandstone material. The migration of clay particles is relevant to the properties of water used in the system and also the electrokinetic properties of clay particles.<sup>[63]</sup>

## CONCLUSION

It is clear from this review that electrokinetic properties of mineral particles are encountered in all walks of life. Understanding of electrokinetics of mineral nanoparticles in a liquid, in addition to the ionic composition of the solution, requires the knowledge of surface charge, zeta potential, surface potential, structure

of EDL at the mineral/liquid interface, and its double-layer thickness. This information is then used to identify the interaction mechanisms between two particles or between a particle surface and a substance (in ionic or non-ionic form), and in turn, the stability of solid-liquid system and the adsorption of an ion (or molecule) on a charged or non-charged mineral. Its practical implications are then explained in terms of the DLVO theory.

## INTRODUCTION

Mixed metal oxide (MMO) nanoparticles (also called heterometal oxide nanoparticles) can play an appreciable role in many areas of chemistry and physics. The unique electronic and magnetic properties obtained when combining two metals in an oxide matrix have been well studied.<sup>[1,2]</sup> However, the most common use for MMOs has been in the area of catalysis, and here they have found use both as the catalyst and as catalyst supports.<sup>[3,4]</sup> Specifically, MMO containing aluminum has found many opportunities in catalysis.<sup>[5–7]</sup>

Mixed metal oxides are also used in many applications in the electronic industry as passive or active components in devices. These exhibit high dielectric, and ferro- or pyroelectric properties, e.g., BaTiO<sub>3</sub>, LiNbO<sub>3</sub>, KTaO<sub>3</sub>, Pb<sub>1-x</sub>La<sub>x</sub>Ti<sub>y</sub>Zr<sub>2</sub>O<sub>3</sub>, etc. The most remarkable MMO materials are surely the thermal-conducting superconductors based on YBa<sub>2</sub>Cu<sub>3</sub>O<sub>7-x</sub>. The technological interest in MMOs such as silica-titania and silica-zirconia arises from their chemical resistance and their thermomechanical or optical properties. SiO<sub>2</sub>-TiO<sub>2</sub> glasses and zircon, SrZrO<sub>4</sub>, are characterized by very low thermal expansion, which confer them a high thermal-shock resistance. SiO<sub>2</sub>-TiO<sub>2</sub> and SiO<sub>2</sub>-ZrO<sub>2</sub> glasses have high refractive indices and are wonderful catalysts or catalyst supports.<sup>[8]</sup> Owing to their refractoriness, these MMOs are difficult to produce by conventional melting techniques; thus, sol-gel technique is used for their preparation. The homogeneity of binary oxide has great influence on structural evolution of the gels during the heat treatment. Magnesium aluminate spinel (MgAl<sub>2</sub>O<sub>4</sub>) is expected to have applications as a structural material at high temperatures because it has a high melting point and superior thermal and chemical properties.

It is also of technological interest as a refractory materials at elevated temperatures. It is important to realize that improved properties are recorded for ceramic materials at nanoscale and these materials are expected to find the most important place in technology in the coming years.

In this entry, we have covered the most important and recent methods of preparation of nanocrystalline MMOs. Special emphasis has been given on sol-gel technique because of its popularity among researchers, resulting in homogeneous and pure MMO nanoparticles. Among physical methods, perhaps flame spray pyrolysis is gaining more importance in recent time. Structure, properties, and applications of MMO nanoparticles have also been discussed. This area of research is wide open and offers scope for development in synthetic and application fields.

## SYNTHESIS OF MIXED METAL OXIDE NANOPARTICLES

Developments in the field of MMO nanoparticles have produced many significant and interesting results in all areas investigated. This attracted attention toward the preparation of these potential new materials with variable composition having unique properties. Researches have explored and developed both physical and chemical methods by which such materials can be prepared.

### Physical Methods

Several physical aerosol methods have been reported for the synthesis of nanosized particles of ceramic materials. The most successful include gas condensation techniques,<sup>[9–12]</sup> spray pyrolysis,<sup>[13,14]</sup> thermochemical decomposition of metal-organic precursors

in flame reactors,<sup>[15,16]</sup> and some other aerosol processes named according to energy sources applied to reach the temperatures required for gas–particle conversion. The experimental details of these physical/aerosol methods have been outlined by Khaleel and Richards.<sup>[17]</sup>

### Vapor condensation method

It involves two steps. In the first step, a metallic nano-phase powder is condensed under an inert convection gas at high pressure, after the supersaturated vapor of metal is obtained inside a chamber. In the second step, the powder is oxidized by allowing oxygen into the chamber. It is a critical step in which the temperature is as high as 1000°C because of the exothermic nature of the reaction. High temperature results in agglomeration into large particles, and often annealing process at high temperature is required for completion of oxidation. Nanoparticles result when supersaturation is achieved above the vapor source. A collection surface cooled by liquid nitrogen is used to collect the particles.

### Spray pyrolysis

Some other techniques with slight modifications also work on same principle. They are aerosol thermolysis, evaporative decomposition of solutions, plasma vaporization of solutions, aerosol decomposition, flame pyrolysis, etc. A new broad name suggested for these techniques is flame spray pyrolysis (FSP) technology. The starting materials, or chemical precursors, are usually the appropriate salts, either in solution or in a sol or in suspension form. Aerosol droplets are generated by nebulizer or atomization technique of the starting chemical precursors. These droplets generated undergo evaporation with solute condensation within the droplet followed by drying and thermolysis of precipitate particles at high temperatures forming microporous particles. They are finally sintered to form dense particles. In this technique, various methods are used for atomization, including pressure, two-fluid, electrostatic, and ultrasonic atomizers. These methods give droplets of different sizes (2–15 μm) at various rates of atomization and various droplet velocities. Tal materials Inc. uses a patented flame spray pyrolysis process developed at the University of Michigan for the direct, large-scale production of inexpensive MMO nanopowders.<sup>[18,19]</sup>

The preparation of a variety of nanosized MMO powders from the thermolysis/flame pyrolysis of a new polymer-matrix-based precursor solution has been reported by Pramanic et al.<sup>[20]</sup> Spinel such as MgAl<sub>2</sub>O<sub>4</sub>, CuFe<sub>2</sub>O<sub>4</sub>, NiFe<sub>2</sub>O<sub>4</sub>, CoFe<sub>2</sub>O<sub>4</sub>, ZnFe<sub>2</sub>O<sub>4</sub>; orthoferrites such as LaFeO<sub>3</sub>; NdFeO<sub>3</sub>; GdFeO<sub>3</sub>;

SmFeO<sub>3</sub>; garnets such as Y<sub>3</sub>Al<sub>5</sub>O<sub>12</sub>, Gd<sub>3</sub>Al<sub>5</sub>O<sub>12</sub>, Gd<sub>3</sub>Fe<sub>5</sub>O<sub>12</sub>, Sm<sub>3</sub>Fe<sub>5</sub>O<sub>12</sub>; and composites such as Fe<sub>2</sub>O<sub>3</sub>·NiO, Fe<sub>2</sub>O<sub>3</sub>·CuO, and Fe<sub>2</sub>O<sub>3</sub>·TiO<sub>2</sub> have been reported.

### Thermochemical/flame decomposition of metal–organic precursors

This method is an example of another type of gas condensation technique. In this method, the starting material is a liquid chemical precursor. It is also known as chemical vapor condensation (CVC). It involves vaporization of chemical precursors, which are then oxidized with the help of a fuel–oxidant mixture (propane–O<sub>2</sub> or methane–O<sub>2</sub>). It combines the rapid thermal decomposition of a precursor carrier gas stream in a reduced pressure environment with thermophoretically driven deposition of the rapidly condensed product particles on a cold substrate.<sup>[16]</sup> The flame temperature varies between 1200 and 3000 K, which allows rapid gas phase chemical reactions. In rapid thermal decomposition of precursor in solution (RTDS), the precursor material dissolved in water undergoes rapid hydrothermal reactions in a near-critical and supercritical water environment. Due to the short residence time and extremely fast quenching rate, the particle growth in the reaction is limited. Both ultrafine metal oxides and MMOs using inexpensive water-soluble precursors are prepared using this method. Some examples of nanocrystalline powders produced using RTDS are (1) Fe<sub>3</sub>O<sub>4</sub> (magnetite) having grain size less than 12 nm from FeSO<sub>4</sub>/urea as precursors, (2) NiFe<sub>2</sub>O<sub>4</sub> (trevorite) having grain size less than 10 nm from Fe(NO<sub>3</sub>)<sub>3</sub>/Ni(NO<sub>3</sub>)<sub>2</sub>/urea as precursors, and (3) NiO/ZrO<sub>2</sub> having grain size nearly 10 nm from Ni(NO<sub>3</sub>)<sub>2</sub>/ZrO(NO<sub>3</sub>)<sub>2</sub>.

### Chemical Methods

The most potential and successful route for preparing homogeneous ceramic materials is liquid phase chemistry. The most widely used and perhaps most reliable method is the sol–gel method. There are many other wet chemistry methods known, such as microemulsion techniques and precipitation from solutions. Another novel technique is the mechanochemical synthesis method, which involves solid-state chemistry reactions.

### Sol–gel technique

The synthesis of MMOs by sol–gel technique is one of several liquid phase methods that is the most widely employed and has been widely reviewed.<sup>[21–28]</sup> Reviews on the preparation of aerogels have also appeared in the literature.<sup>[29,30]</sup> Mainly, three routes are used to

prepare sol-gel ceramic materials, which are distinguished by the nature of the starting material. They are (1) an aqueous solution of inorganic salt, (2) an aggregate of colloidal particles in a solvent, and (3) a network-forming species in organic or aqueous solution. The last route is the most acceptable because network formers can be tailor-made or modified to control the chemistry and processing of the gel, and ultimately its morphology. Usually, alkoxides, bimetallic- $\mu$ -oxoalkoxides, and heterometallic (double, *ter*-, *tert*-) alkoxides are used as precursors in alcoholic solutions. Other precursors include metal  $\beta$ -diketonates and metal carboxylates.

*Hydrolysis and condensation of metal alkoxides:*

The sol-gel route is actually a two-step inorganic polymerization. In the first step, polymerization starts by hydrolysis at the metal-alkoxy linkage yielding alcohol and new reactants, hydroxylated metal centers (M-OH).

The mechanism of this reaction can be outlined as below:

In the second step, condensation or three-dimensional propagation occurs when hydroxylated species condense to form oxypolymers. Polycondensation involves alkoxylation, oxolation, or ololation, a reaction that creates oxygen bridges and releases XOH species (where X=H or R).

The nature of the inorganic framework obviously then determines the relative rates of hydrolysis and

condensation at different centers. The rates of hydrolysis and condensation depend upon the nature of metal in terms of its electrophilicity and ability to expand its coordination number.<sup>[31]</sup> The hydrolysis rates of transition metal alkoxides are very high, as metal centers are highly electrophilic and exhibit several coordination numbers. This sometimes complicates the problem, especially in the case when heterobimetallic alkoxides are used as precursor, as precipitation occurs at different rates and often instantaneously. One of the suitable ways to overcome this problem is the modification of precursor by reacting alkoxide with other ligands when the exchange reaction takes place.<sup>[32]</sup> This results into a new precursor, which may undergo hydrolysis at a much slower rate.

Thus, at times when alkoxy ligands are quickly removed by hydrolysis, then chelating ligands such as acetyl acetone or other  $\beta$ -diketones act as terminating agents that limit the condensation reaction.<sup>[33]</sup> The major steps involved in sol-gel technique<sup>[21,22]</sup> for the preparation of MMOs as outlined in Fig. 1 are:

1. Preparation of a homogeneous solution of pure precursor in an organic solvent, which is miscible with water or the hydrolysis reagent.
2. Preparation of sol from solution by treating the homogeneous solution with H<sub>2</sub>O, or H<sub>2</sub>O with HCl/NaOH/NH<sub>4</sub>OH.
3. Allowing the sol to convert into gel by polymerization (aging).

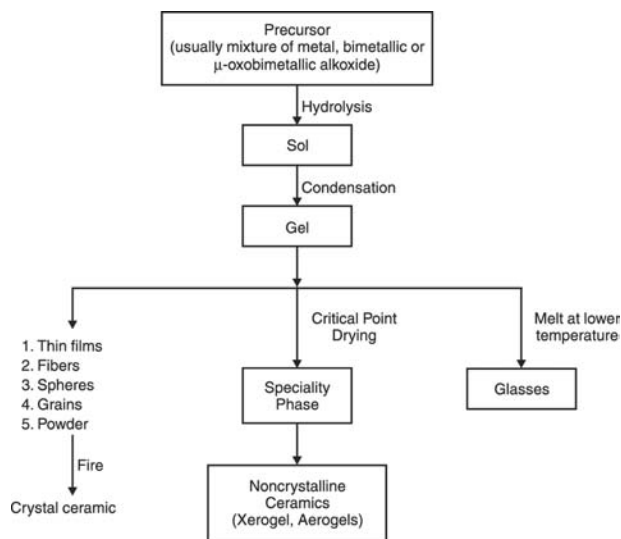

Fig. 1 Steps involved in sol-gel method.

- Shaping of gel into the desired form or shape followed by drying. In this step, solvent is removed. The manner in which the liquid phase is removed from wet gel determines whether the dried material is a highly porous aerogel or a denser xerogel. A xerogel is formed as the solvent evaporates from the wet gel, resulting in collapse of the wet-gel structure. If the network is compliant, the gel deforms because of capillary forces generated by the liquid phase as it recedes into the body of the gel. Supercritical drying (SCD) or ambient pressure upon wet gels results in aerogels. Aerogels are actually nano-scale mesoporous materials of low density and high surface area.

SCD preserves the porosity by bringing the solvent phase into its supercritical state (a state where no liquid–vapor interface exist), so that capillary pressures do not develop. There are two SCD methods. The sol–gel synthesis of  $(\text{Ru}_x\text{Ti}_{1-x})\text{O}_2$  ( $x = 0, 0.14, 0.20, 0.32$ ) involves modification of an alkoxide preparation of  $\text{TiO}_2$  with a ruthenium chloride,  $\text{RuCl}_3$ , refluxed in ethanol. Monolithic aerogels are formed using SCD method with  $\text{CO}_2$ . These were characterized after annealing treatment at  $400^\circ\text{C}$ , which removed the chloride and alkoxide. The resulting oxides consisted of  $\sim 10$  nm nanocrystallites of primarily phase-separated  $\text{TiO}_2$  and  $\text{RuO}_2$  (these rutile phases can form only a solid solution of a few mole percent  $\text{RuO}_2$  and  $\text{TiO}_2$ ). These MMO aerogels show surface areas of approximately  $85\text{ m}^2\text{ g}^{-1}$ .<sup>[34]</sup>

Ambient pressure method involves surface modifications as well as network strengthening.<sup>[35–38]</sup> Surface modification means, for example, that terminal silanols ( $\text{Si-OH}$ ) are replaced by nonreactive groups via silylation or esterification. These modifications inhibit condensation reactions, i.e., conversion of  $\text{Si-OH}$  centers to  $\text{Si-O-Si}$ , which locks in structural collapse by sealing compressed pores shut. This allows the porous network to almost retain its original volume. Network strengthening is done by either aging of wet gel in mother liquor (including thermal treatment in water) or soaking it in a precursor alkoxide [such as  $\text{Si}(\text{OR})_4$ ] during washing or aging steps. One can also use solvents with low surface tension so that pore liquid is exchanged with low-surface-tension solvents just before the ambient-pressure drying. The MMOs so obtained have been named as ambigels and are less porous than the corresponding SCD ceramics but have comparable surface area and pore volume (Fig. 2).<sup>[31]</sup> Finally, conversion of the shaped gel to the desired ceramic material by heating takes place at a much lower temperature than the conventional process of melting of oxides together.

**Fig. 2** The method used to extract the pore fluid from a wet gel creates a dry solid with variable porosity: strong capillary forces create a xerogel, weak capillary forces create an ambigel, and zero capillary force creates an aerogel that nominally retains the low-density framework for the wet gel. *Source:* Reprinted with permission from Ref.<sup>[31]</sup>.

Another widely used method for obtaining MMO aerogels is the prehydrolysis route.<sup>[39,40]</sup> In this method, two alkoxides with different rates of hydrolysis are used as precursors for obtaining MMO aerogels. However, before mixing these together, the one with the lower rate of hydrolysis is hydrolyzed or partially hydrolyzed separately and then mixed with the other alkoxide solution. This is to avoid phase segregation caused by different rates of hydrolysis. Similarly, hydrolysis of metal alkoxide with faster rate of hydrolysis can be slowed by suitable complexation. This is done to promote formation of  $\text{M-O-M}'$  mixed bond, which increases the homogeneity of MMO aerogel. A nonhydrolytic sol–gel route has also been used for preparation of MMO aerogels.<sup>[41]</sup> The  $\text{M-O-M}'$  bridges are obtained by condensation of  $\text{MX} + \text{M}'\text{-OR} \rightarrow \text{M-OM} + \text{RX}$ . In most cases, these reactions are thermally activated. Actually, the condensation completes with redistribution of the ligands, giving complicated halogenoalkoxides,<sup>[42]</sup> which ultimately leads to products after hydrolysis. The surface areas of oxides obtained after calcination was found to be quite high, but a low level of homogeneity on atomic scale was noticed. Syntheses of  $\text{MgAl}_2\text{O}_4$  spinel and  $\text{Mg}_2\text{SiO}_4$  spinel forsterite precursor from a heterogeneous alkoxide solution have been reported in the literature.<sup>[43,44]</sup> The preparation route is shown in Fig. 3. The obtained precursor was composed of a mixture of boehmite [ $\text{AlO}(\text{OH})$ ] and a mixed hydroxide [ $\text{Mg}_4\text{Al}_2(\text{OH})_{14}\cdot 3\text{H}_2\text{O}$ ]. The precursor was converted to a spinel phase through two steps: (1) decomposition of mixed hydroxide at  $\sim 400^\circ\text{C}$  and (2) solid-state reaction between  $\text{MgO}$  (which has decomposed from mixed hydroxide) and  $\gamma\text{-Al}_2\text{O}_3$  (which had been converted from boehmite at higher

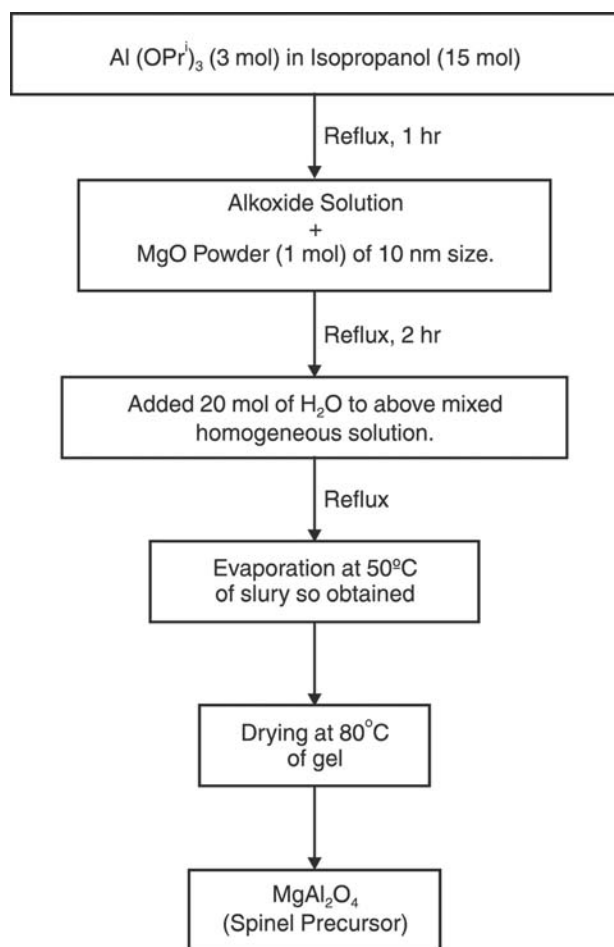

Fig. 3 Preparation route for spinel  $\text{MgAl}_2\text{O}_4$  precursor.

temperature). To prepare almost-monolithic spinel powder, calcination at a temperature of  $1300^\circ\text{C}$  was required. Powder that was calcined at  $1000^\circ\text{C}$  showed extraordinary sinterability, and fully dense polycrystalline spinel could be obtained at sintering temperature as low as  $1400^\circ\text{C}$ .

Synthesis of  $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$  (LSMO)/silica hybrid nanocomposites have been reported by Huang et al.<sup>[45]</sup> Homogeneous granular mixtures can be obtained through sol-gel chemical route in a single step. The precursors used are the following: (1) complexes of  $\text{La}^{3+}$ ,  $\text{Sr}^{2+}$ , and  $\text{Mn}^{2+}$  with EDTA and (2) tetraethoxysilane (TEOS). Silica is produced by an ammonia-catalyzed method, whereas LSMO is obtained by thermal decomposition of the complex precursors. When hydrolysis of silicon alkoxide to form silica oxyalkoxy oligomers takes place in the LSMO precursor solution, both are formed in the same system. Thus, effective combination of both phases achieves a satisfactory level. The microstructure of the composites can be controlled mainly through the calcination temperature. When calcined at  $800^\circ\text{C}$ , silica undergoes some interaction with LSMO, and

Si–O–metal bonds are formed. These bonds establish the connection between silica network and LSMO surface.

Synthesis of pure nanocrystalline  $\text{Al}_2\text{O}_3/\text{MgO}$  powder has been reported by Carnes, Kapoor, and Klabunde.<sup>[46]</sup> The two Mg and Al alkoxide solutions were mixed in desired molar ratios and then allowed to react with a mixture of water in ethanol to yield a hydroxide gel. Upon solvent removal, a fine powder was obtained, which was then heat-treated under dynamic vacuum. The powder has excellent surface area ( $790\text{--}830\text{ m}^2/\text{g}$ ) showing a completely amorphous XRD pattern.

*Bimetallic- $\mu$ -oxoalkoxides as precursors for sol-gel technique:* Homogeneously dispersed bimetallic oxides in nanocrystalline form, of the type  $\text{MAl}_2\text{O}_4$  (where  $\text{M}=\text{Mg}$ ,  $\text{Ca}$ ,  $\text{Mn}$ ,  $\text{Co}$ ,  $\text{Fe}$ ,  $\text{Ni}$ , and  $\text{Zn}$ ) were obtained by preparation of bimetallic- $\mu$ -oxo-bridged (Al–O–M–O–Al) alkoxides  $[(\text{RO})_2\text{Al–O–M–O–Al}(\text{OR})_2]$ , which upon thermal dehydration yield oxides  $[\text{Al–O–M–O–AlO}]$  such that M is homogeneously dispersed in M and  $\text{Al}_2$  ions of empirical formula  $\text{MAl}_2\text{O}_4$  in nanocrystalline form.<sup>[47]</sup> These materials were obtained in high-surface-area forms and were characterized by X-ray diffraction (XRD), electron microscopy (TEM), surface area analyses (BET), and solid-state  $^{27}\text{Al}$  NMR. Comparative studies of hydrolysis of  $\mu$ -alkoxo-bridged alkoxides yielded MMO phases of lower surface area. This method has proved advantageous over other traditional routes. One such method is coprecipitation of metal hydroxides followed by heat treatment at high temperature.

#### Reverse microemulsion/micelle method

It is a promising route for synthesis of MMO nanoparticles.<sup>[48–50]</sup> Surfactants dissolved in organic solvents form spheroidal aggregates called reverse micelles. The polar ends of surfactant molecules organize around small water pools ( $\sim 100\text{ \AA}$ ) in the presence of water. This leads to dispersion of aqueous phase in the continuous oil phase. These reverse micelles are used as water solutions of reactive precursors to prepare insoluble nanoparticles. Various reactive precursors such as alkoxides or metal salt mixtures can be used for synthesis of nanoparticles inside the micelles. Solvent removal followed by calcination lead to the final product.

The above method was adopted to prepare the  $\text{ZnFe}_2\text{O}_4/\text{TiO}_2$  nanocomposite.<sup>[51]</sup> In this method,  $\text{ZnFe}_2\text{O}_4$  and  $\text{TiO}_2$  were prepared by coprecipitation and controlled hydrolysis methods, respectively.  $\text{ZnFe}_2\text{O}_4$  was coprecipitated from a mixed solution of  $\text{Zn}(\text{NO}_3)_2$  and  $\text{Fe}(\text{NO}_3)_2$  in a 1:2 molar ratio at pH 13 and temperature of  $100^\circ\text{C}$ .  $\text{TiO}_2$  was precipitated from mixed solution with a volume ratio of

Ti(OBu)<sub>4</sub>:C<sub>2</sub>H<sub>5</sub>OH:H<sub>2</sub>O ≡ 1:10:100 at pH 2. Both products were washed with deionized water. They were added separately to dodecyl benzene sulphonic acid (DBS), where ZnFe<sub>2</sub>O<sub>4</sub> or TiO<sub>2</sub> nanoparticles were capped with a layer of DBS. These then readily dispersed in organic solvents such as benzene or toluene. The capped ZnFe<sub>2</sub>O<sub>4</sub> and TiO<sub>2</sub> nanoparticles were mixed in various molar ratios, followed by extraction into toluene. Organic phase was removed by distillation, leaving mixed organic sol of ZnFe<sub>2</sub>O<sub>4</sub>/TiO<sub>2</sub>. This sol was distilled to remove toluene solvent and finally heated at 400°C for 2 hr to burn DBS, leaving behind nanocomposite ZnFe<sub>2</sub>O<sub>4</sub>/TiO<sub>2</sub> material. CoFe<sub>2</sub>O<sub>4</sub> nanoparticles were also synthesized by this technique. It uses Co- and Fe-containing surfactants as metal sources.<sup>[52,53]</sup>

#### Low-temperature wet chemical synthesis by precipitation from solutions

It involves dissolving salt precursors, usually chloride, oxychloride, nitrate, etc., in water followed by addition of base solution (NaOH or NH<sub>4</sub>OH) to coprecipitate hydroxides. The hydroxide mixtures are calcined to obtain MMO powder. Its disadvantage is poor control of particle size and size distribution, as fast (uncontrolled) precipitation often causes formation of larger particles and not nanoparticles. Mechanistically, in this solvation sheets of water around metal ion are dehydrated under alkaline conditions, e.g.,

The above scheme tells us the importance of alkaline conditions.<sup>[54]</sup> As an example, manganese ferrite (MnFe<sub>2</sub>O<sub>4</sub>) nanoscale particles ranging from 5 to 180 nm have been prepared from Fe<sup>3+</sup>, Fe<sup>2+</sup>, and Mn<sup>2+</sup> aqueous solution.

## STRUCTURE AND MORPHOLOGY

Control over structural and morphological properties are most crucial for performance of MMO nanoparticles in various applications. Mixed metal oxides are known to have different structural arrangement of constituent ions. The nature of these ions is important (size and charge) in the final adaptation of geometry; however, control over homogeneity, stoichiometry, phase, and crystallinity largely depend upon structure and reactivity of precursors in homogeneous solutions and their fate in subsequent processing steps. The stoichiometry and homogeneity depend upon the ability of mixed precursors, especially on addition of water to

form a single molecular species, so that the ions are distributed evenly.

Structural and morphological challenges initiated the search for suitable methods of preparation of various MMO ceramics. Several new and modified methods have been proposed for preparation of numerous ceramic nanoparticles. For example, in a modified aerogel method, addition of large amount of aromatic hydrocarbons to alcohol-methoxide solutions before hydrolysis to form gel yields ceramic materials with extraordinarily large surface area in comparison to materials obtained without adding it. This is probably because of reduced surface tension of the solvent mixture, which facilitates solvent-removed alcogel-aerogel transformation.<sup>[55,56]</sup>

Mixed metal oxide nanoparticles exhibit unusual surface morphologies and possess more reactive surface because of the presence of high concentrations of edge/corner sites and other defects. Morphological studies indicate that the nanocrystals are more polyhedral and thus possess more defects. Such defects could be of the Frankel or Schottky type (vacancies) or may be manifested as unusual configurations of edges, corners, or crystal planes. A ceramic material with high surface area displays 30–40% of the ceramic moieties on the surface, which allows surface gas reactions to approach the stoichiometric range.<sup>[17]</sup> As MMOs contain a variety of cations, the prediction of structure simply on the basis of radius ratios of cations and oxide ions becomes complicated. This means some simpler approach is required. For example, take a list of known structures and the radii of the ions present in them. The radii of two of the ions present in a given compound are plotted against each other. This is graphically related to arithmetic radius ratio approach. It is seen that compounds with similar structures are grouped together. In Fig. 4, compounds of the type A<sub>2</sub>BO<sub>4</sub> (where B is a higher-valent metal than A) are plotted as a function of radii A and B. In these materials, oxide ions form a closed packed array (framework) and sizes of A and B decide how they fit in (sometimes major distortion in closest-packed structure is noticed). On the basis of fields in Fig. 4, one can predict structures of newly discovered ceramic materials with known *r*<sub>A</sub> and *r*<sub>B</sub> values.<sup>[57]</sup>

### Spinel Structures

It consists of a face-centered cubic arrangement of oxygen ions. A unit cell contains 32 O<sup>2-</sup> ions, 64 tetrahedral, and 32 octahedral sites, which are occupied by A<sup>2+</sup> (A = Mg, Fe, Ca, Zn, etc.) and B<sup>3+</sup> (B = Al, Fe, etc.) cations. The general formula of spinel is written as A<sup>II</sup> B<sub>2</sub><sup>III</sup> O<sub>4</sub> [where A<sup>II</sup> is a Group 2 metal ion or transition metal in +2 oxidation state
